SOREQ
LINAC12
XXVI Linear Accelerator Conference
Tel Aviv, Israel, September 9-14, 2012

Contents

Preface i
Contents iii

Papers ix
SUPB001 – Analyzing Surface Roughness Dependence of Linear RF Losses 1
SUPB003 – Feasibility Study of Short Pulse Mode Operation for Multi-turn ERL Light Source 4
SUPB004 – Linac Optics Design for Multi-turn ERL Light Source 7
SUPB006 – Study of Beam-Based Alignment for Shanghai Soft X-Ray FEL Facility 10
SUPB007 – On-Line Dispersion Free Steering for the Main Linac of CLIC 13
SUPB008 – Specifications of the Distributed Timing System for the CLIC Main Linac 16
SUPB009 – Linear Accelerator based on Parallel Coupled Accelerating Structure 19
SUPB010 – Measurements of a Reduced Energy Spread of a Recirculating Linac by Non-Isochronous Beam Dynamics 22
SUPB011 – Computational Model Analysis for Experimental Observation of Optical Current Noise Suppression Below the Shot-noise Limit 25
SUPB012 – Status of CH Cavity and Solenoid Design of the 17 MeV Injector for MYRRHA 29
SUPB013 – The Beam Commissioning Plan of Injector II in C-ADS 32
SUPB014 – RF Setup of the MedAustron RFQ 35
SUPB015 – Production and Quality Control of the First Modules of the IFMIF-EVEDA RFQ 38
SUPB016 – RFQ With Improved Energy Gain 41
SUPB017 – Tuning Studies on 4-rod-RFQs 44
SUPB018 – Studies of Parasitic Cavity Modes for Proposed ESS Linac Lattices 47
SUPB019 – The Multipacting Simulation for the New-Shaped QWR using TRACK3P 50
SUPB020 – Structural Analysis of the New-Shaped QWR for HIAF in IMP 53
SUPB022 – First Measurements on the 325 MHz Superconducting CH Cavity 56
SUPB023 – Status of the Superconducting CW Demonstrator for GSI 59
SUPB024 – Development of Permanent Magnet Focusing System for Klystrons 62
SUPB025 – Development of Superconducting Radio-Frequency (SRF) Deflecting Mode Cavities and Associated Waveguide Dampers for the APS Upgrade Short Pulse X-Ray Project 65
SUPB026 – Multipacting Analysis of High-velocity Superconducting Spoke Resonators 68
SUPB027 – Mechanical Study of the First Superconducting Half-wave Resonator for Injector II of CADS Project 71
SUPB028 – The Superconducting CH Cavity Development in IMP* 74
SUPB029 – Impact of Trapped Flux and Systematic Flux Expulsion in Superconducting Niobium 77
SUPB031 – The Nonresonant Perturbation Theory Based Field Measurement and Tuning of a Linac Accelerating Structure 80
SUPB032 – The C-band RF Pulse Compression for Soft XFEL at SINAP 83
SUPB035 – RF Photoinjector and Radiating Structure for High-power THz Radiation Source 86
SUPB037 – The Development of Timing Control System for RFQ 89
SUPB038 – Multipole Field Effects for the Superconducting Parallel-Bar Deflecting/Crabbing Cavities 92
SUPB039 – Compact Superconducting Crabbing and Deflecting Cavities 95
MO1A01 – Operational Experience and Future Goals of the SARAF Linac at SOREQ 100
MO1A02 – Status of the European XFEL – Constructing the 17.5 GeV Superconducting Linear Accelerator 105
MO1A03 – SRF Linac Technology Development at Fermilab 110
MO2A02 – Increased Understanding of Beam Losses from the SNS Linac Proton Experiment 115
MO3A01 – Development of H-mode Linacs for the FAIR Project 120
MO3A02 – Commissioning of a New Injector for the RIKEN RI-Beam Factory 125
MO3A03 – FRANZ – Accelerator Test Bench and Neutron Source 130
MO3A04 – Accelerator/Decelerator of Slow Neutrons 133
MOPLB01 – Emittance Control for Different FACET Beam Setups in the SLAC Linac 138
MOPLB02 – Positron Injector Linac Upgrade for SuperKEKB 141
MOPLB03 – Advances in Beam Tests of Dielectric Based Accelerating Structures 144
MOPLB04 – A 10 MeV L-band Linac for Irradiation Applications in China 147
MOPLB05 – Applications of Compact Dielectric-Based Accelerators 150
MOPLB06 – Fermilab 1.3 GHz Superconducting RF Cavity and Cryomodule Program for Future Linacs 153

MOPLB07 – Non-destructive Inspections for SC Cavities . . . 156
MOPLB08 – Normal Conducting Deflecting Cavity Development at the Cockcroft Institute . . . 159
MOPLB09 – Status of the C-Band RF System for the SPARC-LAB High Brightness Photoinjector . . . 162
MOPLB10 – FRIB Technology Demonstration Cryomodule Test . . . 165
MOPLB11 – The Upgraded Argonne Wakefield Accelerator Facility (AWA): a Test-Bed for the Development of High Gradient Accelerating Structures and Wakefield Measurements . . . 168
MOPLB12 – X-Ray Local Energy Spectrum Measurement on Tsinghua Thomson Scattering X-Ray Source (TTX) . . . 171
MOPB001 – Emittance Control for Different FACET Beam Setups in the SLAC Linac . . . 174
MOPB002 – Positron Injector Linac Upgrade for SuperKEKB . . . 177
MOPB003 – Recent Improvements to the Control of the CTF3 High-Current Drive Beam . . . 180
MOPB004 – Design and Operation of a Compact 1 MeV X-band Linac . . . 183
MOPB005 – High Gradient Operation of 8 GeV C-Band Accelerator in SACLA . . . 186
MOPB007 – Study of Microbunching Instabilitity in the Linac of the Shanghai Soft X-Ray Free Electron Laser Facility . . . 189
MOPB011 – Photoinjector of the EBTF/CLARA Facility at Daresbury . . . 192
MOPB012 – First RF Measurement Results for the European XFEL SC Cavity Production . . . 195
MOPB013 – Experimental Results on the PHIL Photo-injector Test Stand at LAL . . . 198
MOPB014 – Electron Model of a Dogbone RLA with Multi-Pass Arcs . . . 201
MOPB016 – In-situ Measurement of Beam-induced Fields in the S-band Accelerating Structures of the Diamond Light Source linac . . . 204
MOPB017 – Integration of the European XFEL Accelerating Modules . . . 207
MOPB018 – Analyzing Surface Roughness Dependence of Linear RF Losses . . . 210
MOPB020 – LLRF System Improvement for HLS Linac Upgrade . . . 213
MOPB021 – Bunch-by-bunch Phase Modulation for Linac Beam-loading Compensation . . . 216
MOPB022 – RF Characteristic Studies on the Whole Accelerating Structure for the BEPCII Linear Accelerator . . . 219
MOPB023 – Progress on the Design and Construction of the 100 MeV / 100 kW Electron Linac for the NSC KIPT Neutron Source . . . 222
MOPB024 – Beam Dynamics Simulation and Optimization for 10 MeV Superconducting e-Linac Injector for VECC-RIB Facility . . . 225
MOPB025 – 1ms Multi-bunch Electron Beam Acceleration by a Normal Conducting RF Gun and Superconducting Accelerator . . . 228
MOPB026 – TRIUMF/VECC e-Linac Injector Beam Test . . . 231
MOPB029 – Commissioning of the X-Band Test Area at SLAC . . . 234
MOPB030 – Performance of First C100 Cryomodules for the CEBAF 12 GeV Upgrade Project . . . 237
MOPB031 – Vibration Response Testing of the CEBAF 12 GeV Upgrade Cryomodules . . . 240
MOPB032 – Stabilization of the Beam Intensity in the Linac at the CTF3 CLIC Test Facility . . . 243
MOPB033 – High Power Coupler Test for TRIUMF E-linac SC Cavities . . . 246
MOPB034 – Novel Technique of Suppressing TBBU in High-energy ERLs . . . 249
MOPB035 – The Linear Accelerating Structure Development for HLS Upgrade . . . 252
MOPB036 – Feasibility Study of Short Pulse Mode Operation for Multi-turn ERL Light Source . . . 255
MOPB037 – Linac Optics Design for Multi-turn ERL Light Source . . . 258
MOPB038 – Single Shot Bunch-by-Bunch Beam Emittance Measurement of the SPring-8 Linac . . . 261
MOPB041 – Advances in Beam Tests of Dielectric Based Accelerating Structures . . . 264
MOPB042 – On-line Dispersion Free Steering for the Main Linac of CLIC . . . 267
MOPB043 – Detailed Analysis of the Long-Range Wakefield in the Baseline Design of the CLIC Main Linac 270
MOPB045 – Specifications of the Distributed Timing System for the CLIC Main Linac . . . 273
MOPB046 – A 10 MeV L-band Linac for Irradiation Applications in China . . . 276
MOPB047 – Applications of Compact Dielectric Based Accelerators . . . 279
MOPB048 – Linear Accelerator Based on Parallel Coupled Accelerating Structure . . . 282
MOPB049 – Design of Compact C-Band Standing-Wave Accelerator for Medical Radiotherapy . . . 285
MOPB051 – Changing Attitude to Radiation Hazards and Consequent Opportunities for LINAC Applications 288
MOPB052 – Fermilab 1.3 GHz Superconducting RF Cavity and Cryomodule Program for Future Linacs . 291
MOPB053 – Non-destructive Inspections for SC Cavities . . . 294
MOPB054 – Test Results of Tesla-style Cryomodules at Fermilab . . . 297

MOPB055 – Development of Superconducting Radio-Frequency (SRF) Deflecting Mode Cavities and Associated Waveguide Dampers for the APS Upgrade Short Pulse X-Ray Project . . . 300
MOPB056 – Multipacting Analysis of High-Velocity Superconducting Spoke Resonators . . . 303
MOPB057 – Mechanical Study of the First Superconducting Half-wave Resonator for Injector II of CADS Project . . . 306
MOPB059 – The Superconducting CH Cavity Development in IMP* . . . 309
MOPB060 – RF Surface Impedance Characterization of Potential New Materials for SRF-based Accelerators . . . 312
MOPB061 – The New 2nd Generation SRF R&D Facility at Jefferson Lab: TEDF . . . 315
MOPB062 – A New Internal Optical Profilometry System for Characterization of RF Cavity Surfaces – CYCLOPS . . . 318
MOPB063 – Superconducting RF Linac for eRHIC . . . 321
MOPB064 – Developing of Superconducting RF Guns at BNL . . . 324
MOPB065 – Impact of Trapped Magnetic Flux and Systematic Flux Expulsion in Superconducting Niobium 327
MOPB066 – Alternative Approaches for HOM-Damped Cavities . . . 330
MOPB067 – Results and Performance Simulations of the Main Linac Design for B*ERL*inPro . . . 333
MOPB069 – Study of HPR Created Oxide Layer at Nb Surfaces . . . 336
MOPB070 – Quality Control of Cleanroom Processing Procedures of SRF Cavities for Mass Production . 339
MOPB071 – Process Developments for Superconducting RF Low Beta Resonators for the ReA3 LINAC and Facility for Rare Isotope Beams . . . 342
MOPB072 – Multipole Expansion of the Fields in Superconducting High-Velocity Spoke Cavities . . . 345
MOPB073 – Cold Testing of Superconducting 72 MHz Quarter-wave Cavities for ATLAS . . . 348
MOPB074 – Thermo-Mechanical Simulations of the Frequency Tuning Plunger for the IFMIF Half-Wave Resonator . . . 351
MOPB077 – Lorentz Force Detuning Compensation Studies for Long Pulses in ILC type SRF Cavities . . 354
MOPB079 – Normal Conducting Deflecting Cavity Development at the Cockcroft Institute . . . 357
MOPB080 – Status of the C-Band RF System for the SPARC-LAB High Brightness Photoinjector . . . 360
MOPB081 – Travelling Wave Accelerating Structures with a Large Phase Advance . . . 363
MOPB082 – RF Parameters of the TE - Type Deflecting Structure for S-Band Frequency Range . . . 366
MOPB083 – Operational experience with the FERMI@Elettra S-band RF System . . . 369
MOPB084 – Design of a C-band Disk-loaded Type Accelerating Structure for a Higher Pulse Repetition Rate in the SACLA Accelerator. . . . 372
MOPB086 – The Nonresonant Perturbation Theory Based Field Measurement and Tuning of a Linac Accelerating Structure . . . 375
MOPB087 – S-Band Loads for SLAC Linac . . . 378
MOPB088 – Fabrication Tests for IMP 162.5 MHz RFQ . . . 381
MOPB089 – X-Ray Local Energy Spectrum Measurement at Tsinghua Thomson Scattering X-Ray Source (TTX) . . . 383
MOPB090 – FRIB Technology Demonstration Cryomodule Test . . . 386
MOPB091 – The Injector Cryomodule for the ARIEL e-Linac at TRIUMF . . . 389
MOPB093 – The Upgraded Argonne Wakefield Accelerator Facility (AWA): a Test-Bed for the Development of High Gradient Accelerating Structures and Wakefield Measurements . . . 392
MOPB094 – Simulation Study on the Longitudinal Bunch Shape Measurement by RF Chopper at J-PARC Linac . . . 395
MOPB095 – Design of MEBT for the Project X Injector Experiment at Fermilab . . . 398
MOPB096 – Beam Loss Mitigation in J-PARC Linac after the Tohoku Earthquake . . . 401
MOPB098 – Planning for Experimental Demonstration of Transverse Emittance Transfer at the GSI UNILAC through Eigen-Emittance Shaping . . . 404
TU1A01 – Status of the IFMIF-EVEDA 9 MeV 125 mA Deuteron Linac . . . 407
TU1A03 – Chinese ADS Project and Proton Accelerator Development . . . 412
TU1A04 – FRIB Accelerator Status and Challenges . . . 417
TU1A05 – Status and Commissioning Plan of the PEFP 100-MeV Linear Accelerator . . . 422
TU2A02 – Overview of SACLA Machine Status . . . 427
TU2A03 – LCLS Operation Experience and LCLS-II Design . . . 432
TU2A04 – High Current ERL at BNL . . . 437
TUPLB01 – The Swiss FEL RF Gun: RF Design and Thermal Analysis . . . 442

TUPLB02 – Deflecting Structures with Minimized Level of Aberrations . . . 445
TUPLB04 – Results of Testing of Multi-beam Klystrons for the European XFEL . . . 448
TUPLB05 – Computational Model Analysis for Experimental Observation of Optical Current Noise Suppression below the Shot-Noise Limit . . . 451
TUPLB06 – Status of the Rare Isotope Science Project in Korea . . . 455
TUPLB07 – Reduced-beta Cavities for High-intensity Compact Accelerators . . . 458
TUPLB08 – R&D Towards CW Ion Linacs at ANL . . . 461
TUPLB09 – Design and Beam Test of Six-electrode BPMs for Second-order Moment Measurement . . . 464
TUPLB10 – Non-destructive Real-time Monitor to Measure 3D-bunch Charge Distribution with Arrival Timing to Maximize 3D Overlapping for HHG-seeded EUV-FEL . . . 467
TUPLB12 – Development of Permanent Magnet Focusing System for Klystrons . . . 470
TUPB001 – The Fine Structure of the Zone of Particle Interaction with a Finite Length Periodic Structure . . . 473
TUPB002 – Deflecting Structures with Minimized Level of Aberrations . . . 476
TUPB004 – Results of Testing of Multi-beam Klystrons for the European XFEL . . . 479
TUPB005 – Computational Model Analysis for Experimental Observation of Optical Current Noise Suppression Below the Shot-noise Limit . . . 482
TUPB006 – Stability Performance of the Injector for SACLA/XFEL at SPring-8 . . . 486
TUPB008 – Major Trends in Linac Design for X-ray FELs . . . 489
TUPB009 – C-Band Accelerating Structure Development and Tests for the SwissFEL . . . 492
TUPB010 – The Swiss FEL RF Gun: RF Design and Thermal Analysis . . . 495
TUPB011 – The Swiss FEL S-Band Accelerating Structure: RF Design . . . 498
TUPB012 – The Swiss FEL C-Band Accelerating Structure: RF Design and Thermal Analysis . . . 501
TUPB013 – Update on the Commissioning Effort at the SwissFEL Injector Test Facility . . . 504
TUPB014 – Comparative Design of Single Pass, Photo-cathode RF-LINAC FEL for the THz Frequency Range: Self Amplification vs. Enhanced Super-radiance . . . 507
TUPB015 – Warm Beamlines and Infrastructure in the European XFEL . . . 510
TUPB018 – Study of Beam-Based Alignment for Shanghai Soft X-Ray FEL Facility . . . 513
TUPB019 – Second CW and LP Operation Test of XFEL Prototype Cryomodule . . . 516
TUPB020 – Status of the European XFEL 3.9 GHz system . . . 519
TUPB021 – Study of Plasma Effect in Longitudinal Space Charge Induced Microbunching Instability . . . 522
TUPB022 – A Passive Linearizer for Bunch Compression . . . 525
TUPB023 – The Optimization of RF Deflector Input Power Coupler . . . 528
TUPB026 – Measurements of a Reduced Energy Spread of a Recirculating Linac by Non-isochronous Beam Dynamics . . . 531
TUPB028 – Status of the Rare Isotope Science Project in Korea . . . 534
TUPB029 – Beam Intensity and Energy Control for the SPIRAL2 Facility . . . 537
TUPB030 – Overview of the Superconducting Linacs of the Rare Isotope Science Project . . . 540
TUPB031 – Beam Envelope Analysis and Simulation . . . 543
TUPB032 – Beam Dynamics of the Linac ALPI-PIAVE in View of Possible Upgrades Scenario for the SPES Project. . . . 546
TUPB033 – Piezoelectric Actuator Based Phase Locking System for IUAC Linac . . . 549
TUPB034 – A Helium Injector for Coupled RFQ and SFRFQ Cavity Project at Peking University . . . 552
TUPB035 – A New Design of the RFQ Channel for GSI HITRAP Facility . . . 555
TUPB036 – Design of Re-Buncher Cavity for Heavy-ion LINAC in IMP . . . 558
TUPB039 – Conceptual Design of Superconducting Heavy Ion Linear Injector for HIAF . . . 561
TUPB040 – Status of the Linac SRF Acquisition for FRIB . . . 564
TUPB041 – Scattering of H^- Stripped Electrons from SEM Grids and Wire Scanners at the CERN LINAC4 . . . 567
TUPB042 – Progress on RFQIII Fabrication in J-PARC Linac . . . 570
TUPB043 – One Design of Heavy Ion Linac Injector for CSRm . . . 573
TUPB044 – Cryogenic System for the ADS Injector II in IMP, CAS . . . 576
TUPB046 – R&D Towards CW Ion Linacs at ANL . . . 579
TUPB047 – Status of the Superconducting RF Activities for the HIE ISOLDE Project . . . 582
TUPB048 – Discussion of the Optimisation of a Linac Lattice to Minimise Disruption by a Class of Parasitic Modes . . . 585
TUPB049 – Superconducting Low Beta Niobium Resonator for Heavy Ions . . . 588
TUPB052 – Studies of Parasitic Cavity Modes for Proposed ESS Linac Lattices . . . 591

TUPB053 – Main Coupler Design for Project X . . . 594
TUPB054 – Coherent Effects of High Current Beam in Project-X Linac . . . 597
TUPB055 – R&D of IMP Superconducting HWR for China ADS . . . 600
TUPB056 – The Multipacting Simulation for the New-shaped QWR using TRACK3P . . . 603
TUPB057 – Structural Analysis of the New-Shaped QWR for HIAF in IMP . . . 606
TUPB058 – An Analytical Cavity Model for Fast Linac-Beam Tuning . . . 609
TUPB060 – Multipacting Suppression Modeling for Half Wave Resonator and RF Coupler* . . . 612
TUPB061 – ADRC Control for Beam Loading and Microphonics . . . 615
TUPB062 – Longitudinal Dynamic Analysis for the Project X 3-8 GeV Pulsed Linac . . . 618
TUPB066 – Reduced-beta Cavities for High-intensity Compact Accelerators . . . 621
TUPB067 – Development of a Superconducting Half-Wave Resonator for PXIE . . . 624
TUPB068 – Cryomodule Designs for Superconducting Half-Wave Resonators . . . 627
TUPB069 – BEAMDULAC-SCL Code for Complex Approach of Beam Dynamic Investigation in SC LINAC 630
TUPB070 – Development of Proton Therapy at the SC Linac with BEAMDULAC-SCL Code . . . 633
TUPB071 – First Measurements on the 325 MHz Superconducting CH Cavity . . . 636
TUPB072 – Status of the Superconducting CW Demonstrator for GSI . . . 639
TUPB073 – Design and Simulation of a Test Model for a Tri-Spoke Cavity at RIKEN . . . 642
TUPB074 – Superconducting CW Heavy Ion Linac at GSI . . . 645
TUPB075 – Beam Dynamics Design of China ADS Proton Linac . . . 648
TUPB077 – Thorium Energy . . . 651
TUPB079 – Design and Beam Test of Six-Electrode BPMs for Second-Order Moment Measurement . . . 654
TUPB080 – Non-destructive Real-time Monitor to Measure 3D Bunch Charge Distribution with Arrival Timing to Maximize 3D Overlapping for HHG-Seeded EUV-FEL . . . 657
TUPB081 – Beam Diagnostics Development for Triumf E-Linac . . . 660
TUPB082 – Beam Loss Track Measurements by a Fast Trigger Scheme in J-PARC Linac . . . 663
TUPB084 – High Dynamic-Range High Speed Linac Current Measurements . . . 666
TUPB090 – Development of Permanent Magnet Focusing System for Klystrons . . . 669
TUPB091 – 176 MHz Solid State Microwave Generator Design . . . 672
TUPB092 – High Power Amplifier Systems for SARAF Phase II . . . 675
TUPB093 – Compact 4 kW Variable RF Power Coupler for FRIB Quarter-wave Cavities . . . 678
TUPB094 – High Power Tests of TRASCO RFQ Couplers . . . 681
TUPB095 – Design of Coupler for Direct Coupled Amplifier to Drift Tube Linac Cavities of the Injector RILAC2 for RIKEN RI Beam Factory . . . 684
TUPB097 – The C-band RF Pulse Compression for Soft XFEL at SINAP . . . 687
TUPB099 – Input Coupler of the J-PARC DTL . . . 690
TUPB100 – Recovery and Status Report of DTL/SDTL for the J-PARC After Earthquake . . . 693
TUPB101 – Beam Loss Occurred at DTL Cavity in J-PARC Linac . . . 696
TUPB102 – Design and Performances of Phase Monitor in J-PARC Linac . . . 699
TUPB103 – CSNS DTL Prototyping and RF Tuning . . . 702
TUPB104 – Study of the Beam Dynamics in the RISP Driver Linac . . . 705
TUPB107 – Amplitude and Phase Control of the Accelerating Field in the ESS Spoke Cavity . . . 708
TUPB108 – Uppsala High Power Test Stand for ESS Spoke Cavities . . . 711
WE1A01 – ERL-Based Light Source Challenges . . . 714
WE1A02 – Status and Future of the CLIC Study . . . 719
WE1A03 – Application of X-band Linacs . . . 724
WE1A04 – The ARIEL Superconducting Electron Linac . . . 729
WE1A05 – Linac-Based Laser Compton Scattering X-Ray and Gamma-Ray Sources . . . 734
WE2A01 – RF Power Production at the Two Beam Test Stand at CERN . . . 738
WE2A02 – Solid State Marx Modulators for Emerging Applications . . . 743
TH1A01 – Results Achieved by the S1-Global Collaboration for ILC . . . 748
TH1A02 – Compact Superconducting Crabbing and Deflecting Cavities . . . 753
TH1A03 – Superconducting Spoke Cavities for Electron and High-Velocity Proton Linacs . . . 758
TH1A04 – Superconducting Linac and Associated Developments at IUAC Delhi . . . 763
TH2A01 – The ESS Linac Design . . . 768
TH2A02 – SPIRAL2 Accelerator Construction Progress . . . 773
TH2A03 – Design and Construction of the Linac4 Accelerating Structures . . . 778

TH2A004 – Computational Model Analysis for Experimental Observation of Optical Current Noise Suppression Below the Shot-noise Limit . . . 783
TH3A01 – Status of ILC . . . 787
TH3A02 – The 12 GeV Energy Upgrade at Jefferson Laboratory . . . 792
TH3A03 – ERL-Based Lepton-Hadron Colliders: eRHIC and LHeC . . . 797
TH3A04 – Plasmas, Dielectrics and the Ultrafast: First Science and Operational Experience at FACET . . . 802
THPLB01 – Linac Construction for China Spallation Neutron Source . . . 807
THPLB02 – Performance of Ferrite Vector Modulators in the LLRF system of the Fermilab HINS 6-Cavity Test . . . 810
THPLB03 – Front-End Linac Design and Beam Dynamics Simulations for MYRRHA . . . 813
THPLB04 – Preliminary Study of Proton Beam Transport in a 10 MeV Dielectric Wall Accelerator . . . 816
THPLB05 – R&D Activities on High Intensity Superconducting Proton Linac at RRCAT . . . 819
THPLB06 – The New Option for a Front End of Ion Linac . . . 822
THPLB07 – Experience with a 4-Rod CW Radio Frequency Quadrupole . . . 825
THPLB08 – High-Power RF Conditioning of the TRASCO RFQ . . . 828
THPLB09 – Status of E-XFEL String and Cryomodule Assembly at CEA-Saclay . . . 831
THPLB11 – Experimental and Simulation Study of the Long-path-length Dynamics of a Space-charge-dominated Bunch . . . 834
THPLB12 – Photoinjector SRF Cavity Development for B*ERL*inPro . . . 837
THPB002 – Preliminary Study of Proton Beam Transport in a 10 MeV Dielectric Wall Accelerator . . . 840
THPB003 – R&D Activities on High Intensity Superconducting Proton Linac at RRCAT . . . 843
THPB004 – Current Status of the RAL Front End Test Stand (FETS) Project . . . 846
THPB005 – Front-End Linac Design and Beam Dynamics Simulations for MYRRHA . . . 849
THPB006 – Post Acceleration of Laser-generated Proton Bunches by a CH-DTL . . . 852
THPB007 – A Pulsed Linac Front-end for ADS Applications . . . 855
THPB008 – A Coupled RFQ-IH Cavity for the Neutron Source FRANZ . . . 858
THPB009 – Status of CH Cavity and Solenoid Design of the 17 MeV Injector for MYRRHA . . . 861
THPB010 – Progress in the Construction of Linac4 at CERN . . . 864
THPB011 – Linac4 45 keV Proton Beam Measurements . . . 867
THPB012 – High Resolution Emittance Measurements at SNS Front End . . . 870
THPB013 – Diagnostics Tools for Beam Halo Investigation in SNS Linac . . . 873
THPB014 – Lattice Design and Beam Dynamics Studies for Project X . . . 876
THPB015 – Performance of Ferrite Vector Modulators in the LLRF system of the Fermilab HINS 6-Cavity Test . . . 879
THPB016 – Concept: Low Energy, Low Intensity NF from ProjectX . . . 882
THPB017 – A Concept: 8GeV CW Linac, Staged Approach . . . 885
THPB020 – Annular-ring Coupled Structure for the Energy Upgrade of the J-PARC Linac . . . 888
THPB021 – Recovery Efforts from the Tohoku Earthquake and Energy Upgrade Preparation of the Beam Transport from the J-PARC Linac to the 3-GeV Synchrotron . . . 891
THPB022 – Beam Phase Measurement for PEFP Linear Accelerator . . . 894
THPB023 – Linac Construction for China Spallation Neutron Source . . . 897
THPB024 – Main Linac Physics Design Study of the C-ADS Project . . . 900
THPB025 – 325 MHz CW Room Temperature High Power Bunching Cavity for the China ADS MEBT1 . . . 903
THPB026 – The Beam Commissioning Plan of Injector II in C-ADS . . . 906
THPB027 – Progress of one of 10 MeV superconducting proton linear Injectors for C-ADS . . . 909
THPB028 – The ESS Low Energy Beam Transport Line Design . . . 912
THPB029 – The ESS RFQ Beam Dynamics Design . . . 915
THPB030 – DTL Design for ESS . . . 918

Abstract

Topographic structure on Superconductivity Radio Frequency (SRF) surfaces can contribute additional cavity RF losses describable in terms of surface RF reflectivity and absorption indices of wave scattering theory. At isotropic homogeneous extent, Power Spectrum Density (PSD) of roughness is introduced and quantifies the random surface topographic structure. PSD obtained from different surface treatments of niobium, such as Buffered Chemical Polishing (BCP), Electropolishing (EP), Nano-Mechanical Polishing (NMP) and Barrel Centrifugal Polishing (CBP) are compared. A perturbation model is utilized to calculate the additional rough surface RF losses based on PSD statistical analysis. This model will not consider that superconductor becomes normal conducting at fields higher than transition field. One can calculate the RF power dissipation ratio between rough surface and ideal smooth surface within this field range from linear loss mechanisms.

INTRODUCTION

RF loss induced by roughness is considered in many RF components, such as micro strip transmission line, wave guide and RF resonator. It can be understood as the RF electromagnetic field penetrates the surface and there the induced current will pass and cause RF loss. [1] However, in a RF wave view, the incident wave is reflected, scattered and absorbed by the rough surface. Inside of a resonator, the reflected, scattered wave contributes to standing wave field, while the absorbed RF wave is attributed to the RF surface loss. These two perspectives may both be used to describe the same RF loss.

In a resonator, only several specific RF standing wave modes can exist to meet the boundary condition which is the resonator geometry. The electric and magnetic field at one location is combination a of EM components of those plane waves. Within the resonator, E and M are separated in space and interchange their energy over a distance. Thus the peak E and M field are always not the same location. With special EM setup, TE, TM, TEM are used to describe the EM field direction, if presumed direction is beam axis. In some sense, it is very tedious and difficult to expand the field into plane wave expansion. If so, the incident direction should also be from all directions. Therefore, a RF loss calculation method is required and independent of direction. It also covers all frequencies or wavelengths.

METHODOLOGY

A rough surface will cost more RF loss. [2] One simple reason is that the surface current have more current path. In another word, the RF wave as more radiation absorption surface. This RF loss will contribute into power consumption and aggravate the quality factor.

If we consider a 2D random rough surface Z= f(x) in Fig.1. We can expand the magnetic field into Fourier series as in x and z direction. [3]

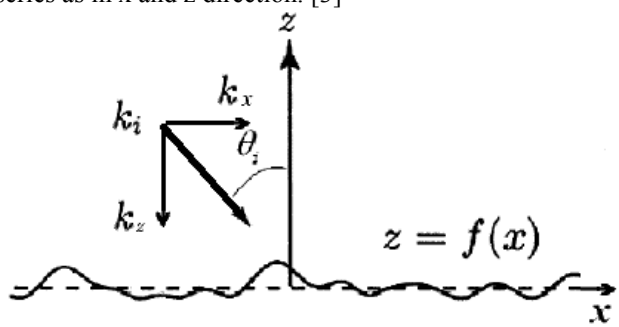

Figure 1: A plane wave incident impinging on a rough surface with incident angle θ_i.

$$\psi(x,z) = \int_{-\infty}^{\infty} dk_x \exp(-jk_x x + jk_{1z} z)\,\tilde{\psi}(k_x)$$

Where $k_{1z} = \sqrt{k_1^2 - k_x^2}$ and $k_1 = \frac{1-j}{\delta}$. Here δ is the skin depth $\delta = \sqrt{\frac{2}{\omega\mu\sigma}}$ and σ is the superconducting conductivity. The physics behind this equation is that the total magnetic field is combination of field component at each spatial wavelength. In another word, the total magnetic field can be expanded into magnetic contribution from each wavelength in spatial frequency.

If we use a second order small perturbation methods, setting

$$\tilde{\psi}(k_x) = \tilde{\psi}^{(0)}(k_x) + \tilde{\psi}^{(1)}(k_x) + \tilde{\psi}^{(2)}(k_x)$$

In first approximation, a fixed constant magnetic field H_0 is applied on the surface. Thus, the equation above becomes:

$$H_0 = \int_{-\infty}^{\infty} dk_x \exp(-jk_x x + jk_{1z} f(x))\,\tilde{\psi}(k_x)$$

Basically, we have done a Fourier transform to redistribute the magnetic field into each surface spatial wavelength in x direction.

By balancing this equation to second order, we obtain:

*Work supported by Jefferson Science Associates. xuchen@jlab.org

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

$$\tilde{\psi}^{(0)}(k_x) = H_0\delta(k_x)$$
$$\tilde{\psi}^{(1)}(k_x) = -jk_1H_0F(k_x)$$
$$\tilde{\psi}^{(2)}(k_x) = H_0\int_{-\infty}^{\infty}dk_x'F(k_x-k_x')F(k_x')\left(-k_1k_{1z}'+\frac{k_1^2}{2}\right)$$

For now, we have calculated the RF magnetic field on this given surface. The power absorbed by the conductor, for a given width w in y direction and length L in x direction, can be calculated from the Poynting vector.

$$P_a = \frac{w}{2\sigma}\mathrm{Re}\int ds\frac{\partial\psi}{\partial n}\psi^*$$

We simplify the results:

$$\langle P_a\rangle = \frac{wL}{2\sigma\delta}|H_0|^2\left\{1+\frac{2h^2}{\delta^2}\left[1-\frac{\delta}{h^2}\int_{-\infty}^{\infty}dk_xW(k_x)\mathrm{Re}\sqrt{k_1^2-k_x^2}\right]\right\}$$

In order to get rid of the external field, we normalize the power dissipation with that of a smooth surface.

$$\frac{\langle P_a\rangle}{P_{a,\mathrm{smooth}}} = 1+\frac{2h^2}{\delta^2}-\frac{4\pi}{\delta}\int_0^{\infty}dk_\rho\left\{k_\rho W_{2D}(k_\rho)\mathrm{Re}\sqrt{\frac{-2j}{\delta^2}-k_\rho^2}\right\}$$

$W_{2D}(k_\rho)$ is the 2D PSD from an isotropic surface.

Researcher have combined TM and TE wave mode into this equation into a 2D problem. They also avoid the assumption that surface field is a constant.

One should note:

1. The RMS and decay parameters (penetration depth) ratio, h/δ, is critical for characterizing the increased losses.

2. Third term reduces to h^2/δ^2, when the k_ρ is small. The second/third term have net contribution if $1/\delta$ and k_ρ are comparable.

3. Generally, higher $W_{2D}(k_\rho)$ brings additional loss.

APPLICATION TO SRF SURFACES

To obtain more accurate RF loss ratio, one needs to extend the PSD into as broad a frequency range as possible. Since all characterization method shave cut-off frequencies, one can at most get an extended PSD. The recent extended frequency range is 1/1.2 cm^{-1}–1/10 nm^{-1}, over 6 decades, with white light interferometry and atomic force microscopy. Because the magnetic field is expanded into horizontal spatial wavelength, the PSD frequency should cover the RF wavelength and beyond. Though an approximation methods is introduced by using Inverse Abel transforms to extend limited range, but obtaining 1D PSD with wider frequency range could improve later calculation accuracy.

$$<W(k_\rho)^{2D}>=-\tfrac{1}{\pi}\times\int_{k_\rho}^{\infty}\frac{dk_\rho}{\sqrt{k_x^{\,2}-k_\rho^{\,2}}}\frac{d}{dk_x}<W(k_x)^{1D}>$$

$$<W(k_x)^{1D}>=2\times\int_{k_x}^{\infty}\frac{k_\rho dk_\rho}{\sqrt{k_\rho^{\,2}-k_x^{\,2}}}<W(k_\rho)^{2D}>$$

This transformation also permits the transformation of the high-frequency behavior of the spectra of one dimensionality to be transformed into the high-frequency behavior of the other without knowledge of their low-frequency behavior.

We investigate SRF surfaces with current polishing methods and materials polished are large/fine/single grain Nb sheets. Buffered chemical polishing, electropolishing and mechanical centrifugal barrel polishing samples are characterized by Atomic Force Microscopy (AFM) and White light interferometry (WLI). Note that these two characterizations have different lateral resolutions and scan scopes which determine the spectral frequency ranges.

1D averaged PSD is calculated by following the routine introduced previously. [4] Such routine includes proper detrending, windowing and averaging.

In this study, the R_q and PSD are used to derive power ratio. Rq value from 4 different locations on each sample is averaged and summarised in Table 1.

Table 1: Averaged R_q with AFM and WLI

Samples	Single crystal		"Standard" fine-grained			
Treatment	After30 µm BCP	Nano polished	+100 µm BCP	+50 µm EP	Centrifugal Barrel Polishing (CBP)	
					Fine Grain	Large Grain
Atomic force microscopy ~5×5µm						
R_q(nm)	1.99	2.84	4.89	4.40	2.76	1.20
Atomic force microscopy ~100×100µm						
R_q(nm)	7.05	13.5	392.90	74.30	70.8	7.71
White light interferometry ~234×312µm (20x magnification)						
R_q (nm)	35.7	1.63	1500.4	291.7	151.8	13.5
White light interferometry ~930×1244µm(5x magnification)						
R_q (nm)	391	5.24	2008.5	642.8	335.5	49.0

One can generalize that Rq value decrease from BCP>EP>CBP Large grain> CBP Fine grain> Single crystal>Nanopolishing samples.

Averaged 1D PSD from AFM/WLI are combined in Fig.2.

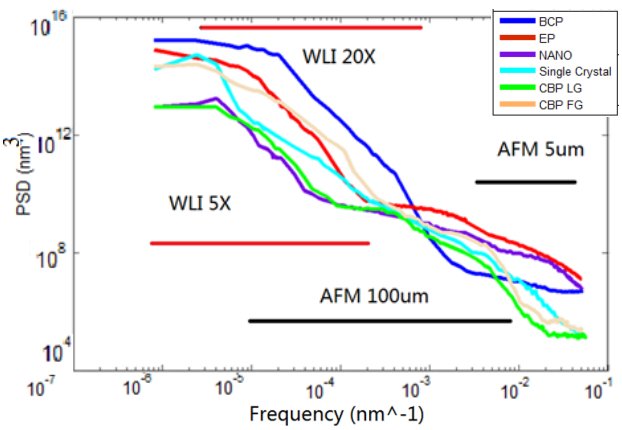

Figure 2: Joint 1D PSD models from AFM/WLI are shown and the characterization frequency domains are indicated.

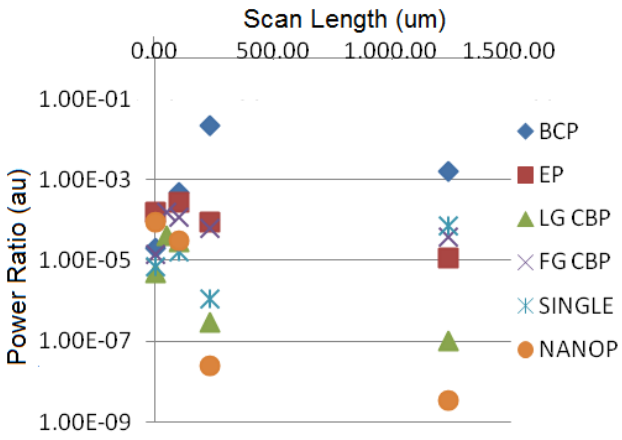

Figure 3: Power Ratio calculated from 1D PSD.

The power ratio is shown in Fig.3 and by inverse Abel transform, the 2D PSD are shown in Fig.4.

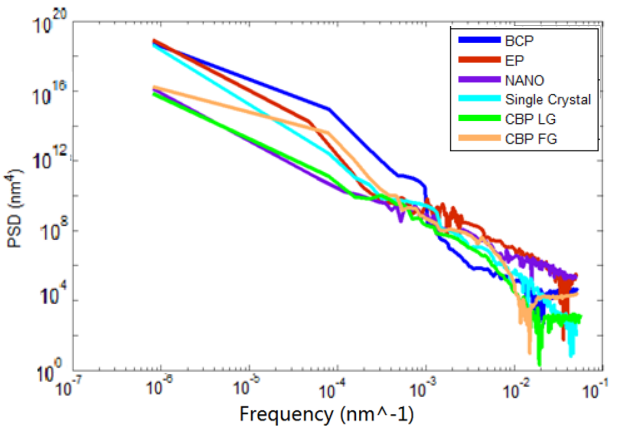

Figure 4: 2D PSD calculated from various surfaces. Power ratio index are illustrated in Fig.5.

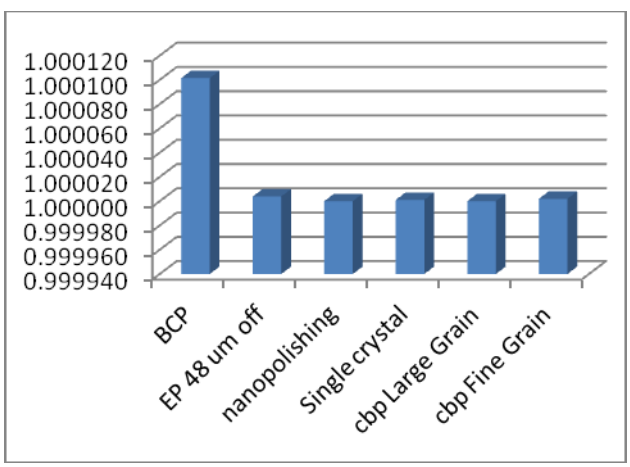

Figure 5: Power Ratio from 2D isotropic PSD.

BCP surface show higher ratio, but other surfaces suggest almost the same close to 1.

DISCUSSION

One can see from power ratio equation that the last term is an integration of 2d PSD.

$$\frac{\langle P_{a,\mathrm{rough}}\rangle}{P_{a,\mathrm{smooth}}} = 1 + \frac{2h^2}{\delta^2} - \frac{4\pi}{\delta}\int_0^\infty dk_\rho \left\{ k_\rho W_{2D}(k_\rho)\,\mathrm{Re}\sqrt{\frac{-2j}{\delta^2} - k_\rho^2} \right\}$$

Without the Re(…), the integrand is simply the square of RMS height. One can infer that if the k_ρ is small enough compared with $2/\delta$, then the Re(…) term reduced into $1/\delta$. In that limit the second and third terms cancel each other. The total power ratio becomes one. This gives substantiates the interpretation that features at larger wavelength have less RF power loss than the small high frequency features. Another understanding is that only features with lateral extent comparable to the penetration length give a significant effect on the additional power loss ratio. Applying this analysis to variously prepared niobium surfaces typical of those in SRF cavities, we find that linear RF losses depend negligibly on roughness for any of the characteristic surfaces considered. On the other hand, SRF materials are particularly susceptible to non-linear and temperature-dependent losses. The non-linear losses are reflected in the observed Q drop with increasing surface magnetic field. We are examining the influence of topography on such losses separately [5].

CONCLUSION

Spectral study suggested that surface roughness doesn't contribute much in the linear RF loss, because current practical surface a smooth enough at a wavelength closed to penetration depth.

FEASIBILITY STUDY OF SHORT PULSE MODE OPERATION FOR MULTI-TURN ERL LIGHT SOURCE*

T. Atkinson†, A. V. Bondarenko, A. N. Matveenko, Y. Petenev,
Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (HZB), Germany.

Abstract

The optic and simulation group at HZB are designing a light source based on the emerging Energy Recovery Linac superconducting technology, the Femto-Science-Factory (FSF) will provide its users with ultra-bright photons of angstrom wavelength at 6 GeV. The FSF is intended to be a multi-user facility and offer a wide variety of operation modes. A low emittance $\sim 0.1\,\mu$m rad mode will operate in conjunction with a short-pulse ~10 fs mode.

INTRODUCTION

This paper continues on from a recent introductory study[1] and highlights the physical limitations when trying to offer interchangeable modes and preserve beam quality. The paper concentrates on the short bunch mode, introducing the multi stage compression schemes in a general manner and presents the first results of the start-to-end beam simulations.

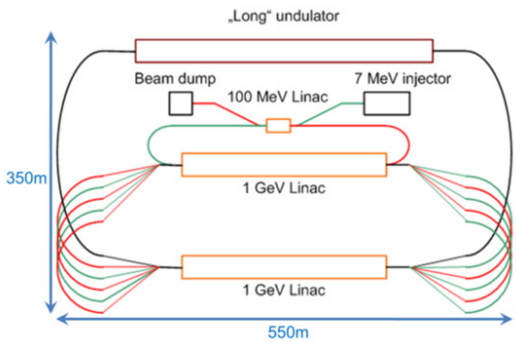

Figure 1: Schematic of the FSF Multi-Turn ERL.

The main design parameters of the FSF are listed in Table 1 and Fig. 1 shows the layout of the light source.

A SRF injector based on the design parameters of the BERLinPro[2] project delivers the 100 MeV electron beam into the main accelerator. Here two 1 GeV linacs are continually traversed until 6 GeV beam energy is reached. Each Arc contains straight sections for undulators and the final energy Arc permits a long straight section for 5000 period undulators.

The beam quality delivered to the long undulators and hence the photon brilliance attainable depends on the machine operating mode.

Table 1: Main design parameters of FSF

Parameter	High Brilliance Mode	Short Bunch Mode
Energy (GeV)	6	6
Charge (pC)	15	4
Bunch Length (fs)	>200	~10
<B> (ph/s/mm^2/mrad^2/0.1%)	10^{22}	10^{21}
B_{peak} (ph/s/mm^2/mrad^2/0.1%)	10^{26}	10^{26}

SHORT BUNCH MODE

Single pass machines do not suffer the same fate as storage rings as equilibrium is never reached. A design based on linear uncoupled optic, helps address a proof-of-principle for the short pulse mode, which is later then tested using a realistic input beam distribution from the BERLinPro injector project.

Compression in the Injector

Producing a femto-second pulse of low energy spread starts at the Gun, Table 2. Here the longitudinal electron beam properties are restricted by the photo-injector laser pulse and the superconducting RF acceleration. The primary subtle compression in the Merger between the Booster and linac minimizes transverse emittance growth.

Table 2: Injector ASTRA[3] simulations

Component	Bunch Length (mm)	Emittance (keV mm)	Energy (MeV)
Gun	0.7	0.3	1.8
Booster	1.0	2	6.6
Linac	0.45	2.2	50

The injector Arc is then used to prepare the beam for the main accelerator. The combination of a second linac to increase the beam energy to 100 MeV and the R_{56} in the Arc compress the beam to $\sigma_t \sim 660\,fs$ with a correlated energy spread of $\Delta E/E \sim 1.5 \cdot 10^{-4}$.

Telescopic Compression

The main acceleration stage uses a scheme based on telescopic compression. In this regime the combination of the linac chirps and the R_{56} in the Arcs are described as a simple focusing (F) and defocussing (f) lens, Eq. 1. The shortest pulse achievable from a multi-turn isochronous structure is with full compression in the final arc. This is however at the expense of a correlated energy spread, blue in Fig. 2.

$$\begin{pmatrix} z \\ \Delta E/E \end{pmatrix}_1 = \begin{pmatrix} f/F & F-f \\ 0 & F/f \end{pmatrix} \begin{pmatrix} z \\ \Delta E/E \end{pmatrix}_0 \quad (1)$$

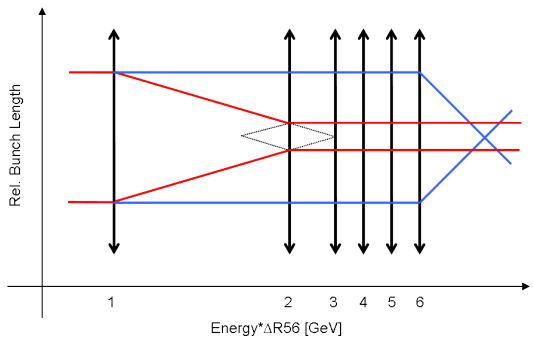

Figure 2: Telescopic bunch compression to preserve energy spread.

In order to remove the correlated energy spread and still produce a short pulse consider an alternative solution based on a telescopic lattice, red in Fig. 2. Implementing the first two arcs as achromats and accelerating either side of on-crest in each linac, the two "lenses" can share the same focal plane, just like in a telescope, to maximize the magnification and recover the energy correlation properties of the injector.

The minimal bunch length of the final beam into the long undulators is restricted by the requirement of an rms energy spread given by $\Delta E/E \sim 1/\text{UndulatorPeriods} \sim 10^{-4}$, to be $\sigma_t \sim 10\,fs$ when implementing purely linear optic.

Simulation Codes

Starting from previous calculations using ASTRA[4] up until the 50 MeV injector linac exit, the beam distribution was converted and tracked onwards through the FSF using Elegant[5].

Short Bunch Simulations

The first 50 m shown in Fig. 3 is the initial bunch compression in the injector Arc to prepare the beam for the first 1 GeV FSF linac of phase $\phi_1 = +8^\circ$ off crest . What follows this a step like bunch compression in the first Arc with $R_{56} = 20\,cm$ till the second 1 GeV linac at $\phi_2 = -20^\circ$ (placed at $s \sim 500\,m$). The second Arc of $R_{56} = 5\,cm$

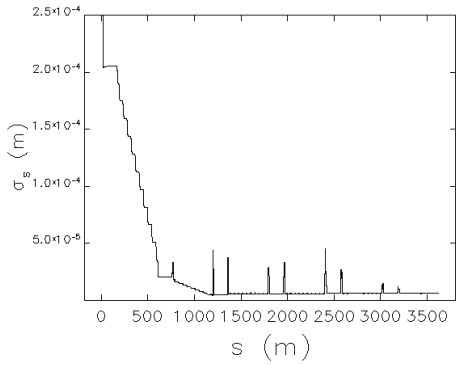

Figure 3: Bunch length variations in the FSF.

then completes the full bunch compression. These longitudinal bunch parameters are then preserved in the remaining isochronous Arcs, with some "spiking" shown due the vertical spreaders.

With the present optic a bunch length $\sigma_t \sim 20\,fs$ and energy spread $\Delta E/E \sim 1 \cdot 10^{-4}$ is achievable at the long undulator entrance Fig. 4.

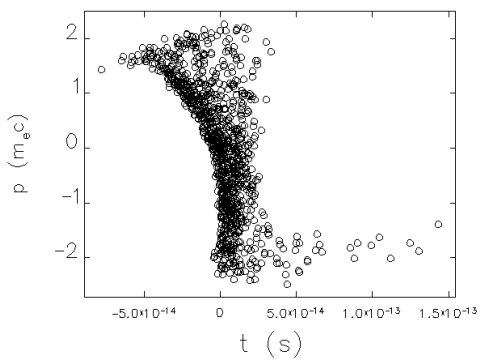

Figure 4: Phase space at long undulator entrance.

Large cumulative distortions due to radiation effects are not envisaged in this two stage process to achieve full compression as the energy after the first main linac is 1 GeV and the bunch charge is reduced for the short pulse mode.

LONGITUDINAL EMITTANCE

The longitudinal emittance can be described as an ellipse occupying a density of particles in $(c\Delta t, \delta)$ phase space. The non-linear properties of RF curvature acceleration can alter the phase distributions varying the normalized emittance.

2nd Order Aberrations

An emittance compensation scheme using higher order magnetic terms created in the Arcs is described here.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Using the linacs relative energy Eq. 2 and the Arcs bunch length Eq. 3 variations respectively one can calculate the emittance variation across the two stages as follows.

$$
\begin{aligned}
&LINAC \\
\delta_1 &= \delta_0 + R_{65} c\Delta t_0 + T_{655}(c\Delta t_0)^2 \quad (2)\\
c\Delta t_1 &= c\Delta t_0
\end{aligned}
$$

$$
\begin{aligned}
&+ARC \\
\delta_2 &= \delta_1 \\
c\Delta t_2 &= c\Delta t_1 + R_{56}\delta_1 + T_{566}\delta_1^2 \quad (3)
\end{aligned}
$$

Keeping only second order terms, assuming $\delta_0 = 0$ and substituting Eq. 2 and Eq. 3 the emittance can be approximated as Eq. 4

$$
\begin{aligned}
\epsilon^2 &= <(c\Delta t_2)^2><\delta_2^2> - <(c\Delta t_2\delta_2>^2 \quad (4)\\
\epsilon^2 &\simeq <(c\Delta t_0)^4><(c\Delta t_0)^2>\left(T_{566}R_{65}^3 - T_{655}\right)^2
\end{aligned}
$$

Emittance Correction

One can interpret Eq. 4 as a useful tool to control the normalized emittance. The accelerating phase determines both the R_{65} and T_{655} terms and sextupoles in the Arc can adjust T_{566} to compensate for them.

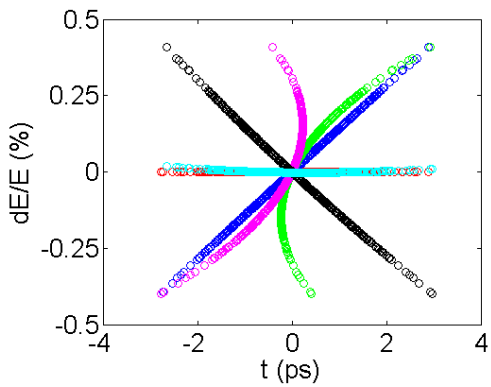

Figure 5: Correction of the 2nd order aberrations.

Fig. 5 demonstrates this concept, showing anticlockwise the variation of the beam phase space from an uncorrelated low emittance flat beam (red) through a non-linear RF chirp (blue). Then the introduction of first and second order magnetic correction, rotating and deforming the phase space (green - magenta - black) before finally a second linac is used to approximately recover the original distribution (cyan).

Emittance Correction Simulations

This scheme was adapted for the two stage telescopic bunch compression in the FSF machine simulations Fig. 6. The second order terms from the off-crest RF acceleration for the short bunch mode were optimized so that they would be fully compensated for by the T_{566} term created in the dipoles in the achromat Arcs.

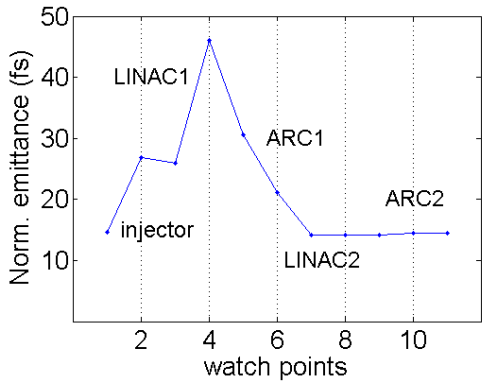

Figure 6: Recovering the injector properties.

Additional correction using sextupoles will be considered for future calculations as an essential tool for the recovery of the injectors longitudinal beam properties.

CONCLUSION

A two stage linear bunch compression scheme for the FSF light source has been presented and simulated using realistic beam parameters from the BERLinPro injector. A compensation scheme to recover the normalized emittance of the injector has been proposed.

LINAC OPTICS DESIGN FOR MULTI-TURN ERL LIGHT SOURCE*

Y. Petenev#, T. Atkinson, A.V. Bondarenko, A.N. Matveenko, HZB, Berlin, Germany.

Abstract

The optics simulation group at HZB is designing a multi-turn energy recovery linac-based light source. Using the superconducting Linac technology, the Femto-Science-Factory (FSF) will provide its users with ultra-bright photon beams of angstrom wavelength at 6 GeV. The FSF is intended to be a multi-user facility and offer a variety of operation modes. In this paper a design of transverse optic of the beam motion in the Linacs is presented. An important point in the optics design was minimization of the beta-functions in the linac at all beam passes to suppress beam break-up (BBU) instability.

INTRODUCTION

In this document we present a design of a Linac optics for a new 3 pass ERL-based LS with 6 GeV maximum energy of electron beam. This future facility is named Femto-Science Factory (FSF) [1].

The schematic layout of the facility is presented in Fig. 1. A beam is created in 1.3 GHz SRF gun with photo cathode. We consider an SRF injector with similar parameters to the B*ERL*inPro injector under development at HZB [2, 3]. Then it passes a 100 MeV Linac and is accelerated to 6 GeV after passing 3 times through each of two 1 GeV main Linac's. In the arcs between the acceleration stages it is assumed to have undulators with 1000 periods. In the long straight section (see Fig.1) a long undulator with 5000 periods is assumed. The main design parameters of FSF are presented in Table 1.

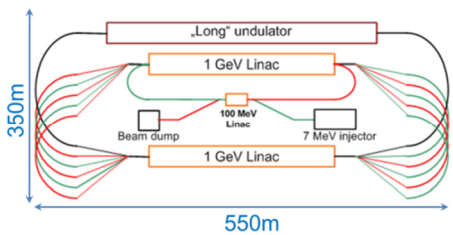

Figure 1: The scheme of FSF.

One potential weakness of the ERLs is transverse beam breakup instability, which may severely limit a beam current. If an electron bunch passes through an accelerating cavity it interacts with dipole modes (e.g. TM_{110}) in the cavity. First, it exchanges energy with the mode; second, it is deflected by the electro-magnetic field of the mode. After recirculation the deflected bunch interacts with the same mode in the cavity again which constitutes the feedback. If net energy transfer from the beam to the mode is larger than energy loss due to the mode damping the beam becomes unstable.

The actuality of this problem was recognized in early experiments with the recirculating SRF accelerators at Stanford [4] and Illinois [5], where threshold current of this instability was occurring at few microamperes of the average beam current. In the works of Rand and Smith in [6] dipole high order modes were identified as a driver of this instability. In late of the 80's the detailed theoretical model and simulation programs had been developed [7, 8]. Nowadays the interest to this problem was renewed. The requirements for more detailed theory and simulation programs [9-11] are given by the needs of high current (~100 mA) ERLs.

The threshold current for the transverse beam breakup may be estimated for the case of a single cavity and single mode for a multipass ERL in the form as [11]:

$$I_{th} \approx I_0 \frac{\lambda\!\!\!^{-2}}{Q_a L_{eff} \sqrt{\sum_{m=1}^{2N-1} \sum_{n=m+1}^{2N} \frac{\beta_m \beta_n}{\gamma_m \gamma_n}}}, \qquad (1)$$

where I_0- Alfven current, Q_a is the quality factor of HOM, $\lambda\!\!\!^{-} = \lambda/2\pi$, λ is the wavelength corresponding to the resonant frequency of the TM_{110} mode, γ_m is the relativistic factor at the m-th pass through the cavity, β_m – is the Twiss parameter, L_{eff} – is the effective length of the cavity, N is the number of passes during acceleration. It should be noted that (1) gives more realistic estimation of the BBU threshold current than a similar expression in [9] with a 1/N(2N-1) dependence on the number of passes. This is the result of an assumption in [9] of integer tunes in every turn of the ERL.

Table 1: Main Design Parameters of FSF

Parameter	High brilliance mode	Short bunch mode
E, GeV	6	6
<I>, mA	20	5
Q, pC	15	4
τ, fs	200-1000	~10
<B>, ph/s/mm2/mrad2/0.1%	$8 \cdot 10^{22}$	$\sim 4 \cdot 10^{21}$
B_{peak}, ph/s/mm2/mrad2/0.1%	10^{26}	$\sim 10^{26}$

Eq. 1 shows that it is preferable to have low β-functions at low energies. Therefore, the design was optimised to minimize beta functions of the beam in the Linac to increase the threshold current of BBU instability from one

point of view and to decrease the beats of the beta functions in the spreaders from another.

As it was shown in [1], for a scheme of FSF, presented in Fig. 1, BBU instability will develop in the 1st cavity of the 1st 1 GeV linac.

In this paper we analyze the influence of the energy gain in the preinjection linac (100 MeV) and two main linacs (1 GeV) on the BBU threshold and propose an optimized solution.

Preinjection Linac Pattern

In this part we would like to discuss BBU instability in the preinjection linac, which is coming after the merger section. In Fig. 1 it is suggested to have a 100 MeV linac. Therefore we have acceleration from 7 to 107 MeV, or deceleration for the same amount of energy. Therefore it is required to have one cryomodule with an acceleration gradient of the cavities of G = 15.5 MeV/m.

Now we would like to analyse model with a linac consisting of two cryomodules with acceleration up to 250 MeV and with a triplet of quadrupole magnets in between them, which role is to change the sign of the twiss parameter α of the beam. Let us find the initial injection twiss parameters to have the equal threshold currents for the entrance and for the middle of the linac. To find that we will use eq. 1 and a model of the linac with one dipole HOM, which we locate at different positions in the linac. In this case we assume that the 1st cryomodule is a long cavity with a transfer matrix M given by [12]:

$$\begin{pmatrix} \cos(\alpha)-\sqrt{2}\sin(\alpha) & \frac{\sqrt{8}\gamma_0 L\sin(\alpha)}{\Delta\gamma} \\ -\frac{3}{\sqrt{8}}\frac{\Delta\gamma\sin(\alpha)}{L\gamma_1} & \left(\cos(\alpha)+\sqrt{2}\sin(\alpha)\right)\frac{\gamma_0}{\gamma_1} \end{pmatrix}, \quad (2)$$

where $\alpha = \frac{1}{\sqrt{8}}\ln\left(\gamma_1/\gamma_0\right)$, $\gamma_{1(0)}$ is the final(initial) normalized energy of the particle, L – the length of the cavity (cryomodule). Also we assume that there is a symmetrical β-functions on acceleration and deceleration in the linac.

Therefore we can transfer the beta function through the 1st cryomodule as:

$$\beta_1 = \frac{\gamma_1}{\gamma_0}\left(\beta_0 m_{11}^2 - 2\alpha_0 m_{11}m_{12} + \frac{1+\alpha_0^2}{\beta_0}m_{12}^2\right), \quad (3)$$

The RF focusing in the second cryomodule is quite weak and we represent it with a cavity without RF focusing for simplicity. So the beta function at the end of the linac might be found as:

$$\beta_2 = \frac{\gamma_2}{\gamma_1}\left(\beta_1 - 2\alpha_1 L + \frac{1+\alpha_1^2}{\beta_1}L^2\right), \quad (4)$$

The minimum of the $\beta_2 = 2L^2/\beta_1$ is given, when

$$\alpha_1 = \frac{\beta_1}{L}, \quad (5)$$

Now we can proceed with an equation for the thresholds:

$$\sqrt{\frac{\beta_0\beta_2}{\gamma_0\gamma_2}} = \frac{2\beta_1}{\gamma_2-\gamma_0}, \quad (6)$$

To find the solution we will vary the initial twiss parameters and look for a maximum value of the thresholds. The numerical solution is presented in Fig. 2.

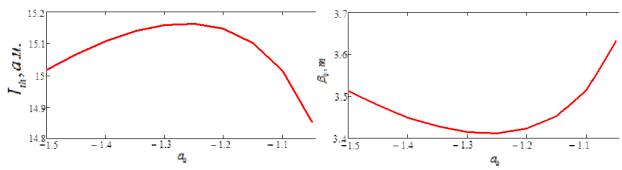

Figure 2: Threshold current, calculated using eq. 1 (without constants, which are the same for all cavities) and initial twiss parameters for preinjection Linac, consisting of two long cavities with a triplet in between.

One can see from Fig. 2 that the maximum threshold current is achieved at $\alpha_0 \sim$ -1.26 and $\beta_0 \sim 3.41$.

Different Acceleration Pattern

In this paragraph we would like to discuss an improvement of the present scheme of FSF, where we have 100 MeV preinjection and then two 1 GeV Linacs (Fig. 1), for the scheme, presented in Fig. 3.

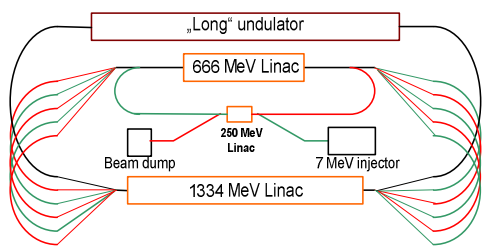

Figure 3: The improved acceleration scheme of FSF.

One of the motivations of this improvement was BBU instability. The new scheme gives roughly 1.7 times better threshold current for the 1-st cavity in the 1-st linac see Table 2, where the instability develops in the first scheme.

The easiest way to see the reason of rebalancing of the energies in the two main linacs is to analyse the eq. 1, specifically the square root in the denominator. We would

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

like to find a balance between the energy gains in two main linacs to have equal threshold currents for them. To do that, we will analyse a model with linacs, when a focusing from a triplets is neglected for the second and the third passes. In this model with the injection energy of about 250 MeV the transverse focusing inside the cavities can be neglected. So, we assume that the beta functions of a beam at the exit and at the entrance to the linac are about the length of the linac for the second and the third passes and for the end of the linacs at the first pass and it is about the length of the one cryomodule [1] at the entrance for the first pass.

Let's introduce G as a gradient of the cavities in MeV/m, $L= 2000$ [MeV] $/G$ is a length of the cavity structure, required to accelerate to the final energy of 2 GeV, x is the length of the first linac and, therefore, L-x is the length of the 2-nd. Now we can find energies $\gamma_{1(2),n}$ for each pass and as we said before $\beta_{1,1(6)} = \beta_{2,1(6)} \sim 12.57$ m and $\beta_{1,n} = x$ or $\beta_{2,n} = L$-x for the first and the second linac respectively and for n=2..5.

We can proceed with the following equation:

$$\sqrt{\sum_{m=1}^{2N-1}\sum_{n=m+1}^{2N}\frac{\beta_{1,n}\beta_{1,m}}{\gamma_{1m}(x)\gamma_{1n}(x)}} = \sqrt{\sum_{m=1}^{2N-1}\sum_{n=m+1}^{2N}\frac{\beta_{2,n}\beta_{2,m}}{\gamma_{2m}(x)\gamma_{2n}(x)}}, \quad (7)$$

when the threshold currents have the same values for the 1-st and last cavities in both linacs. This equation can be solved numerically and gives the result that x ~ L/3 with injection energy – $\gamma_{1,1} = 480$. This explains why we propose a new acceleration pattern in Fig. 3.

Now we proceed with a modeling of the linac optics in Elegant program [13]. Optics for all three passes through the first 666 MeV linac is presented in Fig. 4.

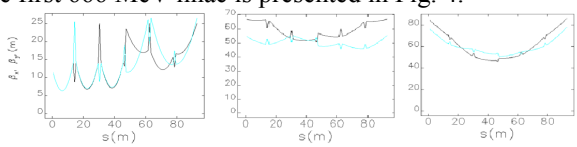

Figure 4: Optics design of the first 666 MeV linac. 3 passes with 250, 2.250 and 4.250 GeV beam injection energy from left to right correspondingly.

Also the optics was designed for the second 1334 MeV Linac and it is presented in Fig. 5.

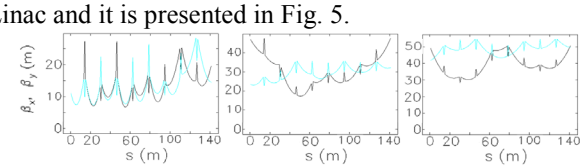

Figure 5: Optics design of the second 1334 MeV linac. 3 passes with 916, 2916 and 4916 MeV beam injection energy from left to right correspondingly.

The threshold currents for the schemes of FSF in Figs. 1 and 3 are presented in Table 2. For the estimations we used the following equation (which is a combination of eq. 1 and [9]):

$$I_{th} = \frac{2c^2}{e\omega\left(\frac{R}{Q}\right)_d Q_d}\frac{1}{\sqrt{\sum_{m=1}^{5}\sum_{n=m+1}^{6}\frac{\beta_m\beta_n}{\gamma_m\gamma_n}}}, \quad (8)$$

and we took a mode with $(R/Q)_d \cdot Q_d = 6\cdot10^5$ Ω, $\omega = 2\pi\cdot2\cdot10^9$ Hz.

Table 2: Threshold Currents for Different Schemes

Linac scheme	I_{th}, A		
	Preinjector	1st Linac	2nd Linac
0.100 + 1 + 1GeV	1.26	0.88	3.73
250 + 666 + 1334MeV	1.21	1.46	3.58

One can see from the Table 2 that the value of threshold current for the 1st main linac was improved. It was also slightly decreased for the 2nd linac and for the preinjection.

CONCLUSION

In the new proposed scheme BBU instability will develop in the preinjection Linac. In the future work we should find a way how to increase the thresholds in the preinjection linac and in the 1st by decreasing the threshold current value in the 2nd linac.

STUDY OF BEAM-BASED ALIGNMENT FOR SHANGHAI SOFT X-RAY FEL FACILITY

Duan Gu#, D.Z.Huang, Meng Zhang, Qiang Gu, M.H.Zhao
Shanghai Institute of Applied Physics, Shanghai 201800, China

Abstract

In linear accelerators, dispersion and transverse wake-field from alignment errors will lead to a significant emittance growth. The performance of the Free Electron Laser (FEL) process imposes stringent demands on the transverse trajectory, dispersion and emittance of the electron beam. So finding an effective Beam-Based Alignment(BBA) procedure is crucial for the success of Shanghai X-Ray FEL facility. This paper presents the preliminary study of different BBA method performances in SXFEL Linac. In addition, a MATLAB based simulation including quadrupole misalignment, dipole field errors and beam position monitor errors have been used to predict the orbit and emittance growth along the beamline and the required corrector current. Comparison with other codes is also presented.

INTRUDUCTION

As a critical development step towards constructing a hard X-ray FEL in China, a soft X-ray FEL facility (SXFEL) was proposed and will be constructed to verify the cascaded HGHG scheme and carry out the research on key technologies for X-Ray FEL. The SXFEL facility will be working at 9 nm soft X-ray band which consists of a 130MeV photo cathode injector, a main linac accelerating the beam to an energy of 840MeV, an undulator section with two stages of HGHG scheme and a diagnostic beamline. The local energy spread is 0.1%-0.15%, the peak current is about 600A and the normalized emittance is 2 mm·mrad[1].

In FEL facilities, misalignments between Quadrupoles and Beam Position Monitors(BPM) cause an increase of the transverse beam size and emittance which turns into an increase of normalized emittance. To keep the normalized emittance due to misalignment below 2 mm·rad, the average Quad-BPM misalignment in the linac must be smaller than 100um.

The traditional optical alignment can no longer meet such strict requirements, but a lot of analytical and numerical studies have been done and proved that Beam-Based Alignment technology can simultaneously eliminate the misalignment and dispersion in linac and undulator section, which obviously will leads to a much smaller emittance growth and transverse beam size. With the method above, a software based on MATLAB has been designed and simulation results have been compared with other software.

guduan@sinap.ac.cn

BBA TECHNOLOGY OVERVIEW

Over past decade, a number of different realizations have been developed to measure the offset of magnetic center of quadrupole magnet[2][4]. Most techniques are based on a common approach, which is to change the quadrupole strength and measure the resulting deflection.

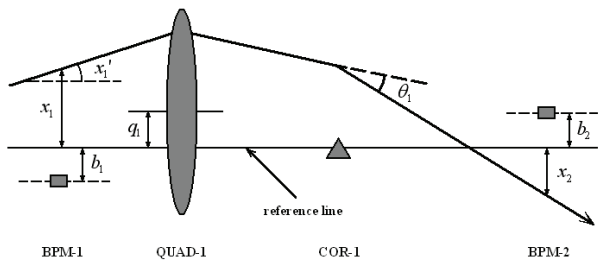

Figure 1: Common approach of BBA.

With respect to the reference line, m_i is the BPM reading at BPM-i. According to Linear optics theory (regardless wakefield effect and Quad-tilt), the transverse misalignment of upstream Quadrupole can be calculated using orbit response matrices, corrector values and inject parameters:

$$m_i = x_i - b_i = (x_i)_1 - b_i$$

$$x_i = R^{(B_1:i)}x_1 + \sum_j^{N_{Ci}} R^{(C_j:i)}c_j + \sum_j^{N_{Qi}} R^{(Q_j:i)}(I - R^{(Q_j)})q_j \quad (1)$$

Where b_i is BPM reading error due to off-axis between electronic center and geometric center. R is the 2×2 transport matrix form BPM-1 or corrector c_j or Q_j to BPM-i.

x_1 is initial incoming parameters, the unknown c_j the corrector strength and Q_j is Quadrupole misalignments, which are defined as:

$$x_1 = \begin{bmatrix} x_1 \\ x_1' \end{bmatrix};\ c_j = \begin{bmatrix} 0 \\ \theta_j \end{bmatrix};\ q_j = \begin{bmatrix} q_j \\ 0 \end{bmatrix} \quad (2)$$

Further more, we can simultaneously correct both orbit and dispersion using so called “Dispersion Free Steering” method. The optimal settings are calculated using the orbit and dispersion response matrices, which are defined as the shift of the orbit or dispersion due to corrector strength change:

$$R_{i,j} = \frac{\Delta x_i}{\Delta \theta_j}\ ;\quad D_{i,j} = \frac{\Delta d_i}{\Delta \theta_j} \quad (3)$$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Where Δx_i and Δd_i is the change of the orbit and dispersion in the BPM-i, and $\Delta\theta_j$ is the change of the strength of corrector-j. The basic aim is to find a setting of $\Delta\theta_j$ which induces orbit and dispersion that minizes in a least squares sense the final orbit and dispersion:

$$(1-w^2)\| x_{meaus}+O\Delta\theta\|^2+w^2\| d_{meaus}+D\Delta\theta\|^2=\min \quad (4)$$

More details about the algorithm procedure and successful correction results can be found at [3].

SIMULATION ON SXFEL LINAC

Soruces of the emittance growth and misalignment in the LINAC of FEL facilities has already been well-studied[2][6]. Usually it consists of field errors and stray magnet fields in the beam line as well as dispersion created upstream of the BPM, for instance, misalignment of Quadrupole, Dipole, Accelerator modules and even BPMs themselves. The Errors and launch parameters used in simulation are shown in Table 1.

Table 1: SXFEL linac Simulation Parameters

Parameter	Δx, Δy/μm (+/-)	Δθ/μrad (+/-)
DIPOLE	150	10
QUAD	150	10
ACC.MODULE	100	--
BPM	150	--
Launching error	100	150

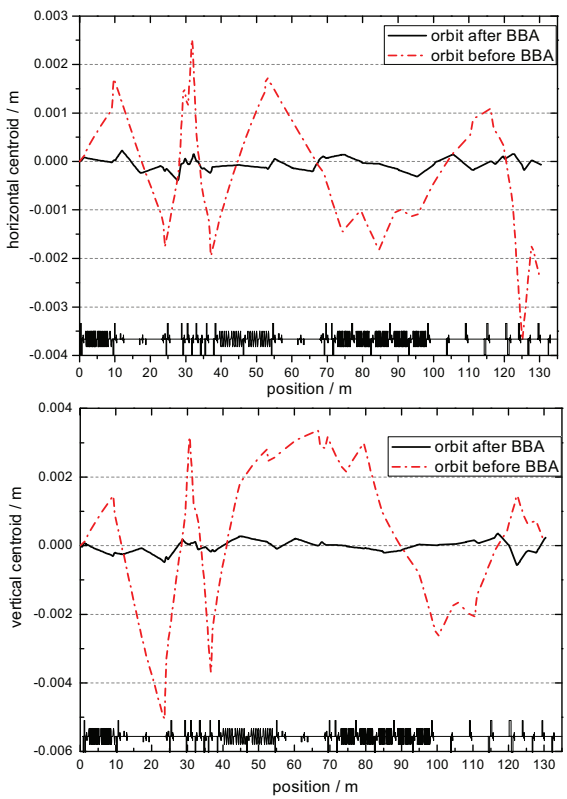

Figure 2: Comparison of orbit before and after correction.

SXFEL linac BBA simulations have been done using Elegant [7] as shown in Figure 2. After applying magnet errors and launch parameters in Table 1, we can get the correct result with Global correction method. As one can see in Figure 2, the deviation can be very large. When the electron beam travels across chicanes, the deviation will be notable increase due to the magnet effects, so these errors must be controlled in a reasonable region during BBA procedure.

In simulation results one can see that after 1st correction, the transverse orbit deviation is decline from 10^{-3}m to 10^{-4}m. Meanwhile the Smoothness of orbit and RMS orbit deviation can meet design requirement for SXFEL linac. Naturally, the impact of these errors on orbit kick and dispersion generation depend on the actual operating conditions of the accelerator, so the orbit must be measured and controlled frequently.

Further more, transverse wakefield effects caused by structure misalignment in accelerate modules is also an important factor which should be considered, as it can lead to a significant emittance growth[8]. By doing simulations, the emittance growth before and after correction are shown in Figure 3. As one can see, after BBA the final emittance growth can be controlled within 5%, and in vertical plane the correct result is much better.

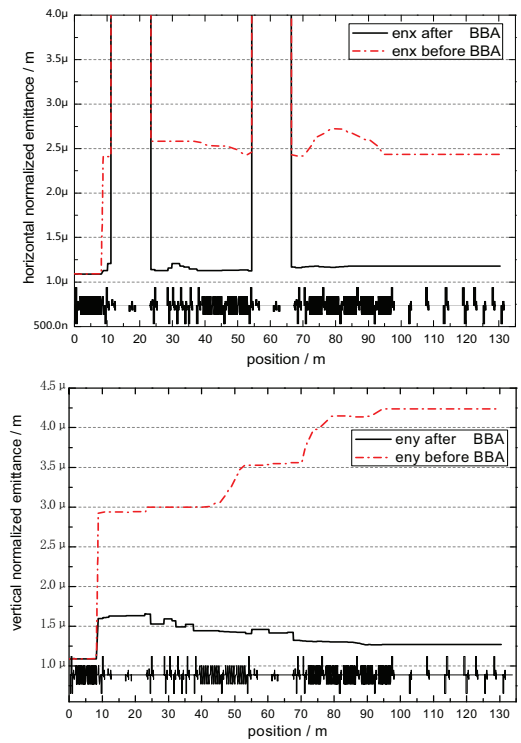

Figure 3: Comparison of emittance growth before and after correction.

CONTROL SOFTWARE DESIGN AND DEVELOPMENT

To assist the design and measurement, an automated control software based on MATLAB has been designed

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

with interfaces to EPICS. This software aims to connecting BBA methods and bottom devices, so we can seem it as a middle level application.

After setting launch parameters and using the BBA method above, the final offset could be determined. The flow diagram of the simulation code is shown in Figure 4.

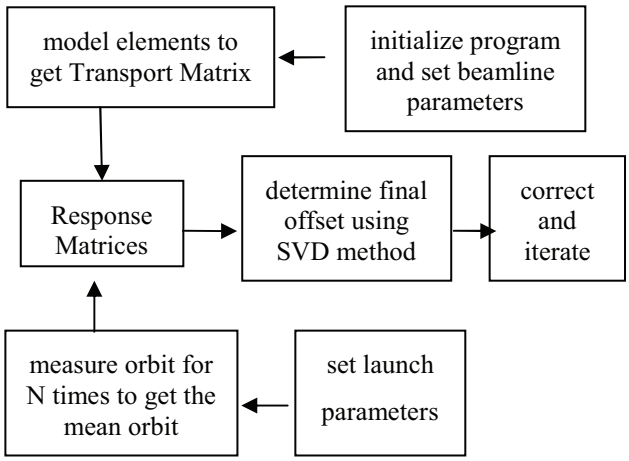

Figure 4: Flow diagram of the control program.

The response matrices are calculated from the quadrupole currents and the estimated energy along the machine. In this case, energy uncertainties such as magnets field errors and calibration errors are not take into account in this preliminary study.

After applying magnet errors and launch parameters in Table 1, we can get the correct result with Global correction method within the Matlab application. The correction results are shown in Figure 5.

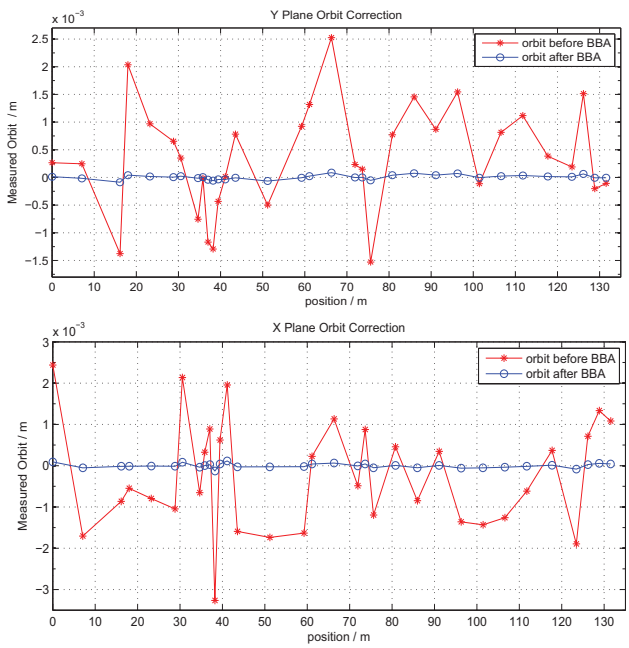

Figure 5: Simulation results from MATLAB BBA codes.

CONCLUSIONS

Preliminary design and simulations of the SXFEL Beam-based Alignment procedure have been presented in this paper, including brief introductions to main linac alignment method, beam dynamics simulations with nominal parameters, and orbit sensitivity studies. Simulations show SXFEL linac beam qualities are well within the capabilities of Beam-based Alignment technology. Further study is on the way to optimize and properly implement this technology into the SXFEL facility.

ON-LINE DISPERSION FREE STEERING FOR THE MAIN LINAC OF CLIC

J. Pfingstner*, D. Schulte, CERN, Geneva, Switzerland

Abstract

For future linear colliders as well as for light sources, ground motion effects are a severe problem for the accelerator performance. After a few minutes, orbit feedback systems are not sufficient to mitigate all ground motion effects and additional long term methods will have to be deployed. In this paper, the long term ground motion effects in the main linac of the Compact Linear Collider (CLIC) are analysed via simulation studies. The primary growth of the projected emittance is identified to originate from chromatic dilutions due to dispersive beam orbits. To counter this effect, an on-line identification algorithm is applied to measure the dispersion parasitically. This dispersion estimate is used to correct the beam orbit with an iterative dispersion free steering algorithm. The presented results are not only of interest for the CLIC project, but for all linacs in which the dispersive orbit has to be corrected over time.

INTRODUCTION

Linear colliders and light sources often require very small beam emittances and beam sizes to reach their goals. This fact makes these machines inherently sensitive to ground motion effects. For short time scales orbit feedbacks can be used to mitigate these effects by steering the beam with the help of beam positioning monitors (BPMs) (see [1] for the CLIC case). For longer time scales, this steering is not sufficient to preserve the beam quality as can be seen in Fig. 1. To be able to operate CLIC over longer time periods, it is essential to correct this remaining emittance growth. The development of such an algorithm is the topic of this paper.

The main reason for the remaining emittance growth is that the BPM positions itself will drift from their original position, which results in a dispersive beam orbit. The according chromatic dilutions decrease the beam quality over time. In the literature, a technique named dispersion free steering (DFS) can be found, which has been developed to correct similar chromatic dilutions (see [3] and [4]). In this paper we modify and extent this basic DFS method, such that it can be used to correct long term ground motion effects in an on-line mode. On-line means in this case that the DFS correction is applied during the normal accelerator operation in a parasitic way, without stopping the physics program. The methode will be explained an evaluated on the example of CLIC, but can be easily utilised for other accelerators.

* juergen.pfingstner@cern.ch

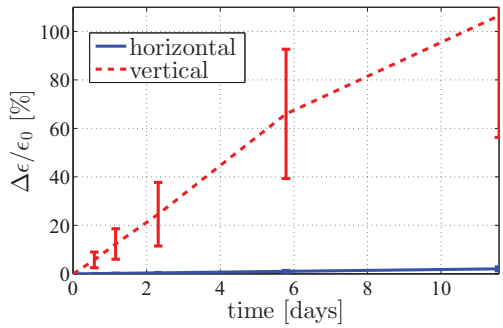

Figure 1: Simulations of the relative emittance growth over long time scales with orbit feedback in the main linac of CLIC. The used ground motion is generates according to the ATL law [2] with a constant A of $0.5\times10^{-6}\,\mu m^2/m/s$, which is the baseline for CLIC. The results have been averaged over 10 random samples of ground motion. For the initial horizontal and vertical emittance 600 nm and 10 nm have been used. The action of the orbit feedback was assumed to be perfect and therefore simulated by applying one-to-one steering without BPM noise, which is an optimistic approximation. It can be seen that already after 1 day the emittance has increased by about 10%.

ON-LINE DFS ALGORITHM

In this section, we will first introduce the basic DFS algorithm. After that the modifications necessary to apply this algorithm in an on-line mode will be discussed.

Basic DFS Algorithm

The DFS algorithm consists of two steps. In the first, the dispersion $\boldsymbol{\eta}$ at the BPMs is measured by varying the beam energy. This energy change can be created by changing the acceleration gradient, scaling the magnet strength and/or changing the initial beam energy. In the second step, corrector actuations $\boldsymbol{\theta}$ are calculated such that at the same time the measured dispersion $\boldsymbol{\eta}$ as well as the beam orbit $\boldsymbol{b}$ are corrected. Such actuations can be calculated by solving the following system of equations for $\boldsymbol{\theta}$ (see [5] for more details)

$$-\begin{bmatrix} \boldsymbol{b}-\boldsymbol{b_0} \\ \omega(\boldsymbol{\eta}-\boldsymbol{\eta_0}) \\ \boldsymbol{0} \end{bmatrix} = \begin{bmatrix} \boldsymbol{R} \\ \omega\boldsymbol{D} \\ \beta\boldsymbol{I} \end{bmatrix} \boldsymbol{\theta}, \qquad (1)$$

where $\boldsymbol{b}_0$ and $\boldsymbol{\eta}_0$ are the reference beam orbit and target dispersion respectively. The third set of equations in Eq. (1) with the unity matrix $\boldsymbol{I}$ on the right side is used to damp too high corrector actuations. The weights ω and β can be

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

chosen to minimise the emittance, which is easiest done in simulation via a parameter scan. The matrices $\boldsymbol{R}$ and $\boldsymbol{D}$ are the orbit and dispersion response matrix.

To increase the robustness, this DFS algorithm is usually applied sequentially to overlapping sections of the accelerator. In the case of CLIC, the main linac is partitioned into 36 fully overlapping sections each consiting of about 28 FODO cells. Note that after the correction of one section, the dispersion of the sections downstream has changed as well. It is therefore necessary to re-measure the dispersion after each DFS correction of one section.

Problem of Low Energy Variations

The primary difference between the basic and the on-line DFS algorithm is that the dispersion cannot be measured straight forward. In the basic method, a large energy deviation will be used to create large dispersive offsets in the BPMs to increase the measurement accuracy. This is however not possible for an on-line algorithm, since only tiny energy variations can be tolerated due to the energy acceptance of the final focus system of CLIC. For the simulations in this paper an energy variation of only 0.5 per mill is used.

Two main problems arise from these small induced energy variations. First of all, the induced orbit variations will be small and the necessary accuracy of the dispersion measurement has to be recovered by combining many measured orbit samples in a stochastic way to filter the noise. This dispersion estimation will be discussed in the next section. The second problem due to the small energy variations comes from the fact that the used energy deviations are so small that they are in the order of the beam energy spread, which is strongly influenced by wakefields. Therefore, changes of wakefields due to the change of beam orbits or cavity positions start to influence the dispersion measurement. This problem can be resolved by an initial cavity alignment (see [6]) before the on-line DFS, which reduces the wakefield effects for the current beam orbit. It is also beneficial to perform a cavity alignment after each full DFS correction of the linac.

Dispersion Estimation

The dispersion is measured in this paper by changing the acceleration gradient, which can be accomplished for the main linac of CLIC by a modulation of the beam intensity of the drive beam. Additionally, the initial beam energy is varied with the help of a bunch compressor. Since the induced energy variations have to be small, the individual dispersion measurements will be disturbed strongly by the influence of BPM noise and the usual jitter of the initial beam energy and the accelerating gradients. Therefore, the dispersion is determined by using many measurements and combining them to a least squares (LS) estimate to ensure the necessary accuracy. Instead of determining the LS estimate via the usual calculation of the pseudo-inverse, a very efficient recursive version of the algorithm can be derived, if the induced energy variations are chosen to be the sequence $\{-\Delta E, +\Delta E, -\Delta E, +\Delta E, \dots\}$. In this case the LS estimate of the dispersion η_N at a BPM at time step $N \in 2\mathbb{N}$ can be written as

$$\begin{aligned} \eta_N &= \left(\boldsymbol{E}^T\boldsymbol{E}\right)^{-1}\boldsymbol{E}^T\boldsymbol{b} = \frac{T_N}{N\Delta E} \quad \text{with} \\ \boldsymbol{E} &= \begin{bmatrix} -\Delta E \\ +\Delta E \\ \vdots \\ -\Delta E \\ +\Delta E \end{bmatrix} \quad \text{and} \quad T_N = \sum_{i=1}^{N}(-1)^i b_i, \end{aligned} \tag{2}$$

where $\boldsymbol{b} \in \mathbb{R}^N$ is the vector of previous BPM measurements. The so obtained estimate η_N can subsequently be used to calculate corrections θ for the next accelerator section according to Eq. (1). The question how many samples N have to be used to create an accurate enough estimate will be answered in the results section of this paper.

Integration of On-Line DFS and Orbit Feedback

When using the on-line DFS algorithm in combination with the orbit feedback, the interaction of the two subsystems has to be considered. At the dispersion estimation the beam energy changes induced by the on-line DFS will create orbit offsets that will couple to the action of the orbit feedback. By choosing the excitation to be a constant value with alternating signs, the induced disturbances are of the highest resolvable frequency of the orbit controller. Due to its design, the orbit controller frequency response demagnifies this frequency component strongly and the orbit feedback will couple only very weakly to the induced orbit offsets.

Another modification to the basic DFS algorithm is necessary, since the orbit controller will react on the changed beam orbits due to the on-line DFS corrections. The orbit feedback would aim to steer the beam back on its previous orbit. Therefore, the BPM centres of the corrected section have to be shifted electronically to the new reference orbit after the DFS correction.

If a section would be DFS corrected without considering the beam orbit in the rest of the downstream linac, the beam would be steered far from its reference orbit. This would lead to an unacceptable emittance growth. Also the orbit feedback would react strongly on the large offsets, which would also decrease the accuracy of the next dispersion estimate. Therefore, the expected beam orbit change $\hat{\boldsymbol{b}}$ in the BPMs after the current section has to be corrected with the correctors after the current section. Simulation showed that it is sufficient to use only the correctors of the next section, which reduced the necessary calculation time of the performed all-to-all steering. The according corrector actuations $\hat{\theta}$ can be calculated by solving

$$-\begin{bmatrix} \hat{\boldsymbol{b}} \\ \boldsymbol{0} \end{bmatrix} = \begin{bmatrix} \hat{\boldsymbol{R}} \\ \beta_0 \boldsymbol{I} \end{bmatrix} \hat{\theta}, \tag{3}$$

where β_0 is a damping factor for the corrector actuations.

RESULTS

To test the on-line DFS algorithm proposed, it was integrated in the simulation framework described in [1], which include the beam tracking in the main linac of CLIC, ground motion generation and the action of the orbit controller. The algorithm was tested on a beamline that was misaligned with about 11 days of ATL ground motion, followed by a one-to-one steering.

To determine how many samples are needed to estimate the dispersion sufficiently well, a simplified procedure was used. Instead of using full-scale simulations, the real dispersion was determined in simulations and corrupted with artificial BPM noise. The influence of the BPM resolution on the on-line DFS correction result is shown in Fig. 2. The effective BPM resolution in the estimate has to be about 5 nm to not worsen the average on-line DFS correction by more than 2%. Assuming a BPM resolution of 100 nm, the noise has to be reduced by a factor of 20. Since the averaging reduces the remaining noise by the factor $1/\sqrt{N}$, where N is the number of used samples, N has to be 400, which corresponds to 8 s of CLIC operation. Considering further that this procedure is repeated for 36 linac sections over two iterations, the full correction time needed is about 10 minutes not including the time needed for the cavity alignment. Additionally to the influence of noise, also the DFS algorithm itself cannot correct the chromatic dilutions fully. With perfectly known dispersion, the initial vertical emittance growth of 107.6% was reduced to 2.5% on average.

The long time periods necessary for the averaging cannot be simulated directly in reasonable time. We therefore only performed full-scale simulations with an N of 100, which corresponds to a real-time operation of about 2 minutes. Different imperfections were applied and on average the emittance growth could be reduced after two iterations to 2.8% with no imperfections, 3.7% with orbit feedback turned on and 10.4% with realistic BPM resolution.

The results for one particular ground motion sample are shown in Fig. 3. It can be observed that at the corrections of the final sections the emittance grows for a short time period. We believe that this behaviour is due to a worse steering and an improvement is subject to future work. Simulations were also performed including short-term ground motion (model B [1]) in combination with the orbit feedback for the dispersion estimation. The observed effect due to the ground motion was seen to be negligible. Another tested imperfection is the jitter of the acceleration gradients. Also here no significant degradation was observed for the maximal specification of 0.5%.

CONCLUSIONS

In this paper an on-line DFS algorithm was presented. Simulation results show that it is capable of correcting dispersive beam orbits due to long term ground motion misalignments efficiently. Two iterations of the algorithm have found to be enough to reduce the according beam emittance growth very efficiently, which takes for CLIC about 10 min. Since the time constant of the correction is much smaller than the emittance growth, there is no need to run the algorithm continuously. The mutual interaction of the algorithm with the orbit feedback was found to be small. Also the influence of ground motion and decelerator gradient jitter can be neglected. The presented algorithm is therefore an essential contribution for the successful operation of CLIC over longer time periods.

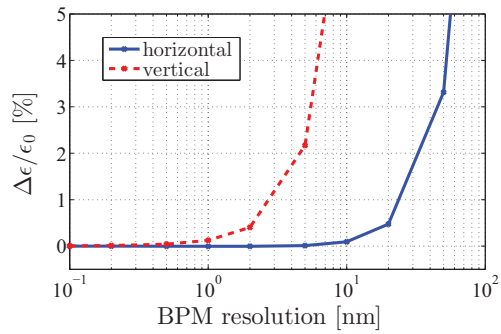

Figure 2: Relative emittance growth due to BPM resolution when using on-line DFS averaged over 20 random samples.

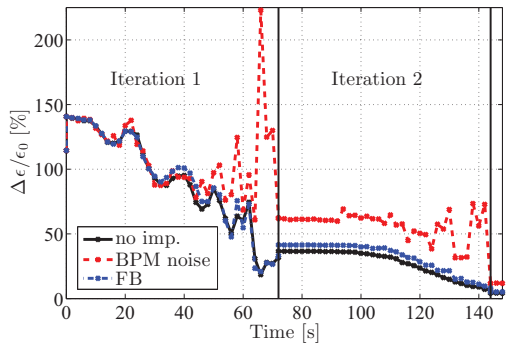

Figure 3: Relative vertical emittance during two iterations of the on-line DFS correction for one particular sample of ground motion. No imperfections are applied for the black curve (4% emittance growth). For the blue curve, the orbit feedback is turned on during the dispersion estimation. The mutual influence of the two subsystems is seen to be small (5% emittance growth). For the red curve a BPM resolution of 100 nm is used (12% emittance growth).

Abstract

The longitudinal phase stability of the CLIC main and drive beams is a crucial element of the CLIC design. In order to measure and control the phase a distributed phase monitoring system has been proposed. The system measures the beam phase every 900 m. The relative phase between the measurement points is synchronized with an external reference system via a chain of reference lines. This paper presents the simulations of error propagation in the proposed distributed monitoring system and the impact on the drive and main beam phase errors and the luminosity. Based on the results the error tolerances for the proposed system are detailed.

INTRODUCTION

The Compact Linear Collider (CLIC) is a proposed 3 TeV center-of-mass energy e^+e^- collider. It is designed to extract the RF energy from high-current low-energy drive beams and use this energy for acceleration of the low-current high-energy main beams that are brought into collision.

Since the main beam acceleration is performed by the RF power extracted from the drive beam, the stability of the relative phasing of the drive and main beams is crucial for the preservation of CLIC's luminosity. A relative phase error of 0.2° @ 12 GHz between the drive and the main beam will cause a luminosity loss of 1% if the error is coherent between the 24 decelerator segments. The same luminosity loss can be caused by an incoherent error of 0.8°. [1]
Additionally to these requirements on the relative drive beam - main beam phase, the phase tolerance between the two main beams at the interaction point (IP) has been set to 0.6° @ 12 GHz [2]. Hence, in order to align the main beam phase a global phase reference over 50 km is needed.

The stated tolerance requirements have to be met on the timescale of ≈50 ns, since this is the beam loading time of the main beam accelerating structures and errors on the shorter time scale will be (at least partially) filtered out by the structures.

PROPOSED DISTRIBUTED TIMING SYSTEMS

The distributed timing system is required to establish the correct beam phase at each turn-around of the linac. This allows to measure and correct the main and drive beam phases along the main linac. There are two approaches for the design of such a system.

The first approach (A) is to use the outgoing main beams to transmit the phase information to a number of local oscillators (Fig. 1, top). These can maintain the phase accurately enough until the main beam returns on the way to the interaction point. This system requires accurate phasing between the outgoing main beams at the first booster linac near the interaction point (Fig. 2).
In the other approach (B) the master clock near the interaction point (IP) would define the nominal phase and distribute it as a signal cascade from one 900 m long decelerator segment to another (Fig. 1, bottom). This system would establish the relative phase of the local timing clocks by an optical connection independently of the beams.

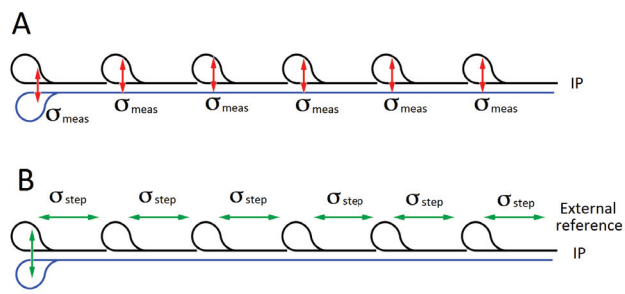

Figure 1: Phase signal propagation for the reference based on the main beam (A) and chained distribution of master clock signal (B).

Approach A has the advantage of having a relatively small error between the main and the drive beams, since the phase measurement at each drive beam decelerator is performed locally and hence no additional error is introduced during the distribution process (see Fig. 3, left). Approach B allows the correction of the main beam at its final turn-around, giving the possibility to reduce the jitter between the e^+ and e^- main beams (Fig. 3, right). However, if the drive beam correction signal is transported from the master clock via the distribution system, the noise introduced by this system would reduce the effectiveness of the phase correction. In the final CLIC design these approaches could be potentially combined.

The proposed timing distribution system is based on state of the art technology for signal distribution via optical fibers tested at XFEL (DESY, Hamburg) [3], [4]. This system is proven to provide <10 fs stability over the distance of several kilometers.
The following analysis determines the specifications of the

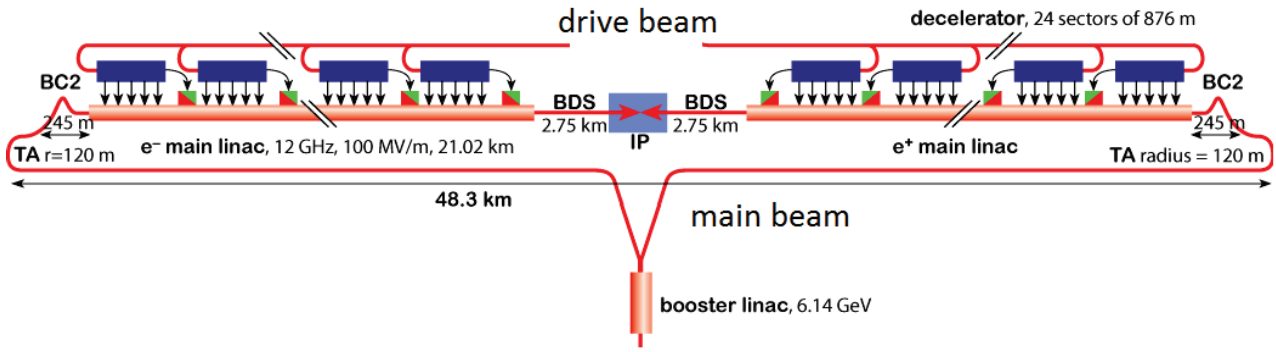

Figure 2: CLIC layout at 3 TeV.

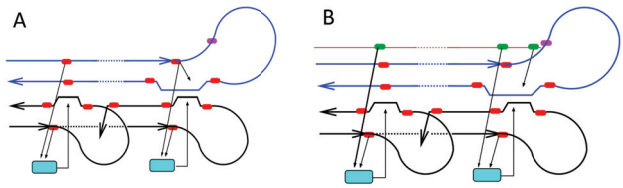

Figure 3: Phase correction system based on the main beam phase measurement (A) and on the external master clock (B) [2].

second approach (distributed timing system) and sets the requirements for the tolerances of this system.

ANALYSIS OF SPECIFICATIONS FOR THE DISTRIBUTED TIMING SYSTEM

Principle of time distribution and phase correction

As shown in Fig. 3 B, the signal from the master clock is used as the synchronization signal for the local oscillators. The master clock itself has a particular noise spectrum [5]. The impact of the noise on the local oscillators can be reduced by integrating the signal over the time intervals longer than the beam propagation time through the machine (≈ 0.2 ms).
The correction of the main beam is performed at the final turnaround with help of a kicker chicane, which can change the path length of the main beam bunches and hence their longitudinal position. The drive beam phase is also corrected via a chicane to the nominal value defined by the master clock at the turnarounds at each of the 24 decelerator modules.

The phase measurements on the main and drive beam after the chicanes ensure that the provided correction had the right value. If it is not the case, this could mean that the path length of the beams in the chicane is not as predicted, the chicane has the wrong R_{56} value or that the waveguide length has changed (e.g. due to temperature variation). To correct for these changes, a pulse-to-pulse feedback system can be introduced. Provided the changes are slow enough, the measured value of the correction error can be used to adjust the relative definitions of the monitors' nominal phase. The new definitions will ensure that the correction for the next pulse will set the drive beam bunches closer to their nominal position relatively to the main beam bunches. Hence, high stability of the local oscillator clocks must be ensured on a timescale of 20 ms, which is the pulse-to-pulse interval of CLIC.

In order to calculate the phase tolerance for signal transfer between the two subsequent decelerators, σ_{step}, (Fig. 1, B), one must calculate the impact of this error on the total phase error. We will assume a random walk of the phase error, which starts from the master clock at the IP and propagates along the machine step by step from one drive beam decelerator segment to another.

e^+ and e^- main beams phase tolerance

For the incoming main beams the relative phase tolerance at the IP is $0.6°$ @ 12 GHz $\hat{=}$ 42 μm $\hat{=}$ 140 fs [2] which corresponds to 1% of luminosity loss. Hence, one must assure that the total phase error introduced by the distributed timing system σ_{dts} is below $(140\text{ fs})/\sqrt{2}$ for each of the main beams.
Additionally to the 24 decelerator modules, each about 900 m long, we must consider that the beam delivery system of each main beam is about 2.75 km long [8]. To simplify the calculation it will be assumed that the distributed timing system for the main beam is 27, instead of 24, sectors long, hence about 2.7 km longer. One can consider the errors at each of the segments as linearly independent. Hence, the tolerance for the phase error introduced in each segment is given by

$$\sigma_{step,mm,1\%} = \frac{140\ fs}{\sqrt{27}\times\sqrt{2}} = 19.05\ fs \hat{=} 5.72\ \mu m. \quad (1)$$

The stated correction system error would cause a luminosity loss of 1%. However, in reality the largest part of the tolerance budget will be reserved for the beam itself and not for the reference jitter. Hence, the calculation only determines the upper limit for the distribution error but not

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the effective system requirement, which will depend on the expected beam phase jitter. Defining the distribution system requirement to causing max. 0.1% luminosity loss, one obtains $\sigma_{step} = 5.72\ \mu m/\sqrt{10} = 1.81\ \mu m$
An advantage of the distributed timing system is that it allows to loosen the phase tolerances on the outgoing main beam by a factor of 7, since the phase correction at the final turnaround of the main beam can reduce the phase error [1], [7]. Also, the phase correction can compensate for the change in the main beam path length, given the path length change is slow enough ($\ll 20\ ms$ pulse interval).

Main beam - drive beam phase tolerance

The error σ_{step} causing 1% luminosity loss can be calculated from the main beam - drive beam relative phase error tolerance. The total error σ_{tot} introduced by the phase correction system at each decelerator must be below 0.8° @ 12 GHz for uncorrelated errors.

We assume a random walk of the distribution error segment by segment. The impact of each error is given by $\sum_{j=1}^{i} \sigma_{step}$ with i being the number of the segment counted from the IP. The total error introduced by the distributed timing system σ_{dts} is given by the sum of the errors in all segments. One should also consider that the main beam bunches are positioned at 30° of the RF wave in the four segments nearest to the IP and at 8° in other 20 segments. Hence σ_{dts} is given by

$$\sigma_{dts}^2 = \sum_{i=1}^{4}\left(\sum_{j=1}^{i}(\sigma_{step}\times\sin 30°)\right)^2 + \sum_{i=5}^{24}\left(\sum_{j=1}^{4}(\sigma_{step}\times\sin 30°)+\sum_{j=5}^{i}(\sigma_{step}\times\sin 8°)\right)^2$$

Normalising σ_{dts}^2 by the RMS value of the stated sine functions and calculating the sums, one obtains

$$\sigma_{step,md,1\%} = 0.059° \triangleq 4.12\ \mu m \qquad (2)$$

This value is of the same order of magnitude as the tolerance given by the main beam - main beam phase error consideration ($\sigma_{step,mm,1\%} = 5.72\ \mu m$) calculated in the previous sub-section. Defining as above the maximal 0.1% luminosity loss as a specification of the distribution system, the requirement for the reference stability will be $4.12\mu m/\sqrt{10} = 1.30\ \mu m$.

The 1% luminosity loss from the reference jitter has been calculated independently for main beam - main beam and main beam - drive beam phase error tolerances. In reality the same reference jitter σ_{step} would cause a luminosity loss via both channels,

$$\Delta\mathcal{L}_{total} = \Delta\mathcal{L}_{md} + \Delta\mathcal{L}_{mm} = 1\% \times \left(\left(\frac{\sigma_{step}}{\sigma_{step,md,1\%}}\right)^2 + \left(\frac{\sigma_{step}}{\sigma_{step,mm,1\%}}\right)^2\right)^2$$

Solving this equation for $\Delta\mathcal{L}_{total} = 1\%$ yields $\sigma_{step} = 3.34\ \mu m$. However, $\Delta\mathcal{L}_{total} = 0.1\%$ defines the specification of $\sigma_{step} = 1.06\ \mu m$ average error introduced by the distributed timing system at each decelerator segment.

CONCLUSIONS AND OUTLOOK

The phase jitter of the distributed timing system at each decelerator segment is calculated to be 3.34 μm for 1% luminosity loss from both the main to main and main to drive beam tolerances.This value is met by demonstrated performances [3], [4], which proves the feasibility of the distributed timing system. However, ideally the specification would be tighter - 0.1% luminosity loss, which requires a distribution system stability of 1.06 μm per segment. Hence, it has to be investigated whether the noise can be significantly reduced.

The demonstrated performance of the signal distribution includes the transformation of the optical signal into electrical and vice versa. One solution could be chaining the distribution by splitting the optical signal at each decelerator, using one part of the signal as a reference and amplifying the other part and sending it to the next decelerator. This would help to avoid transformation noise and might allow to reach the specified target. A dedicated approach would be needed to prove this concept experimentally.

It will be also necessary to demonstrate the reliability of the signal distribution technology to operate unattended in the tunnel.

Abstract

Linear accelerator based on parallel coupled accelerating structure and RF-controlled electron gun is developed and produced. The structure consists of five accelerating cavities. The RF power feeding of accelerating cavities is provided by common exciting cavity which is performed from rectangular waveguide loaded by reactive pins. Operating frequency is 2450 MHz. RF-controlled Electron gun is made on the basis of RF triode. Linear accelerator was tested with different working regimes. The obtained results are following:

- energy is up to 4 MeV, accelerating current is up to 300 mA with pulse duration of 2.5 ns on the half of the width,
- energy is up to 2.5 MeV, accelerating current is up to 100 mA with pulse duration of 5 μs,
- energy is up to 2.5 MeV, accelerating current is up to 120 mA with pulse duration of 5 μs and beam capture of 100%.

The descriptions of the accelerator elements are given in the report. The features of the parallel coupled accelerating structure are discussed. The results of the measuring accelerator's parameters are presented.

INTRODUCTION

Compact linear electron accelerators have wide scientific and industrial applications. The more often linacs are used with energy up to 10 MeV, average beam power up to several kilowatts. In present there are two type of accelerating structures with travelling wave and standing wave. But all of these structures have sequential RF power feeding of the accelerating cells. This is cause of some problems. To supply the accelerating structure total RF power has to go from the first accelerating cell. As the power is attenuated along these structures the initial value of the power must be very high, therefore, there are breakdowns and thermal surface damage in the first accelerating cell. When the breakdown is happened in one of the accelerating cell the operating RF pulse is terminated because of all storage energy of the structure is dissipated in it. Developing of *accelerating structure with given distribution of the power along the cavities is very difficult task. Also there is problem of high order modes, vacuum pumping and etc.

The linear electron accelerator based on new type accelerating structure is developed and produced by Budker Institute of Nuclear Physics of SB RAS, Institute of Chemical Kinetics and Combustion of SB RAS and Institute of Catalysis of SB RAS [1]. The main elements of accelerator are parallel coupled accelerating structure, injector, waveguide track with vacuum RF window, focusing system and klystron KIU-111. The klystron's frequency is 2450 MHz, average power is 5 kW with pulse power of 5 MW [2]. The main goal of our efforts is to test new ideas and devices which are used in the accelerator. The mass of these elements are used in such accelerator for the first time and have some advantages.

PARALLEL COUPLED ACCELERTING STRUCTURE

The scheme of parallel coupled accelerating structure is shown in the Fig. 1 and Fig. 2. RF power from a klystron feeds the exciting cavity (1) through inductive coupling window (7). The exciting cavity supplies the accelerating cavities (2). The RF connection of the exciting cavity with the accelerating cavities is provided by magnetic field through coupling slots (5). The focusing alternative magnetic field is created along the beam axis by periodic permanent magnets (3) with radial magnetization inserted in the iron yoke (4). This kind of focusing provides large enough magnetic field while keeping the weight of the focusing system considerably small. The cupper pins (6) are used to tune the exciting cavity (1) at the resonance frequency.

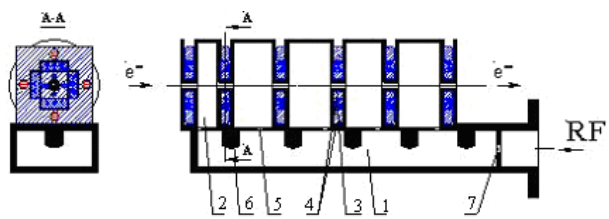

Figure 1: Scheme of the parallel coupled accelerating structure.

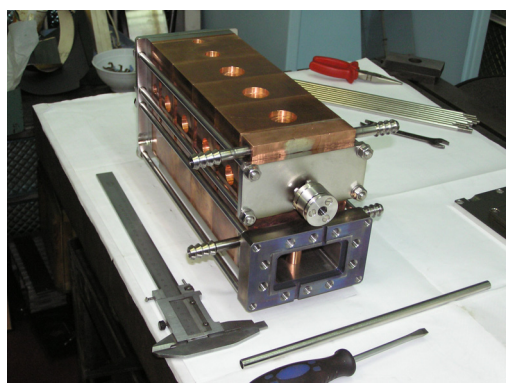

Figure 2: Parallel coupled accelerating structure.

Due to the scheme of RF power supplying this accelerating structure has some advantages versus structures with sequential power feeding. There is no need to have a high power in the first accelerating cavity. So the overvoltage and breakdown problems, thermal surface damage near the coupling slots are absent. The design of parallel coupled accelerating structure allows us to create compact periodic permanent magnet focusing system based on the permanent magnets with radial magnetization (see Fig. 1). The accelerating cavities are not connected with each other by electric field therefore aperture of the drift tubes between cavities is limited only by the beam focusing. By changing the coupling factor between exciting and accelerating cavities it is possible to make the free power distribution along the structure. If breakdown is happened in one of the accelerating cavities the storage energy only this cavity is dissipated, and only in this cavity. So the working RF pulse is not terminated but only amplitude of reflected signal is slightly changed, as it is presented on the Fig. 3.

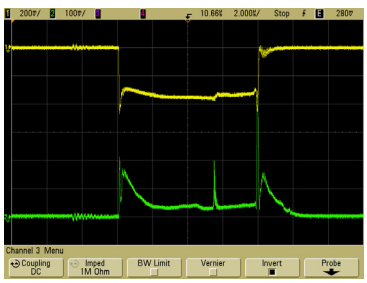

Figure 3: Breakdown in one of the accelerating cavities: 1 - signal from klystron; 2 - reflected signal from accelerating structure.

The accelerating structure can be used as for high average current with high average power as for short nano- and picoseconds duration current pulses with high amplitudes.

INJECTOR

Injector is the electron gun with DC voltage of 50 kV and pulse current up to 1 A. It is based on RF triode GS-34 and shown on the Fig. 4.

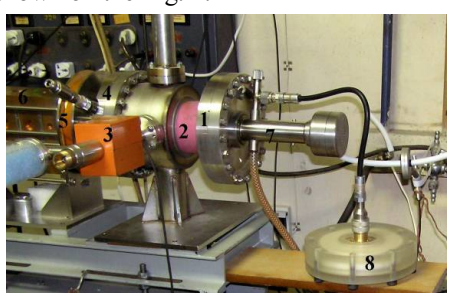

Figure 4: Injector: 1- cathode-grid unit, 2 – ceramics, 3 – vacuum pump, 4 – bunching cavity, 5 – matching solenoid, 6 - accelerating structure, 7 – coaxial cavity for RF beam control, 8 – antenna type RF lead.

Injector can work with following regimes: short pulses with duration of about nanoseconds, long pulses with duration of microseconds and long pulses with RF control for a beam π-chopper. Under using RF control the beam is modulated by coaxial cavity on bunches with length equaled to half wavelength of RF field. Due to this feature, the beam capture can be achieved up to 100%.

The cathode-grid unit 1 (see Fig. 4) is under potential of -50 kV. So, to feed the coaxial cavity 7 the antenna-type coaxial lead (8) was developed and produced. It is shown on the Fig. 5. The antenna-type lead consists of two symmetrical parts of coaxial half-wave resonator. The resonator is cut along perpendicular to the longitudinal axis plane of symmetry. The solid dielectric disk is located between the halves.

The Fig. 6 shows the measured bandpass characteristics. The reflection coefficient S_{11} at the operating frequency is 0.098 and the transmission coefficient S_{21} is 0.976. Bandwidth at the attenuation level of -3 dB is more than 1800 MHz (73%).

Figure 5: Antenna type RF lead.

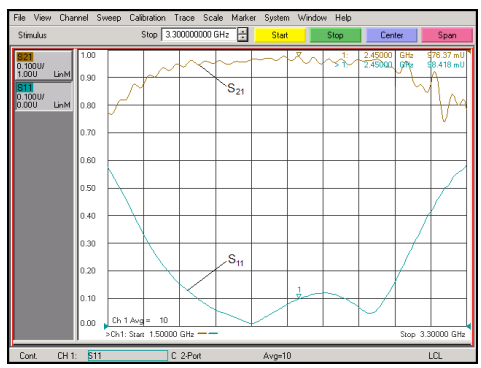

Figure 6: The transmission S_{21} and reflection S_{11} coefficients of the lead.

ACCELERATOR MEASUREMENTS

Accelerator was tested under three regimes.

The first regime is characterized by short beam pulse with duration of 2.5 ns on the half of width (see Fig. 7). The beam energy is about 4 MeV, beam current amplitude is about 300 mA. The Fig. 8 shows the cross section of the beam profile.

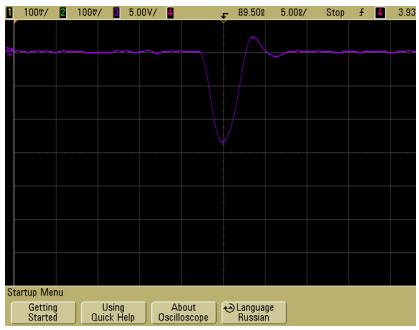

Figure 7: Oscilloscope of the accelerated beam current with duration of 2.5 ns (100 mA per cell).

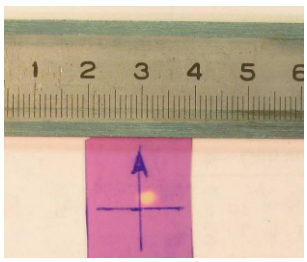

Figure 8: Cross section of the beam profile with pulse duration of 2.5 ns.

In the second regime the beam duration is 4 μs, energy is 2.5 MeV, beam capture is about 50%. Oscilloscope of the beam current and cross section of the beam profile are shown on the Fig. 10 and Fig. 11 correspondingly.

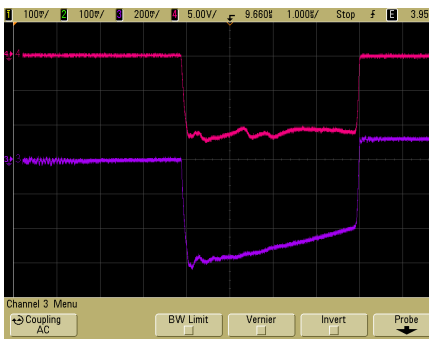

Figure 9: Oscilloscope of the accelerated beam current with duration of 4 μs: 3 – emission beam current (180 mA per cell), 4 – beam current in the end of accelerating structure (100 mA per cell).

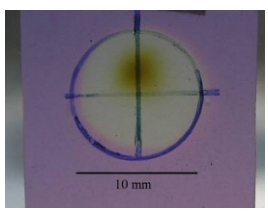

Figure 10: Cross section of the beam profile with pulse duration of 4 μs.

In the third regime the injector operated with RF control. The energy is equaled to 2.5 MeV. The feature of this regime is beam capture of 100%. Oscilloscope of the beam current and cross section of the beam profile are shown on the Fig. 12 and Fig. 13 correspondingly

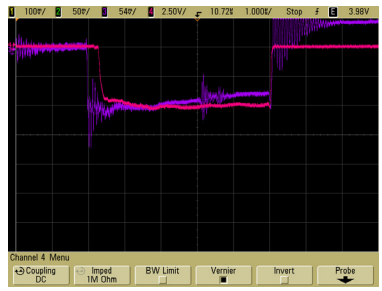

Figure 12: Oscilloscope of the accelerated beam current with RF control: 3 – emission beam current (50 mA per cell), 4 – beam current in the end of accelerating structure (50 mA per cell).

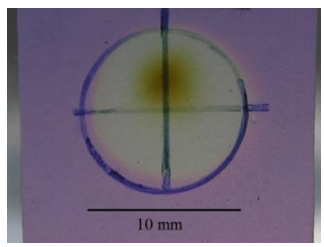

Figure 13: Cross section of the beam profile with RF control.

CONCLUSION

Linear electron accelerator based on parallel coupled accelerating structure and injector with RF control for a beam π-chopper is made, tested and measured. The beam energy is 2.5-4 MeV with total power of 2.4 MW, accelerated beam current is 100-300 mA. These values depend on the beam loading effect. The durations of the beam pulse were changed from 2.5 ns to 5 μs. With RF control the beam capture was achieved 100%. The diameter of cross section of the beam profile was about 3 mm. The beam loading effect is studying.

MEASUREMENTS OF A REDUCED ENERGY SPREAD OF A RECIRCULATING LINAC BY NON-ISOCHRONOUS BEAM DYNAMICS*

F. Hug#, C. Burandt, M. Konrad, N. Pietralla, TU Darmstadt, Darmstadt, Germany
R. Eichhorn, Cornell University, Ithaca, NY, USA

Abstract

The Superconducting Linear Accelerator S-DALINAC at the University of Darmstadt (Germany) is a recirculating linac with two recirculations providing beams for measurements in nuclear physics at small momentum transfers. For these experiments an energy spread of better than 10^{-4} (rms) is needed. Currently acceleration in the linac section is done on crest of the accelerating field. The recirculation path is operated achromatic and isochronous. In this recirculation scheme the energy spread of the resulting beam in the ideal case is determined by the electron bunch length. Taking into account the stability of the RF system the energy spread increases drastically to more than 10^{-3} (rms**).**

We will present a new non-isochronous recirculation scheme which helps cancelling out these errors coming from the RF-jitters. This scheme uses longitudinal dispersion in the recirculation paths and an acceleration off-crest on a certain phase with respect to the maximum. We will present results of the commissioning of the new system including measurements of the longitudinal dispersion in the recirculation arcs as well as measurements of the resulting energy spread using an electron spectrometer.

INTRODUCTION

Operating since 1987 the Superconducting DArmstadt LINear Accelerator (S-DALINAC) is used as a source for nuclear- and astrophysical experiments at the university of Darmstadt [1]. It can accelerate beams of either unpolarized or polarized electrons [2] to beam energies of 1 up to 130 MeV with beam currents from several pA up to 60 µA. The layout of the S-DALINAC is shown in Fig. 1.

Acceleration in the injector and main linac is done by superconducting elliptical cavities with a quality factor of $Q_0 \approx 10^9$. These cavities are operating at a frequency of 3 GHz with a maximum accelerating gradient of 5 MV/m.

The main linac consists of 8 standard 20-cell cavities and can provide an energy gain of 40 MeV. By recirculating the beam two times the maximum energy of 130 MeV can be achieved. In the adjacent experimental hall this beam can be used for different experiments such as electron scattering in two electron spectrometers or experiments with tagged photons. For these experiments an energy spread of $\pm 1 \cdot 10^{-4}$ is required.

# hug@ikp.tu-darmstadt.de

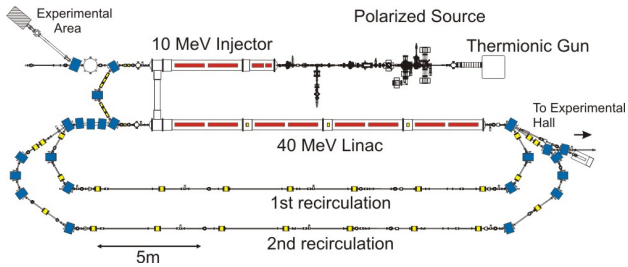

Figure 1: Floor plan of the S-DALINAC.

LONGITUDINAL BEAM DYNAMICS

The S-DALINAC is designed to use an isochronous recirculation scheme originally. On a isochronous working point the electrons are accelerated in the maximum of the accelerating field (on crest) in every turn and the bunch length is kept constantly small ($\pm$ 1°) using achromatic and isochronous recirculation paths. Isochronicity is a property of beam optics and can be described as $\mathrm{d}l/\mathrm{d}E = 0$ meaning that the length of the flight path of all electrons is independent from their energy. Acceleration on crest of the RF-field is the common mode for linear accelerators. Usually amplitude and phase jitters of the cavities are not correlated and the resulting energy spread is mainly determined by the short bunch length. In a recirculating linac the errors can add up coherently throughout the linac passages in a way that every electron sees the same errors in all passes through the linac due to the large time constant of field variations in the superconducting cavities compared to the short time of flight of the ultra relativistic electrons through the linac.

A way to overcome these correlated errors is changing the longitudinal working point to a non-isochronous one. This is the common operation mode for synchrotrons or microtrons In a non-isochronous recirculation scheme the recirculation paths provide a longitudinal dispersion $\mathrm{d}l/\mathrm{d}E = D_L \neq 0$ while the accelerating field is operated at a certain synchrotron phase $\Phi_S \neq 0$ (on edge). The electrons then perform synchrotron oscillations in the longitudinal phase space. Compared to synchrotrons a quite large phase advance per turn is needed to cancel out the RF jitters. In fact a half or full integer number of synchrotron oscillations leads to the best energy resolution of the extracted beam in a way that the resulting energy spread at extraction is only determined by the energy spread at injection while the errors caused by the RF jitters of the main linac are cancelled out. [3,4]

The usability of such a non-isochronous recirculation scheme at the S-DALINAC has been verified already by numerical simulations (see Fig. 2). The new longitudinal

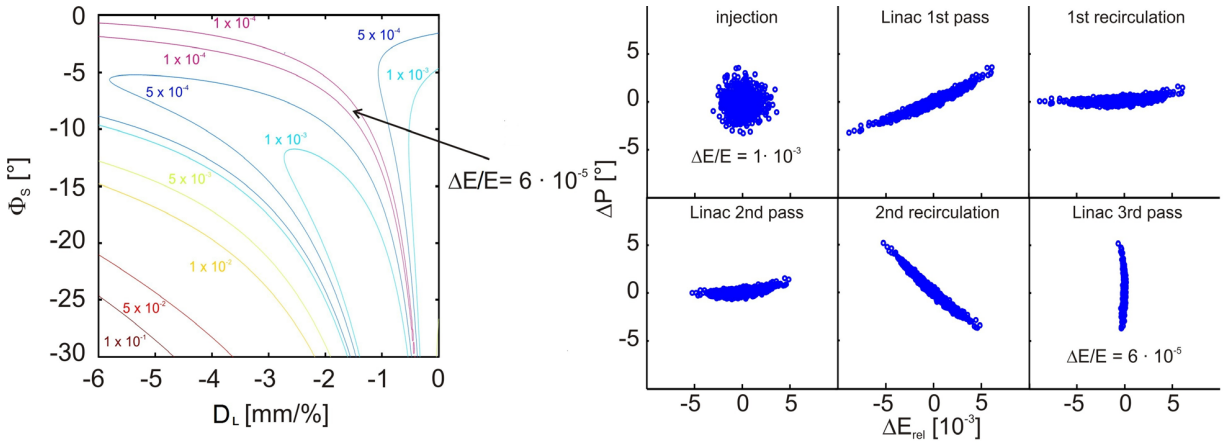

Figure 2: Hillplot of the resulting energy spread at extraction for different sets of longitudinal dispersion and synchrotron phase (left). Beside the isochronous point exist areas of reduced energy spread. The minimum has been determined to D_L = -1.5 mm/% and Φ_S = -9.5° On the right side a bunch of 5000 particle has been tracked through the linac using the optimized parameters. The particles perform a half oscillation in longitudinal phase space ending up on a reduced energy spread.

working point has been determined to D_L = -1.5 mm/% and Φ_S = -9.5° and would lead to a reduction of the energy spread to $\Delta E/E = 6.03 \cdot 10^{-5}$ which satisfies the requirements mentioned above very well. (for more details see [5,6,7])

LATTICE OPTIMIZATION

In order to tune the S-DALINAC to different non-isochronous working points in future optimizations at the recirculation paths had to be carried out. In particular the quadrupole lattice of the recirculation arcs needed to be reviewed to change the value of D_L easily while the transverse dispersion D and the transverse angular dispersion D' both equal zero at the end of every recirculation arc. The result of these optimizations are lattices for both arcs in which D_L can be manipulated easily by changing only the quadrupole gradients in the arcs. Keeping these gradients on a fixed ratio in addition D and D' remain at zero at the end of every arc like required. (for more details on this topic see [7,8])

MEASUREMENT OF LONGITUDINAL DISPERSION

The idea of adapting the concept of non-isochronous recirculation for the S-DALINAC was presented many years before [5], while the realisation, especially tuning the machine to the new longitudinal working point, needed some time. One reason was a lack of beam diagnostics developed meanwhile and described in the section below.

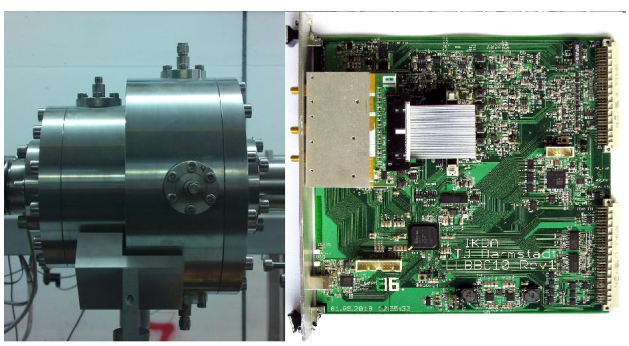

Figure 3: Measurement setup consisting of rf monitor (left) and rf board with FPGA board (right).

For the measurement of the longitudinal dispersion of the recirculation arcs RF monitors located at the beginning of the straight sections behind the last dipoles has been used. Usually, these intensity monitors, which are pillbox cavities at a 3 GHz resonant frequency (see Fig. 3 left), are used for non-destructive measurement of the beam current during operation. The passing cw beam excites an oscillation and the RF signals can be coupled out. Matter of interest is the detection of the phase of the 3 GHz oscillation excited by the beam. This can be done by mixing the RF signal of the monitor with the local oscillator frequency of the RF control system. This down conversion to the base band [9] is done on a RF board (see Fig. 3 right) leading to I/Q values describing the relative oscillation phase of the RF monitor. The I/Q values are converted into real phase values on a FPGA board then. This board is also used for setting amplifications and offsets of the measurement. The hardware is mainly part of the new developed digital LLRF system of the S-DALINAC with minor modifications due to the weak signals coming out of the RF monitors [8,9,10].

To determine D_L out of the phase values the time of flight method is used. For every quadrupole setting, corresponding to a certain dispersion D_L the energy of the beam is changed and the phase on the RF monitor is measured. If $D_L \neq 0$ the time of flight in the arc changes with respect to the beam energy and so does the phase. The results of the measurements on both recirculations is shown in Fig. 4.It can be seen that the measurement fits very well with the simulation results and that D_L can be changed over a large interval including the envisaged value of D_L = -1.5 mm/%.

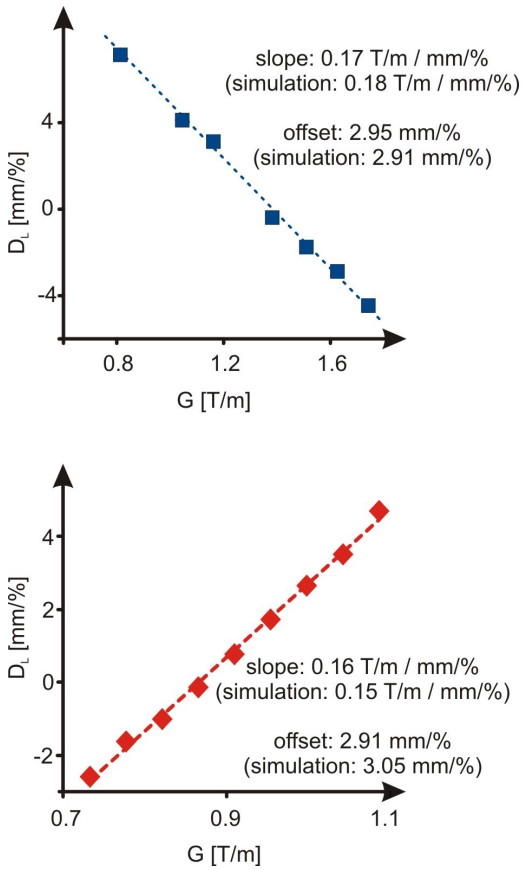

Figure 4: Measured values of D_L in the first recirculation (top) and second recirculation (bottom) for different quadrupole gradients in the arc.

MEASUREMENT OF THE ENERGY SPREAD

Having set up a detection system for D_L and characterized the recirculation arcs allowed to tune the accelerator to its new non-isochronous working point. In order to check the energy resolution of the beam an electron scattering experiment on a thin gold target has been performed. The obtained data is shown in Fig. 5. The energy spread could be reduced from ΔE = 120 keV in the isochronous mode to ΔE = 30 keV in the non-isochronous mode. Both spectra have been measured for about 30 min, which is a typical time between two saves of experimental runs for nuclear physics experiments. After this first proof of principle the following beam time has been successfully performed in the non-isochronous mode.

SUMMARY AND OUTLOOK

Using a new non-isochronous recirculation scheme for the S-DALINAC the energy spread of the electron beam could be reduced significantly. Nevertheless additional experiments are planned to check the effect of different longitudinal working points on the energy spread and compare the data with simulations shown in Fig. 2.

In addition the concept of using a non-isochronous working point to reduce the energy spread of multi-pass linacs might be interesting to overcome beam break-up limits in high current linacs or ERLs as the bunchlength during acceleration is naturally longer which generally leads to weaker excitations of HOMs [11].

COMPUTATIONAL MODEL ANALYSIS FOR EXPERIMENTAL OBSERVATION OF OPTICAL CURRENT NOISE SUPPRESSION BELOW THE SHOT-NOISE LIMIT

A. Nause, E. Gover, Tel Aviv University, Israel

Abstract

In this paper we present simulation analysis of experimental results which demonstrate noise suppression in the optical regime, for a relativistic e-beam, below the classical shot-noise limit. Shot-noise is a noise resulting from the granular nature of the space-charge in an e-beam. It is linear to the beam current due to its Poissonic distribution in the emission process. Plasma oscillations driven by collective Coulomb interaction during beam drift between the electrons of a cold intense beam are the source of the effect of current noise suppression. The effect was experimentally demonstrated [1] by measuring Optical Transition Radiation (OTR) power per unit e-beam pulse charge. The interpretation of these results is that the beam charge homogenizes due to the collective interaction (sub-Poissonian distribution) and therefore the spontaneous radiation emission from such a beam would also be suppressed (Dicke's subradiance [2]). Analysis of the experimental results using GPT simulations will demonstrate the suppression effect. For the simulation results we used a full 3D GPT model of the ATF section in which the experiment took place at.

INTRODUCTION

Shot-noise is a noise resulting from the granular nature of the space-charge in an e-beam. The discreteness of the particles and the randomness of electrons emission from the cathode causes time dependent fluctuations of the charge and current density at any cross section along the beam transport line. This noise was first reported in 1918 by Schottky who made experiments in vacuum tubes.

Noise is best characterized in terms of the Fourier transform of the time-varying fluctuations in electric current, namely, by its spectral density. Gover and Dyunin showed in a 1D model [3] that it is possible to observe and control optical frequency energy and current (shot noise) fluctuations in a dense relativistic charged particles beam. GPT simulations were used to demonstrate this effect for a real-like beam starting from Shot-noise [4]. Moreover, at certain conditions, when the dominant noise in the beam is current shot noise (density fluctuations), it is possible to reduce significantly the beam noise by virtue of a collective interaction process along an interaction length corresponding to a quarter period longitudinal plasma oscillation in the beam. This means that the charge distribution in the beam can be homogenized in this process.

First experimental observation of this phenomenon using OTR from a metallic foil was presented last year [1]. Noise suppression using a dispersive section (dog-leg bend) was demonstrated in SLAC [5]. TR is proportional to the current-noise amplitude [6], and therefore can be used in order to estimate the suppression in the current noise. In this paper we press analysis of the experimental results and demonstrate this effect using full 3D GPT simulations that were carried out for this purpose.

1D Model of Noise Dynamics in Charged Electron Beams

In electron-beam transport under appreciable space-charge conditions, the microdynamic noise evolution process may be viewed as the stochastic oscillations of Langmuir plasma waves [3]. In the linear regime, the evolution of longitudinal current and velocity modulations of a beam of average current I_b, velocity βc and energy $E = (\gamma - 1)mc^2$, can be described in the laboratory frame by [7]:

$$\frac{d}{d\phi_p}\breve{i}(z,\omega) = -\frac{i}{W(z)\breve{v}(z,\omega)} \quad (1)$$

$$\frac{d}{d\phi_p}\breve{v}(z,\omega) = -iW(z)\breve{i}(z,\omega) \quad (2)$$

where $\breve{i}(\omega) = \breve{I}(\omega)e^{i\omega z/\beta c}$, $\breve{v}(\omega) = \breve{V}(\omega)e^{i\omega z/\beta c}$. $\breve{I}(\omega)$, $\breve{V}(\omega)$ are the respective Fourier components of the beam current and kinetic-voltage modulations. The kinetic-voltage modulation is related to energy and longitudinal velocity modulations: $\breve{V}(\omega) = -(mc^2/e)\breve{\gamma} = -(mc^2/e)\gamma^3\beta\breve{\beta}$, $\phi_p(z) = \int_0^z \theta_{pr}(z')dz'$ is the accumulated plasma phase, $W(z) = r_p^2/(\omega A_e \theta_{pr}\epsilon_0)$ is the beam wave-impedance. A_e is the effective beam cross-section area, $\theta_{pr} = r_p\omega_{pl}/\beta c$ is the plasma wavenumber of the Langmuir mode, $r_p < 1$ is the plasma reduction factor, $\omega_{pl} = \omega_{po}/\gamma^{3/2}$ is the longitudinal plasma frequency in the laboratory frame. The single-frequency Langmuir plasma wave model expressions [3] can be solved straightforwardly in the case of uniform drift transport. After employing an averaging process, this results in a simple expression for the spectral parameters of stochastic current and velocity fluctuations (noise) in the beam assuming that they are initially uncorrelated[]:

$$\breve{i}(L,\omega) = \cos\phi_p(L)\breve{i}(0,\omega) + (\sin\phi_p(L)/W_d)\breve{v}(0,\omega) \quad (3)$$

where $\phi_p = \theta_{pr}z$, $\theta_{pr} = r_p\frac{\omega_p'}{v_0}$, $\omega_p' = (\frac{e^2 n_0}{m\epsilon_0\gamma^3})$, $W_d = \sqrt{\mu_0/\epsilon_0}/k\theta_{pr}A_e$.

The beam current noise evolution is affected by the initial axial velocity noise through the parameter

$$N^2 = \overline{|\breve{v}(0,\omega)|^2}/W^2\overline{|\breve{i}(0,\omega)|^2} = (\omega/c\beta k_D)^2 \quad (4)$$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

where $k_D = \omega_{pl}/c\sigma_\beta$ is the Debye wavenumber and $c\sigma_\beta$ is the axial velocity spread. Equation (4) suggests that current noise suppression is possible if the beam is initially cold $N^2 < 1$, and if plasma phase accumulation of $\phi_p(L) \sim \pi/2$ is feasible.

NOISE SUPPRESSION EXPERIMENT

The noise suppression demonstration experiment was conducted on the 70 MeV RF-LINAC of ATF/BNL (figure 1). The OTR measurements were carried out at a fixed point (CTR-1) 6.5 m away from the LINAC exit. Keeping the beam spot sizes on viewer YAG4 wide in all experiments made it possible to measure similar OTR image patterns on the CCD screen in all experiments (see figure 3). The measured signal S_{OTR} was the integrated charge accumulated in all of the pixels of a CCD (charge-coupled device) camera exposed to the OTR emission on the incidence of single electron-beam pulse on the screen. The measured data of $S_{OTR} = Q_b$ in CTR-0 and CTR-1 are shown in figure 2 as a function of the varied bunch charge Q_b in the range 200 to 500 pC. The pulse duration in all experiments remained approximately the same (5 pS) corresponding to an average current of 40 to 100A (figure 4). In a shot-noise-dominated beam, in the absence of collective microdynamics, the current noise and consequently S_{OTR} are proportional to I_b. Our measured data of $S_{OTR} = Q_b$ in CTR-0 lie approximately on a horizontal line, confirming the absence of collective microbunching and current-velocity noise correlation or noise suppression before this point. On the other hand, the data measured on CTR-1 exhibit a systematic drop as a function of charge (200 to 500 pC) for all beam energies (50 to 70 MeV). As the measurement conditions at the two measurement positions and at different beam energies could not be made identical, the absolute suppression level between the two points could not be determined. However, the normalized data of all measurements of noise per unit charge depicted in figure 2 show the scaling with charge for all beam energies. This demonstrates attainment of 20 to 30% relative noise suppression, and confirms the predicted effect of collective microdynamic noise suppression process in the drift section.

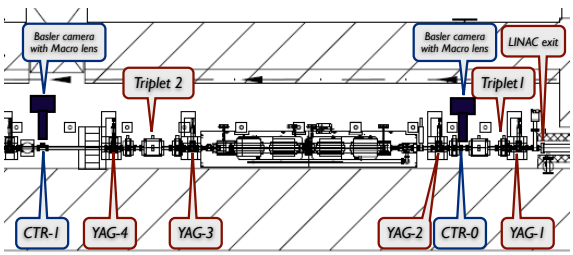

Figure 1: The ATF electron-beam transport set-up is shown from the injector RF-LINAC exit to the OTR viewer site (CTR-1).

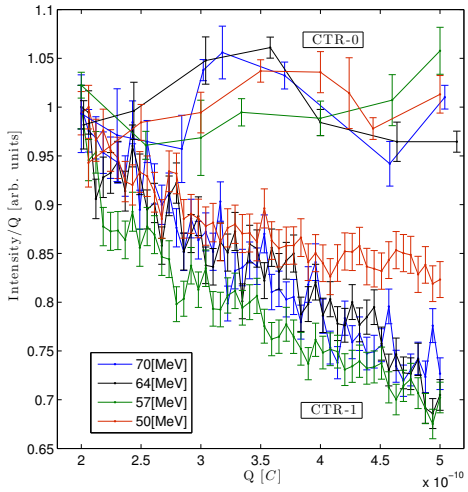

Figure 2: Integrated OTR intensity measurement signals divided by the electron pulse charge. The CTR-1 data correspond to OTR measurement from a screen, intercepting the electron beam 6.5m away from the LINAC exit. The curve's negative slope indicates relative current shot-noise suppression of 20-30% as the beam charge varies from 0.2 to 0.5 nC at different beam energies (50-70 MeV). The CTR-0 data correspond to OTR measurement right after the LINAC exit. Used for reference, its horizontal slope (linear scaling of S_{OTR} with beam charge) indicates that there was no charge suppression before the collective microdynamic process in the subsequent drift section. The error of the camera integrated signal measurement, 3%, was determined from the variance in the value of the signal due to pulse-to-pulse variation, measured repeatedly while keeping all beam control parameters fixed. The charge measurement error is 1%.

COMPUTATIONAL MODEL OF COLLECTIVE MICRODYNAMICS IN VARYING CROSS-SECTION BEAM TRANSPORT

At the exit of the Linac, the beam is current-noise dominated, and $N^2 \ll 1$. However, due to finite emittance, the axial velocity spread becomes significant as the beam is focused and consequently N^2 (Eq (4)) is no longer negligible. Furthermore, at tight focusing the uniform beam expression (Eq. (3)) cannot be used and in order to calculate the noise suppression, one should solve differential equations for variable beam parameters. In this section we show through a model case computational solution of equations (1) and (2), that the axially varying beam cross section and the excess axial velocity spread due to angular spread can account for a substantial moderation of the noise suppression effect that was realized in the experiment. This example also explains some parameter scaling features of the measurement data.

We turn the generic coupled current and ripple voltage

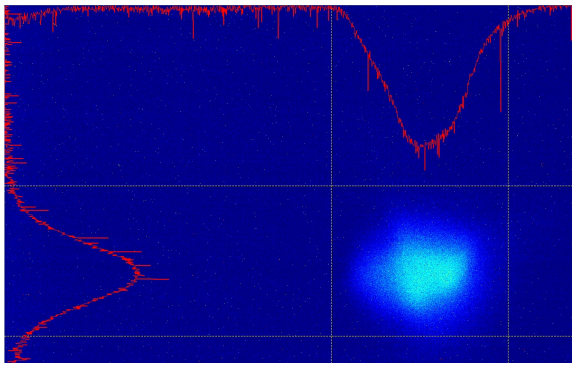

Figure 3: OTR image and axis intensity profiles. Photographed from CTR-1 with a macro lens of 1:1 magnification.

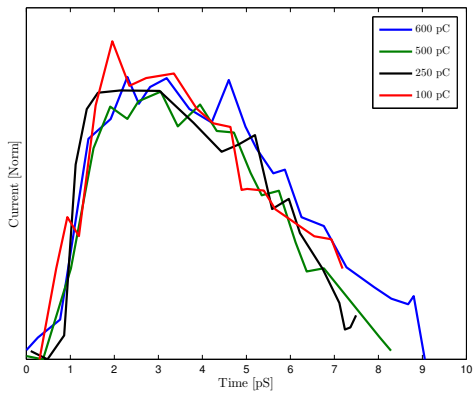

Figure 4: Temporal pulse profile of the e-beam bunch at different bunch charge levels. Pulse duration was approximately 5 pS for all experiments.

equations (1) and (2) into explicit equations in z by substituting $\frac{d}{d\phi_p} = \left(\frac{d\phi_p}{dz}\right)^{-1}\frac{d}{dz} = \frac{1}{\phi_{pr}(z)}\frac{d}{dz}$ and $W(z) = r_p^2/\omega\epsilon_0 A_e(z)\theta_p(z)$:

$$\frac{d}{dz}\breve{i}(z,\omega) = -i\omega\epsilon_0 A_e(z)\theta_p^2(z)\breve{v}(z,\omega) \tag{5}$$

$$\frac{d}{dz}\breve{v}(z,\omega) = -\frac{ir_p^2}{\omega\epsilon_0 A_e(z)}\breve{i}(z,\omega) \tag{6}$$

where $\theta_p^2(z) = eZ_0 I_0/mc^2 A_e(z)\gamma_0^3\beta_0^3$.

This set of equations can be solved explicitly numerically if $A_e(z) = 2\pi\sigma_x(z)\sigma_y(z)$ is given, and the initial conditions $\breve{i}(0,\omega), \breve{v}(0,\omega)$ are specified, and the solution at the end of the drift section L is a linear combination of the initial conditions: $\breve{i}(L,\omega) = A(L)\breve{i}(0,\omega) + B(L)\breve{v}(0,\omega)$. Assuming that the current modulation noise and the focusing enhanced velocity noise are uncorrelated at $z = 0$, we set

$$\overline{|\breve{i}(L,\omega)|^2} = |A(L)|^2\overline{|\breve{i}(0,\omega)|^2} + |B(L)|^2\overline{|\breve{v}(0,\omega)|^2} \tag{7}$$

$$\overline{|\breve{i}(0,\omega)|^2} = eI_b \tag{8}$$

$$\overline{|\breve{v}(L,\omega)|^2} = \left(\frac{mc^2}{e}\gamma_0\beta_0\right)^2\frac{e}{I_0}\sigma_{\beta z}^2 \tag{9}$$

To compute the noise evolution for the parameters of the reported experiment it is necessary to estimate the cross section dimensions $\sigma_x(z), \sigma_y(z)$ along the interaction length. This was done based on the measurements on screens YAG-1 to YAG-4, the recorded quad excitation parameters, and performing full 3-D simulation (with space-charge) using GPT.

The beam axial velocity spread due to energy spread ($\Delta E \simeq 3KeV$) is small, and its effect on the initial velocity noise is negligible. We assume that the initial velocity noise is determined by the standard deviation of the axial velocity spread (equation (9)), which was calculated for each quad setting from the angular spread standard deviations due to the focusing and emittance ($\epsilon_x, \epsilon_y \sim 2-5\mu m$):

$$\sigma_{\beta z} = \frac{1}{4}(\sigma_{\beta x}^2 + \sigma_{\beta y}^2) \tag{10}$$

The coefficients $A(z = L), B(z = L)$ were computed by

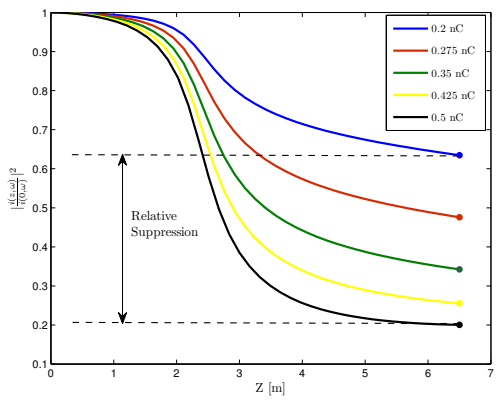

Figure 5: Noise suppression along the collective interaction region as calculated from solution of the coupled differential equations with $\sigma_x(z)$, $\sigma_y(z)$ of 70 MeV.

iterative integration of the coupled linear differential equations (5 and 6) with the initial conditions ((9)). In Figures 5 and 6 we display the results of the model computation of the variable parameters differential equations. The curves show the noise suppression as function of length and of the beam current for the two extreme energy cases E=50 MeV, 70 MeV. The relative suppression factor in the range Q_b=0.2-0.5nC at the drift section exit $L = 6.5m$ is displayed in Fig.() for the two beam-energy examples. Figure 7 can only be regarded as a model explanation for the reduced relative noise suppression effect observed in the experiment. As mentioned, there can be additional factors

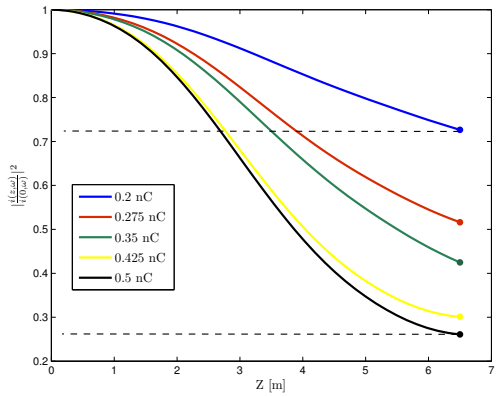

Figure 6: Noise suppression along the collective interaction region as calculated from solution of the coupled differential equations with $\sigma_x(z)$, $\sigma_y(z)$ of 50 MeV.

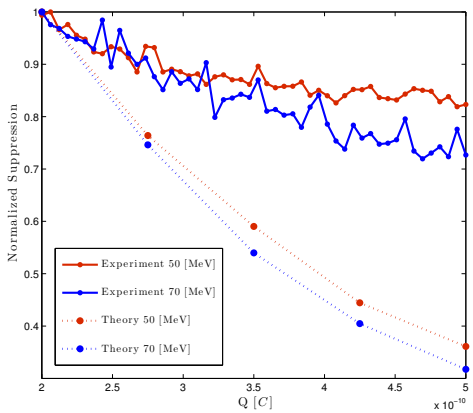

Figure 7: Relative noise suppression rate computed from Eq. 5 and 6 for E=50 MeV, 70 MeV compared to the experimental suppression results.

affecting the suppression rate. It is noted that the computed curves display significantly larger relative suppression in the range Q_b=0.2-0.5nC than the experimental curves, but in either case there is only little dependence on the acceleration energy. In the simple uniform beam model one would expect dependence of the noise suppression factor on the beam energy due to the $3/2$ power dependence of the plasma frequency on γ, which corresponds to smaller plasma phase accumulation at higher beam energy. However, the beam envelope had to be varied in the experiment in different beam energies, and one must keep in mind, that at the higher energy the beam focuses into a tighter waist due to the reduced space charge effect. This tends then to increase the plasma frequency at the waist, where most of the microdynamic process takes place.

This observation is consistent with the point of view that the beam envelope expansion and the beam charge homogenization process are in essence the same process of excess charge beam expansion when viewed in the beam rest frame (independent of the acceleration energy). This is consistent with the plasma phase accumulation theorem of constant plasma phase accumulation in a space charge dominated beam waist [3]. This provides qualitative physical explanation for the weak dependence of the relative noise suppression on the beam energy in the 50-70 MeV range, as depicted in both the experimental (figure 2) and model calculation (figure 7) curves.

STATUS OF CH CAVITY AND SOLENOID DESIGN OF THE 17 MeV INJECTOR FOR MYRRHA*

D. Mäder†, H. Klein, H. Podlech, U. Ratzinger,
C. Zhang, IAP, Goethe-Universität, Frankfurt am Main, Germany

Abstract

The multifunctional subcritical reactor MYRRHA (**M**ulti-purpose h**y**brid **r**esearch **r**eactor for **h**igh-tech **a**pplications) will be an accelerator driven system (ADS) located in Mol (Belgium). The first accelerating section up to 17 MeV is operated at 176 MHz and consists of a 4-rod-RFQ followed by two room temperature CH cavities with intertank quadrupole triplet focusing and four superconducting CH structures with intertank solenoids. Each room temperature CH cavity provides about 1 MV effective voltage gain using less than 30 kW of RF power. The superconducting resonators have been optimized for electric peak fields below 30 MV/m and magnetic peak fields below 30 mT. For save operation of the superconducting resonators the magnetic field of the intertank solenoids has to be shielded towards the CH cavity walls. Different coil geometries have been compared to find the ideal solenoid layout.

INTRODUCTION

Transmutation of long-lived radioactive waste and advanced technologies for future power generation will be investigated with the MYRRHA ADS [1]. The IAP of Frankfurt University is responsible for the development of the 17 MeV injector, a 13 meter long front end of the 600 MeV MYRRHA linac. To achieve the extremely high reliability of the beam supply for the reactor, two injectors will be driven at the same time. With this parallel redundancy the beam can be provided even during a failure of one injector. Because of thermal stress in the reactor not more than 11 beam trips of $t > 3s$ per year are allowed. The following accelerating structures up to 60 MeV are using the concept of serial redundancy [2].

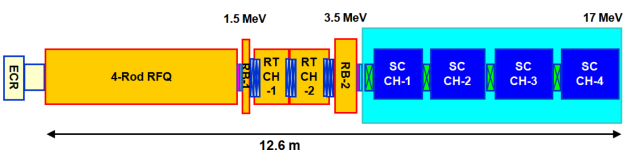

Figure 1: Overview of the MYRRHA injector.

A 4-rod-RFQ will bunch and accelerate the proton beam up to 1.5 MeV [3]. After a five gap CH rebuncher the proton bunches will be accelerated to 3.5 MeV with room temperature CH structures. Quadrupol triplets for focusing and phase probes for diagnostics are placed between the structures. 3 MV/m will be provided by the superconducing accelerators. Four bulk niobium CH cavities are assembled together with four 4.5 Tesla solenoids with coils made of NbTi in one cryomodule [Figure 1].

CH CAVITY DESIGN

Crossbar H-mode (CH) cavities are excellent candidates for acceleration of ions in the low and medium energy range. These resonators driven in the TE_{211}-Mode will be used for all accelerating and rebunching cavities after the 4-rod-RFQ from 1.5 to 17 MeV.

Room temperature CH cavities

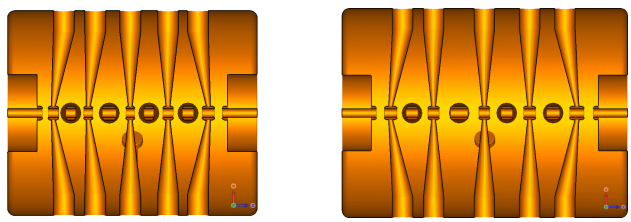

Figure 2: Scheme of the two room temperature CH structures.

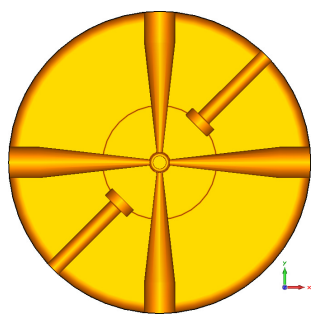

Figure 3: The diagonal tuners act mainly capacatively and provide a total frequency shift of 1 MHz.

CH-1 consists of three and CH-2 of two inclined stems [Figure 2]. Together with the extra volume around the vaults the inclination of the stems increases the induction on the outer stems. This flattens the gap voltage distribution and consequently the thermal load on the stems. The vaults at the resonator ends create additional space outside the cavity and are used for the quadrupole triplet lenses.

Each CH structure is tuned by two mainly capacitively acting tuners that provide a total frequency shift of 1 MHz.

The tuners are mounted on the cavity wall under 45 degree to the horizontal plane [Figure 3].

Table 1: Parameter list of the room temperature CH-1 and CH-2 of MAX.

Parameter	RT CH-1	RT CH-2
Frequency [MHz]	176	176
Q-Factor (85% MWS)	14539	14964
P_{sim} [kW]	16.5	18.5
P_{real} (85% MWS) [kW]	19.4	21.8
$Z_a(\beta\lambda - def.)$ [MΩ/m]	113.5	100.6
U_0 [MV]	1.26	1.37
U_a [MV]	1.03	1.14
β_{avg}	0.066	0.077
No. of Gaps	10	10
Energy Range [MeV]	1.5 – 2.5	2.5 – 3.5
$E_a(\beta\lambda - def.)$ [MV/m]	1.8	1.6
L [mm]	715.2	833.6
$L(\beta\lambda - def.)$ [mm]	568.7	699.3
Diameter [mm]	584	608
Aperture [mm]	25	25

Superconducting CH cavities

One cryo-module will contain all cold parts of the injector. For manufacturing and transportation reasons the superconducting CH structures are not longer than 1.2 m. For this reason the number of gaps decreases with higher β_{avg} from 10 to 7.

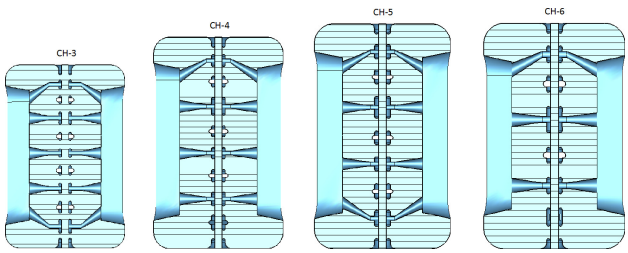

Figure 4: The four superconducting CH cavities in scale relatively to each other.

All superconducting cavities will be made of bulk Niobium and are optimised for an acceleration gradient between 3.5 and 3.9 MV/m and for a flat electric peak field distribution along the gaps. Low electric peak surface fields below 30 MV/m minimise the risk of quenching and ensure a safe operation [Table 2].

SC SOLENOID DESIGN

Superconducting solenoids driven at a maximum magnetic field of 4.5 T are used in the cold part of the injector for transversal focusing. The current densitiy of 300 A/mm^2 in the main coil is ten times smaller than the critical current density, where the solenoid is quenching [4].

Four superconducting solenoids of the same type will be placed between the accelerating cavities. The main coil

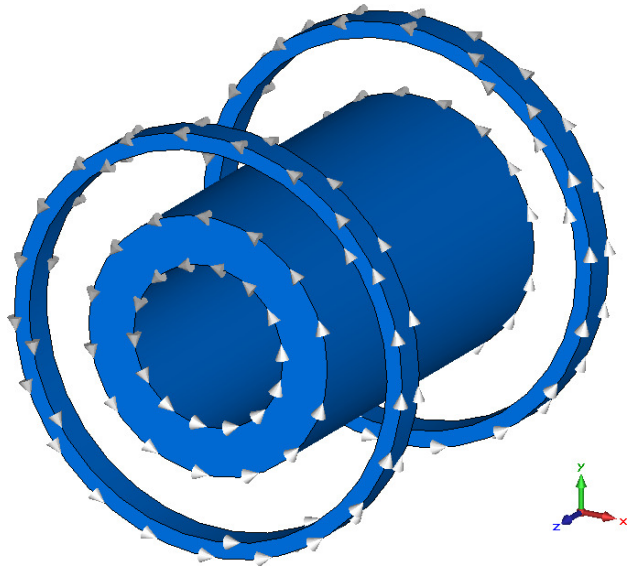

Figure 5: Main and bucking coils of the superconducting solenoid.

of the solenoid is 120 mm long and has 4300 windings of Niobium-Titanium in a copper matrix. To avoid quenching of the neighbouring accelerators the magnetic field of the solenoid has to be reduced. Two bucking coils with 420 windings at the ends of the main coil [Figure 5] minimise the fringe field [Figure 6 and 7]. All multi-filamentary superconducting wires in the solenoid can carry a total current of 120 A.

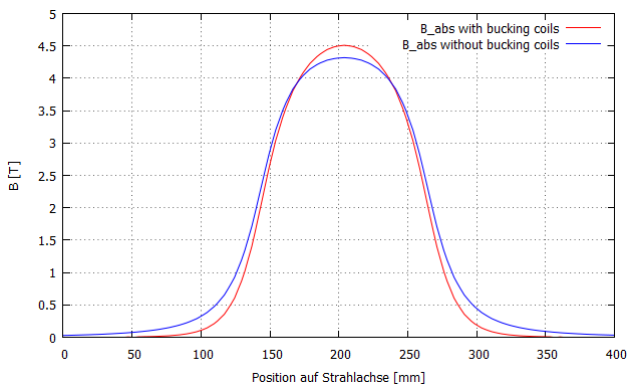

Figure 6: A solenoid with bucking coils has a lower fringe field in comparison with a simple solenoid. Both solenoids are normalized to the same focusing strength.

OUTLOOK

The new tuning concept of superconducting CH structures with static and dynamic tuners on the girders between the stems will be applied for the four sc injector cavities for MAX after a successful demonstration of this concept with a 325 MHz cavity at IAP [5].

The effects of the solenoids fringe field on the CH cavity are under investigation. Further simulations to shield the magnetic flux are necessary.

E_{max}/E_a	7.5	7.6	8.5	8.3
L [mm]	915.9	1075.3	1129.0	1126.9
L $\beta\lambda - def.$ [mm]	901.1	1071.1	1162.1	1178.8
Diameter [mm]	600	650	684	708
Aperture [mm]	30	30	40	40

Additional measurements with a test solenoid close to a CH structure at 4.2K will be performed together with GSI in the demonstrator experiment [6]. A main focus in this layout is to put on high safety margins to reach the specified reliability.

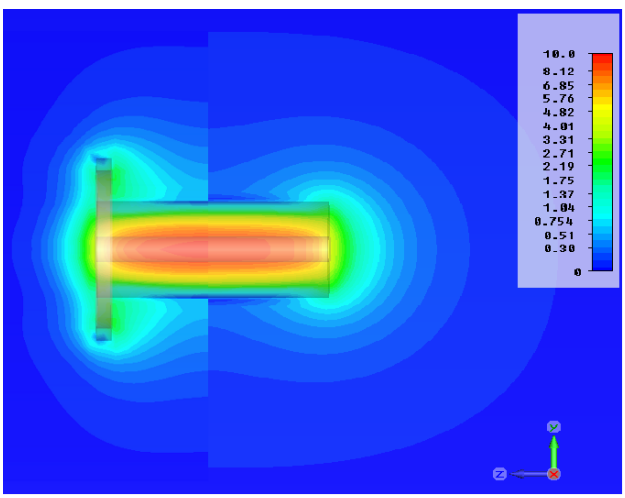

Figure 7: In this graphic two pictures with the magentic flux of a solenoid are merged. On the left side the solenoid with bucking coils is shown. The simple solenoid without bucking coils on the right side creates more spacious magnetic flux. The coloured scale is normalized to the highest field level of the left solenoid (4.5T). Both solenoids would have the same focusing strength, so the simple solenoid would have a less peak field (compare with figure 5).

Abstract

The design work of the Injector II, which is 10 MeV proton linac, in C-ADS project is being finished and some key hard wares are being fabricated. Now it is necessary to definite the operation mode of beam commissioning, including the selection of the beam current, pulse length and repetition frequency. Also the beam commissions plan should be specified. The beam commissions procedures is simulated with t-mode code GPT [1]. In this paper, the general beam commissioning plan of Injector II in C-ADS and simulation results of commissions procedures are presented.

INTRODUCTION

Nuclear energy as a kind of clean energy will be widely used in Chinese energy program in the future. But one of the serious problems is how to handle radioactive waste produced by nuclear plants. ADS, which is the effective tool for transmuting the long-lived transuranic radionuclides into shorter-lived radionuclides, is being studied in the Chinese Academy of Sciences. The road map of the project is shown in Fig. 1.

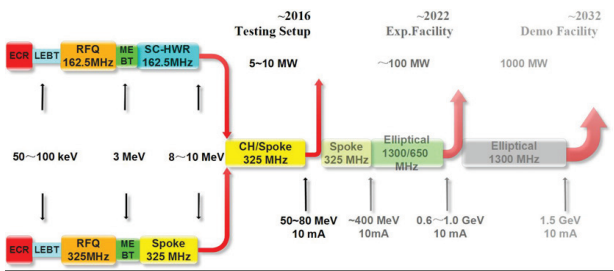

Figure 1: The roadmap of China CAS.

The linac will accelerate the proton with beam current 10mA to about 1.5GeV to produce high flux neutrons for transmutation of nuclear waste.

To ensure technical feasibility in the low energy section, two injectors for the superconduction linac are studded during the first step. One of the injectors, that is Injector II, is been designed and fabricated at Institute of Modern Physics of the Chinese Academy of Sciences.Injector II as part of the ADS is being designed and built at IMP. Injector II is composed of Low Energy Beam transport Line(LEBT), Radio Frequency Quadrupole(RFQ), Medium Energy Beam transport Line(MEBT) and the SC accelerating section. The layout of Injector II is shown in Fig. 2.The LEBT will match the proton beam with 0.035MeV from the ECR source to the RFQ by two solenoids. The RFQ will accelerate and focus the beam from 0.035 MeV to 2.1 MeV simultaneously. The MEBT has two main functions, which are to match the proton beam from the RFQ to the superconducting accelerating section and to place some on line beam diagnostics devices. The superconducting accelerating section will accelerate proton from 2.1 MeV to 10 MeV with 16 superconducting half wave resonator(HWR) cavities. .

The basic parameters of Injector II are listed in Table. 1.

Table 1: The basic parameters of injector II.

Parameters	Value
Particle type	Proton
Operation frequency(MHz)	162.5
Operation mode	CW
Input beam energy(MeV)	0.035
Output beam energy(MeV)	10
Beam current(mA)	10

In this paper, the general beam commissioning plan of Injector II in C-ADS and simulation results of commissions procedures are presented.

THE BEAM DYNAMICS OF INJECTOR II

The MEBT and superconducting section are simulated by TRACK code. The particles distribution out from the RFQ [2] are transported as the initial distribution of the downstream lianc.

The results of the simulation with three-D field map are shown in Fig. 3. The RMS envelopes in both transverse and longitudinal direction are smooth and periodic in the superconducting section. This depicts that there is good matching between MEBT and the superconducting section.

COMMISSIONS BEAMS OF INJECTOR II

The commissions beams will be chopped for the commissioning of RFQ at first stage, then we plan to use unchopped beam for the bulk of the superconducting section commissioning studies. The beam will be consistent with the beam-handing capabilities of the beam diagnostics system in use at the time.

Beam current

The 0.5mA peak current beam will be chosen to be as the initial commissioning study. The reason is we want to reduce the space charge effect as weak as possible to simply the initial commissioning. At the same time the low limitation of measurement dynamics range of the beam diagnostics device should be considered. Also the low current is

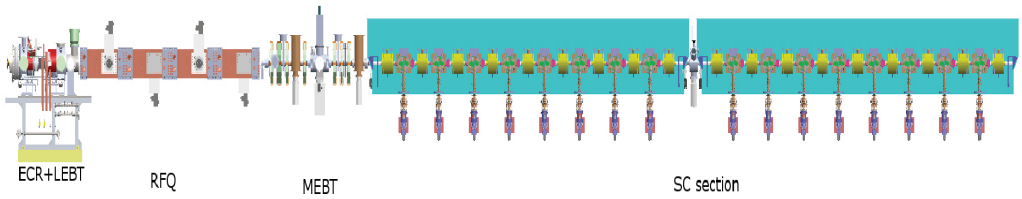

Figure 2: The layout of C-ADS Injector II .

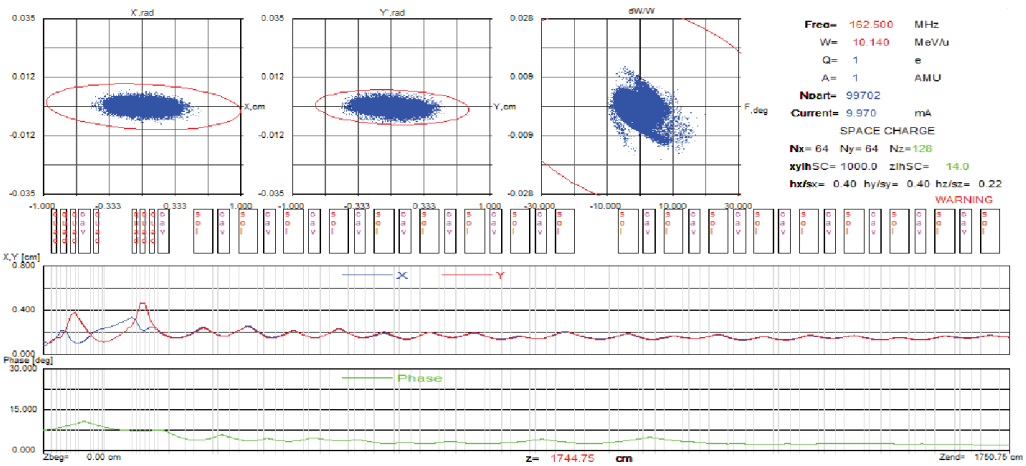

Figure 3: The simulation results of MEBT and the superconducting section.

chosen to minimize dose and activation during initial commissioning. Once the initial linac setup is done, we will increase the current to 1mA, 5mA and finally 10mA.

Pulse length

The pulse length will be set by two factors. One is the limitation of the diagnostics system. The other factor is the machine protect. At the beam commissions stage, the beam will lost on the accelerator element probably. To determine the pulse length, the time dominant code GPT is used to simulated the beam loss in superducting section, which is shown in Fig. 4. . In the Fig.4, the beam loss power distribution is shown supposing the first cavity is broken down. The maximum beam power is 1100W/m. To prevent the quench of superconducting cavity caused by lost beam, the pulse length of commissions at 10mA should be less than 100us.

Repetition rate

The beam commissioning of RFQ will be carried out at repetition rate equal or less that the repetition rate of RFQ RF power supply. Because the energy out from RFQ is 2.1MeV, the radiation activation will be not an issue. For the commissioning of superconducting section, low repetition rate 1Hz will be as initial commissioning beam. ”Beam on demand” mode will be used whenever possible and appropriate in order to minimize activation and thermal damage of the hardware by high energy and high power beam.

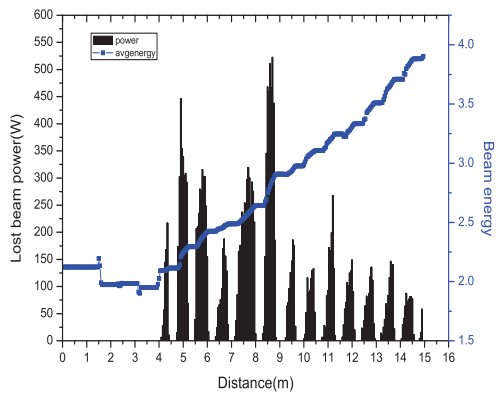

Figure 4: The lost beam power distribution when the first cavity breaks down at 10mA.

THE BEAM COMMISSIONS PLAN OF THE INJECTOR II

In InjectorII, two key sections are RFQ and superducting section. In this paper, the beam commissions plans about this two section are stated. The goal of beam commissions is CW mode at 100KW beam power. An beam dumper will be installed at the end of adjustable HEBT, which will deliver beam with different energy to the beam dumper at different stage.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

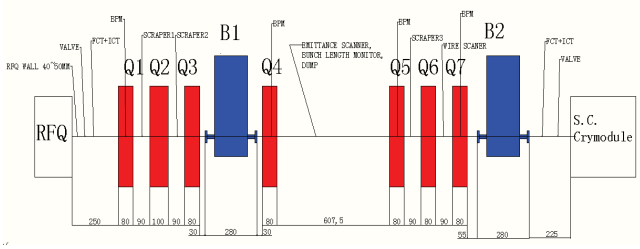

Figure 5: Layout of beam diagnostics in MEBT.

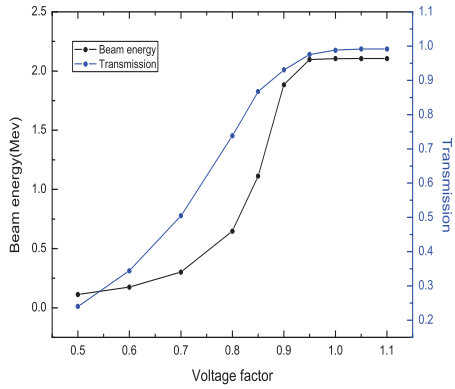

Figure 6: The relation of cavity voltage factor with beam power and transmission.

RFQ and MEBT

The RFQ section will be installed with MEBT at the same time. There are kinds of diagnostics equipments installed at MEBT as shown in Fig. 5. As shown in Fig.5, two sets ICT and FCT are located at the entrance and exit of MEBT to measure the transmission of the RFQ. Also there are other diagnostics equipments to measure the information of beam out from the RFQ, such as emittance, beam halo.

The InjectorII RFQ is designed to accelerated proton beam to 2.1MeV with code PARMTEQ-M [3]. The beam dynamics of RFQ is benchmarked with code TRACK. One of the importance processes of beam commissioning of RFQ is finding the RF operation point by comparing the calculation and experimental results of beam transmission. The simulation results for the beam transmission is given in Fig. 6.

The blue line means the beam transmission rate as a function of the voltage factor, and the black line means output energy evolution with voltage factor. The rehalation can give us an guide in the real beam commissioning experiment.

The superconducting section

For the superconducting section, there are 16 focusing period and one BPM in each period. The BPMs can be used in both transverse orbit correction and RF operation point setting. The RF operation point setting is an main process

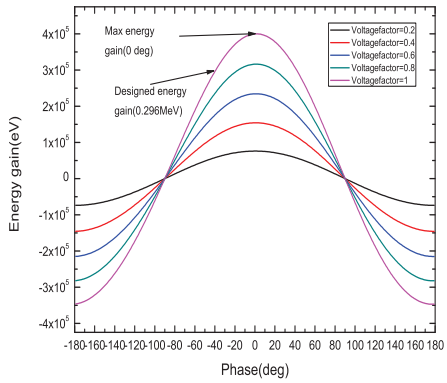

Figure 7: The energy gain of first cavity varying with voltage factor.

in beam commissioning. In the tuning of superconducting cavity, first step is to find the synchronous phase. This can be performed by rotating the phase at low accelerating voltage(150-200KV). Two BPMs down stream are used to find the maximum energy increase, which is correspond to zero degree, and then setting the phase to the designed synchronous phase. Second step is to set the amplitude of field, which can be determined by the beam energy out from the cavity. The beam energy variation with the phase is plotted in the Fig. 7. As shown in Fig.7, maximum energy gain correspond to zero degree, the synchronous phase can be find through this way.

SUMMARY

The installation of Injector II of CADS project will start at the beginning of 2013. the commissioning consists of two main stages, RFQ and superconducting section, is scheduled for 2013. The beam commissioning goal is the proton beam power of 100KW for CW 10MeV out from Injector II. The commissioning beam will begin with peak current 0.5mA, pulse length 100us and repetition rate 1Hz.

RF SETUP OF THE MedAustron RFQ*

B. Koubek, J. Schmidt, A. Schempp, IAP, Goethe University, Frankfurt am Main, Germany
J. Haeuser, Kress GmbH, Biebergemuend, Germany

Abstract

A Radio Frequency Quadrupole (RFQ) was built for the injector of the cancer treatment facility MedAuston in Austria [1]. For the RF design simulations were performed using CST Microwave Studio® and the structure was manufactured by Firma Kress in Biebergemuend, Germany. The simulations and the RF setup of the delivered RFQ are presented in this paper.

INTRODUCTION

The 216.8 MHz MedAustron RFQ was designed to accelerate protons and carbon ions from 8 keV to 400 keV [2] on an electrode length of 1.25 m. It is a state of the art 4-Rod RFQ with quite slim electrodes and newly developed connections of the stems to the electrodes. Usually clamps were used to fix the electrodes to the stems (see Fig. 2). The accuracy of the machining allows us to remove the clamps. Simulations have shown that these new connections are causing less capacitance and hence less disturbing electric field than the clamps.
Fig. 1 shows the RFQ during its preparation at the Institute of Applied Physics (IAP) in Frankfurt am Main. More details about the RFQ basic design parameter can be found in Table 1.

Table 1: Design Parameters of the MedAustron RFQ

Parameter	Value	
Frequency	216.612	MHz
Input Energy	8	keV
Output Energy	400	keV
Beam Current (max)	4	mA
Aperture (min)	2	mm
Modulation Factor (max)	2	
Electrode Length	1250	mm
Intervane Voltage	70	kV
RF Cells	15	
Beam Height in Tank	19.5	mm
Stem Thickness	20	mm
Stem Distance	68	mm
Tank Length	1233	mm
Wall Thickness	40	mm

SIMULATIONS

Simulations have been performed using CST Microwave Studio® for the RF design. During this process two different shapes of the backside of the electrodes have been investigated. One is a broad and the other one a more narrow socket of the electrodes backside. A top view of the two different shapes is shown in Fig. 2.

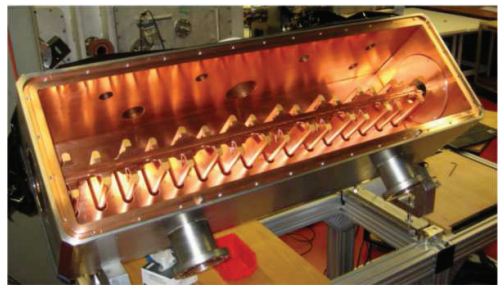

Figure 1: RFQ during preparation at IAP.

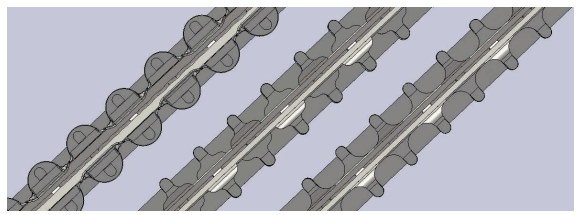

Figure 2: Former clamps (left), new broad (middle) and narrow (right) sockets.

Both shapes are rising the resonance frequency due to less capacitance compared to the old design with clamps. The broad shape increases frequency about one MHz more than the slim one, it shows less inductance and provides a fast and homogenous charge distribution on the electrode tips. Further informations about the RF characteristics of the connections of the electrodes can be found in [3].

MEASUREMENTS AND TUNING

Geometric Measurements

The accuracy of the machining and assembling of the single parts have been checked with a 3-D measurement device. The angle and the distance of the stems, the angle of the electrodes to each other and the position of the beam axis relatively to the reference surfaces have been measured. The measurements have met our expectations. Also no significant longitudinal electrode shift could be measured. Fig. 3 shows the measurement of the angle of the electrodes to each other and the longitudinal shift of the electrodes.

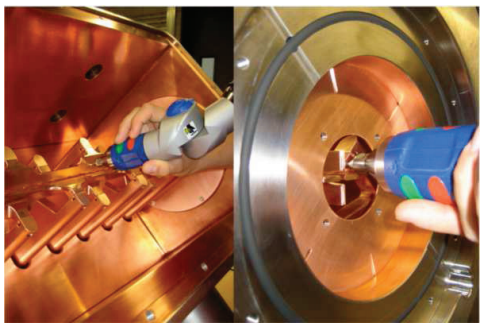

Figure 3: Measurements of the angle and the longitudinal shift of the electrodes using a 3-D measurement device.

RF SETUP

The frequency and flatness tuning have been executed in one procedure. First without the piston tuner to analyse the RF behavior of the RFQ. Later the final tuning was made with the inserted piston tuner on its zero position.
After investigation of the single influence of the tuning blocks, the piston tuner and the input power coupler on frequency and flatness, all the parts together have been adjusted and tuned. The tuning blocks have been fixed with silver screws on individual distance parts made of copper. The whole procedure is very similar to the tuning of the FNAL RFQ described in [4].

Flatness

For operation a homogenous longitudinal voltage distribution (flatness) of the electrodes is required according to the beam dynamics design. By changing the height of the tuning blocks the frequency of the RFQ and the local eigenfrequency of a single cell can be adjusted. Hence an uneven voltage distribution, caused by the modulation of the electrodes or inaccuracies by manufacturing of the RFQ, can be adjusted. The typical banana shaped flatness of the untuned MedAustron RFQ is shown in Fig. 4. It has an unflatness of about ±10 %.

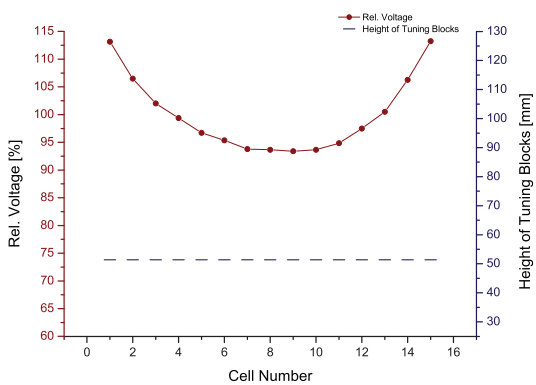

Figure 4: Untuned flatness with equal heights of the tuning blocks.

The flatness tuning is an iterative process to get an equal voltage distribution along the electrodes [5]. Each RF-cell is detuned using a perturbation capacitor (see Fig. 5). From the detuned RF-cell one can calculate the longitudinal voltage distribution of the electrodes. After this a next guess of the tuning block distribution can be made to improve the flatness.

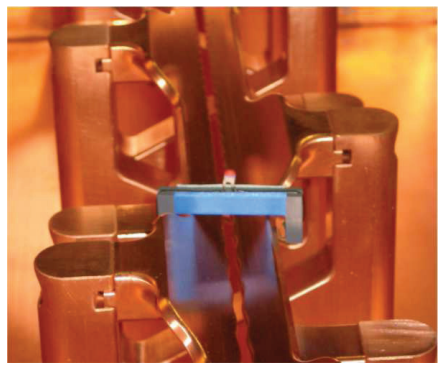

Figure 5: Pertubation capacitor used to detune each cell of the RFQ.

Piston Tuner

The frequency of the RFQ can change under operation due to several reasons. To correct the frequency a piston tuner is used. It has an influence on the resonance frequency by suppressing the magnetic field [6], but it is changing the flatness as well. If the flatness is not adjusted with an inserted tuner it may decrease of about ± 0.8 %. The piston tuner is placed in the middle of the cavity, its influence on the frequency is shown in Fig. 6.

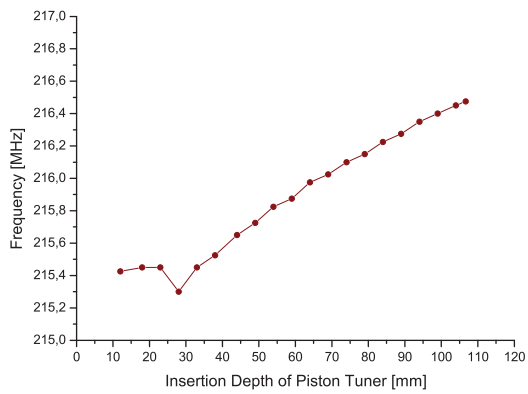

Figure 6: Frequency shift due to the piston tuner.

One can see that the insertion depth of the piston tuner has an almost linear influence on the resonance frequency of the RFQ. Before it enters the RF-cell between the stems it has only weak influence on the frequency. Then there is a small region where it disturbs the resonance of

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the structure. This means one has to regard a minimum insertion depth of the piston tuner. When it enters the RF-cell between the stems it rises the frequency with its depth with an approximately linear behavior.

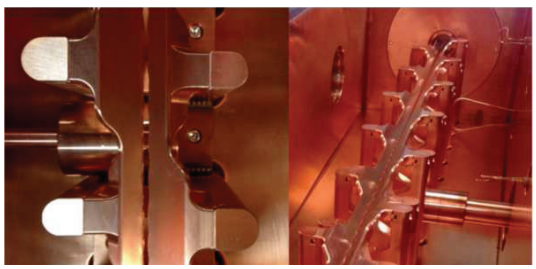

Figure 7: Top and side view of the piston tuner.

RESULTS

After the tuning process the resonance frequency was adjusted to 216.6 MHz with a deviation of the longitudinal voltage distribution of ± 1.7 %. This flatness with its distribution of the tuning blocks is shown in Fig. 8.

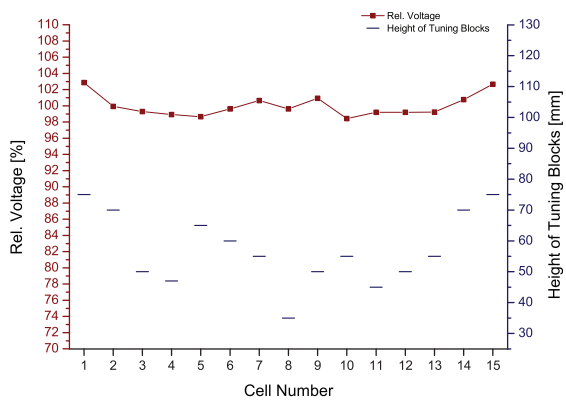

Figure 8: Final flatness and distribution of the tuning blocks.

Finally the piston tuner has been set to be able to adjust the frequency from minimum of 216.4 MHz to maximum 216.9 MHz. This values might rise about 0.1 MHz under vacuum. The overall shift of the piston tuner is about 0.5 MHz. The power coupler has a reflection of -27 dB.
The shuntipedance measured with an perturbation capacitor was 92 kΩm. The RF parameter of the MedAustron RFQ are summerized in Table 2. Overall the tuning process took several weeks and has led to quite satisfactoring results.

Table 2: RF Parameters of the MedAustron RFQ

Parameter	Value	
Frequency	216.612	MHz
Quality Factor Q_0	3600	
Voltage Distribution	± 1.7	%
Shunt Impedance	92.57	kΩm
Reflection Power Coupler	-27	dB
Transmission Pickup 1	-40	dB
Transmission Pickup 2	-39	dB
Transmission Pickup 3	20	dB

OUTLOOK

The MedAustron RFQ has been delivered at the end of July 2012. The ion source, the low energy beam transfer line and the RFQ will be commissioned at the Injector Test Stand (ITS) at CERN [7]. The test stand provides the possibility to prepare the LEBT independently from civil engineering in Austria. As soon as the building is ready the LEBT can move to Wiener Neusadt for commissioning and start of operation [8].

PRODUCTION AND QUALITY CONTROL OF THE FIRST MODULES OF IFMIF-EVEDA RFQ

F. Scantamburlo, A. Pepato, R. Dima, INFN/PD, Padova, Italy,
C. Roncolato INFN/L.N.L., Legnaro, Italy

Abstract

The IFMIF/EVEDA RFQ, designed to accelerate a 125mA D+ beam from 0.1 MeV to 5 MeV at a frequency of 175 MHz, consists of 18 modules with length of ~550 mm each. The production of the modules has been started and 2 prototype modules plus module 16 have undergone all the production steps, including precision milling and brazing. The progress of the construction and especially the fine tuning of the design and engineering phase are reported.

BRAZING PROCEDURE MODIFICATIONS

Once completed the 2 steps brazing of the 1st module prototype, the acquisition of a continuous active scanning measuring machine (Zeiss Accura) allowed a deep and extensive investigation of the internal geometry of the cavity. A wide series of transversal and longitudinal scanning were then performed. The more detailed and reliable measurements showed a lack of symmetry induced by gravitation effect during the 1st step brazing [1]. The final geometry of the cavity resulted still within the acceptable tolerances range for a single module, but not for the complete line, figures 1 and 2. A vertical brazing assembly, which permitted instead a possibility of a single brazing step, has been developed, figure 3. In this respect, the groove geometry, layout and tooling had to be redesigned. We introduced extensive US scanning (destructive test) and inspection (non-destructive) for the qualification of the brazed surfaces (Cu-Cu and Cu-st. steel).

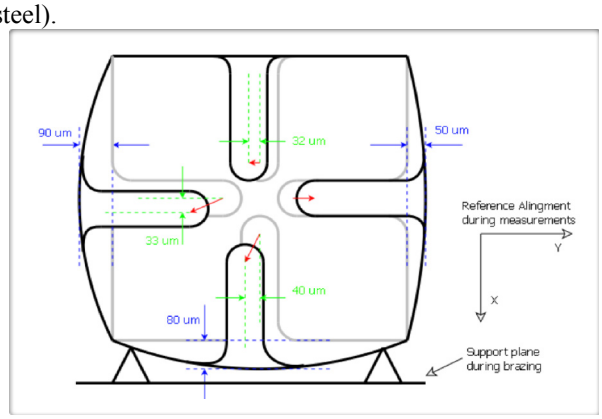

Figure 1: Scheme of the deformation of the cavity of the module 1 prototype after the second brazing

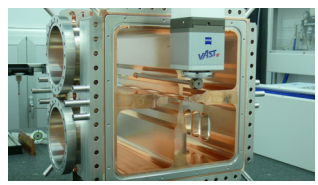

Pole	ΔX [μm]	ΔY [μm]	ΔR_0 [μm]
1	-40	-80	89.44
2	50	0	50.00
3	-32	0	32.00
4	-90	-33	95.86
	mean ΔR_0 [μm]		66.83
	$\partial f/\partial R_0$	[kHz/ μm]	7.60
	Δf	[kHz]	507.87

Figure 2: Module 1 prototype during CMM survey (left) and displacements of the tips (right).

R & D FOR SINGLE BRAZING STEP

With a single brazing step, the number of thermal cycles, reducing the mechanical properties of copper (1 annealing step + 1 final brazing step), is minimized.

The overall precision of the final geometry is optimized.

The cost and the timing of the modules production are also optimized.

Some basic tests on specimens having the same groove design, in order to compare vertical to horizontal brazing, have been performed.

Then two almost full scale tests have been performed finalizing an updated tooling set.

A complete inspection by US scan on slices of the brazed surfaces has been done (destructive). The grooves result always completely empty and no significant voids were detected on the brazing planes, figure 4.

Following these results, the production of the final modules started with SuperModule III-HE section. We adopted the vertical brazing approach but still with 2 brazing steps, until all details were well stated.

We completed the production of the module 16 (April '12), the second prototype module (July '12) and the 1st brazing step of module 17 (July '12).

The 1st single brazing step will be adopted on module 15 by October '12.

THE MODULE 16'S PRODUCTION

The Quality Assurance of the Mechanical Machining

The continuous feedback between the mechanical machining and the measurement results was essential to guarantee the tight design tolerances.

The continuous active scanning survey of the tip geometry is mandatory to check the real geometry with adequate accuracy. The traditional point to point survey measurement (standard approach on CMM's) was attempted, but it failed.

The effectiveness of the active scanning control was essential to adjust and refine the CAM programs and the tooling fine tuning.

A standard procedure for the accurate control of each machining step of all the components and of the assembled module has been established:

- survey and qualification of each component, figure 5 and 6;
- survey and qualification of the dry-assembly of the module before the machining of the common reference planes;
- survey and qualification of the module after each brazing step;
- survey and qualification of the final module compared with the RF measurement.

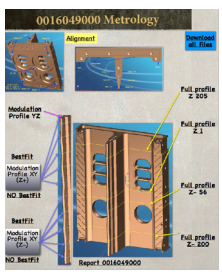

Figure 5: Inspected elements for the qualification of each CuC2 component of the cavity

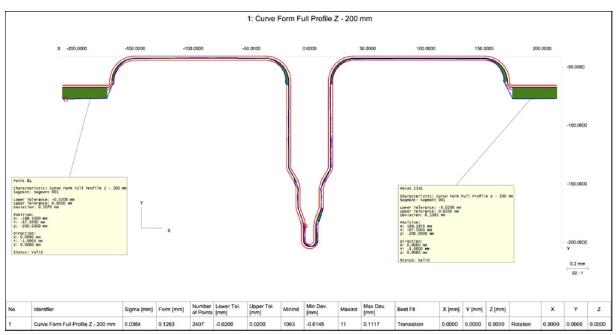

Figure 6: Example of measure of a profile by means active continuous scanning.

The Brazing Procedure, Module Dry Assembly

All the components are aligned to the nominal position and double checked, geometrically and RF.

The assembly is then machined to refine the common planes for the placement of the brazing tooling, figure 7.

The components are then dismantled, chemically cleaned, reassembled in a clean environment by means of the tooling, figure 8.

In this step the 2 sealing st. steel front rings have been mounted in order to provide a relevant constraint, embedding a smooth relative movement of components during the thermal cycle, that could cause an excessive flow down of the brazing material, figure 9.

Figure 7: Module 16 dry assembled before the machining of the common planes

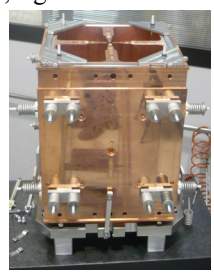

Figure 8: Module 16 assembled with the brazing tooling

The Brazing Procedure, 1st Step

We used Palcusil 10† as brazing material (optimal wetting of the surfaces while allowing for more brazing cycles repairs).

The optical inspection of the brazing joints showed an uniform distribution of the brazing material both on copper-copper and copper-st.steel.

The vacuum tightness of the cavity and of the cooling ducts was well below the specifications (1x10-9 mbar/sec*l).

Nonetheless a relative displacement between the "Ts" and the "Es" profiles was found.

This effect is explained by the relevant different expansion between CuC2 and AISI316LN.

The st. steel ring was not brazed in the first step of the first prototype module. Besides this the structural schemes are slightly different since on the first case the components are separated while in the other they are strictly joined.

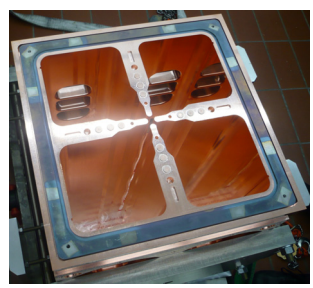

Figure 9: Module 16 after the 1st brazing step.

The Brazing Procedure, 2nd Step

The brazing material used is Cusil‡. During this step all the remaining st. steel components are brazed, figure 10. We encountered 2 problems.

† Palcusil 10 Composition: 59% Ag, 31 % Cu, 10% Pd; liquidus: 854 °C, solidus: 824 °C.

‡ Cusil Composition: 72% Ag, 28% Cu; liquidus : liquidus: 780 °C, solidus: 780 °C.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The junctions between the end side flanges and the copper were just partially brazed (as verified by US inspection).

The dimensional check of the cavity showed unexpected deformations.

The reasons:

- we discovered that the heat treatment of the end side flanges was not done following our specifications (the cooling step was too fast thus resulting on an ineffective annealing process);
- again the relevant different expansion between CuC2 and AISI316LN.

Since the brazed connection was too poor, a 3rd brazing step (using Incusil 10*) was performed to join the copper and the st. steel end side flanges by means of a series of pins, figure 11.

Beside all these problems the module 16 fulfills the specifications in terms of geometrical tolerances and vacuum tightness.

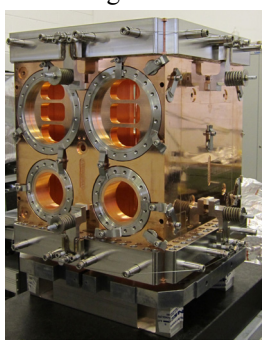

Figure 10: Module 16 before the 2nd brazing step

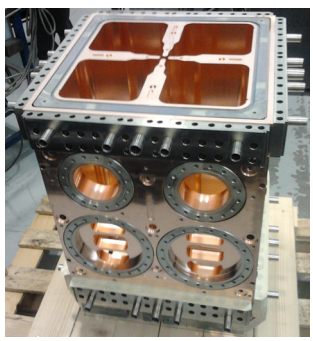

Figure 11: Module 16 after the 3rd repair brazing

Improvements - the results

Keeping in mind the problems found on module 16, a wide range of data for the thermal behaviour of copper and AISI316 were registered in the technical literature [2, 3].

We decided to perform some test with the peculiar material and dimensions to determine the overall relative expansion during our typical brazing cycles.

The tests results were better approximated by the material data as reported in reference [3]. Consequently our design was modified as follows:

- the sealing st. steel ring: any contact between copper and ring on the "Ts" sides (gap about 0.3 - 0.5 mm) was embedded, while the nominal coupling brazing tolerance on the "Es" sides was maintained to ensure a relevant coupling pressure all along the thermal cycle (accepting the residual local deformation at the joint level), figure 12;
- the end side flanges: some almost passing through incisions were introduced, softening the end side flanges stiffness, while ensuring a continuous brazing surface. The local expansion of the cavity was limited to a value around 0.01 mm, figure 13.

All these modifications were introduced and verified on the 1st brazing step of module 17 (sealing st. steel rings) and on the 2nd brazing step of the second prototype module (the incision solution was tested just at one side in order to see the differences).

We developed a more compact and effective constraint fixation made by TZM springs.

This allows for an easier positioning while increasing the contact pressure at high temperature. A more distributed number of constraints are now available.

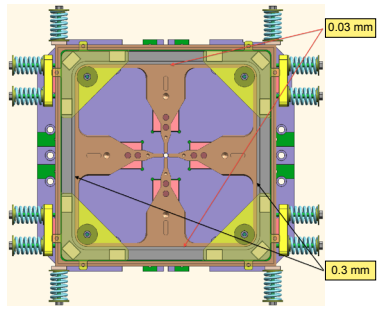

Figure 12: New design of the coupling between copper and sealing st. steel ring avoiding contact with the "Ts"

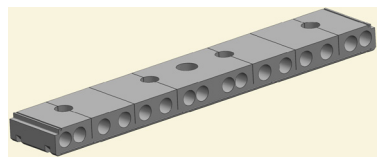

Figure 13: New design of the end side flanges with the incision to reduce the stiffness

WHAT NEXT

The single brazing method will be applied for the first time on the module 15 (October '12).

We assigned a new contract for the production of SuperModule I and the production will start soon.

The production of SuperModule II will be done within INFN. The machining of components is already started.

AKNOWLEDGEMENT

The authors wish to thank the CINEL Scientific Instruments S.r.l. for the active sustaining during R&D phase

RFQ WITH IMPROVRED ENERGY GAIN

A.S. Plastun, NRNU (MEPhI), Moscow, Russia
A.A. Kolomiets, ITEP, Moscow, Russia

Abstract

RFQ structure is practically only one choice for using in front ends of ion linacs for acceleration up to energy about 3 MeV. This limit is due to its relatively low acceleration efficiency. However it isn't intrinsic feature of RFQ principle. It is defined only by vane geometry of conventional RFQ structure with sinusoidal modulation of vanes. The paper presents results of analysis RFQ with modified vane geometries that allow to reach acceleration efficiency compared with IH DTL structures. RFQ with modified vanes was used for design second section of heavy ion injector of TWAC for acceleration of ions with Z/A=0.33 up to 5 MeV/u.

INTRODUCTION

An RFQ output energy doesn't usually exceed several MeV. Using conventional RFQ structure for acceleration of particles for higher energies is impractical because RFQ energy gain decreases rapidly with energy at constant modulation.

Many DTL structures were proposed for beam acceleration following RFQ that use magnetic or radio frequency focusing. The structures are well studied, they can provide good accelerating efficiency and are realized in a number of linacs. In the framework of heavy ion injector development for TWAC facility [1] several designs of second section based on these structures have been studied. In addition it was considered option that uses conventional RFQ with relatively minor modification of RFQ electrodes and resonant structure.

81 MHz RFQ – front end of TWAC injector has been recently successfully commissioned [2]. It is designed to accelerate beam from laser ion source with Z/A = 0.33 up to energy 1.57 MeV/u.

This paper presents result of study of TWAC injector second section design based on modified RFQ. The main goal of the modification was to provide maximum energy gain at focusing sufficient for acceleration beam with current 30 mA up to 5 MeV/u.

ENERGY GAIN IN RFQ

Vanes with Sinusoidal Modulation

The energy gain of a particle in RFQ is

$$\Delta W = e\frac{Z}{A}UT\cos\varphi_S, \qquad (1)$$

e - electron charge, Z - charge number of the particle, A - mass number of the particle, U - voltage between adjacent vanes, T - accelerating efficiency, φ_s - phase of RF field, when synchronous particle is in a maximum of accelerating field.

Voltage U is usually chosen taking into account many different considerations. However it has to be as high as possible to increase energy gain. Its maximum value in this case is fully defined by acceptable surface electric field $E_{s\ lim}$. Most accurately voltage can be found by numerical simulation for real vane geometry and expressed as

$$U = U_{sim}\frac{E_{s\,\mathrm{lim}}}{E_{s\,sim}}, \qquad (2)$$

Here U_{sim} is voltage between vanes in computer model and $E_{s\ sim}$ is maximum field at vane surface obtained from simulation result.

Figure 1 shows results of field simulation in RFQ cell with code OPERA 3D. Simulated cell length $L_c = \beta\lambda/2$ corresponds particle energy at TWAC RFQ output. Curve 1 presents maximum field at vane surface calculated for sinusoidal modulation in $1 \le m \le 5$ range. Aperture for all modulations was constant a = 8 mm, that is average distance from axis to vane was changed as $R_0 = a(m+1)/2$. Simulation results show that for surface field limit $E_{s\ lim}$ = 250 kV/cm (about 2 Kilpatrick units for frequency f = 81 MHz) maximum voltage can reach according formula (2) $U \cong 500$ kV.

Accelerating efficiency T was calculated from simulated distribution of longitudinal field component E_z on axis. T factor for cell with sinusoidal modulation of vanes is limited by value $T \cong 0.7$. It means that the maximum effective accelerating gain per cell with studied parameters doesn't exceed $UT \cong 350$ kV.

Curve 1 shows that there is no sense to increase modulation factor more than $m = 4 \div 5$ because maximum field $E_{s\ sim}$ reduces very slowly for higher m while focusing efficiency rapidly decreases. Figure 2 shows transverse phase advance calculated with the following expression [3]:

$$\sigma^2 = \frac{2}{\pi^2}K^4 + \frac{\pi eUT}{W_{kin}}\sin\varphi,$$

$$K^2 = \frac{Z}{A}\frac{e\overline{G}}{4W_0}\lambda^2.$$

Here $\overline{G}$ is mean value of simulated transverse field gradient along RFQ cell, W_0 - rest mass of proton, λ - wavelength of RF field. Estimation shows that transverse motion is very close to stability border at $m \cong 4$. It defines limiting capability of conventional RFQ with sinusoidal modulation for higher energy gain acceleration.

It is possible to improve accelerating efficiency using trapezoidal modulation proposed in [4]. Cell with this modulation type is shown in Figure 3. The trapezoidal

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

modulation allows 15 ÷ 20% higher accelerating efficiency T due to better of longitudinal field component distribution along axis. It is important that this distribution is kept constant along the RFQ so T rises with particle energy at constant voltage.

However maximum surface field for this modulation type in general is close to the value for sinusoidal modulation.

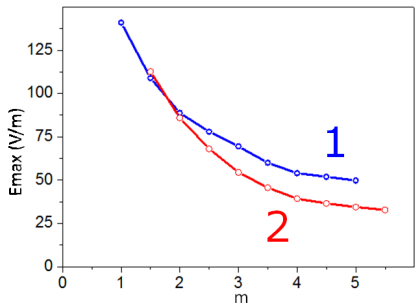

Figure 1: Calculated maximum surface electric field. Curve 1 corresponds to conventional RFQ with sinusoidal modulation, curve 2 – to RFQ with modified vanes.

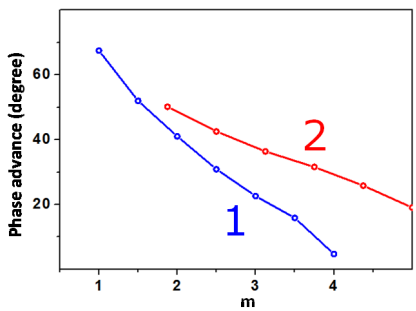

Figure 2: Calculated transverse phase advance. Curve 1 corresponds to RFQ with sinusoidal modulation, curve 2 – to RFQ with improved vanes.

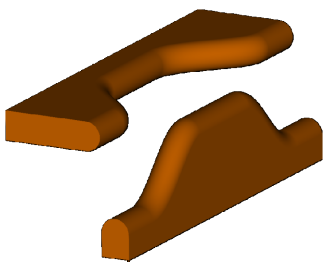

Figure 3: Adjacent vanes with trapezoidal modulation.

Improved Vanes

Whereas trapezoidal modulation considerably improves accelerating efficiency the higher voltage U is required for further energy gain increase. It can be provided if vane geometry allows reducing maximum surface field. Maximum field is reached at vane cross section with exact quadrupole symmetry for RFQ cells with conventional modulation and with parameters corresponding TWAC RFQ output. It was proposed to change vane profile at this cross section to increase distance between adjacent vanes. This can be achieved by transformation of the trapezoidal profile to almost "rectangular" one. Distribution of longitudinal component of field along axis is formed for this profile by "gap" between "rectangles" of adjacent vanes. Vane tips near axis are flat and have about the same curvature radius R_e as the vanes with conventional modulation.

Removing part of vane near axis decreases focusing efficiency. To compensate it more thick flat vanes with curved unmodulated pole are placed at distance from axis $R_q >> a$. Curvature radius of this part of vane is $R_{eq} \cong R_q$. 3D view of improved vanes is shown in Figure 4.

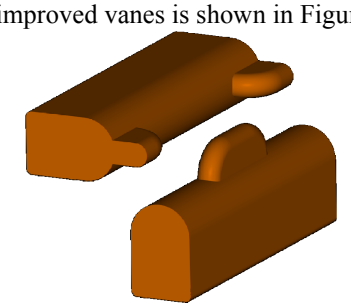

Figure 4: Adjacent vanes with improved profile.

Basic parameters of the improved geometry are shown more detailed in Figure 5. The parameters were optimized to minimize surface field, equalize it on vane surface and to increase focusing efficiency in comparison with conventional vanes with equal modulation.

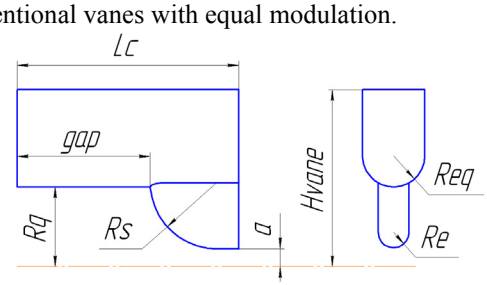

Figure 5: Basic dimensions of improved vanes.

Table 1 allows comparing field simulation results for sinusoidal and improved profiles. The same values for aperture a = 8 mm, cell length L_c = 100 mm, vane tip curvature radius R_e = 5.6 mm and modulation factor m = 4 were used for both cases of simulation.

Table 1: Field Simulation Results

Parameter	Sinus.	Impr.
Limit surface electric field E_{lim}, kV/cm	250	250
Maximum surface electric field $E_{s.max}$ @ 1V intervane voltage, V/cm	0.54	0.39
Voltage U, kV	463	636
Acceleration rate UT, kV	324	513
Transverse phase advance μ, deg	5	26

BEAM DYNAMICS SIMULATION

Improved vane profile was used to design RFQ with parameters corresponds the second section of TWAC injector for detailed computer simulation of beam

dynamics. RFQ was designed using 3D field maps calculated by OPERA code. Basic parameters of the RFQ are shown in Table 2.

Table 2: Basic Parameters of Improved RFQ

Operating frequency, MHz	81.36
Z/A of ions	0.33
Input ion energy, MeV/u	1.57
Output energy, MeV/u	5.0
Transverse emittance, norm, π mm·mrad	1.5
Maximum surface field, kV/cm	250.
Voltage, kV	685.
Electrode modulation	4.5
Cell number	20
Total length, m	3.0

Code TRANSIT written in ITEP has been used for the beam dynamics simulation. Longitudinal and transverse field components along section calculated by OPERA 3D code that was used in TRANSIT are shown in Figure 6.

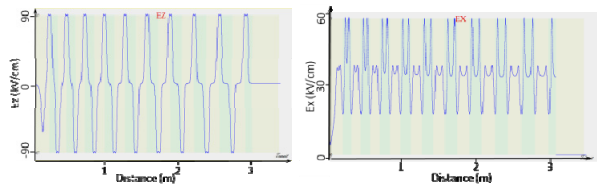

Figure 6: Longitudinal field component on axis (a) and transverse field component at r = 5 mm (b).

Figure 7 shows calculated transverse envelopes that confirm stable transverse particle motion along the section. Simulated envelope size shows that RFQ with improved vanes provides required transverse acceptance.

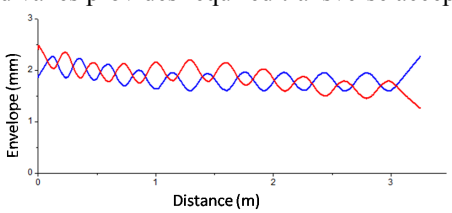

Figure 7: Transverse envelopes calculated with TRANSIT code.

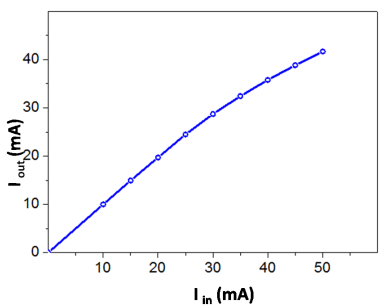

Figure 8: Calculated beam current at RFQ output in dependence on input one.

Simulation results in Figure 8 show that RFQ with improved vanes provides close to 100% beam transmission in required beam current range $0 \le I \le 30$ mA. It is important to say that in spite of complicated vane profile field has good linearity in working area that is evidenced by absence of growth of transverse and longitudinal emittances.

Table 3: Beam Transmission Parameters

Transmission, % (I = 0 / 30 mA)	100 / 98.6
Transverse rms envelope, mm (I = 0 / 30 mA)	2.0 / 3.1
Transverse emittance growth (I = 0 / 30 mA)	1.0 / 1.2
Longitudinal emittance growth (I = 0 / 30 mA)	1.0 / 1.1

CONCLUSION

RFQ structure with improved vane profile is proposed for acceleration following conventional RFQ. Computer simulation showed that new vane profile allows ≈ 30% lower maximum surface field at modulation factor m = 3÷5 comparing with conventional vanes. Accelerating efficiency of new profile is the same as provided by vanes with trapezoidal modulation.

3 m length RFQ has been designed for injector of TWAC facility. It provides about than 3.5 MeV energy gain. Computer simulations confirmed that the structure is capable to accelerate ion beam with current I = 30 mA with transmission about 100% and with only small transverse and longitudinal emittances growth.

ACKNOWLEDGMENT

Authors thank Tatyana Tretiakova for work on adjustment of her codes for RFQ with new vane profile design and beam dynamics simulation.

TUNING STUDIES ON 4-ROD RFQs *

J. Schmidt, B. Koubek, A. Schempp, B. Klump, IAP, Univ. Frankfurt, Germany

Abstract

A NI LabVIEW based Tuning Software has been developed to structure the tuning process of 4-rod Radio Frequency Quadrupole s (RFQs). Its results are compared to measurement data of 4-rod RFQs in different frequency ranges. For the optimization of RFQ design parameters, a certain voltage distribution along the electrodes of an RFQ is assumed. Therefore an accurate tuning of the voltage distribution is very important for the beam dynamic properties of an RFQ. A variation can lead to particle losses and reduced beam quality especially at higher frequencies. Our electrode design usually implies a constant longitudinal voltage distribution. For its adjustment tuning plates are used between the stems of the 4-rod-RFQ. These predictions are based, in contrast to other simulations, on measurements to define the characteristics of the RFQ as it was build - not depending on assumptions of the design. This will lead to a totally new structured process of tuning 4-rod-RFQs in a broad range of frequencies by using the predictions of a software. The results of these studies are presented in this paper.

RESONANT CIRCUITS

A simplified model of the 4-rod RFQ resonator is a chain of LC-oscillators where each RF cell has its own resonance frequency. In these RF cells the stems represent the inductance, while the electrodes form the capacitive part of the circuit. A more detailed model is described in [1].

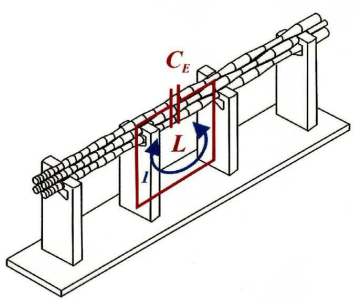

Figure 1: LC Resonator as Equivalent Circuit of a 4-Rod RFQ.

To tune this system, the resonance of each RF cell has to be tuned with tuning plates. They short cut the current path between the stems, to change the inductance of the RF cell. The longitudinal voltage distribution, the so called flatness, is a fundamental parameter in the particle dynamic design of an RFQ. Usually a constant longitudinal voltage along the electrodes is the basis of our design, but other distributions are possible as well [2].

Following the particle dynamics the longitudinal voltage distribution has to be arranged. It is measured using the capacitve perturbation method. A perturbation capacitor sits on a pair of electrodes of one RF cell to cause a frequency shift due to Thomsons law. The resulting frequency shift of the cell is proportional to its voltage (see Eq. 1).

$$U \propto \Delta f_0 = \frac{1}{\sqrt{LC}} - \frac{1}{\sqrt{L(C+\Delta C)}} \qquad (1)$$

THE VOLTAGE TUNING PROCESS

The process of adjusting the flatness is an iterative process of shifting the tuning plates and try to find a set of heights, which results in the desired distribution and total resonance frequency. This process can take some time, especially working on long RFQ structures with a lot of RF cells [3].

Due to several reasons like the changing modulation or differences in the manufacturing, the RFQ has deviations in its characteristics along the electrodes profile [4]. This leads to a different impact of the tuning plates depending on their position in the RFQ.

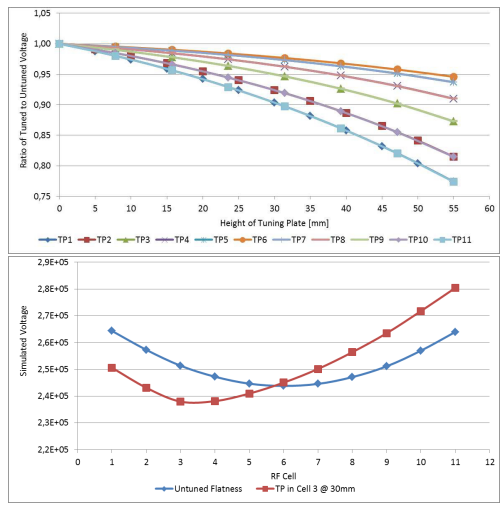

Figure 2: The voltage in z=k from raising tuning plates in all cells (upper graph) and the longitudinal change with a tuning plate in cell k=3 (lower graph).

Raising a tuning plate in cell k $\in [1, n]$ decreases the voltage in cell k and its neighboring cells k$\pm$i with i$<$i$_0$, while the voltage raises in cells k$\pm$i with i$\geq$i$_0$. This behavior is shown in Fig. 2

* Work supported by BMBF

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

In order to quantify this behavior effect functions EC were introduced [5], describing the shift in flatness caused by a change in the position of the tuning plate of each RF cell k. They correspond to the ratio between the tuned and the untuned flatness.

$$U_t(z,h) = U_u(z) + EC(z,h) \times U_U(z) \qquad (2)$$

The single tuning plates all have an individual effect on the RFQ EC_k(z,h). Their superposition describes the total effect of a tuning plate setting with different heights h_k.

$$U_t(z,h) = U_u(z) \times \prod_{k=1}^{n} [EC_k(z,h_k) + 1] \qquad (3)$$

To find the ration $EC_k(z,h_k)$ measurements and simulations of the flatness depending on the longitudinal position z in the RFQ and the heights of the tuning plates have been performed with the aim to find a possibility to split EC(z,h) into two separated functions, one for each k depending just on the z-position and one on the height being valid for all k.

$$EC_k(z,h_k) = EC(h_k) \cdot EC_k(z) \qquad (4)$$

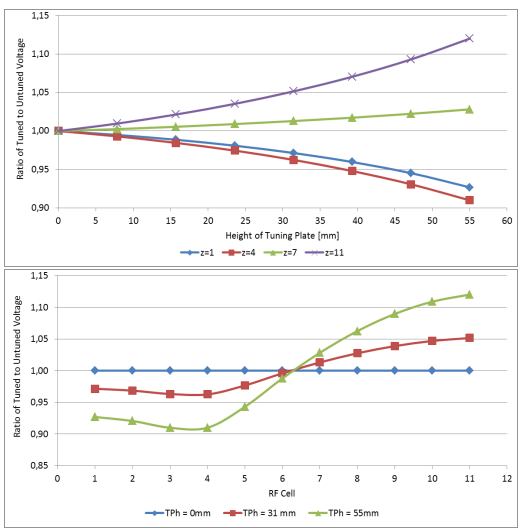

Figure 3: The ratio of the tuned and untuned flatness for a tuning plate in cell k=3 with the height at different z-positions (upper graph) and the corresponding longitudinal change at different heights (lower graph).

STATUS OF THE TUNING PROGRAM

As presented at PAC11 in New York [6] a software has been developed to predict the resulting flatness of an arbitrary tuning plate distribution, which is working well for 4-rod RFQs at 100 MHz. In this version of the program a linear approximation EC(h)=h has been used for the influence of the tuning plates height. Its results in comparison with measurements are presented in Fig. 4

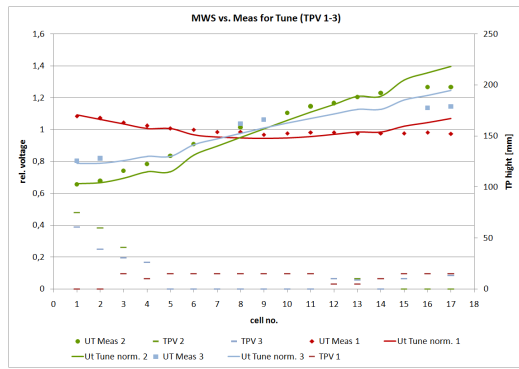

Figure 4: Results of the RFQ tuning program in comparison with three sets of measurements on a 17-cell 100 MHz RFQ [6].

This approximation turns out to be too rough for RFQs with higher frequencies around 200 MHz. Looking at Fig. 3 a square tendency with a - depending on the longitudinal position of measurement z - negative or positive gradient is visible.
To represent this behavior a higher order polynomial fit of the measurement points with different heights was implemented into the software. A comparison of the measured flatness and the simulated predictions with the corresponding tuning plate distribution with a linear and polynomial assumption is shown in Fig. 5.

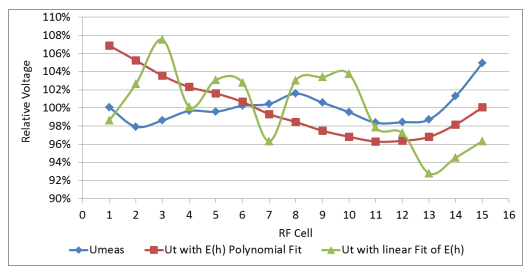

Figure 5: Comparison of the flatness prediction from the RFQ tuning program with linear and polynomial fit in comparison with its corresponding measurement on a 15-cell 200 MHz RFQ.

The measured distribution shows a x^6-like behavior, which is not included in the simulated ones. Even though the fitted version corresponds to the measurement much better, than the linear approximation, it is unfortunately not in a range to work with.

CONCLUSION AND OUTLOOK

Going from 100 to 200 MHz 4-rod RFQs the dependency of the voltage shift to the height of the tuning plate can not be approximated with a linear function anymore. A polynomial fit has been implemented to the simulation software. The results are much better, but are not precise enough to replace the manual iterative process. Other fitting methods have to be tested. Eventually the splitting of

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the longitudinal and height dependency can not be separated as supposed up to now, because their coupling becomes much stronger in high frequency systems. Fig. 6 shows the change in the data sets due to the scaling process for a raising tuning plate in the middle of a 15-cell RFQ. The symmetric increase and decrease of the voltage around the cell of the tuning plate is pictured in the upper graph. This difference disappears with the scaling to h^2 completely. In the scaled case in the lower graph all curves overlap each other and values of the voltage ratios compared to points at higher tuning plate positions gets much smaller.

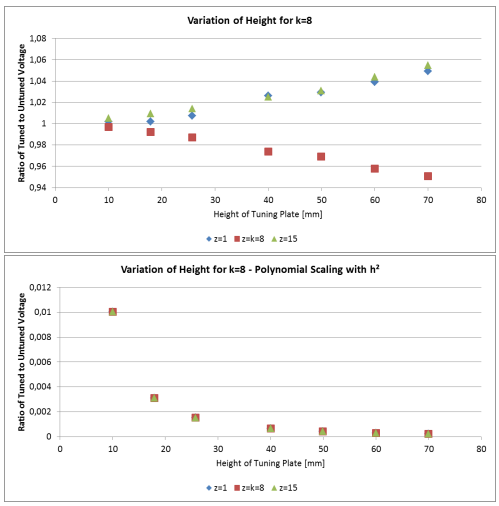

Figure 6: The ratio of the tuned and untuned flatness for a tuning plate in cell k=8 - the middle of the RFQ - with the height at different z-positions before the scaling (upper graph) and the corresponding data after applying a scaling with h^2 (lower graph).

Outlook

The vanishing of the differences in the height dependency at varying z-positions will be analyzed further. It may be an indicator of a strong coupling between the height and z-position dependency. If it is not possible to split them, there need to be another method to make the theory of the effect functions useable.

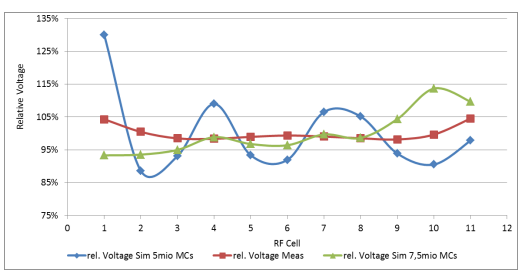

Figure 7: Results of flatness simulations of a 11-cell 200 MHz RFQ with 5 mio. and 7.5 mio. mesh cells in comparison with the corresponding measurement.

In parallel to the development of the simulation software for 4-rod RFQs the simulation of these systems using CST Microwave Studio ® is about to improve, too. As shown in the graph in Fig.7 there is a strong dependency of the flatness simulation results to the meshing of the RFQ.
Both simulation approaches will be followed further, to find a way of predicting the flatness of 4-rod RFQs. At the moment the iterative process is still needed to find the appropriate set up of the tuning plates.

STUDIES OF PARASITIC CAVITY MODES FOR PROPOSED ESS LINAC LATTICES

R. Ainsworth*, Royal Holloway University of London, UK
S. Molloy, European Spallation Source AB, Lund, Sweden

Abstract

The European Spallation Source (ESS) planned for construction in Lund, Sweden, will be the worlds most intense source of pulsed neutrons. The neutrons will be generated by the collision of a 2.5 GeV proton beam with a heavy-metal target. The superconducting section of the proton linac is split into three different types of cavities, and a question for the lattice designers is at which points in the beamline these splits should occur. This note studies various proposed designs for the ESS lattice from the point of view of the effect on the beam dynamics of the parasitic cavity modes lying close in frequency to the fundamental accelerating mode. Each linac design is characterised by the initial kinetic energy of the beam, as well as by the velocity of the beam at each of the points at which the cavity style changes. The scale of the phase-space disruption of the proton pulse is discussed, and some general conclusions for lattice designers are stated.

INTRODUCTION

The European Spallation Source is a facilty, currently in its design phase [1], for the generation of intense pulses of neutrons for studies in applied science. The neutrons are generated through the spallation process when a 5 MW (average) proton pulse is made to impact a heavy metal target.

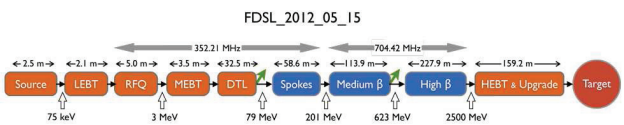

Figure 1: Block diagram of the ESS linac.

	Value	Unit
Final kinetic energy	2.5	GeV
Macropulse current	50	mA
Macropulse repetition rate	14	Hz
Bunch frequency	352.21	MHz

Table 1: Main ESS linac parameters.

A cartoon of the ESS linac is shown in Figure 1, and the main parameters of the proton beam are given in Table 1.

This note concerns the beam dynamics within the superconducting sections of the machine:

Spokes: Two–spoke cavities operating at 352.21 MHz. This section accelerates the beam from the exit of the DTL at 79 MeV to 201 MeV.

Medium β: Five–cell elliptical cavities operating at 704.42 MHz. The geometrical beta of this section is still under discussion, but is likely to be set at a value close to, $\beta_g = 0.65$. In this section, the beam is accelerated from 201 MeV to 623 MeV.

High β: Five–cell elliptical cavities operating at 704.42 MHz. As with the previous section, the geometrical beta is still under discussion, but the likely value is close to, $\beta_g = 0.92$. This section accelerates the beam to its final energy of 2.5 GeV

Given the high intensity of the beam, one major concern is that strong resonances will be excited in the superconducting cavities that will then act to disrupt subsequent bunches. In particular parasitic modes that lie close in frequency to that of the accelerating mode. They are of concern due to there small frequency spread and high R/Q relative to the accelerating mode. If they are found to be a problem, the geometric beta of the cavity may need to be altered or the velocity partitioning between the cavity families may need to be shifted.

LINACS

For the studies into Same Order Modes (SOMs), that is, modes that are part of the same passband as the fundamental accelerating mode, four linacs are investigated as shown in Table 2 where cavities per family denotes the number of cavities in the spoke, medium β and high β sections.

Linacs	Cavities per family	Energy In [MeV]
HS_2011_11_23	36-64-12	50
FD_SL_2012_04_13	32-60-120	79
FD_SSCL_2012_04_16	32-52-128	80
FD_SL_2012_05_15	28- 60-120	79

Table 2: Linacs investigated for SOM simulations.

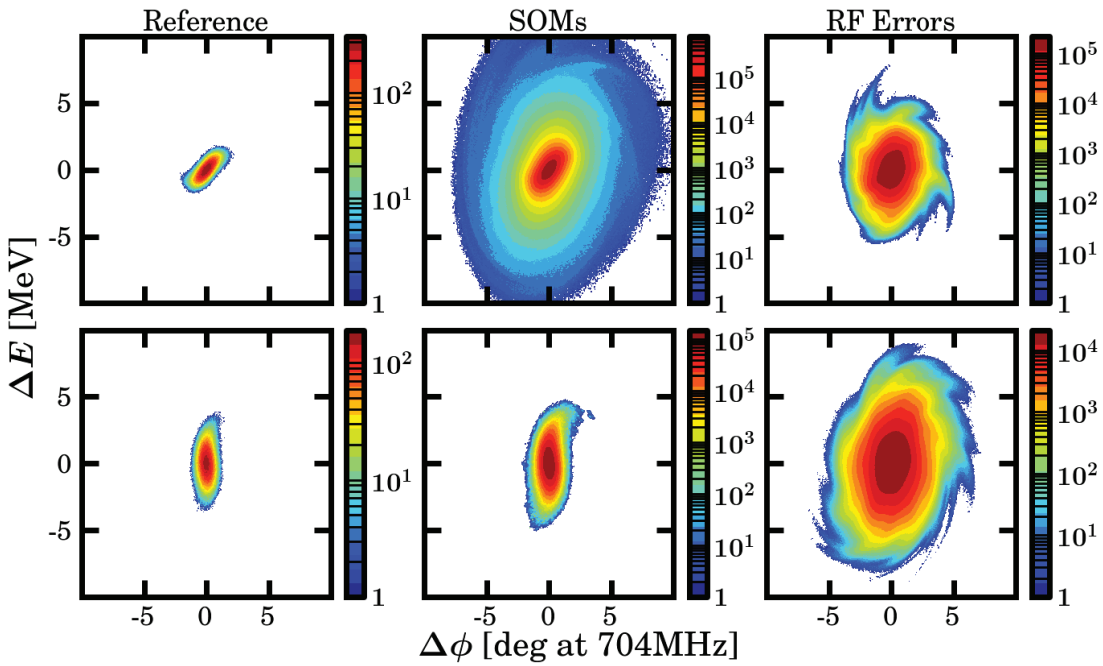

Figure 3: The Pulse phase space distribution at the end of the linac due to different effects.

SIMULATIONS

To explore the effect of these modes, a pulse train of one million point-like bunches was tracked through the superconducting section of the linac. Each bunch adds to the induced fields, these act on subsequent bunches through a kick-drift-kick model [2], and the resulting bunch energy and time errors are calculated.

For each cavity family, the SOM with the highest R/Q is used for simulations. For the spokes, the second mode is used and for the ellipticals, the $4\pi/5$ mode is used. The R/Q that will be seen in each cavity for the whole HS_2011_11_23 linac is shown in Figure 2. Of particular concern are the regions at the beginning of the spoke and medium beta sections where the R/Q of the SOMs are larger than that of the accelerating mode.

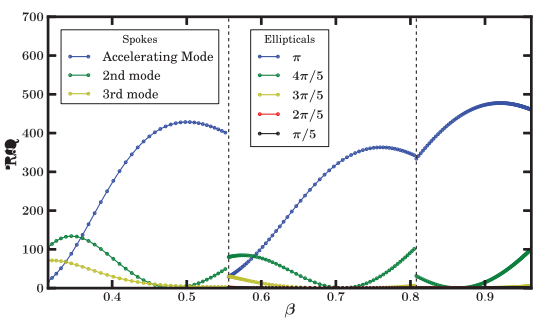

Figure 2: The R/Q for each cavity as a function of particles velocity.

The simulation is performed 1000 times using a different seed for the random number generator to set the frequencies of the SOMs. All other parameters are left constant. In addition, a charge scatter of 1% was also used [3].

Jitter from the RF system will also lead to energy and phase errors. Uniformly distributed errors of $1\%, 1^\circ$ are used in each linac with the exception of the HS_2011_11_23 linac which uses errors of $0.5\%, 0.5^\circ$. Each linac is simulated 1000 times with a different set of uniformly distributed random errors each time. The growth due to RF errors will be used as the acceptable limit in order to gauge the effect of the SOMs.

FREQUENCY SPREAD

The frequency spread of the SOMs will have a large effect on their influence. A smaller frequency spread will result in a larger coherence resulting in a larger influence on the beam. Therefore, it is important to use an reasonable value. In the late 1980's, Ron Sundelin performed a series of studies measuring the distribution of resonant frequencies of SCRF cavities [4]. The frequency spread based on empirical results is given by

$$\sigma = 1.09 \times 10^{-3} \cdot |f_n - f_0|. \quad (1)$$

This means that for the elliptical cavities where the $4\pi/5$ mode is only ~ 1 MHz away from the accelerating mode, the frequency spread will be ~ 1 kHz.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

GROWTH

To quantify the growth, the area, ϵ, of the phase space created all the bunches are compared where the area is given by

$$\epsilon = \pi\sqrt{\langle\Delta E^2\rangle\langle\Delta\phi^2\rangle - \langle\Delta E\Delta\phi\rangle^2}, \qquad (2)$$

where ΔE and $\Delta\phi$ are the energy and phase error of the bunch with respect to the synchronous bunch. The growth ϵ_{RF}/ϵ is used to determine the effects of the RF and set the tolerable growth due to SOMs.

RESULTS

Figure 3 shows the effect of these modes on the pulse phase space of two linacs with different velocity partitioning over the three cavity families. The first column shows the phase space distribution with no external effects such as SOMs or RF errors acting providing a reference distribution to compare to. The middle column shows the case where a SOM is present in each cavity. The last column shows the case when RF errors are applied to the linac in form of amplitude and phase errors. The growth due RF errors is used as an acceptable limit It can be seen that the linac of the top row, which represents an earlier ESS layout, is susceptible to these modes. The bottom row, corresponding to the May 2012 linac layout, shows significantly better performance.

Table 3 shows the growth in due to SOMs and RF errors for each of the linacs simulated. It can be seen that all linacs due except the HS_2011_11_23 linac show negligible growth due to SOMs. It is thought that increasing the Energy input to the spoke section from 50 MeV to 79 MeV was the main reason the effect of SOMs was less in the other linacs. This is because at 79 MeV, the R/Q of the SOMs no longer crossed the accelerating mode in the spoke section.

SOMs	Average Growth	Max Growth
HS_2011_11_23	3.1	56.6
FD_SL_2012_04_13	1.02	1.2
FD_SSCL_2012_04_16	1.01	1.5
FD_SL_2012_05_15	1.02	1.47
RF Errors	Average Growth	Growth
HS_2011_11_23	3.3	13
FD_SL_2012_04_13	4.24	16.2
FD_SSCL_2012_04_16	3.9	14.5
FD_SL_2012_05_15	3.7	16.6

Table 3: Growth in each linac due to SOMs and RF errors.

CURRENT AND DAMPING SCAN

The final investigation was to vary the current, Ib and Q_{ex} for the simulations involving the May Baseline linac FD_SL_2012_05_15. The current was varied from the nominal current of 50 mA to a relatively high current of 150 mA in order to determine a threshold if there is one and how close the nominal current is to the threshold. The Q_{ex} is also varied from 10^4 to 10^9, previous simulations used a relatively high value of 10^8 as the actual value will not be known however it is expected to be similar to that of the fundamental mode which has a $Q_{ex} \sim 10^6$. The results are shown in Figure 4 where the dashed line represents the growth due to RF errors. At the nominal current, negligible growth is observed and it is not until 90 mA where the growth starts to exceed that of RF errors. Losses are also seen at this current for $Q_{ex} > 10^7$.

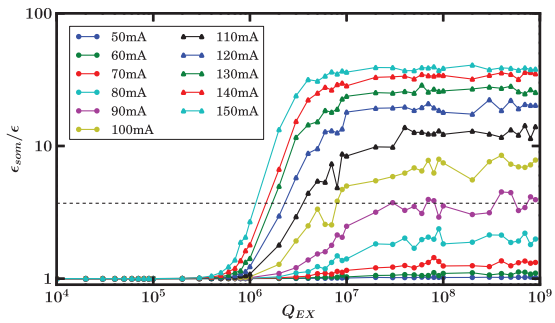

Figure 4: The average longitudinal phase space increase for 100 linacs at varying currents and Qex of the SOMs.

SUMMARY

The influence of parasitic modes in the ESS linac have been investigated with emphasis on modes that lie in the same passband as the fundamental mode. It has been shown that although it is possible to design a linac susceptible to modes in the fundamental passband, the current baseline is not affected at the nominal current and should operate up to currents on 100 mA if upgrades are desired in the future. Therefore, no change is needed to the velocity partitioning of the linac nor the geometric beta of the cavities.

ACKNOWLEDGEMENTS

The authors would like to thank Marcel Schuh for his help in benchmarking the code used in the above simulations.

Abstract

In order to improve the electro-magnetic performance of the quarter wave resonator, a new-shaped cavity with an elliptical cylinder outer conductor has been proposed [1]. This novel cavity design can provide much lower peak surface magnetic field and much higher R_a/Q_0 and G. The multipacting simulation has been done for this new QWR cavity using ACE3P/TRACK3P code, in this paper the simulation results will be presented and analyzed.

INTRODUCTION

In the Heavy Ion Accelerating Facility (HIAF) of IMP, superconducting quarter wave resonators (QWRs) with frequency of 81.25 MHz and β of 0.041, 0.085 will be applied to accelerate the ion beams from 0.3 MeV/u to 17 MeV/u. Because of the extremely high design voltage for the β =0.085 QWR cavity, an elliptical cylinder outer conductor shape has been proposed for it (see Fig. 1).

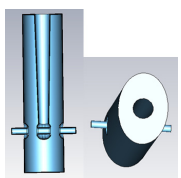

Figure 1: The elliptical cylinder outer conductor QWR model for multipacting simulation.

MULTIPACTING SIMULATION

Parallel codes Omega3P and Track3P which are developed at SLAC have been used, to obtain the field maps and then to analyse the multipacting barriers [2, 3]. When doing the multipacting simulation, one half of the QWR cavity was used taking advantage of the symmetry. Seed particles were initiated on all the RF surfaces. The accelerating gradient was scanned up to 6 MV/m firstly to locate the multipacting band, and then much finer scan interval was used in order to study the multipacting band in detail. 2 eV was used as the initial energy for primary and secondary emissions to study its effect on multipacting and typical niobium secondary electron yield *(SEY) was applied to estimate the multipacting strength* (see Fig. 2). At each field level, 50 RF cycles were used as total running time to obtain resonant trajectories.

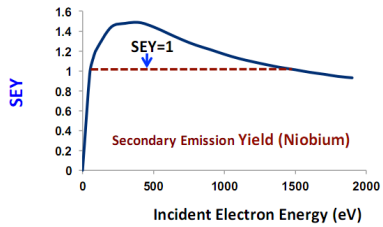

Figure 2: Secondary electron yield (SEY) for Niobium on the dependence of impact energy. The impact energy range relevant to the peak SEY is 150~700 eV. Resonant electrons with impact energies in this range are most dangerous to lead to hard multipacting.

MULTIPACTING SIMULATION RESULTS

Multipacting band at low field level

The distribution of resonant particles identified by Track3P presented the multipacting bands occurred at low field levels, Figure 3, 4 show the expanded plot around this multipacting band and impact positions.

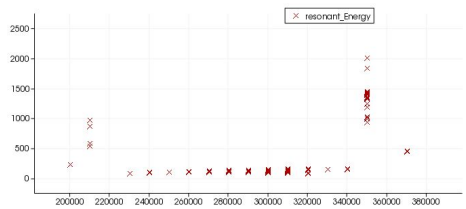

Figure 3: Impact energy vs. accelerating gradient at low field level.

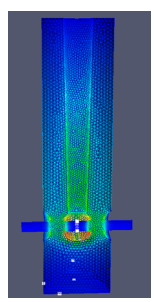

Figure 4: Impact positions at all field levels.

There are two multipacting bands, one at field levels of 0.2 ~0.34 MV/m with impact energies 80~160 eV in the beampipe region (see Fig. 5, 6); the other at around the accelerating gradient of 0.35 MV/m with impact energies 700~2000 eV in the bottom part of the cavity. In consideration of the peak SEY energy for Nb (see Fig. 2), such two bands are expected to be a soft barrier.

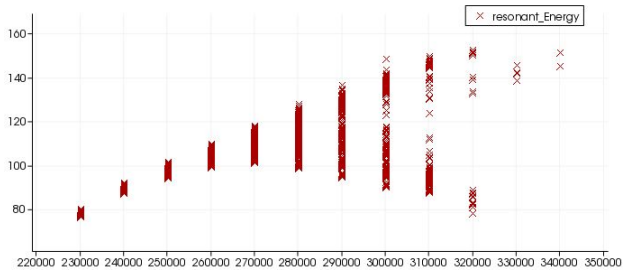

Figure 5: Impact energy vs. accelerating gradient of 0.2~0.34 MV/m.

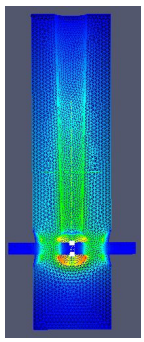

Figure 6: The beampipe impact positions for the accelerating gradient of 0.2~0.34 MV/m.

Rounding effects on Multipacting

Since it is a common method of reducing the B_{peak} near the short plate location by rounding the joints between the short plate and the inner and outer conductors, here let's see what this procedure will bring to the multipacting activities in the cavity. In order to check how the rounding will affect the multipacting status, the simulation will be done for the three situations-(a) rounding only the inner conductor joint, (b) rounding only the outer conductor joint (see Fig. 7) and (c) rounding both joints, separately.

As for the first two cases, the multipacting occurrences are very similar to that of the flat short plate QWR, both in the impact energy span (see Fig. 8, 9) and in the impact positions (see Fig. 10, 11).

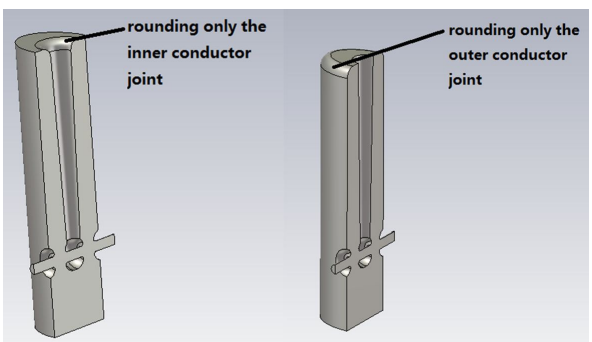

Figure 7: Rounding only one joint between the short plate and the inner or the outer conductor.

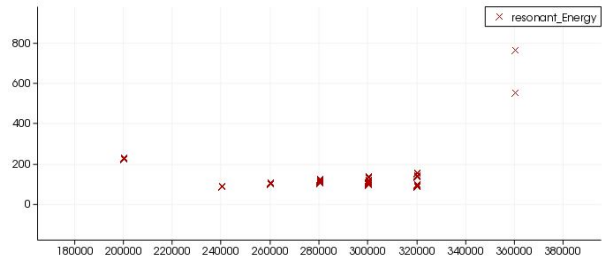

Figure 8: Resonant particle distribution for the case of just rounding the inner conductor joint.

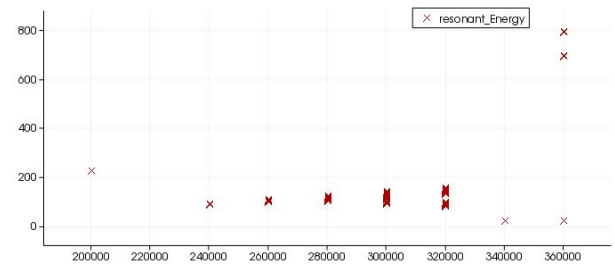

Figure 9: Resonant particle distribution for the case of just rounding the outer conductor joint.

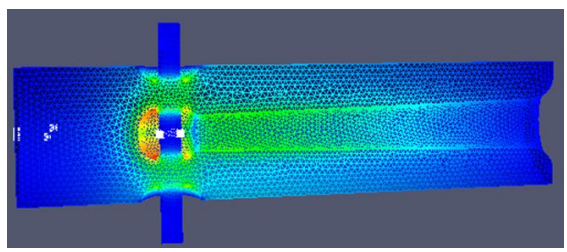

Figure 10: Impact positions for the case of just rounding the inner conductor joint.

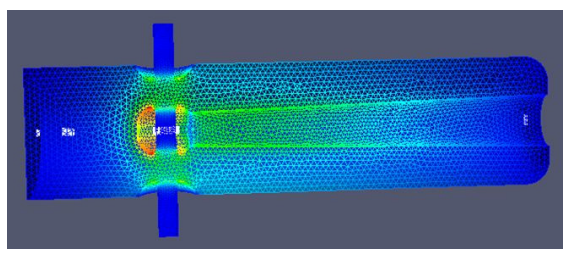

Figure 11: Impact positions for the case of just rounding the outer conductor joint.

However, the multipacting resonances are very critical for the third situation (see Fig. 12). Firstly, the resonant trajectories are expanded to the short plate region and the middle outer conductor (see Fig. 13); and secondly, the impact energies have spread around the peak of the SEY curve (see Fig. 14, 2). As a result, the attempting to lower the Bpeak by rounding both the joints can incur a very serious multipacting in the cavity. The final electro-magnetic design choose not to round the either of the joints speciously since the elliptical cylinder outer conductor cavity shape can offer low enough B_{peak}.

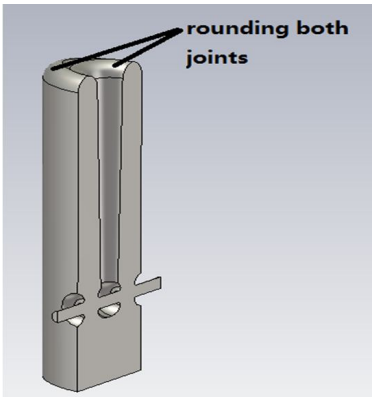

Figure 12: Rounding both joints between the short plate and the inner and the outer conductor.

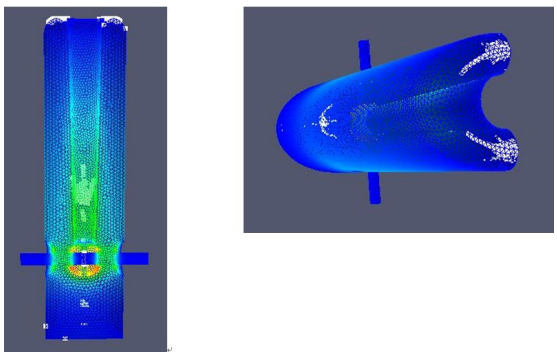

Figure 13: Impact positions for the case of rounding both joints.

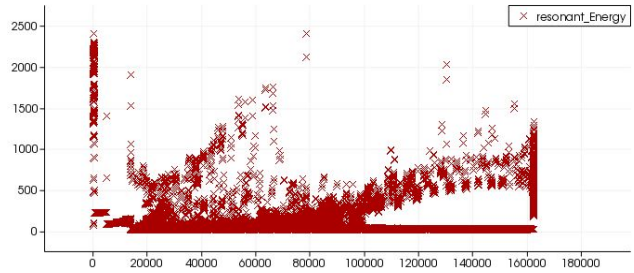

Figure 14: Resonant particle distribution for the case of rounding two joints.

SUMMARY

Track3P was used to analyze the multipacting bands in the elliptical cylinder outer conductor shaped QWR cavity. Only multipacting bands at low field levels were found and the impact energy distributions showed that no hard multipacting bands exist in the cavity. However, rounding the joints between the short plate and both the inner and outer conductors will cause more multipacting bands. The fabrication and test of the prototype cavity is in need in order to see if the experimental data will be in agreement with the simulation results.

STRUCTURAL ANALYSIS OF THE NEW-SHAPED QWR FOR HIAF IN IMP*

C. Zhang#, S. He, R. Wang, M. Xu, W. Yue, S. Zhang, S. Huang, Y. Yang, Y. Huang
T. Jiang, S. Zhang, Y. He, H. Zhao
Institute of Modern Physics, Lanzhou, Gansu 730000, China

Abstract

Since the QWR cavity is very successful for the operation with frequency of 48 to 160 MHz and beta value of 0.001 to 0.2, a new-shaped QWR is being designed for the low energy superconducting section of HIAF in the Institute of Modern Physics [1]. The cavity will work at 81.25 MHz and beta of 0.085，with an elliptical cylinder outer conductor to better its electro-magnetic performance and keep limited accelerating space. Structural design is an important aspect of the overall cavity implementation, and in order to minimize the frequency shift of the cavity due to the helium bath pressure fluctuations, the Lorentz force and microphonics excitation, stiffening elements have to be applied. In this paper, structural analyses of the new-shaped QWR are presented and stiffening methods are explored.

INTRODUCTION

A stable resonant frequency for the superconducting cavity is desired, because excessive frequency fluctuations require extra power to control the RF amplitude and phase. The reasons that lead to frequency fluctuations include the fluctuations in the liquid helium pressure, Lorentz force detuning, mechanical vibration modes and the etching effect from the cavity surface treatment. Since the operating temperature for the QWR cavities is 4.5 K, the helium pressure stability will be determined by the extent to which the cryogenic plant can be controlled. The stiffening measures were intended primarily to reduce the pressure sensitivity.

MECHANICAL SIMULATION

When the EM design has been completed, the mechanical performance of the cavity should be evaluated. We tried to figure out the cavity's helium pressure sensitivity, severity of Lorentz Force Detuning plus the vibration frequency of mechanical modes, and further, to minimize the instabilities using different stiffening measures. Simulations and optimizations have been done by the 3D Multiphysics solver ANSYS-APDL [2]. In the simulation, niobium sheet of 3 mm thickness was firstly used, with the mechanical properties of Young modulus of 105000 N/mm2, Poisson ratio of 0.38 （see Fig. 1）.

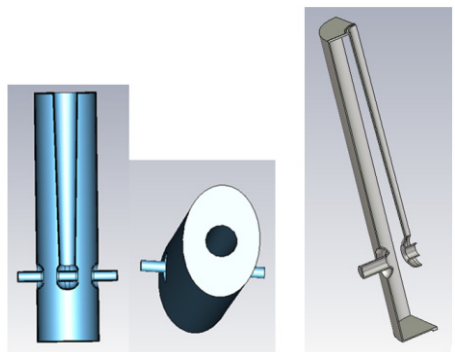

Figure 1: Mechanical model of the elliptical cylinder outer conductor QWR for the structural analysis.

Etching Effects

Surface processing is very important in order to achieve good performance of the superconducting cavity. Either the BCP or the EP is to etch proper thickness of the inner surface, which will change the frequency. According to Slater's perturbation theory, a small deformation in the cavity boundary will lead to a frequency shift.

Using the ANSYS-APDL code, the change in the frequency because of the etching can be calculated. Firstly, you have to get the electro-magnetic field distribution, and then the frequency change caused by the cavity wall's deformation can be obtained. The simulation results show that 1 μm etching thickness will lead to 27Hz increase in the frequency.

Lorentz Force Detuning

The Lorentz force on the cavity surface results from the interaction of the surface electromagnetic fields with the induced surface currents, which will exert pressure to the cavity wall, and the resulting cavity shape deformation ΔV will cause the change in the resonant frequency. The frequency shift caused by Lorentz force is often quantified by K_L which is defined as: $K_L=\Delta f/(E_{acc})^2$.

If the cavity works at the continuous wave mode, then the frequency change will be invariant, it is the static Lorentz force detuning; otherwise, when the cavity works at the pulsed wave mode, the dynamic Lorentz force detuning will be caused. In this paper, only the static situation was considered and 2.5 MV accelerating voltage was to be scaled for the naked cavity whose

beam port is fixed. The simulation result gives the K_L with the value of -0.34 Hz/(MV/m)2 (see Fig. 2).

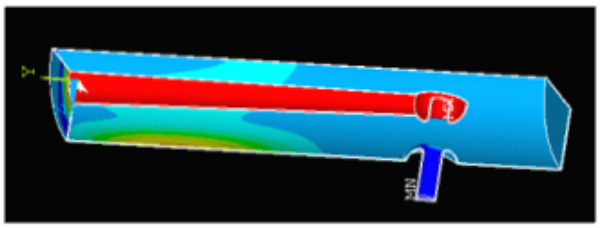

Figure 2: Deformation of the elliptical cylinder outer conductor QWR caused by Lorentz force.

Mechanical Vibration Modes

Mechanical wave in the environment can be transmitted to the cavity by various mediums, and the cavity can resonate mechanically at certain frequencies. Firstly, the naked cavity was simulated for its three lowest modes and results are shown as following, with the vibration frequency of 11 Hz, 13 Hz and 20 Hz, respectively (see Fig. 3).

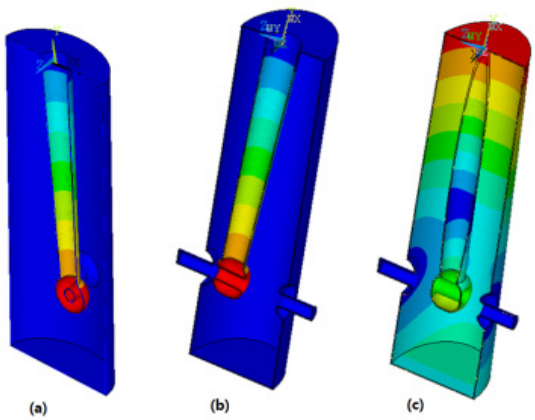

Figure 3: The lowest three vibration modes for the new-shaped naked QWR cavity.

Secondly, stiffening elements were added. A stiffening ring was added on the shorting plate and fixed in the simulation, and in order to reflect more accurately the influence of the tuner, the tuner button was fixed too (see Fig. 4-up). Different radius rings were tested to find out the strengthening effect (see Fig. 4-down). Obviously, the smallest radius ring with 60 mm can increase the mechanical frequency the highest. The vibration mode for the 60 mm stiffened-ring QWR is illustrated in Fig. 5.

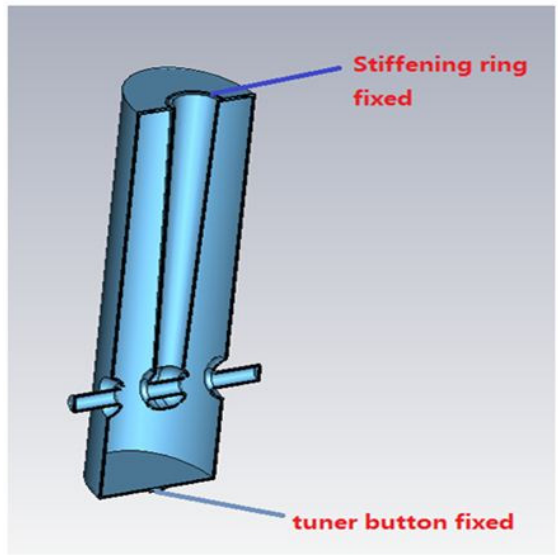

Figure 4: Stiffening ring on the short plate (up); the lowest three vibration modes frequency on the dependence of the radius of stiffening ring (down).

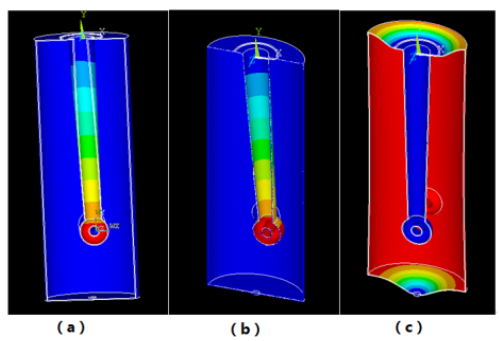

Figure 5: The lowest three vibration modes for stiffened-ring with radius 60mm QWR cavity.

Helium Pressure Detuning

In operation, the superconducting quarter wave resonator cavity with frequency of 81.25 MHz works at 4.3K, at which temperature the liquid helium's pressure fluctuates momently. The optimization goal of the mechanical design should be to minimize the cavity's pressure sensitivity. Mechanical simulations were done to quantify the displacements and the resulting frequency vibration from a constant pressure outside the cavity wall [3].

Firstly, the model we used is the one which have the stiffening ring with radius of 60mm and found that the max displacement appeared on the outer conductor corresponding to longer axis of the elliptical cylinder (see Fig. 6).; then we added two supporting rods on the shorting plate attempting to decrease the deformation caused by squeezing on the cavity wall, but the efficacy is not so good (see Fig. 7); later, thicker material (4mm) was used for the cavity wall and the simulation results showed the max displacement was reduced more than in a factor of 2 (see Fig. 8).

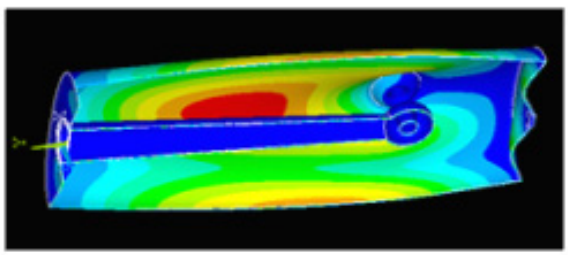

Figure 6: Deformation of ring-stiffened QWR caused by the external pressure, the frequency shift Δf due to the change in ambient pressure ΔP: df/dP~-37 Hz/mbar.

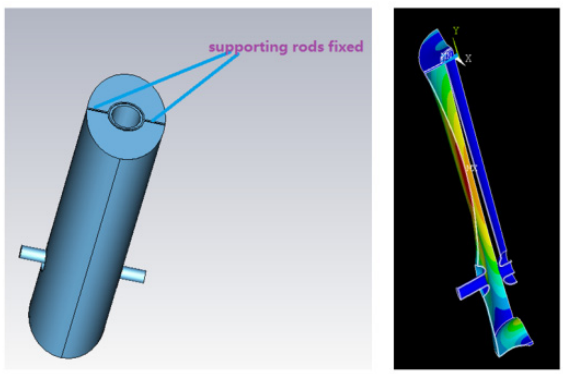

Figure7: Supporting rods on the short plate (left); deformation of ring-and-supporting-rods-stiffened QWR by external pressure: df/dP~-29 Hz/mbar.

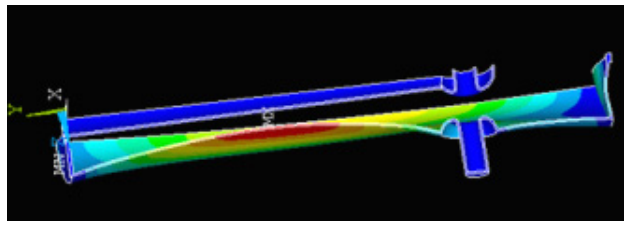

Figure 8: Deformation of ring-and-supporting-rods –stiffened-and-thickened QWR by external pressure: df/dP~-11 Hz/mbar.

CONCLUSIONS

Numerical models have been used to predict the stability of the elliptical cylinder outer conductor quarter wave resonator and relevant stiffening elements have been explored. Major flaws have been encountered in the mechanical models due to the outer conductor's elliptical cylinder shape. Better stiffening measures should be kept searching. In the next stage, the cavity with helium vessel need to be simulated and the fabrication of prototype should be carried out to verify experimentally the mechanical performance.

Abstract

At the Institute for Applied Physics (IAP), Frankfurt University, a superconducting 325 MHz CH-Cavity has been designed and built. This 7-cell cavity has a geometrical β of 0.16 corresponding to a beam energy of 11.4 AMeV. The design gradient is 5 MV/m. Novel features of this resonator are a compact design, low peak fields, easy surface processing and power coupling. Furthermore a new tuning system based on bellow tuners inside the resonator will control the frequency during operation. After successful rf tests in Frankfurt the cavity will be tested with a 10 mA, 11.4 AMeV beam delivered by the GSI UNILAC. In this paper first measurements and corresponding simulations will be presented.

CAVITY LAYOUT

Worldwide there is a growing interest in applications demanding high beam power and quality (e.g. MYRRHA (**M**ulti Purpose H**Y**brid **R**esearch **R**eactor for **H**igh-Tech **A**pplications) [1]). The superconducting CH-cavity is an appropiate structure for these specifications being characterized by a small number of drift spaces between adjacent cavities compared to conventional low-β ion linacs [2]. Applying KONUS beam dynamics, which decreases the transverse rf defocusing and allows the development of long lens free sections, this results in high real estate gradients with moderate electric and magnetic peak fields. In the past a 19-cell, superconducting 360 MHz CH-prototype has been developed and successfully tested [3]. For future operations a new design proposal for high power applications has been investigated. Presently a new cavity operating at 325.224 MHz, consisting of 7 cells, β = 0.16 and an effective length of 505 mm (see table 1) is undergoing first measurements. Referring to the previous structure this cavity utilizes some novel features (see fig. 1):

- inclined end stems
- additional flanges at the end caps for cleaning procedures
- two bellow tuners inside the cavity
- two ports for large power couplers through the girders

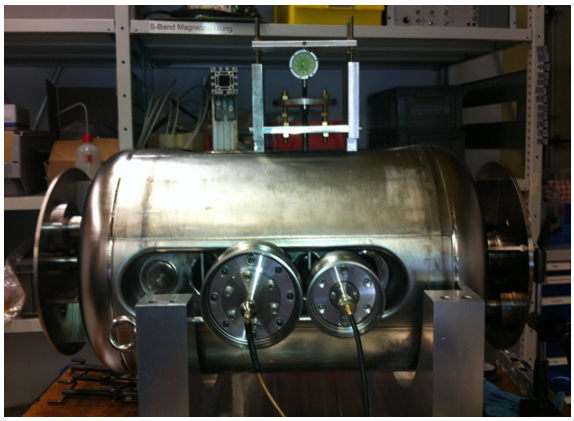

Figure 2: Setup for the test of the dynamic bellow tuners.

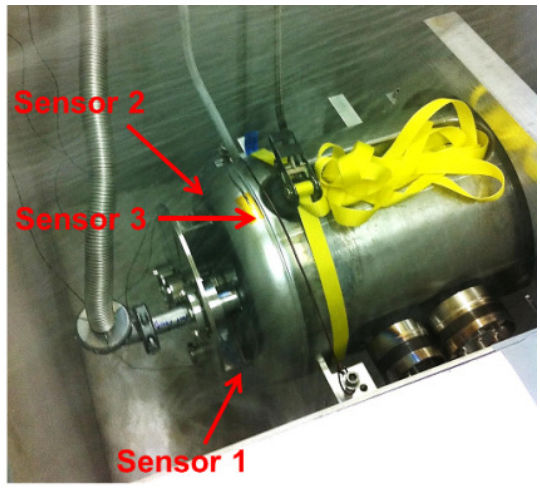

Figure 4: Setup for the preliminary cold test. Thermal sensors on top, alongside and bottom of the end cap.

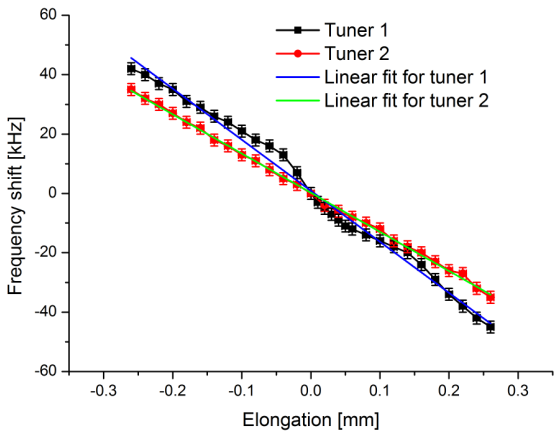

Figure 3: Frequency shift caused by elongation of tuner 1 and tuner 2.

First mechanical and rf tests regarding the scope of the dynamic bellow tuners have been performed at RI (Research Instruments GmbH [8]). The measuring configuration consisted of a framework housing a probe indicator and three spindles applying force via a metal plate on the rod of the tuners in each case (see fig. 2). Proceeding at room temperature the mechanical range of the bellow tuners was limited to $\Delta x = -0.3\ mm..0.3\ mm$ preventively. The measured frequency shift averaged $\Delta f = -172\ kHz/mm$ for tuner 1 and $\Delta f = -132\ kHz/mm$ for tuner 2. The simulated shift for the tuners is ($\Delta f = -150\ kHz/mm$) (see fig. 3).

PRELIMINARY COLD TEST

Prior to the final assembly of the cavity a preliminary cold test was arranged cooling down the cavity to LN_2 temperature. For this purpose the structure has been evacuated and inserted into an insulated metal box (see fig. 4). Three thermal sensors were attached to the top, alongside and bottom of the end caps. The cavity was leak-proof and the last remaining tuner hole was sealed with a Viton plug. This setup allowed a measurement down to an average temperature of roughly -120 °C (see fig. 5). Showing good agreement to the expected shrinkage the frequency shift at LHe should total up to 450 kHz corresponding to a shrinkage of 0.14 %.

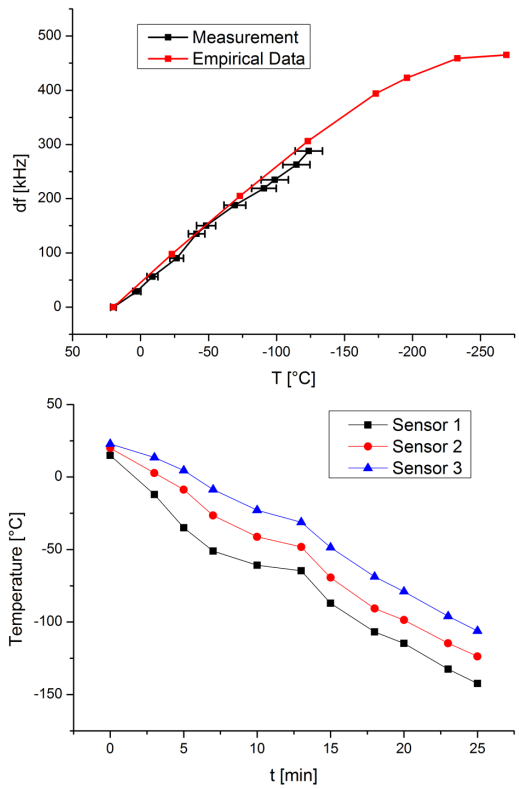

Figure 5: Top: Measured and expected frequency shift due to thermal shrinkage (Empirical data taken from: A.F. Clark, Materials at Low Temperatures). Bottom: Temperature behaviour for all three sensors.

PRESSURE SENSITIVITY

Furthermore pressure sensitivity measurements have been performed. Therefore three probe indicators were positioned on both end caps and on one cavity quarter shell (see fig. 6) to measure the deformation at the according spots. Then the cavity has been evacuated with a rotary vane pump down to 100 mbar and 1 mbar in another measurement, respectively. The frequency shift according to the measurements added up to ≈190 kHz and ≈180 kHz, respectively. According to simulations the shift is 205 kHz. The deformation on the cavity quarter shell was 0.22 mm at 100 mbar residual pressure while the simulated reference value amounts to 0.19 mm (see fig. 7).

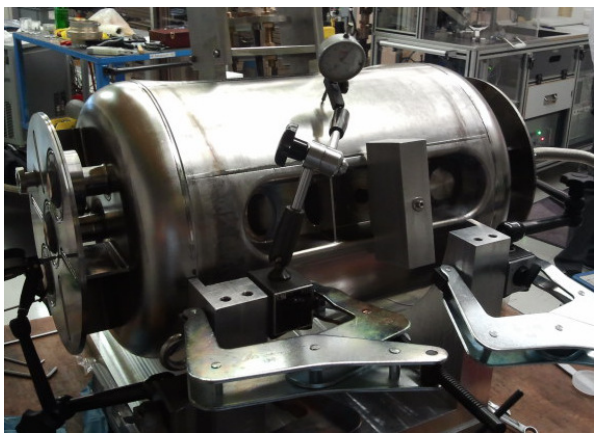

Figure 6: Setup for pressure sensitivity measurement.

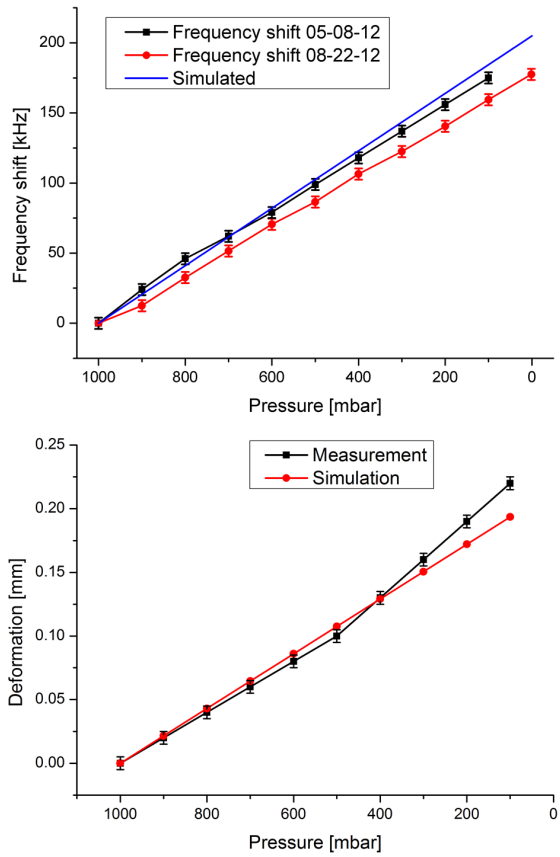

Figure 7: Top: Frequency shift due to evacuation. Bottom: Deformation of the cavity quarter shell versus residual pressure.

Abstract

Since the existing UNILAC at GSI will be used as an injector for the FAIR facility a new superconducting (sc) continuous wave (cw) LINAC is highly requested by a broad community of future users to fulfill the requirements of nuclear chemistry, especially in the research field of Super Heavy Elements (SHE). This LINAC is under design in collaboration with the Institute for Applied Physics (IAP) of Frankfurt University, GSI and the Helmholtz Institut Mainz (HIM). It will consist of 9 sc Crossbar-H-mode (CH) [1] cavities operated at 217 MHz which provide an energy up to 7.3 AMeV. Currently, a prototype of the cw LINAC is under development. This demonstrator comprises the first sc CH cavity of the LINAC embedded between two sc solenoids mounted in a horizontal cryomodule. One important milestone of the project will be a full performance test of the demonstrator by injecting and accelerating a beam from the GSI High Charge State Injector (HLI) in 2014. The status of the demonstrator is presented.

THE SUPERCONDUCTING CW LINAC DEMONSTRATOR

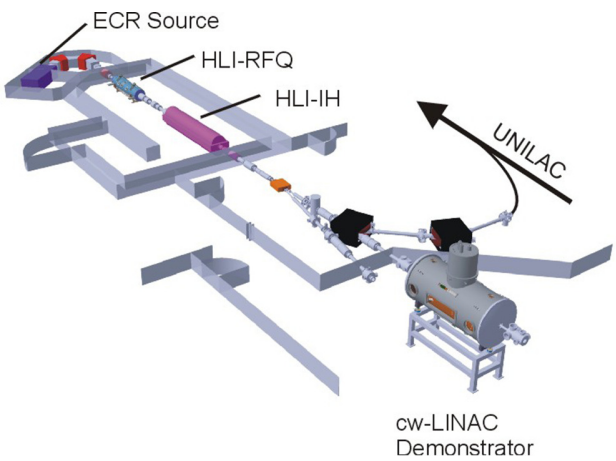

Figure 1: Demonstrator setup with the High Charge Injector at GSI.

The demonstrator will be the first section of the new sc cw LINAC at GSI. It will be operated at 217 MHz which is the second harmonic of the existing 1.4 AMeV GSI HLI. A test of the sc 217 MHz CH cavity, which is the key component of the project, under real operational conditions is the main aim of the demonstrator [2, 3]. It is planned to run a full performance test by injecting and accelerating a beam from the HLI in 2014. Figure 1 shows the cw demonstrator setup and the HLI.

STATUS OF THE SC 217 MHZ CH CAVITY

The sc 217 MHz CH cavity for the cw LINAC demonstrator (see fig. 2) will consist of 15 accelerating cells at a total length of 690 mm while the maximum gradient is 5.1 MV/m. Furthermore, the cavity is designed with the special EQUUS (EQUidistant mUlti-gap Structure) beam dynamics [4].

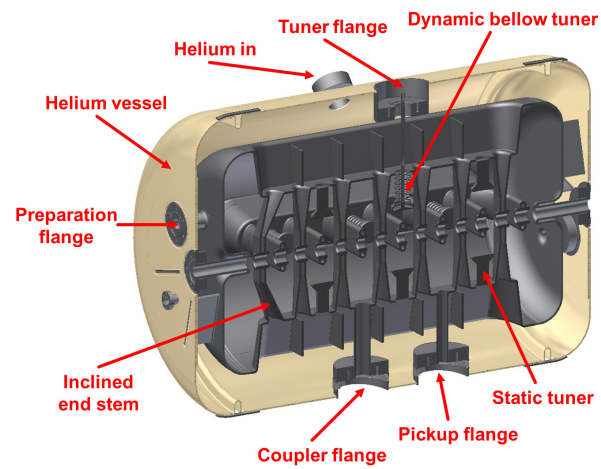

Figure 2: Side view of the sc 217 MHz CH cavity for the cw demonstrator at GSI.

The rf design of the cavity is finished. All main parameters of the cavity are shown in table 1. In June 2012 the production of the cavity has started at Research Instruments (RI) GmbH, Bergisch Gladbach, Germany. It is scheduled to be delivered to the IAP in 2013.

The cavity will be equipped with all necessary auxiliaries like a 10 kW cw power coupler, a titanium helium

vessel, several preparation flanges and a frequency tuning system. Since matching the design frequency during the fabrication and the operation process of a sc CH cavity is a serious challenge, the tuning will be done by capacitive static and dynamic tuners positioned between the stems.

Nine static tuners will be adapted accordingly during the fabrication to hit the design frequency. At a maximum height of 65 mm the frequency shift range of the static tuners is 3.6 MHz. Additionally, three slow bellow tuners (see fig. 3), driven by stepping motors control the frequency of the cavity during operation. They will readjust frequency changes and pressure effects at 4.2 K. Furthermore, two of these bellow tuners are connected to fast reacting piezo elements to compensate limitations like microphonics and Lorentz-Force-Detuning (one in operation, one in spare). The expected frequency shift range for one fast tuner during operation is ± 50 Hz/μm.

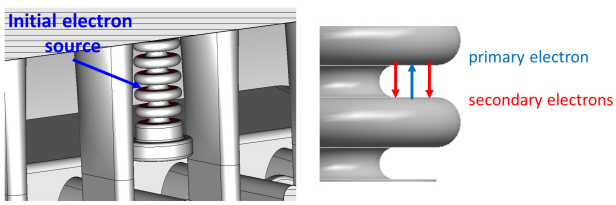

Figure 3: Final design of the 6-cell bellow tuner with the initial electron sources for the multipacting analyses.

To determine the geometry of the bellow tuners several mechanical, rf and multipacting simulations have been performed with ANSYS Workbench, CST MICROWAVE STUDIO and CST PARTICLE STUDIO. The gaps of the bellows are critical spots for multipacting. Figure 3 shows the final geometry of the 6-cell bellow tuner with a gap width of 3.5 mm and the initial electron sources for the multipacting analyses. For the simulations 12000 initial particles were chosen while the energy of the initial electrons has been varied from 2 to 5 eV with an kinetic spread of 50%. The simulated secondary emission yield (SEY)

$$\langle \mathrm{SEY} \rangle = \frac{\text{Total number of secondaries}}{\text{Total number of hits}}$$

for different accelerating gradients is shown in figure 4 as an example for an initial electron energy of 3 eV. As all simulations show, the effect of multipacting does not appear in the tuner gaps.

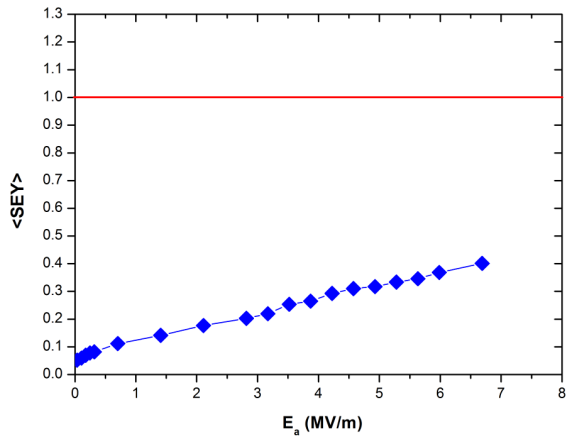

Figure 4: Simulated secondary emission yield for different accelerating gradients at an initial electron energy of 3 eV.

THE HORIZONTAL CRYOSTAT

For the planned beam tests at the GSI HLI a new horizontal cryostat is needed which houses the two sc solenoids and the sc CH cavity (see fig. 5). The final design phase of the cryostat is in progress at the moment. It is going to be built by Cryogenic Limited, London, United Kingdom and scheduled to be delivered in 2014. In comparison to a first concept study [5] the material of the vacuum vessel was changed from stainless steel to aluminum due to cost-efficient production.

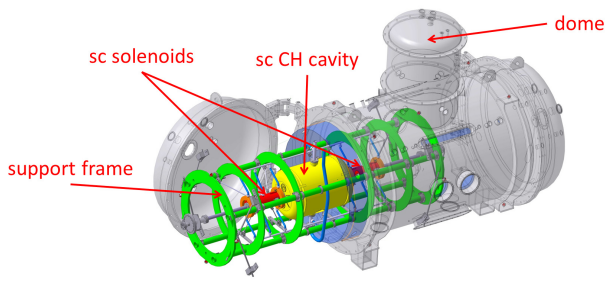

Figure 5: Layout of the horizontal cryostat close to the final design. In the center of the support frame the cavity (yellow) is embedded by two sc solenoids (red).

The main design criteria for the new cryostat are:

- modular design, universally usable - tests of various types of solenoids and CH cavities with different lengths and diameters
- various flanges for assembling options
- a dome for electrical supplies with a reservoir for cryogenic liquids
- a measuring system to control the positions of the cold masses on the beam axis

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Furthermore, the LHe reservoir will have a flow rate of 100 l/h while the estimated losses of the cryostat are roughly 2 l/h.

Table 2: Design parameters of the cryostat

Inner length	mm	2200
Inner diameter	mm	1120
Material tank		Aluminum
Insulating vacuum	mbar	$< 1 \cdot 10^{-5}$
Max. system pressure	bar	< 0.5
Operating temperature	K	4.2
Temperature thermal shield	K	77
Max. static losses (stand by)	W	< 10

To investigate the behavior of the cryostat's support frame under a cryogenic environment, first thermal and mechanical simulations have been performed with CST MPHYSICS STUDIO. Therefore, three different temperature sources were added to a simple model of the cryostat and the cavity to run the stationary solver (see fig. 6). Figure 6 shows the 3D temperature distribution of the support frame with the suspension rods. Heat transfer caused by radiation was not considered in the simulations as well as insulating materials. The outer suspension rods of the support frame were fixed during the simulations. As the contour plots of figure 7 show, the total displacement in x and y direction is roughly 3 mm while in z direction a displacement of 10 mm appears.

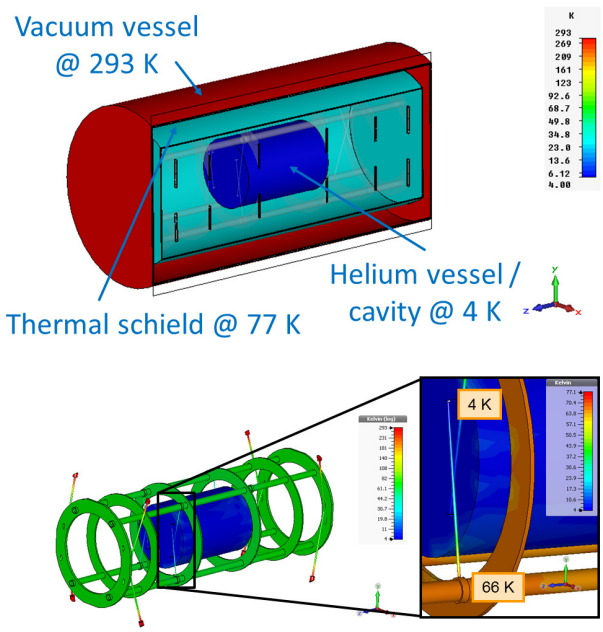

Figure 6: Temperature sources for the thermal stationary solver (top) and 3D temperature distribution of the support frame (bottom).

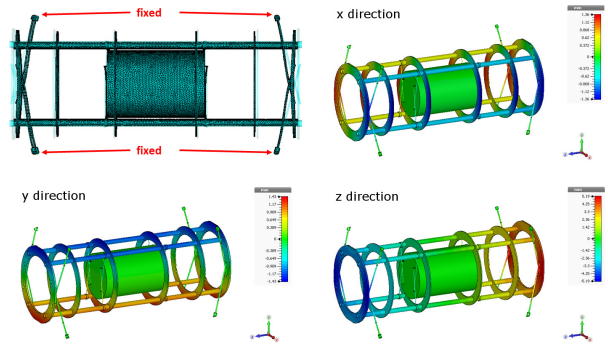

Figure 7: Deformed mesh of the support frame (scaling factor 10) and total displacement in x,y,z direction.

SUMMARY & OUTLOOK

First preparations were done to set up the cw LINAC demonstrator at the GSI HLI. A 3000 l LHe-tank as well as a helium recovery system have been delivered to GSI.

The rf design of the sc 217 MHz CH cavity is completed and its fabrication has started in June 2012 at RI. At present, the final design phase of the horizontal cryostat is in progress. The cryostat as well as the sc solenoids have been ordered from Cryogenic Limited.

The delivery of all main components is expected in 2013/14. After the assembling under clean room conditions and first rf test at the IAP, a full performance test with beam at the HLI is foreseen in 2014. Successful tests of the demonstrator are a fundamental step on the way to the proposed sc cw LINAC.

DEVELOPMENT OF PERMANENT MAGNET FOCUSING SYSTEM FOR KLYSTRONS

Y. Fuwa, Y. Iwashita, H. Tongu, Institute for Chemical Research, Kyoto University, Kyoto, Japan
S. Fukuda, S. Michizono, High Energy Accelerator Research Organization, Ibaraki, Japan

Abstract

A permanent magnet focusing system for klystrons is under development to improve reliability of RF supply system and reduce power consumption. To save production cost, anisotropic ferrite magnets are used in this system. A test model has been fabricated and the power test of a 750 kW klystron with this focusing magnet is carried out. 60 % of the nominal output power has been achieved at a preliminary power test so far.

INTRODUCTION

Distributed Klystron Scheme (DKS) is proposed as one of the RF supply scheme for International Linear Collider (ILC) to reduce the cost and the down time by raising the reliability [1]. Because thousands of relatively small modulating anode (MA) klystrons ware required in DRFS scheme, the failure rate of each component must be reduced. Especially thousands units of electromagnet for klystron beam focusing would cause maintenance problems. Replacing the electromagnets by permanent magnets can eliminate their power supplies and cooling system. Hence the failure rate of the RF supply system can be reduced and cut down the operation cost. A klystron beam focusing system with ferrite magnets is under development is described.

FABRICATION OF FOCUSING MAGNET

Magnetic Materials

There have been precedents for electron beam focusing in klystrons with permanent magnets such as ALNICO, the rare earth (RE) [2,3,4]. Figure 1 shows the B-H curves for these magnet materials and anisotropic ferrite magnets. ALNICO magnets, which have high remanence, shows less coercivity and easily demagnetize. Although RE magnets such as NdFeB has high remanence and coercivity, they are rather expensive and have the resource problem. The anisotropic ferrite magnets have less remanence but higher coercivity than ALNICO. The required magnetic field for beam focusing in klystrons is less than 1 kGauss, therefore the remanence of the anisotropic ferrite magnets is enough high. And the material costs are not expensive, because anisotropic ferrite magnets are composed of iron oxide.

Magnet Field Distributions

Periodic Permanent Magnet (PPM) focusing scheme has relatively well-known magnetic field distribution. In a focusing system with permanent magnet, the alternating magnetic field can be easily generated because an integrated value of magnetic field vector along closed

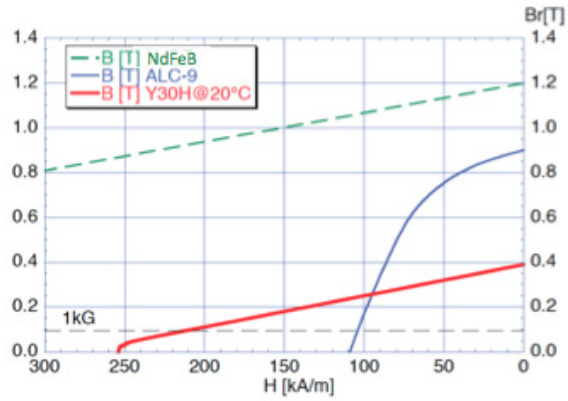

Figure 1: B-H curves of rare earth, ALNICO and ferrite magnets.

curve or infinitely-long axis is zero by the Ampere's law. However, periodicity cause stop bands. For pulse operations, the operating point always crosses such region during pulse rising time and the beam loss causes wall heating and prevents stable operation.

For safe operation, unidirectional magnetic field distribution is applied. Because the required magnet field is not high, anisotropic ferrite magnets can be used. RADIA 4.29[5,6] is used for the magnetic field design. Applied design is shown in Figure 2. Magnets shown in Figure 2 are categorized into two groups. The one group consists of magnets surrounding the klystron body

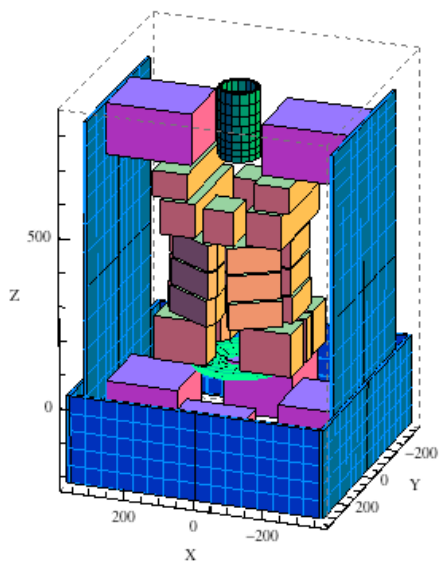

Figure 2: Layout of magnet and iron yoke.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

(yellowish ones in Fig. 2), whose easy axes are parallel to the klystron beam axis. The other group consists of the bottom and the top large magnet bricks (purplish ones in Fig. 2) to form the magnetic field around the cathode and the collector area. Their easy axis is perpendicular to the klystron axis. All magnets are retractable for the insertion of the klystron. Klystrons are usually inserted from the top of the focusing magnets and thus the minimum aperture of the magnets must be larger than most fat part of the klystron such as ceramic insulator. The retractable magnets can open their aperture at the klystron installation time and close at the operation. (see Figure 3). This retracting mechanism can also be used for the field adjustment.

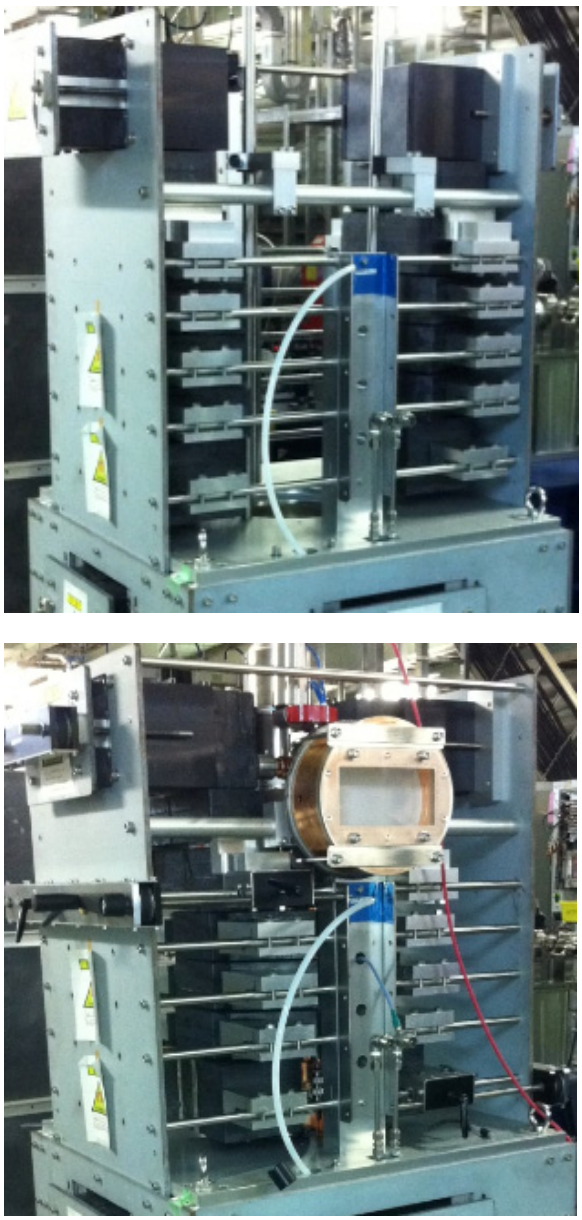

Figure 3: The magnets have larger aperture than the klystron body before the klystron installation (upper). After the klystron installation, the magnets are brought close to the klystron (lower).

KLYSTRON POWER TEST

To evaluate performance of the fabricated focusing magnet, a power test with real klystron (Toshiba E37501) is carried out. Figure 4 shows the E 37501 and Table 1 shows its nominal specification. The magnet field distribution, which is measured, adjusted is applied for power test. Figure 5 shows the longitudinal magnetic field. The blue line shows measured magnetic field generated by permanent magnets and the red line shows that by the electromagnet. The beam transport simulation has been performed by DGUN[7] using measured longitudinal magnetic field. The result of the simulation shows that the beam can pass through the klystron body without loss in the DC state (see Figure 6). Figure 7 shows transverse magnetic field components. The transverse magnetic field components are adjusted less than 10 Gauss by moving magnet's position. In the power test, the klystron was operated with 1 Hz repetition rate and the RF pulse duration was 1 ms so as not to damage the klystron body by unexpected beam loss. The result of the preliminary power test where the klystron cathode voltage is from 45 kV to 65 kV is shown in Figure 8. In Figure 8, red plots are the output maximum output power with our permanent magnets and blue plots are the max output power with an electromagnet measured by Toshiba. About sixty percent of the nominal output power at Toshiba is attained by the permanent

magnets in this early stage experiment. And the energy efficiency is about 33 % for our permanent magnets. This low output power and efficiency are supposed to be caused by the not optimized magnetic field in the cathode area. Figure 9 shows the calculated magnetic field in the cathode area. Although the magnetic field near the axis looks good, that on the outskirts may not be optimum, which results in beam mismatch.

Electric discharges occurred frequently in the operation and prevent stable operation. The electric discharges seem to be caused by the shape of the oil tank; the oil tank has a smaller diameter than that for the electromagnet focusing in order to reduce the distance from the magnets to the axis. This problem will be fixed by a remodeling of the tank. Further study will be continued for a better performance through magnetic field adjustment and so on.

DEVELOPMENT OF SUPERCONDUCTING RADIO-FREQUENCY DEFLECTING MODE CAVITIES AND ASSOCIATED WAVEGUIDE DAMPERS FOR THE APS UPGRADE SHORT PULSE X-RAY PROJECT*

J. Holzbauer†, A. Nassiri, G. Waldschmidt, G. Wu
Argonne National Laboratory, Argonne, IL 60439, U.S.A.

Abstract

The Advanced Photon Source Upgrade (APS-U) is a Department of Energy (DoE) funded project to increase the available x-ray beam brightness and add capability to enhance time-resolved experiments on few-ps-scale at APS. A centerpiece of the upgrade is the generation of short pulse x-rays (SPXs) for pump-probe time-resolved capability using SRF deflecting cavities [1]. The SPX project is designed to produce 1-2ps x-ray pulses for some users compared to the standard 100ps pulses currently produced. SPX calls for using superconducting rf (SRF) deflecting cavities to give the electrons a correlation between longitudinal position in the bunch and vertical momentum [2]. The light produced by this bunch can be passed through a slit to produce a pulse of light much shorter than the bunch length at reduced flux. The ongoing work of designing these cavities and associated technologies will be presented. This includes the design and prototyping of higher- (HOM) and lower-order mode (LOM) couplers and dampers as well as the fundamental power coupler (FPC). This work will be given in the context of SPX0, a demonstration cryomodule with two deflecting cavities to be installed in APS in early 2014.

INTRODUCTION

The SPX project calls for the use of an RF deflecting-mode cavity to chirp electron bunches, giving the electrons a correlation between their longitudinal position in the bunch and their vertical momentum. Synchrotron light produced from this bunch can then be passed through a physical slit to create a shorter light pulse at the proportional sacrifice of total flux. This scheme was first proposed by Zholents [1]; the scheme can be seen in Figure 1.

A significant amount of design work has gone into the RF cavities required for this project, details of which can be found in [2, 3, 4, 5, 6, 7]. This cavity application has many specific challenges including the need to heavily damp all non-operational modes to preserve beam quality for other APS users.

CAVITY DESIGN

The current design is a squashed elliptical dipole-mode cavity with a Y-shaped end group and an on-cell damping

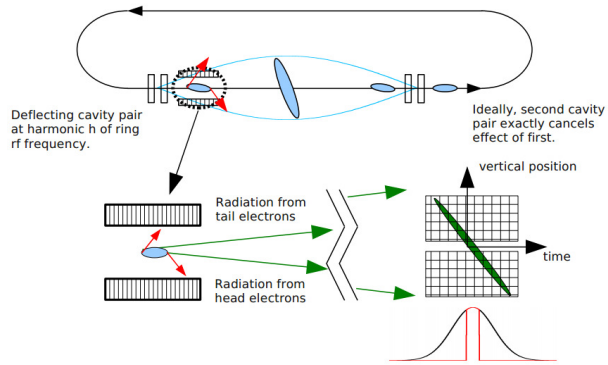

Figure 1: Schematic of Zholent's short pulse x-ray generation scheme. Image credit to [3].

port which can all be seen in Figure 2. Two of the waveguides from the Y end group will be used for damping of higher-order modes (HOMs) while the third will be primarily used as the forward power coupler. The on-cell damper is used primarily to damp the fundamental mode, called the lower-order mode (LOM). A list of the cavity parameters can be seen in Table 1.

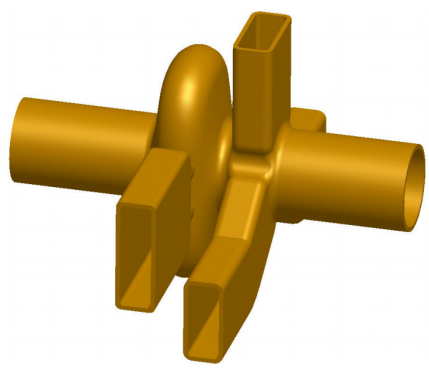

Figure 2: Schematic of a deflecting mode cavity for SPX. The LOM waveguide can be seen on-cell with the Y-end group (HOM dampers and FPC) to the right. Image credit to [3].

At this point, it is expected to use a BCP etching during cavity processing. Given the cavity parameters and this processing technique, 120 mT is the maximum expected reliable peak magnetic field. Given this and the requirement that each deflecting section have a total of 2 MV of

deflecting voltage to achieve 2-ps x-ray pulses [3], each cavity will be run at 0.5 MV deflecting voltage or 100 mT. In order to increase the operational margin, the possibility of electropolishing these cavities is being investigated.

HIGHER-ORDER MODE DAMPING

Because of the tight beam requirements, strong damping of non-operating modes was a focus of the overall cavity design. The squashed elliptical cavity geometry is meant to break the degeneracy of the dipole modes, increasing the frequency of the undesired dipole polarization as was done at KEK in the design of a similar deflecting mode cavity [8]. Significant work has been put into modeling of the cavities' broadband impedances [4], as well as the design of the HOM waveguides and dampers [7]. While the HOM waveguide design has been investigated in concept [9], their detailed design and packaging had not been considered until recently.

HOM Transitional Waveguide

Design of the SPX prototype cryomodule (SPX0) is well underway at JLab. Because of the broadband HOM damping requirements, it was decided to not use a window for the HOM dampers. This meant that all components of the HOM dampers would have to be assembled on the cold mass and had to fit inside the space frame for assembly. This is further complicated by the attachment of the tuner to the cavity very near to one of the HOM waveguide ports, making the HOM transitional waveguide (the waveguide running from the cavity to the damper itself) a very complex shape. This shape can be seen in Figures 3 and 4.

Despite these logistical requirements, the broadband transmission of this waveguide must not be compromised. The sizing of the HOM waveguide leading out of the cavity was chosen to have it's cutoff frequency between the operational frequency (2.815 GHz) and the first higher-order mode (estimated at 2.94 GHz). The waveguide must connect this custom sized waveguide to the HOM dampers which are based on WG340 waveguide. The placement and geometry of this taper was carefully considered to both give adequate attenuation of the operational mode and decent broadband transmission of HOM power.

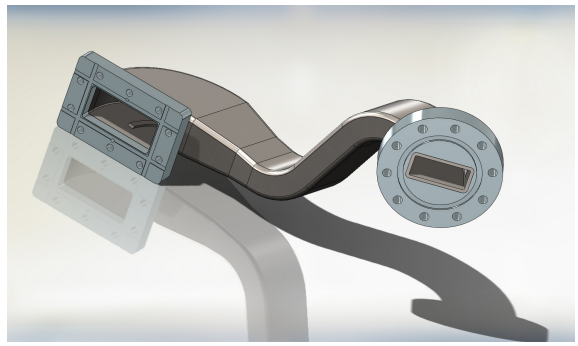

Figure 3: HOM Transitional Waveguide. Flange on the left connects to the cavity while the flange on the left connects to the damper assembly.

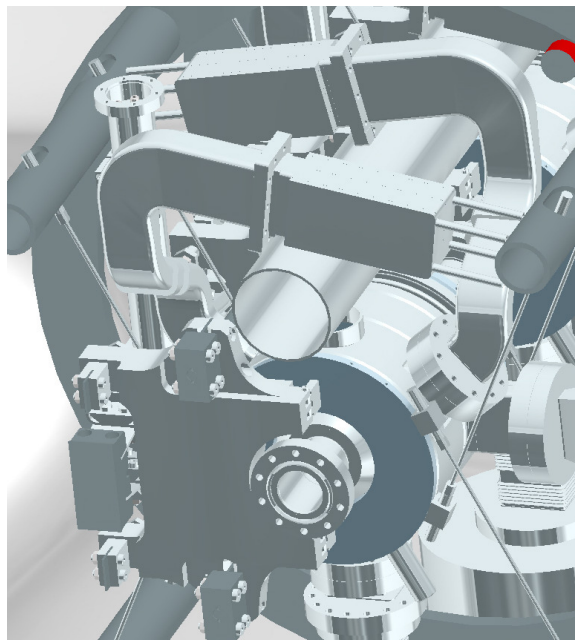

Figure 4: Section view of the SPX0 cryomodule space-frame mock-up. Cavity in helium vessel can be seen at the bottom of the image with tuner attached on the right side of the vessel. The HOM transitional waveguides and dampers can be seen crossing at the top of the image.

Given the space available, it was not possible to make the taper gradual enough to provide adequate broadband transmission because the first HOM (2.94 GHz) was still relatively close to cutoff. A ridge was added to this taper to improve transmission through the transition. The ridge was run through the taper on the wide wall and extended both toward the cavity into the S-Bend section and away from the cavity into the final, large radius bend. While this ridge improved transmission at 2.94 GHz, it also reduced transmission at some higher frequencies (3.0 GHz and 3.2 GHz) due to reflections off of the beginning of the ridge. The length of these ridge extensions was optimized to give the best broadband performance, the results of which can be see in Figure 5. The length of the ridge extension into

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

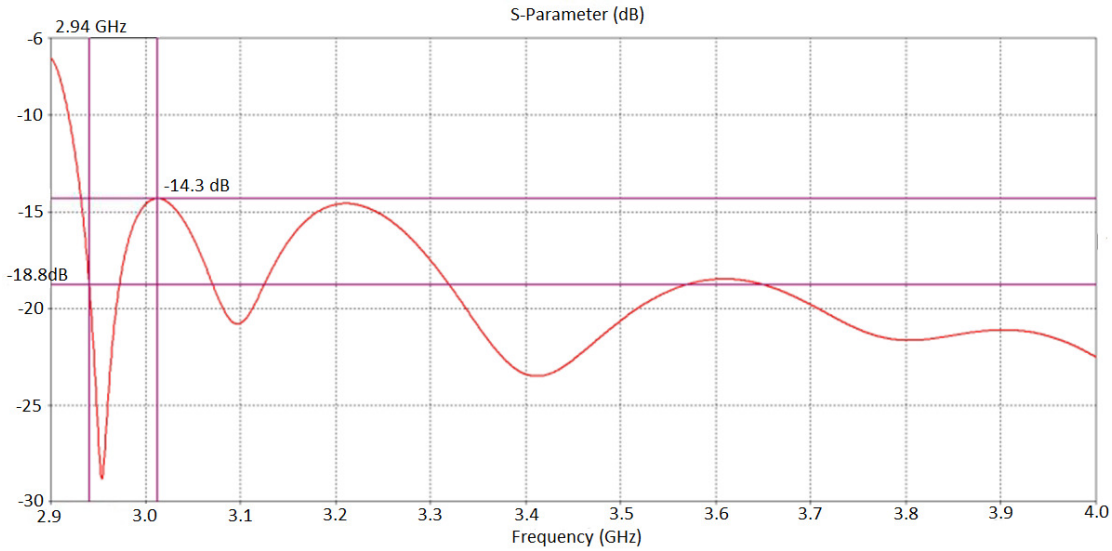

Figure 5: S11 parameter for the HOM Transitional Waveguide with optimized ridge. Reflection at the first HOM (2.94 GHz) is better than -18dB while the additional reflection cause by the ridge at 3.0 and 3.2 GHz is kept better than -14dB.

the S-Bend had the largest effect on performance. Longer ridges improved transmission at the first HOM frequency (2.94 GHz) but reduced performance at the higher frequencies. Without a ridge, S11 at 2.94 GHz was roughly -7dB, an unacceptably high reflection. Unfortunately, any reasonable ridge created the reflection at the higher frequencies which cannot be completely suppressed.

It is desired to keep the evanscant power from the operational mode reaching the HOM damper to below 10 W at full field to reduce total load on the damper. Simulations indicate that this traveling wave power should be 4.5 W, an acceptable number.

Waveguide Fabrication

When fabricated, the waveguide must be both mechancially robust and an adequate thermal barrier to keep the 2K heat load low. The HOM damper is water-cooled at room temperature outside the thermal shield and separated from the HOM transitional waveguide by a bellows, providing thermal resistance. The damper-end flange of this waveguide is expected to be strapped to the 80K cooling circuit. With a 1/8" wall of stainless steel and 10 microns of copper plating to improve RF performance, it is expected that this waveguide will contribute about 1.4 W (dynamic) to the 2 K heat load. Most of this comes from the evanescent fields in the beginning of the waveguide. Several fabrication methods are being considered for this complex geometry including fabrication from stainless steel sheet in parts, forming, and solid casting.

CONCLUSIONS

A credible design has been advanced for the HOM transitional waveguide. Prototyping is expected to begin in the coming months to validate the design and chosen fabrication process. SPX0 will provide an excellent test bed for this design and its interface with the cavity and HOM dampers. Results from this testing will be used to improved this design if necessary for the final SPX cryomodules.

MULTIPACTING ANALYSIS OF HIGH-VELOCITY SUPERCONDUCTING SPOKE RESONANTORS*

C. S. Hopper† and J. R. Delayen
Center for Accelerator Science, Department of Physics,
Old Dominion University, Norfolk, VA, 23529, USA and
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA

Abstract

Some of the advantages of superconducting spoke cavities are currently being investigated for the high-velocity regime. When determining a final, optimized geometry, one must consider the possible limiting effects multipacting could have on the cavity. We report on the results of analytical calculations and numerical simulations of multipacting electrons in superconducting spoke cavities and methods for reducing their impact.

INTRODUCTION

Superconducting multi-spoke cavities for frequencies of 325, 352, 500, and 700 MHz and velocities of β_0 = 0.82 and 1 have been designed and optimized [1, 2, 3] for a variety of possible applications. These applications include, but are not limited to, compact machines such as future light sources and high-energy proton or ion linacs. Here we focus on what regions of these resonators are most susceptible to multipacting events.

When the internal surface of a rf cavity is exposed to the high fields maintained in a superconducting cavity, electrons (known as primary electrons) can be emitted from the metal. The kinetic energy and trajectory of these electrons is determined by the electromagnetic fields, and in many cases, they will come in contact with another part of the surface with a certain amount of impact energy. If this energy falls within the secondary emission yield (SEY) range, then additional electrons, known as secondary electrons, will be ejected [4]. Figure 1 shows a generic SEY curve. The parameters E^I_{oc}, and E^{II}_{oc} are known as the crossover energies for which δ = 1. E_{om} marks the electron energy for which δ is maximum. These parameters can vary greatly between materials. Even for a given material, these parameters can vary widely based on both the bulk properties and surface condition.

For well prepared niobium cavities, the crossover energies are around 150 eV and 1050 eV, while E_{om} is around 375 eV [5]. We have presented preliminary results for crossover energies of 150 eV and 2000 eV previously [2]. When secondary electrons are in resonant trajectories, and each impact energy is in the range for which $\delta > 1$, then a cascade can occur generating excessive heat, thus leading to thermal breakdown. These regions are commonly called barriers, and they are classified as either "soft" or "hard." Soft barriers are those that can be conditioned through and thereby passed. It is believed conditioning occurs because multipacting electrons actually clean the surface to a point where the secondary emission yield is below unity [7]. Hard barriers are those which persist resulting in a limited achievable gradient and quenching.

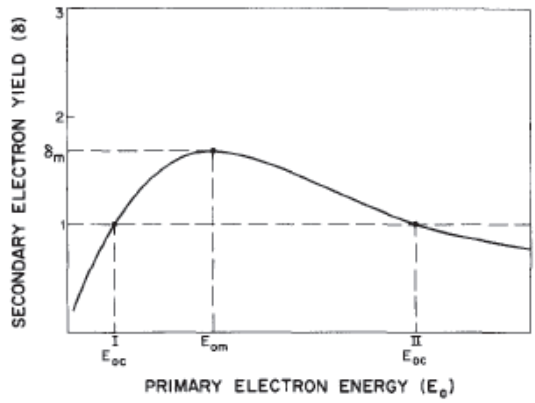

Figure 1: Definition of secondary-electron yield-curve parameters [6]

By improving the quality of the surface, the soft barriers on the gradient can be eliminated. On the other hand, hard barriers can only be overcome by changing the cavity geometry in such a way as to avoid resonant trajectories all together.

Multipacting is also characterized, most commonly, as either one-point or two-point. One-point multipacting occurs when the time of flight of the electron between two impacts is an integer number of rf cycles and that the electron's impact site is approximately the same as it's ejection site. This condition can be described in terms of the cyclotron and rf frequencies as [8],

$$\frac{f}{n} = \frac{eB}{2\pi m} \tag{1}$$

In the case of two-point multipacting, the time of flight is an odd number of half rf cycles and the impact site is not the same as the ejection site. The former condition can be described with the same parameters as (1) [9],

$$\frac{2f}{2n-1} = \frac{eB}{2\pi m} \tag{2}$$

MULTIPACTING ANALYSIS

In order to analyze the multipacting conditions in our optimized multi-spoke cavities, the 3D parallel tracking code Track3P contained in the ACE3P code suite developed by SLAC was used [10]. The cavity was divided into three regions as seen in figure 2. The regions labeled 1 and 3 include the end caps, half of one spoke, and the outer conductor enclosing the end accelerating gaps. The region labeled 2 includes half of each spoke and the outer conductor enclosing the middle accelerating gap. Due to the symmetry, regions 1 and 3 give similar enough results that we will only discuss 1 and 2.

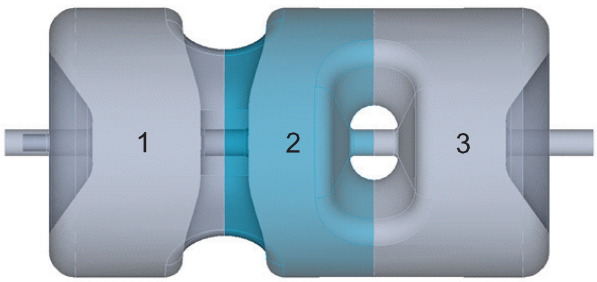

Figure 2: 325 MHz, β_0 = 0.82 cavity divided into three regions for multipacting analysis.

End cells

Figure 3 shows the resonant electrons surviving 50 rf cycles in region 1, along with their impact energies.

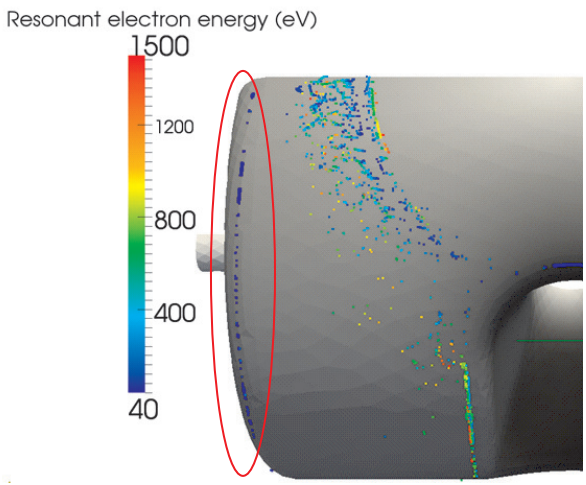

Figure 3: Resonant electrons and their impact energies surviving after 50 rf cycles as simulated by Track3P.

Figure 5 shows a plot of the resonant energies shown in figure 3. Upon inspection of figure 5, there are two observations to take note of. First, it appears that there are possible hard barriers between around 0.4 - 2 eV. Secondly, there are stable multipacting electrons at high field gradients. These electrons are found to be two-point, first order, and reside in the end cap area identified in figure 3. An example of these particle's trajectory is shown in figure 4.

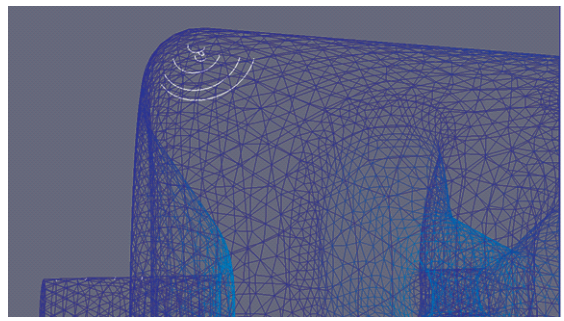

Figure 4: Two-point resonant electron trajectories in the end cap of the cavity.

The question of whether hard barriers exist has recently been tested on a similar cavity operating at 700 MHz, β_0 = 1. The cavity was designed and built in a collaboration between ODU and Niowave [3]. Multipacting analysis of that cavity showed a similar potential for hard barriers at low field gradients, but recent tests at 4.2 K have shown this not to be the case.

To address the question of soft barriers at high field gradient, the inset of figure 5 shows the multipacting electron energies present at 6 MV/m - 10 MV/m for this region of the end cap. The plots are for two different rounding radii at the outer edge, and the picture is of the end cap itself. A more subtle rounding (shown in black) has electrons with resonant impact energies of up to about 250 eV, although most fall below 150 eV. On the other hand, a larger rounding radius (shown in red), results in virtually all of the electron energies being below 100 eV.

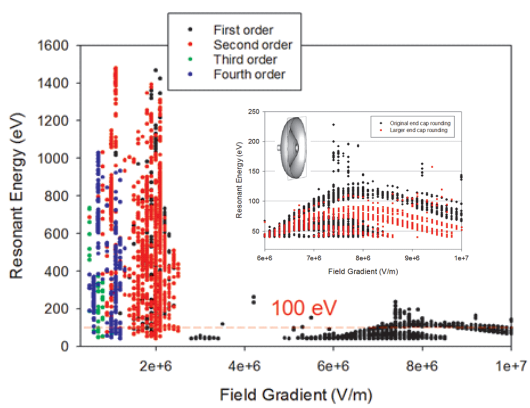

Figure 5: Resonant electron impact energy in region 1 for gradients up to 10 MV/m. The inset shows the impact energies for stable multipacting electrons for two different end cap outer rounding radii.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Center cell

The main regions of stable multipacting electron trajectories in the center accelerating gap are shown in figure 6. The low energy electrons (dark blue in color) are, as in the end caps, the ones that are still present even at high gradients. The energy of these electrons is shown in figure 7, and is similar, but slightly less than that of their counterparts at the end caps. These are also two-point, first order electrons which get trapped in the curvature where the spoke base meets the cylindrical outer conductor. As such, varying the curvature in this region can effect the electron's trajectory and impact energy. The inset of figure 7 is an example of this. For a smaller rounding radius (shown in black), there are a number of resonant electrons with energies between 100 and 120 eV for a field gradient of 7-9 MV/m. By increasing the rounding radius (shown in red), the maximum impact energy is now below 100 eV.

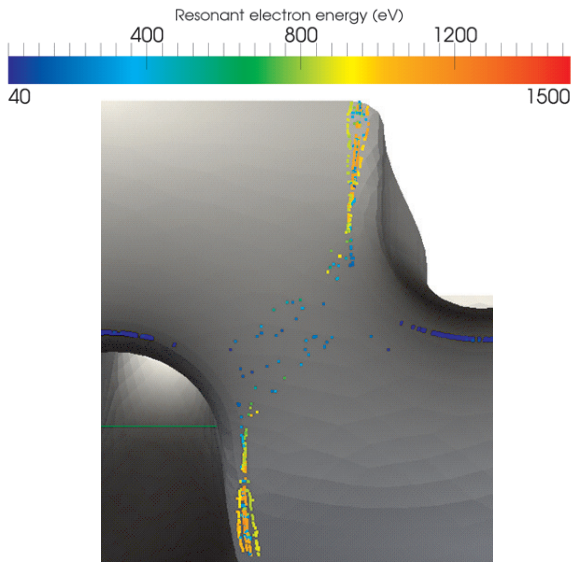

Figure 6: Resonant electrons and their impact energies surviving after 50 rf cycles as simulated by Track3P.

CONCLUSION

Multipacting simulations for multi-spoke cavities show that there is a potential for hard barriers at low field gradients and stable multipactors at high field gradients. However, recent prototype tests of an ODU designed, Niowave fabricated two-spoke cavity operating at 700 MHz has shown that these potential barriers should be able to be processed through.

Additionally, the soft barriers present at high gradients can be minimized by slightly altering the geometry in specific areas of the cavity. Both the end cap and spoke base rounding radius can be increased to a point where the stable, two-point, first order multipactors in these regions are likely to be conditioned away. Experiments at high gradients will have to be done in the future to verify this.

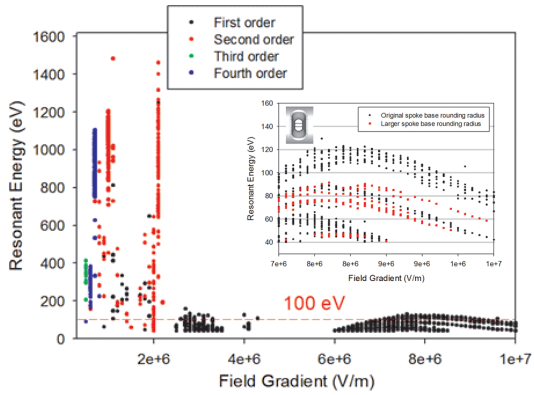

Figure 7: Resonant electron impact energy in region 2 for gradients up to 10 MV/m. The inset shows the impact energies for stable multipacting electrons for two different rounding radii where the spoke base meets the outer conductor.

ACKNOWLEDGMENT

We would like to thank Cho-Kuen Ng and Lixin Ge of SLAC for their helpful discussions on the Track3P code. We also thank Rocio Olave for her multipacting analysis of the 700 MHz cavity.

MECHANICAL STUDY OF FIRST SUPERCONDUCTING HALF-WAVE RESONATOR FOR INJECTOR II OF CADS PROJECT*

Shoubo He#, Yuan He, Weiming Yue, Shenghu Zhang, Ruoxu Wang, Cong Zhang, Mengxin Xu, Fengfeng Wang, Shichun Huang, Yuzhang Yang, Shengxue Zhang, Hongwei Zhao
Institute of Modern Physics, Chinese Academy of Sciences, Lanzhou, Gansu 730000, China

Abstract

Within the framework of the China Accelerator Driven Sub-critical System (CADS) project, institute of modern physics (IMP) has proposed a 162.5MHz half-wave resonator (HWR) Superconducting cavity for low energy section (β=0.09) of high power proton linear accelerators. For the geometrical design of superconducting cavities structure mechanical simulations are essential to predict mechanical eigenmodes and the deformation of the cavity walls due to bath pressure effects and the cavity cool-down. Additionally, tuning analysis has been investigated to control the frequency against microphonics and Lorentz force detuning. Therefore, several RF, static structure, thermal and modal analyses with three-dimensional code Traditional ANSYS have been performed [1]. In this paper, we will present some results about mechanical analysis of the first superconducting HWR cavity in order to further optimization in the near future.

INTRODUCTION

The cavity geometry has been optimized to reach the design frequency 162.5MHz and β=0.09 and also we want to minimize value of peak electrical and magnetic field on the cavity surface relative to the accelerating electrical field on the cavity axes (Bpk/Eacc and Epk/Eacc) [2]. So the fabrication technology and resonator structural properties including cooling down, vacuum, etching and so on, also should be taken into account at the beginning of design. SC HWR cavities are highly sensitive to mechanical deformations due to the small loaded bandwidth of some SCRF applications. So accordingly for HWR the stability of the cavity structure against any external distortions is the primer design goal. In order to improve df/dP for a low Beta HWR cavity, the typical approach is to add some stiffening ribs on the cavity, but it will not be discussed in this paper. Here, we will investigate this type of structure and then we will improve it in the future. Primarily structural analysis was completed to determine the locations of the model that were beyond yield strength.

Since CADS accelerator will work in CW regime, the main goal of our cavity structural design is a minimization of the resonant frequency dependence on the external pressure fluctuations. The general basics of the cavity structural design are to avoid using the plane surfaces as illustrated in Figure 1. Besides, four access ports at each cavity (two at the bottom, two at the top) guarantee draining off of the chemical etching and easy access to the inner surfaces during the high pressure water rinsing (HPR).

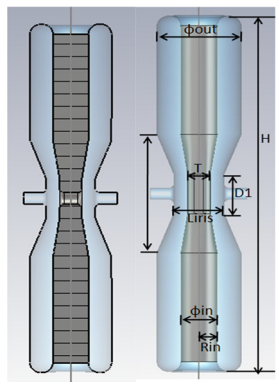

Figure 1: The cross section of HWR cavity with the main geometric parameters: Liris-iris to iris length, T-inner conductor thickness, D1-cavity diameter.

Table 1: Some Properties of HWR Cavity

Para.	Frequency	β	Diamater	Uacc	Epeak	Bpeak
Value	162.5	0.093	40	0.78	25	50
Unit	MHz	---	mm	MV	MV/m	mT

STRUCTURAL ANALYSIS

Injector II of CADS is composed by an ECR ion source, LEBT, RFQ and superconducting accelerating section. And in superconducting accelerating section, there are two cryomodules and each cryomodule is composed of 8 superconducting Half-Wave-resonator cavities and 9 superconducting solenoids. The proton beam will be accelerated from 2.1 MeV to 10MeV. Before structure analysis the geometry of HWR cavity was taken from a sat. model that was generated in software CST Microwave Studio and represented one cavity structure. The ANSYS RF results were compared to CST and to HFSS models of the same cavity for final verification. And the difference among these code result is only about 0.065%.

During mechanical analysis of HWR cavity, the variation of RF Eigen frequency was calculated, including pressure sensitivity, Lorentz force detuning, tuning sensitivity and resonant vibration and etc.. The

relationship between changes in RF frequency and mechanical deformations is given by the Slater Perturbation Theorem as the following equation 1, where E_0 and H_0 are the unperturbed electric and magnetic fields respectively, U_0 is the stored energy, f0 is the original cavity frequency, and Δf is the frequency shift:

$$\frac{\Delta f}{f_0} = \frac{\int_{\Delta v} (\mu_0 \left|\vec{H}_0(\vec{x})\right|^2 - \varepsilon_0 \left|\vec{E}_0(\vec{x})\right|^2) d^3x}{4 \cdot U_0} \quad (1)$$

PRESSURE SENSITIVITY

A sequential coupled field analysis RF-Structural-RF is used to predict the frequency shift due to cavity deformations under external pressure using codes ANSYS. As the cavity stiffening environment is hard to determine when cavity design, it is necessary to provide this research under two cavity beam port boundary conditions: fully fixed and completely free. The same meshed model was used for all types of simulations and that is very important as we can evaluate the frequency shift at the same scale.

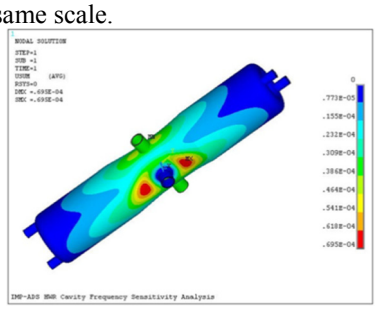

Figure 2: Structural analyses results of HWR with beam pipes fixed (cavity deformation).

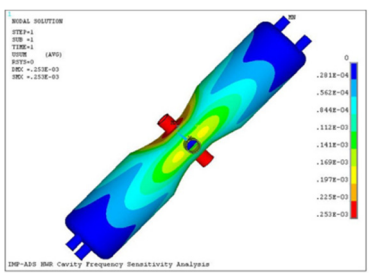

Figure 3: Structural analyses results of HWR with beam pipes free (cavity deformation).

Table 2: Pressure Sensitivity under 1 Atm

Boundary	Displacement	Stress	Δf	df/dp
fix	0.0695	5.786	17.892	23.54
free	0.252	19.066	110.773	145.6
Unit	mm	ksi	kHz	Hz/torr

From the above results we can see that the main frequency shift is caused by the beam port displacements. Although in this analysis the cavity has been simulated without helium vessel. While the helium vessel adds rigidity to the beam ports and in other words it is equivalent approximately to the fully constrained conditions. Whatever the different boundary condition, the cavity seems to be too soft so we need add some ribs on it for strength the cavity. And recently we just explore how to add these stiffening ribs.

Lorentz Force Detuning (LFD)

Since the superconducting HWR cavity will work in cw mode, so it will be static Lorentz force on the cavity walls. The pressure results in a deformation of the SC HWR cavity walls with changing the cavity volume by ΔV. And it creates the frequency shifts, which may be approximated as a perturbation using Slater's Theorem[3]. This shift is usually quantified by KL which is defined as

$$K_L = \frac{\Delta f}{(E_{acc})^2} \quad (2)$$

The numerical coupled analysis for LFD effect has been done and also an initial simulation of the cavity under beam pipes full constrain can be showed. From this formula, we can see that the frequency shift is proportional to the accelerating gradient. With the increase of accelerating gradient, the resonant frequency also decreases. Figure 4 shows the deformation of the cavity with LFD effect .

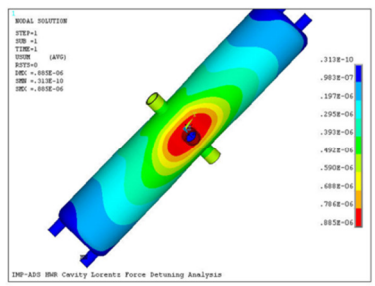

Figure 4: Deformation of the cavity wall (fix boundary condition)

From the above simulation the final fitting curve of the Δ f and E_{acc} is

$$\Delta f = -4.657 E_{acc}^2 - k \quad (3)$$

Finally according to the equation 2, the obtained Lorentz force detuning coefficient K_L is -4.657Hz/(MV/m)^2.

Modal Analysis

Generally speaking, it is difficult to eliminate vibrations in cavities because the situation around the cavity and the helium vessel is extremely complicated. In practice the structural modal analysis need to be provided with helium vessel fixed at the supports and tuner fixed by the tuner stem. While here the results is obtained from naked HWR cavity. And then we have the lowest frequency of modal analysis is 188Hz, which is far from the dangerous frequency obviously. Certainly it is need to

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

be further tested for all the accelerator with helium vessel, coupler, tuner and cryomudule etc. to verify the analysis.

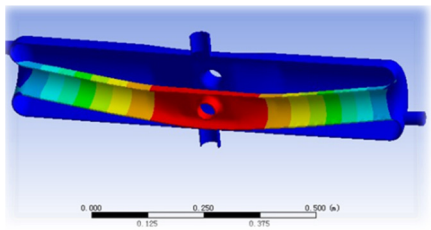

Figure 5: One of Model analyses results of HWR cavity with cleaning pipes free (cavity deformation).

Tuning Sensitivity

The role of the tuner is to ensure that the cavity resonance frequency will match the desired accelerator operating frequency. Tuners are generally made an active part of a complete RF control system which fulfills several functions. It stabilizes the frequency, amplitude, and phase variations induced by sources such as the RF drive, beam current variations, LFD, and microphonics. The usual tuning method for SC cavities is to change the length of the cells by mechanical adjustment of the overall length of the cavity. This method will not only bring in new HOM, but also not cause a big change for previous HOM[4].

The main factors that may be needed at the design of tuner are as follows:

- The tuning sensitivity of HWR cavity is 180KHz/mm;
- The spring constant of the HWR cavity is 2.2KN/mm;
- The limited space available (tuning range) is about 2mm.

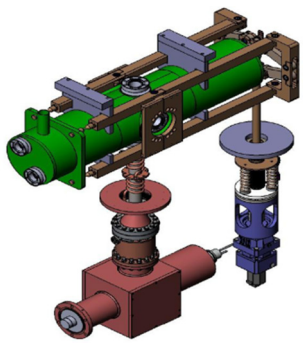

Figure 6: The IMP mechanical tuner: tuner(dark gray), helium vessel (green), and coupler (red).

Considering the fabrication tolerances for the cavity, the tuner may be able to retune the cavity over a range of 150 kHz cantered on the nominal operating frequency of 162.5 MHz.

Figure 7: Mechanical Tuner of HWR cavity test with copper HWR prototype .

CONCLUSION

We Mechanical analysis has been developed for 162.5 MHz SRF HWR cavities for the proposed CADS at IMP. The design of the tuner has been described and results of the static performance of the first copper HWR prototype have been got recently. In view of the mechanical results we find obviously that the SRF HWR cavity is much too sensitivity. So Some stiffening ribs must be added on the cavity wall. Besides, the coupled field analysis is in progress with more realistic boundary conditions ,including helium vessel.

ACKNOWLEDGMENT

We would like to thank Prof. Haipeng Wang and Dr. Gary Cheng of JLAB for the idea of simulations and helpful discussions.

THE SUPERCONDUCTING CH CAVITY DEVELOPING IN IMP*

M.X.XU#, Y.He, S,H.Zhang, Z.J.Wang, R.X.Wang, SH.B.He, W.M.Yue, C.Zhang, SH.CH.Huang, Y.ZH.Yang, SH.X.Zhang, T.C.Jiang, Y.L.Huang, H.W.Zhao, J.W.Xia, IMP, Lanzhou, Gansu 730000,China

Abstract

The Cross-Bar H-type (CH) cavity is a multi-gap drift tube structure operated in the H21 mode [1]. The Institute of Modern Physics (IMP) has been doing research and development on this type of superconducting CH cavity which can work at the C-ADS (accelerator driver sub-critical system of China). A new geometry CH cavity has been proposed which have smaller radius. It's suitable in fabrication, and it's can reduce cost too .Detailed numerical simulations with CST MicroWave Studio have been performed. An overall surface reduction of 30% against the old structure seems feasible. A copper model CH cavity is being fabrication for validating the simulations and the procedure of fabricating niobium cavity.

INTRODUCTION

C-ADS project with ambitious requirement regarding beam power and quality need new superconducting linac development. Superconducting Crossbar-H-Mode (CH)-cavities have two important features meet with the requirements of C-ADS. Superconducting CH cavity have high real estate gradients compared to conventional low-beta ion linacs, this feature will reduce the amount of cavity prominent. For the cross bar structure, CH cavities are more rigidly. This feature satisfy the harsh requirements of C-ADS about reliable. As this reasons, superconducting CH cavities have been choose as a backup cavity type for the C-ADS(see Fig.1). With respect to C-ADS actual application, one prototype of superconducting CH cavity (f=162.5MHz, beta=0.067, 6 cells) is presently being development in IMP.

NEW SHAPE SUPERCONDUCTING CH CAVITY

The superconducting CH cavity has electric and magnetic field structure similar with combine the 4-vane RFQ and DTL's. We can use a semi-analytical approach to estimate basic parameters like frequency. The parameter Rt and r1 are represent the radius of CH cavity and the tube radius of CH cavity respectively. Using this equivalent, we can get the resonance frequency with the radius Rt as following [1]:

$$\omega \approx c\left(\frac{0.73}{Rt^2\left(\frac{25}{144}+\frac{25}{72}Ln\left(\frac{Rt}{r1}\right)-0.2\right)}\right)^{1/2} \quad (1)$$

In case of the superconducting CH cavity of IMP, the frequency is 162.5MHz, r1 was 0.03m. Using the formula (1) can give radius Rt of the CH cavity is 0.29 meter. We have using the software CST to simulation. The radius of CH cavity is 0.32 meter [2].

The superconducting CH cavity is a complex cavity. With the radius of 0.32 meter, there are big surface. This means a large amount of high pure niobium needs and a more chance to come across defects. As in superconducting cavity, perfect surface is important for the cavity quality [3]. This size of CH cavity is not easy to protect from defects and contaminates or not suitable in the vacuum chamber of electric beam welding machine.

We try to cut a part of the girder called undercut [4] (see Fig.2).This undercut will increase inductance in the end of cavity, as this will increase the length of current flow. Increased inductance will lower the resonance frequency that we can get a smaller cavity structure in the same frequency (see Fig.3).

When we change the size of undercut in the girder of CH cavity, the radius will reduce with the width of girder liner. At most, we can reduce the radius of cavity by 20% (see Fig.4). As the radius reducing, the surfaces of the cavity reduce by 30% (see Fig.5).

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

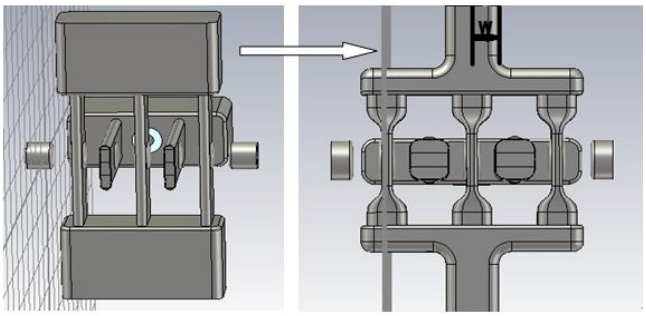

Figure 2: The copper CH cavity structure (left) and the CH cavity of use undercut in girder (right).

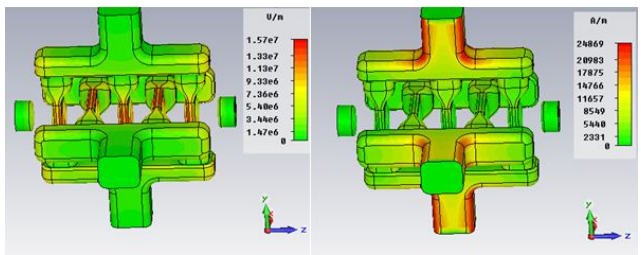

Figure 3: The electric field of use undercut CH cavity (left) and the magnet field of use undercut CH cavity.

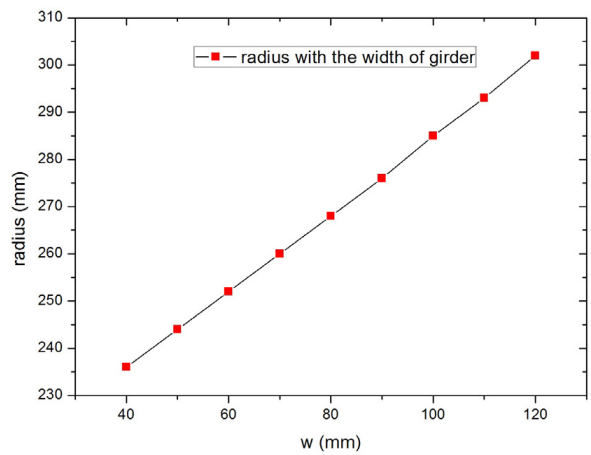

Figure 4: The radius of CH cavity with the width of girder.

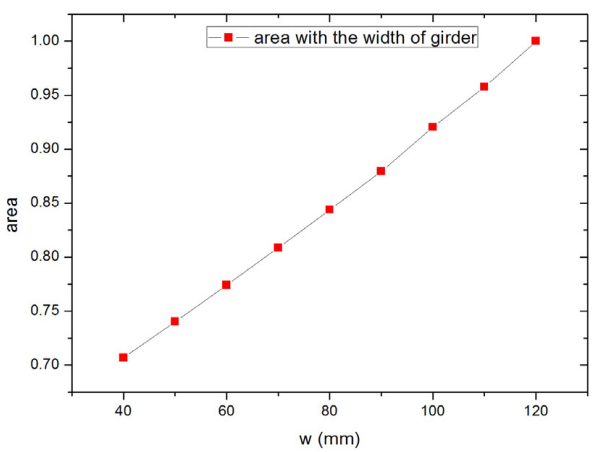

Figure 5: The surface of CH cavity with the width of girder.

This reduction has such advantages: as the cavity size became smaller, deep drawing dies became smaller too. It's easy to hand; the last electron beam welding joint have smaller length, less risk to burn a hole, easy to change position at the EBW; smaller use of high purity niobium, lower cost; less chance to come across defect in surface [4].

Field distribution variation with different undercut girder

The usage of undercut girder leads to a more homogeneous field distribution along the beam axis because the volume for the magnetic field is increased (see Fig.6).

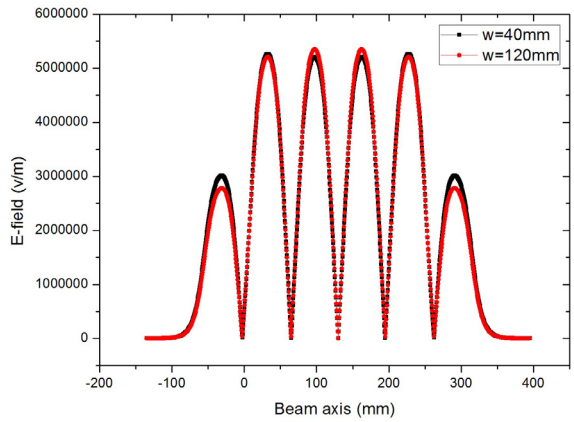

Figure 6: Field distribution of CH cavity with the different width of girder.

Frequency variation with different undercut girder

The frequency tuning is by compress and pulling the two side of cavity along beam axis. Different undercut girder influence the F/l (see Fig.7).

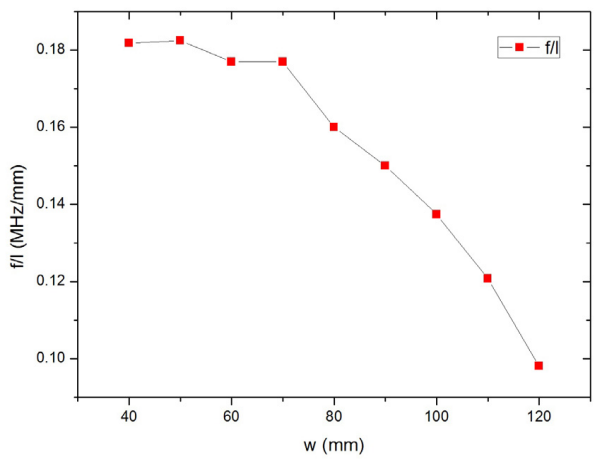

Figure 7: F/l of CH cavity with the different width of girder.

Copper prototype CH cavity fabrication

A copper prototype CH cavity has been built (see Fig.8) to validate the electromagnetic simulations, such as frequency (see Table1), field distribution along the beam axis, coupler size and position, tuning ability. And the CH cavity structure is complicate, need to check the design of dies and the path of electron beam weld in the fabrication.

Table 1: The EM parameters of the copper CH cavity

Parameter	Value	Unit
Frequency	162.5	MHz
Beta	0.067	
Ra/Q0	670	Ω
G	47	Ω
Epeak /Eacc	5.3	
Bpeak /Eacc	6.37	mT/ MV/m

OUTLOOK

We have design a superconducting CH cavity with smaller size. The future optimization will focus on lower the E_{peak} /E_{acc} and B_{peak} /E_{acc} , that it should be possible to reach higher effective voltages . The normal copper CH cavity will be finish at the end of 2012.

Figure 8: Parts of copper CH cavity.

IMPACT OF TRAPPED FLUX AND SYSTEMATIC FLUX EXPULSION IN SUPERCONDUCTING NIOBIUM

J. Vogt, O. Kugeler, J. Knobloch, Helmholtz-Zentrum für Materialien und Energie (HZB)

Abstract

The intrinsic quality factor Q_0 of superconducting cavities is known to depend on various factors like niobium material properties, treatment history and magnetic shielding. To study trapped flux in Niobium we constructed a test stand at Horizontal Bi-Cavity Test Facility (HoBiCaT) at HZB using niobium rods equipped with thermal, electrical and magnetic diagnostics. The focus in this study was on the behaviour of the trapped flux when the sample is slowly warmed up towards the critical temperature T_c. Besides the (incomplete) Meissner effect we observed additional flux expulsion starting at ≈0.1K below T_c. The reduced level of trapped flux is maintained when the sample is cooled down again and can even be improved by repeating the procedure. Possible explanations for the effect are discussed.

INTRODUCTION

We already reported on the impact of temperature gradients during the cool-down on the obtained Q_0 [1]. In the quest for minimization of RF losses in SRF cavities the impact of trapped vortices is one main topic. The vortices have a normal conducting core with a surface resistance about 6 orders above that of superconducting Niobium. This surface fraction is proportional to the trapped magnetic flux. The surface resistance was determined to be 2.2nΩ per μT for a 1.5GHz cavity [2]. A crucial step in avoiding trapped flux is an improved understanding of flux trapping behaviour of Niobium.

The energetically most favourable state of bulk Niobium at 1.8K (4.2K) is the Meissner phase, in which all magnetic field present in the normal conducting state is expelled. However, expulsion of flux can be incomplete, yielding a remaining magnetization of the material even after removing the external field source. The dynamics of this trapped flux is still not well understood. One approach was the investigation of flux that is permitted to penetrate a marginal type II superconductor in the mixed state. Here, the flux tubes form a lattice and several studies [3, 4] indicate a phase transition from localized (solid, fixed regular lattice) flux tubes towards moveable (liquid) flux tubes when the superconductor exceeds certain temperature / magnetic field combinations as indicated by the black dotted "melting line" in Figure 1.

The behavior of flux that is trapped in the Meissner state is uncertain. A continuation of the melting line in this phase is conceivable, so that flux lines in the check region (Figure 1) may be able to exit the Niobium below T_c. In our study, we examine the properties of the trapped magnetic flux in the Meissner phase when the rod is slowly warmed up.

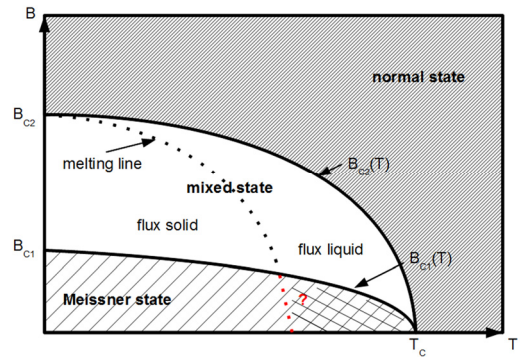

Figure 1: Magnetic phase diagram of marginal Type II superconductor [5]. The added red dotted line indicates a possible extension of the liquid/solid flux interface into the Meissner state. The size of the check region is exaggerated.

EXPERIMENTAL SETUP

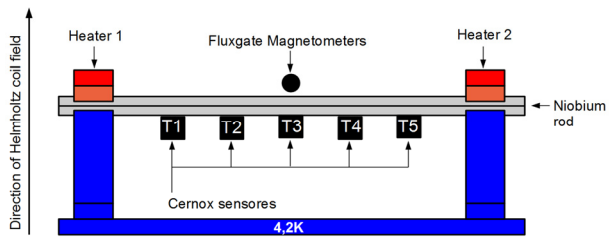

Figure 2: Experimental setup

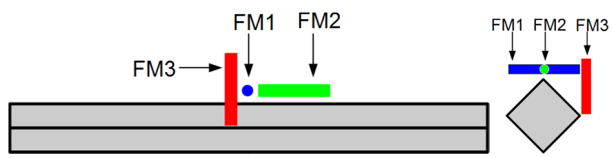

Figure 3: Positions of fluxgate magnetometers (FM): Longitudinal view (left) and cross section (right) of FM1 (black), FM2 (green) and FM3 (red)

For the experiments, a RRR=300 niobium rod (8.4x8.4x300mm) was positioned inside HoBiCaT [6]. It was conduction cooled through the posts to 4.2K. In order to reduce heat transfer into the Helium, heat conductivity was reduced by introducing a kapton foil between rod and support stands. Both ends of the rod were equipped with a resistive heater. They could be individually regulated to control the temperature of the rod with 10mK accuracy. Five Cernox temperature sensors with mK resolution and three fluxgate magnetometers with 1nT resolution (Bartington Mag-01H), one for each spatial direction,

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

were attached along the rod. A Helmholtz coil (HC) for the generation of a vertical magnetic field up to ±300µT enclosed the whole construction. The setup and the positions of the instruments are displayed in Figures 2 and 3.

MANIPULATION OF TRAPPED FLUX

In each of the performed experiments a magnetic field is applied using the HC while the Nb rod is cooled through T_c. Afterwards, the rod is smoothly warmed by manually adjusting the two heaters and the change in the magnetic field is observed by three fluxgate magnetometers (FM). Precise temperature control was exercised to ensure that at no time T exceeded T_c.

Manipulation without applied field

In the first set of experiments the HC is turned off after the rod has reached the minimum temperature. Hence, the signal registered subsequently by the FMs roughly corresponds to the frozen flux inside the rod. Referring to Figure 4, this is position (A).

When the rod is warmed up again, the magnetisation observed by the FMs stays constant until a temperature of T≈9.1K (<T_c) is reached. At this point the amount of trapped flux suddenly starts to drop (B) until a minimum level is reached (C). When the warming is stopped during the decrease and the rod is cooled, the level of trapped flux at the instance of stopping remains - even upon subsequent cooling.

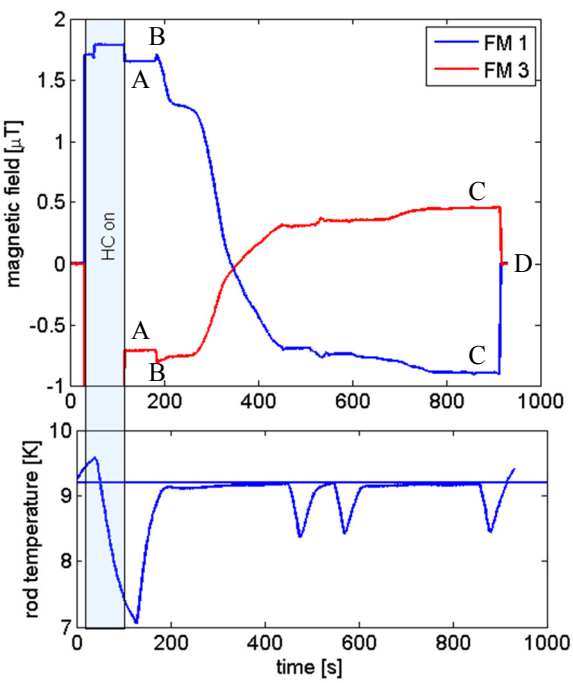

Figure 4: Behaviour of trapped flux and temperature when a HC field of 33µT is applied and trapped: Initially trapped flux (A), minimal trapped flux (C) and level of flux ambient in HoBiCaT ≈3µT (D). This value has been subtracted from all data points.

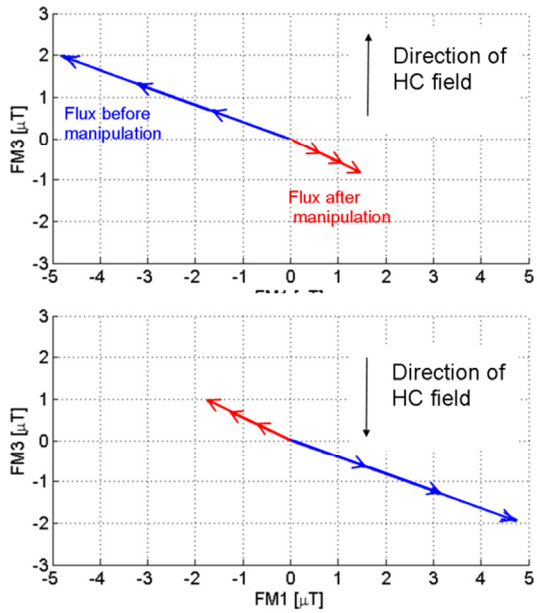

Figure 5: Trapping for HC fields: 33µT, 65µT, 97µT (above) and -32µT, -66µT, -98µT (below). The initially trapped field is blue and the field after additional expulsion is red.

The signals obtained by FM1 and FM3 are displayed in Figure 4. For better visualization their values can be combined to a vector indicating the spatial orientation of the trapped flux, see Figure 5. The signal of FM2 is more than one order of magnitude smaller than the signals of FM1 and FM3 due to the orientation of HC and rod and therefore is not displayed here.

The change in the trapped flux indicates that the warming enables the trapped flux lines to move. A possible explanation could be that the thermal energy exceeds the pinning potential and the pinning potential barrier does not hinder the movement of flux lines anymore ("liquid flux state"). Driving force for the movement could be the strive for approaching the energetically most favourable state – the complete Meissner state – given by a minimum of sc/nc interface area. Not all flux is expelled because different pinning centres have different pinning potentials [7] and not all of them can be exceeded by the thermal activation. Also the driving force reduces, the less flux remains in the sample. We observe:

(1) A redistribution of flux lines (here even change in sign due to geometry) and
(2) A reduction of the absolute amount of frozen flux

The latter is evident from the shortening of the vectors in Figure 5. Table 1 displays the values of the initially trapped field and the minimal trapped field in the end of the procedure for different HC fields. We achieved an expulsion of up to 75%.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Table 1: Magnetic field before and after expulsion

B_{HC} [μT]	$\lvert B_{trapped}\rvert$ [μT]	$\lvert B_{minimised}\rvert$ [μT]	Expulsion [%]
33	1.98	0.50	75
65	3.91	1.19	70
97	5.84	1.88	68
-32	1.87	0.88	53
-66	3.80	1.57	59
-98	5.73	2.26	61

Manipulation with applied field

These investigations raise the question how the flux tubes behave when an external field is not turned off during warm up as opposed to the above experiment, where an external field was trapped but only the ambient field remained during warm up.

Figure 6 displays a typically obtained signal of FM1. In the beginning the rod is normal conducting (A). It is cooled below T_c where flux is expelled by Meissner effect (B). The magnetic field probe measures an increase in the field density outside the rod. Afterwards the rod is slowly warmed using the heaters. Starting at a temperature of (9.08±0.01)K we observe a sudden decrease in expelled flux (C) which coincides with the onset of Paramagnetic Meissner Effect (PME) reported by Thompson [8]. The onset temperature does not depend on the applied field strength in the range of ±300μT tested here. The PME is a phenomenon observed in some high temperature superconductors and in Niobium. These materials exhibit a paramagnetic phase between the perfect diamagnetic behaviour in the Meissner state and the normal conducting state. Note the difference to classical frozen flux which is a topological coexistence of normal conducting and Meissner-like areas.

When the rod is warmed up further, a second effect occurs. When T_c is approached an additional expulsion of flux is evident (D) resulting in a lower level of residual frozen flux (i.e. a higher level of expelled flux). Subsequent repetition of cooling and heating leads to a minimized level of trapped flux (E) and each time we observe the PME. Further repetition leads only to the jumps in magnetisation due to PME but no further change in the level of trapped flux.

A possible explanation for this systematic flux expulsion could be an increased mobility of flux lines in a temperature regime close to T_c consistent with the data obtained in the first set of experiments.

In this set of experiments, HC fields of up to ±300μT were applied leading to expulsion pattern that were all similar to Figure 6. Hence, systematic flux expulsion works under these conditions.

CONCLUSION

The amount of trapped magnetic flux can be manipulated and systematically minimized while the material remains superconducting. The complete Meissner state is thus being approached.

If one could apply such a procedure to SRF cavities, this effect could lead to higher Q_0 values and operation close to the BCS-limit. In addition, the major impact of the cooling dynamics in the temperature range between 9.08K and T_c on the flux trapping behaviour could explain the impact of temperature gradients during the cool-down on the obtained Q_0 values as described in [1].

ACKNOWLEDGMENT

We would like to thank A. Frahm for the design of the testing apparatus and S. Klauke and M. Schuster for help with setting up the experiment.

THE NONRESONANT PERTURBATION THEORY BASED FIELD MEASUREMENT AND TUNING OF A LINAC ACCELERATING STRUCTURE *

W. C. Fang#, Q. Gu, Z. T. Zhao, SINAP, Shanghai, China
D. C. Tong, THU, Beijing, China

Abstract

Assisted by the bead pull technique, nonresonant perturbation theory is applied for measuring and tuning the field of the linac accelerating structure. The method is capable of making non-touching amplitude and phase measurements, real time mismatch feedback and field tuning. Some key considerations of the measurement system and of a C-band traveling-wave structure are discussed, and the bead pull measurement and the tuning of the C-band traveling-wave linac accelerating structure are presented at last.

INTRUDUCTION

The Shanghai soft X-ray Free Electron Laser test facility(SXFEL)is presently being planned and designed at the Shanghai Institute of Applied Physics, CAS [1]. This facility will be located close to the Shanghai Synchrotron Radiation Facility, which is the first 3rd generation light source in mainland China [2]and it requires a compact linac with a high gradient accelerating structure and high beam quality. As a key R&D item, a room temperature C-band (5712 MHz) accelerating structure has been developed [3, 4]. For fabricating the C-band structure with high performance, the bead pull measurement system based on nonresonant perturbation theory has been developed.

There are several methods for RF structure measurement or tuning, such as the resonant perturbation method [5] and the phase shift method, however several limitations appear when they are applied to a traveling-wave accelerating structure. The resonant perturbation method picks up the amplitude of the electromagnetic field, therefore it is limited in the measurement of the standing-wave accelerating structure and the phase shift method only shows the phase information in the RF structure. For the accurate and fast tuning of a traveling-wave linac RF structure, nonresonant perturbation theory is the preferable method, which can measure the electromagnetic field distribution with both amplitude and phase, and this method is capable of making non-touch measurement, which can maintain the clean inner surface of the accelerating structure and reduce its RF breakdown rate. Furthermore, this method is also very effective in performing an accurate and fast real-time tuning of the accelerating structure, which is economical for mass fabrication of accelerating structures.

In this paper we present a cold test application of nonresonant perturbation theory on a linac RF structure [6]. This method based on the bead pull technique can pick up the amplitude and phase distribution of a linac structure, particularly for a traveling-wave structure, and is a preferable and efficient method for accelerating structure cold testing and tuning. In the following we describe firstly the theory of nonresonant perturbation and the tuning procedure and then discuss the key considerations of our measurement system with the bead pull technique. At the end we give several experimental results of our newly developed C-band traveling-wave accelerating structure tuning, which verify the feasibility of this method.

NONRESONANT PERTURBATION THEORY AND TUNING PRINCIPLE

According to nonresonant perturbation theory, the variation of the reflection coefficient in the input port is measured with and without a perturbation bead, which is placed at different points along a line to pick up the amplitude and phase distribution of the electromagnetic field strength, a schematic drawing is shown in Figure 1. Based on the results and post-processing, RF tuning is processed with accurate and fast real-time feedback.

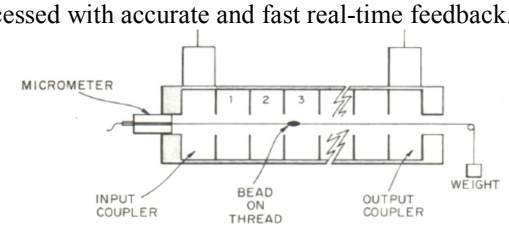

Figure 1: The field measurement based on nonresonant perturbation theory.

Nonresonant Perturbation Theory and Field Measurement

In nonresonant perturbation theory, the desired field strength is calculated as the following [6]:

$$2P_i(\Gamma_p - \Gamma_a) = -j\omega[k_e E_a^2 - k_m H_a^2] \quad (1)$$

For an accelerating structure, the TM mode is used for beam acceleration and the crucial longitudinal electrical field Ez is the unique field component on axis, thus the first equation of equation (1) is used for field measurement, and is renamed as equation(2) with reflected coefficient S11 of the Network Analyzer:

$$\Delta S11 = \Gamma_p - \Gamma_a = S11_P - S11_a = -\frac{j\omega k_e}{P_i} E_a^2 \quad (2)$$

whereS11p and S11a are acquired from the Network Analyzer, respectively corresponding to Γp and Γa in equation (1) above. In equation (2), Ea is complex data, its amplitude is the square root of the amplitude of ΔS11, and its phase is half of the phase ofΔS11. As the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

bead goes through the RF structure, the distribution of Ez on axis can be measured step by step.

Tuning Principle

With the bead pull measurement, the amplitudes and phases of the field can be measured, and after post-processing the local reflected coefficient can be calculated for the later tuning procedure. For the accelerating structure, the field of the center of the ith cell can be expressed by $E_i e^{j\varphi_i}$, which is the superposition of forward and backward waves $a_n e^{j(-2\pi/3(i-n)+\psi_n)}$ and $b_n e^{j(2\pi/3(i-n)+\phi_n)}$, where the center cell is the nth cell of the three cells in Figure 2.

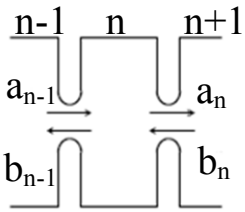

Figure 2: Forward and backward wave of nth cell.

It is supposed that the amplitudes in three adjacent cells are the same, according to [7],

$$a_n e^{j\psi_n} = E_{n-1} e^{j(\varphi_{n-1}-\pi/2)} + E_n e^{j(\varphi_{n-1}-\pi/6)}/\sqrt{3}$$
$$b_n e^{j\phi_n} = E_{n-1} e^{j(\varphi_{n-1}+\pi/2)} + E_n e^{j(\varphi_{n-1}+\pi/6)}/\sqrt{3} \quad (3)$$
$$b_{n+1} e^{j\phi_{n+1}} = E_n e^{j(\varphi_n+\pi/2)} + E_{n+1} e^{j(\varphi_{n+1}+\pi/6)}/\sqrt{3}$$

Based on equations (3), the local reflected coefficient of the nth cell is derived as equation (4)

$$\Gamma_{local,n} = \frac{b_n e^{j\phi_n} - b_{n+1} e^{j(\phi_{n+1}-2\pi/3)}}{a_n e^{j\psi_n}} = A + jB \quad (4)$$

where A and B represent the real and imaginary parts of the reflection respectively.

According to the conclusion in [8], the real part of the reflection coefficient in equation (4) is small and neglected relative to the imaginary part. The left imaginary part is dominated by the frequency detuning of each cell, which is shown in Equation (5).

$$\Gamma_{local} \approx -j\frac{2\beta Q_0 \Delta F}{(\beta+1)^2 + Q_0'^2(\Delta F)^2} \approx j\frac{Q_0 \Delta f_0}{f_0} \quad (5)$$

where f_0 is the eigenfrequency, $\Delta f_0 = f_0 - f$, and $Q_0' = c\varphi/vg$ is the eigen-parameter of each cell. In Equation (5), it is easy to find that the reflection coefficient Γ_{local} is more or less than zero respectively when f_0 is detuned above or below the operating frequency f. Based on this principle, every cell can be tuned independently according to the sign of Γ_{local}.

According to equation (5), in equation (4) A is neglected and B presents the frequency detuning. If B is more than zero, the frequency is more than the design value, and to the contrary, frequency is a little less. This is the rule for the automatic tuning process, and the process is not stopped until B reaches zero.

In equation (4), the left side represents the local reflection$\Gamma_{local,n}$of the nth cell, however in the automatic tuning process, only reflection coefficient Γ_{port} of the input port can be measured, which is the sum of the local reflection coefficients of all cells including coupling cells and periodic cells. Because of the attenuation and reflection of each cell, these reflections are added with different weight, and this is expressed as equation (6),

$$\Gamma_{port} = \sum_1^n C_n \Gamma_{local,n} \quad (6)$$

For a traveling-wave accelerating structure, the attenuated power for the nth cell is [9]

$$\left(\frac{dP}{dl}\right)_n = -2\alpha_n P \quad (7)$$

whereα_n is the attenuation factor of the nth cell and P is the power flow of the nth cell, and equation (7)can be solved as

$$P_n = P_0 e^{-2\sum_1^n \alpha_n} = P_0 e^{-2\tau_n} \quad (8)$$

so that the weight from attenuation can be expressed as

$$\Gamma_{port} = \sum_1^n e^{-2\tau_n} \Gamma_{local,n} \quad (9)$$

In equation (9), the global attenuation for all cells from the input waveguide should be added, and equation (9) is revised as

$$\Delta\Gamma_{port} = |S11| e^{-2\tau_n} \Delta\Gamma_{local,n} \quad (10)$$

where|S11|is the global attenuation factor from the input waveguide, which is equal to the reflection coefficient of the input port when detuning the input coupling cell.

Besides the effect of attenuation, the reflection of each cell also occupies some part of the weight C_n in equation (6),however the reflection of each cell is random. So the reflection of each cell cannot be derived analytically, however it can be calculated by the post-processing of the forward and backward waves in equation (3).

For a constant impedance traveling-wave accelerating structure, equation (10) is modified as

$$\Delta\Gamma_{port} = |S11| \left(\frac{a_n}{a_1}\right)^2 \Delta\Gamma_{local,n} \quad (11)$$

wherea_n is the same as that in equation (3), and $\left(\frac{a_n}{a_1}\right)^2$ includes both the attenuation factor in equation (10) and the reflection from each cell. The square represents the integrated effect of both forward and backward waves.

For a constant gradient traveling-wave accelerating structure, equation (10) is modified as

$$\Delta\Gamma_{port} = |S11| \left(\frac{a_n}{a_1}\right)^2 e^{-2\tau_n} \Delta\Gamma_{local,n} \quad (12)$$

where $\left(\frac{a_n}{a_1}\right)^2$ only represents the reflection factor, and $e^{-2\tau_n}$ is the attenuated factor, which can be calculated from design parameters.

TUNING EXPERIMENTS

Based on the design in [3], the 1.1m C-band traveling accelerating structure has successfully accomplished cold RF testing and tuning, which is shown in Figure 3. It is necessary to point out that a constant impedance structure is adopted for the 1.1m C-band structure at last, which is different from the preliminary one, for simplifying the fabrication process. The 1.1m C-band structure is tested vertically so that the pull-bead can be placed into the structure easily without touching the inner surface of the structure.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Figure 3: Vertical cold RF test for the 1.1m C-band traveling accelerating structure.

Before any tuning, the field distribution on axis is measured, which is shown in Figure 4 left. In Figure 4 left, the field distribution including amplitude and phase is very confused, and it predicts that there are complicated standing waves on axis in the accelerating structure. After the analysis by LABVIEW code in Figure4 right, apparently there are three peaks around the 15th, 22th and 50th cells and it is detuned severely. Similarly, the phase advance per cell has large fluctuation, which is expected to be about 120 degrees. Based on this severe detuning of the C-band accelerating structure, several tuning iterations are proceeded necessarily.

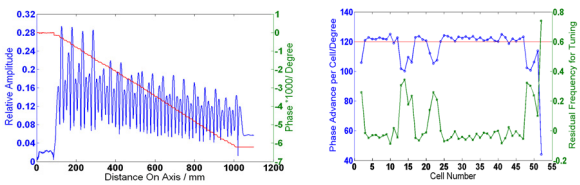

Figure 4: The field distribution and analysis before tuning

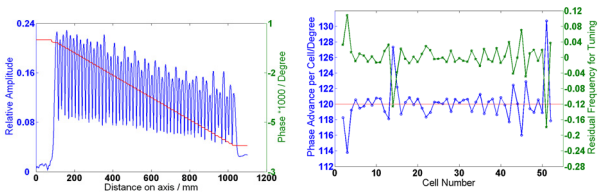

Figure: 5 The field distribution after 1st tuning.

After the first tuning phase, the field distribution and post-processing analysis are shown in Figure 5. In Figure 5 left the amplitude and phase on axis are distributed more smoothly with respect to that before tuning. In Figure 5 right, the phase advance mainly fluctuates between 118 and 122 degrees, and the amplitude of the residual frequency tuning per cell is mainly less than 0.05, which is within the permitted tolerance. However there is some slight detuning among cells, and after four water tubes are brazed, the last tuning phase eliminates the residual detuning finally.

After the final whole-structure tuning, the accelerating structure is almost matched, and the results are shown in Figure 6. According to the design target, the standing-wave ratio on axis is below 1.1 and the amplitude of phase advance fluctuation per cell is 2 degrees, corresponding to the baseline of 120 degrees per cell. In Figure 6 left, the field amplitudes in the center of cells are attenuated exponentially and the standing-wave ratio (SWR) on axis of the accelerating structure is below 1.1.In Figure 6 right, the phase advance per cell fluctuates between 118 and 122 degrees, and correspondingly the residual frequency detuning of all cells is from -0.04 to 0.04, which stays in the range of tolerance from -0.05 to 0.05. However on the both ends of accelerating structure in Figure 6 right, three cells on the each end are detuned out of the range above, which is used for the tuning of couplers.

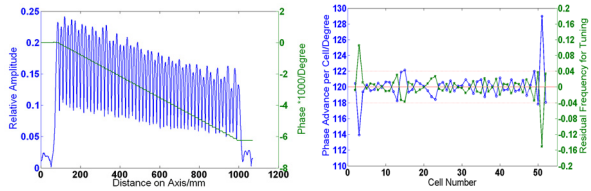

Figure 6: The field distribution after final tuning phase.

CONCLUSION

The nonresonant perturbation theory based on the bead pull measurement technique is an effective means for measuring and tuning a high gradient accelerating structure. The measurement system has been setup and successfully used in the R&D of a 1m long C-band traveling-wave accelerating structure for SXFEL. Now this prototype structure is ready for a high power RF test and since a 1.8 m long C-band constant gradient structure is under development, this measurement system becomes an indispensable tool in the accelerating structure developments.

ACKNOWLEDGEMENTS

We would like to thank Dr. Juwen Wang of SLAC for his helpful suggestion and useful discussion on the development of the measurement system, and appreciate our SINAP colleagues who join in the discussion on the nonresonant perturbation theory.

THE C-BAND RF PULSE COMPRESSION FOR SOFT XFEL AT SINAP

W.C. Wang, Z.T. Zhao, Q. Gu, SINAP, Shanghai, China

Abstract

A compact soft X-ray free electron laser facility is presently being constructed at Shanghai Institute of Applied Physics Chinese Academy of Science (SINAP) in 2012 and will be accomplished in 2014. This facility will be located to the shanghai synchrotron radiation facility (SSRF) which is a third generation light source in china. It requires a compact linac with a high-gradient accelerating structure for a limited overall length less than 230m.The c-band technology which is already used in KEK/Spring-8 linear accelerator is a good compromise for this compact facility and a c-and traveling-wave accelerating structure was already fabricated and tested at SINAP[1], and a c-band pulse compression will be required. There are some reasons, why RF pulse compression devices are quite useful to be applied in RF power supply of the soft XFEL. For it can enhance the peak RF power by expense of RF pulse length, so it will not increase the average power and at the same time reduce the total number of the klystron, it also increases the gradient of the accelerating structure, so we need the c-band pulse compressor. AND a SLED type RF pulse compression scheme is proposed for the C-band RF system of the soft XFEL and this scheme uses TE0.1.15 mode energy storage cavity for high Q-energy storage.

The C-band pulse compression under development at SINAP has a high power gain about 3.1 and it is designed to compress the pulse width from 2.5μs to 0.5μs and multiply the input RF power of 50MW to generate 160MW peak RF power, and the coupling coefficient will be 8.5. It has three components: 3-dB coupler, mode convertors and the resonant cavities. In this paper C-band pulse compression and some components for the c-band pulse compression will be described.

INTRODUCTION

The future c-band accelerator structure of SXFEL is supposed to operate at high acceleration gradient about 40MeV per meter, this requires very high peak RF power about 160MW at frequencies 5712MHz. So as to reduce the total number of the klystron and enhance the peak RF power, the RF pulse compression is needed.

RF pulse compression is one of the methods to compress the RF pulse length and at the same time increase the peak RF power that klystron deliver. RF pulse compression is based on the principle that the RF pulse is stored in a resonance cavity or a delay line and emitted within a short time to create the short RF pulse with high peak power and then deliver it into accelerating section. At present, several RF pulse compressions systems have been already utilized successfully in the s-band or c-band linear accelerator, such RF pulse compression, the SLAC Energy Double (SLED) was the first, it was successfully applied in SLC operation, and now SLED-I，SLED-II，SLED-III（coupled cavities），BPC，DLDS and VPM（BOC）were already developed.

BPC，SLED-II and DLDS use the delay line as the energy storage cavity, have the flat output, high power gain and high efficiency, but the delay line is long and not economical. SLED-III（coupled cavities）use coupled cavities as the energy storage cavity, reduce the length of the delay line, but the output power irregular. It is applied a complex amplitude modulation on the input RF power, it is hard to control the accuracy and the stable. SLED-I has the simple structure and work stable, but it has the low power gain and less efficiency and a decaying exponential output pulse shape, so the technology AM-PM is applied for the flat output pulse shape.

In the soft XFEL, the design goal of the pulse compression is to compress the pulse width from 2.5μs to 0.5μs and to multiply the input RF power of 50MW to generate 160MW peak RF power. To satisfy this requirement for the soft XFEL, we adopted a SLED type pulse compression as the c-band pulse compressor. This scheme use TE0.1.15 mode for the storage cavity to compress an RF pulse into a short square high peak-power pulse for the course of R＆D study of the soft XFEL. Figure 1 shows the schematic diagram. This scheme consists of one 3-db coupler, two mode convertors, and a pair of high-Q resonant cavities.

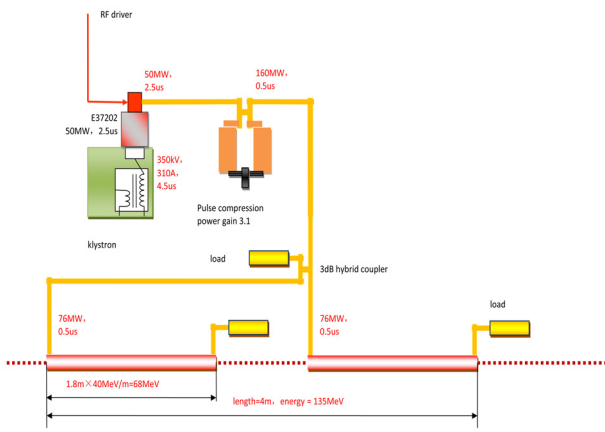

Figure1: C-band 50WM RF Scheme.

C-BAND PULSE COMPRESSOR

C-band Pulse Compressor

For the SLED type RF pulse compression, the expression of the power for the resonant cavity is[2]

$$T_C \frac{dE_e}{dt} + E_e = -\alpha E_K \quad (1)$$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

where $\alpha = 2\beta/(1+\beta)$, $T_c = \frac{2Q_L}{\omega}$, Ee: emitted wave from the coupling aperture, EK: reverse wave that is equal in magnitude to the incident wave Ei from the klystron.

The expression of the energy multiplication factor Vmax is

$$V_{max} = \gamma * e^{-\frac{T_a}{T_c}}[1-(1+g)^{1+v}] * [g*(1+v)]^{-1}\text{-}(\alpha-1) \quad (2)$$

where $\gamma = \alpha(2-e^{-T_1})$, $T_a = (L/gv_{g0})\ln[1/(1-g)]$ is the filling time for the structure.

g is the gradient of group velocity along accelerating structure, v=Ta/TC[ln(1-g)]-1.

Q value of the TE_{0115}mode[3]

TE_{0115}mode was chosen as the resonant cavity mode and the Q factor can be expressed as:

$$Q_0 = \frac{\lambda*[\upsilon_{mn}^2+(p\pi R/l)^2]^{\frac{3}{2}}}{2\pi\delta\left[2p^2\pi^2\frac{R^3}{l^3}+\upsilon_{mn}^2\right]} \quad (3)$$

Optimize the cavity diameter：

The relation among resonant frequency, mode and geometry dimensions can be expressed as:

$$\left(\frac{f_0 D}{c}\right)^2 = \left(\frac{\nu_{mn}}{\pi}\right)^2 + \left(\frac{pD}{2l}\right)^2 \quad (p \neq 0) \quad (4)$$

Considering the resonant frequency, the cost, unloaded Q value, it is suitable to choose the resonant cavity length is 429.18mm and the diameter is 152.6mm. And a tuner also is designed at the end of the each resonant cavities, it used to tune the frequency.

Table 1: Parameters of the pulse compression cavity

Operation frequency	5712MHz
mode	TE0.1.15
Cavity diameter	152.6mm

Iris diameter	48mm
Cavity length	15mm
Quality factor	181710
Power gain	3.1
Coupling coefficient	8.5

The results of simulation by CST are shown in Fig. 2.

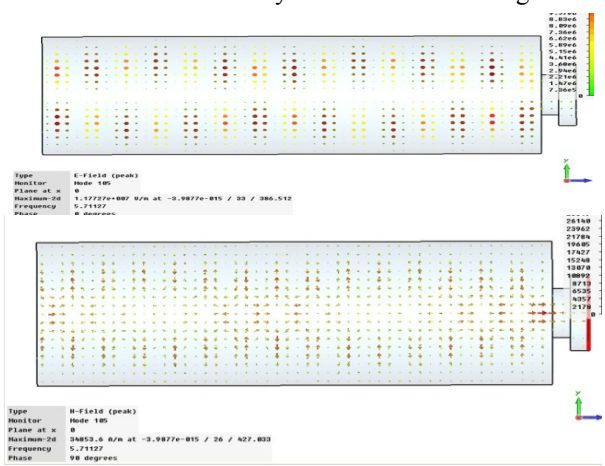

Figure 2: The cavity mode simulated by CST.

COMPONENTS FOR THE C-BAND PULSE COMPRESSION

3-dB Coupler Hybrid

3-dB coupler hybrid is an essential element to direct the flow of RF power for the RF pulse compression system. In the cavity type compressor, through this coupler an output RF power of the klystron is guided to two over coupled cavities, and waves from the each cavity are combined so as to add and transmitted to the accelerating structure. The value of the coupling depends on the width and the length of the coupling region. For 3-dB coupling, they were designed 76mm and 60mm, respectively.

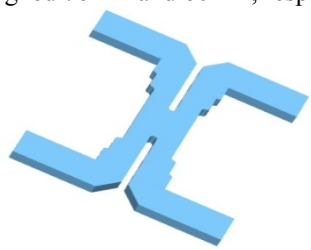

Figure 3: The 3-db hybrid coupling.

The distance of the coupling section L is a function of the width 2a as followings,

$$L = \frac{1}{4\left(\frac{1}{\lambda_{g10}}-\frac{1}{\lambda_{g20}}\right)} \quad (5)$$

Where $\lambda_{g10} = \frac{\lambda}{\sqrt{1-(\frac{\lambda}{4a})^2}}$; $\lambda_{g20} = \frac{\lambda}{\sqrt{1-(\frac{\lambda}{2a})^2}}$

Here we used a ladder type hybrid which has excellent divided ratio, phase condition, broad frequency response characteristics and the coupling is 3dB.

Table 2: Parameters of the 3-db coupler

Coupling region width	76mm
Coupling region length	60mm
First ladder length	176mm
First ladder depth	6.2mm
Second ladder length	124mm
Second ladder depth	13mm
Simulation coupling	S_{21},S_{31}=-3dB; S_{11},S_{41}<-30dB

The results of simulation by CST are shown in Fig. 4.

Mode Converter

Many modes are concentrated around the target TE0.1.nmode in the high-Q cavity of the RF Pulse Compressor. The high purity of the cylindrical TE_{01}mode must be needed to produce the designed Q-value and efficiency. Thus the many unnecessary modes can reduce the high Q-value and the efficiency if we directly connect the rectangular waveguide to the TE_{01}nmode cavity, so that a mode converter is applied between the 3-db coupler and the cavity to reduce unnecessary modes. The mode converter is shown in Fig. 5.

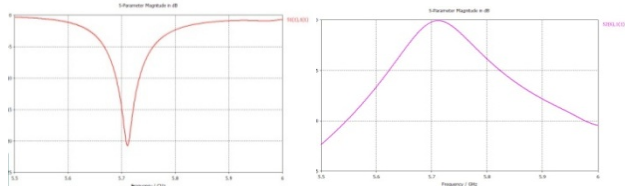

Figure 6: The simulation of the mode convertor.

CONCLUSION

In this paper we designed c-band pulse compression use TE_{0115} mode for the soft the SINAP SXFEL, and it will be fabricated in the future. And also some components for the c-band pulse compression are also designed. The low mode RF pulse comression cavity is fabricated in the SINAP.

RF PHOTOINJECTOR AND RADIATING STRUCTURE FOR HIGH-POWER THz RADIATION SOURCE

S.M. Polozov, T.V. Bondarenko,
National Research Nuclear University (MEPhI), Moscow, Russia.
Yu.A. Bashmakov, Lebedev Physical Institute of RAS (LPI), Moscow, Russia

Abstract

Sources of high-power electromagnetic radiation in THz band are becoming promising as a new method of a low activation introscopy. Research and development of accelerating RF photoinjector and radiating system for THz radiation source are reported. The photoinjector is based on disk loaded waveguide (DLW). Two different designs of accelerating structure were modelled: widespread 1.6 cell of DLW structure and travelling wave resonator structure (TWR). The resonant models of these structures and the structures with power ports were designed. Electrodynamics characteristics and electric field distribution for all models were acquired. Results of picoseconds photoelectron beam dynamics in simulated structures are reported. Designs of decelerating structures exciting Cherenkov radiation are based on corrugated metal channel or metal channel coated with dielectric. Analysis of radiation intensity and frequency band are presented.

INTRODUCTION

THz radiation is nowadays becoming promising in solving such vital problems as national security, biomedicine and in manufacturing processes control. In national security issue THz radiation can be used in introscopy systems. The definition of the weapons, explosives, drags and fissionable materials is the main aim of introscopy. The introscopy of cargo transport is much more complicated objective then passenger introscopy issue. The gamma, electron or neutron facilities are used in introscopy system including cargo introscopy at present. The compact electron or ion gun or accelerator is the basic element of such facilities. The main difficulty is the fact that it is necessary to use an electron linear accelerator (LINAC) which can derive the beam with 3-5 times energy variation. LINACs of this type are utterly complex facilities. All of gamma, electron or neutron facilities have a number of disadvantages as needs of environmental shielding and cargo activation.

High-power THz radiation source based on photoinjector and decelerating capillary channel is now one of the most discussable compact facilities providing monochromatic THz radiation of power high enough to be used for cargo introscopy [1].

Facility is based on two main parts: accelerating structure and decelerating radiating channel. Capillary is placed right after the accelerating structures and is made of copper with either dielectric coated inner surface or corrugated surface.

ACCELERATING STRUCTURES

1.6 cell DLW structure

Accelerating structure consists of two accelerators connected sequentially: 1.6 cell DLW and 9 cell TWR structure.First part of facility accelerating system is 1.6 cell standing wave accelerating structure (figure 1). This accelerating structure by itself comes artlessly as a photoinjector part of the accelerating system.

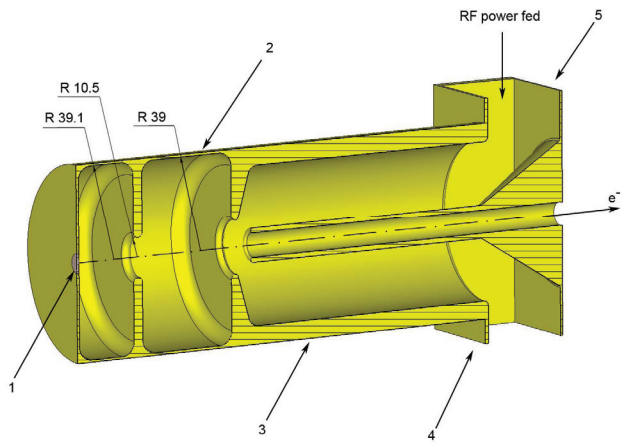

Figure 1. 1.6 accelerating structure: 1 – photocathode, 2 - resonator, 3 – coaxial wave type transformer, 4 – vacuum port, 5 – power input.

This accelerating structure operates on π mode and S-band frequency 2856 MHz (λ=105 mm). Resonant frequency of the structure was tuned to the desired value by means of cell radius variation. Iris profile was made with rounding to eliminate the possibility of breakdown. First cell length is 0.6 of full-sized cell to obtain maximum field amplitude in the center of the photocathode arranged in the cell's sidewall. Performance of the structures was also increased by rounding of shells edges. The rounding radius value was chosen to provide the highest possible shunt impedance and Q-factor.

Structure RF power input in organized by S-band standard rectangular waveguide with the coaxial coupler. RF power is fed into the structure through only one of the connected waveguides; another is used for structure field symmetry and will be applied for vacuum and other accompanying connections. This scheme provides high level of field symmetry in the system that leads to better quality of the accelerated beam.

This type of wave transformer differs from recently used RF power inputs in photoinjectors like ones in BNL Guns [2]. That type was exploiting the scheme of power

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

input through the coupling diaphragm directly into the full-sized cell of the structure in this wise fill cell was a wave transformer.

TWR structure

Travelling wave resonator is a type of ordinary linear accelerator structure with some additions. Basically the accelerating wave propagating in acceleration structure is travelling wave type but the trait that makes this system a resonator is energy recuperation coming out of interlocking RF power input with output and feeding power with directional coupler (figure 2). If the length of the TWR circuit is devisable to the generator wavelength, the magnitude of electromagnetic fields in TWR reaches its maximum and magnitude of the wave incoming to the load from the ring turns to minimum [3].

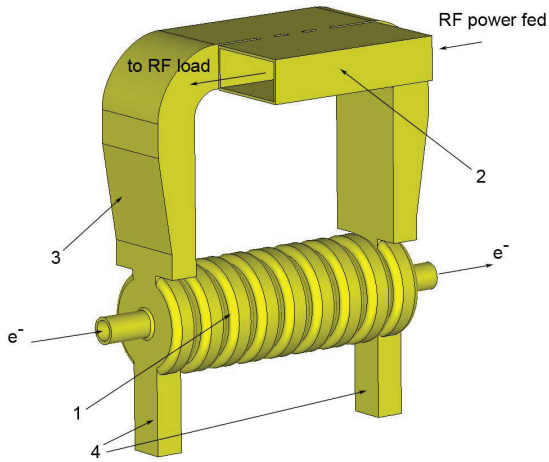

Figure 2. Travelling wave resonator structure: 1 – accelerating structure, 2 – directional coupler, 3 – TWR ring, 4 – vacuum ports.

TWR is based on 9 cell travelling wave S-band structure with $\pi/2$ operating mode. The optimal operation regime of the structure is critical mode. In this regime part of RF power is fed into the accelerating system through the directional coupler and fills in the power resistance losses in the resonators sidewalls. In this case the part of power that is not branched into the TWR ring is summed with the one from generator in the opposite phase and gives the minimal magnitude signal coming to the load. Two main parameters determining efficiency of TWR are the circuit power attenuation factor and the directivity factor of the directional coupler.

Directional coupler with narrow or wide side coupling represents the connection of two waveguides by coupling windows with space shift of quarter wavelength between the windows irradiating in the opposite directions of jointed waveguide. Directional coupler computation included receiving of required transfer coefficient in the forward direction of jointed waveguide C and simultaneously keeping transfer coefficient in the opposite direction of jointed waveguide $|\Gamma|$ below the certain level.

Three coupling window model was applied to provide high directivity level of directional coupler. Enlarging the number of coupling windows doesn't improve the directivity coefficient.

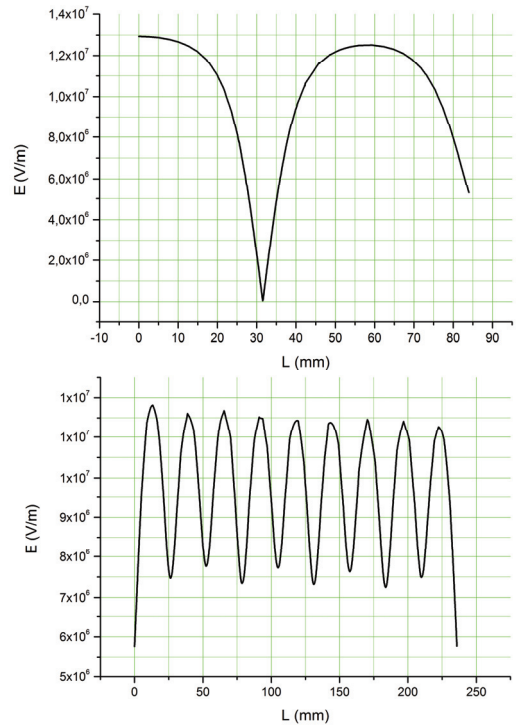

Figure 3. Electrical field magnitude plots at 1 MW power fed for 1.6 cell structure (upper) and for TWR structure (lower)

Taking into account part of the signal branching in the opposite direction and intensity attenuation factor, expression for the magnitude of electrical field spreading in TWR storage ring for critical mode can be written as:

$$A_{TWR} = \pm j \frac{1}{\sqrt{1-e^{-2\alpha_T}}} \frac{C-|\Gamma|}{C} A_{input}, \qquad (1)$$

here A_{TWR} - TWR circuit electrical field intensity magnitude, α_T - TWR ring signal intensity attenuation factor, A_{input} – RF generator signal intensity magnitude.

In considered case transition coefficient of directional coupler C=3.9% that equals to TWR ring decay coefficient at the 14 mm coupling window width, sidewall width between waveguides is 4 mm. Sidewalls width doesn't have much impact on directivity coefficient but ought to be wide enough to provide coupler ruggedness. Transfer coefficient in the opposite direction of TWR ring equals Γ=-48dB. Thus directivity coefficient of directional coupler is D=23dB. Using the formula (1) power in TWR multiplies 9 times vs. input power level.

BEAM DYNAMICS

Beam dynamics simulation in designed accelerating structures was done using BEAMDULAC-BL code

designed in laboratory DINUS of NRNU MEPhI [4]. The simulation was done with the following beam parameters: injection energy W_{inj}=5 eV, feeding RF power P=2.5MW, beam pulse current I=5 A, beam pulse charge Q=1 nC. Photoelectron beam initial radius is r=200 μm that corresponds to the laser spot of the same size focused on the cathode surface. This beam parameters values are similar to most of photoinjectors. The first accelerating section is fed by 1.5 MW and the second by 1 MW power.

The results of photoinjector beam dynamics investigation shows that at this value of RF power fed beam bunch can be accelerated to the energy of 1 MeV. The further acceleration of the beam in TWR section resulted in 5 MeV beam energy that meet the requirements for the beam in THz generation process.

Pencil-shaped and high brightness beam is necessary for Cherenkov THz generator to achieve that beam size preservation can be realized in accelerator using longitudinal magnet field focusing.

CHAPILLARY CHANNEL

Two types of channels could be used for generation of Cherenkov radiation: the conducting (metal) capillary coated by dielectric inside (see Fig. 4a) and the corrugated channel or grating surface also (Fig. 4b). The inner channel radius $d/2$ should be comparable to the wavelength, i.e. should be about 0.1 – 1 mm. The structure period t (the distance between of diaphragms) in the second case should also be comparable to the wavelength.

The main idea of using the capillary channel as a source for radiation lies in a principle of Cherenkov radiation. The phase velocity of the wave propagating inside the capillary channel is less than the electron beam velocity. So the beam propagating in such structure would induce the radiation with the frequency dependent on the channel dimensions.

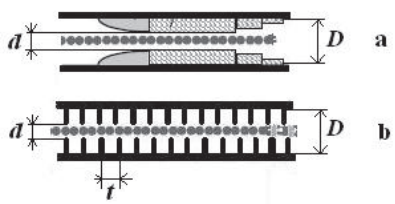

Figure 4. The conducting (metal) capillary coated inside by dielectric (a) and the corrugated channel or grating surface (b).

Different approaches can be estimated for achieving the induced power in the accelerated structures. One of the ideas is based on using the form-factor concept [5]. The decelerating structure parameters such as shunt impedance, Q-factor and group velocity are numerically investigated in terms of TM01 wave excited inside of the capillary. Then radiated power can be founded using the formula for the case of short burst mode when pulse repetition time is much longer than the beam length:

$$P = \frac{\omega}{4}\frac{r}{Q}\left|v_{group}\right| \cdot \left|\frac{q\Phi}{1-\beta_{group}/\beta}\right|^2, \qquad (2)$$

where ω - radiation resonant frequency, r – channel shunt impedance, Q – channel quality factor, q – bunch charge Φ - bunch form-factor, v_{group}, β_{group} - absolute and relative group velocity of the channel. For considered capillary channels Q is about 2000, β_{group} - 0.8 and r is around $3 \cdot 10^4$.

Another concept was discussed by Bolotovsky [6]. In this concept beam energy loss for the Cherenkov radiation is described by the force acting on the moving charge by the induced fields. Electron beam is presented as a point charge because beam sizes are smaller than induced radiation wavelength. The corrugated channel in this concept is presented as a small disk loaded. This method doesn't take in the account beam form factor.

Both cases show alike results for power radiated by the beam propagating in the channels. The goal was to achieve the radiation with 1 THz frequency. Channel length for both designs was 2 cm. Dielectric channel dimensions are: 300 μm channel radius and 30 μm teflon thickness. In case of corrugated channel transverse sizes appears to be smaller: 100 μm cell radius, 80 um diaphragm radius. For the stated above beam parameters the radiated power appears to be around 50 kW in the case of dielectric coated channel and 20 kW in case of corrugated channel in case of 1 nC beam charge and 5 MeV beam energy.

CONCLUSION

RF photoinjector and decelerating system were investigated for high-power THz generator. RF photoinjecr is based on two accelerating sections: 1.6 cell standing wave structure with coaxial power input and travelling wave section based on travelling wave resonator. Both are fed by S-band 2.5 MW magnetron. First is used to emit photoelectrons and to accelerate bunch to 1 MeV. Second is used for further acceleration to 5 MeV.

Decelerating channel can be based on two main concepts: corrugated metal channel and dielectric covered channel. Both are applicable for achieving high radiation power rates.

THE DEVELOPMENT OF TIMING CONTROL SYSTEM FOR RFQ

J. Bai, L. Zeng, S. Xiao, T. Xu
Institute of High Energy Physics, CAS, Beijing, 100049, P.R China

Abstract

In order to meet the need of RFQ accelerator, Timing extension hardware based on VME configuration has been developed. In the future, it will be used in the diagnostics system of CSNS. This paper introduces the function of Timing extension hardware, EPICS driver for Timing extension hardware and MEDM operator interface.

BACKGROUND

The core research of intense-proton beam accelerator is mainly concentrated in the field of beam loss control. Based on the intense-beam RFQ accelerator [1] which accelerates proton beam of 46mA pulse current to 35MeV at more than 7% duty factor, a beam line has been built. In order to do beam loss control experiment, many devices have been developed, one of which is Timing extension hardware. Timing extension hardware, as an important device in the running of RFQ accelerator, provides high accuracy and high stability timing trigger signals for the whole system. In the future, it will be used in the CSNS (Chinese Spallation Neutron Source).CSNS adopts EPICS [2] (Experimental Physics and Industrial Control System) as its software environment. So it is necessary to develop EPICS driver [3] for timing extension hardware.

INTRODUCTION OF TIMING EXTENSION HARDWARE

Timing extension hardware uses VME bus of A24 nonpriviledged data access address modifier [6]. It is listed below as fig. 1. Since A24 space is of predicable size 16MB, default window encompassing the full space is always provided. The A24 window is for VME bus address from 0x000000 to 0xffffff, which is usually mapped by VxWorks subroutine sysBusToLocalAdrs to local memory from 0xfa000000 to 0xfaffffff [6].

```
#define VME_AM_STD_USR_DATA     0x39    /* A24, nonpriviledged data access*/
```

Figure 1: Address Modifiers of A24 nonpriviledged data access

Timing extension hardware based on VME configuration is not only consistent with RFQ requirement, it but also avoids the disadvantage of original timing control system, achieving parameters remedy on line. When operators need to remedy parameters of original timing control system, they have to stop the accelerator and calculate the parameters according to the request of experiments, and then use dip switch to change the parameters. The whole process will last almost two hours and affect the efficiency, stability and continuity. Besides, Timing extension hardware based on VME architecture achieves utility of the same hardware to perform different functions by using reconfiguration of the FPGA, which enhances the flexibility of timing extension hardware.

Timing extension hardware has two types of functions [4]. One is providing primary timing signals for RFQ and secondary timing signals which divide frequency of primary timing signals for beam commissioning and RF system. The other is providing delaying or broadening timing signals according to the needs of various devices. In fact, the principle of these two functions is calculating clock signals. For example, primary timing outputs a timing pulse when it calculates the clock signal to the certain amount. Broadening hardware is triggered by timing signal and starts counting program. It will output a TTL pulse with the width of 3us when counting program reaches to the setting value.

Fig. 2 shows timing signals of RFQ, and the timing extension hardware is shown in Fig. 3.

DTYP

EPICS DRIVER FOR TIMING CONTROL SYSTEM

The functions of timing extension hardware achieve by single read or write register [5]. Table 1 is provided to give an outline about how records access registers step by step.

OPERATOR INTERFACE

The operator interface which is under development makes use of MEDM [7] (Motif Editor and Display Manager). With the interface of Timing control system, operator can chose system clock, logic of primary timing and secondary timing, delay or broaden of every channel and logic of every channel. Besides, primary timing, secondary timing, delay or broaden time of each channel can be set through the Interface. Fig. 4 is the operator Interface for Timing control system.

According to the control of interface, timing extension hardware can work normally.

ACKNOWLEDGEMENTS

The authors would like to thank the CSNS Control Group, Accelerator Center, Institute of High Energy Physics, CAS to provide the EPICS platform to work on and technical support.

MULTIPOLE FIELD EFFECTS FOR THE SUPERCONDUTING PARALLEL-BAR/RF-DIPOLE DEFLECTING/CRABBING CAVITIES*

S. U. De Silva[1,2#], J. R. Delayen[1,2],
[1]Center for Accelerator Science, Old Dominion University, Norfolk, VA 23529, USA.
[2]Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA.

Abstract

The superconducting parallel-bar deflecting/crabbing cavity is currently being considered as one of the design options in rf separation for the Jefferson Lab 12 GeV upgrade and for the crabbing cavity for the proposed LHC luminosity upgrade. The knowledge of multipole field effects is important for accurate beam dynamics study of rf structures. The multipole components can be accurately determined numerically using the electromagnetic surface field data in the rf structure. This paper discusses the detailed analysis of those components for the fundamental deflecting/crabbing mode and higher order modes in the parallel-bar deflecting/crabbing cavity.

INTRODUCTION

The parallel-bar/rf-dipole deflecting/crabbing cavity has been optimized from a rectangular-shaped design with cylindrical-shaped parallel bars into a design with a cylindrical-shaped outer conductor with trapezoidal-shaped parallel bars [1,2], named the rf-dipole cavity. The improved rf-dipole deflecting/crabbing cavity design operating in TE_{11}-like mode has attractive properties with low and balanced surface fields, high shunt impedance and well separated higher order modes (HOMs). The deflecting/crabbing mode is the lowest mode in the rf-dipole design.

Currently the rf-dipole design is being considered as one of the rf separator options for the Jefferson Lab 12 GeV upgrade and as one of the crabbing cavity options for proposed LHC luminosity upgrade operating at 499 MHz and 400 MHz respectively. A 750 MHz design is also being considered as a crabbing cavity for the proposed medium energy electron-ion collider (MEIC) at Jefferson Lab [3]. The first prototypes of the cylindrical-shaped 499 MHz and 400 MHz rf-dipole cavities (Fig. 1 (A) and (B)) are being fabricated and are in preparation for rf testing [4].

The 400 MHz crabbing cavity design was further modified into a square-shaped outer conductor (Fig. 1(C)) with fixed transverse dimensions of <295 mm, to meet the dimensional constraints of the LHC crabbing system. The design was further improved by curving the bar geometry at the beam aperture (Fig. 1(D)) to reduce the transverse field variation across the beam aperture.

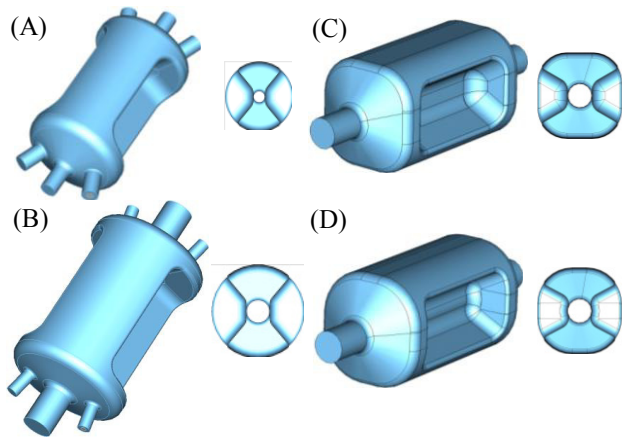

Figure 1: RF-dipole geometries and cross sections of (A) 499 MHz design, (B) cylindrical-shaped 400 MHz design, (C) square-shaped 400 MHz design and (D) square-shaped 400 MHz design with curved inner bar surfaces.

MULTIPOLE FIELD ANALYSIS

In the rf-dipole design, the field varies across the beam aperture off the beam axis generating a non-uniform transverse deflection. The field variation in x and y directions are shown in Fig. 2, for all the rf-dipole designs mentioned in Fig. 1.

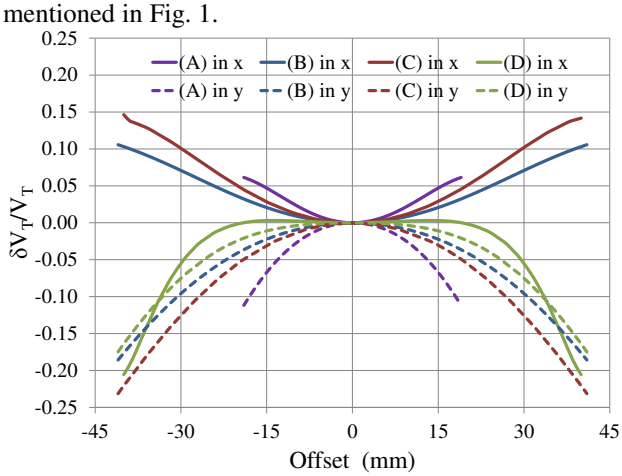

Figure 2: Normalized transverse voltage in x and y directions for designs (A), (B), (C) and (D) in Fig. 1.

The non-uniform transverse fields can generate higher orders of transverse momentum apart from the first order transverse momentum that corresponds to the deflecting or crabbing voltage. These higher order transverse multipole components may lead to perturbations in the beam. This paper presents the higher order multipole components present in the rf-dipole cavity and supressing of those components by modifying the geometry.

Calculation of Multipole Components

The fields in magnets are often expressed in terms of multipole components. The standard representation of multipole fields [5] can be expressed as,

$$B(r,\phi) = B_{ref}\sum_{n=1}^{\infty} a_n + ib_n \left(\frac{r}{r_{ref}}\right)^{n-1} e^{i(n-1)\phi} \quad (1)$$

where B_{ref} is the reference magnetic field at a given radius of r_{ref}.

Similarly, close to the beam axis, the electro-magnetic fields in an rf cavity within the beam aperture can be represented as given in Eq. 2. The symmetry in the rf-dipole cavities doesn't produce any skew components; therefore the fields can be represented as in Eq. 3.

$$E_z(r,\phi,z) = \sum_{n=0}^{\infty} E_z^{(n)}(z) r^n e^{jn\phi} \quad (2)$$

$$E_z(r,\phi,z) = \sum_{n=0}^{\infty} E_z^{(n)}(z) r^n \cos(n\phi) \quad (3)$$

The multipole field components $E_z^{(n)}(z)$ along the beam line can be obtained by using the Fourier series expansion of $E_z(r,\phi,z)$ as shown in Eq. 4.

$$E_z^{(n)}(z) = \frac{1}{r^n}\int_0^{2\pi} E_z(r,\phi,z)\cos(n\phi)\,d\phi \quad (4)$$

In rf cavities with time dependent rf fields, the higher order multipole components with time dependence can be given by $E_{acc}^{(n)}(z) = E_z^{(n)}(z)e^{j\omega t}$.

The higher order multipole components can be determined using the method given by A. Grudiev in Ref. [6]. The transverse momentum imparted by the higher order multipole field components (n>0) can be determined using the Panofsky Wenzel Theorem,

$$\begin{aligned} p_t^{(n)}(z) &= \frac{1}{c} r^{n-1}\int_{-\infty}^{\infty} F_t^{(n)} dz = -j\frac{q}{\omega}\int_{-\infty}^{\infty} \nabla_t E_z^{(n)}(z) e^{j\omega t} dz \\ &= -j\frac{q}{\omega} n r^{n-1}\int_{-\infty}^{\infty} E_{acc}^{(n)}(z) dz \end{aligned} \quad (5)$$

or by using the Lorentz Force,

$$\begin{aligned} p_t^{(n)}(z) &= \frac{1}{c} r^{n-1}\int_{-\infty}^{\infty} F_t^{(n)} dz \\ &= \frac{q}{c} r^{n-1}\int_{-\infty}^{\infty}\left[E_t^{(n)}(z)e^{j\omega t} + cB_t^{(n)}(z)e^{j\omega t}\right] dz \end{aligned} \quad (6)$$

The multipole components (b_n) are defined using the standard definition for magnets [6] as,

$$\begin{aligned} B^{(n)}(z) &= \frac{1}{qc} F_t^{(n)}(z) = j\frac{n}{\omega} E_{acc}^{(n)}(z) \left[T/m^{n-1}\right] \\ b_n &= \int_{-\infty}^{\infty} B^{(n)}(z) dz \left[T/m^{n-2}\right] \end{aligned} \quad (7)$$

These coefficients (b_n) can be used to determine the effect of higher order multipole components on beam perturbations [6].

Multipole Components for the RF-Dipole Cavity

The rf-dipole cavity has zero on axis longitudinal electric field, where the transverse deflection is given by both transverse electric and magnetic fields. The higher order multipole components can be determined using both the methods given in Eqs. 5 and 6. The $E_z(r,\phi,z)$ field data are obtained for each rf-dipole geometry using CST Microwave Studio, at three different radii within the beam aperture. A finer mesh as shown in Fig. 3 is used especially at smaller radii with a fixed number of points at each concentric cylinder.

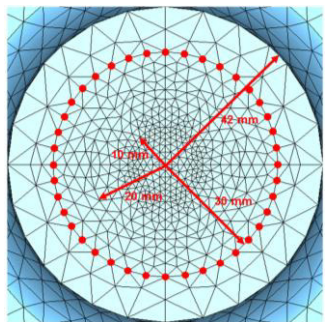

Figure 3: $E_z^{(n)}(z)$ of n = 1, 3 and 5 at r_0 = 1 cm, 2 cm and 3 cm for the cylindrical-shaped 400 MHz rf-dipole cavity.

The Fourier-decomposed field components of $E_z^{(n)}(z)$, $E_x^{(n)}(z)$ and $H_y^{(n)}(z)$ calculated using a MatLAB code at radii of 1 cm, 2 cm and 3 cm normalized to a transverse voltage (V_t) of 1 V are shown in Fig. 4, 5 and 6 for the cylindrical-shaped 400 MHz crabbing cavity. At radii closer to the beam axis the field data has higher noise content. Also, as the order increases, the noise content increases and becomes dominant over the field content. The rf-dipole cavity has components of order 2n for n = 1, 2, 3, etc. In the rf-dipole cavity the $E_z^{(n)}(z)\sin(\omega t)$ components corresponds to that of deflecting cavities and $E_z^{(n)}(z)\cos(\omega t)$ corresponds to the components related to crabbing cavities with a synchronous phase of $\phi_s = 90^0$. The higher order multipole components (b_n) can be determined by either using the Panofsky-Wenzel Theorem (Eq. 5) or using Lorentz Force (Eq. 6).

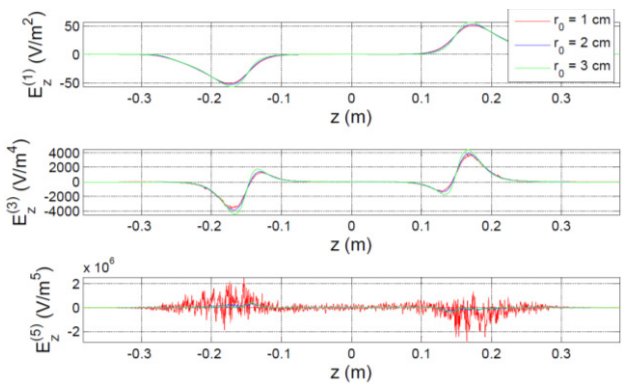

Figure 4: $E_z^{(n)}(z)$ of n = 1, 3 and 5 at r_0 = 1 cm, 2 cm and 3 cm for the cylindrical-shaped 400 MHz rf-dipole cavity.

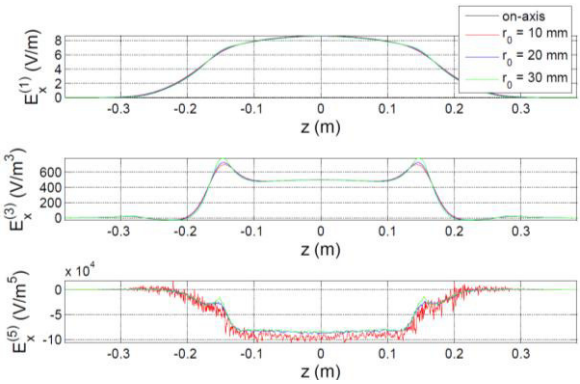

Figure 5: $E_x^{(n)}(z)$ of n = 1, 3 and 5 at r_0 = 1 cm, 2 cm and 3 cm for the cylindrical-shaped 400 MHz rf-dipole cavity.

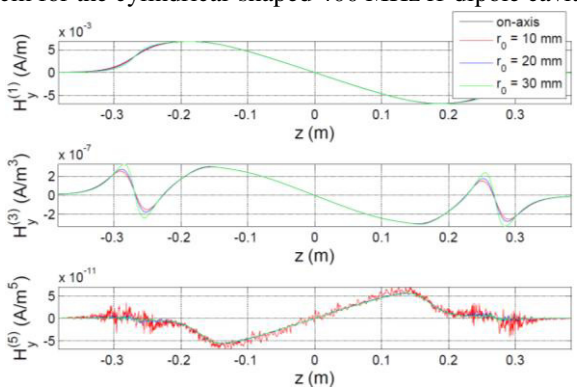

Figure 6: $H_y^{(n)}(z)$ of n = 1, 3 and 5 at r_0 = 1 cm, 2 cm and 3 cm for the cylindrical-shaped 400 MHz rf-dipole cavity.

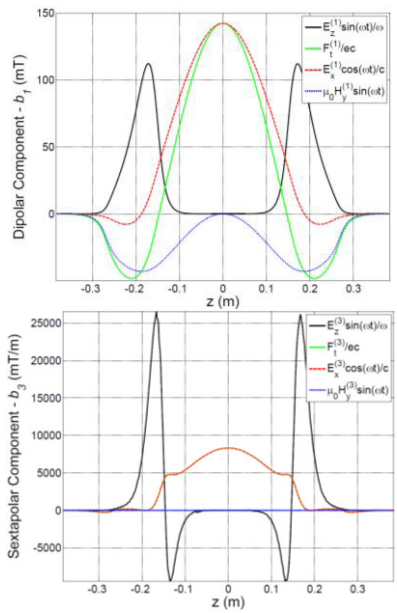

Figure 7: Dipolar and sextapolar field components of the 400 MHz cylindrical-shaped rf-dipole cavity.

The field components of the first two non-zero multipole components are shown in Fig. 7. The components $F_t^{(1)}/c$ and $E_{acc}^{(1)}(z)/\omega = E_z^{(n)}(z)\sin(\omega t)/\omega$ has different dependence on z, however gives the same b_1 when integrated along z, that corresponds to the transverse voltage given by the rf-dipole cavity.

The higher order multipole components of the fundamental deflecting/crabbing mode are shown in Table 1, for the four rf-dipole designs shown in Fig. 1. As seen by the field profiles the b_n for n = 0, 2, 4, 6… are zero. All the higher order multipole components are normalized to a transverse voltage (V_t) of 1.0 MV. Comparing the 400 MHz crabbing cavities of cylindrical-shaped outer conductor, the 400 MHz cavity with a square shaped outer conductor has higher multipole components. The square-shaped 400 MHz rf-dipole cavity with curved bar surfaces has reduced b_3 and b_5, but has higher b_7 compared to the other 400 MHz designs.

Table 1: Multipole components for the rf-dipole cavity designs shown in Fig. 1.

	(A)	(B)	(C)	(D)	Units
V_z	0.0	0.0	0.0	0.0	MV
V_t	1.0	1.0	1.0	1.0	MV

b_2	0.0	0.0	0.0	0.0	mT
b_3	8.3×10^2	3.0×10^2	4.1×10^2	1.0×10^2	mT/m
b_4	0.0	0.0	0.0	0.0	mT/m^2
b_5	$-5..8\times10^5$	-4.6×10^4	-4.1×10^4	-2.2×10^4	mT/m^3
b_6	0.0	0.0	0.0	0.0	mT/m^4
b_7	-7.1×10^8	-1.03×10^7	-2.0×10^7	-6.9×10^7	mT/m^5

CONCLUSION

The higher order multipole components were calculated for the rf-dipole cavity designs of different geometries. The modified square-shaped 400 MHz cavity with curved bar surfaces has improved lower order multipole components. The values of the multipole components are comparable to standard magnets in a beam line. The rf-dipole geometry requires further optimization in suppressing the dominant multipole components, and therefore needs to be considered as a design optimization parameter.

COMPACT SUPERCONDUCTING CRABBING AND DEFLECTING CAVITIES*

S. U. De Silva[1,2#]
[1]Center for Accelerator Science, Old Dominion University, Norfolk, VA 23529, USA.
[2]Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA.

Abstract

Recently, new geometries for superconducting crabbing and deflecting cavities have been developed that have significantly improved properties over those of the standard TM_{110} cavities. They are smaller, have low surface fields, high shunt impedance and, more importantly for some of them, no lower-order-mode with a well-separated fundamental mode. This talk will present the status of the development of these cavities.

INTRODUCTION

Primarily the crabbing and deflecting structures are used to restore luminosity in particle colliders or in separating a single beam into multiple beams. The crabbing concept was initially proposed by R.B. Palmer for collider rings [1] and was later proven for linear colliders [2] as well. The applications of crabbing and deflecting cavities are not limited to the above-mentioned applications but also can be used in many applications for beam diagnostics, emittance exchange, in generating compressed x-ray beams etc. Some of the potential applications at present are the deflecting cavity needed for the Jefferson Lab 12 GeV upgrade [3] to separate the maximum energy beam into the three experimental halls and the deflecting cavity system required for the multi experimental project under Project-X [4]. One of the crabbing applications is the LHC luminosity upgrade that requires a crabbing system for vertical and horizontal crossing at the integrations regions of IP_1 and IP_5 [5].

The stringent dimensional constraints set by these current applications especially operating at low frequencies demands the design and development of compact crabbing and deflecting cavities. Compared to the crabbing and deflecting cavities operating in TM_{110} these compact designs that has been developed have improved properties with low surface fields, high shunt impedance. Most of the designs have no lower order modes (LOMs) with a widely separated higher order mode (HOM) spectrum.

The First Superconducting Deflecting Cavity

The early research in superconducting crabbing and deflecting structures was done in 1970s where the first superconducting rf deflecting cavity as shown in Fig. 1

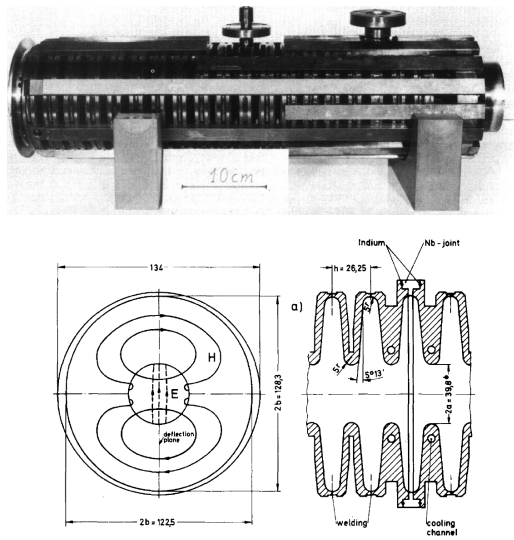

Figure 1: 19-cell end section of the 2.865 GHz rf separator cavity (top) and bi-periodic TM_{110} operating mode (bottom).

was designed and developed in KfK, Karlsruhe in collaboration with CERN [6]. The 2.865 GHz, 104-cell cylindrical-shaped standing wave rf particle separator shown in Fig. 1 installed at CERN in 1977 was capable of delivering a deflection in the vertical plane. The rf separator driven at 1.8 K, in a bi-periodic TM_{110}-type mode (Fig. 1) was in operation until 1981.

The First Superconducting Crabbing Cavity

The first crabbing cavity system was developed and installed in 2007 at KEK [7] for the KEKB electron-positron collider. The crabbing cavity shown in Fig. 2, operating in TM_{110} mode at 508.9 MHz was the only crabbing cavity system that has been in operation in a particle collider until 2010 after the installation in 2007.

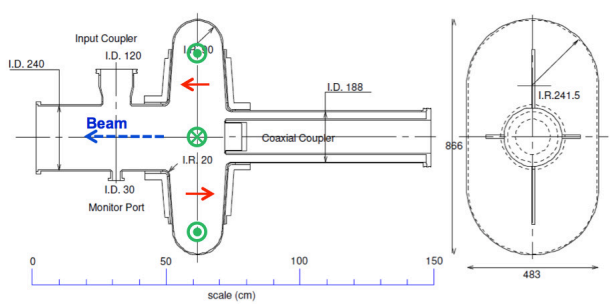

Figure 2: Superconducting 508.9 MHz KEK crabbing cavity.

The KEK crabbing cavity has a squashed elliptical geometry in order to separate the two polarizations of the TM_{110} mode. Since the TM_{110} mode is not the lowest mode in the cavity the crabbing cavity system has larger dimensions to that of a TM_{010} mode of the same frequency and was also required to have a complex higher order mode (HOM) damping scheme in order to damp the lower order mode (LOM) and near by HOMs that were close to the operating crabbing mode. The properties of the KEK crabbing cavity are listed in Table 1. The squashed elliptical geometry at 508.9 MHz operating frequency has higher surface magnetic fields with low shunt impedance.

COMPACT CAVITY DESIGNS

The standard crabbing and deflecting cavities with elliptical geometries operate in TM_{110} mode, which is not the lowest mode in these geometries. Also the squashed elliptical have very large structures at low frequencies. The current compact designs operate in TE or TEM like modes, where the deflection is given by either the electric field or by both the electric and magnetic fields. Some of those compact superconducting crabbing and deflecting cavity designs are

- 4-Rod Cavity by University of Lancaster and Jefferson Lab

- Parallel-Bar Cavity/RF-Dipole Cavity by Old Dominion University and SLAC Accelerator National Laboratory

4-Rod Cavity - U. of Lancaster/Jefferson Lab

The 400 MHz superconducting 4-rod crabbing cavity [8] is an adaptation of the 499 MHz normal conducting rf separator designed by C. Leemann and C.G. Yao at Jefferson Lab for separating the 6 GeV beam into the three experimental halls in the beam switchyard area [8]. The rf separator is a two cell design as shown in Fig. 3, with each cell of ~λ/2 length and diameter.

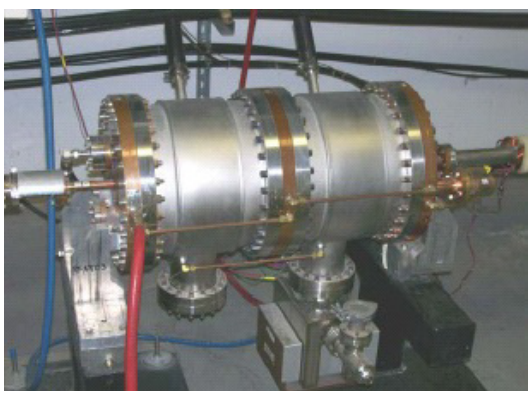

Figure 3: Normal conducting 499 MHz 4-rod rf separator cavity at Jefferson Lab.

The normal conducting 4-rod cavity has a rod configuration that gives 4 fundamental modes, with the electric field configuration shown in Fig. 4. The top left field configuration corresponds to the accelerating mode, which is the lowest mode in the design. The next mode is the deflecting/crabbing mode with the field configuration shown in bottom left of Fig. 4 with the magnetic field circulating around the rods near the end plates. In this geometry both electric and magnetic fields contribute to the net deflection.

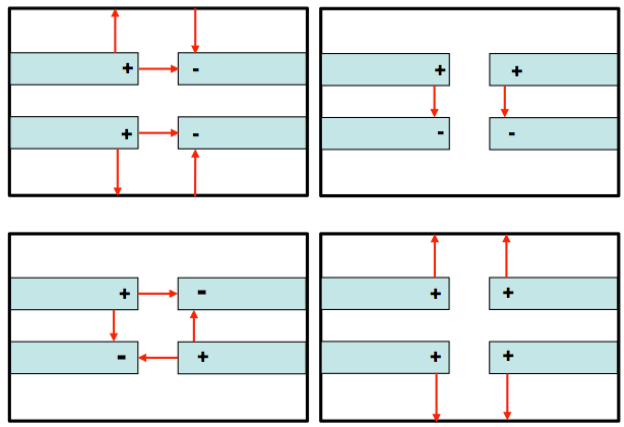

Figure 4: Electric field configuration of the 4 fundamental modes in the 4-rod geometry.

The superconducting 4-rod cavity design (Fig. 5) [9] adapted from the normal conducting design has improved bar geometry and outer conductor that gives a compact design with low surface electric and magnetic fields. The rods are further curved to suppress the higher order multipole components in the cavity.

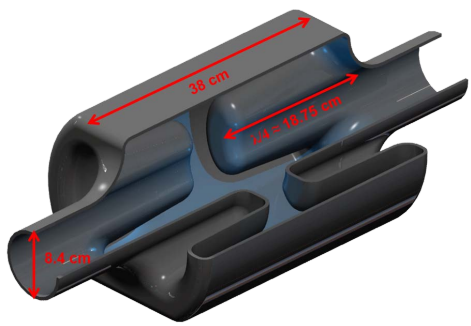

Figure 5: Superconducting 400 MHz 4-rod cavity design from University of Lancaster/Jefferson Lab.

The properties of the superconducting 4-rod cavity are shown in Table 1. This design has very high transverse [*R*/*Q*] therefore high shunt impedance compared to other compact crabbing and deflecting cavities. However the LOM at 375 MHz present close to the fundamental operating mode and the low separation between the operating mode and the next HOM as shown in the HOM spectrum in Fig. 6 require a complex damping scheme in order to damp these modes. The compact crabbing and deflecting structures have a HOM configuration with modes giving a net deflection in horizontal direction or in vertical direction and accelerating modes as shown in Fig. 6. Additionally in the 4-rod cavity there are no hybrid modes present in the geometry.

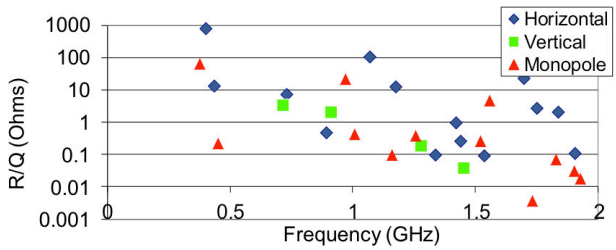

Figure 6: HOM spectrum of the 4-rod crabbing cavity.

Quarter-Wave Cavity - BNL

The standard quarter-wave cavity is modified into a crabbing and deflecting cavity utilizing the strong reentrant shape that gives a TEM field configuration near the outer conductor [10]. However the quarter-wave cavities have a strong on axis longitudinal electric field component that gives rise to an accelerating mode, present within the fundamental deflecting/crabbing mode. The quarter-wave design is modified with a pedestal at the bottom of the cavity to suppress the accelerating field component as shown in Fig. 7 [11]. The length of the longer pedestal at the top of cavity controls the frequency of the design. As shown in Fig. 7 the quarter-wave geometry at 400 MHz is optimized to reduce the surface fields and minimize the longitudinal accelerating component present in the cavity.

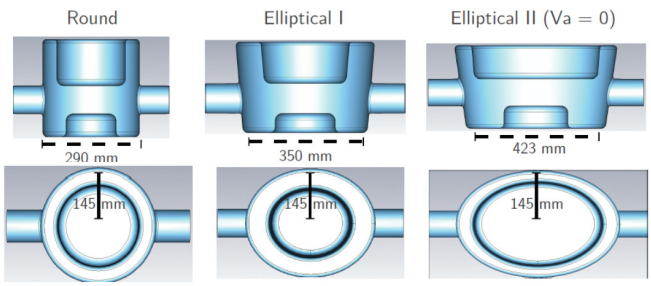

Figure 7: Superconducting 400 MHz quarter-wave deflecting/crabbing cavity by BNL.

The electric and magnetic field content of the quarter-wave crabbing cavity is shown in Fig. 8.

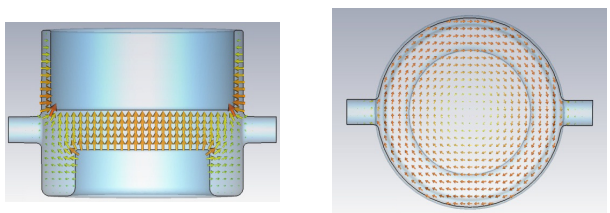

Figure 8: Electric field (left) and magnetic field (right) content of the 181 MHz quarter-wave crabbing cavity designed for eRHIC [11].

The quarter-wave cavity has two design options with the initial asymmetric geometry and a symmetric geometry to completely eliminate the longitudinal accelerating component as shown in Fig. 9. Compared to the asymmetric cavity the symmetric cavity doesn't have a longitudinal electric field component, however has a reduced mode separation between the fundamental deflecting/crabbing mode and the next HOM. The properties of the asymmetric and symmetric quarter-wave cavities are shown in Table 1. The symmetric design has improved surface fields and transverse [R/Q] however has smaller shunt impedance due to the decreased geometrical factor.

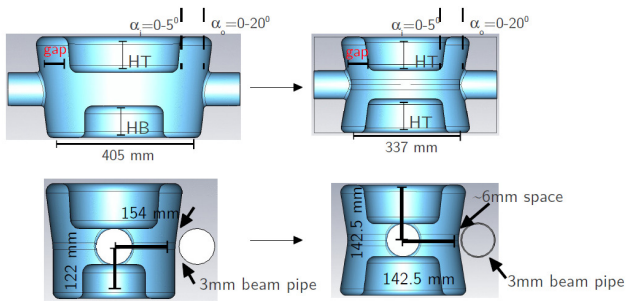

Figure 9: Asymmetric and symmetric 400 MHz quarter-wave crabbing cavities.

The HOM spectrum [8] of the asymmetric quarter-wave cavity is shown in Fig. 10, with a similar mode configuration described in the 4-rod cavity. However the asymmetric cavity also has hybrid modes present in the geometry. One of the attractive features in this design is the absence of any lower order modes.

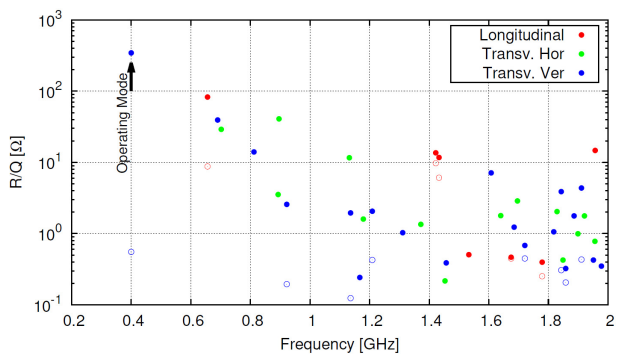

Figure 10: HOM spectrum of the asymmetric quarter-wave crabbing cavity [12].

Parallel-Bar and RF-Dipole Cavity - ODU/SLAC

The parallel-bar cavity [13] with a rectangular outer conductor with cylindrical-shaped bars operating in a TEM-like mode is being evolved into a cylindrical-shaped design with trapezoidal-shaped bar geometry [14] (Fig. 11). The latter design named rf-dipole cavity operates in a TE_{11}-like mode, where the main contribution to the net deflection is given by the transverse electric field.

A similar design was proposed by Zenghai Li at SLAC named the ridged waveguide cavity as shown in Fig. 12 [11] operates in TE_{11}-like mode. Currently ODU and SLAC are collaborating on designing a 400 MHz compact crabbing cavity. Currently the rf-dipole cavity is considered as the 499 MHz rf separator for the Jefferson Lab 12 GeV upgrade, as one of the crabbing cavity

options for the LHC luminosity upgrade operating at 400 MHz, and as the 750 MHz crabbing cavity for the medium energy electron ion collider (MEIC). The field profile of the rf-dipole cavity is shown in Fig. 13.

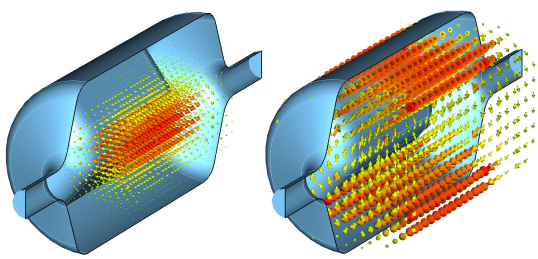

Figure 13: Electric field (left) and magnetic field (right) content in the 499 MHz rf-dipole cavity.

The properties of the 499 MHz and 400 MHz rf-dipole cavities are given in Table 1. The inner bar height and the angle of the trapezoidal shaped bars connecting to the outer conductor allows the rf-dipole design to have both reduced surface electric and magnetic fields. Therefore an rf-dipole cavity can be designed at a given design frequency and beam aperture, with a balanced ratio of peak surface magnetic field to the peak surface electric field as required by the application.

The HOM spectrum of the rf-dipole cavity is shown in Fig. 14. The rf-dipole cavity has no low order modes and the HOMs are well separated.

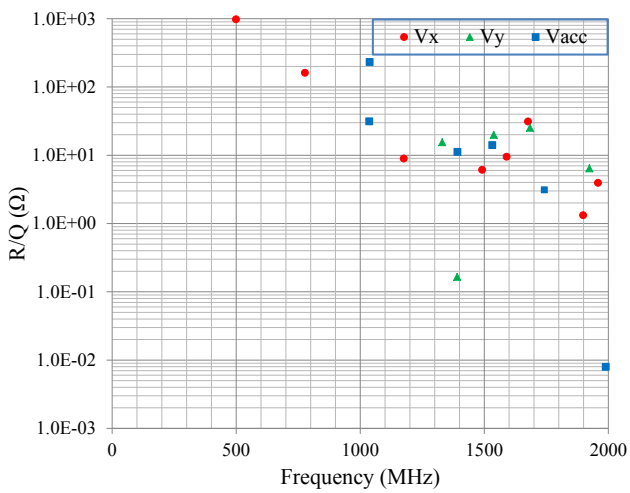

Figure 14: HOM spectrum of the 499 MHz rf-dipole cavity.

The rf-dipole design can be reduced into a more compact design with fixed transverse dimensions with a square-shaped outer conductor as shown in Fig. 15 where

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the frequency of the design is controlled by the curvature of the edges of the cavity. The rf-dipole design is further modified with curved trapezoidal-shaped bar geometry to suppress the higher order multipole components.

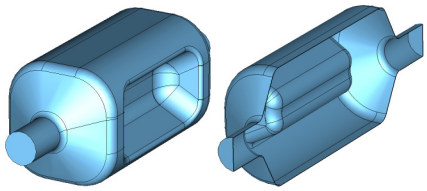

Figure 15: Square-shaped rf-dipole cavity with flat trapezoidal-shaped bar geometry (left) and with curved bar geometry (right).

CAVITY FABRICATION

First prototypes of some of the compact deflecting and crabbing cavities have already being fabricated. Fig. 16 shows the fabricated cavity designs. The prototypes of the 400 MHz 4-rod cavity, the 400MHz and 750 MHz rf-dipole cavities are fabricated at Niowave Inc. and the 499 MHz rf-dipole cavity is currently being fabricated at Jefferson Lab.

Figure 16: Prototype of the 400 MHz 4-rod cavity (top left), 400 MHz (top right), 400 MHz (bottom left) and 750 MHz (bottom right) rf-dipole cavities.

CONCLUSIONS

The development of compact deflecting/crabbing cavities was in response to the strict dimensional requirements in some current applications. All these compact designs have attractive properties in meeting the requirements. The low and balanced surface fields and high shunt impedance in these compact superconducting crabbing and deflecting cavities make them very attractive designs compared to the standard cavities operating in TM_{110} mode. The absence of lower order modes and wide separation in the higher order modes in most of the designs reduces the lower and higher mode damping complexity.

The 4-rod cavity design uses coaxial type couplers in damping the LOM and HOMs. The quarter-wave cavity design uses magnetic loop type couplers placed at the bottom of the cavity to damp the HOMs. The rf-dipole cavity is considering both the options of using the waveguide or a coaxial high-pass filter type coupling in damping the HOMs. Further studies are done on these compact cavities on addressing the important rf-related issues such as multipacting, mechanical analysis, field non-uniformity etc. The fabricated prototypes are in preparation for rf testing.

Soreq NRC Yavne 81800, Israel

Abstract

The Soreq Applied Research Accelerator Facility (SARAF) is built as a user facility. An intense fast neutrons source, a thermal neutrons source and apparatuses for production of isotopes for basic and applied research will be available at the end of construction, foreseen in several years. SARAF is based on a high intensity CW proton / deuteron RF superconducting linear accelerator. Several novel technologies are used in order to build this demanding linac. To reduce technological risks, the construction was divided in two Phases. Phase-I was constructed in order to test and characterize the novel technologies and is in routine operation since 2010. SARAF phase-I, with its single 6 half-wave resonators separated vacuum cryomodule, is the first high current, superconducting low-beta linac in operation and it is presently delivering CW mA proton beams for target developments. Phase-II of this linac will allow acceleration up to 40 MeV and 5 mA CW proton and deuteron beams. Phase-II is now under conceptual redesign. The project status, the operational experience and the future goals of SARAF are described and discussed in this paper.

INTRUDUCTION

System Requirements

The goals of the Soreq Applied Research Accelerator Facility (SARAF) are: 1) to enlarge the experimental nuclear science infrastructure and promote research in Israel, 2) to develop and produce radioisotopes for bio-medical applications and 3) to modernize the source of neutrons at Soreq and extend neutron based research and applications [1,2]. SARAF, when it fulfils its goals, is intended to replace the aging research reactor in Soreq. These goals define the requirements from the accelerator. The requirements were optimized to fulfil all of the above goals, within domestic cost constraints. Production of isotopes for radiopharmaceuticals is mainly done by tens of MeV protons, so this is a basic requirement. Variable energy protons allow optimizing the production yield, while minimizing parasitic isotopes production. Deuterons have two main advantages in isotopes production; the production yield in the (d,2n) reaction is significantly higher than the (p,n) reaction for several targets with mass higher than 100 a.m.u [3]. In addition, at tens of MeV, the neutron yield of deuterons is significantly higher than of protons bombarding the same target [4].

Although linac based neutrons sources are usually based on high energy proton based spallation reactions [5], for tens of MeVs projectiles the neutron yield of deuterons on light element targets is higher by more than a factor of 3 with respect to spallation.

For example, while using a beryllium target, deuterons of 2 mA at 40 MeV, or 5 mA at 25 MeV, are enough to generate a thermal neutron flux that is equivalent to the flux available at the image plane of the neutron radiography apparatus at the Soreq IRR1 5 MW reactor [6].

Tens of MeV deuterons on light element targets generate fast neutrons with a forward flux and neutron energy peaked around the beam energy divided by 2.5 [4]. Such a spectrum is ideal to produce isotopes using (n,2n), (n,p), (n,α) and (n,f) reactions and therefore open new and interesting opportunities for basic and applied research. These reactions are the basis for niche intense radioactive beams at SARAF Phase-II [7,8]. For these reactions, the total amount of fast neutrons is two orders of magnitudes lower than in the spallation reaction. However, the neutron flux in the relevant range for these reactions (5-25 MeV) is higher by an order of magnitude (Fig. 1). The sources of this advantage are the low energy deuteron range in the target, which is shorter than spallation protons by an order of magnitude and the forward peaked structure of the stripping reaction.

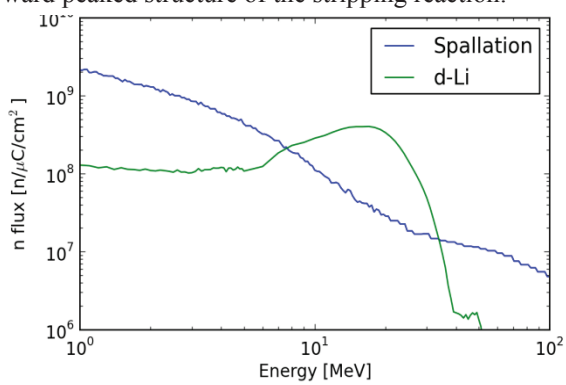

Figure 1: Forward neutron spectra comparison between 40 MeV deuterons on lithium (SARAF/IFMIF [9] like) and spallation 1400 MeV protons on tungsten (ISOLDE) [10]. The spectra were measured and simulated 8 cm downstream the targets at zero degrees.

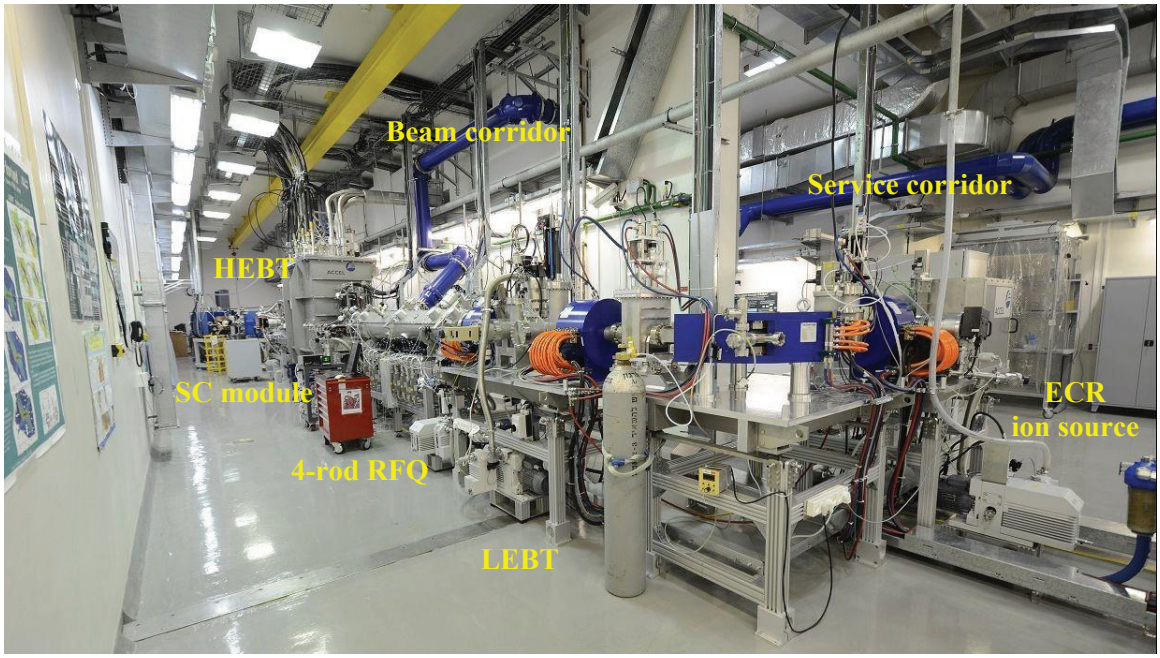

Figure 2: Phase-I 4 MeV protons and 5 MeV deuterons linac in the 4.5 m W, 5 m H and 25 m long beam corridor.

The range of tens of MeVs protons or deuterons in matter is several millimetres, so the power density developed in a tens-of-kW irradiation target is signify-cantly higher than in a MW spallation target. This requires development of new types of targets, based on both solid [11, 12] and liquid metal [13, 14], and force the linac to deliver CW beams in order to avoid a high thermal load in the targets. It also requires developing special beam and target diagnostics and a procedure to slowly ramp the beam intensity on the targets.

System Specifications

The beam specifications that cover all the above requirements are summarized in Table 1.

Table 1: SARAF Linac Top-level-requirements

Parameter	Value	Comment
Ion Species	Protons/Deuterons	$M/q \leq 2$
Energy Range	5 – 40 MeV	Variable energy
Current Range	0.04 – 5 mA	CW (and pulsed)
Operation	6000 hours/year	
Maintenance	Hands-On	Low beam loss

The demands for variable energy, proton and deuteron currents in the mA range and low beam loss that meets the definition of a hands-on maintenance are met only by a superconducting RF linear accelerator. Independently phased cavities are needed in order to allow variable energy at the exit of the linac and efficient acceleration of more than one ion species. Superconducting cavities are needed for large beam apertures that moderate beam loss.

Phase-I of the SARAF linac (Fig. 2) is composed of a 20 keV/u, 7 mA, 0.2 π mm mrad norm. rms emittance ECR ion source + LEBT [15], a 176 MHz, 4 m long, 250 kW, 4-rod RFQ [16,17,18], a 65 cm long MEBT and a 4.5 K 2.5 m long superconducting module housing 6 β_0=0.09 bulk Nb HWRs, 0.85 MV each and 3 6T solenoids in separated vacuum [19, 20, 21, 22]. The Phase-I linac routinely accelerates 1 mA CW protons up to 4 MeV and 10% duty factor deuterons up to 5 MeV. The design and commissioning of the acceleration components and the operation of the entire machine [23, 24] and the 13 m long HEBT line [25] were published in recent years. The next section describes in detail additional beam tuning issues and technical challenges.

BEAM OPERATION

Several beam-on-target experiments were performed last year with proton and deuteron beams of various energies and intensities. Proton beams at the highest available energy of ~3.9 MeV were mainly used for the tests of thin (~25μm) foil targets cooled by liquid metal [11, 12]. The thin foil targets are delicate and there were several incidents of targets being damaged. Following the insight gained from the first experiments, numerous improvements of the target arrangement and beam diagnostics quality were implemented. Initial tuning is performed a 10^{-4} duty cycle pulsed beam on a quartz viewer. Next, the duty cycle is increased to 10^{-2} and the beam position is verified on a thin Tantalum foil. Then, the first solenoid at the LEBT is defocused and the LEBT aperture is closed in order to moderate the CW beam current. The CW beam intensity is ramped up by two orders of magnitude by refocusing this solenoid and reopening the aperture. We found that it is important to ramp the beam intensity without moving its centre on target and without changing the beam distribution shape. To first order, such a ramping procedure does not change the beam distribution on the target. The target surface temperature is tracked using a pyrometer and an infrared (IR) camera. It was found that, in these targets, the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

transverse spatial variation of the temperature is in the order of a square mm, so the beam tune and temperature measurements are performed with mm resolutions.

For 1 mA beam tests, we use beam dump that consists of a 250 micron Tungsten sheet fused to a water cooled cooper plate. A tungsten beam dump is chosen for Phase-I since up to 10 MeV, no activation is induced and moderated neutron radiation is expected. After a few irradiation hours of a 3 MeV 1 mA proton beam, the tungsten surface blisters (Fig. 3). The protons beam (hydrogen) implementation depth is ~30 μm inside the tungsten. The hydrogen pressure blows up the tungsten surface and a hydrogen pressure peak is measured in a nearby residual gas analyser (RGA).

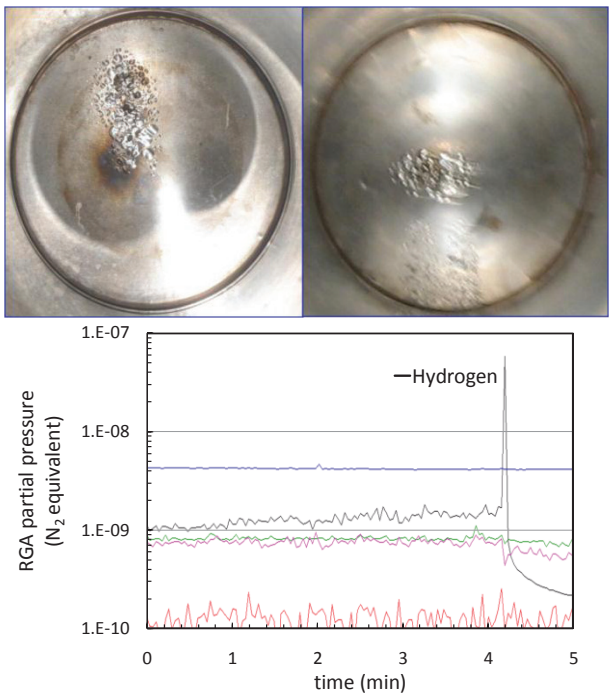

Figure 3: Top - Two 150 mm diameter Tungsten beam dumps after 8 hours of irradiation by 1 mA CW protons at 3 MeV. Bottom - Hydrogen blistering is well presented and detected using a residual gas analyser.

BEAM CURRENT TECNICAL LIMITATIONS

There were, and still are, a few technical issues that limit the beam current below the design value of 2 mA. The cavity sensitivity to helium pressure, calculated to be 16 Hz/mbar, was measured to be 56 Hz/mbar [20]. Three sub-components; the RF coupler, the RF amplifier and the tuner are affected.

Piezo Tuners Upgrade

The cryogenic system ±1.5 mbar pressure variation is manifested by frequency detuning that easily exceeds the cavities loaded bandwidth of 130 Hz. This detuning brings forth challenging demands on the cavities' tuners. The tuners include a coarse tuning stepper motor and a fine tuning piezo electric actuator (Pst150 [26]). In 2009, a dramatic reduction of the actuators range was observed, leading to the replacement of the actuators by modified ones [22]. In 2011 the piezo actuators suffered again from significant reduction of the tuning ranges (Fig. 4). During the winter maintenance period, the tuners were replaced by high voltage piezo actuators (Pst1000 [26]), which operate at 800 V and have superior mechanical strength. A smaller deterioration slope of the tuning range has been observed (Fig. 4) after this modification.

RF High Power Amplifiers (HPA) Upgrade

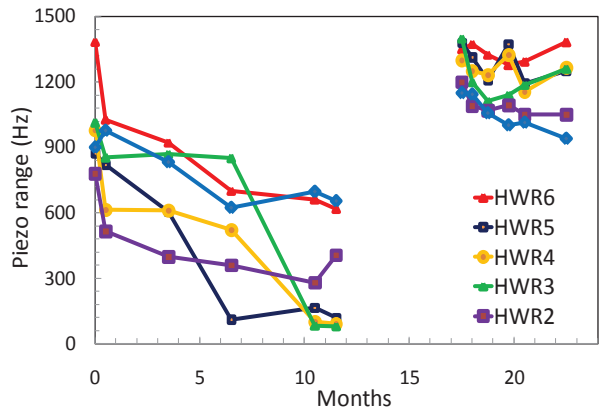

Figure 4: Piezo fast tuners dynamic range since January 2011. At the end of 2011 the piezo actuators were upgraded from low voltage to high voltage.

When the cavity is detuned, the LLRF control system [27] draws extra power from the HPA, in order to keep the cavity at its nominal accelerating voltage. Most of this power is reflected. In order to accelerate a 2 mA beam with maximal energy gain of 0.845 MV, we need 4 kW HPAs. In 2011, the original 2 kW solid state HPAs [28] were replaced by 4 kW HPAs designed and manufactured at SoreqNRC [29]. The operation of the cavities with the new power amplifiers has proven to be more stable.

RF Coupler Warming

After improving the tuners and RF amplifiers, warming of the RF couplers (Fig. 5) has become the main limiting factor in operating the linac at high fields. The capacitive coupler was designed for 4 kW [19]. The coupler enters the cryomodule from the top flange and turns to a middle plane HWR port (Figs. 6-7). The couplers warming phenomena has been recognized already at the commissioning stage [18]. A cooling copper strip line was added between the cold window and the 70 K thermal shield. This helped but not solved the problem. Thus, we are compelled to reduce the field in the 2nd, 3rd and 6th cavities in order to keep the external coupler's temperature below 120 K during long operation (Fig. 5). It is noteworthy that no significant warming is observed at the 5th cavity coupler. This cavity could be operated at a nominal voltage value, just before onset of X-ray emission. In the near future we plan to improve the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

couplers cooling, by replacing the copper strip with a more massive one.

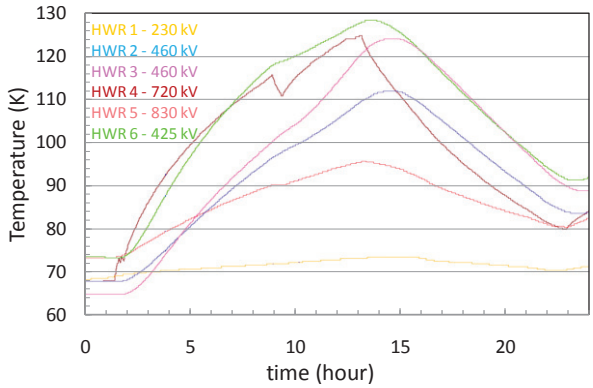

Figure 5: Couplers temperature, measured in the vicinity of the cold window, during beam operation. The RF voltage was turned on at 1h, closed at 9h for 20 min and turned off again at 13h. Beam intensity was ramped between 1h and 13h to 0.2 mA.

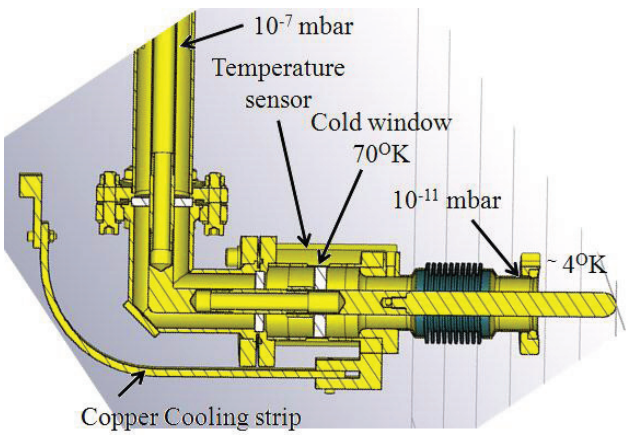

Figure 6: Drawing of the 4 kW RF coupler elbow section around the 70 K window.

At a later stage we will try adding He gas cooling around the window [30]. The cavity sensitivity to vibrations and pressure causes extra reflected power that can heat the coupler. Multipacting can also heat the coupler. A common method of suppressing multipacting is to apply a DC voltage to the coupler inner conductor. Solving the couplers warming problem will allow comfortable operation of the PSM at beam energies of 4.5 and 5.5 MeV for protons and deuterons, respectively, and an increase of the CW beam current to 2 mA.

Figure 7: Coupler elbow section (Fig. 6) photo with the cooling strip connected to the 70 K thermal shield.

PHASE-II RE-DESIGN

The goal of Phase-II is to complete the existing linac to 40 MeV and 5 mA. Novel technologies were explored for the completion of the linac. The main question was whether QWR dipole steering compensation methods are robust enough and can safely lead to a hands-on maintenance QWR proton linac. It was shown, by the Argonne National Laboratory (ANL) Linac Development department, that by using the drift tube face tilting correction method, cold BPM diagnostics and steerer correction after each QWR, the dipole steering is reduced to a negligible value [31]. The comparison between the 176 MHz HWR option and a 109 MHz QWR option showed only slight differences between the options, so for SARAF we opted for a 176 MHz HWR linac, since it enables a smoother transition from Phase-I.

A new conceptual design of a 176 MHz HWR linac was performed by the ANL group for SARAF. All Phase-I limits were addressed and solutions were found.

A MEBT that includes 2 re-bunchers was designed. Extensive simulations proved that it is possible to match proton and deuteron beams into the SC linac at beam currents from 0 to 5 mA, with no need to modify the linac tune design [31].

Varying the depth of the flat dish located in the opposite side to the RF coupler port found to be a good way for minimizating the cavity frequency sensitivity to fluctuations of the helium pressure in the novel design for Phase-II: . The results of sensitivity analyses showed that the flat dish reduces the sensitivity to 2 Hz/mbar in the low beta cavities [32] and 3.5 Hz/mbar for the high beta cavities. This is an improvement of an order of magnitude with respect to the existing Phase-I HWRs.

The HWR internal conductor was designed in a donut shape, in order to reduce the quadrupole effect and to minimize emittance growth [33].

A short 15 kW coupler was designed [34]. It enters the cryomodule from the bottom in order to keep the coupler environment clean throughout the operation life cycle. This forces the orientation of the cavities to be horizontal. A DC bias to the inner conductor is planned, to minimize multipacting, if needed. The simulated total heat load of this coupler at 4.2 K is 1.6 W.

For such a heavy loaded cavity, a dedicated fast tuner is not needed. A pneumatically actuated mechanical tuner, which compresses the cavity along the beam axis, is attached to the SS flanges outside of the helium vessel. The design of the pneumatic tuner is based upon the tuner design used since 2009 in the ANL ATLAS energy upgrade cryomodule. This tuner dynamic range at 2000 lb is 90 kHz, enough to replace both the slow step motor mechanical tuner and the dynamic piezo tuner [32].

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The cryomodules that were designed for SARAF by ANL are based on the ANL experience gained in ANL in recent ATLAS upgrade projects. Special care is taken to simplify assembly, maintenance, alignment, resonator cleanliness, operating and auxiliaries system interfacing, without interfering with beam dynamics optimization [35]. The low (high) β module is 4.8 m (4.6 m) long and hosts 7 HWRs and 7 (4) solenoids. Each SC solenoid unit includes X-Y steerers and a cold BPM. The modules design fits into the existing SARAF beam corridor and leaves enough space to insert and extract modules alongside the linac.

STATUS OF THE EUROPEAN XFEL – CONSTRUCTING THE 17.5 GeV SUPERCONDUCTING LINEAR ACCELERATOR

W. Decking, DESY, Hamburg, Germany
for the European XFEL Accelerator Construction Consortium*

Abstract

The European XFEL is presently under construction in Hamburg, Germany. It consists of a 1.2 km long superconducting linac serving an about 3 km long electron beam transport system [1]. Three undulator systems of up to 200 m length each produce hard and soft x-rays via the self-amplified spontaneous emission (SASE) process. We will present the status of the civil construction and the accelerator components. The production of the 100 superconducting accelerator modules is distributed between industries and a collaboration of accelerator laboratories. We describe the carefully orchestrated production sequence, quality assurance measures and risk mitigation mechanisms. The last module is scheduled to be installed in the accelerator in spring 2015 and commissioning with beam will start in summer of that year.

OVERVIEW

The European XFEL is being constructed as an European Research Infrastructure under the participation of 12 European countries. The construction of the electron accelerator is entrusted to a consortium of 16 laboratories led by DESY, Hamburg. The laboratories contribute to the accelerator 'in-kind', i.e. by delivering sub-systems and parts under their own responsibility.

The facility will provide hard and soft X-rays for a wide range of scientific applications. In its initial stage it will host three independent photon beam lines serving two experiments each. Final extension will show three experiments for each of the five independent photon beam lines.

The European XFEL employs superconducting accelerator technology, leading to unique features compared to other X-ray FELs being constructed or in operation worldwide. It is capable of accelerating up to 27000 bunches per second, distributed into 10 pulses of 600 µs length. Bunches can be injected into two separate electron beam lines hosting two resp. up to three undulators in a row. Flexible bunch patterns and plans to provide individual bunch properties will make the European XFEL a true multi-user facility.

Progress in the electron gun development for the European XFEL and the success of LCLS led to a redefinition of the expected accelerator performance. The final energy of 17.5 GeV, together with the long undulators and the anticipated low emittance beams out of a photo-cathode gun will allow reaching photon wavelength as short as 0.5 nm [2].

The installed linac and its infrastructure bear the possibility to be converted into a CW (or quasi-CW) accelerator in the future with the potential to reach up to 6 GeV final energy (for an update on the R&D towards this option see [3]).

Table 1 gives an overview of the main parameters of the facility.

Table 1: European XFEL Parameters

Quantity	Value
maximum electron energy	17.5 GeV
macro pulse repetition rate	10 Hz
RF pulse length (flat top)	600 µs
bunch repetition frequency within pulse	4.5 MHz
bunch charge	0.02 – 1 nC
electron bunch length after compression (FWHM)	2 – 180 fs
beam power	500 kW
# of modules containing eight 9-cell superconducting 1.3 GHz cavities	101
accelerating gradient for 17.5 GeV	23.6 MV/m
# of 10 MW multi-beam klystrons	27
average klystron power for 0.03 mA beam current at 17.5 GeV	5.2 MW
photon wavelength	0.05 – 4 nm

A normal-conducting photo-cathode RF gun produces high brightness electron beams. The injector building allows the later installation of a second, completely independent injector. The main linear accelerator is sectioned into three units with 4, 12 and 84 modules each, intercepted by normal conducting bunch compressor and diagnostic sections. A collimation and beam distribution section follows the linac, where the beam can be fed into the two separate undulator beam-lines and/or a commissioning and pulse-picker dump. Each beam-line is terminated by a solid state beam dump capable of accepting up to 300 kW of continuous beam power. The SASE photon beam is delivered through up to 800 m long photon beam lines to the experimental hall. See Fig. 1 for a bird's eye view of the facility.

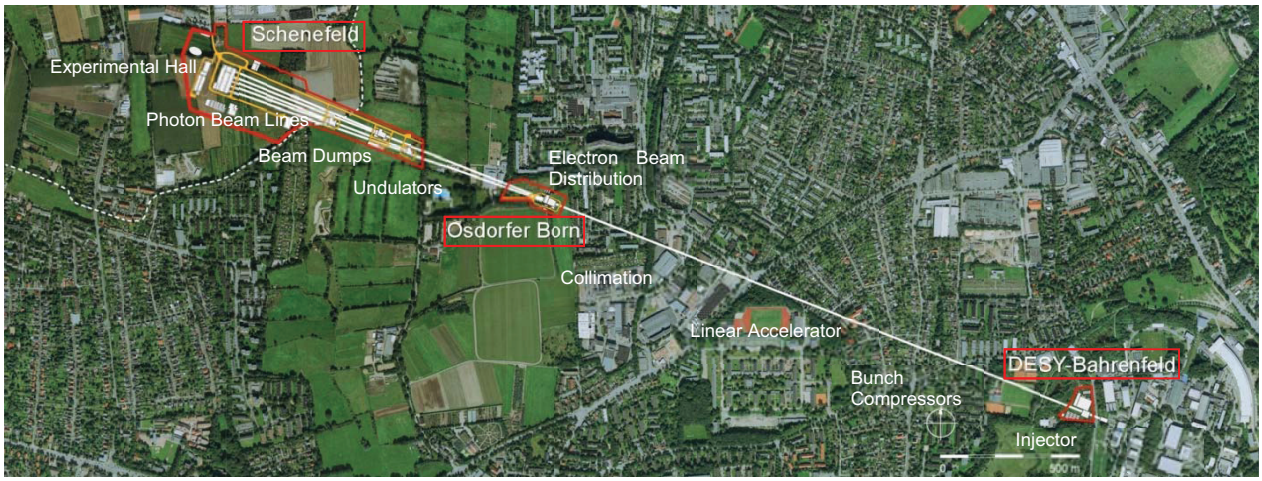

Figure 1: Bird eye's view of the European XFEL site showing the location of the three surface areas and the tunnel routing below the cities of Hamburg and Schenefeld.

STATUS

Civil Construction

The European XFEL requires a large amount of civil construction at three construction sites: on the DESY campus the injector building, modulator hall and accelerator module test facility (AMTF), the large experimental hall, tunnel separation shafts, dump shafts, office buildings and infrastructure buildings on the future XFEL experimental campus at Schenefeld 3.3 km to the west of DESY and a tunnel separation shaft and surface infrastructure buildings in between (see Fig. 1). About 5.8 km of underground tunnel connect these construction sites and fan out on the Schenefeld campus. They will host the accelerator and up to 5 independent photon beam lines and were constructed with the help of two tunnel boring machines. Work started in July 2010 and finished in June 2012, well within schedule (see Fig. 2).

Figure 2: View of the completed accelerator tunnel.

About 150000 m^3 of underground buildings had to be excavated and built. Most of the tunnel connection underground halls are finished, while the experimental hall is projected to be delivered in 2013.

Finally 12000 m^2 of surface buildings have to be erected. Most of the surface buildings on the DESY campus are about ready with the AMTF already close to start operation, the surface buildings on the other sites are only just being started. Their completion is of utmost importance for the machine installation, as they host the access devices like cranes and elevators and also mayor parts of the infrastructure.

Infrastructure Installation

With the hand-over of the main accelerator tunnel the installation of the technical infrastructure into the accelerator tunnel has begun. It will last until 2013 before first accelerator components can be delivered into the tunnel. In parallel infrastructure installation takes place in the other tunnels, shafts and buildings as they become available [4]. Planning of the infrastructure for the accelerator and the future experimental campus is a major task for DESY.

Accelerator Components

Apart from the superconducting accelerator about 3 km of so-called 'warm' beam lines have to be installed.

The photo-cathode gun will be of the same type as already in operation at the FLASH facility, DESY Hamburg, and the Photo-Injector Test Stand Zeuthen (PITZ), DESY Zeuthen. The gun body foreseen for the European XFEL is manufactured and will be conditioned and characterized at PITZ in the coming 9 months. The photo-cathode laser will be supplied by the Max Born Institute under the responsibility of DESY. It uses Yb:Yag lasing material and a pulse stacking system to provide a > 20 ps flat top with a steep rise and fall time.

The warm electron beam vacuum system is constructed by BINP and DESY. Up to a distance of 30 meters from the superconducting accelerator the vacuum system has to be particle free to avoid contamination of the cold modules in case of a vacuum leak in the warm vacuum. The undulator vacuum chambers, made of aluminium with stringent specifications on the surface roughness and

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

oxide layer to minimize resistive wall wake fields, pose an additional challenge.

Normal conducting magnets are produced by BINP and Efremov Institute. A total of more than 700 electro-magnets have to be delivered. The more than 120 undulator quadrupoles used for the focussing lattice in the undulator section are already on site, while the first batch of magnets that will be installed in the injector is due in autumn this year.

Beam instrumentation consisting of beam position and charge monitors, transverse beam profile monitors and various devices to measure longitudinal bunch properties are provided by DESY, PSI and INR. Most diagnostic devices have been developed and tested at FLASH and are now in the final engineering phase or already in series production.

A synchronisation system allows the measurement of beam arrival at certain stations up to 10 fs accuracy. Lasers and other devices can be locked to this system to allow synchronised pump-probe experiments [5].

The three undulator systems use moveable gap undulators of 5 m length and a period length of 40 resp. 68 mm. The contract for 91 undulators is awarded and first prototypes are on site for establishment of the fine tuning procedures.

SUPERCONDUCTING ACCELERATOR

Cavity Fabrication

The performance goal for the 800 9-cell cavities is an accelerating gradient of 23.6 MV/m at $Q_0=1\times10^{10}$.

The cavities are manufactured in industry according to the procedure previously developed at DESY (build to print). The performance is not guaranteed by the producers, in case of low performance the cavities will be re-treated at DESY. Nb sheets and parts are supplied to the producers via DESY.

The Nb sheets and tubes are produced by four different companies which have been pre-qualified for production of the required high purity sheets. All parts are individually quality controlled at DESY through an eddy current scan and tactile 3d dimension measurements before they are delivered to the cavity manufacturers.

Production of the cavities has been contracted to two companies. Both companies have erected the necessary infrastructure for the mechanical fabrication and the proper surface treatment of the cavities. After deep drawing the half cells are e-beam welded into dump bells and finally into 9-cell cavities. RF measurements and quality inspections are performed at each production step. All documentation is stored in the XFEL project EDM system by the contracting companies. The companies have also access to selected relevant information.

The surface treatment consists of an approx. 100 µm electro-polishing, ethanol rinsing, outside chemical polishing and high temperature annealing prior to cavity tuning. The cavity tuning is performed at the companies with special equipment that was developed and manufactured at DESY. After tuning the final surface treatment is either performed with another electro-polishing step or a 10 µm chemical polishing prior to the welding into the Titanium Helium vessel. Finally the cavities are dressed with auxiliary parts and higher-order mode couplers and shipped to DESY for acceptance test.

The complete procedure and infrastructure at the companies is qualified with reference cavities and pre-series cavities. First measurements of the reference cavities (production at companies and surface treatment and RF test at DESY) show performance above specification [6]. The surface treatment is established at the companies in a step-wise procedure, with the RF performance being tested after each treatment step.

Each of the 800 cavities is acceptance tested with a CW power test in a vertical cryostat. The tests are performed in a dedicated section of the AMTF hall. One vertical cryostat is already delivered to AMTF, while the 2nd is expected in November 2012. The infrastructure for vertical cavity testing is supposed to be fully operational by end of this year.

After reception and initial inspection the cavities are installed four each into an insert that allows parallel cool down and testing. The complete procedure of assembly, cool down, testing, warm up and disassembly will take about one week. The testing is performed by a team of specialist from IFJ Krakow. Presently the training and development of all steps is performed at the existing DESY infrastructure.

Accepted cavities will then be shipped to CEA Saclay for string assembly. A limited number of non-conforming cavities can be re-treated at the DESY infrastructure.

Module Assembly

The module assembly integrates all individual parts of a super-conducting module [7]:

- The power couplers are procured and warm conditioned by LAL Orsay. The copper plating of coupler parts turned out to be more challenging than anticipated and the involved parties work hard on the solution of the remaining problems.
- The cavity tuners are delivered by DESY.
- The cold vacuum pieces like bellows and intersections are made available by BINP Novosibirsk and DESY.
- The cold quadrupole package, consisting of a super-conducting quadrupole/steerer package delivered by CIEMAT Madrid to DESY, where the magnets are tested and equipped with a vacuum insert for rf-shielding.
- Beam position monitors both from DESY (button type) and CEA Saclay (re-entrant cavity type). The BPMs are connected to the quadrupole in the clean room at DESY and the complete unit is integrated into the cavity string.
- Cold masses from INFN Milano and DESY.

Module assembly starts with the assembly of the cold coupler parts to the individual cavities in an ISO4 clean room. Eight cavities are then connected together with the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

quadrupole package into one cavity string, again under ISO4 clean room conditions. The cavities in the string are then equipped with tuners and magnetic shielding. The 2K He pipe is welded together and the complete string is connected to the He return pipe (cold mass), see Fig. 3. The cold mass is responsible for the mechanical rigidity of the system. All components are carefully aligned to each other and insulation shields and superinsulation are installed. Finally the cavity string/cold mass assembly is inserted into the cryostat. The warm parts of the couplers are installed and the coupler vacuum system is connected. The string is aligned within the cryostat and the complete assembly is prepared for transportation by assembly of end-caps, nitrogen filling of the cavities and assembly of surveillance instrumentation.

The string and module assembly is performed at CEA Saclay. Dedicated infra-structure has been set up during the past years, consisting of clean rooms, assembly halls, offices and ware houses [8]. Assembly of one module per week is foreseen. All critical parts of the infrastructure are laid out redundant to allow for maintenance, correction of non-conforming assembly steps or eventually a higher assembly rate.

Figure 3: Assembly of the cold mass at CEA Saclay.

Commissioning of the infrastructure and training of CEA staff has been performed since 2010 through the assembly and disassembly of XFEL prototype modules. The final assembly of 103 modules (3 pre-series and 100 series modules) is done by an industrial operator under the supervision of CEA staff. The respective company has been selected and the contract signed, training will start in autumn this year on the pre-series modules.

An assembly rate of one module/week requires careful planning of all logistics. On one hand a sufficient supply of sub-components has to be available on site, while on the other hand storage space is limited and the production of sub-components is just ramped up in time to match the assembly schedule. At least weekly video conference meetings of all involved parties are necessary despite the careful planning involving modern project planning tools.

After assembly the modules are transported by truck to DESY. A special shock absorbing frame is used to avoid misalignment and damage to the module. Shock-meters are in operation during the transport to record any unusual acceleration. The road transport has been tested with an assembled and tested module and no performance degradation has been observed.

Each of the 103 modules is tested at DESY at the AMTF. Three individual test stands (see Fig. 4) allow a through put of 1 tested module per week. The complete procedure of installation on the test bench, cool-down, testing, warm-up and disassembly is estimated to take about 2 weeks. The task is performed by the same specialist team responsible for the testing of the modules.

Figure 4: View of the module test stand in the AMTF.

Conforming modules can be stored partially on the DESY site for later installation. A small percentage of non-conforming modules could be disassembled and repaired in the DESY infrastructure.

RF System

An RF system unit consists of a 10 MW multi-beam klystron, pulse transformer, modulator and the wave-guide distribution to the individual input couplers. Contracts for all components are placed with industry.

The modulators will be placed outside of the tunnel in a dedicated hall on the DESY site. The pulse is fed into the tunnel with up to 2 km long pulse cables. These cables will be installed in the lower section of the tunnel below the floor slabs that form the transport way in the tunnel. Most of the cables are delivered and their installation into the tunnel will start this year before the floor slabs will be put finally into place.

Except for the injector and the photocathode gun one klystron feeds 4 modules (32 cavities in total). The pulse transformer and klystron are placed in the tunnel below the modules. This requires the klystron to be oriented horizontally. Prototypes of the multi-beam klystrons are in operation at the FLASH facility and show good performance [9].

The LLRF system for regulation of the RF has been developed at FLASH during the past years. In its final version it is based on the MicroTCA industrial standard. In-loop and outer-loop performance measurements show an RMS amplitude and phase regulation of $\Delta A/A = 5 \times 10{-}5$ and $\Delta\Phi = 0.009\circ$, resulting in an expected beam energy stability lower than 0.005% [10], [11].

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Development of this system has greatly benefited from activities in the framework of the ILC R&D [12].

Accelerator Installation

The complete accelerator will be installed into the approximately 5.4 m diameter underground tunnel. The modules are suspended from the ceiling. This allows installing rf components and electronics easily accessible below the modules.

Module installation takes place in batches of 12 modules. These modules form one cryo-string. Each string is connected by string connection boxes. Some pre-sorting of modules is possible, with best performing module preferably at the beginning of the linac. Within a cryo-string, four modules with similar performance will be fed by one klystron.

Cooling is supplied by the existing cryo-plant that was previously used for the HERA accelerator. This plant is being refurbished to cope with the next 20 years of operation and the required 2K Helium production. Cryogenic components like transfer lines, valve boxes, connection boxes and test-cryostats are developed by BINP Novosibirsk, DESY, IHEP Protvino and WUT Wroclaw.

SUMMARY

Construction of the European XFEL is well under way with the goal of first beam in the accelerator by mid of 2015. Most of the underground civil construction is finished and the surface buildings are on schedule. Infrastructure installation has started and the procurement of accelerator components is well under way. One of the biggest challenges is the timely production of 101 super conducting accelerator modules. The production sequence has been set up and full rate series production is expected in one year.

Commissioning of the European XFEL starts with the injector in mid-2014. This includes the RF gun, one 1.3 GHz module, a third harmonic system [13], the laser heater and a section that allows bunch slice diagnostics. During the one year commissioning of the injector the remaining linac can be installed in parallel. Cool down of the main linac can only start when the complete linear accelerator is installed in mid-2015. First lasing can be expected by end of 2015.

SRF LINAC TECHNOLOGY DEVELOPMENT AT FERMILAB*

Vyacheslav Yakovlev# and Camille Ginsburg, Fermilab, Batavia, IL 60510, USA

Abstract

Superconducting linear accelerators are being developed for different applications: for fundamental research at the high-energy and high-intensity frontiers, in nuclear physics, for spallation neutron sources, for synchrotron radiation sources, etc. The linac applications dictate the requirements for the superconducting acceleration system, and, thus, for SRF technology. Fermilab is currently involved in two projects: ILC and Project X, both based on SRF technology. For high-intensity frontier investigations, Project X – a multi-experiment facility – is being developed based by a wide collaboration of US National and Indian Laboratories. In the CW H^- linac several families of SC cavities are used: half-wave resonators (162.5 MHz); single-spoke cavities, SSR1 and SSR2 (325 MHz); elliptical 5-cell beta=0.61 and beta=0.9 cavities (650 MHz). The pulsed 3-8 GeV linac is based on 9-cell 1.3 GHz cavities. In this paper the basic requirements for the CW superconducting Project X linac are considered as well as its specific technology challenges.

INTRODUCTION

The application of SRF technology to electron and hadron linacs has a long – almost 50 years long – and successful history. Superconducting RF cavities are now widely used and are planned to be used in linear accelerators for different applications, for example: (i) high-energy physics (SPL [1], ILC [2]) and the high-intensity frontier (Project X [3]); (ii) new X-ray free electron lasers (XFEL [4], NGLS [5], Cornell ERL [6]), (iii) spallation neutron sources (SNS [7], ESS [8]), (iv) nuclear physics and rare isotope production (ATLAS [9], ISAC-II [10], CEBAF [11], SARAF [12], SPIRAL –II [13]), (v) ADS accelerators (MYRRHA [14], Indian ADS [15], China ADS [16]). The recent progress in development of superconducting acceleration cavities was achieved substantially in connection with the ILC project, see Fig 1, where a sketch of the ILC is presented. For such a long machine, high acceleration gradient is essential: 35 MeV/m with a duty factor of 0.5%. The 9-cell ILC cavity (see Fig. 2) operates at 1.3 GHz. The ILC collaboration [2], which includes Fermilab, achieved impressive results in the development of cavity processing (which includes electro-polishing and 120°C baking, see Fig. 3) and clean assembly techniques. These developments allowed the achievement of cavity gradients at quite high and gradually increasing production yields, see Fig. 4 [17]. At Fermilab, the work on building ILC-type cavities and cryo-modules is continuing.

*Operated by Fermi Research Alliance, LLC, under Contract DE-AC02-07CH11359 with the U.S. DOE

#yakovlev@fnal.gov

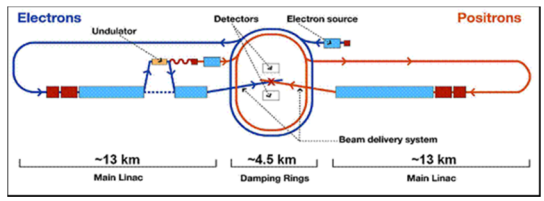

Figure 1: The ILC project sketch (2007 Reference Design).

The new large accelerator facility which is under development at Fermilab, Project X [18], is based on a CW H^- superconducting linac, which has requirements very different from what is suitable for ILC, creating new problems and new challenges.

Figure 2: Photo of the ILC 1.3 GHz 9-cell SC cavity [Fermilab Visual Media Services].

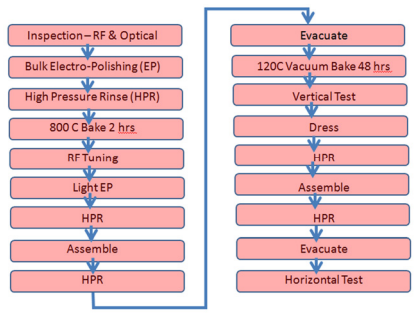

Figure 3: ILC Cavity Processing Basic Recipe.

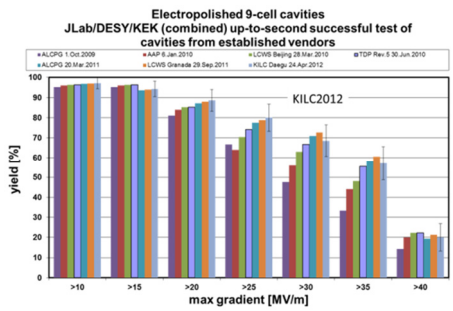

Figure 4: ILC gradient yield. ILC cavities reach 35 MV/m in vertical test more than half the time after one or two processing cycles.

DISCUSSION

Project-X, a multi-MW proton source, is under development at Fermilab. The Project X configuration is shown in Fig. 5. It enables a world-leading program in neutrino physics, and a broad suite of rare decay experiments. The facility is based on 3-GeV 1-mA CW

superconducting linac [19]. In the second stage, about 5-9% of the H^- beam is accelerated up to 8 GeV in a SRF pulsed linac to the Recycler/Main Injector. The beam from the CW linac is directed to the 8 GeV linac for further acceleration in the Main Injector up to 120 GeV, for the long baseline neutrino program.

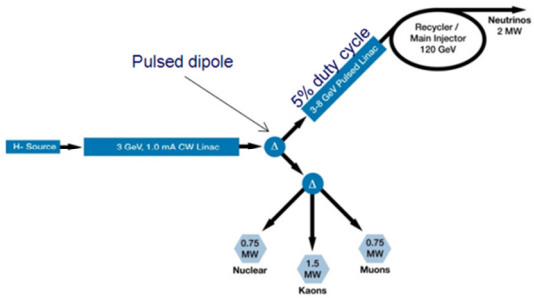

Figure 5: Project X configuration.

The 3-GeV CW linac of the Project X, see Fig. 6, contains (i) a front end with a room-temperature injection system having an H^- source, a Low-Energy Transport Line (LEBT), a 162.5 MHz RFQ, a Medium-Energy Transport Line (MEBT) with a beam chopper, (ii) a low-energy section based on 162.5 MHz Half-Wave Resonators (HWR) and 325 MHz Single-Spoke Resonators (SSR), and (iii) a high-energy section based on 650 MHz 5-cell elliptical cavities. The accelerator details for each SRF section are summarized in Table 1.

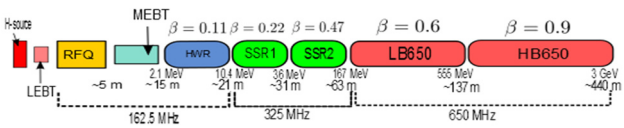

Figure 6: 3-GeV CW linac of the Project X.

Table 1: Accelerator details of the linac sections. CM: Cryomodule; D: Doublet, S: Solenoid, R: Resonator, R^n: n-Resonators Sequence.

Section	f[MHz]	Cav/mag/CML_{CM}[m]		Cell
HWR	162.5	8/8/1	5.26	S-R
SSR1	325	16/8/2	4.76	R-S-R
SSR2	325	36/20/4	7.77	$S\text{-}R^2$
LB650	650	42/17/7	7.1	R^3-D
HB650	650	152/19/19	11.21	$D\text{-}R^8$

The cavity design parameters for the low-energy sections and high-energy sections are shown in Tables 2 and 3, respectively. The HWR cryo-modules are developed by ANL [20]. The layout of the HWR cavity is shown in Fig. 6. SSR1 cavities [21], see Fig. 7, are designed by Fermilab and have been built by Zanon and Roark/Niowave. Two of them have been processed and tested showing performance consistent with design parameters. The helium vessel and tuners (coarse and fine) are also designed. The SSR2 cavity design is in progress [22]. Fermilab designed two 5-cell 650 MHz elliptical cavities for the high-energy section, at beta=0.61 (LE650) and beta=0.90 (HE650) [23]. JLAB has also developed a version of the LE650 cavity [24] with increased aperture, 100 mm versus 88 mm for FNAL design. JLAB has built and tested two single-cell cavities, see Fig. 9. One of them, #2, met Project X specifications (Q_0=2e10 at the nominal gradient).

Table 2: Cavity design parameters for the Project X low-energy section

Section	beta	Aper-ture, mm	Gain MeV	E_{peak} MV/m	B_{peak} mT	R/Q Ohm	G Ohm
HWR	0.11	33	1.8	40	62	225	48
SSR1	0.21	30	2.0	28	70	242	84
SSR2	0.47	40	3.3	32	60	292	109

c)

Figure 12: Cryo-module design for a) HWR (ANL), b) SSR1 (FNAL) and c) HE650 MHz (FNAL).

The cryo-modules of Project X have substantial operational differences compared to the ILC: 100% and 0.5 % duty cycle, respectively, and thus, a big difference in RF load: ~200 W/CM at 17 MeV/m and ~5 W/CM at 35 MeV/m, respectively. Thus, achieving high gradients is not an issue for the Project X cavities, but low RF load, or high Q_0, is. RF load in the CW regime determines the power consumption of the cryogenic system, which, in turn, determines (i) the capital cost of the cryogenic system (cost of a cryogenic system is proportional to (RF load)$^{0.6}$ $\propto Q_0^{-0.6}$ for big machines [25]) and thus the cost of the entire project (cost of the cryogenic system is about 15% of the cost of a big machine); and (ii) operation cost, which is proportional to RF load, or Q_0^{-1} . Note that higher Q_0 also allows somewhat higher gradient, which may reduce the linac civil construction costs. The influence of RF load on the capital and operational cost of the Project X cryogenic system was analysed in [26]. The RF load was estimated using the averaged data on BCS resistance (the total surface resistance which determines Q_0 is the sum of residual resistance and BCS resistance) for ILC cavities [27] and Halbritter's model [28] for its gradient dependence (parameter γ=1 was taken based on these data). The cryogenic efficiency, i.e., the coefficient of performance (COP), was taken to be 890 W/W at 1.9 K, which corresponds to a modern level of cryogenic techniques [26]. In Fig. 13 a normalized capital cost of a cryogenic plant is shown versus the cavity operating temperature for two values of surface residual resistance, 5 nOhm and 10 nOhm. One can see that reduction of the residual resistance by a factor two decreases the cost by 30%. Note that the plant cost is about 75% of the total cost of the cryogenic system.

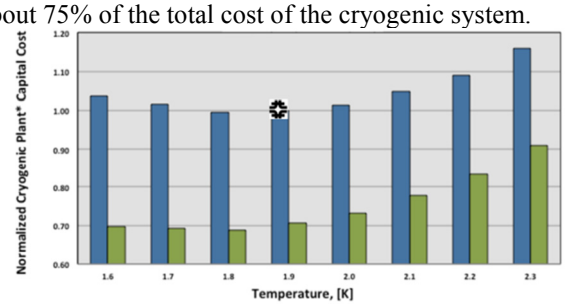

Figure 13: Normalized cryogenic plant cost versus operating temperature for different residual resistances: 10 nOhm (blue) and 5 nOhm (green).

Different approaches to reduce Q_0 are under development now. One of them is cavity processing in a nitrogen atmosphere, which creates a bulk layer of NbN on the cavity surface. NbN is a superconductor having a critical temperature of up to 16K compared to 9.2K for Nb, which gives the potential for lower surface resistance. The very first experiment [29] demonstrated the record $Q_0 \approx 7.5e10$ at 2K for a large-grain 1.3 GHz single – cell cavity (Fig 14). Another approach is hydrofluoric acid (HF) rinse of a cavity, with which one experiment [30] demonstrated a 35% increase in Q_0 at B_{peak} =70 mT for a 1.3 GHz fine-grain cavity, see Fig. 15. High-temperature baking (1400° C) is a third approach, which demonstrates Q_0~4.5e10 at B_{peak} =90 mT [31] also for 1.3 GHz, see Fig. 16. B_{peak}/E_{acc} =4.26 mT/MeV/m for all three of these cavities. Note that a Q_0 increase is demanded for any large CW superconducting accelerator, such as NGLS or ADS accelerators.

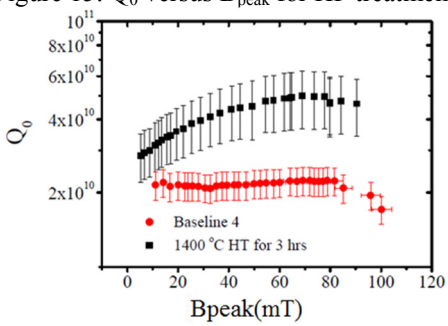

Figure 16: Q_0 versus B_{peak} for high-temperature baking.

Another critical issue for Project X and other large SC accelerators with modest beam current, e.g., NGLS, is small beam loading. Optimal coupling to the planned 1mA beam current at Project X would require relatively narrow cavity bandwidths. SC RF cavities are made from Nb sheet and the walls of the cavities are deliberately kept thin to maximize heat transfer to the surrounding superfluid helium bath. The thin walls of the cavities and the narrow operating bandwidths make them susceptible to detuning due to variations of the helium bath pressure or to mechanical vibrations (microphonics). Typically, the main source of vibration is helium pressure fluctuations [32]. As the cavities detune, additional RF power is required to maintain the accelerating gradient. If sufficient reserve RF power is not available to maintain the gradient, the beam can be lost. Sufficient reserve RF power must be provided to compensate for the peak detuning levels expected, not just for the average detuning. For narrow bandwidth cavities, providing sufficient reserve RF power can significantly increase both the acquisition cost and the operational cost of the machine. For the high-energy part of Project X, the bandwidth is about 23 Hz. In this case, a maximal detuning of 20 Hz requires an RF power overhead of 43% [33].

Microphonics can be mitigated by using the following approaches, or a combination of them: (i) providing sufficient reserve of RF power to compensate detuning; (ii) reducing the sensitivity of the cavity resonant frequency *f* to the helium bath pressure (*P)* fluctuation (*df/dP*), i.e., passive damping; (iii) actively damping microphonics using a fast tuner controlled by feedback from measurements of the cavity resonant frequency; (iv) decreasing the helium bath pressure fluctuations. To minimize *df/dP*, a number of approaches are used. A "self-compensating" scheme [34] was suggested for a triple spoke cavity, see Fig. 17. In this case, the cavity and helium vessel geometry are optimized such that a change in the stored energy of the electric field in the cavity is close to the change of stored energy of the magnetic field. Another approach is mechanical coupling of the cavity and the helium vessel, which improves the system stiffness [21], see Fig. 18. A third approach [35] exploits the idea of using a special element coupled to the cavity and separated from the helium vessel by a bellows which stretches the cavity in case of excess pressure, compensating the frequency changes caused by the cavity walls being squeezed. In SSR1 we use all these approaches to reduce *df/dP* to an acceptable level [21]. Active damping of microphonics for high – Q0 cavities was pioneered at Cornell [36]. Active piezo feedback reduces the microphonics amplitude by 70 %, see Fig. 19, and allows cavity operation with loaded Q up to 1e8. At Fermilab, an active microphonics compensation system was successfully developed and tested [37] for the SSR1 cavity at 4 K. The system allows a reduction in the r.m.s. detuning to 0.45 Hz, and peak detuning to 1.46 Hz, see Fig, 20. The system provides a very narrow peak without any evidence of long tails, which could cause rare trips. (Note that the Project X requirement is < 1 trip in 500 hours.) This approach for microphonics compensation satisfies Project X requirements, and may be useful for other large CW accelerators.

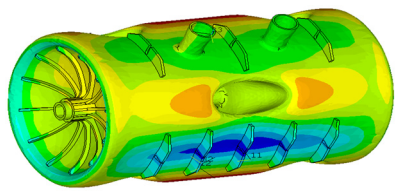

Figure 17: Self-compensating scheme for a triple-spoke cavity. Final adjustment of *df/dP* is reached by cutting the stiffening ribs on the He vessel walls.

CONCLUSIONS

Fermilab is proceeding with SRF activity connected to ILC and Project X. SRF for ILC is well-developed, and the international team has made good progress in achieving high accelerating gradient. New large CW linacs such as Project X, NGLS, ADS projects, ERL's, etc., need not high gradient, but high Q_0 at modest gradient. New SC material research concentrates on the achievement of high Q_0. Another critical issue for new CW projects is microphonics. Dedicated research is ongoing to develop both passive and active means for microphonics compensation suitable for large SC linacs with low beam loading.

INCREASED UNDERSTANDING OF BEAM LOSSES FROM THE SNS LINAC PROTON EXPERIMENT *

J. Galambos#, A. Aleksandrov, M. Plum, A. Shishlo, ORNL, Oak Ridge, TN 37831, USA,

Abstract

Beam loss is a major concern for high power hadron accelerators such as the Spallation Neutron Source (SNS). An unexpected beam loss in the SNS superconducting linac (SCL) was observed during the power ramp up and early operation. Intra-beam-stripping (IBSt) loss, in which interactions between H^- particles within the accelerated bunch strip the outermost electron, was recently identified as a possible cause of the beam loss. Results from a set of experiments using proton beam acceleration in the SNS linac support IBSt as the primary beam loss mechanism in the SNS SCL.

SNS BEAM LOSS EXPECTATIONS

The SNS accelerator consists of an RFQ (output energy of 2.5 MeV), a Drift Tube Linac (output energy of 85 MeV, a Coupled Cavity structure (output energy of 186 MeV) and an elliptical cell superconducting cavity structure with design output energy of 1 GeV. The SNS linac accelerates a 1 msec pulse H^- beam, which is subsequently captured in a storage ring to produce a sub μs intense pulsed neutron source.

A major advantage of superconducting RF linacs for H^- and proton acceleration is the inherently large beam aperture, which greatly alleviates the issue of beam loss relative to copper accelerating structures. During the design stage of SNS the multi-particle beam simulations indicated no beam loss in the superconducting linac (SCL) region [1,2]. Nonetheless, there was a reluctance to assume no superconducting linac beam loss and a minimal loss in this area was allocated in the beam loss budget [3], attributed to gas stripping in the warm sections between cryomodules.

OBSERVED SCL BEAM LOSS

Loss History

Early in the power ramp-up phase of the SNS operation, unexpected residual activation was measured along the SNS superconducting linac, in the warm sections between the cryomodules. The warm sections are the limiting aperture restrictions in the SCL, so it is not surprising that the observed beam loss is located in these regions. The build-up of measured residual activation over the period of the SNS power ramp-up and initial operation is shown in Fig. 1, where the the average warm section residual activation levels are superimposed on the operational beam power level. Initially, the loss detectors did not register the beam loss causing this activation, but they were moved closer to the beam pipe in the warm sections, and subsequently did detect the beam loss. Beam loss is rather uniformly distributed along the SCL.

Beam Loss Magnitude

Based on the measured residual activation levels, the beam loss can be expected to be < ~1 W/warm-section, which corresponds to < 10^{-4} fractional beam loss throughout the SCL at 1 MW. Quantifying beam loss fractions at this level is difficult. One method of producing very small fractional controllable beam spills in the SNS SCL is with a laser profile device [4]. The short pulse laser strips the outermost H^- electron from about 10^{-6} of a nominal beam pulse, creating H^0 that is subsequently lost downstream. By comparing the additional beam loss signal produced by the known amount of beam lost from the laser pulse to the measured beam loss during production, we estimate the fractional beam loss during neutron production in the SNS SCL to be a few $\times 10^{-5}$.

Possible Loss Causes

Initially, causes of the unexpected beam loss were suggested to be poor matching (transverse or longitudinal); beam halo from the ion source, or produced during acceleration; and residual gas stripping. Longitudinal tails were considered a likely loss contributor because of the sensitivity of SCL beam loss to the longitudinal setup of the upstream warm linac. Different longitudinal tunes were applied in the SCL, trading final energy for increased acceptance, but minimal impact was observed on the baseline SCL beam-loss level. The transverse match is a natural suspect, however adjustments of matching quadrupoles at the linac lattice transitions generally affect beam loss at local loss points, as opposed to the observed uniform beam loss through the SCL. Additionally, for the design transverse optics, beam mis-steering does not affect beam loss, indicating the presence of additional aperture available for the transverse tune. Finally, residual gas stripping in the upstream warm linac was addressed by measuring the change in beam loss with deteriorated warm linac vacuum to determine the impact from gas stripping and extrapolating back to ideal vacuum conditions. This indicated that gas stripping was not a major contributor to the SCL beam loss. The measured vacuum level in the warm sections between superconducting RF cryomodules is much lower than the design assumptions, and is too low to contribute to significant gas stripping beam loss.

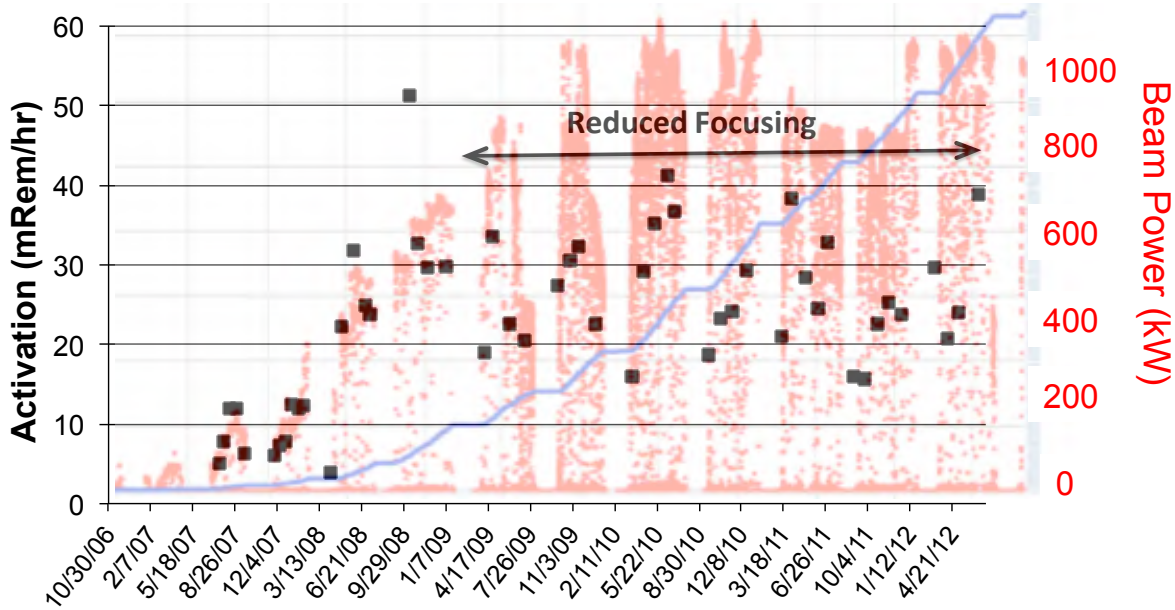

Figure 1: History of the SNS residual activation along the SCL (black marks) since initial operations, superimposed on the operational beam power level (red background). Activation levels are the average hot-spot measurement in the warm sections along the SCL, at 30 cm taken about 24 hours after the end of a run.

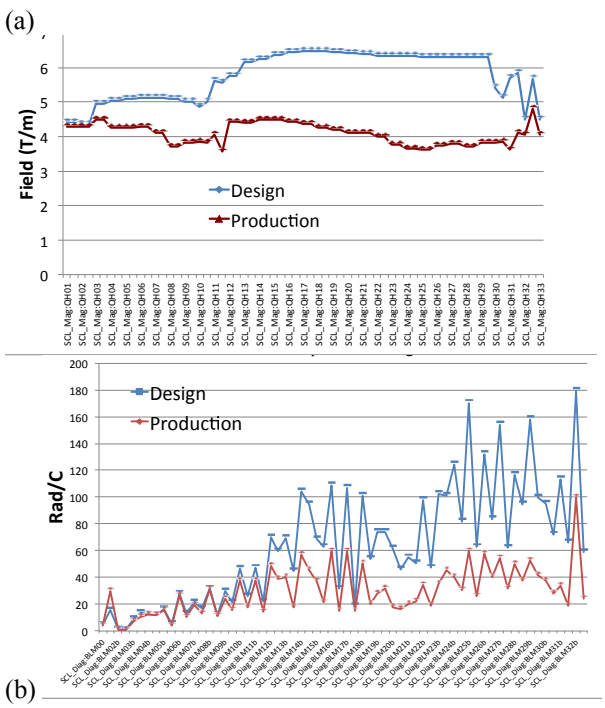

Figure 2: (a) Comparison of transverse field levels for design and production optics, (b) Measured beam loss distributions along the SCL for design and production optics. Beam loss is normalized to the transmitted charge.

Reduced Focusing Operation

A key feature of the SCL activation build-up, shown in Fig. 1, is a roll-over at the onset of reduced focusing operation. In early 2009, empirical observations revealed reduced beam loss with lower transverse focusing in the SCL. Initially modest quadrupole field level reductions were applied, but eventually the applied field level was reduced up to 40%, beyond which losses began to increase. Reducing the applied focusing strength was the primary contribution to the activation buildup "roll-over" in early 2009. Fig. 2 shows the transverse focusing field along the SCL for both the design level, and the empirically derived minimal loss condition (referred to as "production" optics here). Also shown in Fig. 2 is the measured beam loss distribution along the SCL for the design and production lattice optics. There is a systematic reduction of beam loss along most of the SCL with the reduction of the applied field. This was the single largest observed influence on loss reduction. While it initially seemed counter-intuitive that increasing the beam size would reduce beam loss, this observation proved to be a valuable insight into an unforeseen beam loss mechanism in H^- linacs.

INTRA-BEAM STRIPPING

Intra-Beam Stripping (IBSt) refers to the stripping of the outer electron from an H^- ion in an accelerated beam due Coulomb collisions with other H^- ions in the beam. This loss mechanism was examined at CERN over 20 years ago [5], but had not been considered in the SNS design. V. Lebedev first proposed this process as a loss mechanism for H^- linacs [6], and in particular for the SNS. The loss rate is proportional to the beam density squared and the cross-section for stripping. For the centre-of-mass relative velocities of the H^- particles in the bunch along the SNS SCL linac, the cross section is fairly constant [6].

PROTON BEAM AT SNS

A direct test of the IBSt loss mechanism hypothesis is to replace the H^- beam with a comparable proton beam. A set of experiments to this effect has been described in refs. [7, 8]. A simple way to produce a proton beam at SNS is to insert a thin foil into the beam to convert the H^- to H^+. The Medium Beam Energy Transport (MEBT) between the RFQ and Drift Tube Linac (DTL) is a convenient location for this purpose for the following reasons:

1. There is an available actuator for foil attachment near the start of the MEBT.
2. There are 10 independent quadrupole power supplies that can be adjusted to rematch the resultant proton beam into the downstream permanent magnet DTL.
3. Following the rematch, the beam transport through the linac is the same for H^- and protons.
4. Commercially available foils are suitable for this energy range (2.5 MeV).

Creating the Proton Beam

A 5 μg/cm^2 thick foil was chosen, which strips nearly all the beam (> 99.9%, and the un-stripped beam is lost soon afterwards in the MEBT). Foil scattering is estimated to produce minimal energy loss compared to the inherent beam energy spread, and a transverse emittance growth of only 10-20%. One limitation of the foil is beam heating. To avoid foil damage, we limit the beam pulse length to 50 μs, compared to production pulse lengths of 850 μs. The foil is 16 mm diameter, quite large compared to the RMS beam size of 1.5 - 2 mm.

Machine Setup for Protons

The foil is inserted just after the first quadrupole in the MEBT, leaving 9 additional adjustable quadrupole power supplies available to match the proton beam into the downstream DTL. The matching scheme swaps the H^- and proton horizontal and vertical Twiss parameters at the DTL entrance, while minimizing the beam size in the MEBT. The RF phases throughout the linac are adjusted by 180 degrees to provide the same longitudinal focusing and acceleration for protons as for H^-. The focusing elements in the coupled cavity linac (CCL) and SCL are left the same for the proton and H^- beams, with the exception of minor adjustments for loss tuning at the lattice transitions between the CCL and SCL.

Measured beam profiles at end of the SCL are compared for the proton and H^- beams in Fig. 3. The horizontal and vertical planes are swapped, as expected, and the general shape of the profiles is similar, indicating that the transport of the protons beam is comparable to that of the H^-. The Twiss parameters at the end of the SCL are also measured using a set of four profile measurement devices at the start of the transport section that directly follows the SCL. These parameters, shown in Table 1, indicate that the horizontal and vertical planes are effectively swapped between the two beams, as expected.

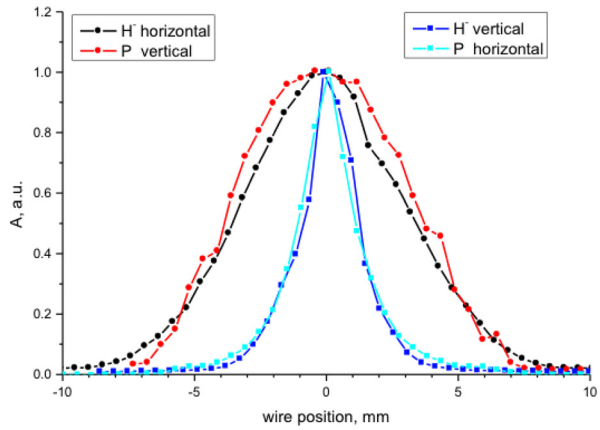

Figure 3: Measured beam profiles at the end of the SCL

Table 1: Twiss Parameters at the SCL Exit (from Ref. [7])

	Proton vertical	**H⁻ horizontal**
ε_{norm} (π-mm-mrad)	0.47	0.55
α	-2.0	-2.2
β	10.3	12.9
	Proton horizontal	**H⁻ vertical**
ε_{norm} (π-mm-mrad)	0.71	0.80
α	1.8	2.4
β	10.0	11.9

Proton Beam Transmission

For H^- beams, the transmission from the MEBT through the SCL is better than the accuracy of the current measurement (> 99%). However, for the proton beam, the transmission varies from 98% at nominal current to 86% at reduced beam intensity, with losses occurring primarily in the MEBT. This is due to the fact that the MEBT optics are intensity dependent (due to space charge), but are not adjusted with current here. Because the proton beam size is larger than the H^- (in the upstream MEBT near the foil), it is more sensitive to transmission loss.

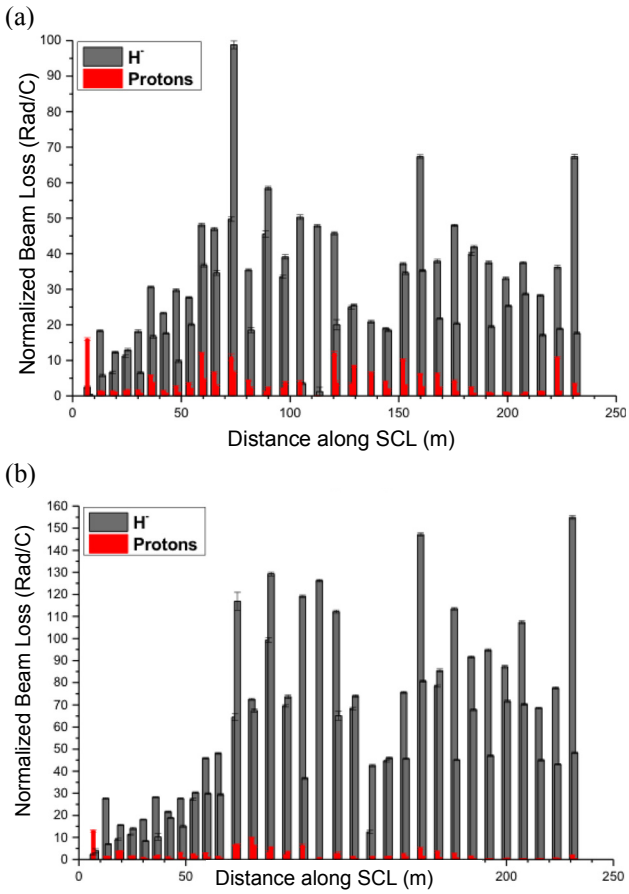

Figure 4: Beam loss along the SCL for the case of 30 mA, for proton and H^-; (a) for production optics, and (b) for design optics. Reproduced from References 7 and 8.

PROTON-H^- BEAM LOSS COMPARISON

Beam loss is primarily detected in the SNS SCL by ion chamber beam loss monitors (BLMs) [9], distributed 2 per warm section between cryomodules. Figure 4 shows a comparison of the measured beam loss along the SCL for the case of an H^- and a proton beam, with a 30 mA current. Beam loss shown here is normalized to the transmitted charge, and the values represent an average over 20 pulses, although the pulse-to-pulse variation is small. Both the H^- and proton beam cases are for 45 μs pulse lengths. Minor adjustments of the proton beam setup were performed to minimize loss (adjustments of linac RF phases by 1-2 degrees and lattice matching quadrupoles up to a few percent), as was also done for the H^- beam.

There is a dramatic reduction in beam loss throughout the SCL for the proton beam case. Many BLM readings are near the limit of detectable beam loss for the proton beam case. The BLM response for equivalent proton and H^- beam loss was verified to be the same by inserting intercepting devices into the beam directly upstream and downstream of the SCL. The much reduced beam loss throughout the SCL for protons, for a beam with similar properties as the H^- beam, signifies a beam loss mechanism unique to the H^- beam.

Loss Dependence on Intensity

It is interesting to examine the dependence of the beam loss on the beam intensity. The IBSt loss rate scales with the square of the beam density or, for constant bunch length and transverse beam size, with the square of beam current. The measured beam loss normalized to the transmitted charge (shown in Fig. 5) should vary linearly with the beam current for IBSt. Fig. 5 shows the beam loss for protons and for H^- vs. beam current. In this case each loss measurement shown in Figure 5 is the average of all BLMs along the SCL. Measurements are shown for both the design optics (strong focusing) and for the production optics (weak focusing).

For both the strong and weak focusing cases the H^- normalized beam loss varies close to linear with beam current, consistent with IBSt expectations. Also the strong focusing case (design optics) shows a higher loss rate than the weak focusing case (production optics) at all intensities, consistent with IBSt expectations. For the proton beam cases, there is no meaningful variation of the normalized beam loss with beam intensity, as expected without the possibility of IBSt mechanism (the slight decrease in normalized beam loss with intensity may be an artifact of the background subtraction method used in the BLM signal processing). There is also no meaningful difference in the normalized beam loss between the weak and strong focusing cases for the proton beam, also consistent with the lack of an IBSt loss mechanism. The slight fall-off from a linear dependence of the H^- loss vs. beam current at high values is not understood. It may be due to a dilution of the beam density due to increasing space charge forces.

SUMMARY

A series of beam measurements using a proton beam at the SNS accelerator shows much-reduced beam loss compared to an equivalent H^- beam. The H^- beam loss scaling with both intensity and focusing strength and the lack of an observable effect of the proton beam loss rate on intensity or focusing strength are all consistent with expectations of the IBSt beam loss mechanism. This loss mechanism should be considered for all future H^- linac designs. Evidence for IBSt has also been found at LANSCE [10].

For SNS, we expect to be able to tolerate the present beam loss rate with beam powers of up to 2-3 MW, without incurring the penalty of high radiation areas throughout the linac. However, efforts are aimed to reduce existing halo and operate with even larger beam sizes in an effort to further minimize IBSt effects.

DEVELOPMENT OF H-MODE LINACS FOR THE FAIR PROJECT*

Abstract

H-mode cavities offer outstanding shunt impedances at low beam energies and enable the acceleration of intense protons and ion beams. Crossed-bar H-cavities extend these properties to energies even beyond 100 MeV. Thus, the designs of the new injector linacs for FAIR, i.e. a 70 MeV, 70 mA proton driver for pbar-production and a cw intermediate mass, superconducting ion linac are based on these novel cavities. Several prototypes (normal and superconducting) have been built and successfully tested. Moreover, designs for a replacement of the 90 MV Alvarez section of the GSI - Unilac will be discussed to improve the capabilities as the future FAIR heavy ion injector.

INTRODUCTION

The scientific program of FAIR requires the construction of a new 70 MeV, 325 MHz proton injector [1] for the SIS18. This machine will provide at least 35 mA of protons at a repetition rate of 4 Hz.

Beside the new proton linac, FAIR also requires a massive upgrade of the GSI UNILAC linear accelerator [2].

The UNILAC started operation in 1975 and it is one of the eldest DTL still active. Almost 40 years of high duty factor operation (up to 25 %) led to the increasing number of failures occurred in the last years. That represents a strong reliability issue for the new FAIR facility.

Additionally, the Alvarez-DTL is equipped with DC quadrupoles, which is a disadvantage for short pulse operation and limits the machine flexibility in case of the multibeam operation (different ion beam with specific magnetic rigidities and beam currents). That constraint, together with the challenging requirements of 15 mA of U^{28+}, favours the replacement of the existing DTL section by a new high energy linac with short beam pulses at low repetition rate (HE-Linac).

The linac upgrade program will be completed by a new superconducting cw heavy-ion linac [3] with an adjustable energy from 3.5 to 7.3 AMeV for the super heavy elements program (SHE-Linac).

The choice of the RF cavity type represents the most critical key for such a massive upgrade. The experience with high current operation at the HSI and HLI led to the natural decision to base the UNILAC replacement on IH-DTL cavities. On the other hand, the successful R&D performed at the Frankfurt University on room temperature [4] and superconducting CH-DTL [5] justifies the use of that kind of structures for the new proton linac and for the cw SHE linac.

H-MODE CAVITIES

H-Mode cavities are characterized by a slim tube geometry resulting in a high shunt impedance and a uniform power loss distribution (see Fig.1). Beam dynamics is designed according to an asynchronous injection energy lattice like the KONUS [6] or the EQUUS [3]. Alternatively an APF [7] lattice can be used.

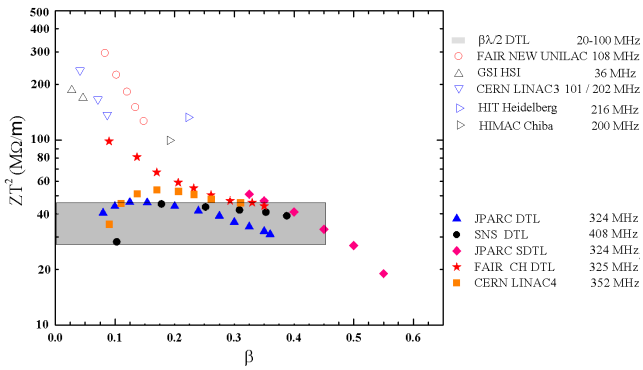

Figure 1: Effective shunt impedance of several ion and proton accelerators as function of the velocity profile.

The IH-DTL, exited in the $TE_{11(0)}$ mode is by far the most efficient RF structure in the β range from 0.01 to 0.2. For $\beta \leq 0.1$ it is competitive with superconducting structures, concerning the plug power demand, even at cw operation. Several IH-DTL are routinely in operation and this structure has established as standard solution for heavy ion in the frequency range between 30 and 200 MHz.

The CH-structure, exited in the $H_{21(0)}$ mode has a larger diameter for a given frequency compared with the IH-structure. Cavities with frequencies from 150 MHz to 3 GHz can be realized, making the CH-structure feasible for proton and ion acceleration up to 100 AMeV. Additionally, the crossbar geometry is so robust to ensure the mechanical stability required for superconducting operation. At present, the s.c CH-DTL is the only multi gap superconducting structure available at low energy.

THE CH-DTL FOR FAIR

The FAIR requirement of a dedicated proton injector pushed an intensive R&D activity in order to explore the capabilities of the room temperature CH-DTL. In 2006 a first test model was successfully built at the University of Frankfurt and later copper plated at the galvanic workshop of GSI. This 340 MHz cavity comprises eight equidistant cells of length $\beta\lambda/2$=45 mm, and was used to test all fabrication steps including welding, copper plating and designing of an efficient cooling system. Moreover, a tuning strat-

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

egy based on exchangeable drift tubes was adopted, and a new geometry based on larger half drift tube was developed to tune the end cells (see Fig.2). This cavity was successfully tested with a 2 kW, cw amplifier.

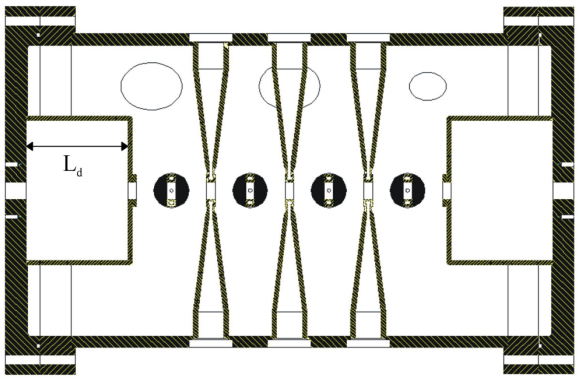

Figure 2: The geometry of the first room temperature CH-DTL.

Later on, the 3 MW 324 MHz klystron developed for JPARC opened new perspectives for the optimization of the CH-DTL. At low energy, the KONUS beam dynamics requires short sections in contrast with the high shunt impedance which favours longer cavities . To overcome this problem a coupling scheme to match one klystron to two CH sections have been developed [8].

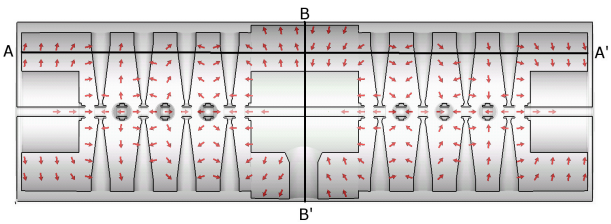

Figure 3: The electric field on the axis of a coupled CH-DTL.

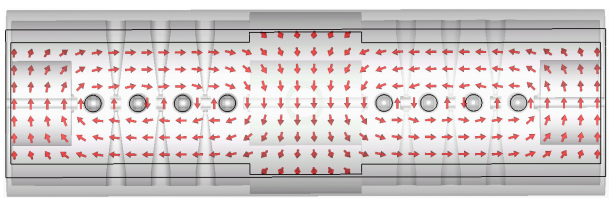

Figure 4: The magnetic field orientation inside a coupled CH. Field is shown in the plane A-A' of Fig.3.

The coupled structure consists of two CH-DTL connected through a single cell resonator. This intertank section oscillates in the Alvarez mode and the large drift tube houses an electromagnetic quadrupole triplet. The radius of the single cell resonator has to be adjusted so that the resonance frequency of this unit matches the adjacent CH cavities. RF simulations have proven that an effective coupling is achieved with this geometry. Fig. 3 and 4 show the distribution of the electric and magnetic field along the coupled structure. In particular, Fig.5 shows how the coupling cell oscillates in a TM mode like the standard DTL.

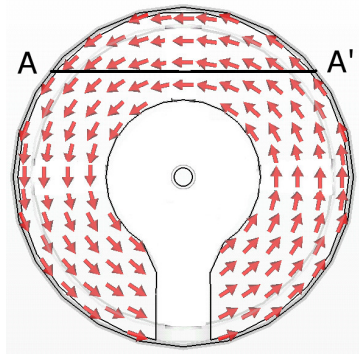

Figure 5: The magnetic field orientation inside the coupling cell. Field is shown along plane B-B' of Fig.3

Successful RF measurements on the scaled model of the second cavity of the FAIR proton injector was the milestone for the construction of the full scale prototype [9].

The main parameter of this structure are listed in Tab.1

Table 1: Main Properties of the second resonator of the FAIR Proton Linac. * indicates that calculation have been performed with a 15% reduced σ.

Energy Range (MeV)	11.7-24.4
RF frequency (MHz)	325.2
Effective Voltage (MV)	13.5
Beam Aperture (mm)	20
Magnet Aperture (mm)	30
Length (m)	2.7
RF Losses*	1.34

The cavity was delivered at the university of Frankfurt in late 2011. In a first step dummy stems and exchangeable drift tube made of Aluminum were mounted inside the cavity. Seventeen provisional tuners were installed along the structure, six in the fist CH, one in the intertank section and ten in the second CH, respectively.

First frequency measurements were in good agreement with simulations. The experimental value of 323.7 MHz is very close to the expected one of 324.4 MHz. The cavity was designed at a lower value with respect the operational frequency of 325.2 MHz to take into account the inductive effect of the tuners.

A measured field distribution along the beam axis is shown in Fig.8 while, Figs.9 and 10 compare the measured voltage with the reference one calculated with LORASR.

At present, stainless steel stems are ready for being welded inside the cavity. Copper plating will be performed in early 2013. The prototype will be then tested with a 3 MW klystron in the dedicated test bench recently built at GSI.

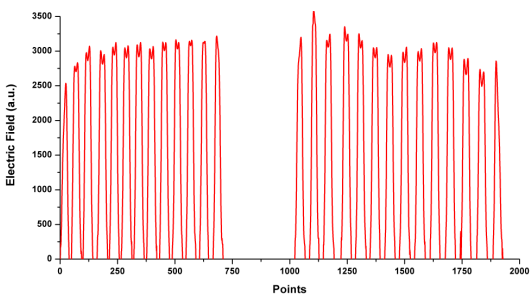

Figure 8: The measured field distribution on the axis.

The Proton Linac

The design of the FAIR proton injector is sketched in Fig.12: up to 100 mA of proton will be extracted from an ECR ion source at 95 keV. The beam is first accelerated by an RFQ to the energy of 3 MeV. After a matching section, the beam enters the first part of the drift tube linac, composed of three pairs of coupled CH-DTLs. At the energy of 37 MeV a 1.6 meter long dedicated diagnostic section is installed.

At that energy, space charge effects are reduced and the KONUS offers the possibility to build long lens free sections. For that reason, the high energy section is based on standard lens free CH cavities with slightly larger beam

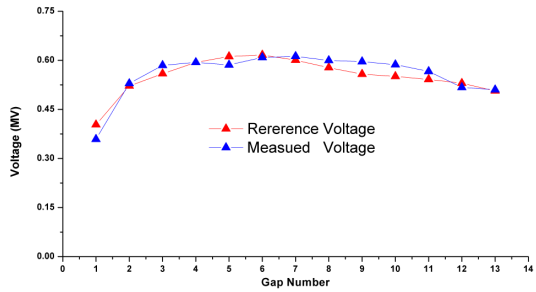

Figure 9: The voltage distribution in the first CH section.

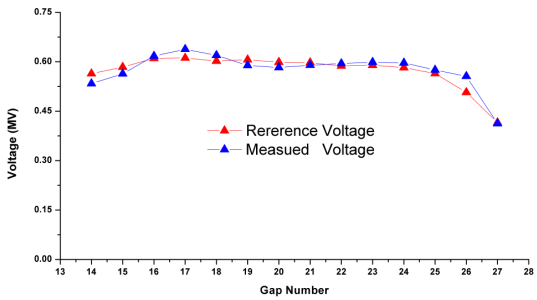

Figure 10: The voltage distribution in the second CH section.

aperture at each cavity ends. In this way the number of quadrupole triplets is reduced and the mechanical and RF design is simplified. Electromagnetic 3D simulations showed that three CH-DTL made of 21 gaps each could cover the energy range from 37 to 70 MeV within an rf power demand around 1 MW per individual cavity.

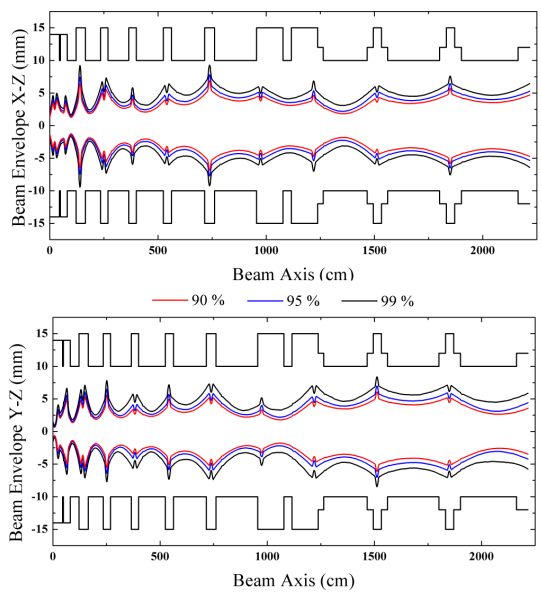

Figure 11: Beam envelope for the FAIR proton linac when 70 mA are injected in the DTL section.

The linac was designed assuming an RFQ output current ranging from 45 to 70 mA using the LORASR code. The

beam envelopes, shown in Fig.11, for the design current of 70 mA shows a large safety margin against beam losses.

Fig.13 presents the emittance including the current stated along the abscissa at the injection point. The red curve is the upper limit for the emittance that the injector, at given current, must provide. This limit is obtained from the foreseen multi-turn scenario and it depends mainly on several synchrotron parameters, such as circumference, injection energy, acceptance and filling factor. For a proper injection the linac emittance must remain below the straight line. This brilliance analysis shows that the best window for an effective injection would be around 55 mA.

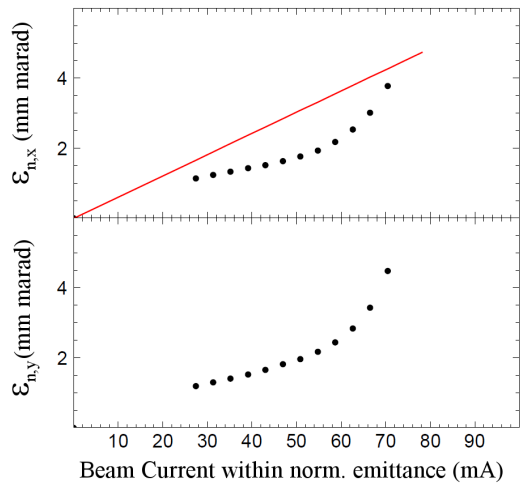

Figure 13: Brilliance analysis at the end of the proton linac in comparison with the synchrotron acceptance.

Finally, Tab.2 shows the beam evolution to the final energy of 70 MeV.

THE CW SHE LINAC

All chemical elements from 107 to 112 have been discovered at GSI.

Table 3: Main parameter of the s.c. cw SHE LINAC

A/q	6
Frequency (MHz)	217
Max. Beam Current (mA)	1
Injection Energy (AMeV)	1.4
Output Energy (AMeV)	3.5-7.3
Length (m)	13

To keep the Super Heavy Element (SHE) program at a competitive level an upgrade of the High Charge Injector (HLI) is ongoing, including a new 28 GHz ECR source and a new cw four-rod RFQ [10].At present, behind the new RFQ the existing IH-DTL injects a 1.4 AMeV beam inside the Alvarez DTL section of the UNILAC.

As the UNILAC should be operated as injector for FAIR, a strong limitation of the beam time for the SHE program is expected. To offer and adequate beam time for the nuclear chemistry program a dedicated linac is request by many scientific users. The design of a low energy cw linac would considerably profit from a multigap superconducting structure. At present, the CH-DTL is the only multigap structure which can be operated as superconducting DTL.

For that reason, a collaboration between GSI, IAP Frankfurt and HIM Mainz worked out a conceptual design based on s.c CH-DTL.

That new linac consists of nine superconducting CH-cavities operated at 217 MHz. The first three cavities accepts the beam from the HLI and perform the first stage of acceleration to 3.5 AMeV. At this point, the energy variable part begins and the final energy can be adjusted up to 7.3 AMeV within an energy spread of $\pm$ 3 AkeV. Beam focusing is provided by seven superconducting solenoids. The general parameters are listed in Table 3.

The demonstrator

The so called *Demonstrator* project includes the construction of the first s.c CH cavity with the s.c. solenois at the cavity ends, and the assembly of the components in the cryostat. A full performance beam test is foreseen at the HLI within 2014 at earliest [11].

The s.c. 217 MHz CH-structure [12] consists of 15 equidistant gaps for a gradient of 5.1 MV/m. The structure, shown in Fig.14, has inner total length is 0.69 m. Optimized field distribution is shown in Fig.15

Nine static tuners, one slow and two fast bellow tuners, will be mounted to ensure the proper frequency matching.

Further rf, mechanical and multipacting simulations are

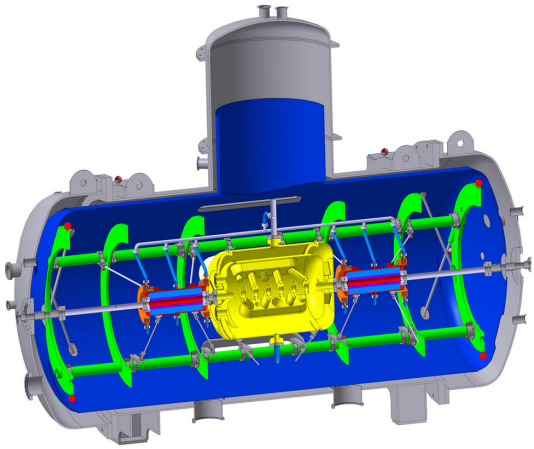

Figure 14: The demonstrator project.

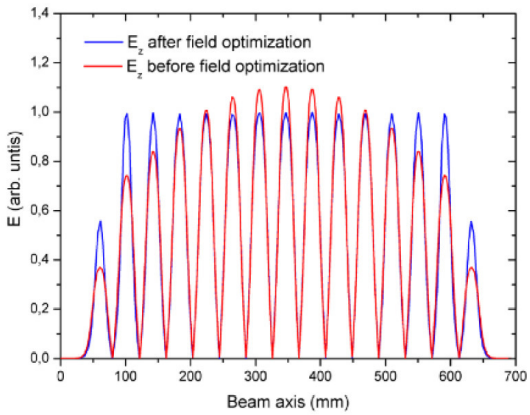

Figure 15: Field distribution of the demonstrator CH-DTL.

in progress at the moment to determine the final geometry of the dynamic bellow tuners.

THE HE LINAC

A new High Energy Linac (HE-LINAC) is presently under discussion at GSI. This new machine has to replace the 90 MV DTL section of the UNILAC.

A first proposal [13] was to increase the prestripper energy to 3 AMeV with 3 IH-DTL. The higher energy would allow generation of U^{37+} which would be further accelerated to 11 AMeV by another 4 IH-DTL.

Recently a less ambitious solution, consisting in the replacement of the Alvarez DTL, is under investigation. Six IH cavities would cover the energy up to 11.4 AMeV in approximatly 25 meter including a new matching section behind the charge separator.

This solution is more cost effective compared to the previous one, and will leave plenty of space available for a future linac upgrade. At the energy of 11.4 the frequency can be raised to 325 MHz and CH cavities could be used to increase the energy. Additionally, alternative solutions to the present gas stripper, like a C-foil or a plasma stripper are under investigation in order to generate higher charge states.

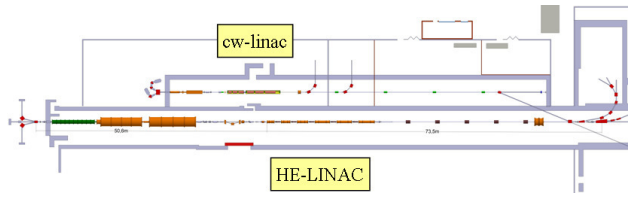

Figure 16: The proposed upgrade of the UNILAC insludig the new HE and SHE linac.

ACKNOWLEDGMENT

The authors would like to express their gratidute to the collegues of the mechanical workshop of IAP Frankfurt and of the galvanic laboratory of GSI. This work has been supported by the Federal German Ministry for Education and Research BMBF-06FY9089I and by HICforFAIR within the LOEWE funding program of the State of Hesse.

b) Sumitomo Accelerator Service Ltd., Shinagawa, Tokyo, Japan

Abstract

A new injector for the RIKEN RI-Beam Factory (RIBF) was fully commissioned in October 2011. The injector accelerates ions of $m/q = 6.8$ up to 670 keV/u. To save cost and space, a direct coupling scheme was adopted for RF coupling between the DTL cavity and amplifier, based on an elaborate design with the Microwave Studio software package. The new injector has been successfully commissioned and worked very stably for beam service time, increasing the uranium beam intensity by an order of magnitude. Moreover, it is now possible to independently operate the RIBF and GARIS facilities for super-heavy element synthesis.

INTRODUCTION

Role of new injector

Since 2008, the accelerator complex at the RIKEN RI-Beam Factory (RIBF) has provided various heavy ion beams according to the programs of the RIBF experiments. The developed beams so far are polarized- and unpolarized-deuteron, ^{4}He, ^{14}N, ^{18}O, ^{48}Ca, ^{70}Zn, ^{124}Xe and ^{238}U. Among them the experiments of the new RI production require intense beams. Initial experiment using the uranium beams was carried out in November 2008, at 0.4 pnA. This intensity is insufficient for radio isotope production experiments at the RIBF. Our final goal is to realize a 1 pμA beam current for each ion.

The new injector project started because the main injector, the RIKEN Heavy Ion Linear Accelerator (RILAC) [1], was tasked with super-heavy elements (SHE) search [2]. This was a problem because the RIBF experiments could not be performed when SHE search experiments were performed. Also, the beam currents for uranium and xenon beams were unsatisfactory. Therefore we designed and built a new injector, the RIKEN Heavy Ion Linear Accelerator (RILAC2), dedicated for the acceleration of intense uranium and xenon beams to energies of 670 keV/u, which is the injection energy of the RIKEN Ring Cyclotron (RRC) [3].

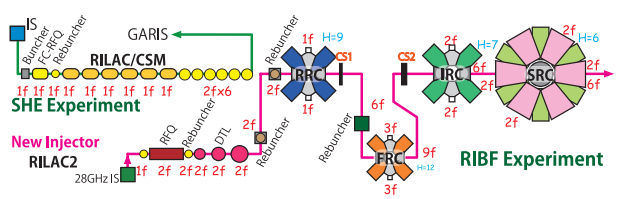

Figure 1: RIBF accelerator complex.

Xe and U acceleration by cyclotron cascades

In RIBF, Xe and U beams are accelerated by cyclotron cascades of RRC, the fixed frequency ring cyclotron (fRC) [4], the intermediate-stage ring cyclotron (IRC) [5], and the world first separate-sector superconducting ring cyclotron (SRC) [6]. In this scheme shown in Fig. 1, the intense $^{238}U^{35+}$ beams from the ion source can be accelerated by the RRC without charge stripping, before injection to the RRC. Using the stripper after the RRC, the charge state is converted to 71+ at an energy of 10.75 MeV/u for injection into the fRC. Then $^{238}U^{71+}$ beams are accelerated using the fRC with velocity gain of about 2 to suit the injection energy of the IRC. Before injection to the IRC, the charge state is converted to 86+.

For uranium, the first stripper (CS1) utilizes a 0.3 mg/cm^2 carbon foil and the stripping efficiency is about 18%. The second stripper (CS2) utilizes 17$\sim$19 mg/cm^2 carbon foil, and the stripping efficiency is about 33%. Owing to the heat load by the intense beams, these efficiency values go down with increased beam dose.

To maximize the average current, the stripper foils are changed frequently, typically 2 or 3 times/day. To increase the beam current, the stripper foil lifetime must be extended.

Injection to RRC

The beams from the RILAC2 are injected into the RRC. Layout of the key devices of the RRC is shown in Fig. 2. The function of the isochronous cyclotron is to increase the velocity of ions by the ratio of the extraction radius to the injection radius. The velocity gain of the RRC is four and the energy of the extracted beams is 10.75 MeV/u. In the case of $^{238}U^{35+}$ acceleration, the magnetic rigidity is 3.2 T·m, which is 91% of the maximum value of the RRC. The operating dee-voltage of the resonator is about 60 kV. The resonators of double-gap type with a dee angle of 23.5° provide 230 kV/turn acceleration voltage with a harmonic number of 9, resulting the total number of revolutions of 325. The gap between turns at the extraction radius is only 5.5 mm, excluding the effect of betatron motion. Therefore beam loss during cyclotron acceleration is prone to occur in the electrostatic deflection channel (EDC). Acceleration

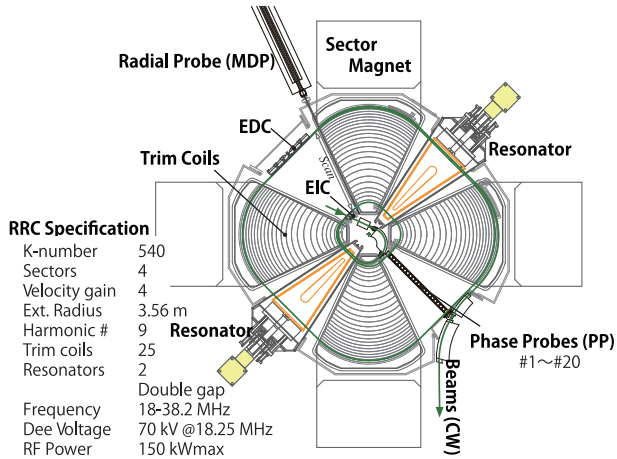

Figure 2: Layout of RRC showing injection and extraction orbits and diagnostic devices of radial-probes and 20 set of phase-probes.

voltage error is required to be within $\pm 0.1\%$ amplitude and $\pm 0.1^\circ$ phase, because unstable acceleration voltage causes fluctuations in the beam orbit and size [7]. As an injector of cyclotrons, stability of the RILAC2 RF system is required so that the injection timing of the beams remains within the acceptance of the cyclotron RF.

NEW INJECTOR RILAC2

Overview

As RILAC2 was to be installed in the remaining space of the AVF cyclotron hall, a compact design was needed. The picture after installation is shown in Fig. 3a.

The RILAC2 consists of a superconducting ECR ion source (SC-ECRIS), low-energy beam transport line (LEBT), prebuncher (BUN), RF quadrupole linac (RFQ), rebuncher, drift tube linac (DTL), and high-energy beam transport line (HEBT). Figure 5 shows a schematic of the RILAC2. While the prebuncher is operated at the fundamental frequency of 18.25 MHz, RFQ and DTL cavities

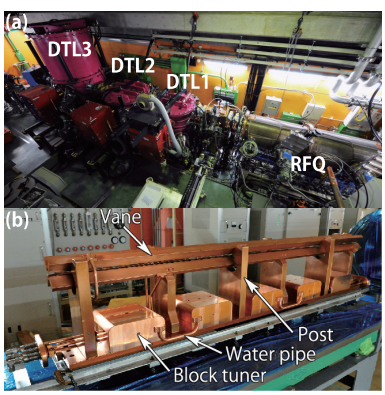

Figure 3: Pictures of RILAC2. (a)The RILAC2 accelerators installed in the AVF hall.(b)Resonator of RFQ showing the tuner blocks for frequency modification.

are operated at the second harmonic.

Superconducting ECR ion source

A new SC-ECRIS was designed and constructed to provide uranium beams 100 times more intense than those from the RIKEN 18-GHz ECRIS at RILAC [8]. Owing to the set of six solenoid coils, the plasma volume is as large as 1100 cm^3 and it is able to produce various magnetic field distribution on axis, which is both of classical B_{min} and so-called "flat B_{min}" [9]. Beam commissioning was performed in 2008 using a 18 GHz microwave power source. Last year, a new 28 GHz gyrotron power source was introduced, aiming for much higher intensity. The achieved intensities for $^{124}Xe^{25+}$ and $^{238}U^{35+}$ are 250 eμA and 60 eμA, respectively. The value 60 eμA is 30-fold that of the 18-GHz ECRIS.

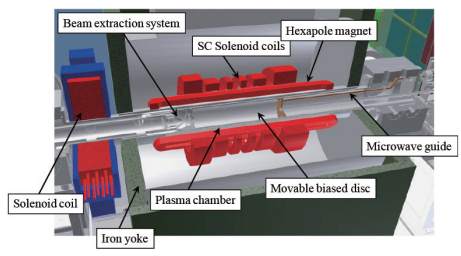

Figure 4: Cut view of SC-ECR.

RFQ Linac and Drift Tube Linac

Table 5 summarizes the design parameters of the RFQ linac and the DTL.

The RFQ linac is based on the four-rod structure. The cavity was originally developed by Nissin Electric Co., Ltd. [10]. While the original cavity had a resonant frequency of 33.8 MHz and accelerated m/q = 16 ions up to 84 keV/u in continuous wave (CW) mode, this was later modified to have a resonant frequency of 36.5 MHz and to accelerate m/q = 6.8 ions up to 100 keV/u [11]. The modification was made by adding tuner blocks between the posts which support the vanes (Fig.3b). The wall loss of the tuner blocks was estimated as 2 kW in total with the designed inter-vane voltage of 42 kV. The unloaded Q value was about 80% of ideal. The main amplifier is based on the tetrode (EIMAC 4CW50,000E) which is basically the same as that for the RILAC injector RFQ [12]. The RF power is fed through a capacitive coupler which matches the input impedance of the cavity to 50 Ω. The maximum output power is 40 kW. Owing to its relatively low frequency, the RFQ has a large focusing strength (B) of 6.8 with 42 kV inter-vane voltage, which is provided with only 18 kW RF power. The maximum modulation (m) is 2.35.

The main accelerator part of the RILAC2 is a drift tube linac (DTL) with newly designed cavities. These cavities operate in CW mode as same as RFQ. As minimization of the installation space was required, the cavities were based

the quarter-wavelength structure with a resonant frequency of 36.5 MHz, twice the 18.25 MHz beam frequency. The DTL cavities are directly coupled to amplifiers without using long coaxial lines, further compacting the DTL structure. The DTL cavities were carefully designed to accommodate the significant frequency change due to direct coupling of the tetrode (EIMAC 4CW50,000E) [13]. The coupling was designed by using Micro Wave Studio (MWS) under the following assumptions: that the Q of the actual cavity is 78% of ideal; that the resonant frequency of the cavity itself as obtained from the calculation using MWS is 75 kHz less than that of the actual cavity; that the capacitance of the tetrode is 55 pF; and that the load resistance of the tetrode is ∼700 Ω.

Low-power tests were carried out with the actual DTL cavity coupled with the amplifier (Fig. 6). In the case of DTL3, the resonant frequency of the cavity was about 0.1% higher than that of the calculation by MWS package. The unloaded Q value was 78% of ideal. The position and the size of the coupling disk of the coupler were determined by measuring $|S_{11}|$ using a network analyzer. Afterward, the coupler position was finely tuned by performing high-power tests.

When the first excitation of the DTL3 cavity by pulsed-power from the amplifier, the RF power was completely reflected due to multipactoring. After 24 hour conditioning with pulsed-power, it was observed that the pickup signal of the cavity was gradually developed. Subsequently, we

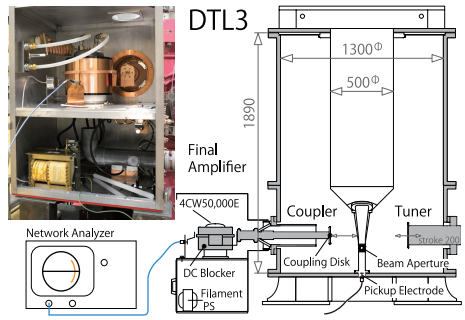

Figure 6: Setup of low-power test showing amplifier is directly coupled to DTL cavity through a capacitive coupler.

changed the conditioning power mode to CW operation, in which a large ratio of the reflection was allowed, and the gap voltage increased up to 35 kV in the first 15 minutes overcoming of levels of multipactoring.

Long-term test was performed measuring the amplitudes and the phases of the cavities continuously using commercially available RF lock-in amplifiers (SR844). The monitor system [14] is useful for determining whether the RF-feedback system works normally or not. The low-level circuit, which consists of auto-gain control and phase-lock, is based on analog feedback. The long-term stability of the amplitude and the phase of the RFQ and DTL cavities are $|\Delta V/V| \leq 0.1\%$ and $\Delta\phi \sim 0.1°$, respectively (Fig. 7).

BEAM COMMISSIONING

Acceleration test

Since the first beam of ^{124}Xe was successfully accelerated on Dec. 12, 2010, production of ^{124}Xe and ^{238}U beams has been repeatedly performed. Beam tuning was made starting with design parameters and fine adjustment was performed to maximize the beam transmission efficiency. As a result of the work described in Ref. [15], the transmission efficiency of RILAC2 has recently improved to 70∼80% (Fig. 8a). The beam energy was tuned by changing voltages and phases in the RILAC2 RF systems to 670 keV/u, as confirmed by the TOF method.

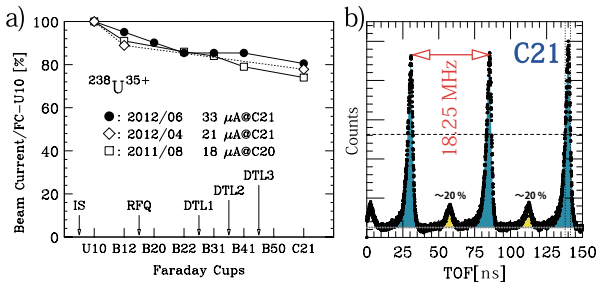

Figure 8: a) Ratio of beam current, as measured by Faraday cups, to IS. b) TOF spectrum at C21.

As shown in Fig. 8b, a prebuncher converts DC beams to bunched beams with frequency 18.25 MHz. Bunching efficiency is typically 80%, the remainder (denoted by yellow hatch in Fig. 8b) lost at RRC injection. In the case of ^{238}U^{35+}, if 75% of the 60 eμA beams from the ion source are accelerated by RILAC2 and RRC transmission efficiency of 80% is achieved, the beam current at the RRC is about 1 pμA, which corresponds to 2.6 kW. Because the cooling of the EDC stands less than 300 W, the extraction efficiency better than 90% is desirable.

The intensity and TOF timing of the beams are continuously monitored by detecting a signal from pickup electrodes induced by bunched beams. Figure 9 shows changes in the PP-S71 pickup signal over 24 hours. The longitudinal acceptance of the RRC is about ±3° in the RF phase. The corresponding timing is ±0.2 ns. Owing to stable operation of the RF system of the RILAC2 and the double rebuncher system (B7 and S6) downstream of the RILAC2, beam intensity and injection timing were stable enough for injection to the RRC (see Fig. 10). .

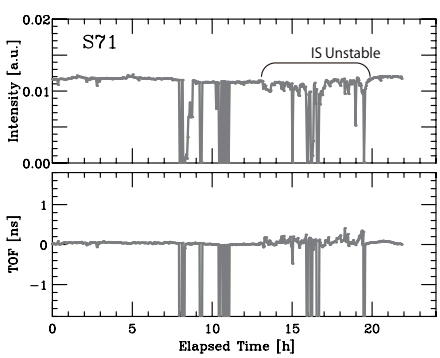

Figure 9: Measured intensity and timing at S71.

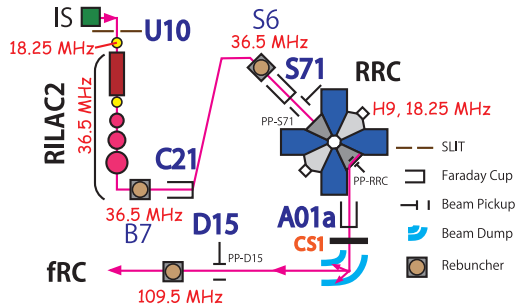

Figure 10: Schematic layout of acceleration with RRC.

Commissioning to RIBF

To date, RILAC2 has provided ^{238}U and ^{124}Xe beams for nuclear physics experiments at the RIBF, as listed in Table 2. During beam service time, RILAC2 operation has been very stable and the break time resulting from the rf down time of RILAC2 was less than 0.3% of the total scheduled beam service time. Nonetheless, maximizing the beam current on target requires elaborate tuning, and transmission efficiency of the RRC was as low as 50∼60%, as obtained from the ratio of measured current of A01a to that of S71.

Due to bunching efficiency, 20% of beams are lost at RRC injection. To extract the accelerating beams with 100% efficiency, beam-turns must be separated at EDC. The turn-pattern of beams circulating in the cyclotron is measured using a differential probe. Figure 11 shows data measured during ^{124}Xe beam service time in 2012. The turn separation at the extraction radius was particularly poor. Experimentally, the turn pattern was measured by cutting the beam at the exit of IS in horizontal and vertical directions, using a set of slits at U10 (Fig.11b). Nonetheless, the separation obtained remains imperfect.

The poor turn separation is partly due to the low voltage of the acceleration cavity. It is difficult to increase the voltage because the 18.25 MHz operation frequency is the lower limit of the cavity, and the tuners are very close to the dee electrode. The turn separation cannot be obtained if the beam's longitudinal emittance from RILAC2 does not match the acceptance of RRC. This problem has not yet been solved.

Table 2: Beam production for RIBF using RILAC2.

Nuclei	Beam Service Time	RRC out	SRC out
^{238}U	17/10/11∼ 07/12/11	0.3 pμA	3.5 pnA
^{124}Xe	11/12/11∼ 18/12/11	0.7 pμA	15 pnA
^{124}Xe	16/06/12∼ 05/07/12	1 pμA	24 pnA

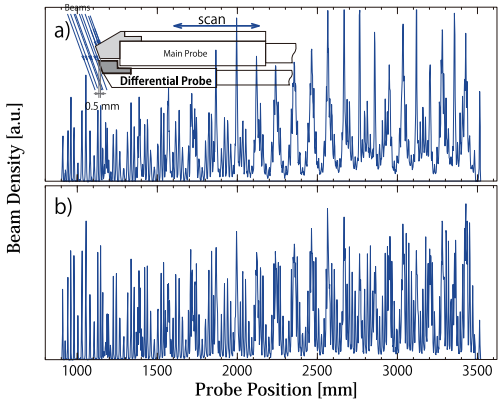

Figure 11: Turn pattern of the circulating beams in RRC. a) U10 slits were set ±5 mm in horizontal and vertical directions. b) ±1 mm and ±2 mm in horizontal and vertical directions, respectively.

Lifetime of charge strippers

Although the transmission efficiency of the RRC remains unsatisfactory, the beam current from the RRC has been greatly improved. As already reported in Ref. [16], the lifetime of the carbon stripper foil was as short as 0.5 days with 4 eμA beams during beam service time in December 2009. Exchanging the stripper foils requires several hours, and due to differences in their thickness, the RF-phase of following accelerators must be retuned. Since the beam intensity at FC-A01 was expected to exceed 10 eμA last year, we have developed carbon nanotube/sputter-deposited carbon (CNT-SDC) foil on a rotating cylinder system [17]. Its rotational speed was 0.05 revolutions per minute. It worked very well over the beam service time in December 2011, the lifetime being 4∼5 days with the maximum beam current of 3.5 pnA at the SRC. This intensity was 4-fold than in December 2009.

For ^{124}Xe acceleration, it is necessary to strip the charge from 19+ to 46+ using a fixed carbon foil. The beam intensity on the stripper foil in June 2012 was about 18 eμA. The frequency of the foil exchange was 3 times/day. Due to the heat load of energy loss at the foil, the foil became significantly thinner within a few hours. The intensity and the timing of the stripped ^{124}Xe beams observed at D15, which is located about 34 m downstream from the stripper, were gradually decreased and advanced as shown in Fig. 12. The beam intensity at the SRC was 24 pnA to the maximum.

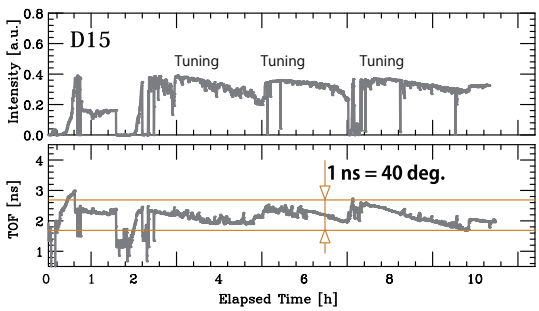

Figure 12: Intensity and timing change at D15.

SUMMARY AND PLANS

In December 2011, ^{238}U beams were successfully provided from RILAC2 and accelerated to 345 MeV/u for a beam service time of 50 days. The reliability fo the rf part of the RILAC2 was more than 97.7% during the beam service time listed in Table 2. Because it is no longer realistic to use carbon foils, we are now preparing a gas stripper system with He [18] for the beam service time scheduled this fall. The gas stripper system with N_2 is also useful for Xe acceleration. In addition, the beam chamber of the analyzing magnet downstream from the charge stripper (see Fig. 10) has been equipped with a beam dump, allowing it to withstand a 10 kW beam load.

ACKNOWLEDGEMENT

The authors thank the staff of Sumitomo Heavy Industries Ltd. for their contributions towards construction of the RILAC2. The authors also thank the operators of the Sumitomo Accelerator Service Ltd. for their cooperation in beam commissioning.

FRANZ – ACCELERATOR TEST BENCH AND NEUTRON SOURCE

O. Meusel, L.P. Chau, M. Heilmann, H. Podlech, U. Ratzinger, K. Volk, C. Wiesner
IAP, University Frankfurt/Main, Germany

Abstract

Accelerator based neutron sources are used for different kinds of research programs in nuclear astrophysics, material science and for the development of next generation nuclear power plants. The challenge of existing and planned neutron sources is to provide highly brilliant ion beams with high reliability.

The Frankfurt neutron source FRANZ is not only a neutron source but also a test bench for novel accelerator and diagnostic concepts for intense ion beams. The experiment consists of a compact linear accelerator for the acceleration of an intense proton beam to 2MeV producing neutrons via the ^{7}Li(p,n) reaction. The final beam intensity will be 200mA. Therefore the space charge and space charge compensation effects can be studied with high statistical significance along the accelerator.

The hot filament-driven gas discharge ion source already delivers 240mA beam current with a proton fraction of 92%. The low energy beam transport LEBT section is equipped with four solenoids matching the beam into a chopper system and into a RFQ-IH combination already under construction. Coupling of the RFQ accelerator stage and the IH drift tube cavity offers the possibility to use only one power amplifier as a driver for both of these resonators and reduces investment costs. The compact design of the low-β accelerator stage is optimized for high beam intensities to overcome the expected strong space charge forces in this accelerator test bench.

The presentation will give a brief overview of the FRANZ accelerator and discusses the beam dynamics, comparing numerical and experimental results.

INTRODUCTION

To advance the development of accelerator technology a dedicated test bench was needed. Different work groups are now able to test their devices under realistic conditions with respect to the interplay of each of the accelerator components. The main focus of the planned experiments is to reach the intensity and power limits for conventional RF accelerator technics. The question of these limits is highly relevant for several future accelerator projects and the basis of next generation accelerator concepts.

It is planned to use a proton beam with beam energies of 2MeV with energy variation of about ± 0.2MeV. These parameters enable various experiments by the use of thermal neutrons produced by the ^{7}Li(p,n) reaction at the end of the accelerator test bench. Therefore an astrophysical research program was launched for the measurement of neutron caption cross sections relevant for nucleo synthesis [1].

Figure 1 shows the scheme of the experimental setup of the FRANZ facility. It consists of a high voltage terminal faciliating ion source operation, a low energy beam transport section including a chopper system, the main accelerator, a bunch compressor and target stations. Two operation modi for the experiments will be available. The compressor mode will deliver a 1ns beam pulse with a repetition rate of 250 kHz and an estimated peak beam current of 9.6A. The activation mode uses a cw beam to produce a continuous neutron flux. Because of the average power density the proton beam in activation mode is limited to a current of about 8 mA for the use of solid targets and up to 30 mA for liquid metal targets.

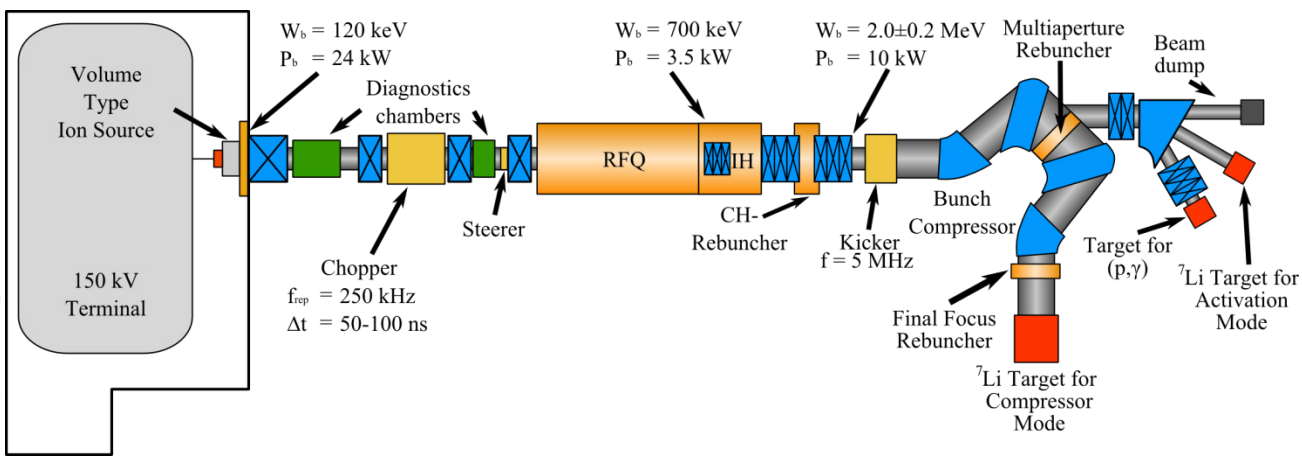

Figure 1: Experimental setup of the FRANZ facility. The accelerator test bench and neutron source consist of a 2MeV proton accelerator equipped with bunch compressor and several target stations.

ION SOURCE

A volume type ion source was chosen for FRANZ to extract the proton beam from a hot filament driven gas discharge plasma [2]. Figure 2 shows the design of the ion source. The life time of the filament is limited to about one month of operation. On the other hand the plasma temperature of a gas discharge at moderate arc power as well as the confining magnetic field is very low compared with other source types e.g. ECR sources. Therefore the beam emittance is small and gives the possibility to investigate causes of emittance growth during beam transport and acceleration along the whole test bench.

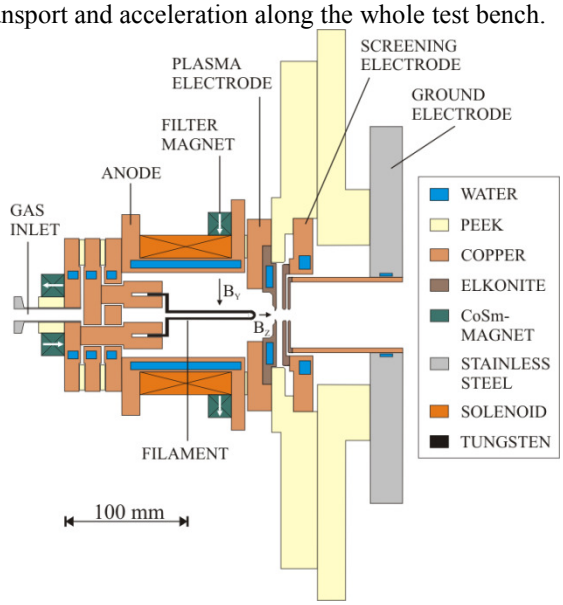

Figure 2: Crossectional view of the volume type ion source under construction.

Numerical simulations using of the IGUN code [3] show that for the planned beam intensities a triode extraction system keeps quite well the beam emittance during the extraction phase when compared with other extraction schemes [4]. The simulations for the extraction and beam transport were performed for multi species beam with measured fractions H^+ = 91%, H_2^+ = 7%, H_3^+ = 2%.

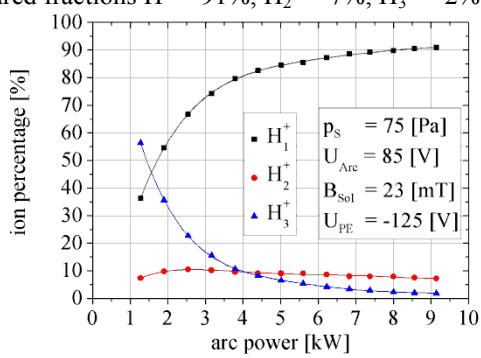

Figure 3: Measured beam composition as a function of the arc power.

The chosen aspect ratio of S = 0.61, an emission area of 0.5 cm^2 and an extraction field strength of 6.2 kV/mm result in a simulated beam radius of r_{beam} = 5.5 mm, ε_{rms} = 0.085 π mm mrad and a divergence angle of r' = 84.5 mrad. The measured total beam current was 261mA.

LEBT SECTION WITH CHOPPER

The LEBT section consists of 4 solenoids for beam focussing and includes partial of space charge compensation due to residual gas ionisation. Figure 4 shows a scheme of the planned LEBT. The first and second solenoid will be used for separation of ion species and to match the proton beam into the chopper system. Downstream of the chopper two solenoids will focus the beam into the acceptance of the RFQ. Two pumping and diagnostic tanks will be used for several non interceptive diagnostics e.g. optical beam profile measurement and beam potential measurements using a residual gas ion energy analyzer.

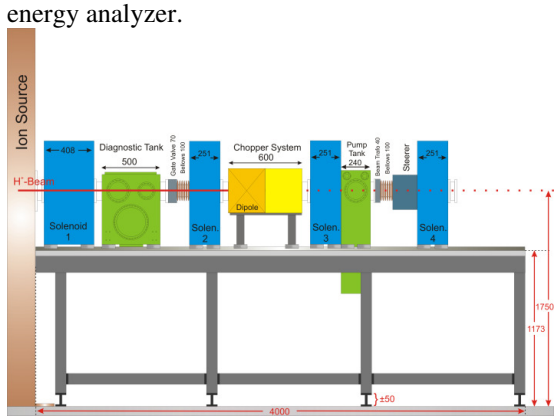

Figure 4: Scheme of the LEBT section with four solenoids and the chopper device.

The chopper system consisting of a pulsed Wien filter combined with a massless septum provide the 100 ns proton beam pulses. Figure 5 shows the arrangement of the chopper system.

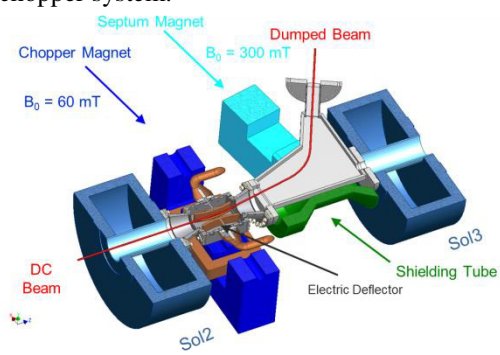

Figure 5: Cross sectional view of the chopper system consisting of a pulsed ExB filter, a septum magnet with magnetic shielding tube and an apertur.

A fast electric kicker compensates the magnetic force of the static chopper magnet with a repetition rate of 250 kHz. The massless septum consisting of a septum magnet and a shielding tube provides the post separation and a pulse with a flat top of at least 50 ns. Numerical simulation of the ExB chopper system shows an influence of secondary electrons. The high production rate of

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

electrons in the chopper system gives the possibility for partial space charge compensation of short beam pulses. Preliminary studies result in approximately 30% of space charge compensation by the use of a these device. For the electric deflector the secondary electrons bear the risk of sparking and sputtering from the electrodes. Therefore the shortening tubes will be used as screening electrodes. Beam transport and chopping leads into an emittance growth by a factor of 4. It seems possible to reduce this value further by optimization of beam transport with respect to the filling degree of the solenoids and a detailed description of space charge compensation. Pulsed beam with proton densities of $n_p = 8.2 \times 10^{14}$ m^{-3}, generalized perveance of $K = 3.1 \times 10^{-3}$ will be injected in the coupled RFQ-IH accelerator.

COUPLED RFQ-IH DTL

In order to minimize installation costs and to use one compact common rf amplifier a coupling of the RFQ and IH-DTL is planned [4]. Figure 6 shows a crossectional view of the coupled accelerator stages. Both of the cavities can also be used separately. The RFQ is 1.75 m long and needs an input power of 150 kW. Numerical simulations using the PARMTEQM code show a beam transmission of 95% with acceptable emittance growth at the design current I = 200 mA for an electrode voltage of about 75 kV. Output energy of the RFQ will be 0.7 MeV. The IH-DTL will boost the proton beam to its final beam energy of 2 MeV. The power consumption of the IH cavity is in a range of about 45 kW to establish a gap voltage of 300 kV. Due to the fact that a RFQ acts like a buncher, the incoming proton beam will also be compressed longitudinally. Beam transport simulation show the micro bunch phase width is in the range of 60 degree. The average bunch current increases up to 1.2A and the resulting compression ratio is $\eta = 6$.

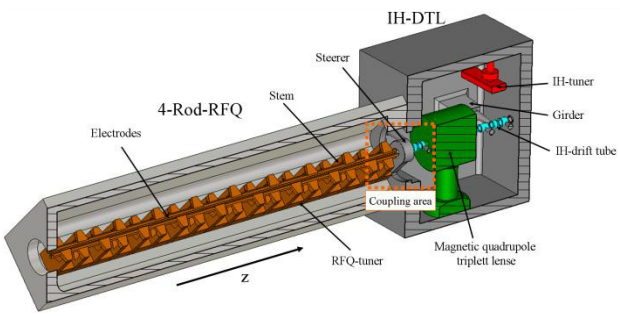

Figure 6: Cross sectional view of the coupled RFQ-IH accelerator.

BUNCH COMPRESSOR

By applying the bunch compressor concept of the Mobley type for high current beams a split magnetic dipole array include edge focusing was chosen. The periodic deflection by the RF kicker at one focus of the bending system guides up to 9 bunches on different paths to the final focus, where the neutron production target is located. As shown in figure 7 two rebuncher cavities are needed to focus the beam longitudinally.

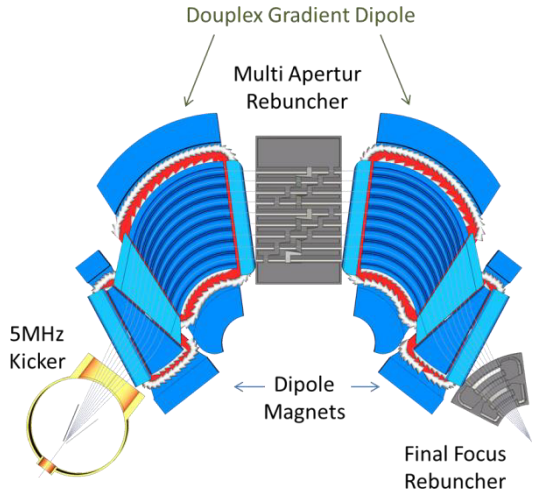

Figure 7: Scheme of the Mobley type bunch compressor.

By choosing adequate parameters all 9 bunches will overlap at the target and produce a 1.1 ns proton pulse with a proton density of $n_p = 8.2 \cdot 10^{14}$ m^{-3}. Space charge forces become dominant, the generalized perveance is $K = 2.2 \cdot 10^{-3}$. Figure 9 shows the bunch current as a function of time, the peak current is 9.6 A. The compression ratio downstream of the whole proton injector is of $\eta = 48$.

CONCLUSIONS

In a first step the beam current will be limited up to 50mA. Detailed multi particle transport simulations show that the activation mode using a 30 mA cw beam will be limited by the rf power consumption, target power deposition and radiation safety. The compression ratio of the compressor mode is 48. The resulting proton density and space charge force leads into increasing beam spot sizes and pulse duration at the ^{7}Li(p,n) target. Right after the first measurement period an intensity upgrade on 150mA and later on 200mA is planned.

Abstract

An accelerator/decelerator for slow neutron beams has been demonstrated. The energy of a neutron can be increased or decreased by flipping the neutron spin (directly coupled to magnetic dipole moment) in magnetic field. This device is a combination of a gradient magnetic field and an RF magnetic field. Test experiments were performed by using very slow neutrons at High-Flux Reactor at Institut Laue-Langevin. Acceleration and deceleration for focusing of neutrons at the detector position was observed. Focusing neutrons enables us to transport the neutrons while maintaining density from source to experimental position. This will be a powerful technique for measurement of the permanent electric dipole moment of neutrons, which require a high density of neutrons.

INTRODUCTION

Particle accelerators have continually evolved since their invention, and nowadays are applied not only in physics experiments but also in various fields such as medical science. The properties of the beam should be optimized for each use by accelerating, decelerating, focusing and/or defocusing. Recently the neutron beam becomes important as a probe for new science including particle physics with extremely high precision. Although the ray of neutrons has been handled by some optical devices, for example, mirrors and lenses, it is impossible to control the velocity by the electric field used in an ordinary accelerator because the neutron is an electrically neutral particle. A neutron accelerator which manipulates the velocity has the advantage that experiments can be performed with high precision.

One of the most useful applications of the neutron accelerator is space-time focusing. In the case of pulsed neutrons, during transport of the neutrons to the experimental area, the neutron pulses spatially spread as some neutrons travel faster whereas some travel slower. The density decreases according to the velocity spread of the neutron pulse. When fast neutrons are magnetically decelerated and/or slow neutrons are accelerated properly in the middle of the transport, these neutrons can reach the experimental area at the same time (Fig. 1) [1, 2, 3, 4]. The density can be kept from the source to the arrival position by focusing. This enables us to utilize instantaneous-intense pulsed neutrons in order to suppress the systematic errors for some experiments which require dense neutrons, for example, search for neutron electric dipole moment (nEDM) to reveal the origin of matter in the universe. Although experimental searches have been pursued in the world [5, 6, 7, 8, 9], the nEDM has not yet been observed. The present upper limit is $|d_n| < 2.9 \times 10^{-26} e\mathrm{cm}$ (90% C.L.) [9], which is very close to the predictions of some physics beyond the standard model of particle physics, for example, supersymmetry. Using the space-time focusing and high power pulsed neutron source, we can improve experimental sensitivity by one or two orders of magnitude to search for nEDM.

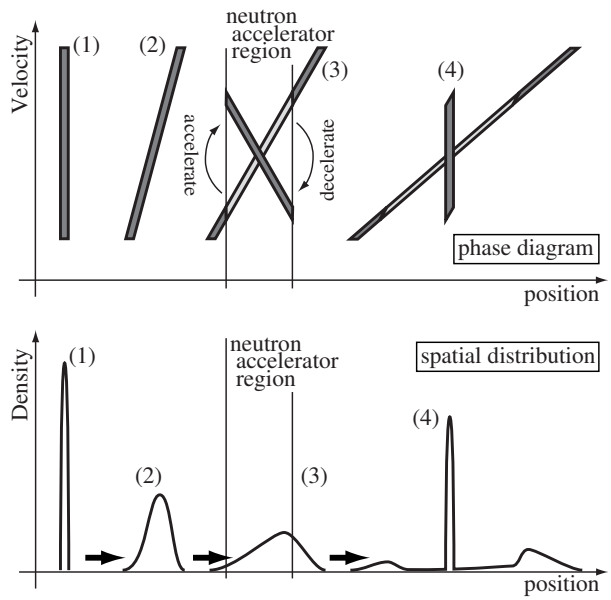

Figure 1: Concept of space-time focusing by using neutron accelerator. (1) Neutrons are generated as a pulse. (2) Neutrons spread spatially during transport. (3) Neutrons are accelerated/decelerated properly. (4) Some neutrons are focused at the experimental position. This figure illustrates the behavior of polarized neutrons.

NEUTRON ACCELERATOR FOR FOCUSING

For the acceleration/deceleration of neutrons, we can utilize flipping of neutron spin in magnetic field. Although this change is too small to be used for the focusing of fast neutrons, it is enough to realize the focusing with very slow neutrons. Such slow neutrons which have the kinetic energy of less than about 200 neV, called as ultracold neutrons (UCNs), are used in nEDM experiments. In this demonstration, we use adiabatic fast passage method (AFP), which is one of the spin flippers [12]. When a neutron passes through an RF magnetic field in the surrounding static field with smooth gradient, the neutron's spin flips with energy gain or loss corresponding to spin polarization. The change of the neutron kinetic energy is written as $2\mu B$, where B is the magnetic field at the spin flip position and μ is magnetic dipole moment of neutron. After the magnetic field, the velocity becomes into $\sqrt{v^2 \pm 2\mu B/m}$ from the incident velocity of v, where m is neutron mass and $\pm$ is represented gain and loss of the energy. In the case of deceleration, the time of flight of a neutron with the initial velocity v is written as

$$T = \int_0^{L_f} \sqrt{\frac{m}{2(E_0 - \mu B(z))}}\, dz + \int_{L_f}^{L} \sqrt{\frac{m}{2(E_0 - 2\mu B(L_f) + \mu B(z))}}\, dz, \quad (1)$$

where L_f is spin flip position, L is detector position and $E_0 = mv^2/2$ is initial kinetic energy of the neutron. When we select L_f for each velocity of the neutron properly, the time of flight can be kept constant. Because the spin flip occurs under the resonance condition, which is written as

$$\hbar\omega = 2\mu B(L_f), \quad (2)$$

where ω is the frequency of RF field, changing the frequency can be utilized to select the spin flip position (Fig. 2). There is a time lag for arriving at the spin flip position for each velocity, therefore, the frequency is represented as a function of time $\omega(t)$, which can be calculated the equations above numerically when T and $B(z)$ are given. The AFP spin flipper with time-changing RF frequency is required for focusing of neutrons.

We made the prototype of the magnetic accelerator in order to demonstrate the space-time focusing. A closeup view of the accelerator system is shown in Fig. 3. This consists of a compact static magnet to generate the gradient field with 1 T at the maximum and an RF coil to generate the resonance RF field. The change of neutron kinetic energy corresponding to 1 T is 120 neV, The magnet has anisotropic inter-poles in order to generate a homogeneous gradient of the magnetic field along the direction of neutron beam (Fig. 4) [13, 14]. The strength of the field decrease from 1 T to 0.5 T in 20 cm. The RF coil is an one-turn coil with length of 20 cm, which covers the gradient of the static field (Fig. 5). The RF frequency can be

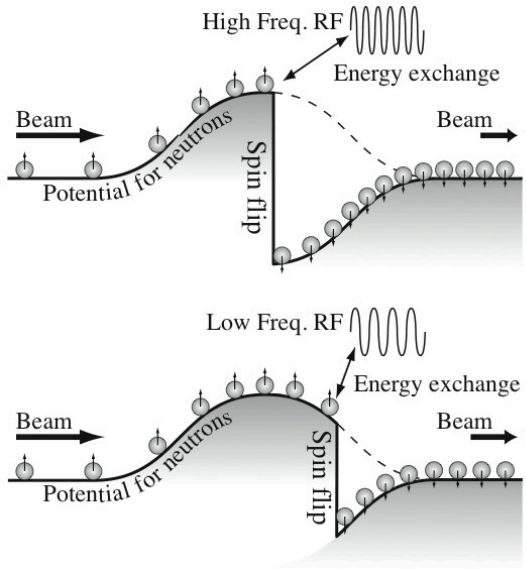

Figure 2: Control of deceleration by using AFP spin flipper with variable frequency RF. Top and bottom shows large and small deceleration respectively.

modulated automatically from 30 MHz to 15 MHz by using electric circuits with variable capacitors and a signal generator (Fig. 6). The control of the capacitors selects the spin flip position L_f, which can be synchronized with the neutron pulse. The RF power is supplied by a wideband amplifier with 1 kW output.

EXPERIMENTS AND RESULTS

The space-time focusing experiment was performed at the PF2 TES beam line in the High Flux Reactor at Institut Laue Langevin. The whole experimental setup is shown in Fig. 7. Very slow neutrons including UCNs were provided

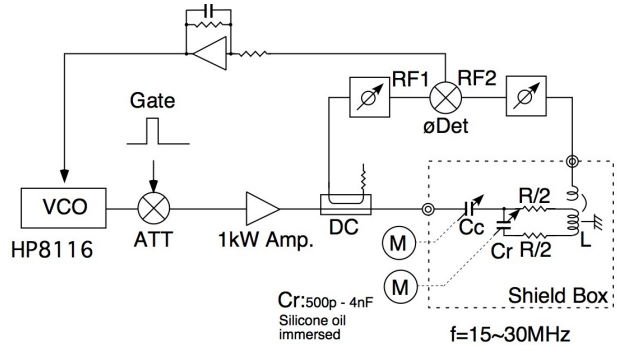

Figure 6: Electric circuit to match the resonance condition of RF.

from the turbine, which decelerates the neutrons from the reactor by using continuous reflections off rotating mirrors [15]. A mechanical shutter is used to supply pulsed neutrons. The shutter opened for 20 ms once every 2 s. A neutron-absorbing cadmium pipe is inserted just before the shutter in order to reduce the number of reflections by limiting the neutron divergence. A neutron detector, which is a ^{3}He gas detector, is set at 5.6 m downstream from the shutter. The neutrons were transported with reflections off the mirror inside the guide tube. The size of the guide is 6 cm in vertical and 3 cm in horizontal. The guide consists of assembled glass plates with nickel coating, which has high reflectivity for neutrons. Since we are going to accelerate/decelerate neutron velocity only in the transport direction, non-specular reflection at the guide surface should be suppressed as much as possible. The glass plates were polished and aligned parallel enough to keep the velocity in the transport direction. The measurements of the neutron velocity distribution through the guide tube were consistent with the simulations without non-specular reflections at the surfaces. The static magnet and RF coil were arranged midway between the shutter and the detector. The RF coil was wound to the guide tube.

We measured the TOF spectrum of the neutrons through this setup for two cases. The RF was ON and OFF. The

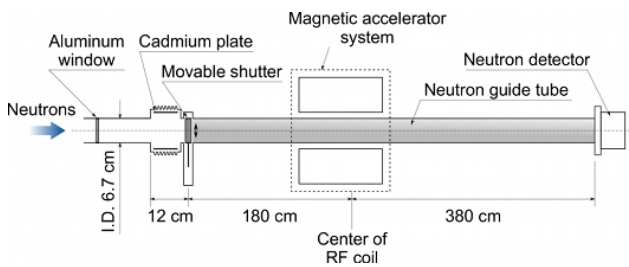

Figure 7: Experimental setup. Neutron accelerator is installed in the middle of the guide tube. The RF and data acquisition systems are synchronized with the shutter operation.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

static magnetic field is constantly applied throughout the experiments. In the case of RF-OFF, the spins of the neutrons are not flipped and the net velocities are not changed before and after the static magnet. In the case of RF-ON, the RF field is applied only when neutrons with velocity from 5.7 m/s to 5.0 m/s reach the accelerator position. This caused the partial change of the shape of the TOF spectrum, which enables us to compare the case of RF-ON to that of RF-OFF easily. In the arrival time-lag of 80 ms between the neutrons of the velocity range, the frequency of the RF is swept from 28.6 MHz to 17.5 MHz, which are corresponding to 120 neV and 70 neV of the energy exchange respectively. For this demonstration, the variable capacitor were moved with the constant speed as the approximation of the frequency function $\omega(t)$. The measurement time was about 4 h for both cases. The measured TOF spectra are shown in Fig. 8. The top and bottom histograms represent the cases of RF OFF and ON, respectively. The lines show the Monte Carlo simulations with and without focusing. The non-specular reflections at the guide surfaces are not considered in these simulations. For RF-ON case, the line is calculated with spin flip efficiency of 0.5. Both of the observed histograms are in good agreement with the simulations. The ratio of these two histograms is shown in Fig. 9. The decelerated neutrons focused at the time between 1.2 s and 1.4 s can be seen. The loss of constant energy makes only defused spectrum and can not make the excess indicated in the figure.

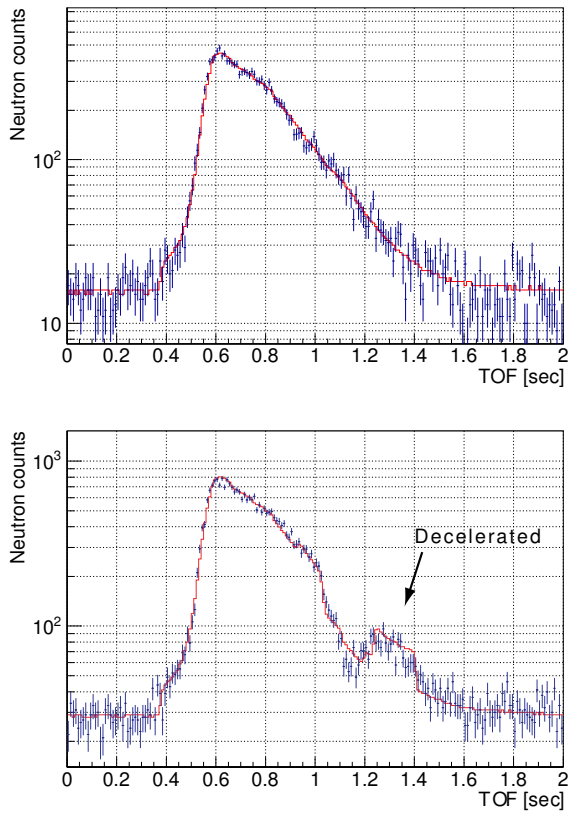

Figure 8: Neutron TOF spectra. Top and bottom show the case of RF OFF and ON respectively. Lines show the simulations.

CONCLUSION

We have successfully developed the accelerator/decelerator for slow neutrons and demonstrated neutron space-time focusing for transport of UCNs with keeping density. The results are in good agreement with simple simulations with controlling the velocities of neutrons [16]. The efficiency of the spin flip was low, however, this can be improved with the amplitude of the RF field.

This result shows the feasibility of neutron accelerator for effective transport of UCNs for various experiments. The neutrons can be gathered only in the experimental area at the focus time. When a shutter at the entrance of the experimental area closes just after the injection of the focused pulse, the UCNs can be localized only in the experimental area with high density without spreading in the guide tubes. The combination of this device and a highly-instantaneously-intense pulsed source, for example, SNS and J-PARC, enable us to utilize neutrons most effectively. It should be mentioned that the excitation current of our magnet and its stray field is constant during the experiment in contrast to the method mentioned in reference [3]. This is fairly advantageous to nEDM experiments, which requires an extremely precise magnetic field control. The constant excitation of the magnet eases a quick modulation of the accelerating energy. In addition, since this device can manipulate the longitudinal phase space distribution of the neutrons flexibly, it can adjust not only the time

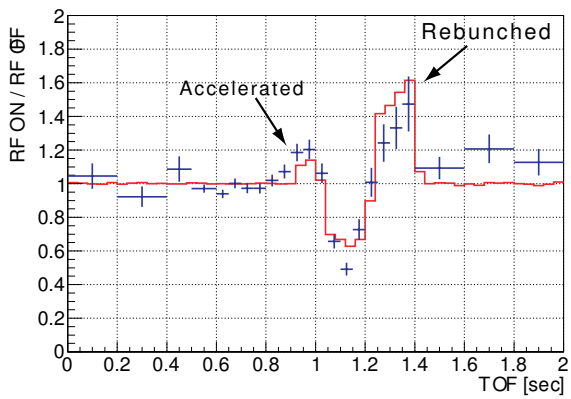

Figure 9: The ratio of these two TOF histograms. Line shows the simulation with focusing.

structure but also the energy distribution, suggested in reference [1, 2]. These features widen the application of this system. We are now planning the new nEDM experiment using this focusing technique at J-PARC [17].

EMITTANCE CONTROL FOR DIFFERENT FACET BEAM SETUPS IN THE SLAC LINAC*

F.-J. Decker, W. Colocho, N. Lipkowitz, Y. Nosochkov, J. Sheppard, H. Smith, Y. Sun, M.-H. Wang, G.R. White, U. Wienands, M. Woodley, G. Yocky, SLAC, Menlo Park, CA 94025, USA

Abstract

The linac beam at SLAC requires different setups for different users at the FACET (Facility for Advanced aCcelerator Experimental Tests) area, like highly compressed, intense bunches, or lower charge, long bunches. These require typically a lengthy tuning effort since with an energy-time correlation (or "chirp") the bunch transverse wakefield kicks can be compensated with dispersive trajectory oscillations and vice versa. Lowering the charge or changing the bunch length will destroy this delicate balance. Besides the typical steering to minimize BPMs (Beam Position Monitors) with correctors, we applied different techniques to try to localize beam disturbances like dispersion with phase changes, RF-kicks and RF quadrupole fields turning a klystron off and on, or varying the phase, and finally wakefield kicks with different beam intensities. It is also important to quantify BPM to quadrupole offsets with "bowtie" plots and that the correctors give the expected kicks with orbit response matrix measurements.

INTRODUCTION

Good transverse beam emittances at different places along the SLAC Linac get typically achieved in the following way. The beam gets steered relatively flat (< 0.5 mm) using BPMs (Beam Position Monitors) and then with a lengthy tuning scheme, linac oscillations or bumps are introduced which minimize the emittance measured with wire scanners. Over the years this process typically achieved small emittance growth numbers of 50 to 100% over the initial values of 30 and 2.5 mm-mrad for x and y, so 50 by 5 mm-mrad was expected for the FACET beam in Sector 20.

Typically twice that amount and often more was only achieved. There are a few explanations (excuses) which could cause this. The typical beam rate was 10 Hz, so tuning was three times slower than at 30 Hz. The FACET chicane needed special attention, so linac tuning was cut short. And the final spot sizes after the chicane and final focus were about the same, like 30 μm, even if the emittance just in front of the chicane changed by a factor of three (300 → 100 mm-mrad in x), discouraging further linac tuning.

Additionally, frequent user requested beam changes in current and bunch length made it necessary to tune the beam emittances up again, which would make it even trickier for smaller emittances. It is assumed that the main root cause for this is that after just steering flat the initial emittance is as high as 1200 mm-mrad, and the subsequent tuning cancels this with equally large corrections. When these cancelations are not local, or are charge / bunch length dependant, small say 10% variations will create 10% of 1200 mm-mrad = 120 mm-mrad.

So the goal is to localize and reduce emittance increasing effects. For that we try to find and categorize all possible mechanisms, like dispersion, wakefield, RF-kicks, and develop procedures like special steering methods and component alignment.

Goal: Get Linac closer to good emittances with BPMs etc. so the tuning part is less.

1. BPMs
2. Correctors
3. Quads (old BBA: straight orbit)
4. BPM-to-Quad: bowtie plot or Quad change
5. Corrector strength (LOCO, R12 meas.)
6. Lattice (Quad) strength: Oscillation data
7. RF-kicks: a) sin-cos, b) dipole-quadrupole-lens
8. Measure dispersion
9. Measure with different charge (wakefield)
10. Measure with different bunch lengths
11. Others

The different methods (numbers in ( ) below) and their relevance are discussed in the following sections.

STEERING TECHNIQUES

Steering the beam to the center of a BPM (1) gets the beam down the linac relatively fast, but usually ends up with big beam emittances. Additionally we can look at the corrector (2) values along z and check for certain patterns, e.g. stronger values with + – + might indicate a BPM with a big unreal offset. With our "SVD Steering" we can adjust a gain parameter to prefer BPMs (gain high) or correctors (gain low), but this method just supports what is believed more correct.

The next step is also using the quadrupole (3) strengths in a way to get a straight trajectory. When a BPM reading is say Δx =1 mm and the corrector strength is cor = 0.03 kG-m, the two can be compared by dividing cor by the quadrupole strength Q = 20 kG: cor/Q = 1.5 mm. So the beam gets more bend up by the corrector than the $Q\Delta x$ bends it down (focussing magnet). Figure 1 shows an example where the orbit was steered flat (below 0.3 mm) but its corresponding cor/Q-values are up to 1.3 mm. This led to a global alignment of the Linac of up to 7 mm [1]. Equalizing the two locally will give a straight non-bend beam orbit and therefore no dispersion is generated. But an offset in a BPM might indicate also an offset in the RF nearby structure, causing wakefield kicks.

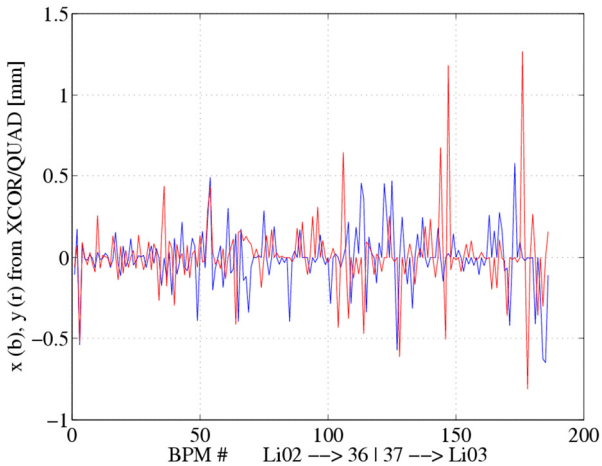

Figure 1: The absolute orbit is steered flat, but the corresponding corrector/quadrupole values for x (blue) and y (red) indicate big bending around 145.

BEAM BASED ALIGNMENT

Besides the global alignment of the Linac using optical targets inside the accelerator supporting light-pipe, there are several methods using the beam to find misalignments and then fix them. The last paragraph indicates already one such approach. Instead of steering so that $\Delta x = cor/Q$ we can align the quadrupole and accelerator locally by moving it in the $+x$ direction by Δx and putting the corrector to zero. This was done in a few places and needs to be done at all locations. But before doing this we need to be sure that the values of Δx, *cor*, Q are correct.

The BPM reading Δx can have an offset x_{off} with respect to the quadrupole and this can be measured with the beam by the bowtie-scan method (4). By varying one corrector in front of the quadrupole and measuring the effect of a downstream BPM for two different quadrupole settings versus the BPM inside the quadrupole you get a bowtie-like plot where the center of the bowtie gives the BPM offset x_{off}. This method is very lengthy requiring a few setting for each quadrupole setting and again for the other plane y. A faster but not as precise method is using just the difference orbit for the two different quadrupole settings and using the focussing model (R12s) to determine the kicks in x and y at the same time. This method should be about ten times faster and will allow us to get the BPM offsets for all BPMs in quadrupoles.

Checking the corrector strengths (5) is next and done typically by varying a corrector over a certain range that the beam is not lost and then the response matrices R12s from the corrector (point 1) to downstream BPMs (points 2) are compared to the expected from the model. When everything is aligned the exact values are not too critical since the correctors are close to zero, but to get there and for steering and for making closed three-corrector bumps (see below) it is helpful to have the right values.

The lattice or quadrupole strength (6) can be check with oscillation data, where two correctors in x, x' and two in y, y' generate oscillations which then can be fitted with expected behaviour calculated with the model. Figure 2

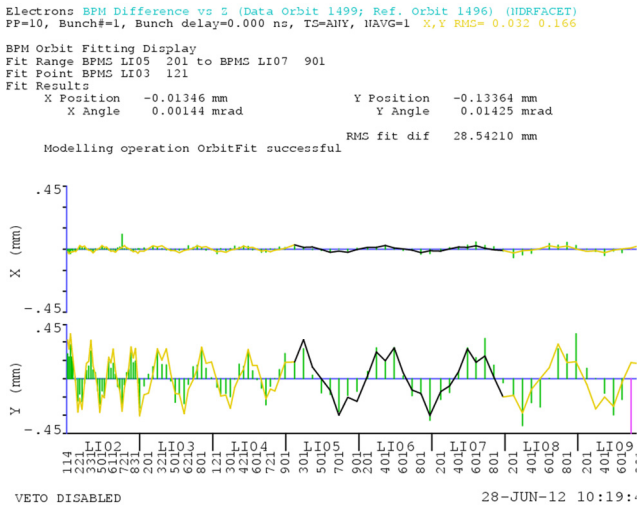

Figure 2: Oscillation data in y, at Li07 501 there seems to be an additional kick pointing to a weaker quadrupole.

shows an example where there seems to be a 15% weaker quadrupole at Li07 501. A wider grid scan can point out nonlinearities, while a few more corrector settings can trace out the design matched beam ellipse in phase space which then can be checked down the linac. With this method (at LCLS) sudden mismatches, coupling and 3% BPM scale errors were found.

RF KICKS

All the above mentioned steering and compensation techniques get messed up by RF kicks (7), and their behaviour is quite interesting. There can be sin and cos terms, an x and x' part, dipole-, quadrupole-, or lens-type kicks, even 2nd harmonic part was observed (Fig. 3).

To distinguish whether it is an angle or position effect two (nearly) closed bumps were made, one with the maximum at the beginning of the accelerator structure and one at the end (Fig. 4).

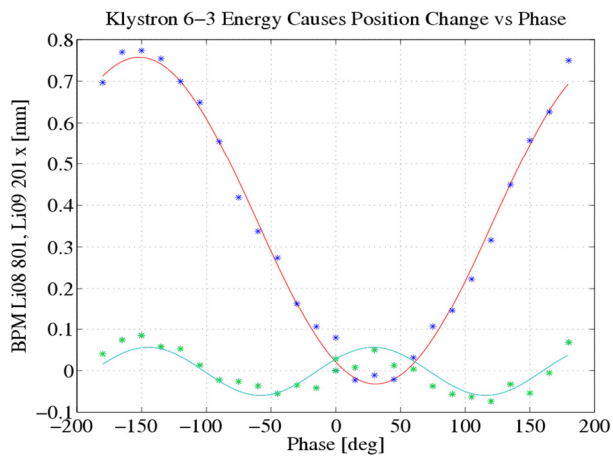

Figure 3: The phase of klystron 6-3 was varied and the resulting downstream orbit observed. At BPM Li09 201 it was up to 800 µm and in phase with acceleration, two BPMs earlier, near the zero-crossing, a 100 µm 2nd harmonic-like effect was seen.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

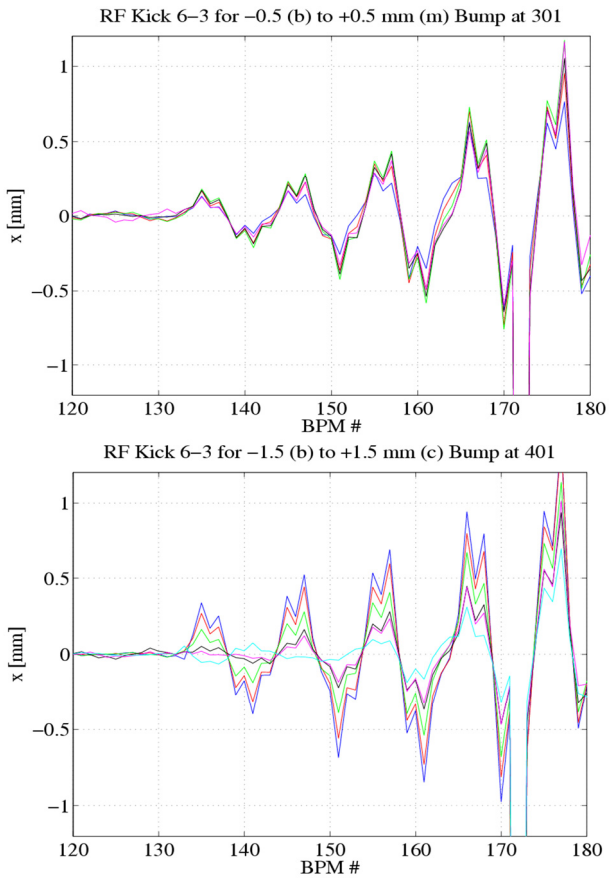

Figure 4: The RF kick of klystron 6-3 (between BPM # 132 and 133) is barely influenced by a bump with the maximum at its front at 301 (top), while at its end at 401 a +1 mm bump cancels the RF kick (bottom). Further downstream seems to be more and more dispersion.

MEASUREMENT FOR SETUP CHANGES

When the beam parameters like charge, bunch length, energy profile change the beam emittances are typically negatively influenced. By localizing and fixing the before mentioned effects as local as possible emittance growth should be minimized. Checking how much dispersion (8) the beam has at a certain point seems to be easy. The energy gets changed by ΔE and with the measured transverse position x: $x = \eta_x \cdot \Delta E/E$ the dispersion η_x is defined. The problem with the linac is that there are many ways to change the energy and on top of that there can be a change due to RF kicks when a klystron is turned off. We typically want to know how the head and the tail of a bunch having different energy due to an energy chirp might behave differently. To check that, we vary the injection phase into the linac by ±1° and then we look at the difference orbit. Since the average chirp phase before the chicane in Sector 10 is about –24° the energy change at the chicane should be about ΔE = 7.8 GeV · (cos(23°)–cos(25°)) = 111 MeV or 1.23% at 9 GeV. Any resulting orbit change in the linac is like dispersion and can be reduced with bumps or dispersion free steering methods.

The beam charge (9) and the bunch length (10) are parameters often asked by the FACET user to be changed. By dithering the damping ring capture phase the throughput and so the number of particles down the linac was varied from 2E10 to 1E10. The resulting orbit changes hint where wakefields might be an issue and where observed early in the linac (Li03). The amplitude of the RTL (Ring-To-Linac) bunch compressor can be adjusted similarly quickly to vary the bunch length, but this fast method wasn't tried yet.

To be more complete other methods and effects (11) should be mentioned too. A) There were the ballistic data measurements, were all quadrupoles, correctors and klystrons are turned off in a sector or two and the BPMs analysed before beam losses occurred. B) Hysteresis in the correctors makes the results questionable. C) Similar to the LCLS undulator where different energies are used to align the undulator, we can scale the quadrupoles and correctors while the actual energy profile and RF kicks stay fixed. With positrons which are bend magnetically in the opposite directions, while the RF kicks are typically the same (dipole kicks) the different effects can be better separated [3]. D) Electronic noise from klystrons causes a different reading for the BPMs in a nearby crate whether the klystron is on beam time or on standby.

Finally two more things should be mentioned. We changed the basic setup of the linac in two ways to make it less susceptible to dispersion. First a "staggered" chirp was introduced, which slowly increases the energy versus z correlation, and 2nd a lower 76 deg per cell lattice was used to be less susceptible to the necessary energy spread.

SUMMARY

The beam emittance control for FACET is basically done by tuning, starting at very high values (sometimes 250 times higher). This paper discusses more than twelve possible approaches to reduce the initial value locally as good as possible, so that any longitudinal or intensity changes are not coupled into the transverse dimensions.

ACKNOWLEDGMENT

The FACET team wants to thank the many support groups which make the four months short FACET runs possible, and especially the operations group for their interest and dedication to improve the beam conditions.

Abstract

This paper reports on a present status of a positron injector linac upgrade for SuperKEKB. A development status of a flux concentrator for positron focusing is shown. An influence of offset layout of the flux concentrator and the target on a positron yield is described. Positron capture by L-band and large aperture S-band accelerating structures are compared in a viewpoint of satellite bunch elimination. Beam optical design compatible to electrons and positrons of different beam energies is discussed.

INTRODUCTION

The KEKB-factory is now under an upgrade to SuperKEKB for a forty times higher luminosity [1]. The injector linac is required to supply beams of higher charge and smaller emittance as shown in Table 1.

Table 1: Linac Beam Specifications

	KEKB (e^-/e^+)	SuperKEKB (e^-/e^+)
Injection Energy (GeV)	8.0 / 3.5	7.0 / 4.0
Bunch Intensity (nC)	1.0 / 1.0	5.0 / 4.0
Number of Bunch /pulse	2 / 2	2 / 2
Emittance (μm)	300 / 2100	$20 / 92_{[H]}:7_{[V]}$

To generate low emittance electron beams of 5 nC bunch intensity for injection, a photo-cathode RF gun is introduced [2] to replace the existing thermionic gun and the RF bunching section. The electron beams are accelerated up to 7.0 GeV over the entire linac and injected into the HER. Electron beams of 10 nC for positron production will also be generated with the RF gun. In a case high intensity operation of the RF gun is not stable, the thermionic gun is also used and the beams from these two guns are switched. To generate low emittance positron beams, a damping ring (DR) of 136 m circumference is introduced at a side of the linac and connected at the beam switch-yard No.2 (SY2). Beams generated in a positron capture section (PCS) are accelerated up to 1.1 GeV and injected into the DR. Positrons are extracted after 40 ms from the DR, injected back to the linac and accelerated up to 4.0 GeV for injection to the LER. Energy gain of the positrons from existing six accelerator modules (typically 160 MeV per each module) from the PCS to the SY2 is not sufficient for this 1.1 GeV injection to the DR. The PCS is relocated 40 m upstream to have a sufficient energy margin for the DR. To increase positron beam intensity four times as much, capture efficiency is enhanced in two aspects. At first, an existing 2-T pulsed coil of short field length (45 mm) right behind a positron production target, is replaced with a flux concentrator (FC) type of 5-T pulsed solenoid of long field length (200 mm). An adiabatic matching characteristics of a solenoidal field distribution with a FC, gives wider energy acceptance for positrons. As a second aspect, existing S-band accelerating structures with conventional aperture (21 mm in diameter) used in a solenoidal field of the PCS are replaced with large aperture S-band (LAS) structures (30 mm) or L-band structures (35 mm) to enlarge transverse phase space acceptance. Total length of the PCS is extended from 8 m to 16 m to boost positron beam energy from the PCS from 80 to 120 MeV. This increase of the beam energy at a transition from solenoidal to quadrupole focusing region is effective in reducing beam loss around an optical matching section.

In December of 2013, we will start a preliminary positron beam commissioning of the injector linac within limited operation parameters. A beam commissioning with the DR will be started in February of 2015. Development, fabrication and installation of the components are ongoing to be in time for the schedule.

In the following sections, as topics of significance in the positron injector linac upgrade, flux concentrator development, target protection and offset positron production, large aperture accelerating structures development, satellite bunch elimination and electron/positron compatible optics design are described .

FLUX CONCENTRATOR DEVELOPMENT

Flux concentrator is a pulsed solenoid composed of a primary coil and a copper cylinder with a conical hole inside. Induced eddy current flows through a thin slit to a inner surface and generates a strong field of several Tesla. Achievable field strength is mainly determined by a hole diameter and a primary pulsed current. They are constrained from a required aperture size, a power supply capacity and break-

* E-mail: <takuya.kamitani@kek.jp>

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

down limit. We have been collaborating with BINP, SLAC, Frascati and IHEP on the FC development for KEKB linac upgrade. We have performed a high power operation test of a BINP-type FC at KEK and experienced a breakdown problem. The prototype is disassembled and under careful inspection at BINP. For a coming preliminary positron beam commissioning in December of 2013, we will use a more conventional FC, two type are considered as candidates. One is a spiral slit FC based on the SLAC design. Frascati and IHEP also have been using this type of FC. The other type is a simple straight slit FC. A peak longitudinal field strength at a same current is lower with the SLAC type, but a contribution of a transverse field component which is not axial-symmetric is also smaller. Considering an effect of target offset from a field center described later, evaluation of positron capture efficiency by a particle tracking using detailed 3D field distribution is ongoing. Since the FC is installed right behind the target and its radio-activation level will be very high and a replacement work will not be easy. Thus, an engineering design to avoid mechanical failure or water and vacuum leakage problems is critically important. Decision of installation model among the candidates will be made soon with a comparison in the capture efficiency performance and engineering design consideration.

POSITRON PRODUCTION TARGET

We have used 14 mm thick (4.0 radiation lengths) amorphous tungsten and later 10 mm thick crystal tungsten for the positron production target. In the beam commissioning for SuperKEKB, an amorphous tungsten will be used to avoid precise axis alignment mechanism. For a pulse-by-pulse switching of electron and positron injections, a small hole for electron beam passage is bored a few mm apart from a center of the target. To optimized a positron yield, the target was placed on a common central axis of the pulsed coil and the DC solenoids in the KEKB linac. Thus, electron beam entered into solenoid field at a few mm offset from the axis and traveled through an excursion orbit by a fringe field. It becomes a problem at SuperKEKB, since an electron beam for injection have a small emittance as 20 μm. Emittance growth in this excursion orbit is not acceptable and a hole for electron passage should be centered on the axis of the DC solenoids. An aperture diameter of the FC is only 7 mm in the present design and the tungsten target of 4 mm diameter and the hole of 2 mm diameter should be well contained in the aperture. As a consequence, center axis of the FC has 2 mm offset from the beam line and target center has 1.5 mm offset from the FC center. We expected the offsets degrade the positron yield 20 to 30 % by a preliminary simulation study. More detailed study on this offset effect is to be done by the tracking simulation.

LARGE APERTURE CAPTURE SECTION

To enlarge a transverse phase space acceptance of the PCS, accelerating structures with larger aperture will be used. As a first candidate, we started R and D for L-band structure which had an appropriate field strength and an aperture diameter as described in Table 2. A first prototype L-band structure has been fabricated and under a high-power RF processing in a test stand. Since a large outer dimension of an RF coupler of the structure gives strong impact on a DC solenoid design, an L-band structure of slimmer body is in consideration by installing a dummy load inside the structure in a collinear geometry. In a selection of the L-band frequency, we cannot use simple half frequency (1428 MHz) of the S-band because it is not compatible with 2 bunch operation with 96 ns interval which was defined from phase synchronization constraint of the linac and the storage rings. Instead, we adopted 1298 MHz which is 5/11 of the S-band frequency. This co-prime frequency relationship was found to be useful in elimination of satellite bunch particles as described later.

The other candidate is a large aperture S-band (LAS) structure as described in Table 2. It has a larger aperture diameter (30 mm) compared with conventional S-band structures (21 mm). The LAS has a very large group velocity and a field strength is relatively low, however operation with a pulse compression by the SLED gives comparable field strength. The LAS structures are used not only in the PCS, but in subsequent two accelerator modules of quadrupole focusing region to improve transverse acceptance as described in the next section.

Table 2: Specifications of Large Aperture Structures

	L-band	LAS
RF frequency (MHz)	1298.182	2856.000
number of cells	24 + 2	57 + 2
accel. length (mm)	2001	2064
disk aperture 2a (mm)	39.4 $\rightarrow$ 35.0	31.9 $\rightarrow$ 30.0
group veloc. v_g/c (%)	0.61 $\rightarrow$ 0.39	4.2 $\rightarrow$ 3.5
shunt imp. r_0 (MΩ/m)	45.7 $\rightarrow$ 47.6	46.1 $\rightarrow$ 48.4
filling time T_f (μs)	1.360	0.180
accel. field (MV/m)	12.2@15MW	6.93@10MW
same with SLED	–	16.42

Positrons emerged from the target have wide range of energy due to a cascade shower process and long bunch tail due to path differences in spiral orbits. Simulation studies show that a positron capture in decelerating phase and a formation of a main bunch by RF phase slip is useful to reduce particles at tails of an energy distribution [3]. However, particles which are not captured in the main bunch, experience further phase slips. They can be captured in subsequent phase positions and form satellite bunches. They can have comparable beam energy as those in the main bunch and will not be eliminated by an energy collimation. A fraction of satellite particles go out of RF buckets are lost at the DR injection. Due to a civil engineering constraint, a beam loss at DR is strictly limited to be below 0.2 % of a design beam intensity (4 nC x 2 bunch). Thus, elimination of satellite particles in the linac is a critical issue for a DR

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

operation.

In a case we use six 2-m long L-band structures in the PCS, satellite bunches are formed in L-band wave-length intervals. Due to the co-prime relationship to the S-band wave-length, satellite bunches are accelerated or decelerated in abnormal phases in the downstream S-band linac modules and are eliminated in the linac or in an energy collimation. It is shown that a beam loss at DR injection will be suppressed to be an allowable level 0.05% [3]. In a case of a hybrid of two L-band and four LAS structures, the loss becomes 0.2%, but still acceptable. To suppress an initial construction cost by avoiding L-band component construction, it is recommended to start a beam commissioning with a configuration of all LAS structures in the PCS. In this case, the loss becomes 0.4% and further improvement is necessary. A preliminary simulation study indicates that raising S-band deceleration field around 20 MV/m can reduce satellites. More detailed study will be done soon.

POSITRON/ELECTRON COMPATIBLE OPTICS

By using accelerating structures with larger aperture, a transverse acceptance of the PCS which corresponds to an RMS emittance is enlarged from 2000 μm to 4000 μm. As described in the previous section, the PCS is relocated to a 40 m upstream position and a beam energy from this section is raised from 80 MeV to 120 MeV. As a consequence of these changes, a quadrupole focusing system after the PCS till the SY2 needs an upgrade and an addition and rearrangement of quadrupole and steering magnets will be made. In the two accelerator modules after the PCS, LAS structures of 30 mm aperture diameter are used to enlarge the transverse acceptance and quadrupoles are installed in 70 cm interval outside of the structures. In the subsequent three modules, ordinary S-band structures of 20 mm aperture are used and quadrupoles are placed in the same interval. In the subsequent four modules, quadrupole triplets are placed between the S-band structure and the interval changes from 3m to 5m according to the beam energy.

In this region between the positron production target and the SY2 before the DR, both of low energy, huge emittance positrons and high energy, low emittance electrons pass through the same quadrupole focusing system. Almost all quadrupoles in this region are DC magnets. To avoid a beam loss of the positrons, focusing strengths are optimized for them. Thus, electrons are focused in a ready-made quadrupole fields which are weak for the energy of electrons. Slight optimization to moderate electron beam size is performed within a range in which the positron optics is not significantly modified. Fig. 1 shows beam size of the positrons and the electrons.

Even with this compromised optics for the electrons, the beam sizes are kept sufficiently small. For independent orbit control of the positrons and the electrons, 12 pulsed steering magnet pairs are installed in addition to existing DC steerings. Orbit correction performance and emittance growth with this limited number of steerings should be checked by simulations and underway.

In the region after the DR till the end of the linac, both of the electrons and the positrons have low emittance and not precisely same but high energy. Quadrupole triplets and steerings are placed in 20 m interval. Total number of magnets are not so large for this region and there are no quadrupoles outside the structure, hence we decide all the quadrupoles and steerings here to be pulsed magnets. It will be useful for a precise independent matching to the storage rings and for an independent orbit control to suppress emittance growths for positrons and electrons.

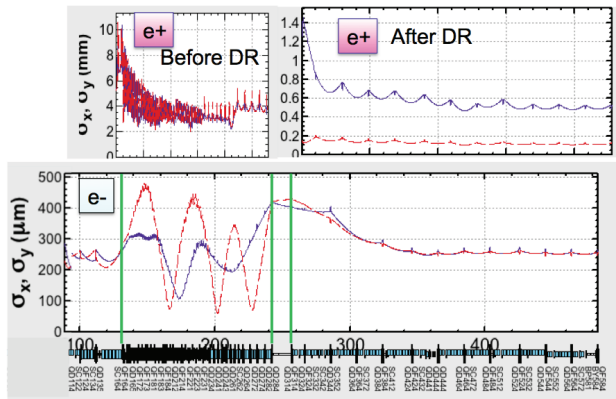

Figure 1: Positron/electron beam optics design.

SUMMARY

The KEKB positron injector linac is under an upgrade for SuperKEKB. Two types of flux concentrator in different slit geometry are in comparison by simulations and a prototype fabrication. An influence of an offset layout of the FC and the target is discussed. As accelerating structures to be used in the capture section, L-band and large aperture S-band structures are compared in a viewpoint of satellite bunch elimination. Performance of a compatible optics for electrons and positrons of different beam energies with DC quadrupoles is studied. A preliminary positron beam commissioning of the injector linac will be started in December of 2013.

Abstract

Diamond is being evaluated as a dielectric material for dielectric loaded accelerating structures. It has a very low microwave loss tangent, high thermal conductivity, and supports high RF breakdown fields. We report on progress in our recent beam tests of the diamond based accelerating structures of the Ka-band and THz frequency ranges. Wakefield breakdown test of a diamond-loaded accelerating structure has been carried out at the ANL/AWA accelerator. The high charge beam from the AWA linac (~70 nC, σ_z ~ 2 mm) was passed through a rectangular diamond loaded resonator and induce an intense wakefield. A groove is cut on the diamond to enhance the field. Electric fields up to 300 MV/m has been generated on the diamond surface to attempt to initiate breakdown. Wakefield effects in a 250 GHz planar diamond accelerating structure has been observed at BNL/ATF accelerator as well. We have directly measured the mm-wave wake fields induced by subpicosecond, intense relativistic electron bunches in a diamond loaded accelerating structure via the dielectric wake-field acceleration mechanism. A surface analysis of the diamond has been performed before and after the beam test.

INTRODUCTION

Diamond has been proposed as a dielectric material for dielectric loaded accelerating (DLA) structures [1-3]. Dielectric Loaded Accelerator structures using ceramics or other materials and excited by a high current electron beam or an external high frequency high power RF source have been under extensive study for many years [4-7]. Low loss microwave ceramics, fused silica, and CVD polycrystalline and single crystal diamonds [11] have been considered as materials for dielectric based accelerating structures to study of the physical limitations encountered in developing field strengths > 100 MV/m at microwave [4-6] and > GV/m at THz frequencies in a dielectric based wakefield accelerator [6,7,11,12]. THz radiation has been generated recently by a short ~10 GV/m pulse within a 100 μm diameter quartz fiber [7]. A planar diamond-based DLA structure was proposed recently by Omega-P, Inc., where the dielectric loading of this structure was to be made of diamond slabs fabricated using CVD (chemical vapor deposition) technology [2].

Our choice of CVD (Chemical Vapor Deposition) diamond as a loading material will allow demonstration of high accelerating gradients; up to 0.5-1.0 GV/m as long as the diamond surface can sustain a 0.5-1.0 GV/m short pulse (~ 10 ns) rf field without breaking down. Diamond has the lowest coefficient of thermal expansion, highest thermal conductivity (2×10^3 Wm^{-1} K^{-1}) and extremely low loss tangent ($<10^{-4}$) at Ka-W frequency bands. Secondary emission from the CVD diamond surface can be dramatically suppressed by diamond surface dehydrogenation or oxygen termination [3,6,8-12]. The CVD process technology is rapidly developing, making the CVD diamond fabrication process fast and inexpensive. Given these remarkable properties, diamond should find numerous applications in advanced accelerator technology [3]. Planar diamonds are available commercially in various grades including single crystal diamonds. The goal of this research is to perform a wakefield acceleration experiment using a diamond loaded structure and to test diamond for breakdown.

Euclid Techlabs had performed two wakefield experiments with diamond loaded accelerating structures: a 25 GHz structure at the Argonne Wakefield Accelerator of ANL and a 250 GHz structure at the Accelerator Test facility of BNL [9].

BEAM EXPERIMENTS WITH THE DIAMOND BASED DLA STRUCTURES

Significant progress has been made in the development and testing of high gradient dielectric accelerating structures (DLA) [1]. As various engineering challenges (breakdown, dielectric losses, efficient RF coupling) have been overcome, the technology of high gradient RF or wakefield driven dielectric loaded structures appears increasingly attractive as a viable option for high energy accelerators. Typical DLA considered in experiments is a cylindrical, dielectric tube with an axial vacuum channel inserted into a conductive sleeve or a rectangular waveguide loaded with planar dielectric pieces. In this paper we will focus on the latter structure. The dielectric constant, thickness of dielectric and the size of a vacuum gap are chosen to adjust the phase velocity of the fundamental mode at certain frequency to the beam velocity ~ c. In the application to particle acceleration, the dominant TM_{01} mode is of main interest.

We report here the results of a wakefield breakdown test of single crystal diamond-loaded rectangular accelerating structure [10]. The high charge beam from the AWA linac (~70 nC, σ_z = 2 - 2.5 mm) was transported through a rectangular diamond - loaded resonator and induced an intense wakefield [12]. A deep (200 μm) and narrow (20 μm) groove is cut on the diamond surface to enhance the field (by approximately a factor of ε). Electric fields at least of 300 MV/m were present on the diamond surface in the groove (decay time ~ 35 ns). A surface analysis of the diamond was performed before and after the beam test. No breakdown-type damage was observed on scanning electron microscopy images [10].

Structure design was presented earlier in [10], Fig.1. Parameters of the structure were determined via parametric simulations with constraint on the thickness of commercially available diamond plates, and the minimal gap size was determined by beam dynamics [11].

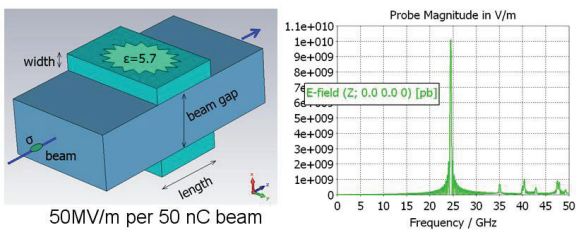

Figure 1: Left: geometry of the diamond resonator: length = 4mm, width = 1.2mm, beam gap = 4mm and overall width = 8mm. Right: spectrum of the wakefield (simulation).

To achieve stronger fields on the surface of the diamond two small 20 and 25 micron – wide, 220 micron deep grooves were laser cut on the diamond surface transverse to the beam propagation direction. There is a large field enhancement in these grooves: the field at the entrance to the groove is higher by a factor of ~ ε (5.7) than it would be in its absence [10] – a five time field enhancement because of the boundary conditions for the electric field at the surface of dielectric. For deep and narrow scratches (aspect ratio of 10 and higher) such enhancement is practically ε. As the groove becomes wider and shallower the field enhancement drops.

Diamond laser cutting is not a trivial procedure. Multistage cleaning was used to get rid of partial conductivity from carbon deposits. Special technology has been used that allowed removing practically all remaining carbon. SEM measurement confirmed that the laser cutting was successful as well as that target values of groove widths were achieved [11], Fig. 2.

In the experiment we manage to transport 72 nC charge through the structure, which corresponded to at least 300 MV/m on the surface of the groove. The bunch length measurement was not available, so for this estimate we used maximum value of 2.5mm. Shorter bunch length yields higher gradient.

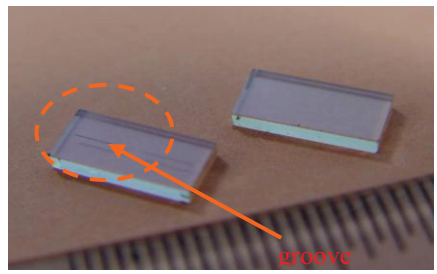

Figure 2: Field Enhancement groove machined in a planar diamond sample.

We used scanning electron microscopy to analyze the condition of the diamond surface before and after the experiment. Besides the presence of lint the surface did not undergo noticeable changes, Fig.3.

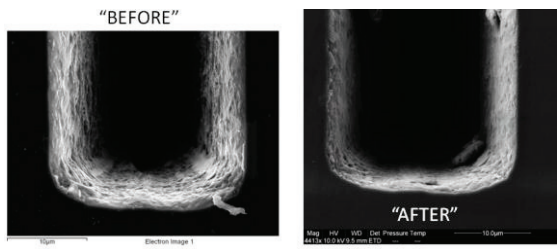

Figure 3: SEM measurement of the groove: right – before, left – after the test.

WAKEFIELD ACCELERATION IN A 250 GHZ DIAMOND STRUCTURE

Recently, we have directly measured THz wakefield acceleration/deceleration in a diamond loaded dielectric accelerating structure.

Proof of principle experiments at BNL/ATF [9] have studied wakefields in diamond structures in the 250 GHz regime. It should be noted especially that in this experiment diamond was for the first time used as a loading material for a wakefield dielectric based accelerating structure [9]. Fields produced by a leading (drive) beam were used to accelerate a trailing (witness) electron bunch, which followed the drive bunch at a variable distance. The energy gain of a witness bunch as a function of its separation from the drive bunch describes the time structure of the generated wakefield. By sweeping the separation between the drive beam and the witness beam and energy measurements of the witness beam a 0.25 THz frequency wakefield was directly sampled at the scale of about one wavelength [9,13].

The general experimental methodology is the following: a pair of beams is generated: - a high charge drive beam, followed by a smaller witness beam at a variable distance *d*. The drive beam generates a wake there and the witness beam is accelerated or decelerated depending on the delay between the two beams. We record the witness beam energy change, ΔE as a function of *d*.

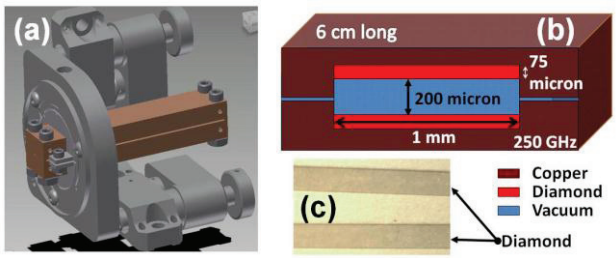

Figure 4: (a) 250 GHz structure mounted on a positioning holder; b) structure dimensions; c) photo of diamond after the experiment exhibiting no visible damage.

In the experiment we used 75 micron thick polycrystalline diamond plates loaded in a 6 cm long waveguide, Fig.4. The beam gap was 200 microns. This structure yields a wakefield dominated by a TM_{11} – like mode with 1200 micron wavelength (0.25 THz). The ATF drive beam is very short and also excites higher order modes, hence the wake is not a pure sine wave [9].

The subpicosecond drive and witness beams are produced by the technique described in [9]. A beam accelerated off-crest hence having a linear energy chirp (the head of the beam having lower energy than the tail) passes through a a dispersionless translating section. A mask is placed between the dogleg dipoles where the beam transverse size is dominated by the correlated energy spread. After the second dipole magnet the transverse pattern introduced by the mask becomes the longitudinal charge density distribution. In our case the mask was motorized and allowed creation of a drive beam followed by a witness beam at a variable delay [9].

Calibration is done via coherent transition radiation (CTR) interferometry. We fitted the recorded transverse profile by a gaussian distribution with σ_x = 50 μm, σ_y = 350 μm. The longitudinal wakefield produced by a beam with this current distribution was numerically calculated and compared with the experimental results.

The relative change in witness beam energy depending on the drive – witness separation is measured on the spectrometer. Compared to the beam energy, when it does not go through the structure, we observe energy gain and loss in the interval from -0.6 to +0.65 MeV for the witness beam following a drive beam through the DLA structure. This yields a 10.8 MV/m gradient for a 6 cm structure. The measurement accuracy was limited by the spectrometer resolution (σ = 0.028 MeV), estimated using the sharpest features obtained on the spectrometer by measuring the FWHM (full width half maximum) and dividing it by 2.355 to obtain the equivalent Gaussian width. Fig. 5 shows the measured energy change (diamonds) as a function of drive – witness separation with error bars. The shape of the experimentally mapped wake (diamonds) agrees well with the theoretical (scaled) prediction (circles) based on the wakefield (solid line) calculated for the drive beam current distribution (dashed line).

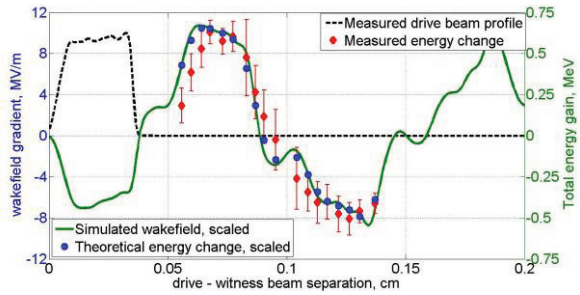

Figure 5: Energy gain of the witness beam as a function of separation from the drive beam.

SUMMARY

The emphasis of this paper is to present progress on development and fabrication of new types of diamond waveguides to be used for high gradient dielectric accelerating structures. We reported the results from development of a diamond DLA of GHz frequency range and wakefield tests of diamond-loaded rectangular accelerating structures at THz frequencies. We have directly measured THz wakefield acceleration and deceleration in a diamond loaded dielectric accelerating structure in an experiment where diamond was used for the first time in a wakefield dielectric based accelerating structure. In the 25 GHz frequency range, we achieved field levels on the order of 300 MV/m (35 ns pulse) in the structure using the 72 nC, 15 MeV beam at the Argonne Wakefield Accelerator Facility. Single crystal diamond plates produced by chemical vapor deposition (CVD) were used in the structure. A surface analysis of the diamond has been performed before and after the beam tests.

Abstract

The electron linear accelerator has wide applications, and the demands for the irradiation applications are keeping growing in China. A high beam power 10 MeV L-band Linac has been developed recently as a joint venture of Institute of High Energy Physics (IHEP) and Wuxi EL-PONT Company in China. The Thales TH2104U klystron, 2 A thermionic electron gun and 3 m long L-band disk-loaded constant impedance RF structure were adopted. A stable electron beam of 10 MeV / 40 kW has been obtained in the last April. In this paper the detailed design issues and beam commissioning results are reported.

INTRODUCTION

IHEP in China has very rich experience in the electron linac design and development. When requested to transfer the technology to industry, many S-band electron linacs have been developed for medical and irradiation applications. For the S-band irradiation linac, the beam power is limited to be ~20 kW because of the RF structure heating/cooling issues. Due to the scaling law of $P \sim f^1$ between the RF power consumption of the accelerating structure and the frequency, L-band structure [1][2] is usually adopted for the nature extending to much higher beam power up to ~100 kW level. For any high beam power machines the power efficiency is a concern. According to Eq. (1), the maximum conversion efficiency η_{max} of the RF power to the beam power dependents only on the attenuation factor τ[3], and smaller τ is preferred.

$$\eta_{\max} = \frac{1}{2}\left[\frac{\left(1-e^{-2\tau}\right)^2}{\left(1-e^{-2\tau}\right)-2\tau e^{-2\tau}}\right] \quad (1)$$

However, there is a compromise among power efficiency, power dissipation as well as heating, peak beam current and beam energy. It is known that τ is independent of frequency, and for SLAC type 3m long disk-loaded TW structure τ is ~0.57. Suppose a 3 m long L-band structure of 34 cavities is used, τ can be roughly estimated to be 0.57*34/86=0.225. With SUPERFISH simulation and cold test, τ is shown[4] to be 0.22, which is in good agreement with the simple scaling. By putting 0.22 into Eq. (1) one can get an efficiency η_{max} of 90%, which is very excellent. In this condition, the beam current is ~900 mA according to Eq. (2).

$$i_{\eta_{\max}} = \left(\frac{P_T}{rl}\right)^{1/2}\left[\frac{\left(1-e^{-2\tau}\right)^{3/2}}{\left(1-e^{-2\tau}\right)-2\tau e^{-2\tau}}\right] \quad (2)$$

Table 1 shows the design parameters for the 10 MeV / 40 kW L-band linac. The linac is a machine with very heavy beam loading; the beam energy range of 8 to 12 MeV can be easily controlled by simply adjusting the gun bias voltage (i.e. the gun emitting beam current), but above 10 MeV is not recommended for prevention of the neutron production.

Table 1: Design parameters for the 10MeV L-band linac

Beam energy (MeV)	10
Beam power (kW)	40
RF frequency (GHz)	1.3
Peak beam current (mA)	530
Duty cycle (%)	0.75
Klysron peak power (MW)	10

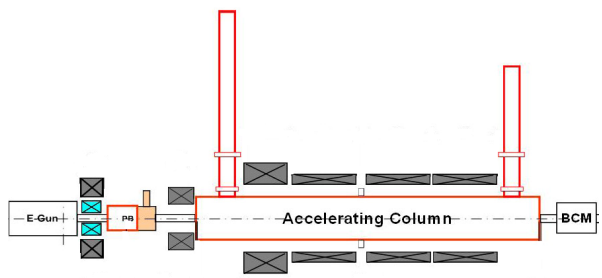

Figure 1: The schematic of the L-band linac.

DETAILED DESIGN AND SIMULATION

Figure 1 shows the schematic of the high power 10 MeV L-band linac, which mainly consists of an electron gun, an RF power source and an accelerating column. The electron gun is the 80 kV BEPC type [5] gun with 2 A Y646B cathode grid assembly. The gun system is separated from the other subsystems, which makes it easy for maintenance. The gun emitting current and the beam energy are adjustable. The RF power source is a 10 MW Thales TH2104U klystron with 130 kW average power, and the modulator was designed to make it work at 100 kW. Fig. 2 shows the Thales TH2104U klystron and its parameters.

*Work supported by the joint venture foundation of IHEP and the Wuxi EL-PONT Company in China.

Frequency	1300	MHz
Output power	10	MW
Gain	> 47	%
Pulse width	> 55	μs
Duty cycle	> 1.1	%
Output average power	> 130	kW
Efficiency	45	%
Beam voltage	167	kV
Beam current	136	A

Figure 2: Thales TH2104U klystron and its parameters.

With 10 MW TH2104U klystron and a 3 m long L-band RF structure, a 10 MeV / 40 kW electron beam with a beam current of 530 mA as listed in Table 1 can be obtained. Except for the klystron, the RF structure is a key issue for the high power electron linac. The simple constant impedance structure with the cell dimension scaled from the 3 m long SLAC type disk-loaded TW structure was used, but the first 6 cells are β changed for the beam bunching requirement. Simulations with the EGUN and PARMELA codes have been conducted [6], and the simulation results were confirmed by measuring the beam performance in later commissioning. Even without the pre-buncher, a proper beam with more than 40% transmission efficiency was obtained, which is also confirmed with the machine commissioning. Fig. 3 shows the simulated beam energy spread and beam size, which are good enough for an irradiation machine.

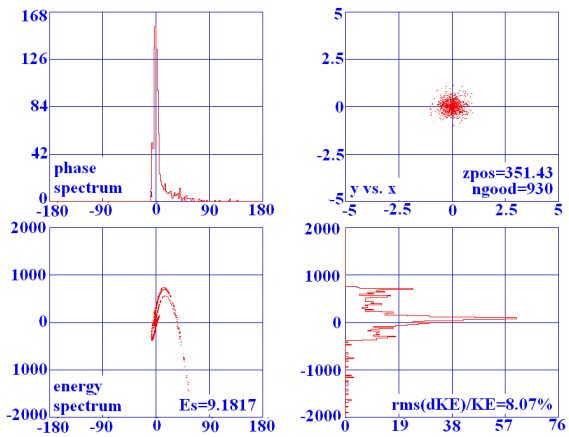

Figure 3: The simulated beam phase space.

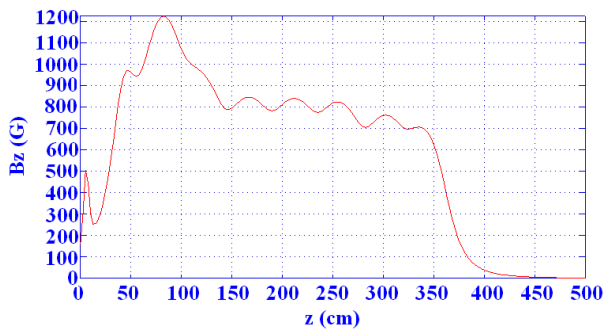

Figure 4: The solenoid magnetic field distribution along the 10 MeV / 40 kW linac.

Fig. 4 shows the designed solenoid magnetic field distribution along the whole linac. As the RF structure heating is a concern for the design of the high power electron linac, the structure iris temperature rise and its deformation were also simulated [7] and shown in Fig. 5, which indicates the maximum temperature of 62 °C under the design parameters and a tolerable deformation of ~17 μm. The cooling system is a simple water jacket around the accelerating column; A special cooling design is required if even higher beam power up to 100 kW is needed.

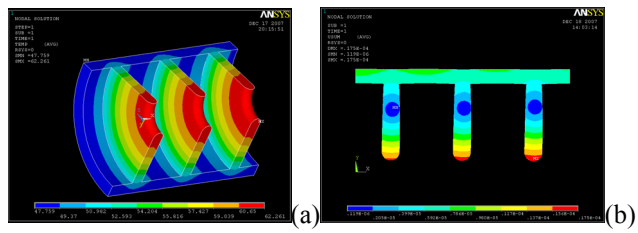

Figure 5: ANSYS results for the structure heating under the design parameters: (a) the iris temperature rise; (b) the structure deformation.

COMMISSIONING AND BEAM TEST

The machine was installed at EL PONT Company in 2009; the machine processing and commissioning were started right after the entire subsystems ready. The first beam was obtained on November 3rd, 2010. Fig. 6 is the picture of the whole linac, and Fig. 7 shows the modulator.

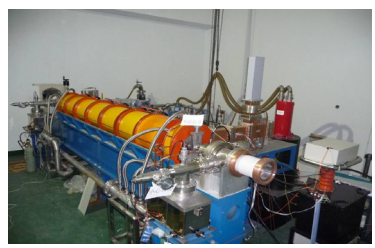

Figure 6: Picture of the L-band linac.

Figure 7: Pictures of the modulator.

Table 2 shows the milestones of the high power L-band electron linac development and commissioning progress. Almost two years were taken to get the first beam, and the main time consuming task is the klystron purchase, which takes one year and a half with almost 6 months delay. From the first beam @ 5Hz to the 40kW stable beam almost half year was taken to reach the design goal. During the high power processing process, many lessons have been learnt, such as beam instability, beam duct heating and degassing, beam loss and so on.

Fig. 8 is the beam testing results with the beam energy of 11.2MeV at 600mA beam current shown in (a) and the beam current profile measured with BCT shown in (b), which is better than the design prediction.

Table 2: Milestones of the L-band linac development

Date	Activity
October, 2007	Proposal and design
Auguest, 2008	Manufacture, purchase
September, 2009	Assembly at EL PONT
November 3rd, 2010	First beam
November 6th, 2010	Beam at 5 Hz
March 31st, 2011	30 kW
April 24th, 2011	40 kW

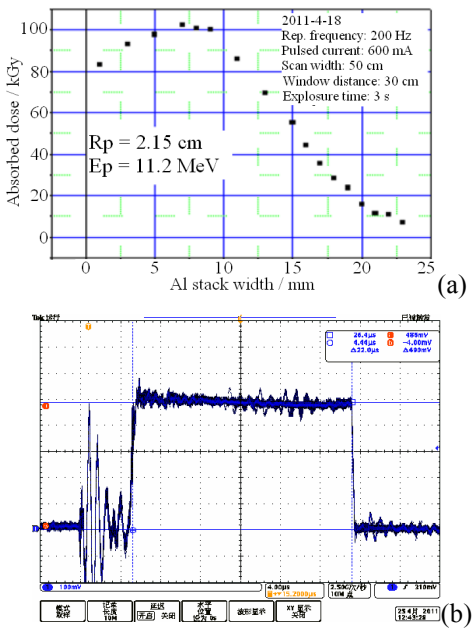

Figure 8: The beam testing results. Time-scale is 4 μs/division.

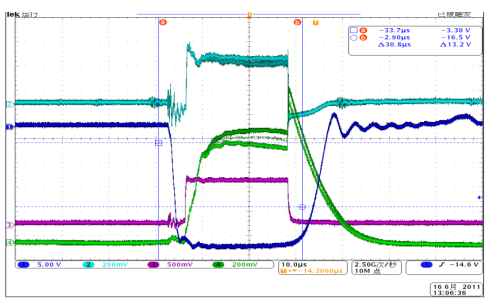

Figure 9: Machine status: blue line is the modulator high voltage waveform, turquoise the beam current from BCT, pink forward RF, and green reflected RF. Time-scale is 10 μs/division.

Many problems have been encountered during the beam testing and the machine commissioning; in particular the beam instability has very strong impact on the beam quality, the beam duct heating and the vacuum degradation, so systematic investigations were conducted for more than two months. Finally the RF driven source problem was found by monitoring the voltage standing-wave ratio (VSWR) as shown in Fig. 9, in which channel (1) in blue is the modulator high voltage waveform, channel (2) in turquoise the electron beam current from BCT, channel (3) in pink the forward RF, and channel (4) in green the reflected RF. It can be seen that the beam instability is correlated with the reflected RF (not the arcing but the VSWR change), which means the frequency is not correct even the indicator still shows 1300 MHz. After the problem was fixed, the beam instability was gone. In addition, the bunching effect of the pre-buncher was found not so strong, and taking out it would make the machine architecture much simpler.

SUMMARY

The high power 10MeV L-band electron linac is the first 40 kW irradiation linac developed and constructed in China. The first beam was obtained on November 3rd, 2010, which confirmed the design and the simulation predictions. After a few months machine processing, the designed beam parameters were achieved on April 24th, 2011. The formal beam testing was conducted by the National Institute of Metrology on December 26th, 2011, and the testing beam current is 720 mA with energy of 9.9 MeV. If the machine works at a duty cycle of 0.7% as already processed, the beam power can reach 50 kW. The conversion efficiency η from the RF power to the beam power is ~72%, a little bit lower than the theoretical prediction, which is partially because the RF power into the accelerating structure is lower than 10 MW, and/or the beam loss. Nonetheless, 72% is not bad. Now the machine has been put into operation at EL PONT Company.

ACKNOWLEGEMENT

The high beam power 10 kW / 40 MeV electron linac facility is a joint venture of IHEP and EL-PONT Company in China. Many works not mentioned here were accomplished by EL-PONT, such as infrastructure, power supply, cooling system, beam scan or deliver system and so on. Many thanks to all EL-PONT staffs for their contributions to the machine design, development, commissioning and operation.

APPLICATIONS OF COMPACT DIELECTRIC BASED ACCELERATORS*

C. Jing#, S. Antipov, P. Schoessow, and A. Kanareykin, Euclid Techlabs LLC, Solon, OH, USA
J.G. Power, M. Conde, and W. Gai, ANL, IL, USA

Abstract

Important progress on the development of dielectric based accelerators has been made both experimentally and theoretically in the past few years. One advantage of dielectric accelerators over their metallic counterparts is their compact size, which make them attractive for industrial or medical applications. In this article, we discuss the design of dielectric based accelerators focusing on those technologies relevant toward these needs.

DIELECTRIC LOADED ACCELERATOR

The first studies of using RF driven dielectric-loaded circular waveguide for particle acceleration can be traced back to the early 1950's [1]. In recent years, because of its geometrical simplicity and availability of low loss dielectrics, theoretical and experimental investigations on dielectric based accelerators have been intensively revived. Among them, externally powered Dielectric-Loaded Accelerators (DLA), dielectric wakefield accelerators, and dielectric laser accelerators have attracted the most attention. In this paper, we concentrate on externally powered DLA technologies and possible application.

DLA structures can be made as simple as a dielectric tube surrounded by a conducting cylinder. Most of them use uniform, linear ceramic tubes so that they work as constant impedance accelerating structures. The TM_{01} mode (traveling wave accelerator) or TM_{01n} mode (standing wave) are the fundamental accelerating modes. Unlike conventional metallic accelerating structures, DLA structures do not require any structure periodicity to slow the phase velocity of the guided wave below the speed of light. For a given radius, the phase velocity of each guided wave mode in a DLA structure is governed by the dielectric constant of the material and its wall thickness. In general, for the same a/λ, where a is the radius of the beam opening and λ is the wavelength, the DLA structure can be made much smaller than a disk-loaded accelerating structure due to the high dielectric constant of the material used. This small size may be favored for applications with tight space requirements. It also facilitates the use of quadrupole lenses or a permanent solenoid around the structure to prevent the beam from breaking up in the case of high current beam acceleration. For example, for an X-band structure, given $a/\lambda=0.156$, the diameter of a cell of a 120-degree traveling wave disk-loaded accelerating structure is larger than 2 cm, but the outer diameter of the dielectric tube in a DLA structure is only 1 cm if the dielectric constant of the tube is 20.

However, the choice of dielectric constant should be considered as far more complicated than the requirement of a reduced transverse dimension. It is strongly linked with other accelerating parameters as well. A very good estimate of the group velocity of a traveling wave DLA structure is given by $V_g/c \approx 1/\varepsilon_r$ (where c is the speed of light and ε_r is the relative dielectric constant of the loaded material) when a/λ is less than 15%. The quality factor of a DLA structure can be roughly estimated as $Q \approx 5.22\times10^4/\{\sqrt{[f<GHz>\times(\varepsilon_r-1)]}+5.22\times10^4\times\tan\delta\}$, where f is the frequency of the TM01 mode in units of GHz and $\tan\delta$ is the loss tangent of the loaded material.

PARAMETER CHOICE

DLA structures are generally preferred for use in a short structure powered by short, high frequency RF pulses, which reduces the probability of RF breakdown but needs a short filling time to achieve a high RF-to-beam efficiency [2]. Consider the rough design of an X-band travelling wave DLA structure. From the group velocity estimate, we choose $\varepsilon_r=10$ for a structure with $V_g=10\%$ c. Then Q can be estimated to be 3400. Since the size of the beam opening (2a) is independent of Q but tightly related to the R/Q (figure of merit of an accelerating structure) and shunt impedance R (they both increase as the beam opening decreases), we can choose a as small as the beam emittance allows to obtain both a large R/Q and R. Meanwhile the filling time (defined as L/V_g, where L is the length of the structure) remains short since the group velocity is unrelated to the beam opening. It should be pointed out that a/λ of DLA structures cannot be chosen too small since it will increase the wakefield and thus the risk of beam break-up.

Transverse wakefield damping in DLA structures has been well studied [3]. Its implementation is rather simple: an axially slotted copper jacket filled with RF absorber or metallized strips on the outer surface of the dielectric tube surrounded with RF absorber. The low Q of the DLA structures also helps the damping of long range wakefields.

Figure 1 shows a few parameters of X-band (11.7GHz) travelling wave DLA structures. Three different dielectric constants are used in the plots, representing three commonly used low loss materials: Alumina ($\varepsilon_r=10$, $\tan\delta=1\times10^{-4}$), MgCaTiO ($\varepsilon_r=20$, $\tan\delta=1\times10^{-4}$) and Quartz ($\varepsilon_r=3.8$, $\tan\delta=6\times10^{-5}$). Figure 1(a) clearly shows that the group velocity is bounded by the reciprocal of the dielectric constant as the beam opening decreases. The quality factor of a DLA structure is the combined contribution of metal wall losses and dielectric losses, but

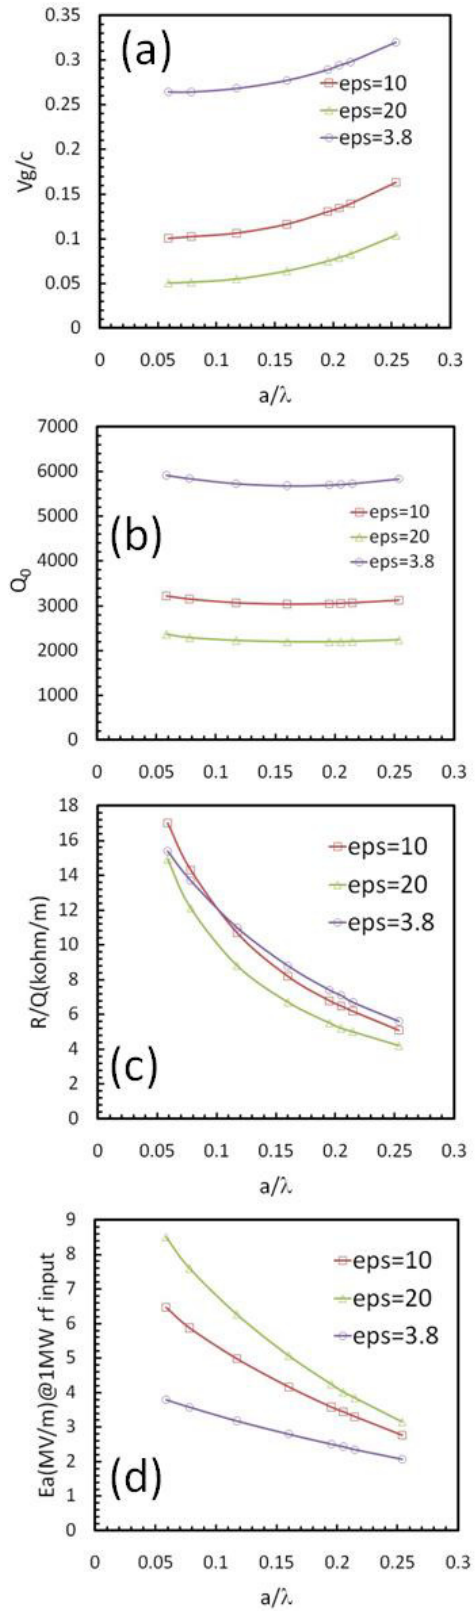

Figure 1: Dependence of parameters in DLA structures on the scaling parameter a/λ: (a) group velocity; (b) quality factor; (c) R/Q; (d) accelerating gradient.

it remains nearly constant across different size of beam channel (Fig. 1b).

From Fig. 1(c) and 1(d) we can see that the R/Q values for different dielectrics can approach or cross each other for small beam channels but the gradient in a higher ε_r DLA structure is always higher. This is because of the strong dependence of the gradient E_a on the group velocity, $E_a^2=[R/Q]\times 2\pi f\times P/V_g$, where P is the input RF power. Again, the low V_g leads to a long RF filling time which then requires a longer RF pulse to power the structure and accelerate the beam. The strong pulse length dependence of the RF breakdown rate will limit the accelerating gradient. However, in an application that does not need to operate with the gradient at a high risk level, a high dielectric constant material should be preferred since it will provide a higher gradient for a given RF power.

MULTIPACTOR

One principal effect that has limited further advances in DLA technology in the past is the problem of multipactor. The fraction of the power absorbed at saturation in the DLA structure was found to increase with the incident power, with as high as 30% of the incident power per unit length being absorbed if the dielectric material has a high Secondary Electron Yield (SEY). A thin film TiN coating, which reduces SEY, can reduce the multipactor loss below 10%. Using geometric factors, particularly the introduction of surface grooves to reduce the multipactor in DLA structures is also under investigation. However, lessons from other work show that one challenge to the success of this approach is the strong dependence upon a few critical dimensions of the groove design, which leads to a very tight machining tolerance and in turn increases the fabrication difficulties and costs.

In fact, the most effective approach to completely terminate multipactor is to use an external solenoid field. Analytical models, numerical simulations, and practical example in other applications have successfully demonstrated its effectiveness [4, 5]. In DLA structures, an external DC magnetic field in the longitudinal direction can continuously reduce the period for secondary electrons hopping on the dielectric surface (and thus spoil the resonance condition) when the ratio of the gyro-frequency to RF frequency is in the range of 0.7 to 1 (The gyro-frequency, Ω, is a plasma parameter; for electrons it is defined as $\Omega=eB/m_ec=1.76\times10^7B$ rad/s, where B is the magnetic field component perpendicular to the electron motion plane). It is equivalent to a solenoid field range from 2.8 kG to 4 kG for an X-band DLA structure. This approach is more attractive than other techniques since it can maintain all the advantages of regular DLA structures, and it is independent of the accelerator parameters other than the operating frequency.

TUNING

The need for frequency tuning (or phase velocity adjustment) of any accelerating structure arises from the fact that the phase velocity of the assembled accelerating

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

structure will, in general, differ from the design phase velocity due to various sources of error. In a DLA structure, these errors can be caused by machining tolerances of the dielectric dimensions, thermal expansion of the structure, dielectric constant heterogeneity, etc. The common way of tuning all-metal structures is using temperature variation or slight mechanical deformation of the accelerating structure walls. The DLA structure does not admit this possibility because the ceramic loading is usually made of a brittle microwave thermostabilized ceramic that does not allow any noticeable mechanical adjustment of its geometrical parameters. At the same time, the permittivity of BST ($Ba_xSr_{1-x}TiO_3$) ferroelectric has a strong temperature dependence. If a thin, low loss ferroelectric layer having relatively high dielectric constant (ε_r>100, tanδ<5×10^{-3}) is introduced, the DLA structure can be easily tuned by controlling its temperature. Introducing a relatively thin ferroelectric layer does not change the basic accelerating structure parameters significantly but it makes the overall average permittivity of the dielectric loaded resonator tunable in the range from tens of kHz to tens of MHz depending on the thickness of ferroelectric material [6].

RF COUPLING

Besides the dielectric loaded section, a DLA structure requires a RF coupler to feed in the high power RF signal. A well designed coupler should possess a high mode conversion efficiency (e.g. TE_{10} mode in rectangular waveguide to TM_{01} mode in DLA structure), and be less susceptible to high power breakdown. Figure 2 show three coupling schemes commonly used in DLA structures. In Fig. 2(a), the metallic RF coupler is separated from the DLA section. The tapered dielectric matching section is a part of the DLA structure that matches the impedance of the TM_{01} mode between the empty and dielectric-loaded waveguide. This coupling method can reach a very broad bandwidth at a cost of the extra length of the dielectric taper. It is worth pointing out the importance of fabricating the entire dielectric tube in a single piece. Any micro gap caused by a dielectric joint is subject to RF breakdown due to the strong field enhancement. Figure 2(b) shows a coaxial type coupling, where the impedance matching is accomplished in the coupler section so that the DLA section remains a simple straight tube. This design is very effective and compact, but the beam hole in the inner conductor of coaxial coupler may limit its usefulness in high gradient applications (i.e. where a/λ is small). Figure 3(b) shows a variation of the side coupling configuration, which is simple in fabrication but generally exhibits a smaller bandwidth than the axial coupling.

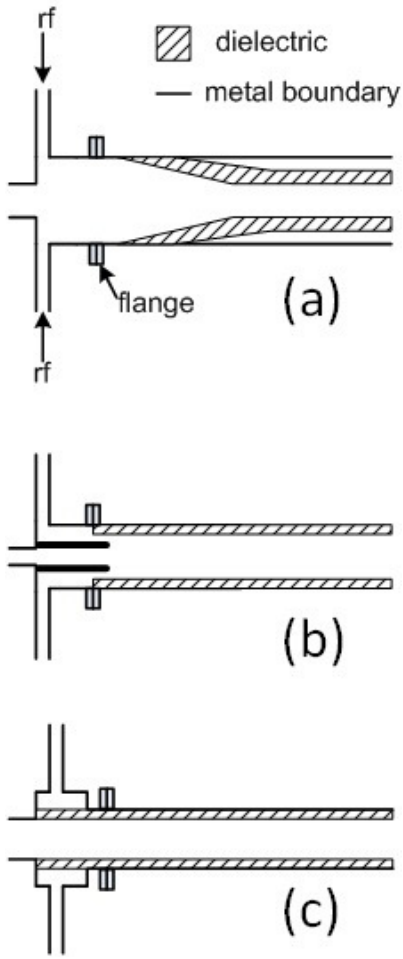

Figure 2: Three commonly used RF coupling schemes in DLA structures; (a) mode launcher; (b) coaxial coupler; (c) side coupling.

REMARKS

DLA technologies have seen significant progress for a decade. At present, it is possible to build and use a practical DLA structure. We expect that its compactness and low cost will eventually make it broadly useful in many applications.

FERMILAB 1.3 GHz SUPERCONDUCTING RF CAVITY AND CRYOMODULE PROGRAM FOR FUTURE LINACS*

C.M. Ginsburg#, Fermilab, Batavia, IL 60510, USA

Abstract

The proposed Project X accelerator and the International Linear Collider are based on superconducting RF technology. As a critical part of this effort, Fermilab has developed an extensive program in 1.3 GHz SRF cavity and cryomodule development. This program includes cavity inspection, surface processing, clean assembly, low-power bare cavity tests and pulsed high-power dressed cavity tests. Well performing cavities have been assembled into cryomodules for pulsed high-power tests and will be tested with beam. In addition, peripheral hardware such as tuners and couplers are under development. The current status and accomplishments of the Fermilab 1.3 GHz activity will be described, as well as the R&D program to extend the existing SRF pulsed operational experience into the CW regime.

INTRODUCTION

Work by the International Linear Collider (ILC) [1,2] community, which includes Fermilab, has motivated substantial world-wide infrastructure development and cavity performance progress. At Fermilab, this has translated to a very large commitment of resources for infrastructure and personnel development. The developed capability has led to the possibility to use the 1.3 GHz infrastructure for development of Project X [3,4], although the performance requirements are somewhat different [5]. The Project X 3 GeV CW linac requires high Q_0 at gradients (E_{acc}) in the range $15<E_{acc}<20$ MV/m; 1.3 GHz cavities can be used to investigate high Q_0. In addition, the Project X 3-8 GeV pulsed section operates at 1.3 GHz and requires ILC-like cavities with E_{acc}~25 MV/m. The status of Fermilab 1.3 GHz infrastructure, accomplishments and plans are described.

INFRASTRUCTURE

The cavities are fundamentally of the Tesla design [6], made of high RRR niobium with an elliptical cell shape, for superconducting operation at 2K. Cavity qualification has been described in detail elsewhere [7] and includes cavity inspection, surface processing, clean assembly, and one or more cryogenic qualification tests which typically include performance diagnostics. Cavities which reach the performance requirement in vertical (bare) qualification test, typically $E_{acc}>35$ MV/m, are dressed and horizontally tested. Cavities which reach the performance specification in horizontal (dressed) qualification test, also typically $E_{acc}>35$ MV/m, are assembled into cryomodules.

The joint ANL/FNAL facility is the primary infrastructure [7] for surface processing of 1.3 GHz cavities, and includes electropolishing (EP). New infrastructure at Fermilab includes two high temperature furnaces for hydrogen degassing, see Fig.1. In addition, a centrifugal barrel polishing (CBP) machine for 1-cell and 9-cell 1.3 GHz cavities has been introduced for R&D and may be used for production cavity preparation in the future, see Fig.2. CBP may be used in place of the standard bulk electropolishing step, to reduce acid use. CBP has been demonstrated to be a useful repair technique [8], and may have other benefits as well, such as reducing cavity performance sensitivity to minor manufacturing or material defects; these studies are not yet complete. A new R&D surface processing facility [9] is now fully operational for the full suite of standard EP processing for 1-cell 1.3 GHz cavities. The R&D EP tool is shown in Fig.3.

ILC AND CONSIDERATIONS FOR CW

ILC R&D contributed substantially to cavity gradient performance. A worldwide effort by participating laboratories, including Fermilab, to optimize cavity processing and to develop new cavity vendors for high gradient cavities was implemented. As part of this work, a systematic analysis of cavity vertical test data was performed [10]. The data set is comprised of cavities fabricated by established vendors (ACCEL/RI, AES, MHI, Zanon), and processed by established laboratory surface processing (JLab, DESY, KEK), including electropolishing. If a cavity does not reach 35 MV/m after the initial EP processing stage, we assume it would be re-processed. Standard 2nd pass processes may include EP, HPR, or 120C bake, and are selected based on 1st pass performance at the discretion of the laboratory. There are 51 cavities in the 1st pass plot, and 35 in the 2nd pass plot. The difference in number of cavities reflects the fact that the 2nd pass may not have take place yet, or may have been done with a non-standard process. The gradient distribution of cavities which are not included in the 2nd pass yield is the same as those which are included. The ILC gradient yields, representing percentage of cavities reaching either 25 MV/m (blue points) or 35 MV/m (red points) are shown in Fig.4. ILC cavities reach 35 MV/m more than half the time after one or two EP processing cycles. For Project X, the gradient yield at 25 MV/m is of interest. In 1st pass, (69±6)% of all 51 cavities achieve >25 MV/m; and (86±13)% of 7 cavities achieve >25 MV/m considering only cavity tests taking place in 2012. In 2nd pass, (80±7)% of all 35 cavities achieve >25 MV/m; and (92±7)% of 13 cavities achieve >25 MV/m considering only cavity tests taking place in 2010-2012.

Ongoing efforts to improve cavity performance yields, either 1st pass or 2nd pass, include applying localized grinding (pioneered by KEK) to performance-limiting defects, and CBP. Many (~12) cavity repairs have been achieved through these two methods; however, at this time, cavity performance after these repairs has not been included in yield plots.

Two approaches for Q_0 optimization for Project X are being pursued at Fermilab now: venting cavities after hydrogen degassing in a nitrogen atmosphere [11], and using a hydrofluoric acid rinse as the final processing step [12]. Both approaches show promising results.

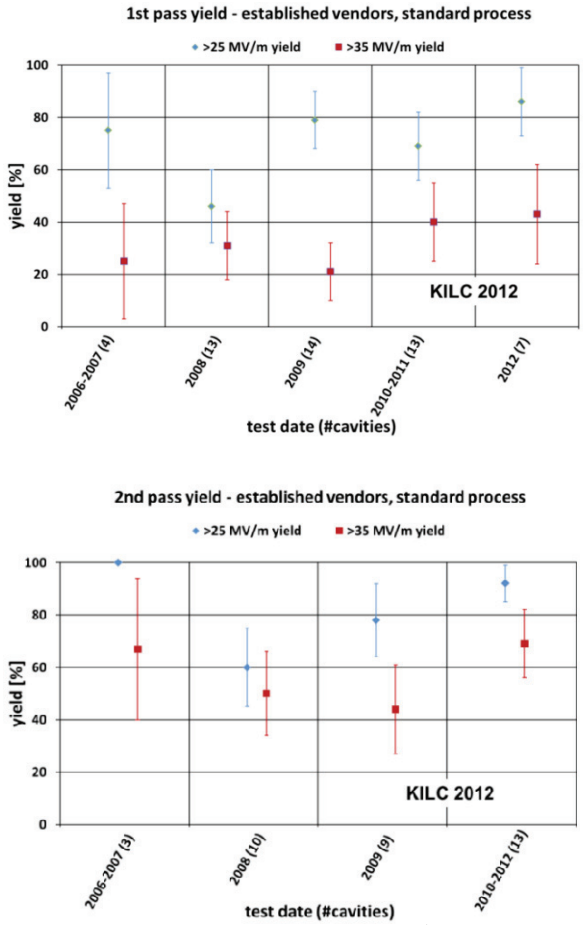

Figure 4: ILC cavity gradient yields: 1st pass (top) and 2nd pass (bottom), as a function of time. Blue points are >25 MV/m yield and red points are >35 MV/m yield.

ACCOMPLISHMENTS

Fermilab provides stewardship for 80 9-cell cavities for the ILC/Americas region. The status of these cavities is shown in Table 1. The bare cavities are processed and tested in strong collaboration with JLab, Cornell and ANL; see Fig.5 for vertical test performance.

Table 1: 9-cell Cavity Status August 31, 2012

ordered	80
received	69
processed	47
vertically tested	47
dressed	22
horizontally tested	19
CM2 installed	8

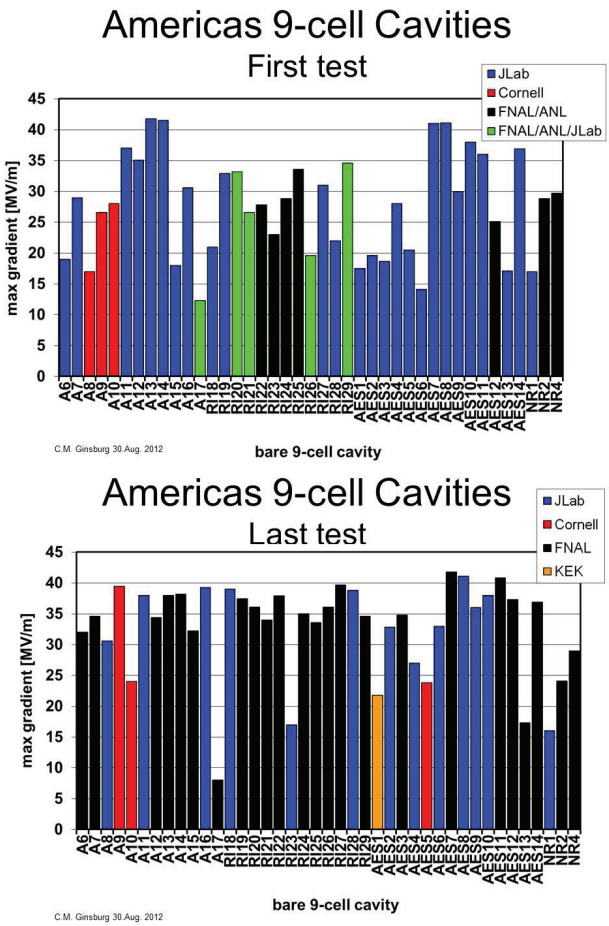

Figure 5: Gradient performance of all Americas cavities in first test (top) and last test (bottom). The test location is designated by the histogram bar color. An overall improvement is seen after additional process and test.

Two 1.3 GHz cryomodules have been assembled at Fermilab: CM1 and CM2. CM1 was built from a DESY "kit" containing parts from DESY and INFN, including surface processed, dressed, tested cavities. The magnet position is occupied by a "dummy" magnet. CM1 has been tested cold with excellent results [13]. CM2 is an 8-cavity string with a quadrupole package. CM2 is comprised of cavities which were surface processed and reached 35 MV/m in vertical test at JLab. These cavities were dressed and horizontally tested at Fermilab, then assembled into CM2. The summary of final cavity performance before CM2 assembly [14] is shown in Fig.6. CM2 will be tested at NML first without beam and then with beam within a year. All components are available for the assembly of CM3, which is expected to proceed within about a year.

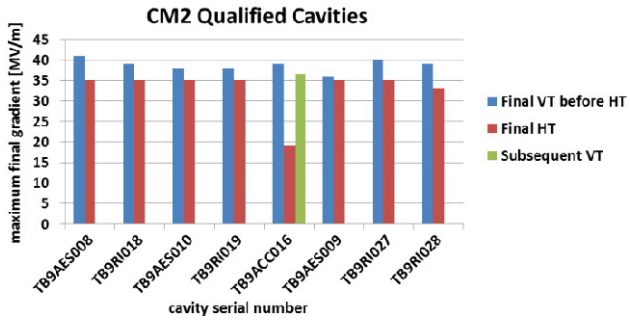

Figure 6: Gradient performance of CM2 cavities in vertical (blue) and horizontal tests (red). In one case, a subsequent dressed-cavity vertical test was performed after failed horizontal test.

Abstract

Starting from the high-resolution camera for inspection of the cavity inner surface – so-called Kyoto Camera, high resolution T-map, X-map and eddy current scanner have been developed. R&D for radiography techniques is also going on to detect small voids inside the Nb EBW seam, where the target resolution is 0.1 mm. Some radiography tests with X-rays induced from an ultra short pulse intense laser were carried out. The local treatment technique on the found defects is also realized by the Micro-Grinder.

INTRODUCTION

Non-destructive Inspections play important roles in improving yield on production of high performance SC Cavities. Starting from the high-resolution camera for inspection of the cavity inner surface [1], high-resolution T-map, X-map and eddy current scanner [2,3,4,5,6] have been developed. We are also investigating radiography to detect small voids inside the Nb EBW seam, where the target resolution is 0.1 mm. We are carrying out radiography tests with X-rays induced by irradiations of an ultra short pulse intense laser on a target metal sheet. Defects found by the inspection technique can be locally treated by the Micro-Grinder.

CAVITY CAMERA UPDATE

In order to inspect the SPL cavity at CERN, whose frequency is about a half of ILC cavity and the diameter is about twice larger, the illumination system has been enhanced to illuminate the wider surface area (see Fig. 1). Although the iris diameter is about twice larger than that of ILC's, the bore diameter at the flange position is limited (just below ø80mm). This limits the camera cylinder diameter is ø70mm. Fig. 2 shows the modification on the illumination system to illuminate the wider area with enough strength. While the former system used two LED's for each strip, the new system uses 14 LED chips on a line and two lines consist one strip. Thus 28 LED chips are used for a strip. Furthermore, the LED chip has three LED's in a package. This illumination system should provide enough light for the wider cavity surface area. Because of the larger cavity size, the working distance is longer than former model and a bigger lens system is adopted. Fig. 3 shows the overview of this system. The illumination plate on the cylinder is shown in Fig. 4. The camera cylinder can be rotated to see the annular area in a cavity without movement of the cavity, while the cavity table can rotate the cavity if it does not wear its He jacket around. The table has a function to move the cavity in its axial direction.

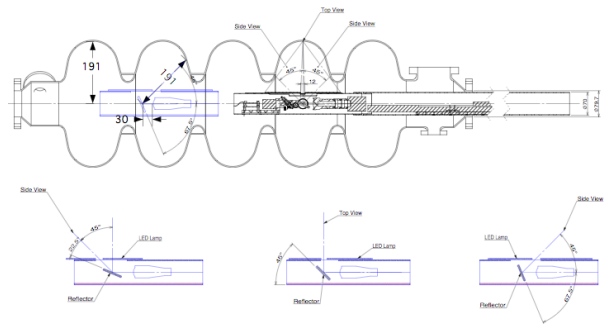

Figure 1: CavCam3 in SPL cavity.

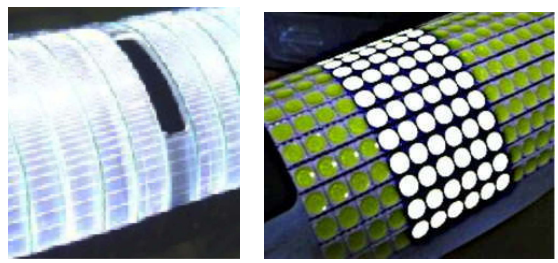

Figure 2: Enhanced illumination for wider surface area (Armadillo Illumination). 28 LED chips (right) instead of 2 LED's per strip (left) are installed.

Figure 3: Latest CavCam-3 for SPL cavity at CERN.

Figure 4: All the LED's are lighten. A diffusing panel will be install on the LED's to form the light strip. 14 chips/line x 2 lines/strip x 10 strips/side x 2 sides = 560 chips are used.

HIGH DENSITY T-MAP & X-MAP

The high density Temperature mapping system (T-map) and X-ray mapping system are under development. These systems utilize multiplexing technique to reduce the number of lines from the sensors to the measurement circuits. The temperature sensors are put on a Nb cavity surface during the vertical test to detect the temperature rise from the quench phenomena due to a defect on the inner surface, if any. Since one temperature sensor / cm^2 is assumed for the surface density, 1024 sensors will be installed on a cell and about nine thousands of sensors will be need to be connected to the measurement circuit. The number of lines needed for these connections is reduced by multiplexing the analog signals in the cryogenic area. The reduced lines include the three power supply lines (0V, ±5V), one clock line, one reset line, and two signal lines for each type of system (t-map and X-map) as shown in Fig. 5. T-sensors are installed on the inner side and X-sensors are located on the other side. T-sensors contact on the cavity surface (see Fig. 6). As shown in Fig. 7 the leaves can be instantly attached on a cell, which helps to reduce the installation time for a vertical test.

A dedicated X-map system for installation under the stiffener ring is also developed (see Fig. 8). Only X-sensors are installed on the PCB, which can slide into the space under the stiffener ring as shown in Fig. 9.

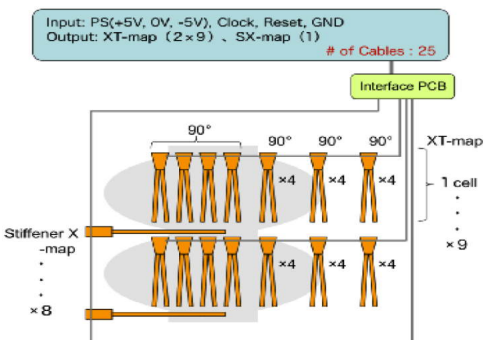

Figure 5: The inter-connection for the XT-map system.

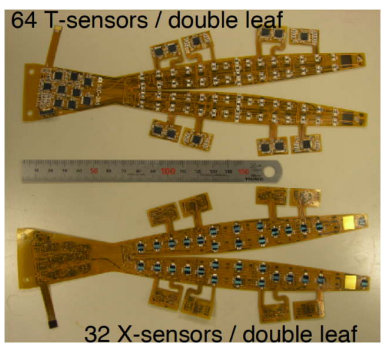

Figure 6: Leaf shaped flexible PCB.

HIGH RESOLUTION EDDY CURRENT SCAN

A Nb sheet before the press to form the cup will be inspected by a Eddy current scan [7]. Using a multi-frequency Eddy current probing system, a small void just under the surface, which may appear after surface treatments such as electropolishing (EP), would be detected. The depth information would be obtained from the three different frequency data simultaneously acquired during the measurement. The detected hole size is currently ø100µm x 50µm depth (see Fig. 10).

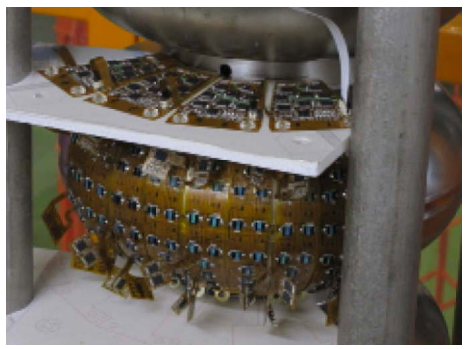

Figure 7: Installed XT-map leaves on a cell.

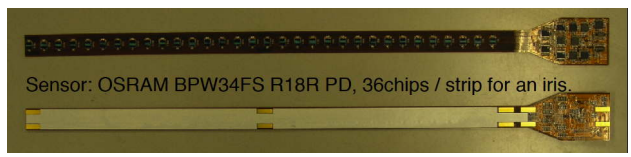

Figure 8: Stiffener X-map.

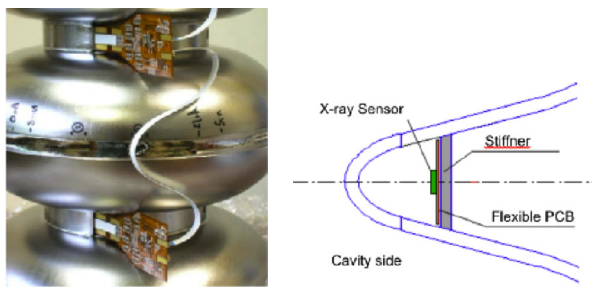

Figure 9: Installed stiffener X-map ribbons. The ribbons go under the stiffer ring.

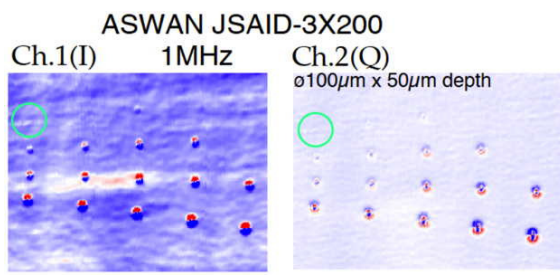

Figure 10: The high resolution eddy current scanner can detect the drilled holes on the Nb sheet down to ø100µm x 50 µm depth.

RADIOGRAPHY EFFORT

In order to inspect the EBW seam especially for possibly buried defects under the surface, various radiography techniques have been investigated such as

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

X-ray CT, and neutron CT. Since Nb has larger atomic number, high energy X-rays tend to be preferred for a better transmission. The contrast, however, becomes worse for high energy X-rays. Although the phase contrast techniques should have better contrast even in this case, it is not a handy way. After some trials, laser induced X-ray radiograph is under investigation (see Fig. 11). Fig. 12 shows the obtained radiography images for targets of Zr and Ag, where Zr is supposed to be better because of the X-ray energy just below the K absorption edge of the Nb. Further study is needed for better visibility and practical applications.

LOCAL REPAIR TECHNIQUE

Using the inspection devices, defects on the surfaces can be identified and analyzed. For those defects judged as harmful, the local repair technique should be applied. The micro-grinder can be inserted into the cavity, while the grinding head is retracted (see Fig. 13)[8]. After its positioning, some amount of water is applied to the area and the head with abrasives can start to grind. The grinding time can be limited by a timer up to 99 minutes. Additional EP and following processes are applied to the treated cavity to bring the cavity back to the line. Several cavities have been already repaired and show satisfactory results (see Fig. 14).

NORMAL CONDUCTING DEFLECTING CAVITY DEVELOPMENT AT THE COCKCROFT INSTITUTE

G. Burt, P. K. Ambattu, A. C. Dexter, B. Woolley, C. Lingwood, Cockcroft Institute, Lancaster, UK
S. Buckley, P. Goudket, C. Hill, P. A. McIntosh, J. Mackenzie, A. Wheelhouse,

A. Grudiev, CERN, Geneva, Switzerland
R M. Jones, UMAN, Manchester, UK

Two normal conducting deflecting structures are currently being developed at the Cockcroft Institute, one as a crab cavity for CERN linear collider CLIC and one for bunch slice diagnostics on low energy electron beams for Electron Beam Test Facility EBTF at Daresbury. Each has its own challenges that need overcome. For CLIC the phase and amplitude tolerances are very stringent and hence beamloading effects and wakefields must be minimised. Significant work has been undertook to understand the effect of the couplers on beamloading and the effect of the couplers on the wakefields. For EBTF the difficulty is avoiding the large beam offset caused by the cavities internal deflecting voltage at the low beam energy. Prototypes for both cavities have been manufactured and results will be presented.

INTRODUCTION

Transverse deflecting cavities are required for many applications on accelerators, including crab cavities, bunch separators, emittance exchange and for bunch length diagnostics. These cavities usually operate in a TM_{110}-like mode. The Cockcroft Institute in the UK is participating in the design of several deflectors for a range of applications including crab cavities for ILC [1], CLIC [2] and LHC [3] and a bunch length diagnostic for EBTF [4]. In this paper we concentrate on the normal conducting rf deflectors for CLIC and EBTF.

CLIC CRAB CAVITY

CLIC requires a crab cavity to rotate the bunches prior to the interaction point (IP) to achieve an effective head-on collision. As the bunch size at the IP is very small (~5 nm) the luminosity is very sensitive to the crab cavities RF phase and amplitude. This means that the beamloading must be minimised and correction applied. The beamloading is dependent on the longitudinal electric field experienced by the bunch. In crab cavities the longitudinal electric field is zero on axis but has a linear variation as the bunch goes off axis. This means the beamloading could be positive or negative depending on the beam offset. As the bunch train for CLIC is short (~200 ns), the beamloading cannot be compensated for in a single bunch train, the feedback would occur over several trains. Unless the jitter on the beam offset is much less than the bunch size the compensation will not be successful, hence the beamloading must be minimised instead [5]. In order to reduce the effect of beamloading the cavity is designed with a large power flow so that any power induced by beamloading is smaller in comparison. This is achieved by using a high group velocity travelling wave structure.

Another issue affecting beamloading is the perturbation of the input and output couplers. Couplers break the symmetry of the cavity and can give rise to monopole components to the deflecting field. A dual feed coupler keeps the symmetry of the structure and avoids monopole components but is more complex coupling arrangement requiring splitters. A single feed is the simpler coupling arrangement however this gives the end cells a large monopole component of the rf field. We have investigated methods of single feed coupling without inducing monopole component.

Single-feed Couplers

In order to minimise the monopole component of rf field in the end cells while using a single-feed coupler a number of options were investigated. Initially cancelling the monopole kick from the two end cells was studied. Consider particle moving at the speed of light. If the cell is rotated the monopole component has the sign of the real part of the voltage flipped. Hence if the input and output couplers are mounted on opposite side the real parts should cancel. If the lengths of the cells are adjusted so that the voltage is entirely real then the entire monopole component is cancelled. This however is not sufficient in travelling wave deflecting structures as the power put into the output cell will be extracted through the output coupler while the power in the input cell will travel down the structure. Hence it is necessary to cancel the beamloading in each cell individually.

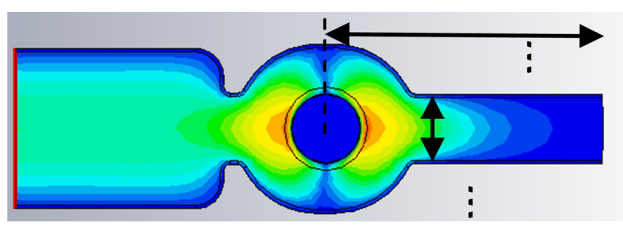

Figure 1: Dummy waveguide and input coupler on the CLIC crab cavity

In order to restore the symmetry of the cell a dummy waveguide opposite the coupler was studied. Using a

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

dummy waveguide was found to significantly reduce the monopole component but not reduce it to zero. The real part is reduced to zero, but the imaginary component is not and hence gives the minimum voltage. The reason for this is because there must be a power flow across the cell, from the coupler to the dummy waveguide. This means that there cannot be a full standing wave in the cavity and there must be a travelling wave component.

Another method of symmetrising the cell is to couple from the side with a TE_{02} mode coupler. This allows an equal power flow to each side hence avoiding a monopole component. However the cavity is now vertically asymmetric and hence there is a small vertical kick. However this symmetry can be recovered by adding a dummy waveguide. The TE02 mode splitter must carefully be designed to avoid excitation of a TE01 mode which gives rise to a monopole component to the fields.

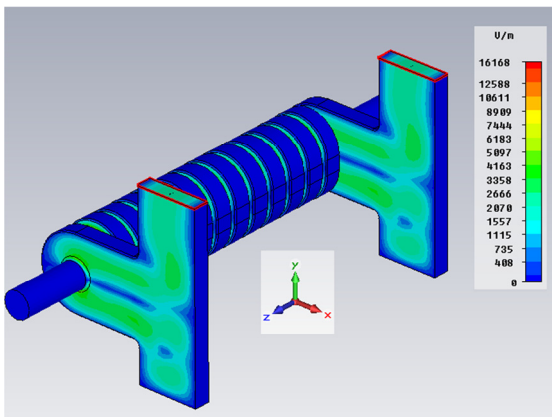

Figure 2: TE_{02} mode coupler

Wakefield Damping

As the cavity is close to the final focus magnets, where the beta function is large, it is very sensitive to transverse wakefields. It is necessary to damp any long-range wakefields within a few bunches to avoid large transverse offsets at the IP. The vertical wakefield is the most sensitive, due to the small vertical beam size, and is dominated by the opposite polarisation of the crabbing mode, known as the same order mode (SOM). As the wake is dominated by a single mode it is proposed to have this modes frequency at the zero-crossing, where the mode frequency is a half integer harmonic of the beam frequency. This means that each bunch induces a voltage 180 degrees out of phase with the previous bunch hence cancelling each other. For CLIC it is proposed that the cell has an elliptical cross-section such that the crabbing mode is at 11.99 GHz while the SOM is at 12.98 GHz. However the SOM still requires significant damping due to the very tight tolerances on vertical kicks. Choke damping and waveguide damping were both considered. Choke cavities are difficult for deflecting cavities as the choke must be polarised to damp one polarisation but not the other. Options are to use an elliptical cavity, an elliptical choke or a slotted choke [6]. The slotted choke achieved the best performance; however widening the slot to achieve better damping also reduces the Q of the crabbing mode which could be problematic due to enhanced heating. For this reason a waveguide damper was chosen for CLIC, as shown in Fig.3, as a waveguide coupler shows strong damping of the SOM without affecting the crabbing mode.

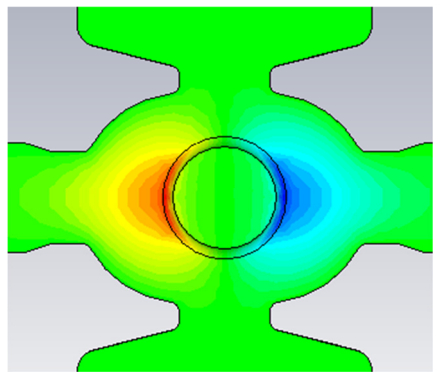

Figure 3: Damped elliptical cell of the CLIC crab cavity

Cavity Prototype

Two prototype cavities have been manufactured. One has been made by Shakespeare Engineering, a UK company, to be tested at SLAC and the other has been made at VDL, to be tested at CERN. The CERN cavity has had the parts machined and is due to be brazed soon. The SLAC cavity, shown in Fig. 4, has been fully manufactured and is currently undergoing tests at Cockcroft before shipping to SLAC.

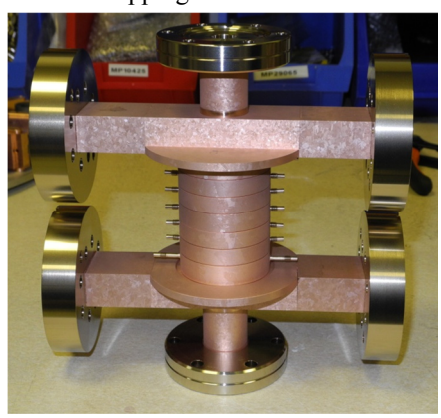

Figure 4: CLIC crab cavity prototype manufactured by Shakespeare Engineering.

EBTF TRANSVERSE DEFLECTING CAVITY

The Electron Beam Test Facility (EBTF) at Daresbury Laboratory will deliver low energy (5/6 MeV) short bunches (down to 40fs RMS) to a number of industrial experimental stations and for fundamental scientific research. In order to measure the longitudinal profile of the bunch an S-band transverse deflecting cavity will be inserted into the beamline. A transverse kick of around 5 MV is required, hence a 9 cell design has been chosen. The design of the transverse deflecting cavity has been influenced by the competing demands of high RF efficiency [7] and minimising the equal and opposite

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

unwanted transverse kick at the entrance and exit of the cavity which causes the low energy electrons to be displaced while traversing the cavity [8]. The coupler has a dummy waveguide to minimise the on-axis longitudinal electric field.

Minimising transverse offset

As a transverse deflecting cavity has a finite size the beam experiences a range of phases as it crosses the cavity. This means for a zero-crossing it experiences a finite force, initially in one direction and then in the other such that the net transverse momentum at the centre of the bunch is the same at the start and end of the cavity. However this does result in a transverse offset as the beam travels transversely inside the cavity. It was found that due to the beampipe the electrical centre of the end cell was not at the geometric centre. This resulted in an uneven kick producing a net transverse momentum when leaving this cell, which wasn't removed until experiencing the opposite force at the other end cell. This gave a much larger transverse offset in the cavity, of 4 mm, due to the low energy of the bunch. As the beam was offset the beamloading was much higher which significantly altered the beam energy. For ultra-relativistic beam this offset is small and typically ignored. For low energy beam of EBTF is could not be ignored and has to be minimized.

In order to counteract this effect the end cells were made much shorter such that transverse kick in the end cells for a zero-crossing particle was minimised. The final cavity is shown in Fig. 5. The particle tracking simulations in GPT [9] show the transverse offset inside the cavity is minimised, shown in Fig. 6.

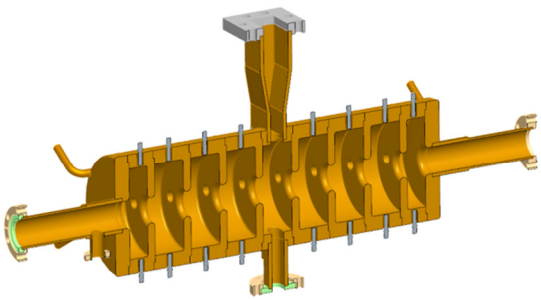

Figure 5: EBTF Transverse deflecting cavity with shortened endcells.

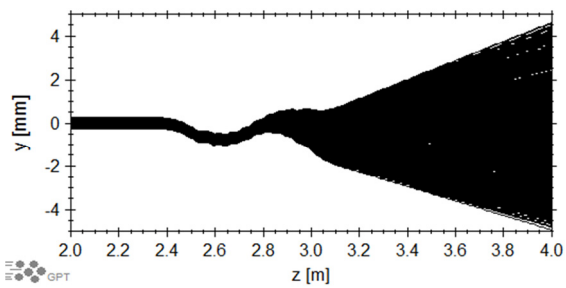

Figure 6: GPT tracking simulation of EBTF transverse motion.

Prototype Cavity

A 3-cell prototype has been produced by Research Instruments (shown in Fig. 7), to verify brazing procedure, and a contract has been placed with them for a full 9-cell structure.

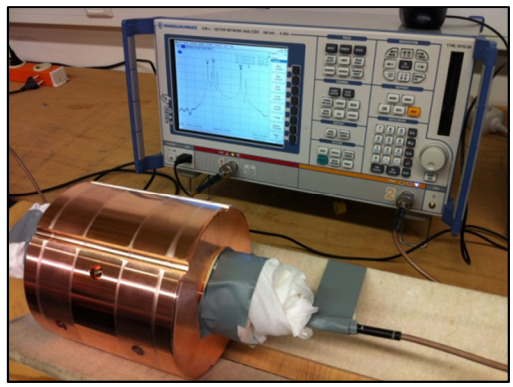

Figure 7: 3-cell prototype of the EBTF Transverse deflecting cavity.

SUMMARY

The Cockcroft Institute has a proven track record of designing deflecting cavities for numerous applications. High power testing is expected to be done on both cavities in the next few months.

ACKNOWLEDGEMENTS

This work has been supported by STFC via the Cockcroft Institute core grant and the EU through the EUCARD grant.

STATUS OF THE C-BAND RF SYSTEM FOR THE SPARC-LAB HIGH BRIGHTNESS PHOTOINJECTOR

R. Boni, D. Alesini, M. Bellaveglia, G. Di Pirro, M. Ferrario, A. Gallo, B. Spataro,
INFN-LNF, Frascati, Italy
A. Mostacci, L. Palumbo, ULRS, Rome, Italy

Abstract

The high brightness photo-injector in operation at the SPARC-LAB facility of the INFN-LNF, Italy, consists of a 150 MeV S-band electron accelerator aiming to explore the physics of low emittance high peak current electron beams and the related technology. Velocity bunching techniques, SASE and Seeded FEL experiments have been carried out successfully. To increase the beam energy so improving the performances of the experiments, it was decided to replace one S-band travelling wave accelerating cavity, with two C-band cavities that allow to reach higher energy gain per meter. The new C-band system is in advanced development phase and will be in operation early in 2013. The main technical issues of the C-band system and the R&D activities carried out till now are illustrated in detail in this paper.

THE SPARC-LAB AT FRASCATI LNF

The SPARC-LAB is a research facility of the INFN Frascati Laboratory (LNF) whose purpose is to conduct advanced research in the field of high brightness, low emittance electron beams [1]. The facility, able to operate also in the velocity bunching configuration, feeds six 2m. long undulators and integrates the 150 MeV S-band photo-injector with a 220 Terawatt, Ti:Sa ultrashort laser system. FEL radiation in the SASE, Seeded and HHG modes have been performed from 500 nm down to 40 nm wavelength. The photo-injector SPARC, a single bunch electron accelerator, consists of a laser driven RF Gun followed by three traveling wave (TW), constant gradient, $2\pi/3$ accelerating cavities, with the first two immersed in a solenoidal field to keep down the beam emittance growth. A second beam line has been also installed and is now hosting a narrow band THz radiation source.

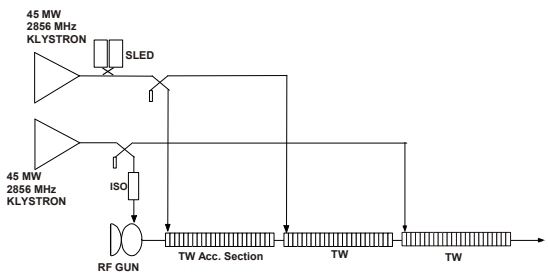

Figure 1: the SPARC photoinjector present layout

To improve the performances of the experiments and recuperate the energy that is lost in the velocity bunching configuration. it was decided to increase the beam energy by replacing the third S-band section with two, 1.4 m. long, C-band TW accelerating structures that allow to operate at higher gradient. The choice of a higher frequency, e.g. the X-band, was also considered but then discarded because more expensive and technically more challenging.

THE C-BAND RF SYSTEM

The C-band technology is relatively new in linear accelerators compared to the standard and widely used S-band systems. Nevertheless it can be considered sufficiently mature since it is already employed in other accelerator laboratories like the Spring8 (JP) and the PSI FEL (CH) facilities.

R&D of the accelerating structure

The third S-band accelerating section, that is a 3 m. long SLAC-type unit, shown in Fig.1will be replaced with two, 1.4 m., C-band sections supplied with a 50 MW, 5712 MHz Toshiba klystron through a SKIP-type pulse-compressor [2]. In order to ease design and construction, the C-band sections are constant impedance (CI) structures with large (14 mm) iris diameter to minimize the surface electric field on the iris edges and improve the pumping speed. Also, the group velocity increases and this reduces the filling time. It must be remarked that the typical exponential decay of the input compressed pulse is partially compensated by the RF losses of the CI structure, resulting in a quasi-constant field amplitude along the section. Input and output waveguides are coupled to the beam-pipe instead of to the end-cells. A 50 cm long prototype was designed at LNF and built by a local firm. Brazing and vacuum test have been made at LNF [3].

The prototype, shown in figure 2, has been power tested at KEK, in the frame of a collaboration established ad hoc with the INFN.

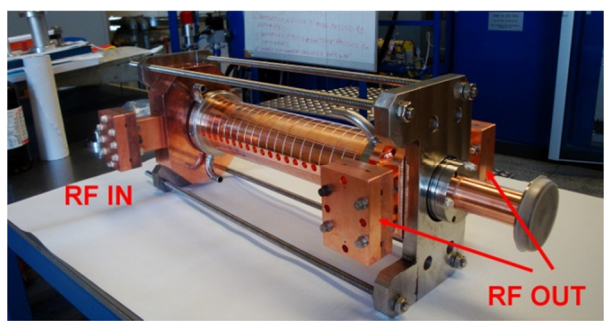

Figure 2: The C-band prototype tested at KEK.

The KEK RF station consists of a 50 MW - 2.5μsec Toshiba E37202 klystron, followed by a pulse

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

compressor. The results of the power tests, reported in detail in the ref. [4], was very successful and well beyond our expectations. The C-band prototype was tested up to 110 MW peak - 200 nsec - 50 Hz to a maximum average gradient of 55 MV/m, with a breakdown rate of the order of 10^{-6} bpp/min after about 300 hours of RF conditioning. A picture of the prototype is shown in figure 2.

Following the positive results of the KEK power test, we started the construction of two 1.4 m accelerating sections. The next figure 3, shows the concept of the beam-pipe coupling. This type of coupling allows the first RF cell to be mechanically unperturbed, i.e. there are no slots on the cell outer wall that normally cause heating and degrade the performances.

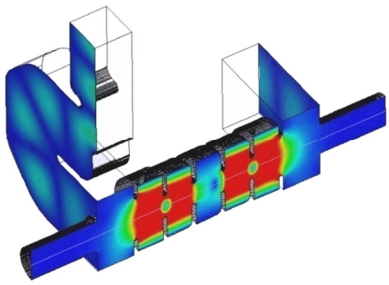

Figure 3: The waveguide beam-pipe coupling

Further, the symmetric coupling guarantees low quadrupole components on the longitudinal axis [3]. The same concept of beam-pipe coupling is applied at the accelerating section output, with two opposite flanges without combiner. So we use 2 loads per section but the power dissipated by each load is halved.

The actual accelerating structures consist of 71 cells and are 1.4 m. long, to leave 20 cm for the insertion of a pumping unit in the 3 m. left available by the 3rd S-band section. The new C-band sections have been manufactured The cells and the waveguide couplers have been machined by a local firm; then, low power test and brazing of two halves have been made at LNF where a vacuum furnace of 80 cm of internal height is available. After joining mechanically the two halves, the first C-band section was tuned at LNF by adjusting the plungers on each cell wall. The last brazing will be made shortly by a local firm, where a 2 m. long vacuum furnace is available. The C-band actual section in shown in the next figure 4. The figures 5 and 6 show the low power measurements made in laboratory with the bead perturbation technique. The following table 1 shows the main specifications of the C-band accelerating structures.

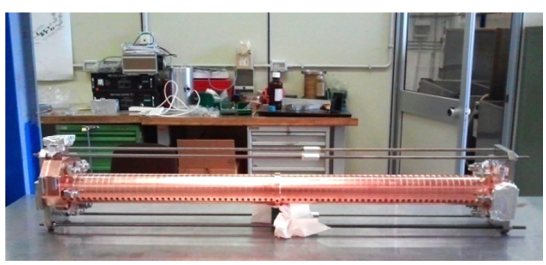

Figure 4: The two halves of one C-band section before the final brazing

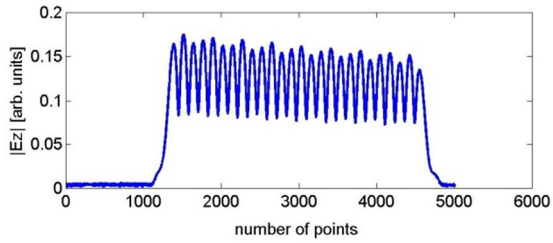

Figure 5: RF field profile of half C-band section

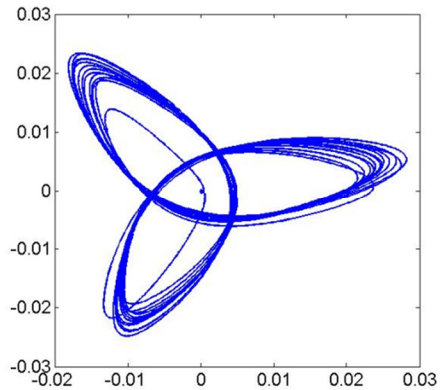

Figure 6: Phase advance per cell in the polar plane

Table 1: C-band structures main parameters

Frequency (MHz)	5712
type	TW, CI
structure	Disk loaded
Phase advance per cell	2π/3
n. of cells	71
Coupling type	beam-pipe
Iris radius (mm)	7.0
Group velocity/c	0.0283
Shunt impedance (MΩ/m)	82.9
Surf. peak E field/Acc. field	2.17
Filling time (nsec)	150
Total length with couplers (cm)	140

The RF power needed to produce the accelerating field is about 60% of input power. The residual 40% will be dissipated by two RF water-loads, supplied by CML-Engineering, connected to the output coupling ports of the accelerating sections.

The power transmission system

The layout of the complete C-band system is presented in figure 7. The RF power will be distributed to the accelerating structures by means of a network of rectangular WR187 waveguides (WG) made of OFHC copper. The total WG length from the klystron to the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

accelerating sections is about 10 m. and the RF losses are of the order of 10% since the attenuation is 0.035 dB/m.

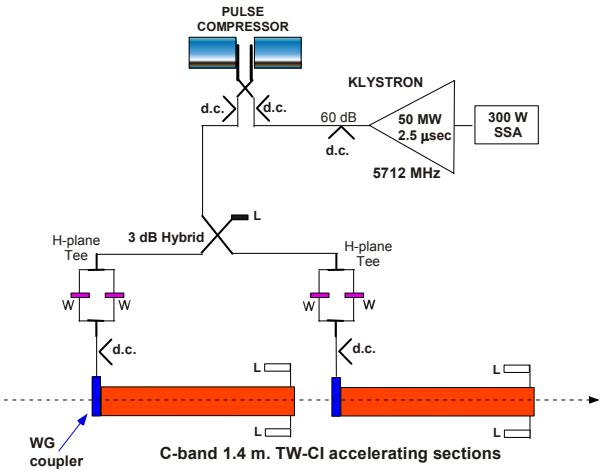

Figure 7: Layout of the SPARC C-band system

The C-band pulse compressor (PC) is under construction by the Division of Technology Development of the IHEP, Beijing, China. It is a double slot coupled cylindrical resonator system that follows the concept of the model "SKIP" developed by KEK. The PC output power is divided in two by a 3 dB hybrid junction and then delivered to the accelerating sections through two RF windows. The RF is split and recombined with two H-plane Tees. In this way the peak power through each RF window is halved as we are not sure of the actual capacity of them to handle power levels in excess of 100 MW peak.

The H-plane Tee s11 is -20 dB and the phase unbalance between outputs is about 1°. They have been designed and brazed at LNF. The machining was made by the local firm Comeb.

The RF Power Station

The RF power station consists of the Toshiba klystron E37202 driven by a solid state 400 W amplifier supplied by MitecTelecom. The pulsed klystron modulator is also a full solid state system made by Scandinova. The table 2 lists the main parameters of the RF power station. The klystron have been successfully RF tested on a dummy load up to 40 MW – 2 µsec – 10 Hz. The klystron RF conditioning is still ongoing.

Table 2: C-band power station main parameters

Frequency (MHz)	5712
Max klystron power (MW)	50
RF pulse width (µsec)	2.5
Klystron input RF power (W)	300
Klystron beam voltage (kV)	350
Max RF pulse rep. rate (Hz)	10

The Low Level RF System

The control of the C-band accelerating structures will be achieved by a digital low level RF (LLRF) system where all RF signals are down-converted to intermediate frequencies which are then digitized and processed with powerful digital processing platforms. The drive signal is finally up-converted to control the RF high power chain The schematic layout of the digital control system is shown in the figure 8.

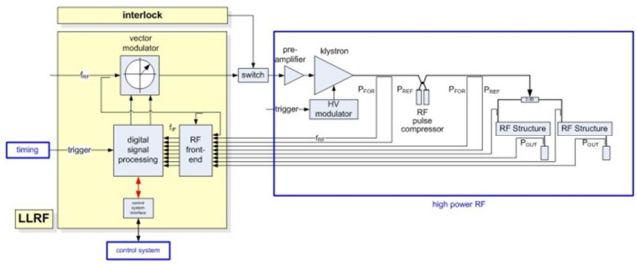

Fig. 8: Schematic layout of the digital LLRF system.

A processing board based on VME64x is under development by the PSI laboratory (CH) in collaboration with INFN. It includes a multi-core PowerPC processor and a high performance field programmable gate array Xilinx Virtex-6 on the main board and provides a variety of I/O interfaces. The goal of the digital signal processing is to implement all static algorithms like the digital down-conversion from intermediate frequency to base-band, filtering, I/Q to amplitude/phase conversions and averaging calculations in firmware in the FPGA while using the PowerPC for more sophisticated high level applications like pulse-to-pulse feedback algorithms.

Abstract

A Technology Demonstration Cryomodule (TDCM) has been developed for a systems test of technology being developed for FRIB. The TDCM consists of two half wave resonators (HWRs) which have been designed for an optimum velocity of beta=v/c=0.53 and a resonant frequency of 322 MHz. The resonators operate at 2 K. A superconducting 9T solenoid is placed in close proximity to one of the installed HWRs. The 9T solenoid operates at 4 K. A complete systems test of the cavities, magnets, and all ancillary components is presented in this paper.

INTRODUCTION

The SRF Department at Michigan State University had developed and tested four cryomodules prior to the first demonstration cryomodule for FRIB. Two of the cryomodules are working reliably in the ReA3 linac at MSU [1]. The TDCM, shown in figure 1, is the first cryomodule that demonstrates FRIB specific technology and encourages a transition to large scale engineering and quality assurance methods [2].

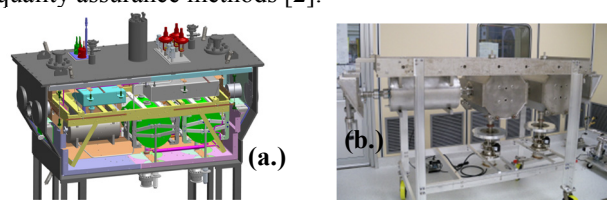

Figure 1: (a.) Rendering of TDCM in cryostat (b.) Cold mass assembly in cleanroom.

In developing the FRIB TDCM, a baseline cryomodule production method evolved for FRIB. The technical and schedule related setbacks encountered during the TDCM campaign eventually yielded reliable fabrication, processing, and certification techniques. SRF-related infrastructure and utility usage required for the TDCM assisted in finalizing planning for a new SRF high bay which will support FRIB cavity processing, vertical testing, cold mass assembly, and cryomodule bunker tests.

TDCM RELEVANCE TO FRIB

The TDCM is a developmental snapshot, and much of the technology improved as more detailed engineering analysis and sub component testing programs provided opportunities for design optimization [3- 5]. Some of the key differences are: a "bottom-up" style from the "top-down" TDCM style [4]; the rail system, support system, heat and magnetic shields assemblies were simplified; Improvements to alignment methods; an internal heat exchanger replaces the external heat exchanger; the 4K thermal intercepts will be parallel circuits as opposed the series connection in the TDCM.

With much of the cryogenic circuitry and alignment systems optimized in the baseline design before TDCM testing took place, alignment and continuous 2K operation aspects were not tested. The plumbing of the RF coupler 4K intercepts [6] required steady flow in the static state required continuous overfilling of the 4K header to ensure the couplers stayed cooled during RF conditioning.

TDCM DEVELOPMENT

Individual tests or more detailed engineering analyses conducted on the cavities, couplers, tuners, and cryogenic circuits used in the TDCM led to design optimizations and improved processing [7- 9].

Initial dunk tests showed low field emission onset values and thermal breakdown below the operating gradient; FRIB processing optimization for the HWR began during the TDCM campaign. The TDCM cavities were field emission-free [10] prior to the installation of the helium vessels.

Initial tests still showed signs of multipacting in the cavity. Repeated measurements on several cavities show a recurring barrier at 2 MV/m E_{acc}. This barrier self-conditioned as the RF power was raised, and in most tests only observed during initial 4K measurements.

During the initial dunk tests, it was discovered Q_0 was lower after a thermal cycle with no change otherwise. A closer investigation for Q-disease showed a strong reduction in the Q_0 after a 15 hour soak at 100K. The cavities were sent to JLAB for a furnace treatment to remove hydrogen from the bulk. Subsequent 'Q-soaks' and thermal cycles showed no signs of degradation. A 600°C furnace treatment was added to the baseline processing plan and a furnace has been installed at MSU [9].

After being jacketed with a helium vessel, the 1st cavity was certified using the vertical cryostat configuration [5], and no field emission was observed. This helium vessel design utilized a titanium bellows at the beamport to reduce the tuning force required for the scissor-jack tuner.

*This material is based upon work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

After this cavity had been installed on the TDCM cold mass, the next jacketed cavity developed a large leak from the helium to insulating space found at the titanium bellows. The bellows were removed from the already certified cavity, requiring additional machining and welding.

TDCM TESTING

RF Amplitude and Phase Control

The resonators in the FRIB linac will operate with a very narrow BW for amplitude and phase control. For the HWR, the 30 Hz RF bandwidth available for control presents a technical challenge and increasing the RF BW has a very large impact on cost. The low level RF controller was developed at MSU and employs an ADRC algorithm [11] which is required to ensure a dynamic stability within 2% (peak-to-peak) amplitude and 2 degrees (peak-to-peak) phase. The resonators do not have fast tuning implemented to cancel microphonics. Measurements were done using a fast (1.6 kHz) data acquisition of the RF signals. The results are shown in figure 2, where the measured cavity and amplitude stability is within the limits of the measurement uncertainty. During the measurements, the cavity field was kept just below a multipacting barrier in the cavity and with the slow tuning feedback to the scissor-jack mechanical tuner turned off.

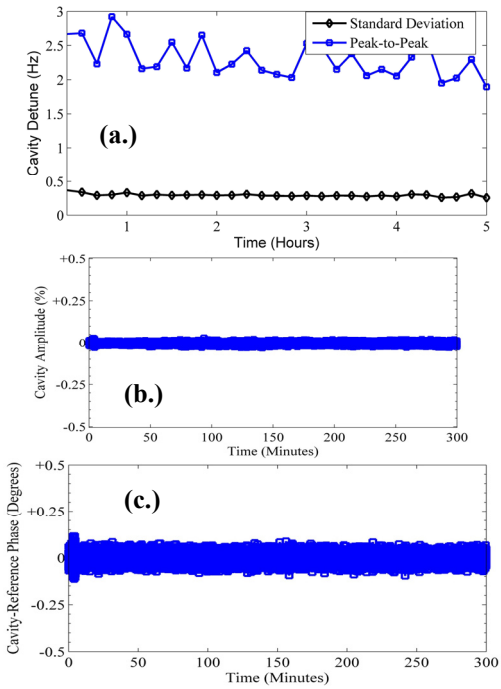

Figure 2: (a) Closed loop detuning, calculated from the forward phase changes while regulating with the cavity amplitude and phase (b, c) well within the design specification.

The 'cavity detune' (Δf) in Figure 2a is inferred from the changes in the forward phase ($\Delta\varphi_f$) and is calculated from $\Delta f = BW \times \Delta\varphi_f$. The closed loop detune inferred from the measurement agreed well with some shorter duration open loop measurements done a 2K. A slow drift of 8 Hz over five hours was measured, justifying the necessity of a slow tuner. During this measurement, the bath pressure was well regulated (less than 0.7 Torr peak-to-peak).

The next round of measurements was performed using the feedback to the slow tuner. The measured amplitude and phase stability was higher (1.4%, 0.6°, peak-to-peak), but still within the FRIB specification. It was noticed that the tuner drive was constantly moving, which created a mechanical oscillation at 110 Hz, causing a closed loop detune of 24 Hz peak-to-peak.

RF Couplers

The RF couplers had been conditioned for multipacting barriers prior to the installation into the cold mass [6]. The multipacting that was conditioned had returned after installation to and cooling of the TDCM, with similar onset levels. Coupler conditioning did not completely remove the multipacting from the coupler above 2 kW after 10 hours of RF pulses. The multipacting was suppressed by applying an external magnetic field through a coil winding around the coupler. Figure 3 shows a plot the current on the probe near the ceramic disk; 6.8 kW peak power was achieved with 4.5 kW average forward power while driving 1 MHz off-resonance. A detailed multipacting analysis [12] shows that the location of the two-point multipacting in the coaxial line depends strongly on the boundary condition at the cavity port. With the rf system 'detuned' from the cavity, the boundary condition at the coupler port is that of a short circuit, and a single two-point multipacting node exists at the voltage peak, which is approximately half way between the coupler port and the ceramic disk. However, when driving the cavity on resonance, two voltage peaks exist on the transmission line. The magnetic field suppression did not suppress the multipacting when locked to the cavity resonance.

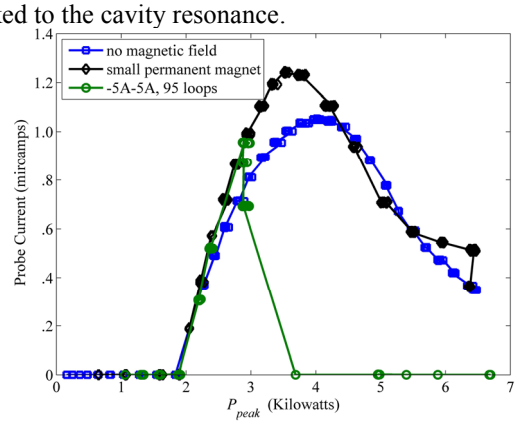

Figure 3: Multipacting suppression in the FPC while driving from the cavity off-resonance.

Tuners

The bellows used to reduce the force required to tune the cavity was replaced with a rigid connection to the helium vessel. A measurement of the tuning ratio of

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

360:1 greatly exceeds the expected 8:1 ratio showing that the scissor-jack mechanism was not performing as expected. This resulted in a reduced tuning sensitivity of the actuator controller (from 1.8 Hz/step to 0.03 Hz/step), which may explain the mechanical effects on the performance of the LLRF with the tuner engaged. Additional testing will be performed on an alternate tuning concept which utilizes a pneumatic drive.

Cryostat

Static load measurements on the TDCM cryostat were performed by recording liquid level as a function of time using the level sensor to infer the evaporation rate. This rate was calibrated by using a gas meter to measure the mass flow of the helium gas at room temperature. The mass flow measurement and nominal liquid volume boil-off from the header dimensions had roughly good agreement. Neither the level vs time nor the gas meter methods were calibrated with a known heat source. An evaporation rate of 2.85 W to the 2K header and 4.0 Watts to the 4K header was measured and repeated four times, with a spread of 0.22 W peak to peak.

Cavity Dynamic Load

The cavity dynamic loads, measured the same as the static load measurements described above, could not be accurately measured below the multipacting barriers (1.67 MV/m E_{acc}), since the resolution of this type of measurement is ~0.5 W. This resolution exceeds the heat load measured in the last Dewar test (0.10 Watts at 1.67 MV/m). With helium processing, a reasonable field level (4 MV/m) was reached. The dynamic load of 1.5W @ 4 MV/m yields a Q_0 of 1.2E10. This measurement was done in the last hours of the TDCM test. The load from the RF coupler at this field (850W forward power) was negligible considering a load measurement done with 4.5 kW forward power off resonance was less than the measurement resolution.

Magnets & Magnetic Field Interactions

The Earth's magnetic field is shielded from the cavities with a global mu-metal shield. Measurements on the shield showed an attenuation factor of at least 25 was achieved; however accurate measurements of the residual magnetic fields with the cold mass installed were not performed. Prior to energizing the magnets, the low field Q_0 (@1.67 MV/m) showed the possibility of high residual magnetic fields trapping fluxes up to 200 mG, but the Q drop at this field could also be explained as either measurement error or multipacting.

The 9T solenoid has a fringe field such that the flux at the nearest cavity surface is 250 Gauss. The revised FRIB specification for this fringe-field is 650 Gauss. The magnet was powered to full field; the cavities were warmed up to 30 K, and then re-cooled. The dynamic loads were measured again at 2K. The difference in the dynamic loads was less than the 0.5 W measurement resolution. A magnetic field cancellation procedure was performed by varying the power supply current, I, in a decreasing and alternating manner, e.g. a series,$\{(-0.9)^n I\}_{n=0}^{40}$ which took 5 hours to complete. The dynamic load measurement performed after this degaussing and further RF conditioning yielded a quality factor close to that measured in the vertical test.

TDCM Outlook and Future Tests

The TDCM test ended abruptly after taking only limited dynamic load data due to an unexpected cryoplant failure. A suspected helium leak in the transfer line that supplied the TDCM required mass flow rates of 3-5 g/s to maintain level in the liquid helium levels, though static load measurements indicate only 0.5 g/s is required. Therefore, running the TDCM test in parallel to NSCL experimental programs in impossible due to the unavailability of this LHe supply rate.

Though the TDCM completed a successful first round of testing in mid-2012, additional testing will be done by end of 2012. The next round of testing will focus primarily on the high power RF conditioning that commenced in the later stages of the TDCM measurements.

A new transfer line is being procured and installed to supply the TDCM from a refrigerator that is separate from the NSCL experimental program. While the transfer line is being built, the cryostat is being opened up to make some adjustments. Magnetic material found on the internal scissor jack tuning mechanisms is being removed. The RF couplers are undergoing an in-situ bake (~100-120C, 72 hours) in an effort to reduce the multipacting intensity. Additional measurement equipment will be installed to determine the dynamic load of the couplers to the intercepts and the remnant fields from the 9T solenoid before and after degaussing steps.

ACKNOWLEDGMENTS

The authors would like to thank Greg Velianoff, Jon Wlodarczak, Tom Russo, John Brandon, Mike Holcomb, and Jie Wei for their help in late night and evening shifts during RF conditioning; JLab for degassing the HWR's installed in the TDCM; Peter Kneisel, Curtis Crawford, and Bob Laxdal for their advice given regularly in weekly teleconference.

Abstract

Electron beam driven wakefield acceleration is a bona fide path to reach high gradient acceleration of electrons and positrons. With the goal of demonstrating the feasibility of this concept with realistic parameters, well beyond a proof-of-principle scenario, the AWA Facility is currently undergoing a major upgrade that will enable it to achieve accelerating gradients of hundreds of MV/m and energy gains on the order of 100 MeV per structure. A key aspect of the studies and experiments carried out at the AWA facility is the use of relatively short RF pulses (15 – 25 ns), which is believed to mitigate the risk of breakdown and structure damage. The upgraded facility will utilize long trains of high charge electron bunches to drive wakefields in the microwave range of frequencies (8 to 26 GHz), generating RF pulses with GW power levels.

AWA FACILITY

The mission of the Argonne Wakefield Accelerator Facility (AWA) is to develop technology for future accelerator facilities. The AWA facility has been used to study and develop new types of accelerating structures based on electron beam driven wakefields. In order to carry out these studies, the facility employs a photocathode RF gun capable of generating electron beams with high bunch charges and short bunch lengths. This high intensity beam is used to excite wakefields in the structures under investigation.

The facility is also used to investigate the generation and propagation of high brightness electron beams, and to develop novel electron beam diagnostics.

The AWA high intensity electron beam is generated by a photocathode RF gun, operating at 1.3 GHz. This one-and-a-half cell gun typically runs with 12 MW of input power, which generates an 80 MV/m electric field on its Magnesium photocathode surface. A 1.3 GHz linac structure increases the electron beam energy, from the 8 MeV produced by the RF gun, to 15 MeV. The linac is an iris loaded standing-wave structure operating in the $\pi/2$ mode with an average accelerating gradient of 7 MV/m; it has large diameter irises to minimize the undesirable wakefields generated by the passage of high charge electron bunches.

The charge of the electron bunches can be easily varied from 1 to 100 nC, with bunch lengths of 2 – 2.5 mm rms, and normalized emittances of 3 to 100 π mm mrad.

The AWA laser system consists of a Spectra Physics Tsunami oscillator followed by a Spitfire regenerative amplifier and two Ti:Sapphire amplifiers (TSA 50). It produces 1.5 mJ pulses at 248 nm, with a pulse length of 2 to 8 ps FWHM and a repetition rate of up to 10 pps. A final KrF Excimer amplifier is optionally used to increase the energy per pulse to 15 mJ.

The generation of electron bunch trains (presently up to 16 bunches) requires each laser pulse to be divided by means of beam splitters into a laser pulse train. The charge in each electron bunch is determined by the energy in each laser pulse and the quantum efficiency of the photocathode material. Typically, single bunches of 100 nC can be produced (with a maximum of 150 nC occasionally reached).

WAKEFIELD ACCELERATION

The use of electron beam driven wakefields to achieve high gradient acceleration has received considerable attention. It offers the advantage of using a relativistic beam to transport the energy to the accelerating structures, decreasing the difficulties of generating and distributing RF power by conventional means; wakefields naturally constitute RF pulses that are of short duration and high peak intensity [1].

Research at the AWA facility has been exploring various types of wakefield structures, including photonic band gap structures, metallic iris loaded structures, and also more exotic schemes using metamaterials. The main focus of the facility, however, has clearly been the development of dielectric loaded structures. They offer the advantage of simple geometry and easy fabrication with accelerating properties that compare favourably with conventional iris loaded metallic structures: the axial electric field is uniform across the transverse cross section of cylindrical structures, and the uniform cross section of the structures presents no geometric features to cause field enhancement. The damping of the undesirable deflecting dipole modes seems to be more easily accomplished in dielectric loaded structures as well; planned experiments will explore the use of longitudinal slots on the metallic outer shell of dielectric structures, as a possible scheme to damp dipole modes. Dielectric structures also hold the promise of withstanding higher electric fields without material breakdown. A significant advantage offered by wakefield structures, in comparison

with other wakefield schemes, is the ability to accelerate positron bunches or electron bunches in basically identical fashion.

AWA FACILITY UPGRADES

The AWA Facility has several major upgrades presently underway, which will considerably enhance its capabilities.

A new one-and-a-half cell RF gun (Fig.1) has been commissioned, and it will replace the existing RF gun as the source of drive bunches. The new RF gun operates with a Cesium Telluride photocathode, and thus, due to the higher quantum efficiency of Cs_2Te, it will be able to generate longer bunch trains with high charge per bunch. We plan to generate trains with up to 32 electron bunches, each separated by one L-band RF period, and with up to 100 nC per bunch. (It should be noted that the two upper limits, i.e. 32 bunches and 100 nC per bunch, cannot be reached simultaneously, since this would load the accelerating fields in the RF gun to an unacceptable level.) These longer bunch trains will, of course, generate longer RF pulses when traversing the wakefield structures.

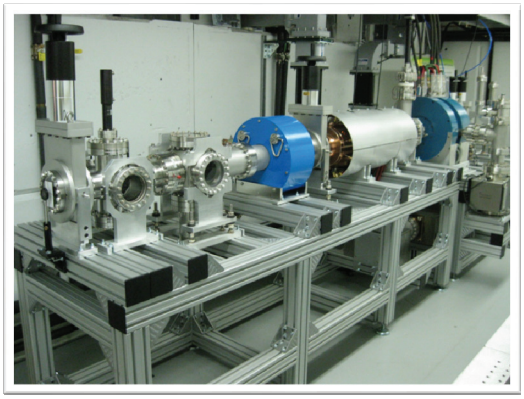

Figure 1: The new AWA RF gun (between the blue solenoids), followed by the first one of the six new linac tanks, another focusing solenoid, and two vacuum crosses for laser beam input and beam profile measurements (YAG screen). A combination of ICT and FCT (Integrating Current Transformer and Fast Current Transformer made by Bergoz) is installed in between the two crosses.

Three additional L-band RF power stations, consisting of one 30 MW Litton klystron and two 25 MW Thales klystrons, and their respective modulators, will power six new linac tanks in the drive beamline. These new klystrons have been commissioned to full power.

The new linacs [2] will be seven-cell standing-wave π mode structures, designed to operate with 10 MW of input power and 11.2 MeV energy gain. Thus, the operation of the six new linac tanks will increase the energy of the beam produced by the drive gun from 8 MeV to 75 MeV. This will, of course, allow significantly more energy to be extracted from the drive beam as it drives wakefields in the structures under test. The higher beam energy also implies a smaller physical transverse emittance of the bunches, facilitating their propagation through smaller aperture wakefield structures, and generating even higher wakefield amplitudes.

The fabrication of the first one of the six new linac tanks has been completed, and good field flatness across the cells has been achieved (Fig.2). It has been installed just downstream of the new RF gun (Fig.1). The fabrication of the remaining five linac tanks is under way, and their final brazing cycles are scheduled for October of 2012.

The commissioning of the new drive gun will free up the existing gun, which will then be used to generate a witness beam to probe the wakefields produced by the drive bunches.

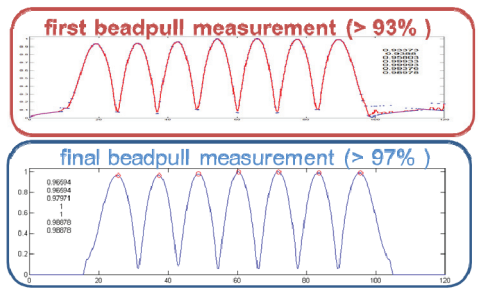

Figure 2: Bead-pulling RF measurement of first linac tank, showing good field balance across the cells.

A new beamline switchyard (Fig. 3) will be constructed to allow concomitant experiments: (a) collinear wakefield acceleration; (b) RF power generation and two beam acceleration; (c) phase space manipulation (emittance exchange, etc); (d) high brightness beam generation; (e) beam diagnostic development. This flexible beamline switchyard will allow a quicker and more efficient transition among several concurrent experimental setups.

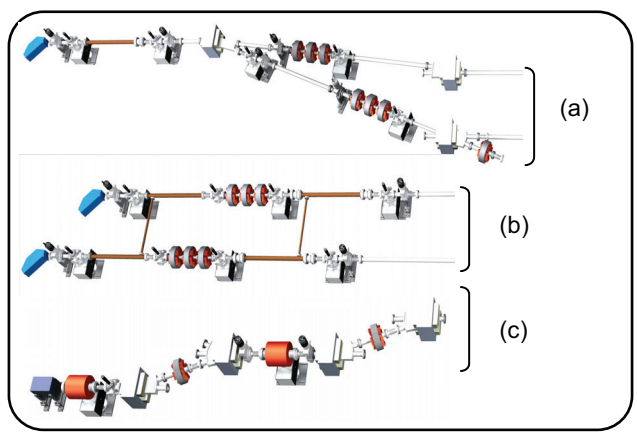

Figure 3: Different legs of the new AWA beamline switchyard will be dedicated to specific types of experiments: (a) collinear wakefield acceleration; (b) two-beam-acceleration and RF power generation; (c) phase space manipulation (emittance exchange) and beam diagnostic development.

Figure 4: The expanded AWA bunker: (a) plentiful interior space is now available for the installation of the new linac tanks and new beamline switchyard; (b) new RF power circulators and waveguides have been installed on the roof of the expanded bunker, ready to connect the new klystrons to the new linac tanks.

CONCLUDING REMARKS

In the past few years AWA has demonstrated high gradient fields (100 MV/m) in dielectric based wakefield structures [3]. Generation and extraction of RF power using beam driven dielectric structures has also been demonstrated [4 - 6]. Several experiments exploring new designs and new features of dielectric based wakefield structures will be conducted in the near future.

Concomitantly, AWA is undergoing upgrades that will enhance its capabilities. These upgrades will allow the generation of longer bunch trains with high charge per bunch. The higher beam energy will make it possible to excite high gradient wakefields in longer accelerating structures, thus generating hundreds of MV/m over meter scale structures. The second RF gun will provide "witness" bunches to probe the wakefields, demonstrating high gradient acceleration.

Once the upgrades are completed, the goal is to achieve accelerating gradients on the order of 0.5 GV/m in structures with approximately 3 mm apertures. The generation and extraction of RF pulses with power levels on the order of GW shall also be demonstrated. As an example, Table 1 shows the main parameters of a pair of structures that will be tested as soon as the upgraded AWA Facility becomes available. The actual hardware is seen in Fig. 5.

Abstract

Thomson scattering X-ray source, in which the TW laser pulse is scattered by the relativistic electron beam, can provide ultra short, monochromatic, high flux, tunable polarized hard X-ray pulse which is can widely used in physical, chemical and biological process research, ultra-fast phase contrast imaging, and so on. Since the pulse duration of X-ray is as short as picosecond and the flux in one pulse is high, it is difficult to measure the x-ray spectrum with traditional spectra measurement methods. In this paper, we introduce an iterative statistical algorithm (Expectation-Maximization) to reconstruct the spectra from the attenuation data, and the results of the X-ray spectrum measurement experiment on Tsinghua Thomson scattering is also presented.

INTRODUCTION

Thomson Scattering sources (also called Inverse Compton Scattering), which can be bright X-ray sources typically produce photons, have attracted a lot of interest as the technologies for producing low-emittance high-brightness relativistic electron sources and ultra-short high-power lasers have progressed. The X-rays that are generated by the interactions between laser and electron, exhibit high directivity, and have a polarized tunable quasi-monochromatic spectrum. The knowledge of the spectrum of an X-ray source is a key point for the development of any kind of application, for example in imaging both contrast and absorbed dose strongly depend on energy. However, direct methods performing a standard spectrometric measurement based on single photon energy measurement to detect the X-ray spectrum of Thomson Scattering sources have always been considered troublesome to implement because the beam is too intense to cause pulse pile up problems. Thomson Scattering source can produce up to 10^8 photons, bunched in 10ps long pulse [1]. An alternative way to measure the spectrum might request the measurement to be integral-type, which will not be affected by the high rate of incidence of photons. The analysis of attenuation data (transmission curves), which can provide some information about the spectral distribution of an X-ray source, as not affected by the rate of incidence of photons, is a good candidate to measure the X-ray spectrum of the Thomson Scattering X-ray source. Although there are several problems with this method, such as low accuracy, non-unique solution to ill-condition system and instability with different measurement error [2], this method can still give good estimation and reconstruction of spectra with some improvements based on the property of the measured spectra.

In this article, we introduce an iterative statistical algorithm (Expectation-Maximization) [3] to reconstruct the spectra from the attenuation data on simulated measurement. Results show that this method can give good approximations for the mean energy of the spectra, while it is not sensitive to the specific spectral distribution and the energy broadening. In order to reconstruct the shape of the spectra, especially the energy broadening, we present a new method based on the Expectation-Maximization algorithm. An preliminary experiment is also carried out on Tsinghua Thomson scattering X-ray source, the measured maximum X-ray energy is about 53keV, which is agreed well with the simulations.

OVERVIEW OF TTX

The scheme of TTX is shown in figure 1. This machine includes a 50MeV electron linac based on the photocathode RF gun and a Ti: Sapphire TW laser system. The laser system generates both the 266nm UV pulse for photocathode and the 800nm IR pulse for scattering interaction. The two pulses are derived from one 79.3MHz Ti:Sapphire oscillator in order to reduce the time jitter between the electron beam and the IR pulse. The linac system consists of a BNL/KEK/SHI type 1.6 cell S-band photocathode RF gun, a 3m S-band SLAC type travelling wave accelerating section, generates 40~50MeV ultra-short high brightness electron pulse for scattering interaction. The laser system is synchronized with the RF system through a timing circuit, with a timing jitter no greater than 0.5ps. The parameters of electron and laser were listed in the table 1.

In previous experiment, we succeed to generate and detect the X-ray signal with head-on colliding mode. The results from the MCP and X-ray CCD are shown in figure 2.

LOCAL ENERGY SPECTRUM MEASUREMENT

X-Ray Spectrum Measurement from the Analysis of Attenuation Data

The relative transmission function $T(x)$ responding to an attenuator of thickness x is related with the spectrum of an X-ray beam in the following way[1]:

$$T(x)=\frac{S(x)}{S(0)}=\int_0^{E_{\max}} e^{-\mu(E)x}F(E)dE \qquad (1)$$

where $S(x)$ is the signal measured with an absorber of thickness x, and $S(0)$ is the signal measured without any absorber. $\mu(E)$ is the total attenuation coefficient of the attenuator in which are included both photoelectric and Compton effects for photons of energy E. $F(E)=\phi(E)\bullet C(E)$, where $\phi(E)$ represent the spectrum distribution of photons and $C(E)$ represent the energy response determined by the way to measure the signal $S(x)$. $E_{\max}$ is the maximum energy of the spectrum.

When we treat the problem from its numerical point of view by discretizing the integral, the Eq.(1) turns out a linear system of the form

$$T=A\bullet F \qquad (2)$$

where $T\in R^M$ represent the attenuation curve as a function of the attenuator and $F\in R^N$ is the discretized spectrum. Generally, the linear system described by Eq.(1) translates, after the disctretization, into an ill-conditioning linear system in Eq.(2). Here the Expectation-Maximization (EM) algorithm is used to obtain an approximation to the exact solution of the system Eq.(2)[2]. Expectation -Maximization algorithm is an iterative statistical algorithm with the form [3][4]:

$$F_n^{(k+1)}=F_n^{(k)}f_n,\quad f_n=\frac{\sum_m A_{nm}{}^t\dfrac{T_m}{\sum_{n'}A_{mn'}F_{n'}^{(k)}}}{\sum_m A_{nm}{}^t} \qquad (3)$$

Numerical Simulation

A Monte Carlo numerical simulation experiment is carried out to verify the method first. During the simulation process, Monte Carlo method is used to simulate the Thomson Scattering and calculate the attenuation curve through silicon with different thickness to justify the reliability and feasibility of this method. Figure 3 shows the results for the reconstruction of local spectra for different two points in the X-ray spot.

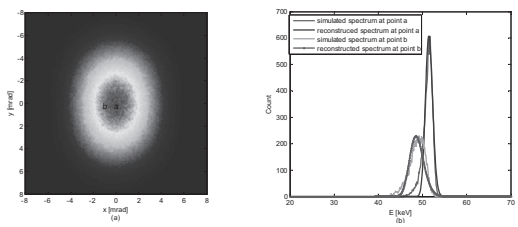

Figure 3: (a) X-ray profile simulated by CAIN and the two points selected to reconstruct local spectra. (b) Simulated and reconstructed spectra at two different points with 0.5 mrad collecting angles and 5% Gaussian random error.

It can be observed that the EM method performs well to reconstruct the local spectra of Thomson Scattering source. However, as the collecting angles increase, the X-ray spectra are not close to Gaussian distribution any more. To solve this problem, we propose an assumption that according to the spectral distribution features of Thomson Scattering, as the collecting angles increase, the right half of spectra remains almost unchanged. So we

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

can treat the right-half spectra of the small collecting angles given by EM algorithm as the right half for spectra of other angles within a certain range. Then we can reconstruct the spectra with the attenuation data more accurately as under this assumption, the mean energy will have direct and close relationship with the shape of spectra. Fig.4 shows the reconstruction result (top) and the simulation result (bottom) for Thomson Scattering spectra within the collecting angle range from 0.5mrad to 5mrad.

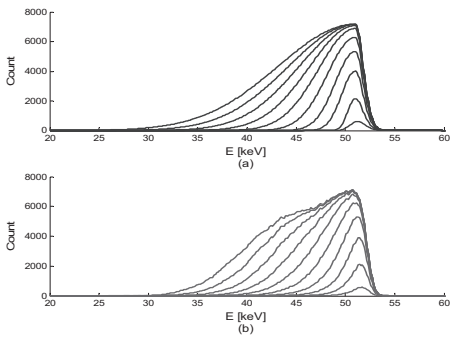

Figure 4: (a): Representative reconstruction results of spectra for collecting angles ranging from 0.5 mrad to 5 mrad with an equal interval of 0.5 mrad (b): The simulated spectra for the Thomson Scattering source with collecting angles of the same range with CAIN.

Experiment Results

A preliminary experiment is carried out on TTX to measure the X-ray spectrum. The scheme of the experiment is shown in figure 5. The silicon wafers with different thickness are used as attenuator, a CsI screen and CCD camera are used as the X-ray intensity monitor.

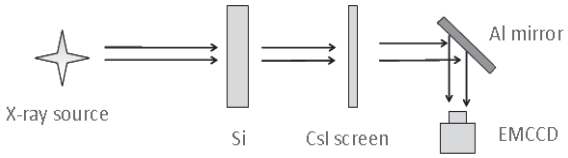

Figure 5: The scheme of the X-ray spectrum measurement.

The typical X-ray profile with attenuators is shown in figure 6. The sheltered part is used to obtain the attenuation curve and the unsheltered part is used to X-ray intensity normalization to cancel the jitter influence. The attenuation curves for point a, b, and c, the reconstructed X-ray spectrum from the attenuation curves are also shown in figure 6. The maximum X-ray energy at the center of profile is 53keV, which is agreed well with the theory expectation and simulations.

In Thomson scattering X-ray source, the X-ray energy is a function of scattered angle. In figure 7, the mean energy of the X-ray as a function of scattered angle is shown and compared with the theory and simulation expectations. The measured results are a little different to the theory curve but agreed well with the simulation results, since in theory curve the emittance effect of the electron beam is not included.

Reconstruction spectra results from measured attenuation for collecting angles ranging from 0.5mrad to 5mrad with an equal interval of 0.5mrad are shown in figure 8:The deposition efficiency of CsI screen is considered.

EMITTANCE CONTROL FOR DIFFERENT FACET BEAM SETUPS IN THE SLAC LINAC*

F.-J. Decker, W. Colocho, N. Lipkowitz, Y. Nosochkov, J. Sheppard, H. Smith, Y. Sun, M.-H. Wang, G.R. White, U. Wienands, M. Woodley, G. Yocky, SLAC, Menlo Park, CA 94025, USA

Abstract

The linac beam at SLAC requires different setups for different users at the FACET (Facility for Advanced aCcelerator Experimental Tests) area, like highly compressed, intense bunches, or lower charge, long bunches. These require typically a lengthy tuning effort since with an energy-time correlation (or "chirp") the bunch transverse wakefield kicks can be compensated with dispersive trajectory oscillations and vice versa. Lowering the charge or changing the bunch length will destroy this delicate balance. Besides the typical steering to minimize BPMs (Beam Position Monitors) with correctors, we applied different techniques to try to localize beam disturbances like dispersion with phase changes, RF-kicks and RF quadrupole fields turning a klystron off and on, or varying the phase, and finally wakefield kicks with different beam intensities. It is also important to quantify BPM to quadrupole offsets with "bowtie" plots and that the correctors give the expected kicks with orbit response matrix measurements.

INTRODUCTION

Good transverse beam emittances at different places along the SLAC Linac get typically achieved in the following way. The beam gets steered relatively flat (< 0.5 mm) using BPMs (Beam Position Monitors) and then with a lengthy tuning scheme, linac oscillations or bumps are introduced which minimize the emittance measured with wire scanners. Over the years this process typically achieved small emittance growth numbers of 50 to 100% over the initial values of 30 and 2.5 mm-mrad for x and y, so 50 by 5 mm-mrad was expected for the FACET beam in Sector 20.

Typically twice that amount and often more was only achieved. There are a few explanations (excuses) which could cause this. The typical beam rate was 10 Hz, so tuning was three times slower than at 30 Hz. The FACET chicane needed special attention, so linac tuning was cut short. And the final spot sizes after the chicane and final focus were about the same, like 30 μm, even if the emittance just in front of the chicane changed by a factor of three (300 → 100 mm-mrad in x), discouraging further linac tuning.

Additionally, frequent user requested beam changes in current and bunch length made it necessary to tune the beam emittances up again, which would make it even trickier for smaller emittances. It is assumed that the main root cause for this is that after just steering flat the initial emittance is as high as 1200 mm-mrad, and the subsequent tuning cancels this with equally large corrections. When these cancelations are not local, or are charge / bunch length dependant, small say 10% variations will create 10% of 1200 mm-mrad = 120 mm-mrad.

So the goal is to localize and reduce emittance increasing effects. For that we try to find and categorize all possible mechanisms, like dispersion, wakefield, RF-kicks, and develop procedures like special steering methods and component alignment.

Goal: Get Linac closer to good emittances with BPMs etc. so the tuning part is less.

1. BPMs
2. Correctors
3. Quads (old BBA: straight orbit)
4. BPM-to-Quad: bowtie plot or Quad change
5. Corrector strength (LOCO, R12 meas.)
6. Lattice (Quad) strength: Oscillation data
7. RF-kicks: a) sin-cos, b) dipole-quadrupole-lens
8. Measure dispersion
9. Measure with different charge (wakefield)
10. Measure with different bunch lengths
11. Others

The different methods (numbers in ( ) below) and their relevance are discussed in the following sections.

STEERING TECHNIQUES

Steering the beam to the center of a BPM (1) gets the beam down the linac relatively fast, but usually ends up with big beam emittances. Additionally we can look at the corrector (2) values along z and check for certain patterns, e.g. stronger values with + – + might indicate a BPM with a big unreal offset. With our "SVD Steering" we can adjust a gain parameter to prefer BPMs (gain high) or correctors (gain low), but this method just supports what is believed more correct.

The next step is also using the quadrupole (3) strengths in a way to get a straight trajectory. When a BPM reading is say Δx =1 mm and the corrector strength is cor = 0.03 kG-m, the two can be compared by dividing cor by the quadrupole strength Q = 20 kG: cor/Q = 1.5 mm. So the beam gets more bend up by the corrector than the $Q\Delta x$ bends it down (focussing magnet). Figure 1 shows an example where the orbit was steered flat (below 0.3 mm) but its corresponding cor/Q-values are up to 1.3 mm. This led to a global alignment of the Linac of up to 7 mm [1]. Equalizing the two locally will give a straight non-bend beam orbit and therefore no dispersion is generated. But an offset in a BPM might indicate also an offset in the RF nearby structure, causing wakefield kicks.

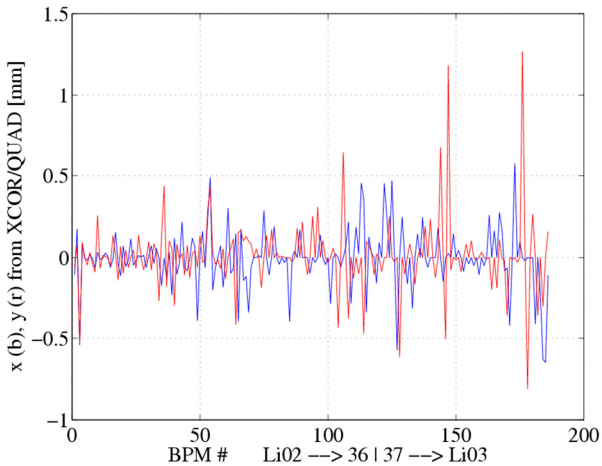

Figure 1: The absolute orbit is steered flat, but the corresponding corrector/quadrupole values for x (blue) and y (red) indicate big bending around 145.

BEAM BASED ALIGNMENT

Besides the global alignment of the Linac using optical targets inside the accelerator supporting light-pipe, there are several methods using the beam to find misalignments and then fix them. The last paragraph indicates already one such approach. Instead of steering so that $\Delta x = cor/Q$ we can align the quadrupole and accelerator locally by moving it in the $+x$ direction by Δx and putting the corrector to zero. This was done in a few places and needs to be done at all locations. But before doing this we need to be sure that the values of Δx, *cor*, Q are correct.

The BPM reading Δx can have an offset x_{off} with respect to the quadrupole and this can be measured with the beam by the bowtie-scan method (4). By varying one corrector in front of the quadrupole and measuring the effect of a downstream BPM for two different quadrupole settings versus the BPM inside the quadrupole you get a bowtie-like plot where the center of the bowtie gives the BPM offset x_{off}. This method is very lengthy requiring a few setting for each quadrupole setting and again for the other plane y. A faster but not as precise method is using just the difference orbit for the two different quadrupole settings and using the focussing model (R12s) to determine the kicks in x and y at the same time. This method should be about ten times faster and will allow us to get the BPM offsets for all BPMs in quadrupoles.

Checking the corrector strengths (5) is next and done typically by varying a corrector over a certain range that the beam is not lost and then the response matrices R12s from the corrector (point 1) to downstream BPMs (points 2) are compared to the expected from the model. When everything is aligned the exact values are not too critical since the correctors are close to zero, but to get there and for steering and for making closed three-corrector bumps (see below) it is helpful to have the right values.

The lattice or quadrupole strength (6) can be check with oscillation data, where two correctors in x, x' and two in y, y' generate oscillations which then can be fitted with expected behaviour calculated with the model. Figure 2

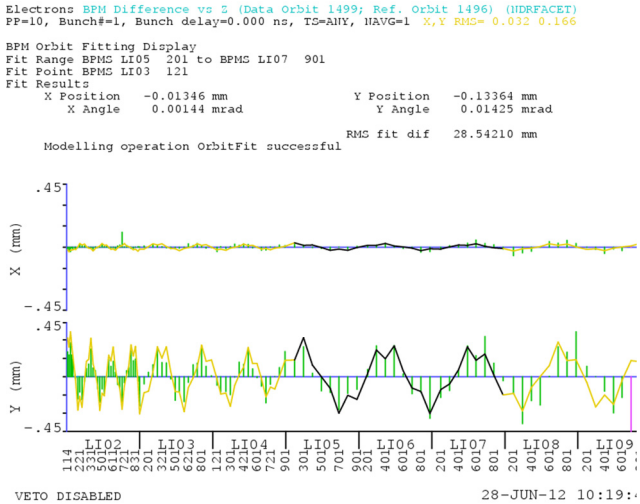

Figure 2: Oscillation data in y, at Li07 501 there seems to be an additional kick pointing to a weaker quadrupole.

shows an example where there seems to be a 15% weaker quadrupole at Li07 501. A wider grid scan can point out nonlinearities, while a few more corrector settings can trace out the design matched beam ellipse in phase space which then can be checked down the linac. With this method (at LCLS) sudden mismatches, coupling and 3% BPM scale errors were found.

RF KICKS

All the above mentioned steering and compensation techniques get messed up by RF kicks (7), and their behaviour is quite interesting. There can be sin and cos terms, an x and x' part, dipole-, quadrupole-, or lens-type kicks, even 2nd harmonic part was observed (Fig. 3).

To distinguish whether it is an angle or position effect two (nearly) closed bumps were made, one with the maximum at the beginning of the accelerator structure and one at the end (Fig. 4).

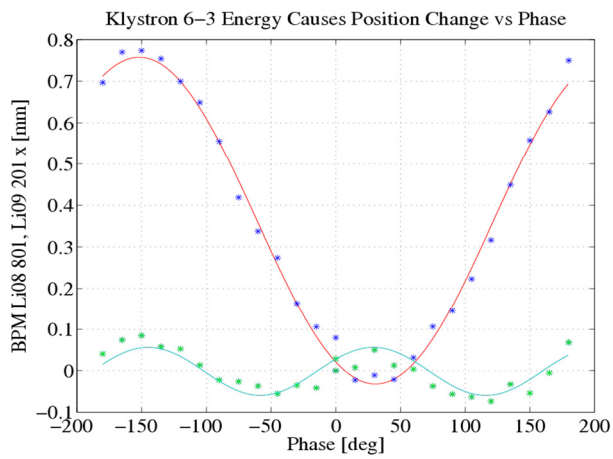

Figure 3: The phase of klystron 6-3 was varied and the resulting downstream orbit observed. At BPM Li09 201 it was up to 800 µm and in phase with acceleration, two BPMs earlier, near the zero-crossing, a 100 µm 2nd harmonic-like effect was seen.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

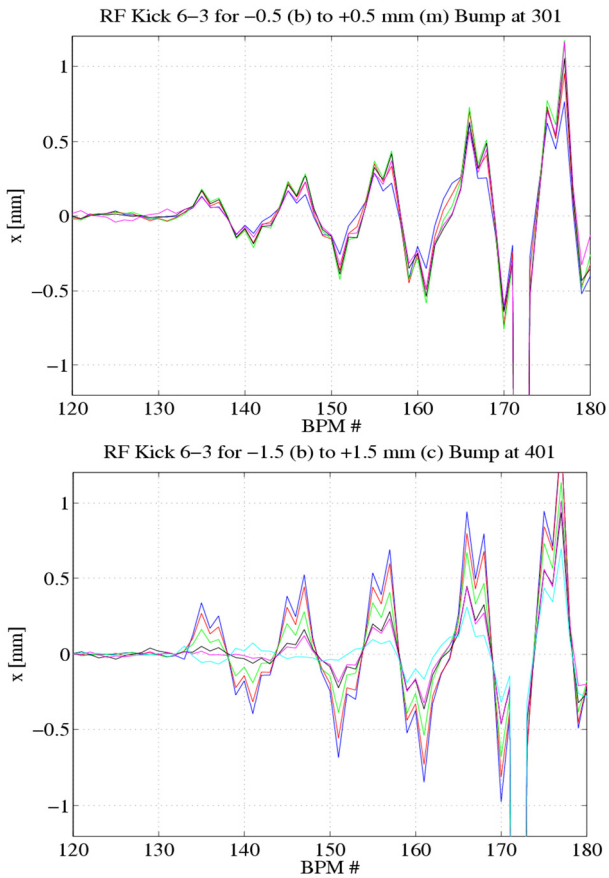

Figure 4: The RF kick of klystron 6-3 (between BPM # 132 and 133) is barely influenced by a bump with the maximum at its front at 301 (top), while at its end at 401 a +1 mm bump cancels the RF kick (bottom). Further downstream seems to be more and more dispersion.

MEASUREMENT FOR SETUP CHANGES

When the beam parameters like charge, bunch length, energy profile change the beam emittances are typically negatively influenced. By localizing and fixing the before mentioned effects as local as possible emittance growth should be minimized. Checking how much dispersion (8) the beam has at a certain point seems to be easy. The energy gets changed by ΔE and with the measured transverse position x: $x = \eta_x \cdot \Delta E/E$ the dispersion η_x is defined. The problem with the linac is that there are many ways to change the energy and on top of that there can be a change due to RF kicks when a klystron is turned off. We typically want to know how the head and the tail of a bunch having different energy due to an energy chirp might behave differently. To check that, we vary the injection phase into the linac by ±1° and then we look at the difference orbit. Since the average chirp phase before the chicane in Sector 10 is about –24° the energy change at the chicane should be about ΔE = 7.8 GeV · (cos(23°)–cos(25°)) = 111 MeV or 1.23% at 9 GeV. Any resulting orbit change in the linac is like dispersion and can be reduced with bumps or dispersion free steering methods.

The beam charge (9) and the bunch length (10) are parameters often asked by the FACET user to be changed. By dithering the damping ring capture phase the throughput and so the number of particles down the linac was varied from 2E10 to 1E10. The resulting orbit changes hint where wakefields might be an issue and where observed early in the linac (Li03). The amplitude of the RTL (Ring-To-Linac) bunch compressor can be adjusted similarly quickly to vary the bunch length, but this fast method wasn't tried yet.

To be more complete other methods and effects (11) should be mentioned too. A) There were the ballistic data measurements, were all quadrupoles, correctors and klystrons are turned off in a sector or two and the BPMs analysed before beam losses occurred. B) Hysteresis in the correctors makes the results questionable. C) Similar to the LCLS undulator where different energies are used to align the undulator, we can scale the quadrupoles and correctors while the actual energy profile and RF kicks stay fixed. With positrons which are bend magnetically in the opposite directions, while the RF kicks are typically the same (dipole kicks) the different effects can be better separated [3]. D) Electronic noise from klystrons causes a different reading for the BPMs in a nearby crate whether the klystron is on beam time or on standby.

Finally two more things should be mentioned. We changed the basic setup of the linac in two ways to make it less susceptible to dispersion. First a "staggered" chirp was introduced, which slowly increases the energy versus z correlation, and 2nd a lower 76 deg per cell lattice was used to be less susceptible to the necessary energy spread.

SUMMARY

The beam emittance control for FACET is basically done by tuning, starting at very high values (sometimes 250 times higher). This paper discusses more than twelve possible approaches to reduce the initial value locally as good as possible, so that any longitudinal or intensity changes are not coupled into the transverse dimensions.

ACKNOWLEDGMENT

The FACET team wants to thank the many support groups which make the four months short FACET runs possible, and especially the operations group for their interest and dedication to improve the beam conditions.

Abstract

This paper reports on a present status of a positron injector linac upgrade for SuperKEKB. A development status of a flux concentrator for positron focusing is shown. An influence of offset layout of the flux concentrator and the target on a positron yield is described. Positron capture by L-band and large aperture S-band accelerating structures are compared in a viewpoint of satellite bunch elimination. Beam optical design compatible to electrons and positrons of different beam energies is discussed.

INTRODUCTION

The KEKB-factory is now under an upgrade to SuperKEKB for a forty times higher luminosity [1]. The injector linac is required to supply beams of higher charge and smaller emittance as shown in Table 1.

Table 1: Linac Beam Specifications

	KEKB (e^-/e^+)	SuperKEKB (e^-/e^+)
Injection Energy (GeV)	8.0 / 3.5	7.0 / 4.0
Bunch Intensity (nC)	1.0 / 1.0	5.0 / 4.0
Number of Bunch /pulse	2 / 2	2 / 2
Emittance (μm)	300 / 2100	$20 / 92_{[H]}{:}7_{[V]}$

To generate low emittance electron beams of 5 nC bunch intensity for injection, a photo-cathode RF gun is introduced [2] to replace the existing thermionic gun and the RF bunching section. The electron beams are accelerated up to 7.0 GeV over the entire linac and injected into the HER. Electron beams of 10 nC for positron production will also be generated with the RF gun. In a case high intensity operation of the RF gun is not stable, the thermionic gun is also used and the beams from these two guns are switched. To generate low emittance positron beams, a damping ring (DR) of 136 m circumference is introduced at a side of the linac and connected at the beam switch-yard No.2 (SY2). Beams generated in a positron capture section (PCS) are accelerated up to 1.1 GeV and injected into the DR. Positrons are extracted after 40 ms from the DR, injected back to the linac and accelerated up to 4.0 GeV for injection to the LER. Energy gain of the positrons from existing six accelerator modules (typically 160 MeV per each module) from the PCS to the SY2 is not sufficient for this 1.1 GeV injection to the DR. The PCS is relocated 40 m upstream to have a sufficient energy margin for the DR. To increase positron beam intensity four times as much, capture efficiency is enhanced in two aspects. At first, an existing 2-T pulsed coil of short field length (45 mm) right behind a positron production target, is replaced with a flux concentrator (FC) type of 5-T pulsed solenoid of long field length (200 mm). An adiabatic matching characteristics of a solenoidal field distribution with a FC, gives wider energy acceptance for positrons. As a second aspect, existing S-band accelerating structures with conventional aperture (21 mm in diameter) used in a solenoidal field of the PCS are replaced with large aperture S-band (LAS) structures (30 mm) or L-band structures (35 mm) to enlarge transverse phase space acceptance. Total length of the PCS is extended from 8 m to 16 m to boost positron beam energy from the PCS from 80 to 120 MeV. This increase of the beam energy at a transition from solenoidal to quadrupole focusing region is effective in reducing beam loss around an optical matching section.

In December of 2013, we will start a preliminary positron beam commissioning of the injector linac within limited operation parameters. A beam commissioning with the DR will be started in February of 2015. Development, fabrication and installation of the components are ongoing to be in time for the schedule.

In the following sections, as topics of significance in the positron injector linac upgrade, flux concentrator development, target protection and offset positron production, large aperture accelerating structures development, satellite bunch elimination and electron/positron compatible optics design are described .

FLUX CONCENTRATOR DEVELOPMENT

Flux concentrator is a pulsed solenoid composed of a primary coil and a copper cylinder with a conical hole inside. Induced eddy current flows through a thin slit to a inner surface and generates a strong field of several Tesla. Achievable field strength is mainly determined by a hole diameter and a primary pulsed current. They are constrained from a required aperture size, a power supply capacity and break-

* E-mail: <takuya.kamitani@kek.jp>

down limit. We have been collaborating with BINP, SLAC, Frascati and IHEP on the FC development for KEKB linac upgrade. We have performed a high power operation test of a BINP-type FC at KEK and experienced a breakdown problem. The prototype is disassembled and under careful inspection at BINP. For a coming preliminary positron beam commissioning in December of 2013, we will use a more conventional FC, two type are considered as candidates. One is a spiral slit FC based on the SLAC design. Frascati and IHEP also have been using this type of FC. The other type is a simple straight slit FC. A peak longitudinal field strength at a same current is lower with the SLAC type, but a contribution of a transverse field component which is not axial-symmetric is also smaller. Considering an effect of target offset from a field center described later, evaluation of positron capture efficiency by a particle tracking using detailed 3D field distribution is ongoing. Since the FC is installed right behind the target and its radio-activation level will be very high and a replacement work will not be easy. Thus, an engineering design to avoid mechanical failure or water and vacuum leakage problems is critically important. Decision of installation model among the candidates will be made soon with a comparison in the capture efficiency performance and engineering design consideration.

POSITRON PRODUCTION TARGET

We have used 14 mm thick (4.0 radiation lengths) amorphous tungsten and later 10 mm thick crystal tungsten for the positron production target. In the beam commissioning for SuperKEKB, an amorphous tungsten will be used to avoid precise axis alignment mechanism. For a pulse-by-pulse switching of electron and positron injections, a small hole for electron beam passage is bored a few mm apart from a center of the target. To optimized a positron yield, the target was placed on a common central axis of the pulsed coil and the DC solenoids in the KEKB linac. Thus, electron beam entered into solenoid field at a few mm offset from the axis and traveled through an excursion orbit by a fringe field. It becomes a problem at SuperKEKB, since an electron beam for injection have a small emittance as 20 μm. Emittance growth in this excursion orbit is not acceptable and a hole for electron passage should be centered on the axis of the DC solenoids. An aperture diameter of the FC is only 7 mm in the present design and the tungsten target of 4 mm diameter and the hole of 2 mm diameter should be well contained in the aperture. As a consequence, center axis of the FC has 2 mm offset from the beam line and target center has 1.5 mm offset from the FC center. We expected the offsets degrade the positron yield 20 to 30 % by a preliminary simulation study. More detailed study on this offset effect is to be done by the tracking simulation.

LARGE APERTURE CAPTURE SECTION

To enlarge a transverse phase space acceptance of the PCS, accelerating structures with larger aperture will be used. As a first candidate, we started R and D for L-band structure which had an appropriate field strength and an aperture diameter as described in Table 2. A first prototype L-band structure has been fabricated and under a high-power RF processing in a test stand. Since a large outer dimension of an RF coupler of the structure gives strong impact on a DC solenoid design, an L-band structure of slimmer body is in consideration by installing a dummy load inside the structure in a collinear geometry. In a selection of the L-band frequency, we cannot use simple half frequency (1428 MHz) of the S-band because it is not compatible with 2 bunch operation with 96 ns interval which was defined from phase synchronization constraint of the linac and the storage rings. Instead, we adopted 1298 MHz which is 5/11 of the S-band frequency. This co-prime frequency relationship was found to be useful in elimination of satellite bunch particles as described later.

The other candidate is a large aperture S-band (LAS) structure as described in Table 2. It has a larger aperture diameter (30 mm) compared with conventional S-band structures (21 mm). The LAS has a very large group velocity and a field strength is relatively low, however operation with a pulse compression by the SLED gives comparable field strength. The LAS structures are used not only in the PCS, but in subsequent two accelerator modules of quadrupole focusing region to improve transverse acceptance as described in the next section.

Table 2: Specifications of Large Aperture Structures

	L-band	LAS
RF frequency (MHz)	1298.182	2856.000
number of cells	24 + 2	57 + 2
accel. length (mm)	2001	2064
disk aperture 2a (mm)	39.4 $\rightarrow$ 35.0	31.9 $\rightarrow$ 30.0
group veloc. v_g/c (%)	0.61 $\rightarrow$ 0.39	4.2 $\rightarrow$ 3.5
shunt imp. r_0 (MΩ/m)	45.7 $\rightarrow$ 47.6	46.1 $\rightarrow$ 48.4
filling time T_f (μs)	1.360	0.180
accel. field (MV/m)	12.2@15MW	6.93@10MW
same with SLED	–	16.42

Positrons emerged from the target have wide range of energy due to a cascade shower process and long bunch tail due to path differences in spiral orbits. Simulation studies show that a positron capture in decelerating phase and a formation of a main bunch by RF phase slip is useful to reduce particles at tails of an energy distribution [3]. However, particles which are not captured in the main bunch, experience further phase slips. They can be captured in subsequent phase positions and form satellite bunches. They can have comparable beam energy as those in the main bunch and will not be eliminated by an energy collimation. A fraction of satellite particles go out of RF buckets are lost at the DR injection. Due to a civil engineering constraint, a beam loss at DR is strictly limited to be below 0.2 % of a design beam intensity (4 nC x 2 bunch). Thus, elimination of satellite particles in the linac is a critical issue for a DR

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

operation.

In a case we use six 2-m long L-band structures in the PCS, satellite bunches are formed in L-band wave-length intervals. Due to the co-prime relationship to the S-band wave-length, satellite bunches are accelerated or decelerated in abnormal phases in the downstream S-band linac modules and are eliminated in the linac or in an energy collimation. It is shown that a beam loss at DR injection will be suppressed to be an allowable level 0.05% [3]. In a case of a hybrid of two L-band and four LAS structures, the loss becomes 0.2%, but still acceptable. To suppress an initial construction cost by avoiding L-band component construction, it is recommended to start a beam commissioning with a configuration of all LAS structures in the PCS. In this case, the loss becomes 0.4% and further improvement is necessary. A preliminary simulation study indicates that raising S-band deceleration field around 20 MV/m can reduce satellites. More detailed study will be done soon.

POSITRON/ELECTRON COMPATIBLE OPTICS

By using accelerating structures with larger aperture, a transverse acceptance of the PCS which corresponds to an RMS emittance is enlarged from 2000 μm to 4000 μm. As described in the previous section, the PCS is relocated to a 40 m upstream position and a beam energy from this section is raised from 80 MeV to 120 MeV. As a consequence of these changes, a quadrupole focusing system after the PCS till the SY2 needs an upgrade and an addition and rearrangement of quadrupole and steering magnets will be made. In the two accelerator modules after the PCS, LAS structures of 30 mm aperture diameter are used to enlarge the transverse acceptance and quadrupoles are installed in 70 cm interval outside of the structures. In the subsequent three modules, ordinary S-band structures of 20 mm aperture are used and quadrupoles are placed in the same interval. In the subsequent four modules, quadrupole triplets are placed between the S-band structure and the interval changes from 3m to 5m according to the beam energy.

In this region between the positron production target and the SY2 before the DR, both of low energy, huge emittance positrons and high energy, low emittance electrons pass through the same quadrupole focusing system. Almost all quadrupoles in this region are DC magnets. To avoid a beam loss of the positrons, focusing strengths are optimized for them. Thus, electrons are focused in a ready-made quadrupole fields which are weak for the energy of electrons. Slight optimization to moderate electron beam size is performed within a range in which the positron optics is not significantly modified. Fig. 1 shows beam size of the positrons and the electrons.

Even with this compromised optics for the electrons, the beam sizes are kept sufficiently small. For independent orbit control of the positrons and the electrons, 12 pulsed steering magnet pairs are installed in addition to existing DC steerings. Orbit correction performance and emittance growth with this limited number of steerings should be checked by simulations and underway.

In the region after the DR till the end of the linac, both of the electrons and the positrons have low emittance and not precisely same but high energy. Quadrupole triplets and steerings are placed in 20 m interval. Total number of magnets are not so large for this region and there are no quadrupoles outside the structure, hence we decide all the quadrupoles and steerings here to be pulsed magnets. It will be useful for a precise independent matching to the storage rings and for an independent orbit control to suppress emittance growths for positrons and electrons.

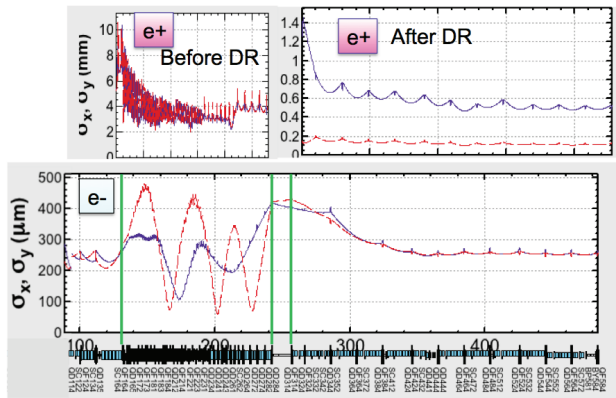

Figure 1: Positron/electron beam optics design.

SUMMARY

The KEKB positron injector linac is under an upgrade for SuperKEKB. Two types of flux concentrator in different slit geometry are in comparison by simulations and a prototype fabrication. An influence of an offset layout of the FC and the target is discussed. As accelerating structures to be used in the capture section, L-band and large aperture S-band structures are compared in a viewpoint of satellite bunch elimination. Performance of a compatible optics for electrons and positrons of different beam energies with DC quadrupoles is studied. A preliminary positron beam commissioning of the injector linac will be started in December of 2013.

RECENT IMPROVEMENTS TO THE CONTROL OF THE CTF3 HIGH-CURRENT DRIVE BEAM

B. Constance, R. Corsini, D. Gamba, P. K. Skowroński, CERN, Geneva, Switzerland

Abstract

In order to demonstrate the feasibility of the CLIC multi-TeV linear collider option, the drive beam complex at the CLIC Test Facility (CTF3) at CERN is providing high-current electron pulses for a number of related experiments. By means of a system of electron pulse compression and bunch frequency multiplication, a fully loaded, 120 MeV linac is used to generate 140 ns electron pulses of around 28 Amperes. Subsequent deceleration of this high-current drive beam demonstrates principles behind the CLIC acceleration scheme, and produces 12 GHz RF power for experimental purposes. As the facility has progressed toward routine operation, a number of studies aimed at improving the drive beam performance have been carried out. Additional feedbacks, automated steering programs, and improved control of optics and dispersion have contributed to a more stable, reproducible drive beam with consequent benefits for the experiments.

INTRODUCTION

The Compact Linear Collider [1] (CLIC) is a leading contender for the next generation of high energy lepton colliders. As an essential precursor to proceeding with such a facility, the CLIC Test Facility (CTF3) at CERN has been built to demonstrate many of the technologies required for stable drive beam generation and RF power production. The complex consists of a 120 MeV e^- linac, a chicane for bunch length control, a 42 m Delay Loop (DL), an 84 m Combiner Ring (CR) and finally the CLIC Experimental Area (CLEX). A thermionic gun produces 4 Amp pulses of 1.4 us, typically at a repetition rate of 0.83 or 1.67 Hz. A sub-harmonic buncher operating at 1.5 GHz, followed by a 3 GHz buncher, generates a beam bunched at half the acceleration frequency. Since energy efficiency is key to the CLIC design, the 3 GHz CTF3 linac operates in a fully loaded configuration. In order to maximise the RF power available, 5.5 us pulses from the klystrons are compressed to around 1.4 us using resonant cavities, increasing peak power by a factor of two to over 30 MW.

As laid out in the CLIC design, at CTF3 a system of bunch frequency multiplication and pulse compression is used to generate a high-current drive beam. Injection into the DL and CR is achieved using transverse deflecting RF cavities. By coding the beam phase with a series of 180° phase shifts, 140 ns sections of the pulse may be alternately injected or allowed to bypass the DL. On exiting the DL, the delayed sections interleave with those sections bypassing. This results in a train of four 140 ns sub-pulses, separated by 140 ns, with a current of some 8 Amps and a 3 GHz bunch frequency. These four sub-pulses are then stacked in the CR before extraction to CLEX, where the final 12 GHz pulse is 140 ns long. The combined current is typically around 28 Amps before transport, since some fraction of the charge is lost to satellite bunches in the unused RF buckets.

In CLEX, the combined pulse may be directed to one of two experimental beamlines. The Test Beam Line (TBL) contains at present 12 Power Extraction and Transfer Structures (PETS), with 16 expected by end of the 2012, and is used primarily for studies into the phase and amplitude stability of the produced 12 GHz RF power and the transport of the decelerated drive beam [2]. The second beamline serves the Two-Beam Test Stand (TBTS), an experiment which is also provided a probe e^- beam by the CALIFES accelerator. The probe beam fills the role of the CLIC main beam, allowing for two-beam acceleration studies [3].

OPTICAL MODEL VERIFICATION

Control of the transverse linear optics at CTF3 is achieved using a MAD-X model of the machine. Optical transition radiation screens at key points in the lattice allow measurements of the beam emittance and Twiss parameters using standard quadrupole scan techniques. Based on these measurements, quadrupole currents are rematched using the model predictions to ensure the correct beam parameters at critical locations. Of course, the success of this method depends on the validity of the model.

Discrepancies between the predicted and measured optical functions at some screens inspired a campaign to verify the MAD-X model using beam-based optics measurements. The horizontal and vertical planes were assumed to be uncoupled and treated independently. Using a pair of calibrated dipole corrector magnets separated by a drift length, a series of beam orbits may be injected into the lattice with arbitrary positions and angles. The series of orbits can be chosen in such a way that they map out, or paint, the matched phase space ellipse expected at the location of the second corrector. In effect, each orbit behaves as a macroparticle on the matched ellipse. The orbits evolve as they propagate through the lattice in a way governed by the linear transport matrix, and thus so too does the ellipse they describe. By spacing the orbits at regular intervals covering the full phase space, and observing how the ellipse has changed at some downstream position, information is obtained about all four elements of the two-dimensional transfer matrix.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

To reconstruct the ellipse at a downstream point requires a measurement of both the position and angle at this point. At CTF3, the Beam Position Monitors (BPMs) available give only position information, and therefore measurements from two adjacent BPMs are combined to calculate the orbit angles. For this step it is necessary to assume the MAD-X model between the two BPMs is correct.

For practical measurements, it is advantageous to take pairs of orbits on the ellipse separated by a 180° phase advance and use them to form a difference orbit. In this way slow drifts of the beam will be canceled. In addition, mean difference orbits over a number of pulses may be taken. To further reduce sensitivity to jitter and drifts, several similar ellipses of different areas or psuedo-emittances may be painted. Then, a fit can be made between the difference orbits at a given phase over all ellipses and a single, normalised ellipse generated.

To extract the transfer matrix from an ellipse reconstructed at some point s in the lattice, each set of N orbits is formed into a matrix $\mathbf{x}(s)$:

$$\mathbf{x}(s) = \begin{pmatrix} x_1(s), & x_2(s), & \dots & x_N(s) \\ x_1'(s), & x_2'(s), & \dots & x_N'(s) \end{pmatrix} \quad (1)$$

Then, letting s_B denote the location of the reconstruction BPM and s_K the location of the kicker:

$$\mathbf{x}(s_B) - \mathbf{M}\mathbf{x}(s_K) = 0 \quad (2)$$

Which may be solved numerically for the transfer matrix $\mathbf{M}$. Here, the equation was solved using a non-linear fitting routine implemented in MATLAB [4] with the symplectic constraint imposed in addition.

As reconstruction of the ellipse requires an assumption of the transfer matrix between BPMs, it is necessary to require consistency over multiple measurements to be certain of a measured transfer matrix's veracity. Take the situation in figure 1. In the first step, matrix $\mathbf{M_1}$ is measured assuming $\mathbf{N_1}$ to be correct. In the second step, $\mathbf{M_2}$ is measured assuming $\mathbf{N_2}$. If both $\mathbf{M_1}$ and $\mathbf{M_2}$ are consistent with MAD-X, then since $\mathbf{M_2} = \mathbf{N_1}\mathbf{M_1}$ the original assumption of $\mathbf{N_1}$ is upheld. It is possible to proceed pairwise through all BPMs in the lattice in this manner.

After making measurements of various sections of CTF3, the MAD-X model was found to accurately represent the lattice in most cases. One notable exception was

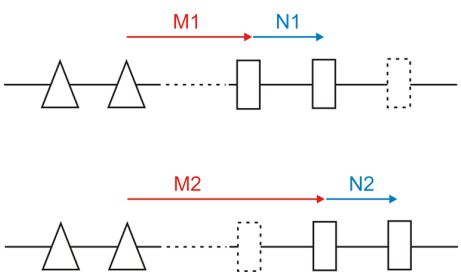

Figure 1: Procedure for measurement of the transfer matrix $\mathbf{M_1}$ between the second corrector magnet and first BPM.

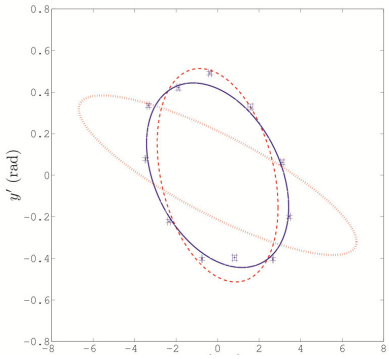

Figure 2: Reconstructed vertical ellipse at the DL BPM named BPI0358. Data points show the difference orbits. The solid blue ellipse is generated by the symplectic fit to the data, and is compared to the MAD-X prediction before (dotted red) and after (dashed red) optimisation of the main dipole FINT property.

the DL, where good agreement was obtained in the horizontal but a discrepancy was clear in the vertical. This suggested an error in the modeling of the main dipole fringe fields. By using an iterative procedure again developed in MATLAB, it was possible to fit the dipole field integral (FINT property in MAD-X) to provide the best possible match with the measurements. At each step in the iteration, the new model matrices must of course be used to reconstruct the ellipses.

In figure 2 an example of a reconstructed ellipse is shown, along with the MAD-X prediction before and after optimising the field integral. Figure 3 shows the four measured matrix elements throughout the DL lattice, again with the MAD-X predictions. In addition, a direct measurement of R_{11} and R_{12} was made by injecting a cosine- and sine-like orbit respectively, and is included for comparison. The missing measurements in the centre of the DL are due to faulty BPMs, and the matrices are given with respect to the DL injection point.

ONLINE DISPERSION MEASUREMENT

By taking advantage of CTF3's RF pulse compression system, a simple method to monitor dispersion during tuning is in use. A programed phase ramp ensures a flat top to the compressed RF pulses. By appropriate modification of the phase ramp, a step in the RF may be introduced such that the second half of the pulse has around 2 MW (∼10%) lower power than the first half. During tuning, this is done with the RF from the klystron that drives the final two cavities. Online orbit display software is then used to display the mean orbits of the first and second half of the beam pulse, along with a difference between the two. This difference is proportional to the dispersion function.

In figure 4, the orbits of the beginning and end of the pulse are shown along the linac, bypassing the DL and in the TL1 transfer line leading toward the CR, as is the difference between them. In the second plot a quadrupole in the

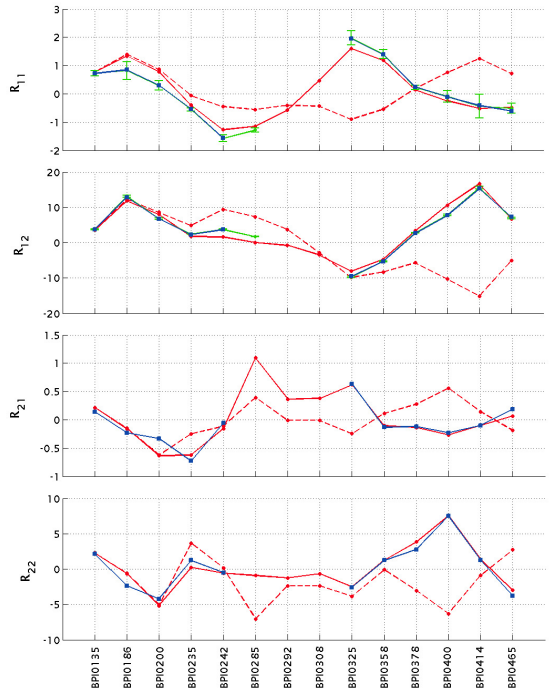

Figure 3: Vertical transport matrices for the DL. Matrices from MAD-X before (dashed red circles) and after (solid red circles) optimisation of the main dipole FINT are compared with the measured matrices extracted from reconstructed ellipses (solid blue squares) and direct measurements of R_{11} and R_{12} (green error bars).

dispersive region of the chicane, between the BPMs 0242 and 0258, has been used to minimise the downstream dispersion.

AUTOMATIC ORBIT CLOSURE

Closure of the CR orbit and of the orbit exiting the DL are very important to the generation of a well-combined beam, since different sub-pulses of the beam take different paths through the machine and are stored in the CR for different numbers of turns. To aid in operation, automatic

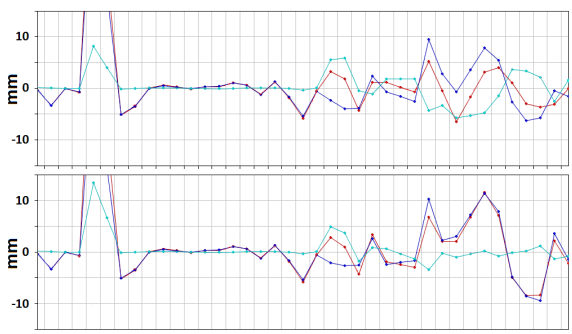

Figure 4: Horizontal orbit in the linac and TL1 before (top) and after (bottom) dispersion correction. The blue and red orbits have high and low energy respectively, and cyan shows the difference between the two.

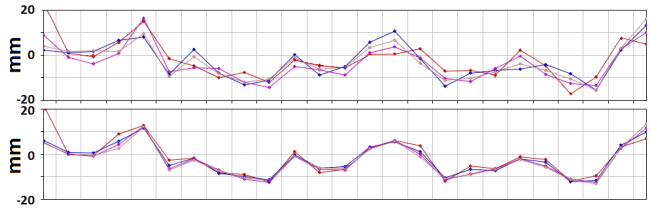

Figure 5: Horizontal orbit in the CR before (top) and after (bottom) automatic steering to inject onto the closed orbit. Each trace shows one of the four turns.

software has been developed to steer the beam in the DL out onto the same trajectory as the bypassing sub-pulses. Similarly, software is used to steer the beam onto the closed orbit of the CR. Based on measured response matrices, the system is automatic and can operate as a slow feedback to counter beam drift.

In figure 5, the horizontal orbits of four turns in the CR are shown. The 4 Amp pulse has been shortened to prevent combination. The second plot shows the effects of automatically steering the beam onto the closed orbit, which had previously been found by storing the beam for around ten turns and allowing the orbit oscillations to damp. The apparent residual difference between the turns in some BPMs is an artifact due to a droop of the BPM signal baselines. Well behaved BPMs such as 0650 and 0695 show the true orbit difference.

CONCLUSION

Beam-based measurements of the linear optics have been performed, and an error in the MAD-X model of the DL corrected. Ensuring the delayed sub-pulses and sub-pulses which bypass the DL are optically matched leads to easier transport of the combined pulse. The use of online dispersion monitoring and automatic steering has allowed for a faster and more precise setup of the beam, improving reproducibility. Coupled with recent improvements in dynamic control of CTF3, such as feedbacks which have improved the stability of the compressed RF pulses [5, 6], these developments have led to a more stable environment for research.

Abstract

A compact 1 MeV linac has been produced at the Cockcroft Institute using X-band RF technology. The linac is powered by a high power X-band magnetron and has a 17 keV 200 mA thermionic gun with a focus electrode for pulsing. A bi-periodic structure with on-axis coupling is used to minimise the radial size of the linac and to reduce the surface electric fields.

INTRODUCTION

Small, low-energy linacs are required by industry for the production of X-rays to be utilised in security applications and for non-destructive testing. Mobile cargo scanning systems used in the security industry typically use S-band (3 GHz) RF linacs to accelerate electrons produced from a pulsed electron gun to the required energy (typically 1-5 MeV depending on the type and thickness of the material to be scanned) [1]. Typically all the power supplies, control electronics and water cooling are placed on the back of a truck along with a robotic arm which will have the linac cavity, electron gun and target attached, along with a substantial amount of lead shielding. For mobile security applications the weight of the linac is critical to the mobility of the linac. Using higher frequency linacs reduces the cavity radius and hence the weight of the lead shielding required. For this reason an ultra-compact 9.3 GHz, 1 MeV linac has been designed at the Cockcroft Institute.

LINAC DESIGN

The linac is to be driven from a 1 MW e2v magnetron. As magnetrons are not very frequency stable the structure must be tolerant to changes in frequency. This is made more difficult by the requirement to have a small iris to have the maximum possible R/Q. In order to increase stability the structure was chosen to work in a $\pi/2$ mode. As every 2nd cell is empty there are two options to keep the R/Q high, to use a side coupled structure or an on-axis coupled bi-periodic structure. As we also want to keep the structure diameter small it was decided to use the latter. The structure is electrically coupled through the iris, this doesn't have as much coupling as magnetic coupling through slots in the wall, but is simpler to manufacture and operate. A 5 mm iris diameter was chosen to give sufficient coupling between the cells.

Although the electron gun is pulsed it has a pulse width that is several thousand RF periods hence it is necessary to bunch the electron beam within the linac cavity before acceleration. The electron beam is injected into the cavity from the gun at a relatively low energy (17 keV) and the electron velocity will not become close to the speed of light until after several cells of the cavity. This requires the length of each cell to be carefully optimised using beam dynamics codes to track each electron through the cavity such that the synchronous phase varies along the structure. As the electron velocity is dependent on the accelerating gradient, the electric field amplitude must be chosen before optimising the cavity. A peak accelerating gradient of 30 MV/m was chosen as a compromise between structure length and peak surface electric field, and this resulted in a structure with 8 accelerating cells.

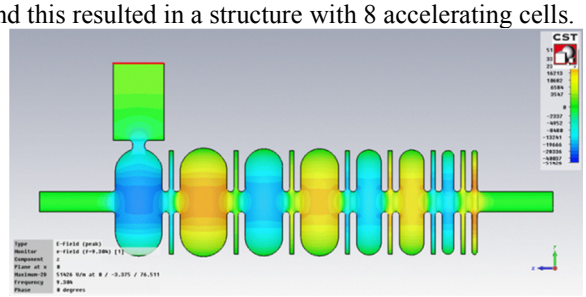

Figure 1: Compact Linac Cavity modelled in CST [4].

Particle tracking including space charge has been performed in ASTRA[2] as well as full PIC simulations in VORPAL [3], shown in Figure 2 and 3. It is observed that space charge forces are quite large in the front end of the linac where the cavity field is very low, resulting in particles spreading and hitting the cavity walls. This however is not expected to cause much heating or radiation as the impact energy is low. As the particles travel further downstream, they get bunched and transversely focused and at the exit of the linac reach 1 MeV and 50 to70 mA on average which is sufficient to produce the desired range of X-ray dose for many applications.

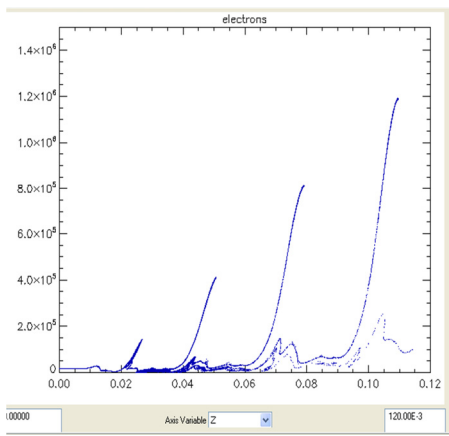

Figure 2: Electron energy, in eV, as a function of longitudinal position in the linac, in metres.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

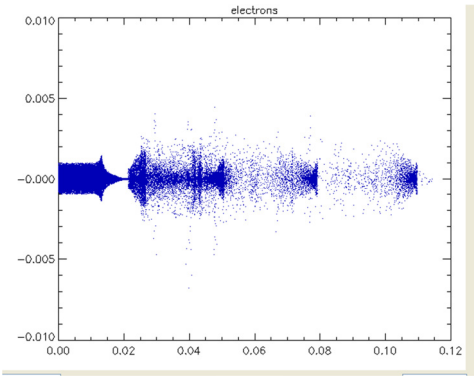

Figure 3: Electron horizontal offset plotted against longitudinal position in metres.

After optimising the basic cell shape and the length of each cell, it is necessary to model the full cavity in an RF simulation code, design an RF waveguide input coupler and to adjust the cell dimensions to account for the perturbation due to the ohmic losses. This was performed in CST Microwave Studio [4].

CAVITY MANUFACTURE

The linac cavity has been manufactured by Shakespeare Engineering, a UK precision Engineering company. The cavities were delivered to Daresbury Laboratories for final tuning and RF measurement. The cavity frequencies were measured using a vector network analyser and a resonant perturbation technique is employed to measure the field profile of the cavity. Both processes are performed in a clean laminar flow environment.

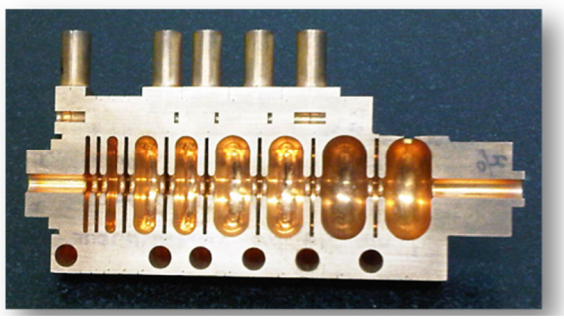

Figure 4: Cross-section of the manufactured cavity.

It was found that the manufacturing tolerances on the cavity manufacture had not been met resulting in the field only being present in some of the cells. This was confirmed by cutting a cavity in half with wire EDM, as shown in Figure 4. A new cavity is currently being manufactured to resolve some of the issues in the first cavity.

The cavity was then connected to the electron gun and pumped down. The installed cavity is shown in Figure 5.

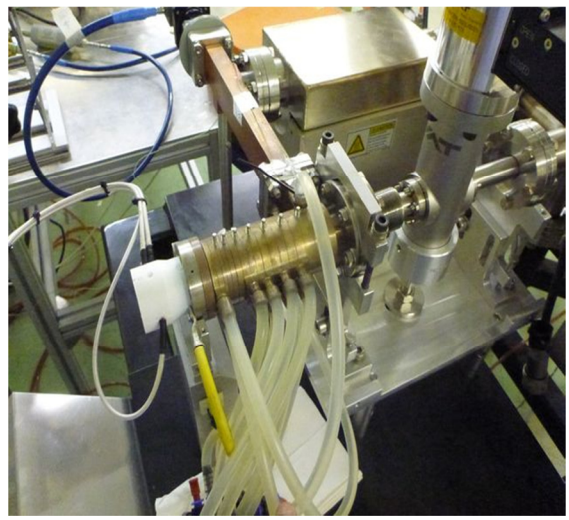

Figure 5: Compact linac cavity and gun installed.

DIAGNOSTICS LINE

In order to accurately measure the energy, current and spot size of the accelerated electron bunch a diagnostics line was constructed at the end of the linac. Integrating current transformers were placed on the cathode supply of the electron gun and in between the linac and the tungsten target for the measurement of beam current. A movable stepper drive section allowed the tungsten target to be removed from the beamline and replaced with either a straight section or a slit.

To measure the beam energy an ex-SRS dipole magnet was placed to deflect the beam down an angled beamline terminated in a Faraday Cup. The electrons energy can be calculated from the magnetic field required to deflect the beam to the Faraday cup. The magnet had previously been calibrated by the magnet group in ASTeC Department, STFC and hence the magnetic field could reliably be worked out from the magnet supply current.

In addition a radiation monitor was used to measure the X-ray production when the target is placed in the beamline.

The full diagnostics line is shown in Figure. 6.

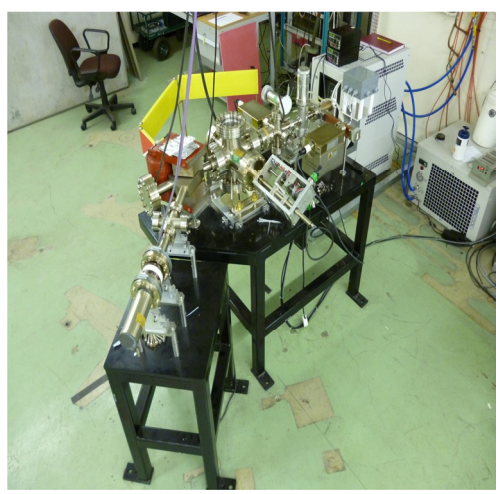

Figure 6: Compact linac Diagnostics Line.

LINAC TESTING

The linac was fully assembled in July 2011, and commissioning started with testing of the electron gun. The electron gun was found to produce 160 mA as measured by an ICT on the cathode input.

A 1.3 MW, e2v magnetron and modulator is used as the RF power source. The cavity was then tested at high power, and was found to operate well up to an input power of 800 kW, well above the design power of 450 kW. However as the field profile is not as expected it is difficult to work out what gradient this is.

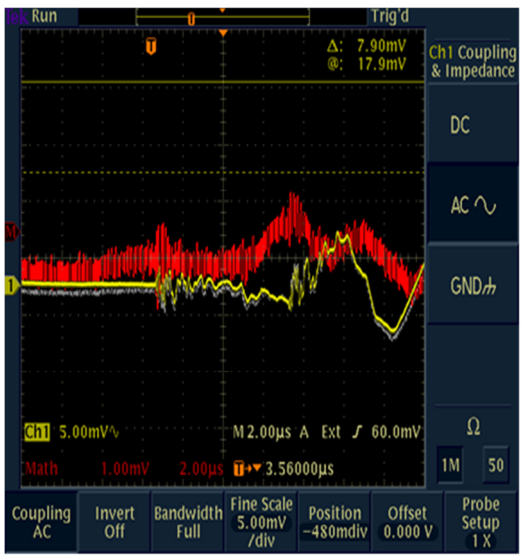

Figure 7: Faraday cup signal after the spectrometer magnet at 610 keV.

The electrons were then injected into the cavity. As there is no field in the first few cells the beam is not effectively bunched, hence a higher power is required to reach high energy. With an input power of 800 kW the maximum electron energy was measured on the spectrometer to be 610 keV. However it should be noted that due to the lack of bunching some electrons may reach a higher energy but with too low a current to be measured on the Faraday Cup. The signal from the Faraday cup is shown in Figure 7.

CONCLUSION

A compact linac has been designed and tested. Due to the cavity manufacture not meeting the design tolerances the field profile was far from ideal and field was only measured in the last 5 cells. This resulted in a lack of bunching and a lower beam energy at the output of 610 keV. A new cavity that better matches the design specification is currently being manufactured by Shakespeare Engineering and commissioning is expected to restart in the near future.

ACKNOWLEDGEMENTS

HIGH GRADIENT OPERATION OF 8-GeV C-BAND ACCELERATOR IN SACLA

T. Inagaki#, T. Sakurai, C. Kondo, Y. Otake, RIKEN SPring-8 Center, Hyogo, 679-5148, Japan.

Abstract

In X-ray free electron laser facility, SACLA, C-band high gradient accelerator was employed in order to shorten the 8-GeV accelerator length. In total, 64 klystrons, 64 RF pulse compressors, and 128 accelerating structures are used in SACLA. Since the C-band accelerator generates high acceleration gradient (nominal 35 MV/m), associated with a high RF breakdown rate, reliability of the high power RF components and the reduction of the trip rate less than several trips per an hour are the key issues for the stable operation. At beginning of beam commissioning in 2011, the trip rate of the C-band accelerator was still high. Major causes of the trips were an RF breakdown in an accelerator cavity and an abnormal discharge in a thyratron tube. After the RF conditioning time of 700 hours, the RF breakdown rate was reduced to be 1/10 comparing with the beginning stage of the RF conditioning. Concerning the thyratron discharge, we confirmed most of the discharges do not influenced to the next pulse generated by a klystron modulator and it can be excluded from the trip items of an interlock system. We currently operate the accelerator with the beam energy as much as 8.5 GeV, and the acceleration gradient of 38 MV/m in average, with an acceptable trip rate of of once per 20-30 minutes, which provides stable laser for XFEL user experiments. Availability of the C-band high gradient accelerator for compact accelerator is confirmed.

INTRODUCTION

SACLA (SPring-8 Angstrom Compact Free Electron Laser) [1] is a unique X-ray free electron laser (XFEL) facility, aiming to generate an X-ray laser with a compact electron accelerator and an in-vacuum undulator. The compactness is important to be able to construct within an available space in the SPring-8 campus, and for lower construction costs. In order to shorten the 8 GeV accelerator length, a C-band (5712 MHz) accelerator is employed. A higher frequency is chosen to produces a higher acceleration gradient. The nominal acceleration gradient is about 35 MV/m, which is twice higher than that of conventional S-band accelerators.

Figure 1 shows the configuration of the SACLA accelerator. For the energy from 400 MeV to 1.4 GeV, 12 C-band acceleration units accelerate an electron beam at -48 degree off crest phase, which provides an energy chirp for the following bunch compression chicane BC3. After BC3, the 52 C-band acceleration units accelerate the beam up to the target energy around 5 GeV to 8 GeV, dependent on a laser wavelength.

Since SACLA is the single-pass FEL facility, if only one unit out of 64 makes a trip (interlocked failure), it surely changes the beam energy and makes a serious influence to the laser properties. For example, when each unit makes one trip per 3 days on average, the beam trip is almost hourly occurred in total. Therefore reduction of the trip rate is the crucial point for stable laser provision.

The beam commissioning was started in March 2011 and the first lasing at a 0.12 nm wavelength was achieved in June [1]. At that time the trip rate was high due to the insufficient conditioning time for RF components [2]. Major causes of these trips were RF breakdown (arcing) in cavities and abnormal discharge (pre-trigger) of thyratrons. Then we lowered the beam energy to 7 GeV, and a pulse repetition rate up to 10 pps, because the beam energy and the repetition rate were not so important for immediate beam commissioning. Instead, a high beam energy of over 8 GeV and low trip rate were required for user runs. Hence we spent much effort to reduce the trip rate. Careful RF conditioning effectively reduced the number of the RF breakdowns. Since March 2012, the SACLA accelerator is stably operated for the user experiments with the energy up to 8.5 GeV and the acceleration gradient of 38 MV/m in 10 pps.

C-BAND ACCELERATOR SYSTEM

Figure 2 shows the configuration of the C-band accelerator system. Two 1.8 m long accelerating structures are connected to a 50 MW pulse klystron with

an RF pulse compressor (SLED) system. For the nominal operation the output power of the klystron is about 35-40 MW with 2.5 μs pulse width. The RF power is once stored to two high Q cavities of the SLED. When an RF phase is inversed by a phase switch keying (PSK) using an in-phase and quadrature (IQ) modulator [3] at 2 μs point of the pulse, the stored RF power is extracted from the SLED cavities .The RF power is about 200 MW in peak, and 140 MW on average for the 300 ns filling time of the accelerating structure [2]. The RF power is fed into two accelerating structures (R_{sh}~54MΩ/m and τ~0.53) to obtain a nominal acceleration gradient of 35 MV/m. Even though we designed the cavity wall thickness of 4 mm and round off the corner of iris with a radius of 2 mm, the maximum surface electrical field is about 100 MV/m. In order to sustain such a high RF field, the structure is made of pure oxygen-free-copper with HIP treatment, carefully machined and brazed with clean environment [4].

The klystron is driven by a compact 110-MW high-voltage pulse modulator, which equips a conventional line-type pulse forming network (PFN) circuit and a thyratron tube [5]. Capacitors constituting the PFN are charged by an inverter-type highly-precion HV charger. The charged voltage is precisely regulated within about 10 ppm (rms), which stabilizes the RF output phase and amplitude of the klystron within 100 ppm and 0.2 degree, respectively.

REDUCTION OF TRIP RATE

RF Conditioning

RF conditioning is the process to obtain a higher RF field in the cavity, which clean the cavity surface and reduce the number of the RF breakdown. By the summer of 2011, we performed the RF conditioning of more than 1,000 hours and realized to operate at an acceleration gradient of 35 MV/m [2]. In order to raise the acceleration gradient up to 38 MV/m, we performed the additional RF conditioning during the night time. Figure 3 shows the progress of trip rate reduction. The RF breakdown rate P(t) is exponentially decreased with a elapsed time. The time constant of decrease of the RF breakdown rate is 240 hours. After an RF conditioning time of 2 months (700 hours), the RF breakdown rate was decreased to be 1/10 and it showed proved the possibility to obtain a high-energy electron beam up to 8.5 GeV.

In order to investigate the availability of further high acceleration gradient, we gradually raised the RF power and measured the trip rate. Figure 4 shows the trip rate depending on the acceleration gradient. We found the RF breakdown rate is proportional to the 30th power of the acceleration gradient (red dashed line in Figure 4). After a measurement time of 116 hours at a maximum acceleration gradient of 39.3 MV/m, the RF breakdown rate decreased to be 2/3 of the initial rate at the acceleration gradient of 37.8 MV/m. It proved the potential to obtain a higher acceleration gradient by further RF conditioning.

Thyratron Abnormal Discharge

Our thyratron is e2v CX-1836, which equips three control grids and is filled with deuterium gas. Figure 5 shows the waveform of a charging cycle. In normal operation, the thyratron is triggered after charging period of 15 ms. But it occasionally discharged during the charging period, without a trigger pulse. Then the interlock system detects insufficiency of a charging voltage and halts the next charging. This discharge phenomenon is known as the "pre-trigger" of the thyratron, but the rate of it is much higher than that of our

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

expectation. The rate seems independently of the charging voltage (see Figure 4), and was not reduced during the conditioning (see Figure 3). Therefore, it becomes a dominant reason of the interruption of the accelerator operation, especially at low energy (< 8 GeV). In normal operation, the thyratorn conducts huge current (~5 kA) by generating plasma of the deuterium gas. After PFN capacitors are fully discharged, the plasma density drops within the nominal recovery time (~20 μs) and the connection is closed [6]. We suppose the same recovery occur after the abnormal discharge. In the left figure of Figure 5, the charging voltage was raised again after the abnormal discharge occurred. It means the withstanding voltage is surely recovered and we need not to halt the next HV pulse.

We modified the interlock system not to halt the operation by the single discharge event. When the second discharge occurred within one minutes, the interlock system halts the next charging for the machine protection. In June 2012, we tentatively modified 25 units. The trip rate of the modified unit is drastically reduced to be roughly 1/3 of the previous halt rate. The remaining 39 units were modified in this summer shut down period.

PRESENT OPERATIONAL STATUS

Thanks to these improvements, we have operated SACLA with beam energy of up to 8.5 GeV. So far the C-band accelerator has operated about 10,000 hours, without any serious troubles of high power RF components of 64 units.

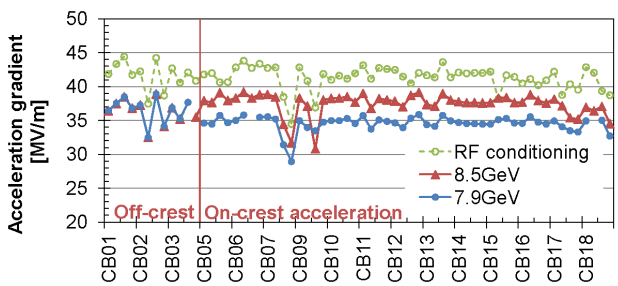

Figure 6: Typical acceleration gradients at each C-band unit in the cases of 8.5 GeV (red) and 7.9 GeV (blue). Maximum acceleration gradient values of individual RF units in the RF conditioning are also displayed (green).

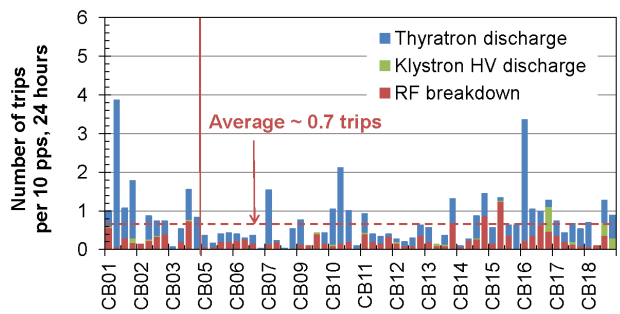

Figure 7: Trip rate of each C-band unit in July 2012. The acceleration gradient was set about 35 MV/m (7.9 GeV case of Figure 6).

Figure 6 shows the acceleration gradient of each C-band acceleration unit in two sets of typical beam energy. The averaged electrical gradient is about 38 MV/m and 35 MV/m for 8.5 GeV and 7.9 GeV, respectively. We have several standby units as a backup for troubles.

Figure 7 shows the trip rate of each unit in July. In average, the number of trips per one unit in 24 hours is 0.7 events and 1.1 events for 7.9 GeV and 8.5 GeV cases, respectively. The trip rate of the SACLA accelerator is the sum of the trip rate of the 64 units, which is once per 30 minutes for the 7.9 GeV case and once per 20 minutes for the 8.5 GeV case in 10 pps. These trip rates are still not sufficiently low to our requirement but an acceptable level for the user experiments. The trips are still dominantly caused by the thyratron discharges (65%). Since we modified the interlock systems of 39 units in this summer, we expect the trip rate will be highly reduced and we will increase the repetition rate to 20 pps or more.

SUMMARY

Since the C-band accelerator of SACLA generates high acceleration gradient as high as 35-38 MV/m, reliability of high power RF components and reduction of a trip rate are the key issues. The trip is dominantly due to an RF breakdown and an abnormal discharge of a thyratron tube. In order to reduce the number of RF breakdown, we performed an RF conditioning time of 700 hours. The RF breakdown rate was reduced to be 1/10 at an acceleration gradient of 38 MV/m. In order to reduce the number of a machine trip due to thyratron discharge, we modified the function of an interlock system. Thanks to these improvements, the trip rate was decreased and we were able to raise the beam energy. SACLA is currently operated at a beam energy of up to 8.5 GeV and an acceleration gradient of 38 MV/m, with an acceptable trip rate of once per 20-30 minutes in 10 pps. We confirmed the validity of the C-band high gradient acceleration for compact and stable XFEL facility.

STUDY OF MICROBUNCHING INSTABLITY IN THE LINAC OF THE SHANGHAI SOFT X-RAY FEL FACILITY*

Dazhang Huang#, Qiang Gu†, Meng Zhang, SINAP, Shanghai, China

Abstract

The microbunching instability (μBI) in the LINAC of a FEL facility has always been an issue which may degrade the electron beam quality. As the result, the whole facility may not be working properly. Therefore, learning how to control and reduce the instability is the key to the success of a FEL project. Shanghai soft X-ray FEL project (SXFEL) has been proposed and the feasibility study is finished. Once it is built, it will be the first X-ray FEL facility in China. In this article, detailed study will be given based on the design parameters of the facility to gain better understanding and control over the possible microbunching instability in SXFEL, which is critical to the success of the FEL project.

INTRODUCTION

The proposed Shanghai soft X-ray FEL facility is planned to be built in a few years. It will be a cascading HGHG FEL facility which will be working at 9 nm soft X-ray band. The electron beam energy of it at the exit of the LINAC will be around 840 MeV, the peak current will be around 600 A. The normalized emittance of the electron beam at the LINAC exit will be 2.0 – 2.5 mm.mrad.

Both the analytical and numerical studies show that μBI- induced growth of the global/slice energy spread in the LINAC is not ignorable; it also reduces the smoothness of the longitudinal beam current profile. Therefore, without proper control, the instability will be a serious problem and may impair the FEL process thereafter.

One way to control the instability is to increase the uncorrelated energy spread of the beam, which can be done by a laser heater [2][8], and it will also be implemented in SXFEL.

COMPUTATION AND ANALYSIS OF THE INSTABILITY

The basic principle of the microbunching instability in the LINAC of a FEL device has already been well-studied [1][2][3]. It is similar to the amplification mechanism in a klystron amplifier. The initial density modulation or white noise can be transferred into energy modulation by the impedances when the beam is being accelerated including the longitudinal space charge (LSC), coherent synchrotron radiation (CSR) and the structural impedance. When the beam is passing through the dispersive section such as the bunch compressor (chicane), the energy modulation will be turned back into the much stronger density modulation, in such a way that the microbunching instability is developed. Moreover, the CSR effect in the dispersive section will also form a positive feedback to enhance the instability. More dispersive sections in the LINAC will have more serious μBI problem. Figure 1 is the schematic description of the instability process.

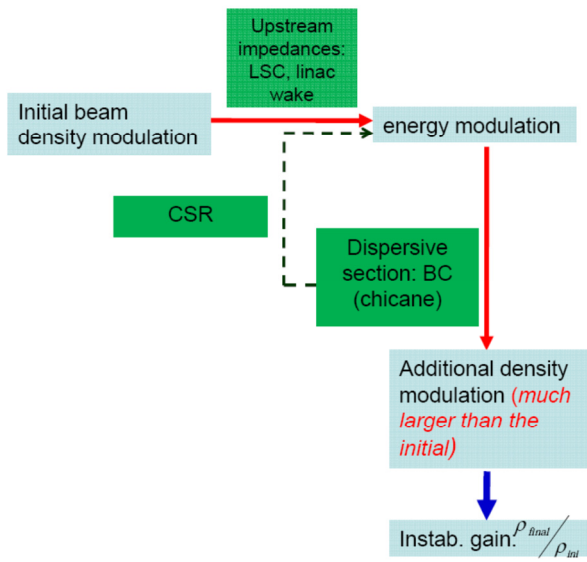

Figure 1: The microbunching instability process.

As discussed above, in the LINAC, the microbunching instability is mainly driven by the LSC, CSR and structural impedances. Since the structural impedance is more complicated and its effect on the instability is not as significant as the other two, in this article, we will be focusing on the microbunching instability introduced by the LSC and the CSR impedance.

The basic layout of the SXFEL LINAC is the following:

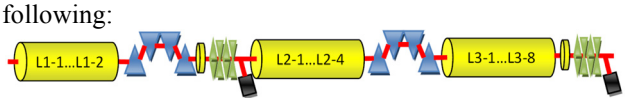

Figure 2: The layout of the SXFEL LINAC.

The SXFEL LINAC includes both S-band and C-band accelerating structures, one X-band structure to suppress the non-linear higher order mode (HOM), and two chicane-type bunch compressors (BC1 & BC2). Since there are two bunch compressors, the microbunching instability in the SXFEL LINAC is not negligible. The computation and simulation in the following is based on the design parameters of the LINAC, and the beam parameters out of the injector tracked by PARMELA [4]. Those parameters are listed in table 1.

Microbunching Instability Driven by the Longitudinal Space Charge (LSC) Impedance

In general, the microbunching instability driven by the longitudinal impedance has already been studied in details [1]. The gain of the instability is computed by [1]:

$$G = Ck|R_{56}|\frac{I_0}{\gamma_0 I_A}\frac{|Z(k)|}{Z_0}\exp\left(-\frac{1}{2}C^2k^2R_{56}^2\frac{\sigma_\gamma^2}{\gamma_0^2}\right) \quad (1)$$

Where

$$C = 1/(1+hR_{56})$$

is the compressing factor. For the longitudinal space charge, the impedance takes the form [5][6]:

$$Z_{LSC}(k) = \frac{iZ_0}{\pi k r_b^2}\left[1 - \frac{kr_b}{\gamma}K_1\left(\frac{kr_b}{\gamma}\right)\right] \approx \begin{cases} \frac{iZ_0}{\pi k r_b^2}, & \frac{kr_b}{\gamma} \gg 1, \\ \frac{iZ_0 k}{4\pi\gamma^2}(1 + 2\ln\frac{\gamma}{r_b k}), & \frac{kr_b}{\gamma} \ll 1, \end{cases} \quad (2)$$

Table 1: Main beam parameters used in the μBI calculation for SXFEL (obtained from Elegant [10] simulation)

Parameter	Value
Electron energy before BC1 (MeV)	208.4
Uncorrelated energy spread before BC1 (keV)	7.67
Electron energy before BC2 (MeV)	425.1
Uncorrelated energy spread before BC2 (keV)	51.1
Compression ratio (BC1×BC2)	5×2
Peak current before BC1 (A)	60
Beam radius before BC1 (mm)	0.40
Beam radius before BC2 (mm)	0.26

The instability gain as a function of the initial modulation wavelength introduced by the LSC at the exit of SXFEL LINAC is shown in Figure 3 below. The gains in the 1st and 2nd bunch compressors are illustrated separately.

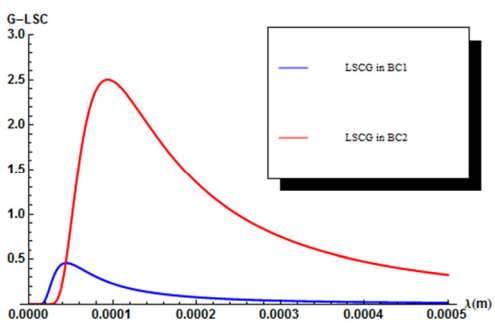

Figure 3: (color): The microbunching instability gain driven by the longitudinal space charge impedance as a function of modulation wavelength in the 1st (blue) and 2nd bunch compressors (red).

Microbunching Instability Driven by the Coherent Synchrotron Radiation (CSR) Impedance

As we already know, the electron beam in a bunch compressor can generate coherent synchrotron radiation (CSR). It can also be a source of modulation of the beam density at wavelengths small compared to the bunch length [3]. In other words, the microbunching instability can be produced from white noise due to the CSR effect in a bunch compressor.

The gain of the CSR-driven microbunching instability in a bunch compressor has already been well defined [2]. Assume a beam uniform in z and Gaussian in transverse and energy variables, the total gain induced by the CSR effect can be expressed as [2]:

$$G_f \approx \left|\exp\left[-\frac{\bar{\sigma}_\delta^2}{2(1+hR_{56})^2}\right] + A\bar{I}_f\left[\left(F_0(\bar{\sigma}_x) + \frac{1-e^{-\bar{\sigma}_x^2}}{2\bar{\sigma}_x^2}\right)\exp\left(-\frac{\bar{\sigma}_\delta^2}{2(1+hR_{56})^2}\right) + F_1(hR_{56},\bar{\sigma}_x,\alpha_0,\phi,\bar{\sigma}_\delta)\right] + A^2\bar{I}_f^2F_0(\bar{\sigma}_x)F_2(hR_{56},\bar{\sigma}_x,\alpha_0,\phi,\bar{\sigma}_\delta)\right| \quad (3)$$

According to reference [2], the first term on the right side of Eq. (3) represents the loss of microbunching in the limit of vanishing current, the second term is the one-stage microbunching amplification at low current, and the last term corresponds to the two-stage amplification at high current.

The computed microbunching instability gain driven by the CSR impedance as a function of modulation wavelength in SXFEL is shown in Figure 4. Again, the gains in the 1st and 2nd bunch compressors are illustrated separately.

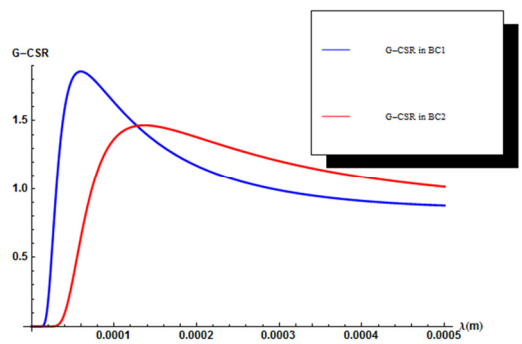

Figure 4: (color): The microbunching instability gain driven by the CSR impedance as a function of modulation wavelength in the 1st (blue) and 2nd bunch compressors (red).

Total Growth Rate of Microbunching Instability in SXFEL LINAC and Analysis

The total gain/growth rate of the instability in the SXFEL LINAC computed by analytical equations and by ImpactZ [7] is shown in Figure 5. Both the analytical solution and ImpactZ simulation peaks around ~ 100 um,

The amplitude of the two peaks looks different. It may be because of the small difference between the input parameters in the analytical computation and those in the simulation. For an example, the gain is very sensitive to

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the slice (uncorrelated) energy spread and R_{56} in the chicane, etc. Figure 6 below show the peak gain as a function of the relative uncorrelated energy spread of the beam before BC1. Moreover, it may be due to the excessive suppression of noises - It is known that the beam input in the simulation includes both the numerical and physical noises; it is possible that some of the "real" physical noises are incidentally smoothed out as well while we do numerical smoothing to the input beam profile.

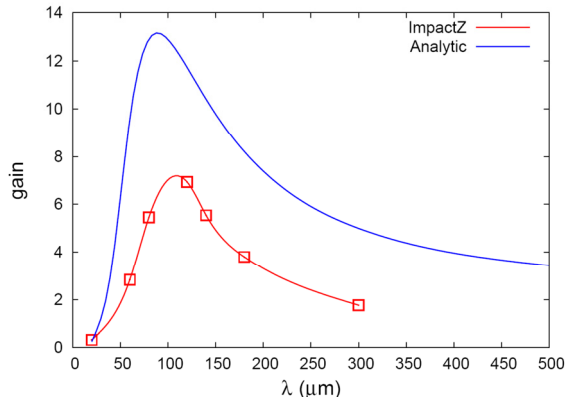

Figure 5: (color): The total μBI gain at the exit of SXFEL LINAC as a function of the modulation wavelength computed by analytical equations (blue) and ImpactZ [7] simulation (red) based on the current machine parameters.

As one can see in Figure 6, as the slice (uncorrelated) energy spread of the beam rises, the peak gain of the instability starts to fall very rapidly. It is indeed consistent with the theoretical expectation. It also tells us that in reality the gain may be very different from what we have calculated because of the possible variations of the "real" uncorrelated energy spread. Therefore, the laser heater [2] [8] is introduced to increase the uncorrelated energy spread of the beam by laser-beam interaction, in such a way to control the growth of the instability. Although the design is still not fully completed, the ongoing numerical simulation shows that it is able to reduce the gain significantly [9].

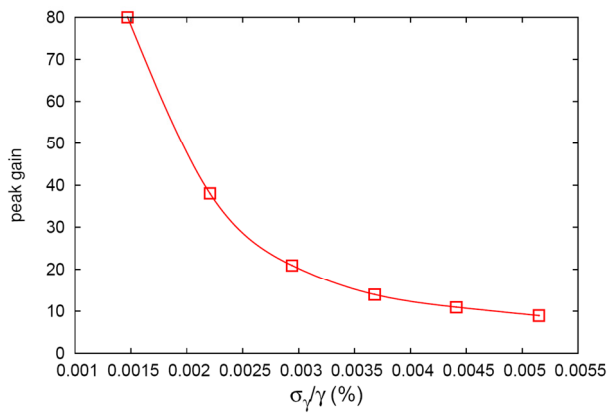

Figure 6: The peak gain computed as a function of the relative uncorrelated energy spread before the 1st chicane.

CONCLUSIONS

Microbunching instability is an important issue in the LINAC of a FEL facility. If the gain of the instability is too large, the quality of the electron beam will be destroyed and is harmful to the whole FEL device.

Both the analytical computation and numerical simulation show that the microbunching instability in SXFEL is not negligible, and the LSC impedance induced growth is larger than that driven by the CSR impedance. Moreover, the gain is very sensitive to some critical beam and lattice parameters such as the energy spread and the R_{56} in the chicanes, etc.

As a matter of fact, a laser heater is needed to suppress the instability. Further study is on the way to optimize and properly implement the laser heater into the SXFEL lattice.

PHOTOINJECTOR OF THE EBTF/CLARA FACILITY AT DARESBURY

B.L. Militsyn*, D. Angal-Kalinin, N. Bliss, C. Hill, S.P. Jamison, J.K. Jones, J.W. McKenzie, K.J. Middleman, M.D. Roper, B.J.A. Shepherd, R.J. Smith, R. Valizadeh, A.E. Wheelhouse, STFC ASTeC, Daresbury Laboratory, Warrington, WA4 4AD, UK

Abstract

A photoinjector designed for Electron Beam Test Facility (EBTF) and Compact Linear Accelerator for Research and Applications (CLARA), a proposed FEL test facility is described. The photoinjector is based on a 2.5 cell S-band photocathode RF gun operating with a copper photocathode which is driven by a third harmonic of Ti: Sapphire laser (266 nm) installed in dedicated thermally stabilized room. The injector will be operated with laser pulses with energy of up to 2 mJ, a pulse duration of 80 fs RMS and initially a repetition rate of 10 Hz, with the aim of increasing this eventually to 400 Hz. At a field gradient of 100 MV/m provided by a 10 MW klystron, the gun is expected to deliver beam pulses with energy of up to 6 MeV. Bunch length and emittance of electron bunches essentially depend on the bunch charge and vary from 0.1 ps at 20 pC to 5 ps at 200 pC and from 0.2 to 2 mm·mrad respectively. Additional compression of the electron bunches required for CLARA will be provided with a velocity bunching scheme and a dedicated chicane.

INTRODUCTION

The Electron Beam Test Facility (EBTF) is a 6 MeV electron accelerator designed to provide low emittance, short pulse beams to two user stations [1-2]. It will also act as the front end for the proposed CLARA accelerator [3-4]. Initially, the beam for EBTF will be delivered by a 2.5-cell, S-band, normal-conducting, RF gun originally designed for the ALPHA-X project [5].

The front end of EBTF (Fig. 1) has been designed as a photoinjector diagnostics suite to fully characterise 6D phase space of bunches. A variety of YAG screens and slits will be used to characterise the beam transversely. Longitudinal characterisation of the beam will be provided with energy spectrometer comprising a dipole magnet and a YAG screen. Bunch length will be measured using a Transverse Deflecting Cavity (TDC) [7] to streak the longitudinal position of the particles onto the transverse plane, thus making it viewable on the YAG screen. Furthermore, if the streak is performed in the vertical plane as planned, then passing the beam around the horizontal spectrometer will make the longitudinal phase-space directly viewable on the screen. Combining the TDC with the transverse beam diagnostics will allow time-sliced emittance measurements to be made. For better thermal stability the injector is mounted on an artificial granite support.

PHOTOINJECTOR BEAM DYNAMICS

The EBTF photoinjector has been modelled both in ASTRA and GPT. The simulations presented are at the maximum bunch charge of 250 pC to show the effects of space charge. For the simulations, an intrinsic emittance of 0.9 mm·mrad per mm RMS beam size is used [6]. The simulations presented here are based on the factory measured laser pulse length of 80 fs RMS. An optimisation of the photoinjector beam line was performed looking at the beam parameters at 1, 3, and 10 m from the photocathode to observe their evolution, as shown in Fig. 2. It was found that energy spread is highly sensitive to solenoid strength due to space charge. The energy spread could be controlled by operating further off-crest in the gun, at a phase of -35° from that of maximum energy gain.

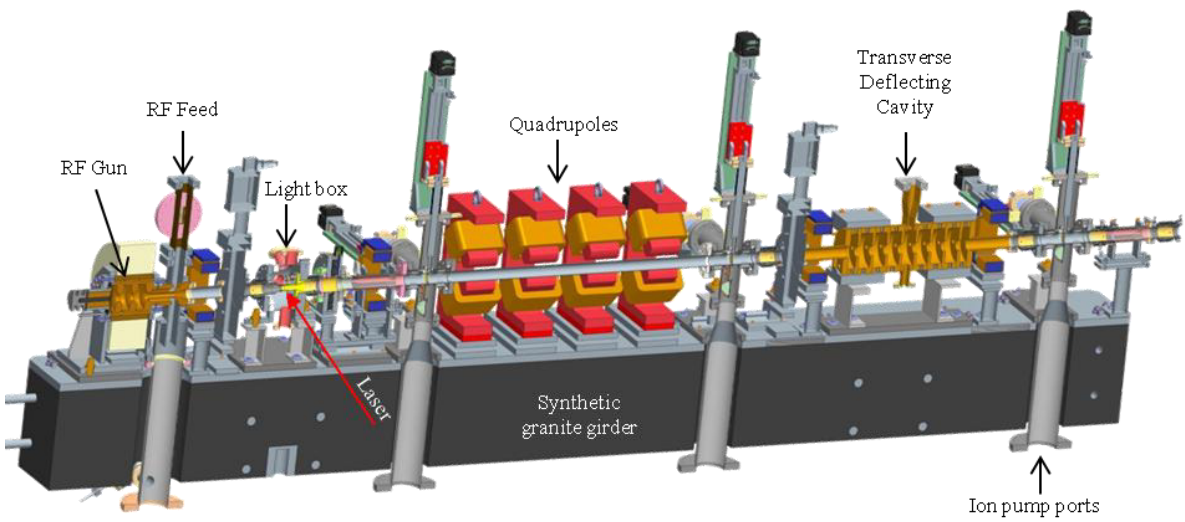

Figure 1: CAD drawing of the EBTF photoinjector

To use the TDC for the bunch length diagnostic, four quadrupoles are located before it and are used to minimise the beam size in the streak plane, whilst keeping both transverse beam sizes relatively constant, as shown in Fig. 3. Minimising the transverse beam size reduces the energy spread increase when passing through the TDC, because longitudinal electric field, zero on axis of the TDC, increases linearly with distance from the axis. Since the TDC also gives, due to imperfectly matched electric and magnetic fields, an offset to the beam as well as a streak, , corrector coils are used either side of the cavity to keep the beam on axis. Fig. 4 shows the optimised particle trajectories from the cathode through the TDC to the screen.

PHOTOINJECTOR RF SYSTEM

To provide the required 6 MeV beam energy for the EBTF RF gun a K2 ScandiNova klystron modulator capable of providing 250 kV, 150 A pulses of up to 3 µs at a repetition rate between 1–400 Hz, has been procured and recently commissioned.

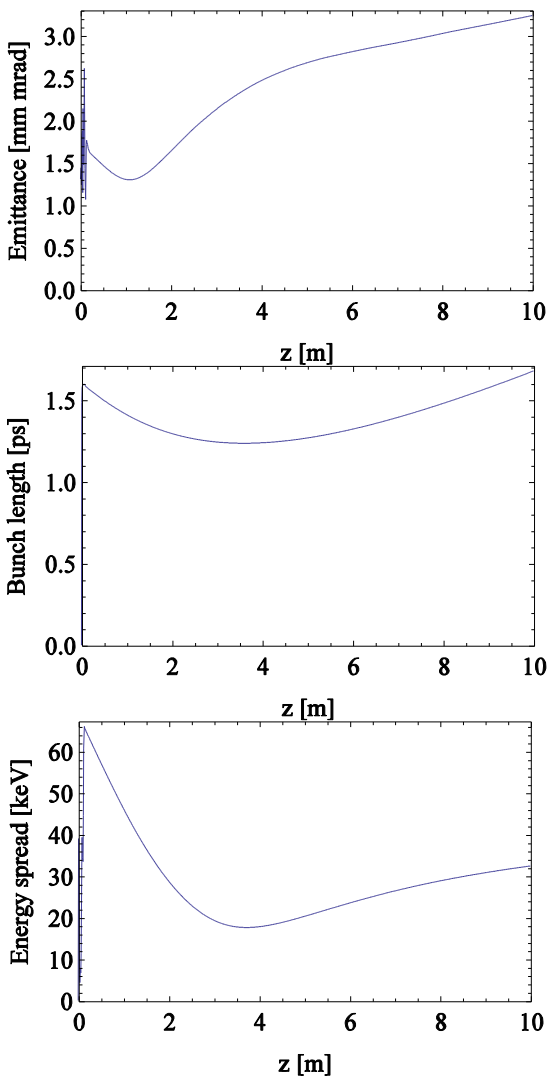

Figure 2: Evolution of beam parameters up to 10 m.

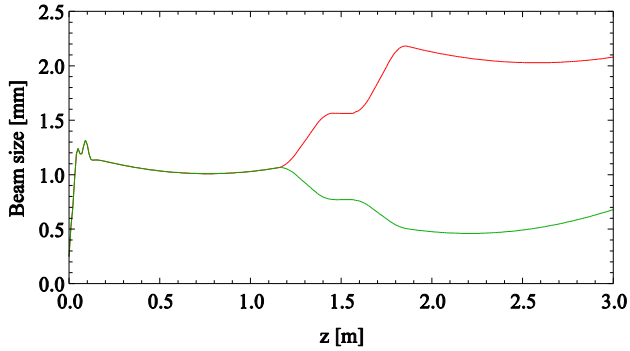

Figure 3: Horizontal (red) and vertical (green) beamsizes through the transverse deflecting cavity.

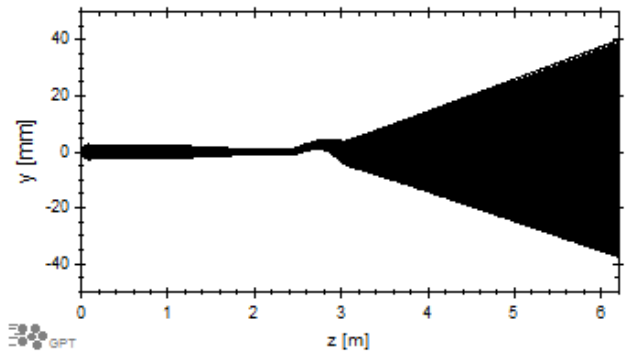

Figure 4: Vertical trajectories with the transverse deflecting cavity providing a streak.

The modulator is used to power a Thales TH2157 klystron capable of providing a peak RF output power of 10 MW at 2998.5 MHz and will be operated at a repetition rate of 10 Hz for the EBTF RF gun. For a 3 µs pulse width the modulator is designed to maintain a voltage stability of ±0.1 % with a 1 µs peak voltage top flatness of ±0.1 %. During the modulators acceptance tests jitter measurements were performed; the pulse to pulse jitter was ±1.3 ns and the pulse width jitter was ±2.7 ns.

The low level RF (LLRF) system for EBTF will consist of an ultra-stable and low noise master oscillator produced by RALAB AG, which will output locked frequencies to drive the laser and RF system. Reference distribution between the oscillator and the RF system at a frequency of 2998.5 MHz will be via temperature stabilised dielectric cables (LCF38-50J). To minimise the effect of temperature change during operation, these cables will be held at 24±0.1°C, a region where they are particularly stable.

The LLRF control of phase and amplitude for the RF gun will be via an in house built digital LLRF control system using heated and temperature stabilised RF front ends, a LLRF 4 FPGA control card [9] and a remote calibration system which will measure and correct for errors on a slow control loop as environmental factors change. Thus it will be possible to correct for pulse to pulse errors using this system and expect to achieve 0.1% amplitude and 0.1° phase stability and be able to compensate for environment changes on the machine over the period of the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

day. Additionally the temperature of the RF gun will be stabilised to ±0.1°C to ensure that it is maintained at its operating frequency.

PHOTOCATHODE AND DRIVE LASER

The photocathode is a polycrystalline, oxygen-free, copper disc (Fig. 5), polished to 1µm roughness. It forms an integrated part of the 2.5-cell gun cavity and is placed at the back wall of the first half-cell. Prior to installation the cathode is degreased by washing in acetone, ethanol and finally in de-ionized water (>10 MΩ). Carbon contamination is then removed from the surface by ozone cleaning. The gun is pumped down and baked to 150°C in order to achieve pressure in the region of 10^{-10} mbar. The emission area of the photocathode plate is locally baked to a temperature of 200°C to remove oxide.

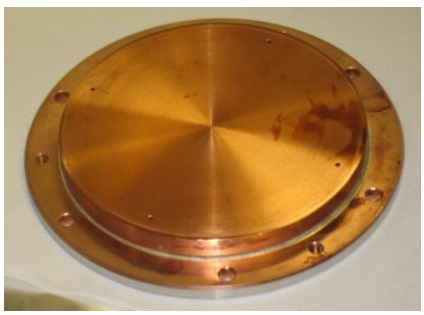

Figure 5: The photocathode of the EBTF gun.

Future developments will look at the use of higher quantum efficiency photocathode materials like single-crystal copper and other metals such as Mg, Pb, and Nb. For Cu and Nb, high-purity metal discs of 10 mm diameter and 2 mm thickness will be inserted into the cavity wall, whilst Mg will be directly deposited onto the wall surface.

The photocathode will be driven by a frequency-tripled Ti:Sapphire laser system with a repetition rate of up to 400 Hz. The pulse energy at 266 nm is 2 mJ and the pulse duration is 80 fs RMS, giving a peak power of ~10 GW. As generated, 99% of the pulse energy is contained within a beam diameter of 20 mm and so the beam intensity is ~2 GW/cm^2. The intention is to focus the UV beam to a spot size of ~1 mm FWHM on the cathode, which will increase the beam intensity to nearly 1 TW/cm^2. Significant difficulties in the transport of the full beam power will be encountered and early operation will be likely at reduced power.

To prevent beam disruption through non-linear effects, as much of the ~14 m long transport path as possible will be in vacuo and no refractive optics will be used; all beam focusing will be done with mirrors. One air to vacuum window will be required in the laser room at the entrance to the vacuum system and this will be made from calcium fluoride to prevent two-photon absorption (TPA). The laser transport vacuum will be isolated from the gun vacuum by differential pumping so that no window will be required where the beam intensity is at its highest.

The very high beam intensity also leads to a high risk of damage to the optics. All but the final mirror will have a standard ultra-fast, multi-layer dielectric coating with a high damage threshold. The final mirror sits in the gun vacuum and has a simple protected aluminium coating on a copper substrate to prevent damage from accumulated electrical charge. The photon damage threshold of this mirror will be found experimentally.

CONCLUSION

EBTF photoinjector is being installed presently at Daresbury laboratory (Fig. 6).The first commissioning stage is scheduled to begin around November-December 2012.

Figure 6: EBTF photoinjector in the assembling stage.

ACKNOWLEDGMENT

The authors would like to acknowledge the EBTF design team, the ALPHA-X collaboration and Strathclyde University.

FIRST RF MEASUREMENT RESULTS FOR THE EUROPEAN XFEL SC CAVITY PRODUCTION

A. Sulimov, P. Borowiec, V. Gubarev, J. Iversen, D. Kostin, G. Kreps, K. Krzysik, A. Matheisen, W.-D. Moeller, D. Reschke, W. Singer, DESY, Notkestrasse 85, 22603 Hamburg, Germany

Abstract

The first reference cavities (RCV) for the European XFEL Project are being tested within the collaboration of Research Instruments (RI), E. ZANON, IFJ-PAN and DESY:

- production and warm RF measurements of cavities and their components at RI and ZANON;
- surface preparation at DESY;
- cold RF tests at DESY by IFJ-PAN.

Purpose of the RCV is to establish a stable cavity fabrication and qualification of the surface preparation infrastructure at industry.

All necessary RF measurements were done, starting with mechanical fabrication in 2011, till the tuning and cold cavity RF tests in 2012.

We present the first results of RF measurements within RCV production for the European XFEL.

INTRODUCTION

For the first time the superconducting (SC) cavities for the XFEL are not only fabricated by industry, but also the full preparation "ready for cold RF test".

Before starting the (pre-)serial production each supplier of XFEL SC cavities (RI and ZANON) has produced 4 dummy (DCV) and 4 reference (RCV) cavities to qualify the new equipment and check the sequence of the fabrication process.

The main aspects of the RF measurements procedure for the European XFEL were described in [1].

These measurements allow checking the RF quality of the cavity (tuning, cold RF tests) and help to predict the mechanical parameters (length after tuning or deformation during transportation).

PRODUCTION OF PARTS

The main ideas of cavity parts (dumb-bells (DB) and end-groups (EG)) control are quick tests of their shapes before final cutting and checking the correspondence of the pi-mode frequency to part's length after trimming.

Only extensive 3D shape measurements can give the final results of the cell shape status, but RF measurements can give a prognosis for a series of 32 DB in one hour. The necessary field distribution for the fundamental mode can be obtained relatively easy by cavity tuning even for a wrong shape, but the behaviour of the higher order modes (HOM) spectrum is not predictable in this case. So a wrong shape is more critical and dangerous for HOM and beam dynamics.

The results of final RF measurements, when the parts are ready to be welded together in a cavity, are collected in the XFEL database [2].

Some examples of statistical values are shown in figure 1: the correspondence of pi-mode frequency to the length for DB (a) and EG (c). As a DB consists of two half-cells the symmetry of their volumes is additionally checked (b). These values are limited by ±0.1. In case a DB is out of tolerance, it has to be checked mechanically and additionally compensated or reshaped.

CAVITY FABRICATION

To guarantee that the cavity length after tuning will be in tolerance of ± 3 mm, we make a prediction of this value twice: before and after cavity welding.

This prediction is based on the known length, pi-mode frequency of cavity parts, the amount of chemical treatment before and after welding, shrinkage of welding seams and other mechanical factors.

To compare these predictions with real values the data were collected in table 1. One can see the good accordance of predicted length deviation (first two columns). Only for cavities CAV00503 and CAV00506 the differences are a little higher and reach about 1 mm. It can be explained by the reduction of real shrinkage during cavity welding of about 0.08 mm per weld.

The difference between predicted and real values could partly be due to the different amount of chemical treatment before tuning: about 130 µm for cavities CAV00001-004, and about 180 µm for others. The influence of other factors is being analyzed.

Table 1: Length deviation relative to planned value

Cavity	dL, mm		
	predicted before welding	predicted after welding	real value
001	1.64	1.65	0.93
002	1.08	0.41	-0.45
003	3.18	3.20	2.60
004	3.03	3.07	2.18
500	0.00	0.11	2.43
502	0.02	0.16	1.09
503	0.50	1.45	3.41
506	0.49	1.12	3.10

After the cavity welding the results of all warm (at room temperature) RF measurements are collected in the XFEL database [3] as presented in figure 2. These data are accessible to the public.

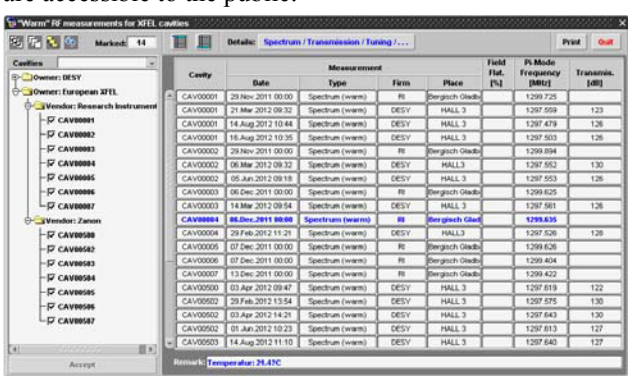

Figure 2: Presentation of warm RF measurements in XFEL database.

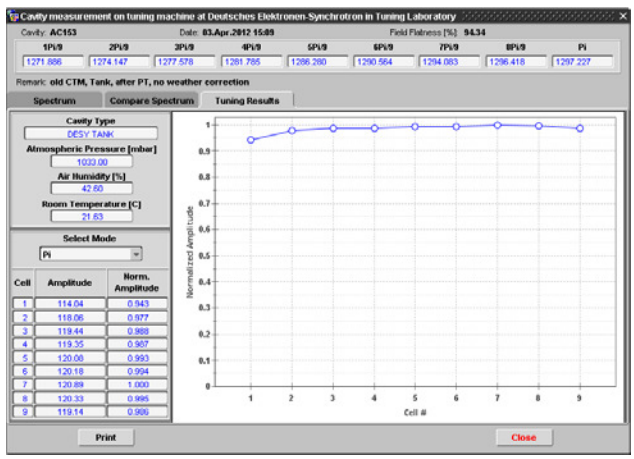
TUNING

The reference cavities were tuned once before the cold RF test. Results of these tuning procedures are summarised in table 2. The pi-mode frequencies for cavities CAV00001-004 are higher (about 1297.60 MHz) than for others (about 1297.44 MHz) because of the difference in planned additional chemical treatment: 40 µm and 10 µm correspondingly.

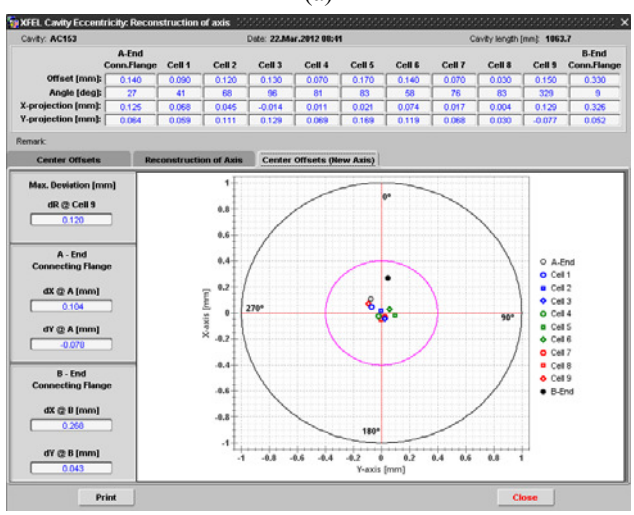
Table 2: Parameters after tuning

Cavity	Length, mm	Pi-mode frequency, MHz	Field flatness, %
001	1282.34	1297.623	99
002	1280.95	1297.644	97
003	1284.00	1297.585	98
004	1283.58	1297.545	99
500	1283.83	1297.411	99
502	1282.49	1297.419	98
503	1284.81	1297.458	97
506	1284.50	1297.459	98

As all tuning procedures for the reference cavities were done at DESY, no data transfer to the XFEL database was foreseen. An example of results' presentation is shown in figure 3 for cavity AC153. This cavity should be mounted into XFEL Module XM-3.



(a)



(b)

Figure 3: Tuning results: (a) - RF measurements, (b) - eccentricity

TRANSPORTATION

Each cavity has a long way from the manufacturers (RI or ZANON) to DESY for the cold RF test, then to CEA (Saclay, France) to be assembled inside the accelerating module and finally back to DESY for the module RF test and installation into the XFEL tunnel.

Comparison of cavity's spectra before and after transportation helps to control the absence of cavity deformation. Results and analysis of spectra comparison can be done automatically in the XFEL cavity database by choosing two spectra for a cavity. The Root mean-square error for the relative spectrum (RS) (1) multiplied by the operational frequency 1.3 GHz (MSE) helps us to estimate a possible deformation (cell's detuning) of a cavity.

$$RS = \{R_i\} = \{F_i/f_i - F_N/f_N\}, \quad (1)$$

where i = 1…9, $\{F_i\}$ and $\{f_i\}$ – two spectra.

As an example for cavity CAV00002, the value of MSE is only 4 kHz. The exceeding of the 10 kHz limit for MSE means that the cavity's field flatness could be lower than the critical 90%. In this case additional measurements and investigation of transportation errors have to be done.

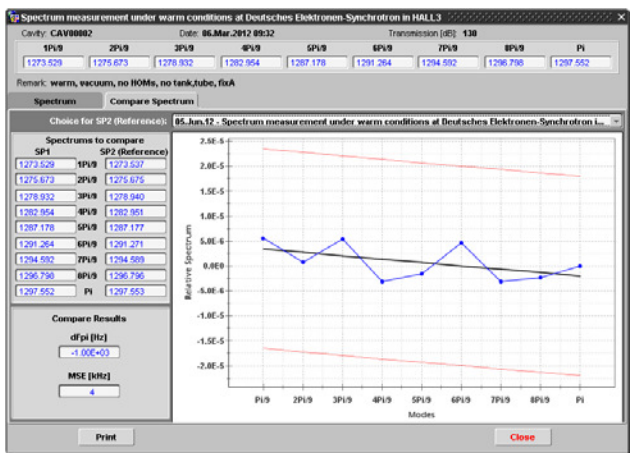

Figure 4: Comparison of two spectra (two columns at the left panel) for CAV00002. RS – blue broken line.

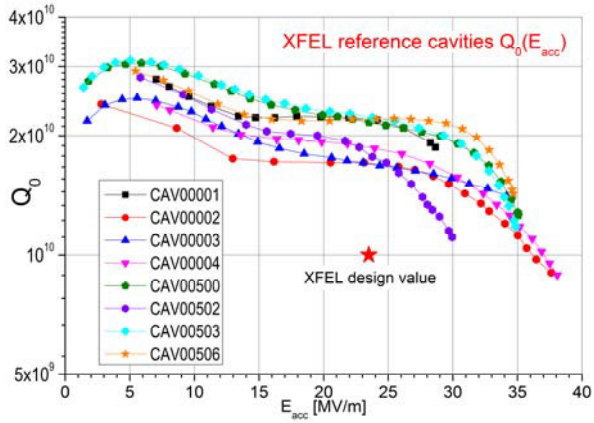
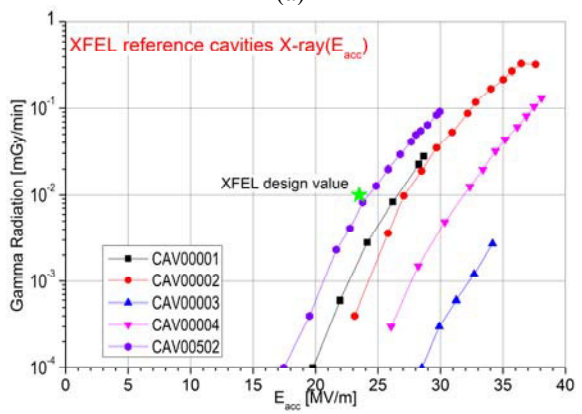
COLD RF TESTS

As a final quality check of the cavity a CW RF cold test is done after all preparation steps are finished. RCV were tested in LHe at 2K without cavity tank and HOM couplers feedthroughs in order to get a first performance evaluation. Later, during XFEL cavity production, cavities will be tested with all auxiliaries.

Results of the first cold RF tests (see figure 5) after the cavities' tuning and final chemical treatment at DESY of all reference cavities show the correspondence with the XFEL operation specification ($E_{acc} \geq 23.6$ MV/m with a Q-value $Q_0 \geq 10^{10}$ and radiation X-ray < 10^{-2} mGy/min).



(a)



(b)

Figure 5: Cold RF test results: after surface preparation at DESY: (a) – $Q_0(E_{acc})$, (b) – X-ray(E_{acc}).

SUMMARY

The fabrication of 8 reference cavities by RI and ZANON allows us not only a test of the quality of the companies' infrastructure, but also of the communication between the members of the European XFEL Project.

The results of all measurements reflect the high quality of the so far produced cavities, which have reached accelerating gradients from 28 to 38 MV/m.

This presentation also shows the diversity of XFEL database abilities, such as collecting of all data, their presentation and automatic calculations.

ACKNOWLEDGMENTS

We would like to thank all participating colleagues from E. ZANON, Research Instruments, IFJ-PAN and DESY, whose enthusiastic effort allows us to push forward the work on cavities for the European XFEL Project.

Abstract

The PHIL accelerator is in operation since November 2009. Its main goals are the R&D on photo-injectors and to provide electron beam to users. We report on the experimental characterization of the electron beam produced by a 3 GHz 2,5 cells RadioFrequency (RF) gun and operation with a Magnesium photo-cathode.

INTRODUCTION

The PHIL beamline [1,2] is rather simple : the photo-injector at 3 GHz called AlphaX [3] equipped with a couple of solenoids, a pair of steerers, a third solenoid to transport and focus the electron beam and a dipole to analyse the beam energy. The main diagnostics are Integrated Current Transformers (ICT) from the Bergoz Company to measure the charge and YAG screens coupled with a CCD camera to measure the transverse profile of the beam. Main parameters of the electron beam are summarized in table 1.

Table 1: PHIL Electron Beam Parameters, with Cu Photo-Cathode Except Few Runs with Mg*.

Energy (MeV)	< 5
Charge (nC), single pulse	0.01-0.4; 1*
Energy spread (%)	< 1
Emittance (πmmmrad)	< 5
Repetition rate (Hz)	5

COMMISSIONING

The RF gun has been commissioned several times rather easily. Generally it took a day to reach 5.5 MW with a RF pulse duration of 2.5 µs which is equivalent to an accelerating field of 70 MV/m. The RF commissioning has been repeated several times due to some changes of photo-cathode; we tried raw copper, copper polished with diamond paper and magnesium photo-cathodes. The commissioning took place smoothly thanks to the elliptical shape of the irises between the cells. It leads to a ratio of the surface electrical to the accelerating field close to one, thus reducing breakdown hazards.

Dark Current

The dark current or charge has been measured as a function of the accelerating field for raw copper and hand polished photo-cathodes. It was not possible to compare with the optically polished photo-cathode because of a breakdown in the RF circulator which did not allow us to increase the electrical field above 40 MV/m.

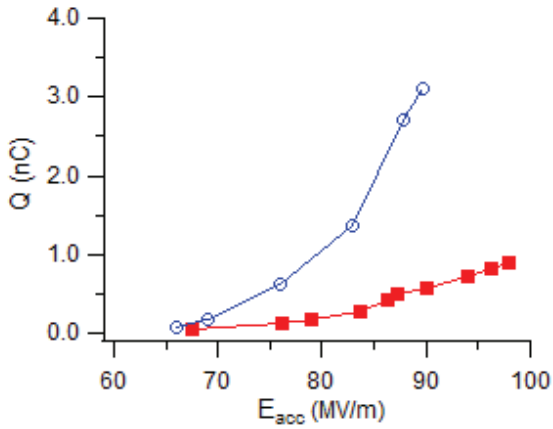

Figure 1: dark charge produced by field emission in the gun for raw copper (round points) and hand polished copper (square points) photo-cathodes.

The reduction of dark current due to the use of a polished photo-cathode is spectacular. At 90 MV/m, the dark charge with polished photo-cathode is 5.5 times lower than in the raw copper case. However, the analysis of these results according to the Fowler-Norhdeim formula [4] showed that the field amplification factor, β, has the same order of magnitude, around 100. The lower charge with the polished copper comes actually from a reduction of the emission area.

BEAM PERFORMANCES

To compare performances of different photo-injectors and also for user experiment, it is important to characterize the electron beam as a function of parameters as the relative phase between the RF and the laser, the accelerating gradient, the energy and spot size of the laser.

Dephasing Curve

The best performances of the electron beam are obtained when the electron beam is accelerated near the crest of the RF wave. However there is a range around the optimum phase on which the gun can be operated. Measurements of the beam charge as a function of the relative phase between the laser and the RF is shown in figure 2.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

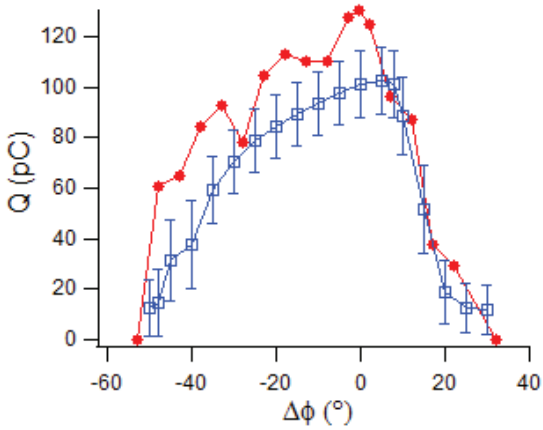

Figure 2: beam charge as a function of the relative phase between the RF and the laser for 56 MV/m, blue curve with squares and 92 MV/m, red curve with circles.

Behaviour is similar as observed in other experiments [5]. The width of the dephasing curve increases versus the accelerating gradient. Below the phase corresponding to the maximum charge, there is a slow increase due to the Schottky effect related to the increase of the accelerating gradient. On the right side of the curves, the slope is very abrupt; in less than 10° the charge can decrease by 50 %. It means that the beam performances are very sensitive to the phase. Besides there is evidence of a slow drift of the phase which is being investigated.

Transverse Dimensions and Emittance

Transverse dimensions of the electron beam are measured through the fluorescence light emitted by the beam into YAG:Ce screen. This light is then transported by a metallic mirror, an achromatic lens to a CCD camera. Four monitors are installed, the first at around 2 meters away from the photo-cathode, the second is placed just after a focusing coil in the middle of the beamline (3.5 m from the photo-cathode), the third is at the end of the straight line and the last on the deviated line after the dipole for the beam energy measurement.

Example of typical measurements is shown in figure 3.

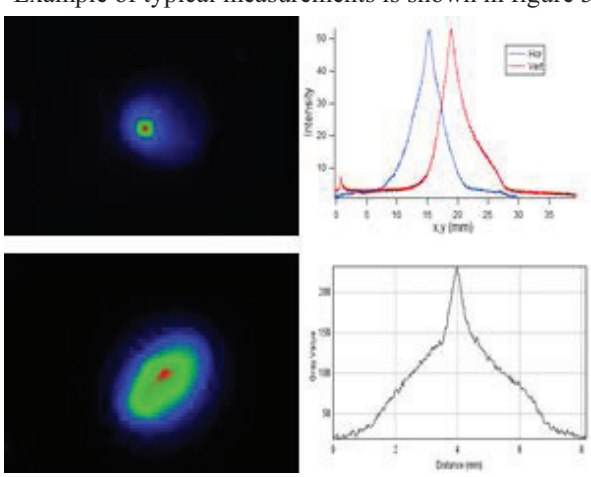

Figure 3: YAG screen images; top, 1st screen with the 1st focusing coil at 90 A; down, 2nd screen with 99 A and the 2nd focusing coil at 29 A; Q = 180 pC, E_{acc} = 63 MV/m.

The difference between both images is clear: on the first screen, the beam appears mostly round although with a vertical width 12 % larger than the horizontal one. On the second screen, it is elliptical tilted at roughly 45°; the width along the big axis is 51 % larger than on the other axis. The profile on the first screen is probably due to the laser which has a vertical width also 5 % larger than the horizontal one. However it is not enough to explain the huge ellipticity of the electron beam measured on the second screen. It looks like the action of a quadrupole or it would mean that the vertical emittance of the beam is 50 % larger than in the other direction. Both hypothesis do not seem compatible with our set-up, this problem is still under investigation. In addition there are also some problems of halo and parasitic images that we are striving to understand.

In spite of these problems, we used a solenoid scan to measure the emittance. A direct measurement with a mask made of vertical and horizontal slits is foreseen in 2013, technical drawings are under way. The principle of the measurement with the solenoid is similar to the one with the quadrupole. One measures the beam transverse dimensions as a function of the magnetic force and, knowing the coil transfer matrix, it is possible to deduce the beam matrix at the entrance of the coil. Such measurement is shown in figure 4.

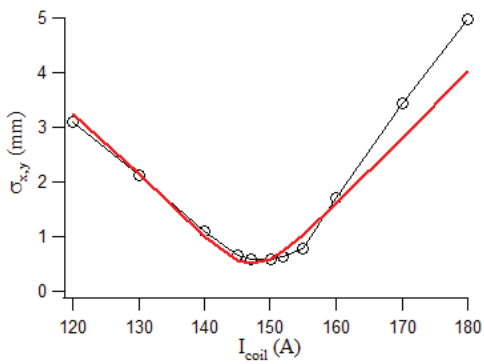

Figure 4: rms beam size, black curve with round points; least square fit restricted to [130, 160] A, red curve; Q = 150 pC, E_{acc} = 80 MV/m.

Some reasonable assumptions have been made to simplify the analysis: the beam is round and no coupling terms between the X and Y directions in the input beam matrix. So, only 3 parameters of the beam matrix must be found: σ_{11}, σ_{12} and σ_{22}. The fit was restricted to the current range [130 A; 160 A] because on the whole range of current it converged to a solution giving an imaginary emittance. So, the result of the fit is a normalized emittance of 4.6 πmmmrad. With the parameters of the experiment, PARMELA simulation gives an emittance of 2.6 πmmmrad at the entrance of the coil. The discrepancy between the simulation and the experiment can have multiple origins: problems with the images, magnetic errors, RF phase error and the fact that this method based on the transport matrix formalism neglects the space charge force. In the simulation, the emittance increases by

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

30 %, between the position of the YAG screen and entrance of the solenoid, due to the space charge.

Energy spread

The energy spectrum of the electron beam is measured thanks to a dipole recycled from the TTF accelerator. It is a 60° bend with 70 cm of curvature radius. The YAG screen used to measure the beam is close to the focal plane of the dipole, at 13 cm, which means there is a small contribution of the transverse dimension on the measurement. We performed a measurement of the energy spread as a function of the RF phase, shown in figure 5.

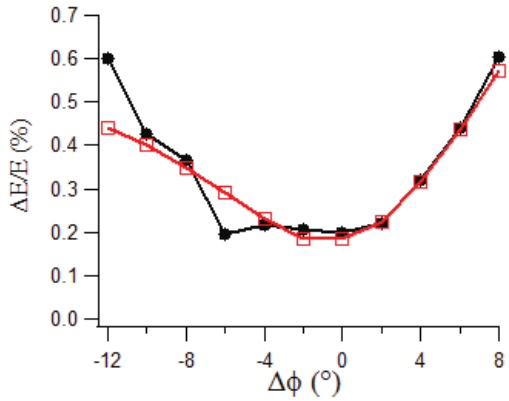

Figure 5: rms energy spread as a function of the RF phase with Q = 100 pC and E_{acc} = 54 MV/m; measurements, black curve with rounds; PARMELA simulations, red curve with squares.

The minimum energy spread is roughly 0.2 %. PARMELA simulations have been performed with the experimental parameters. The agreement with the measurements is quite satisfying. It means also that the contribution of the emittance in the measurement is negligible as we had assumed.

MAGNESIUM PHOTO-CATHODE

Several experiments have been performed elsewhere with magnesium (Mg) photo-cathode to produce higher charge [6]. The advantage of such materials is the relative easiness and low cost to carry out compared to cesium telluride for instance. We used a disk of pure Mg of 10 mm diameter and 2 mm thickness and press fitted in the centre of the copper end plate of the RF gun without baking or cleaning. The RF commissioning was 3 times longer than with the simple copper plate. The first beam with this photo-cathode produced very low charge, 80 pC at the maximum but it was expected. To have access to the good properties of pure Mg, one has to remove the oxide layer on the surface. The simplest way to do it is to focus the laser down to 0.1 mm; to scan the photo-cathode in presence of a RF field of 50 MV/m and to make explode the top oxide layer. After having performed this procedure, we measured the charge as a function of the laser energy, see figure 6.

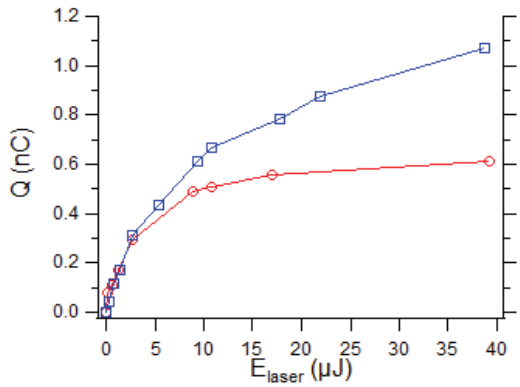

Figure 6: beam charge measured with an ICT as a function of the laser energy deposited on the Mg photo-cathode for 2 accelerating gradients; 45 MV/m, red curve with circles; 62 MV/m, blue curve with squares.

The laser cleaning led to a dramatic increase of the extracted charge, up to 1.1 nC with an accelerating field of 62 MV/m while it was only 80 pC before. Actually, we are limited by the space charge force which prevents the electrons to go out. As one can see, increasing the accelerating gradient allows one to extract more charge. The linear part of the curves, below 5 μJ, means a yield of 0.11 nC/μJ. If we could operate the gun at 90 MV/m, we could produce 4.4 nC with the maximum laser energy.

CONCLUSION

Experimental characterisation of the alphaX photo-injector has been performed. Charge, emittance and energy spread have been measured and are in good agreement with the simulations. Obtaining of high charge with magnesium photo-cathode has been demonstrated. Next step will be to operate at high gradient routinely in order to improve beam quality and higher charge. We plan also to test other RF guns and to perform user experiments.

ELECTRON MODEL OF A DOGBONE RLA WITH MULTI-PASS ARCS *

S.A. Bogacz#, G.A. Krafft, V.S. Morozov, Y.R. Roblin, Jefferson Lab, Newport News, VA, USA
K.B. Beard, Muons, Inc., Batavia, IL, USA

Abstract

The design of a dogbone Recirculated Linear Accelerator, RLA, with linear-field multi-pass arcs was earlier developed [1] for accelerating muons in a Neutrino Factory and a Muon Collider. It allows for efficient use of expensive RF while the multi-pass arc design based on linear combined-function magnets exhibits a number of advantages over separate-arc or pulsed-arc designs. Such an RLA may have applications going beyond muon acceleration. This paper describes a possible straightforward test of this concept by scaling a GeV scale muon design for electrons. Scaling muon momenta by the muon-to-electron mass ratio leads to a scheme, in which a 4.5 MeV electron beam is injected at the middle of a 3 MeV/pass linac with two double-pass return arcs and is accelerated to 18 MeV in 4.5 passes. All spatial dimensions including the orbit distortion are scaled by a factor of 7.5, which arises from scaling the 200 MHz muon RF to the frequency readily available at CEBAF: 1.5 GHz. The footprint of a complete RLA fits in an area of 25 by 7 m. The scheme utilizes only fixed magnetic fields including injection and extraction. The hardware requirements are not very demanding, making it straightforward to implement.

MUON RLA WITH TWO-PASS ARCS

A schematic layout of a dog-bone-shaped muon RLA, proposed for future Neutrino Factory [2] is illustrated in the top portion of Fig. 1. Reusing the same linac for multiple (4.5) beam passes provides for a more compact accelerator design and leads to significant cost savings. In the conventional scheme with separate return arcs [4], different energy beams coming out of the linac are separated and directed into appropriate arcs for recirculation. Therefore, each pass through the linac would require a separate fixed-energy arc, increasing the complexity of the RLA. We propose a novel return-arc optics design based on linear combined-function magnets with variable dipole and quadrupole field components, which allows two consecutive passes with very different energies to be transported through the same string of magnets [6].

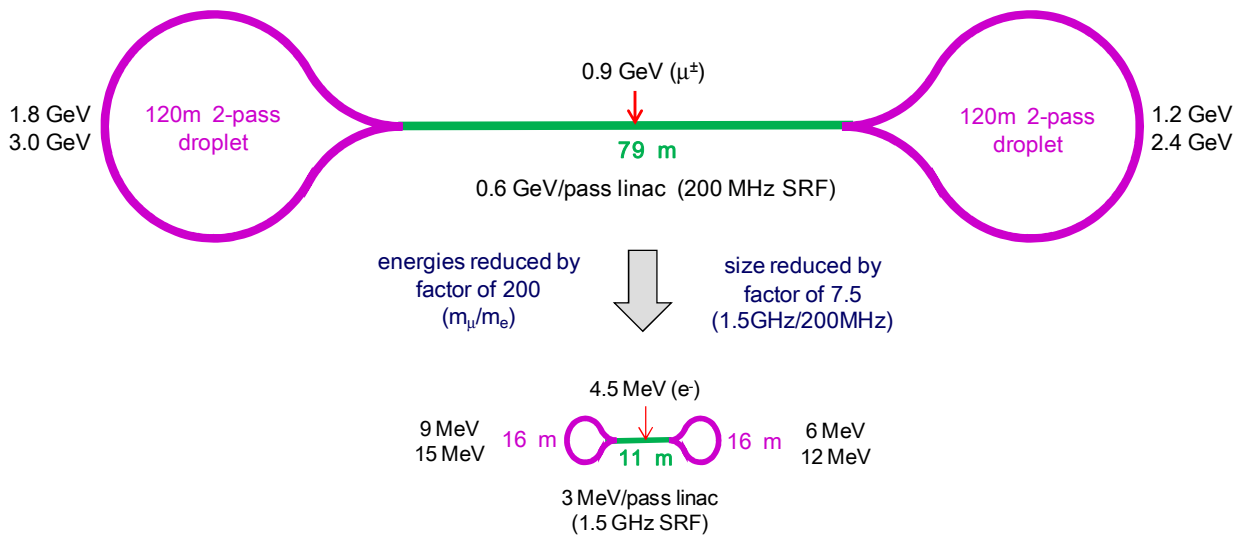

Figure 1: Schematic layout of a GeV-scale muon RLA with two-pass return arcs. A path to an 'electron model' is outlined: scaling 3.6 GeV muon RLA to 18 MeV model and replacing 200 MHz RF with a 1.5 GHz CEBAF cavity

SCALED DOWN ELECTRON MODEL

Here, we propose a straightforward test of this concept by scaling the above GeV-scale muon RLA design for electrons. Scaling muon momenta by the muon-to-electron mass ratio (~ 200) yields a scheme, in which a 4.5 MeV electron beam is injected into the middle of a 3 MeV/pass linac with two double-pass return arcs and then is accelerated to 18 MeV in 4.5 passes.

The second scaling, would involve replacing the original low frequency (200 MHz) RF, required to accommodate inherently long muon bunches, with readily available high frequency CEBAF RF (1.5 GHz). All spatial dimensions including the orbit distortion would then scale down by the ratio of the two frequencies (factor of 7.5). As a consequence, the scaled down electron model would fit in a modest test cave of 25 by 7 meters.

For the remainder of this paper, we will describe the principle of multi-pass arc architecture, a possible magnet design and field requirements, as well as a complete conceptual RLA design.

MULTI-PASS ARC OPTICS

Design Concept

The droplet arc design consists of super cells, which are required to satisfy the following basic conditions at two discrete energies (6 and 12 MeV):

- Each super cell exhibits periodic solutions for the orbit and the Twiss functions.
- At the beginning and at the end of each super cell, the periodic orbit offset, dispersion and their slopes are all zero.

The first condition ensures that the super cells bending in the same direction are optically matched while the second one provides optical matching of the cells bending in the opposite directions. The second condition also implies that the beam is centered in the linac and that the linac is dispersion free.

Linear Optics

Optics solution satisfying the above conditions can be obtained using only same-direction bends, which significantly shortens the arc (by almost a factor of 3) compared to the conventional linear NS-FFAG lattice [3], which involves alternating the 'outward-inward-outward' bends in the underlying triplet structure. We make the bending angle of each combined function magnet variable with a constraint that the bending angles of all magnets in a super cell must add up to the required fixed total bend. Such a solution combines compactness of the design with all the advantages of a linear NS-FFAG [5], namely, large dynamic aperture and momentum acceptance essential for large-emittance muon beams, and no need for a complicated compensation of non-linear effects, simpler combined-function magnet design with only dipole and quadrupole field components. We use the maximum possible bend of 60° per super cell to accommodate the largest possible number of magnets in the super cell and therefore to have the largest number of free parameters for optics tuning. The extra free parameters were used to control the maximum values of the orbit deviation, and beta functions and dispersion. Figure 2 shows solutions for the periodic orbit and dispersion of the outward-bending super cell at 6 and 12 MeV/c, respectively. An inward-bending super cell is identical to the outward-bending cell except that its bends are reversed. The super cell consists of 24 combined function magnets with dipole and quadrupole field components. The magnets are 6.5 cm long and are separated by 3 cm gaps. The total arc length is 16 m. In terms of magnetic field requirements, the maximum needed dipole field is about 650 Gauss while the maximum quadrupole gradient is about 850 Gauss/cm.

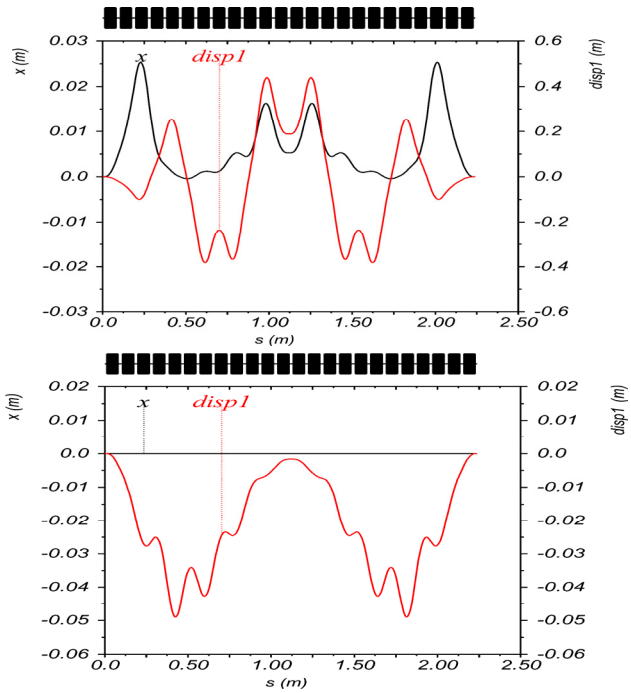

Figure 2: 6 MeV (top) and 12 MeV (bottom) periodic orbits and dispersions of the outward bending super cell.

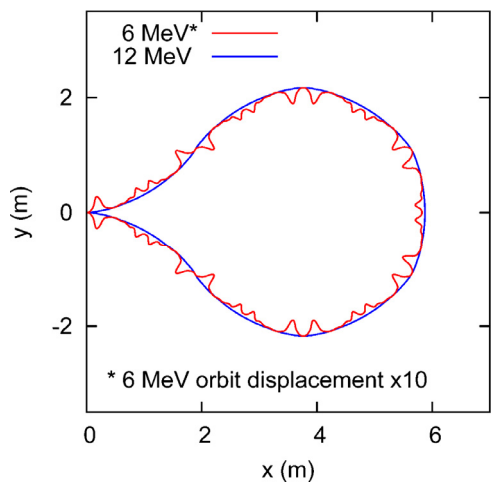

Figure 3: Layout of the 6 and 12 MeV reference orbits.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Figure 3 illustrates geometric layouts of the 6 and 12 MeV closed periodic orbits. Note that because of the varying bending angles, the arc is not perfectly circular. The largest orbit separation occurs only in a small number of magnets and is caused by the necessity to spread/recombine the different momenta orbits at the beginning of the arc.

ARC TO MULTI-PASS LINAC MATCHING

As a proof-of-principle, one can design a multi-pass linac with energy gain of 3 MeV per pass, which is matched by-design to previously described two-pass arcs for both passes simultaneously. As described in [4] the above multi-pass linac optics can be accomplished by appropriately 'tailored' focusing profile along the linac - the strengths of individual linac's fixed-field quadrupoles. Here, they are treated as free parameters used to control the beta functions at linac's ends for all consecutive passes. The proof-of-principle solution [6] was designed by modifying the so-called bi-sected linac profile [4], where the quadrupole strengths increase linearly (in a mirror-symmetric fission) from the linac's center toward the ends.

MAGNET DESIGN AND FIELD QUALITY

Design Choice

Each of 7 super-periods required to complete the droplet arc is configured with 24 individual combined function magnets: 6.5 cm in length and with 5 cm of the horizontal aperture. These magnets will be mounted on a rectangular vacuum chamber; 2.3 meter long and shaped into a 60^0 arc. As for the magnet design, a combined function Panofsky quadrupole with integral dipole windings, similar to Jlab's FEL design [7], provides a very attractive solution for an independent electrical control of both the magnetic field and its gradient.

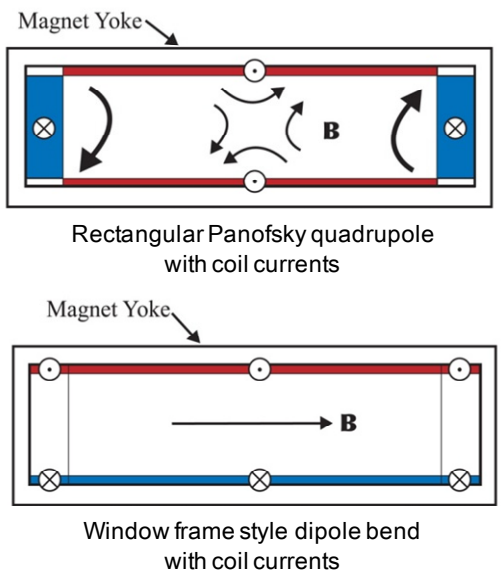

Figure 4: Quadrupole and Dipole Current Flows [7].

Relatively weak magnets, satisfying our strength requirements, can be built 'flattened' with no compromise to their field gradient uniformity and have a window frame-like yoke that, at full quadrupole current, is not near saturation [7]. Superposition of a dipole onto the Panofsky quad adds current to one of the four coils and subtracts it from its opposing coil. This is accomplished by adding variable current coils to the vacant corners of the original Panofsky design as illustrated in Fig. 4.

Field Quality Requirements – Error Sensitivity

The two-pass arc optics, illustrated in Fig. 2, was checked for error sensitivity. We launched a mini Monte Carlo simulation by creating 25 virtual arc lattices with statistically distributed magnet mis-alignment (200 μm, rms, displacement error) as well as magnet mis-powering (with 10^{-4} relative field error, rms) for both the dipole and quadrulpole components. Using pairs of horizontal and vertical correctors placed after each magnet the resulting orbit deviation was steered back to to the design orbit within 20 μm level, which corresponds to the accuracy of the orbit measurement (BPM accuracy).

CONCLUSIONS

We propose a straightforward test of a GeV scale muon RLA by scaling the muon design for electrons (via the muon-to-electron mass ratio). Presented 'electron model' features: a 4.5 MeV electron beam injected at the middle of a 3 MeV/pass linac combined with two double-pass return arcs. The beam is accelerated to 18 MeV in 4.5 passes. All spatial dimensions of the full scale RLA are shortened by a factor of 7.5, as a consequence of using a readily available 1.5 GHz CEBAF cavity, rather than the original 200 MHz RF. The footprint of a complete RLA 'demo' fits in an area of 25 by 7 m. The scheme utilizes only fixed magnetic fields including injection and extraction. Engineering design and fabrication of linear-field combined-function magnets does not seem to present a challenge [7].

IN-SITU MEASUREMENT OF BEAM-INDUCED FIELDS IN THE S-BAND ACCELERATING STRUCTURES OF THE DIAMOND LIGHT SOURCE LINAC

C. Christou
Diamond Light Source, Oxfordshire, UK

Abstract

Higher order modes induced by beam in the accelerating structures of the Diamond Light Source pre-injector linac have been directly measured using directional couplers in the high-power waveguide network. These modes are compared with an electromagnetic simulation of the structures and the use of the higher order modes for alignment of the beam to the structure is investigated.

DETECTION OF INDUCED FIELDS

Much work has been done on the analysis of wake fields using dedicated test accelerators, particularly at the ASSET facility in SLAC [1, 2] and the SBTF at DESY [3]. Extension of the method to a low-energy device in a user facility with minimal disturbance to the installed hardware offers scope for cost-effective physics studies and diagnostic development. In the work presented here, wake fields and structure higher order modes are studied in the Diamond Light Source pre-injector linac. This device uses two 5.2 m DESY linac II-type accelerating structures to generate a 100 MeV electron beam suitable for injection into the booster synchrotron [4]: the layout of the linac is shown in Figure 1. The structures are normal-conducting constant gradient designs, operating in the $2\pi/3$ mode at 3 GHz. Each structure is independently powered by a TH2100 klystron amplifier which provides a 5 µs pulse of around 20 MW five times per second in normal operation.

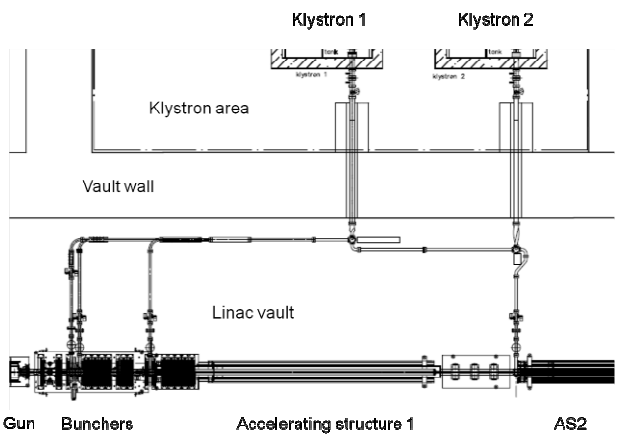

Figure 1: The Diamond linac

Directional couplers, manufactured by Spinner, are mounted in the waveguide network at the exits of the klystrons and at the windows of the accelerating structures. These couplers measure forward and reverse power and monitor operation and protect the klystrons. If either one of the klystrons is left unpowered, the beam can drift through the accelerating structure and the directional coupler can be used as a monitor of the beam-induced wake fields in the structure.

Signals were discernible on an Agilent DS091304A 13 GHz-bandwidth oscilloscope for beam drifting through bunchers and through both accelerating structures in single-bunch mode and in multibunch mode. The most intense signals were obtained for high charge (1 nC) single bunches drifting through the second accelerating structure at 47 MeV (corresponding to the standard operating gradient of the first accelerating structure) with good temporal bunching; Figure 2 shows an oscilloscope trace recorded for these parameters.

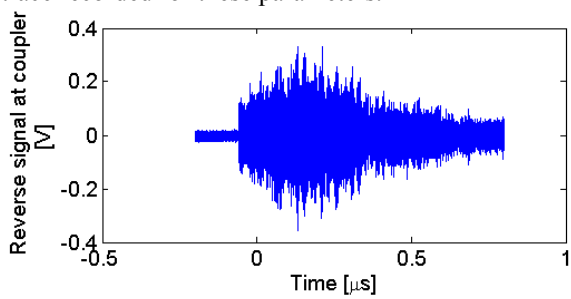

Figure 2: Passage of single bunch detected at the directional coupler in the non-powered RF line

There is rich spectral content to this induced signal, as can be seen in Figure 3. Two measurements are shown in this figure, recorded with and without beam in the structure, establishing that the most intense peaks in the spectrum are the third and fourth harmonics of the 3 GHz RF power fed to the first accelerating structure. The fundamental 3 GHz signal is not transmitted from structure to structure.

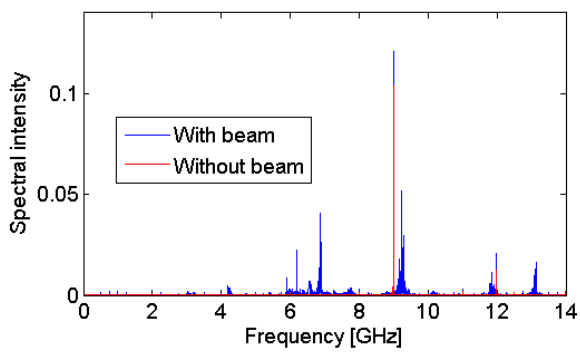

Figure 3: Frequency content of induced pulse

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The wake can also be differentiated from the RF noise by making a small change to either the master oscillator frequency or the cavity temperature and observing that the RF signals shift only with frequency and the wake signals shift with only temperature, as shown in Figure 4.

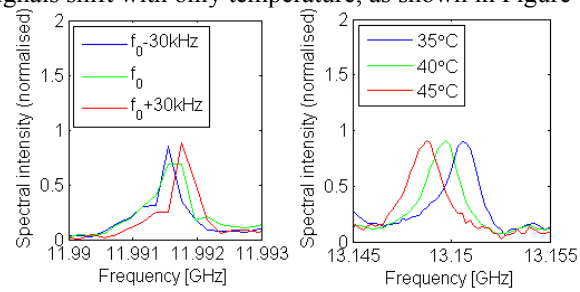

Figure 4: Effects of RF frequency and structure temperature change. The fourth harmonic of the RF frequency changes with frequency (left) and the wake-induced signal changes with cavity temperature (right).

STIMULATION OF HIGHER ORDER MODES

The trajectory of the beam in the accelerating structures can be controlled by steerer magnets located upstream of both structures. Scanning the current of the final vertical steerer before the second accelerating structure and recording the spectrum at each current gives the plot shown in Figure 5.

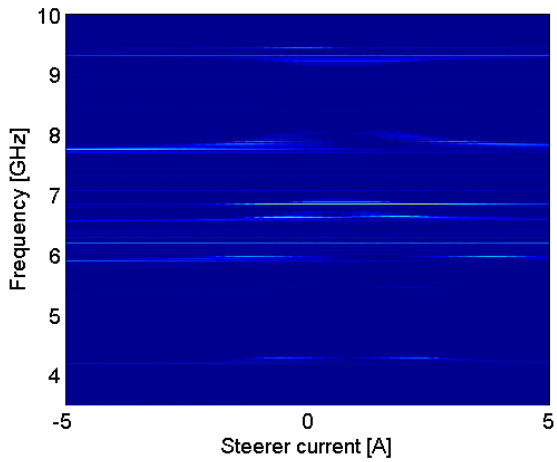

Figure 5: Frequency spectra explored by scanning steerer

Several points are immediately apparent from this plot, firstly that the frequency spectrum consists of bands rather than lines, and that these bands shift in frequency as the steer is applied. This effect arises from the constant-gradient design of the structure, requiring a tapering of cell dimensions along the structure to compensate for the loss in RF power as the pulse propagates along the structure: although the fundamental accelerating mode remains constant along the structure, the higher order modes are free to drift. Secondly, the monopole and multipole modes are easily distinguished, as the higher order azimuthal modes have a null on axis and so are absent from the spectrum when the beam is well aligned, with steerer current of approximately 1 A in this case, and grow as the beam leaves the axis.

The most intense modes are given in Table 1: this gives the lower and upper frequency limits of each band, and identifies each mode as a monopole or multipole mode.

Table 1: Classification of intense modes

Mode type	From [GHz]	To [GHz]
Multipole	4.19	4.35
Multipole	5.38	5.50
Multipole	5.90	5.98
Multipole	6.57	6.72
Monopole	6.78	6.92
Multipole	7.69	8.05
Monopole	9.13	9.32
Multipole	9.43	6.46
Monopole	11.78	11.98
Monopole	13.04	13.13

IDENTIFICATION OF MODES

Categorisation of all wake field modes is numerically intensive as the observed signal arises from a system of 156 coupled oscillating cells, each of different dimension, with TM, TE, TEM and hybrid modes all possible. To reduce the complexity of the calculation, CST Microwave Studio was used to model cells at the entrance, middle and exit of the linac; in each case studying resonant modes of the single cell, and coupling in structures of two, three and six cells of the same type. Dispersion curves in each case were then calculated by interpolating between the calculated modes for each cell type, and the behaviour of the cells was assumed to vary smoothly along the structure.

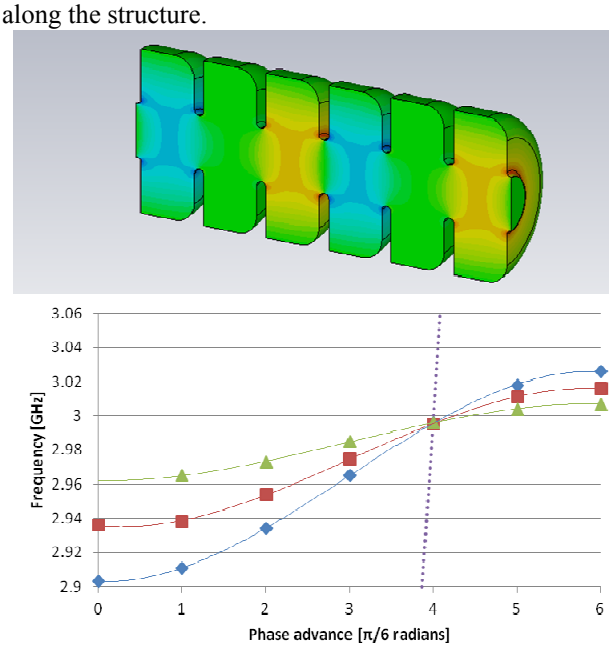

Figure 6: Simulation of accelerating mode

The validity of this approach is demonstrated in Figure 6, in which the TM01 accelerating mode is calculated for the three cells at the beginning (blue), middle (red) and

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

end (green) of the structure, and is shown to intersect with the $v = c$ light line (dotted), representing the relativistic electron bunch, at a phase advance of 4π over the 6 cells of the model, that is $2\pi/3$ radians per cell, near 3 GHz.

The first intense mode observed is a TM11-like mode shown at the top of Figure 7. This is a dipole mode, and so the spectrum shows a null for well steered beam. The dispersion curve intersects the light line from 4.15 GHz to 4.42 GHz, with the modes up to 4.35 GHz exiting via the first cell, and modes above that trapped and invisible. Agreement with the observed spectrum is good.

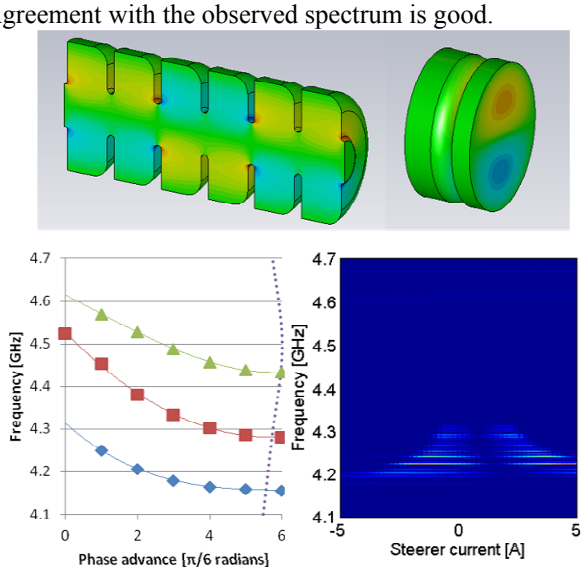

Figure 7: Simulation, dispersion curve and measurement of TM11-like mode

This approach was repeated for all modes up to the second monopole TM02 mode near 7 GHz. Results are shown in Figure 8; agreement with the model is good.

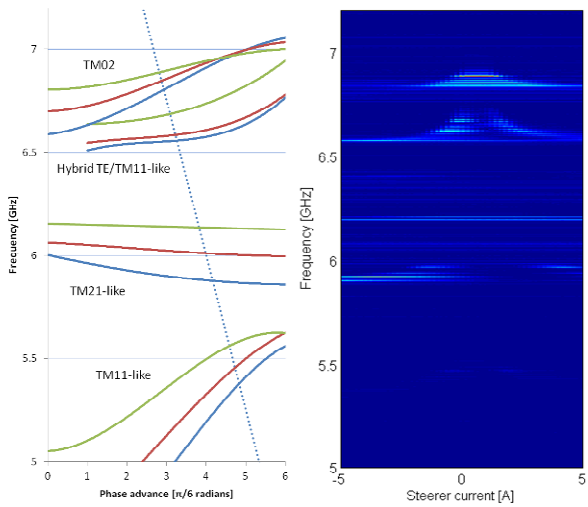

Figure 8: Scaling of dipole mode intensity in the buncher

The most intense spectral features can be clearly identified; although categorisation is difficult because of mode hybridisation and the degeneration of the simple pillbox modes in the shaped cell (for example the branches of the TM11-like mode at 4.3 and 5.5 GHz).

INDUCED FIELDS AS A DIAGNOSTIC

The trajectory-dependence of the dipole mode intensities allow the accelerating structures to be used as cavity BPMs. The absence of dipole modes in a well aligned beam is clear, leading to the possibility of an automatic multi-steerer alignment routine for the linac. A simple proof-of-principle experiment was carried out in which two steerers were scanned at the entrance to the second structure, and the ratio of the total integrated intensities of the hybrid dipole mode and monopole mode between 6.5 and 7.0 GeV was used as a measure of beam alignment. This ratio is plotted in Figure 9. The optimal position is clear, even without the ability to discriminate between horizontal and vertical position.

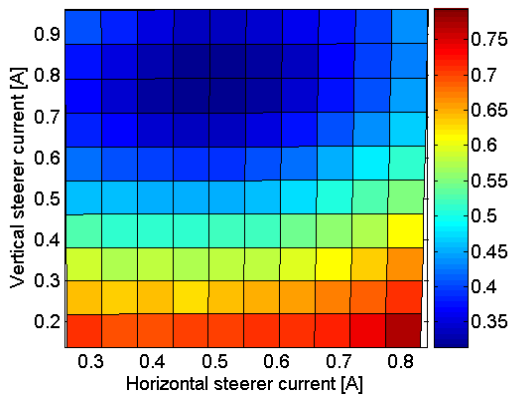

Figure 9: Optimisation of beam steer through the accelerating structure. The colour indicates the ratio of dipole to monopole intensity.

CONCLUSIONS

The directional couplers installed on the Diamond linac have been used to measure higher order modes in the structures, and CST Microwave Studio models have been used to unambiguously identify the spectral content. This simple measurement offers the opportunity to study accelerating structures in situ, and to optimise linac performance by using the accelerating structures as cavity BPMs. Use of the structures as both accelerators and position monitors offers a potential reduction in accelerator complexity and total length in future linacs.

Abstract

The production of the 103 superconducting accelerating modules for the European XFEL is an international effort. Institutes and companies from seven different countries (China, France, Germany, Italy, Poland, Russia and Spain), organized in 12 different work packages contribute with parts, capacity for work and facilities to the production of the modules. Currently the series production of the individual parts started or is approaching. Personnel is trained for the assembly and testing of parts and as well for the complete modules. Here we present an overview and the status of all these activities.

INTRODUCTION

In the early 1990s the Tera Electronvolt Superconducting Linear Accelerator (TESLA) collaboration started working on the development of a pioneering superconducting accelerator technology [1]. The concept has proved so successful that it was also chosen for the European XFEL [2].

Each superconducting accelerating module for the European XFEL consists of several parts provided by different work packages (WPs). The core parts are the superconducting 1.3 GHz nine-cell cavities provided by WP04. They are used for beam acceleration. For beam focusing and steering each module contains a superconducting quadruple magnet from WP-11. A beam position monitor produced by WP-17 is attached to the magnet. The rf power is fed into the cavities via power couplers delivered by WP-05. The frequency tuners from WP-07 are used for keeping the cavities on resonance. Bellows connecting the individual cavities are part of the WP-08, the 'cold vacuum', likewise the coupler vacuum system. WP-06 organizes the Higher Order Mode (HOM) and pick up (PU) antennas. All these parts are installed inside the cryostat. The cryostat is also called 'cold mass' and part of the WP-03.

The final assembly is done in the responsibility of WP-09 (string assembly) and WP-03 (module assembly) at CEA, Saclay and the final module operation test is performed by WP-10 at the Accelerator Module Test Facility (AMTF) at DESY, Hamburg. Proper rf control in the later accelerator will base on properties measured during the modules tests. This item is the task of WP-02. Before transportation into the XFEL tunnel for installation, each module receives a waveguide system tailored by WP-01 to the cavity performances.

Providing infrastructure and support needed for parts tracking, quality control and nonconformity handling for all these activities is the task of the WP-40.

SUPERCONDUCTING CAVITIES

More than 800 superconducting TESLA type cavities [3] will be used for the European XFEL. They are mechanically manufactured and surface treated [4] by the two companies Ettore Zanon (EZ) and Research Instruments (RI) and delivered to DESY ready for vertical testing in the AMTF by a Polish team from IFJ-PAN, Krakow. Always eight cavities with similar performance will be put together and shipped to CEA for the string and module assembly.

Both companies manufactured reference cavities which have been surface treated at DESY and vertically tested. These cavities showed promising maximum gradients above 28 MV/m. They are used for the qualification of the companies' infrastructure created for the cavity treatment (clean room, degreasing and ultrasonic cleaning, HPR, (electro) chemical surface treatment, annealing furnaces, slow venting slow pumping systems etc.). The commissioning of the infrastructure is ongoing. The series delivery to DESY will start in November (RI) and in December (EZ).

COLD MAGNETS

The accelerating modules of the XFEL linac will be equipped with one combined superconducting magnet [5] per module, which consists of a main superferric quadrupole for focusing and two nested corrector dipoles for beam steering. The magnet series production is being done under the supervision of CIEMAT in Spain: ANTEC produces the magnets while Trinos Vacuum Projects takes care of the helium vessel, assembly and tests (electrical, pressure and vacuum). The magnetic measurements are done at DESY as a common German and Polish in-kind contribution. The conduction cooled current leads are produced at CECOM in Italy under DESY supervision while the copper coating of the beam pipe is being done by Galvano-T in Germany.

The three pre-series units have been successfully produced and tested. Green light has been given to series production in June, 2012.

POWER COUPLERS

LAL Orsay contributes to the XFEL project with the delivery of 800 power couplers [6, 7] to CEA for the assembly of 100 accelerator modules. The tasks consist of the industrial monitoring and coupler quality control at the production sites and the rf conditioning and testing at the LAL campus [8].

A 70 m^2 clean room used for the coupler preparation at LAL is under construction. The 5 MW power rf station has been installed for the conditioning of 8 couplers simultaneously. The industrial production by Thales and RI is in the last process validation phase and the mass production start is scheduled for the end of the year.

FREQUENCY TUNERS

The goal of the XFEL cold tuning system [2] is the adjustment of the cavity frequencies to the accelerator rf frequeny with a resolution better than 1 Hz. The XFEL slow tuner is based on the TTF/SACLAY tuner [9]. This tuner design is working in the TTF Linac since 1997 with high reliability. In addition, the tuning system will also compensate Lorentz Force De-tuning (static and dynamic) using piezoelectric actuators [3].

All the orders for the tuner parts have been made and the fabrication is in good progress. The drive units and piezo systems will be checked by industry prior to delivery. The first full tuner systems are available at CEA. An automatic system has been developed to verify the correct tuner installation during the string and module assembly.

BEAM POSITION MONITORS

Beam steering through the linac requires proper information on the beam position. It is provided by one beam position monitor (BPM) per module. Two different types are used, 1/3 will be re-entrant and 2/3 button BPMs [10]. Both types have different advantages and disadvantages.

The ramp up of the BPM series production is in time with the magnets arriving DESY and the last one will be produced and available mid-2013. The individual production rates of both BPM types are under investigation.

BEAM AND COUPLER VACUUM

The cavities are connected via Copper coated bellows without RF-shields. A novel sealing system has been developed [11]. It consists of rigid Nb-Ti flanges EB welded to the Niobium cavities and massive aluminum rings as gaskets. The bellows are being fabricated by BINP, Novosibirsk and delivered to CEA after particle cleaning at DESY [12].

The production of these units has been started. The first components have been delivered for the installation into the pre-series modules.

The rf power input coupler has two ceramic windows [6]. This design enables the complete closure of the cavity in the clean-room by mounting the coupler up to the first window, thus preventing any contamination during further assembly of the module. Between the two windows a common vacuum for all eight couplers is established by a sputter ion pump and a Titanium sublimation pump (TSP).

The coupler pump line systems are fabricated at BINP. After particle-cleaning at DESY, the items are delivered to CEA. The TSP and the sputter ion pumps are purchased by DESY and delivered to CEA. The delivery of the components started.

HOM AND PU ANTENNAS

HOMs are excited by beam and can spoil the beam quality [13]. Therefore, every cavity contains two HOM couplers, one at each end, to filter these modes and couple them out via coaxial antennas and cables transferring them to loads, located outside the module [14]. In addition, each cavity is equipped with a PU antenna taking a small portion of the rf power for the rf control electronics regulating amplitude and phase of the accelerating rf mode.

NCBJ (former INS-Swierk) provides, as in-kind contribution, 1616 HOM and 808 PU antennas and all cables and feed-throughs for their output lines. More than 200 sets are already on stock. They will be followed by 105 sets delivered every 3 months.

CRYOSTATS

The TESLA cryostat technology [15] incorporates the string of accelerating cavities and a cold focusing magnet together with all cryogenic process lines avoiding separate cryo-lines. Cryogenic boxes at the beginning and the end of a chain of several modules are used for the helium supply. This leads to a compact arrangement of the accelerating cavities and comparatively low cryogenic losses and is well suited for longer linacs like the XFEL.

The cryostats for the XFEL [16] are provided by IHEP, Beijing and EZ. The cryostat delivery from EZ to CEA already started with a rate of two per month. The IHEP cryostats will first arrive at DESY before being transported to CEA. IHEP starts the cryostat delivery in October.

STRING AND MODULE ASSEMBLY

An assembly infrastructure, called the 'XFEL Village', has been set up at CEA and is used by an industrial operator for the integration of the accelerator modules under CEA supervision. Two lines of seven workstations, designed to produce one module per week, will gradually integrate the different components of the module over seven weeks. Work will begin in the 112 m^2 ISO4 clean room with the assembly of the cold coupler parts to the cavities, and then the cavities and quadrupole package in a string. After string roll-out, five workstations are designed for cryostat integration, cavity alignment, ISO5 assembly of power coupler parts [17] and final inspection and shipment.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The industrial operator contract has been awarded to the company ALSYOM. The transfer of knowledge will occur through the assembly of three pre-series modules until March 2013 when ramping up the assembly rate will start with the series modules.

MODULE OPERATION TESTS

After transportation [18], the accelerator modules will be received at the AMTF by the Polish team from IFJ-PAN, Kraków. The team performs the complete test cycle starting with the entrance inspection and installation of each module at one of the three module test stands operating in parallel. The functional test includes the cool down to 2 K, the measurements of the cryogenic losses and the rf operation of all cavities to determine all required parameters like the maximum cavity gradients and the levels where field emission starts [19, 20]. After warm up the modules are handover to the next work package for wave guide installation.

The training of IFJ-PAN personnel for the assembly and testing of the modules is actually done at DESY's Cryomodule Test Bench (CMTB) and is well advanced, likewise the software and testing procedures developed by the team.

RF CONTROL TESTS

Stable rf field provided by the digital rf control is essential for the XFEL electron beam quality. Good knowledge of parameters permits the adjustment of the rf control for optimal performance. At the AMTF the subsequent parameters will be determined: the individual cavity quench voltage, the range and characteristic of the cavity slow tuning motors, the performance of the piezo actuators and sensors, the sensitivity to microphonics, the identification of other fundamental modes, the performance and characteristics of the cavity loaded Q versus the coupler motor position and the Lorentz force detuning compensation. Finally, nominal module operation will be established. A full description of the LLRF tests is given in [21].

WAVE GUIDE INSTALLATION

The variation of the cavity performance of each module will be accommodated by tailoring the rf power distribution via the wave guide system [22]. By doing so, the average accelerating voltage provided by each module is optimized. The wave guide systems will be assembled and tested in a separate infrastructure in the AMTF hall and also attached in the AMTF to the modules before the installation in the XFEL tunnel.

INFORMATION AND PROCESS SUPPORT

Module integration needs reliable procedures for gathering, processing and archiving the complete mandatory fabrication information. A solution has been established based on the concepts of tracking and tracing [23] and with the help of a central collaboration and documentation platform, the DESY Engineering Data Management System [24].

SUMMARY AND OUTLOOK

The work on the XFEL accelerating modules enters now the phase when all the series productions of the different components need to start to supply the final assembly at CEA with sufficient parts. Deviations of some components and infrastructure installations from the original schedule are addressed together with corrective measures. Furthermore, the preparation phase for the module series assembly started and the training of the personnel performing the module operation tests is well advanced. In all, quite some international machinery starts working for the production of the XFEL accelerating modules.

ACKNOWLEDGEMENTS

The authors acknowledge the significant contributions from numerous colleagues at all institutes joining the consortium for the construction of the European XFEL cold linac. Many people from industry are contributing to this effort as well.

[2]College of William and Mary, Williamsburg, VA 23187

Abstract

Topographic structure on Superconductivity Radio Frequency (SRF) surfaces can contribute additional cavity RF losses describable in terms of surface RF reflectivity and absorption indices of wave scattering theory. At isotropic homogeneous extent, Power Spectrum Density (PSD) of roughness is introduced and quantifies the random surface topographic structure. PSD obtained from different surface treatments of niobium, such as Buffered Chemical Polishing (BCP), Electropolishing (EP), Nano-Mechanical Polishing (NMP) and Barrel Centrifugal Polishing (CBP) are compared. A perturbation model is utilized to calculate the additional rough surface RF losses based on PSD statistical analysis. This model will not consider that superconductor becomes normal conducting at fields higher than transition field. One can calculate the RF power dissipation ratio between rough surface and ideal smooth surface within this field range from linear loss mechanisms.

INTRODUCTION

RF loss induced by roughness is considered in many RF components, such as micro strip transmission line, wave guide and RF resonator. It can be understood as the RF electromagnetic field penetrates the surface and there the induced current will pass and cause RF loss. [1] However, in a RF wave view, the incident wave is reflected, scattered and absorbed by the rough surface. Inside of a resonator, the reflected, scattered wave contributes to standing wave field, while the absorbed RF wave is attributed to the RF surface loss. These two perspectives may both be used to describe the same RF loss.

In a resonator, only several specific RF standing wave modes can exist to meet the boundary condition which is the resonator geometry. The electric and magnetic field at one location is combination a of EM components of those plane waves. Within the resonator, E and M are separated in space and interchange their energy over a distance. Thus the peak E and M field are always not the same location. With special EM setup, TE, TM, TEM are used to describe the EM field direction, if presumed direction is beam axis. In some sense, it is very tedious and difficult to expand the field into plane wave expansion. If so, the incident direction should also be from all directions. Therefore, a RF loss calculation method is required and independent of direction. It also covers all frequencies or wavelengths.

METHODOLOGY

A rough surface will cost more RF loss. [2] One simple reason is that the surface current have more current path. In another word, the RF wave as more radiation absorption surface. This RF loss will contribute into power consumption and aggravate the quality factor.

If we consider a 2D random rough surface Z= f(x) in Fig.1. We can expand the magnetic field into Fourier series as in x and z direction. [3]

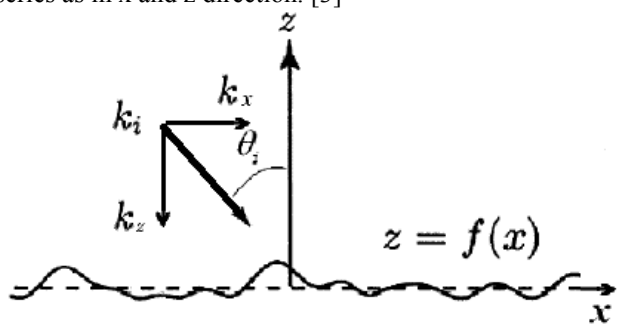

Figure 1: A plane wave incident impinging on a rough surface with incident angle θ_i.

$$\psi(x,z) = \int_{-\infty}^{\infty} dk_x \exp(-jk_x x + jk_{1z} z)\,\tilde{\psi}(k_x)$$

Where $k_{1z} = \sqrt{k_1^2 - k_x^2}$ and $k_1 = \frac{1-j}{\delta}$. Here δ is the skin depth $\delta = \sqrt{\frac{2}{\omega\mu\sigma}}$ and σ is the superconducting conductivity. The physics behind this equation is that the total magnetic field is combination of field component at each spatial wavelength. In another word, the total magnetic field can be expanded into magnetic contribution from each wavelength in spatial frequency.

If we use a second order small perturbation methods, setting

$$\tilde{\psi}(k_x) = \tilde{\psi}^{(0)}(k_x) + \tilde{\psi}^{(1)}(k_x) + \tilde{\psi}^{(2)}(k_x)$$

In first approximation, a fixed constant magnetic field H_0 is applied on the surface. Thus, the equation above becomes:

$$H_0 = \int_{-\infty}^{\infty} dk_x \exp(-jk_x x + jk_{1z} f(x))\,\tilde{\psi}(k_x)$$

Basically, we have done a Fourier transform to redistribute the magnetic field into each surface spatial wavelength in x direction.

By balancing this equation to second order, we obtain:

*Work supported by Jefferson Science Associates. xuchen@jlab.org

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

$$\tilde{\psi}^{(0)}(k_x) = H_0\delta(k_x)$$
$$\tilde{\psi}^{(1)}(k_x) = -jk_1H_0F(k_x)$$
$$\tilde{\psi}^{(2)}(k_x) = H_0\int_{-\infty}^{\infty}dk_x'F(k_x-k_x')F(k_x')\left(-k_1k_{1z}'+\frac{k_1^2}{2}\right)$$

For now, we have calculated the RF magnetic field on this given surface. The power absorbed by the conductor, for a given width w in y direction and length L in x direction, can be calculated from the Poynting vector.

$$P_a = \frac{w}{2\sigma}\mathrm{Re}\int ds\frac{\partial\psi}{\partial n}\psi^*$$

We simplify the results:

$$\langle P_a\rangle = \frac{wL}{2\sigma\delta}|H_0|^2\left\{1+\frac{2h^2}{\delta^2}\left[1-\frac{\delta}{h^2}\int_{-\infty}^{\infty}dk_xW(k_x)\mathrm{Re}\sqrt{k_1^2-k_x^2}\right]\right\}$$

In order to get rid of the external field, we normalize the power dissipation with that of a smooth surface.

$$\frac{\langle P_a\rangle}{P_{a,\mathrm{smooth}}} = 1+\frac{2h^2}{\delta^2}-\frac{4\pi}{\delta}\int_0^{\infty}dk_\rho\left\{k_\rho W_{2D}(k_\rho)\mathrm{Re}\sqrt{\frac{-2j}{\delta^2}-k_\rho^2}\right\}$$

$W_{2D}(k_\rho)$ is the 2D PSD from an isotropic surface.

Researcher have combined TM and TE wave mode into this equation into a 2D problem. They also avoid the assumption that surface field is a constant.

One should note:

1. The RMS and decay parameters (penetration depth) ratio, h/δ, is critical for characterizing the increased losses.

2. Third term reduces to h^2/δ^2, when the k_ρ is small. The second/third term have net contribution if $1/\delta$ and k_ρ are comparable.

3. Generally, higher $W_{2D}(k_\rho)$ brings additional loss.

APPLICATION TO SRF SURFACES

To obtain more accurate RF loss ratio, one needs to extend the PSD into as broad a frequency range as possible. Since all characterization method shave cut-off frequencies, one can at most get an extended PSD. The recent extended frequency range is 1/1.2 cm^{-1}–1/10 nm^{-1}, over 6 decades, with white light interferometry and atomic force microscopy. Because the magnetic field is expanded into horizontal spatial wavelength, the PSD frequency should cover the RF wavelength and beyond. Though an approximation methods is introduced by using Inverse Abel transforms to extend limited range, but obtaining 1D PSD with wider frequency range could improve later calculation accuracy.

$$<W(k_\rho)^{2D}>=-\frac{1}{\pi}\times\int_{k_\rho}^{\infty}\frac{dk_\rho}{\sqrt{k_x^2-k_\rho^2}}\frac{d}{dk_x}<W(k_x)^{1D}>$$

$$<W(k_x)^{1D}>=2\times\int_{k_x}^{\infty}\frac{k_\rho dk_\rho}{\sqrt{k_\rho^2-k_x^2}}<W(k_\rho)^{2D}>$$

This transformation also permits the transformation of the high-frequency behavior of the spectra of one dimensionality to be transformed into the high-frequency behavior of the other without knowledge of their low-frequency behavior.

We investigate SRF surfaces with current polishing methods and materials polished are large/fine/single grain Nb sheets. Buffered chemical polishing, electropolishing and mechanical centrifugal barrel polishing samples are characterized by Atomic Force Microscopy (AFM) and White light interferometry (WLI). Note that these two characterizations have different lateral resolutions and scan scopes which determine the spectral frequency ranges.

1D averaged PSD is calculated by following the routine introduced previously. [4] Such routine includes proper detrending, windowing and averaging.

In this study, the R_q and PSD are used to derive power ratio. Rq value from 4 different locations on each sample is averaged and summarised in Table 1.

Table 1: Averaged R_q with AFM and WLI

Samples	Single crystal		"Standard" fine-grained			
Treatment	After30 µm BCP	Nano polished	+100 µm BCP	+50 µm EP	Centrifugal Barrel Polishing (CBP)	
					Fine Grain	Large Grain
Atomic force microscopy ~5×5µm						
R_q(nm)	1.99	2.84	4.89	4.40	2.76	1.20
Atomic force microscopy ~100×100µm						
R_q(nm)	7.05	13.5	392.90	74.30	70.8	7.71
White light interferometry ~234×312µm (20x magnification)						
R_q (nm)	35.7	1.63	1500.4	291.7	151.8	13.5
White light interferometry ~930×1244µm(5x magnification)						
R_q (nm)	391	5.24	2008.5	642.8	335.5	49.0

One can generalize that Rq value decrease from BCP>EP>CBP Large grain> CBP Fine grain> Single crystal>Nanopolishing samples.

Averaged 1D PSD from AFM/WLI are combined in Fig.2.

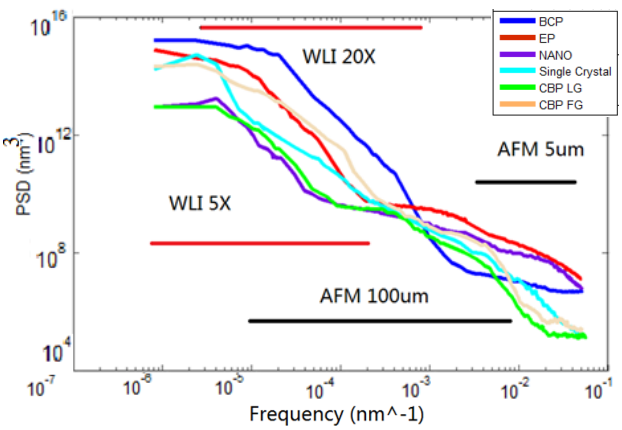

Figure 2: Joint 1D PSD models from AFM/WLI are shown and the characterization frequency domains are indicated.

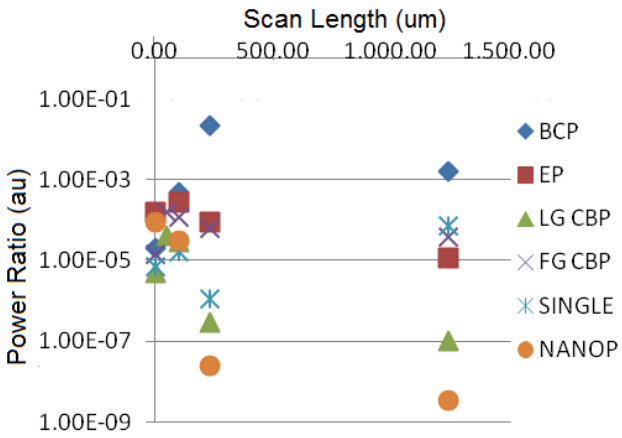

Figure 3: Power Ratio calculated from 1D PSD.

The power ratio is shown in Fig.3 and by inverse Abel transform, the 2D PSD are shown in Fig.4.

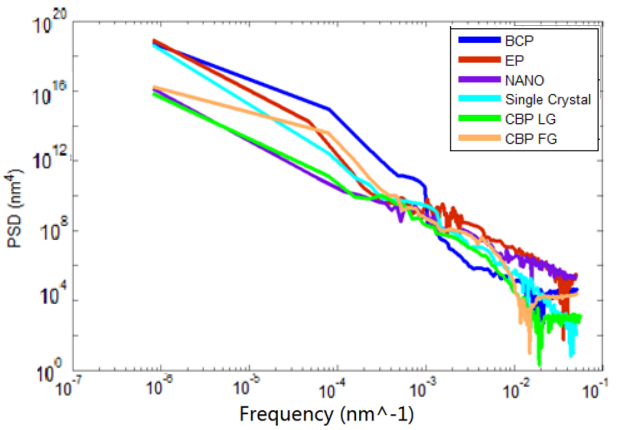

Figure 4: 2D PSD calculated from various surfaces.

Power ratio index are illustrated in Fig.5.

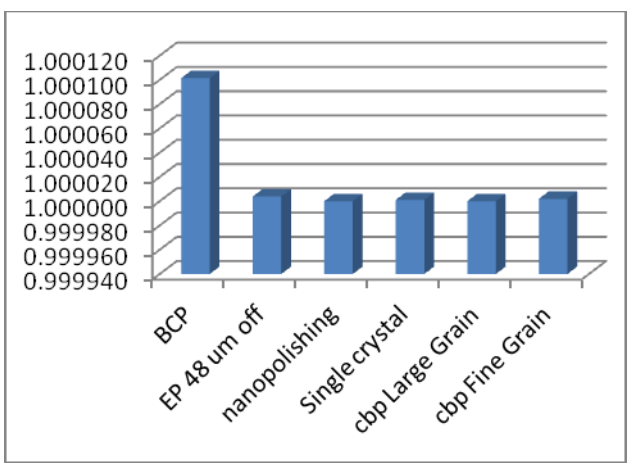

Figure 5: Power Ratio from 2D isotropic PSD.

BCP surface show higher ratio, but other surfaces suggest almost the same close to 1.

DISCUSSION

One can see from power ratio equation that the last term is an integration of 2d PSD.

$$\frac{\langle P_{a,\mathrm{rough}}\rangle}{P_{a,\mathrm{smooth}}} = 1 + \frac{2h^2}{\delta^2} - \frac{4\pi}{\delta}\int_0^\infty dk_\rho \left\{ k_\rho W_{2D}(k_\rho)\,\mathrm{Re}\sqrt{\frac{-2j}{\delta^2} - k_\rho^2} \right\}$$

Without the Re(…), the integrand is simply the square of RMS height. One can infer that if the k_ρ is small enough compared with $2/\delta$, then the Re(…) term reduced into $1/\delta$. In that limit the second and third terms cancel each other. The total power ratio becomes one. This gives substantiates the interpretation that features at larger wavelength have less RF power loss than the small high frequency features. Another understanding is that only features with lateral extent comparable to the penetration length give a significant effect on the additional power loss ratio. Applying this analysis to variously prepared niobium surfaces typical of those in SRF cavities, we find that linear RF losses depend negligibly on roughness for any of the characteristic surfaces considered. On the other hand, SRF materials are particularly susceptible to non-linear and temperature-dependent losses. The non-linear losses are reflected in the observed Q drop with increasing surface magnetic field. We are examining the influence of topography on such losses separately [5].

CONCLUSION

Spectral study suggested that surface roughness doesn't contribute much in the linear RF loss, because current practical surface a smooth enough at a wavelength closed to penetration depth.

LLRF SYSTEM IMPROVEMENT FOR HLS LINAC UPGRADE*

G. Huang, H. Lin, Y. Liu, W. Zhou, K. Jin, D. Jia,
NSRL USTC Anhui Hefei 230029 P. R. China

Abstract

The linac beam energy will be upgraded from 200MeV to 800MeV, in order to realize the full-energy injection of storage ring at Hefei Light Source. This paper introduces the improvement of linac LLRF system, which is composed of phase reference and driver signal transmission and distribution, phase stability system, phase reversal device for SLED. The LLRF prototype has been constructed, and the test results are described in the paper.

800MEV LINAC INTRODUCTION

The layout of 800MeV linac is shown in Figure 1, and the parameters in Table 1.

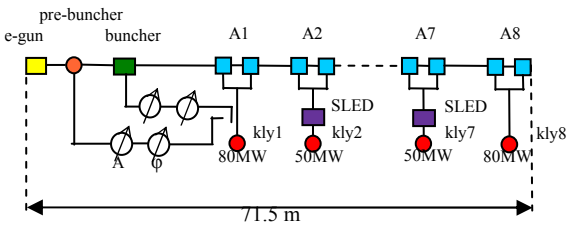

Figure 1: 800MeV Linac layout

Table 1: Linac parameters

	200 MeV	800 MeV
Beam current	50mA	1 A
Beam pulse	0.1-1μs	1 ns
Repetition /Hz	0.5	1
Energy spread	0.8%	0.5%
RF freq. / MHz	2856	2856
Acc. section	4	8
klystron	5 (20MW)	6 (50MW) +2 (80MW)
SLED	0	6

The 800MeV Linac is composed of injector (prebuncher, buncher) and eight accelerating sections. the prebuncher is a single resonant cavity, and the buncher is a 1-meter travelling wave accelerating construct. Each accelerating section contains two 3-meter constant gradient travelling wave accelerators. The design energy of linac is 1GeV, one accelerating section may stand by when linac beam energy is 800MeV.

PHASE REVERSAL DEVICE FOR SLED

Six SLEDs will be installed in RF stations from the 2nd to 7th. The SLED parameters are listed in table 2, and the test result of the SLED prototype is shown in Figure 2.

Table 2: Parameters of SLED

Freq. /MHz	2856
Q_0	~100000
β	5
Insert Loss /dB	0.2
Tuning range /kHz	± 500
Pulse time /μs	4
Power Gain /dB	7
VSWR	1.05

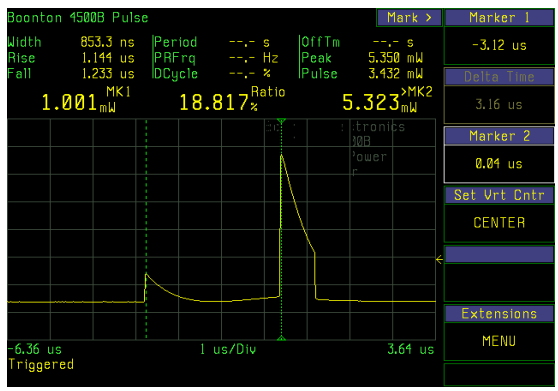

Figure 2: SLED RF output profile

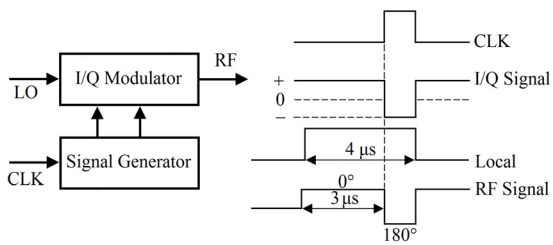

Figure 3: Schematics of the 180° phase reversal system

Table 3: Parameters of IDOH-01-45

Carrier (LO) Freq. /MHz	2000−4000
RF Freq. /MHz	LO ± 100
I & Q Freq. /MHz	DC-100
Conv. Loss /dB	10
Amplitude Balance /dB	1.0
Max. Phase Balance /°	8.0
Isolation /dB	30
VSWR min.	1.5:1

The phase reversal device for SLED showed in figure 3 is consist of fast pulse signal generator and I/Q modulator. The I/Q Modulator is the IDOH-01-45 manufactured by Pulsar Microwave company, and the parameters are

*Work supported by NFSC-CAS(11079034)
grhuang@ustc.edu.cn

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

shown in table 3. The I/Q pulse voltage signals is generated by Agilent 33250A , which voltage resolution is 0.1 mV. The voltage applied to the I/Q port of Modulator is about ±500 mV, so the voltage accuracy could be 0.02%.

Figure 4 shows the stability and accuracy test for phase reversal device. In 2700 seconds, the average reversal phase is 180.5°, phase error (rms) is less than 1°, and maximum phase deviation is 1.5°.

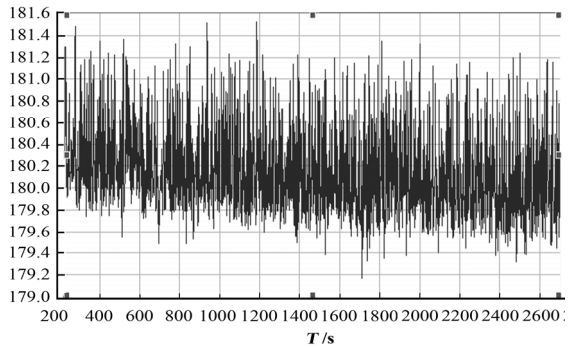

Figure 4: Phase reversal system test results

LINAC RF PHASE STABILITY

The most of new accelerator and upgrade of old one tend to select the digital LLRF system for phase stability [1-4]. But limited by budget, a simple analogy LLRF system is used for HLS 800MeV linac phase measure and control [5]. The analogy system is good enough if the linac is only used as an injector. The design requirements for stability of accelerating phase is ± 1°.

The RF phase stability system contains I/Q demodulator, data acquisition equipment, electronic phase shifter (EPS). The data acquisition equipment is Pico4424 virtual oscilloscope, I/Q demodulator is IDOH-01-458, the type of electronic phase shifter is S7-H67-444A (Pulsar Microwave Company), whose voltage set range is 0-10 V, corresponding phase shift is 360°. The control voltage comes from one 16 bits DAC PCI board.

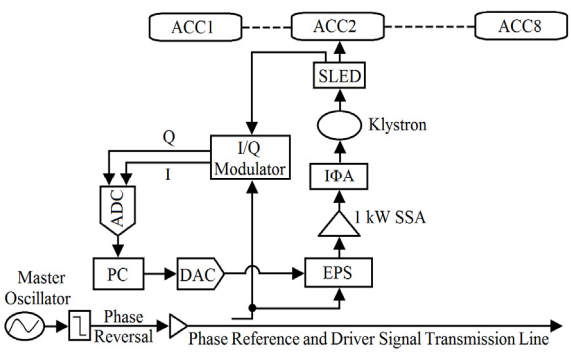

Figure 5: Diagram of phase stability system

The resolution of Pico4424 virtual oscilloscope is 16 bit， and the minimum resolution voltage is 0.03 mV under the voltage range set at 500 mV. When the LO signal of IDOH-01-458 set to 10 dBmW, RF signal is about 0 dBmW, the voltage rang of I/Q output signal is about ± 200 mV. The phase of RF signal changes 0.1°, I/Q voltage vary at least 0.2 mV, which is larger than Pico4424 resolution. Therefore the phase measuring resolution can reach 0.1°.

In the laboratory environment (room temperature stable, no external noise interference), we made a phase stability system prototype on the table test, test device is shown in Figure 7. The RF output of EPS connects to the RF signal input of I/Q modulator, to form the feedback loop. Figure 8 is open loop phase measuring results. The test lasted 2100 second, the rms error of phase measurement is less than 0.1°, which shows that the phase measurement resolution is ±0.1°. The maximum phase deviation is ±0.15 °, it means the measuring precision can reach ± 0.2°. Figure 9 shows the phase closed loop test, the phase feedback control accuracy is set to ± 0.5°. In order to avoid feedback overshoot even or self-excited, each feedback turn adjusts 30 ~ 90% of phase deviation. Setting up different target phase by control program, the loop response to different phase deviation 1°, 2°, 5°, 10°, and 20° has been examined. The loop feedback is stable without overshoot under any phase deviation.

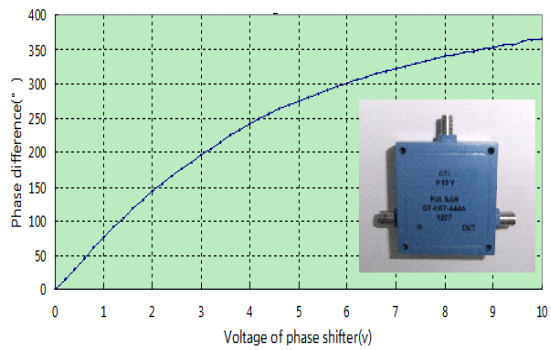

Figure 6: Phase shift *vs* control voltage

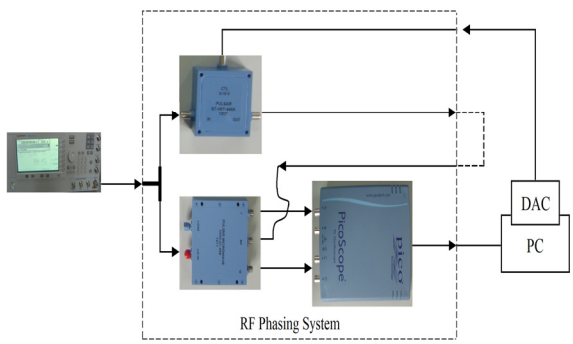

Figure 7: Self-test for RF phase stability system

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

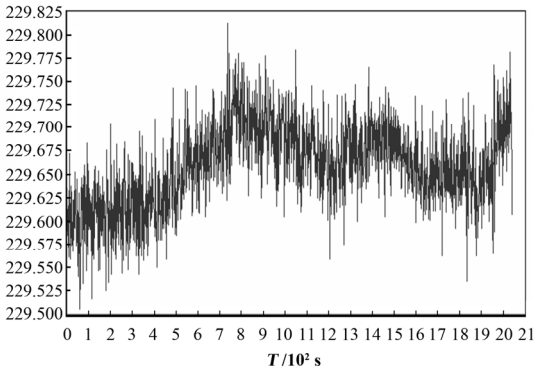

Figure 8: Phase measurement resolution

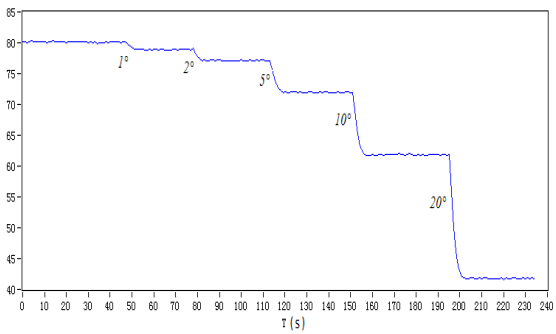

Figure 9: Loop response to different phase deviation

We tested the phase stability system in the No.1 RF station of 200MeV Linac. As shown in Figure 10, the loop is set to open before 1700 second, the RF phase drifted 1.3°. After then the loop is closed, the stable phase set at 87°, and the closed-loop control accuracy is ± 0.5° in the first 3000s, after that is ± 0.3 °. The result shows that the phase error can be controlled in ± 0.5°, but failed in ± 0.3°, since the online phase noise is ± 0.3° (Figure 11). Therefore the online closed-loop phase stability is ± 0.5 °.

NSRL USTC Anhui Hefei 230029 P. R. China

Abstract

If the linac is loaded by a high intensity, long pulse multi-bunch beam, the energy of the beam drops with time during the pulse within the accelerating structure filling time [1, 2]. The bunch phase modulation method is introduced to compensate the beam loading effect. In this method the bunch phase in the RF accelerating field is changed bunch-by-bunch, the bunch energy gain in the RF filed gradually grows up, which cancels out the drop due to beam loading. The relationship between the beam phase distribution and the linac parameters is calculated in this paper.

BEAM LOADING EFFECT

When a bunch train passes through a travelling wave accelerating structure, the loaded accelerating fields U_{acc} is defined by [3].

$$U_{acc}(t) = U_{rf}(t)\cdot\cos\varphi - U_b(t) \quad (1)$$

Where U_{rf} is the accelerating voltage conducted by input RF power(unloaded accelerating voltage), φ is the bunch phase in RF filed, U_b is the beam loading voltage,

There are two kinds of travelling-wave accelerating structure–constant impedance and constant gradient, normally used in linac. In case of constant impedance structure, the U_{rf} and U_b is expressed by

$$U_b(t) = \begin{cases} I\cdot R_M[(L-z-\frac{1}{\alpha})(1-e^{-\alpha z})+z] & t<T_F \\ I\cdot R_M\cdot L(1-\frac{1-e^{-\tau}}{\tau}) & t\geq T_F \end{cases} \quad (2)$$

$$U_{rf}(t) = \begin{cases} \sqrt{2\alpha P_0 R_M}\cdot L(\frac{1-e^{-\alpha\cdot v_g\cdot\tau}}{\tau}) & t<T_F \\ \sqrt{2\alpha P_0 R_M}\cdot L(\frac{1-e^{-\tau}}{\tau}) & t\geq T_F \end{cases} \quad (3)$$

$$z = v_g\cdot t \qquad \tau = \alpha L$$

Where I is beam current, TF is the filling time, RM is shunt impedance per length, L is the length of accelerating structure, α is attenuation coefficient, P_0 is RF input power, vg is group velocity.

U_b is the sum of each bunch induced voltage U_i. The attenuation and superposition of bunch induced voltage is shown in Figure 2.

$$U_b = \sum_{i=1}^{n} U_i \quad (4)$$

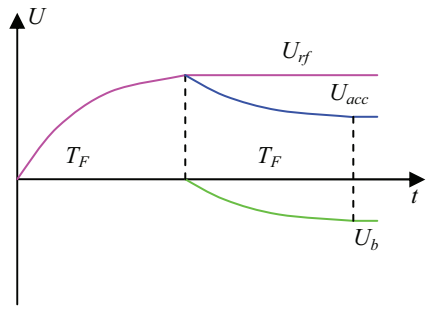

Figure 1: Transient beam loading effect.

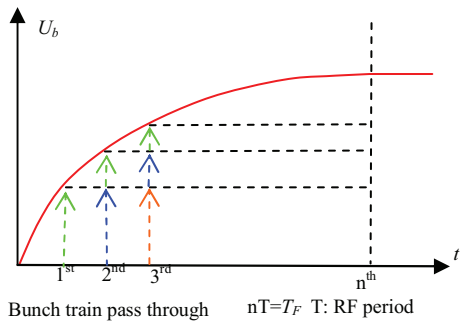

Figure 2: Attenuation and superposition of bunch induced voltage.

Some methods are used to compensate the transient beam loading. For a short pulse beam, the beam is injected before RF power is filled up (early injection method) [4]. In case of long pulse beam, the amplitude or phase of RF power is ramped to keep the U_{acc} constant during the filling time of beam injection [5, 6].

PRINCIPLE OF PHASE MODULATION METHOD

We propose the bunch phase modulation method to compensate the transient beam loading. The idea is that the bunch phase (φ) in the RF accelerating filed is changed bunch-by-bunch, therefore the bunch energy gain in the RF filed gradually changes. If the trends of the gain change is exactly contrast of the rise up of beam loading, all bunches will obtain the same energy.

Since the bunch phase shifts continuously, the beam loading is the vector superposition of all bunch's induced voltage, which is shown in Figure 4.

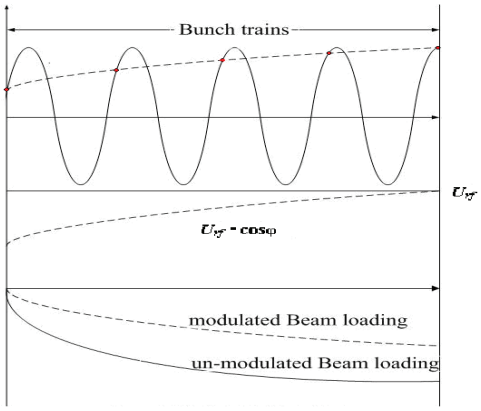

Figure 3: Principle of bunch phase modulation.

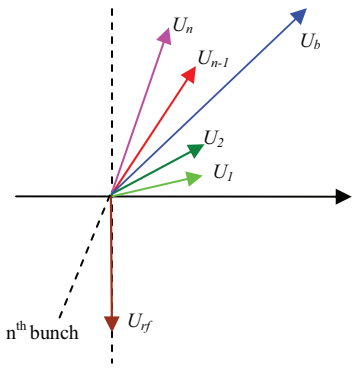

Figure 4: Vector diagram of phase modulated bunch.

CALCULATION OF THE BUNCH PHASE DISTRIBUTION

In order to calculation the beam loading of multi–bunch with different phase, we define

$$u_n = U_b(nT) - U_b((n-1)T) \tag{5}$$

Where T is RF period time.

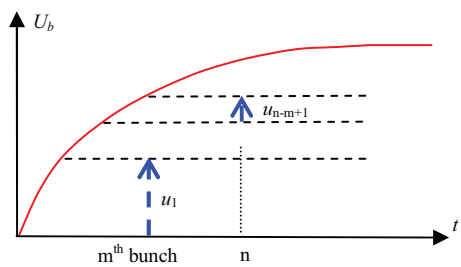

Figure 5: Bunch induced field attenuating with time.

When a bunch passes through the accelerating structure, its induced voltage in the structure is u_1, and then attenuates to u_n after nT times. So that at the moment when the nth bunch enter the accelerating structure, the voltage of the mth bunch is

$$u_n^m = u_{n-m+1} \tag{6}$$

All bunches will obtain the same energy gain U_{const}.

For the No.1 bunch with phase φ_1

$$U_{const} = U_{rf}\cos\varphi_1 - u_1$$

and the No.2

$$U_{const} = U_{rf}\cos\varphi_2 - u_1 - u_2\cos(\varphi_1 - \varphi_2)$$

Therefore the No. n

$$U_{const} = U_{rf}\cdot\cos(\varphi_n) - \sum_{i=1}^{n} u_n^i \cdot \cos(\varphi_i - \varphi_n) \tag{7}$$

A MATLAB code is programmed to find out the optimum phase distribution, the parameters of constant impedance accelerating structure listed in Table 1 come from the HLS (Hefei Light Source) 200 MeV Linac. The beam pulse length is assumed as the filling time (TF), the relative bunch amount is 2370. The calculating result is shown in Fig. 6-8.

Table 1: Accelerator Parameters

L /m	3
T_F/μs	0.83
α	0.177
Freq. /MHz	2856
R_M / MΩ/m	60
U_{rf} /MV	30MV

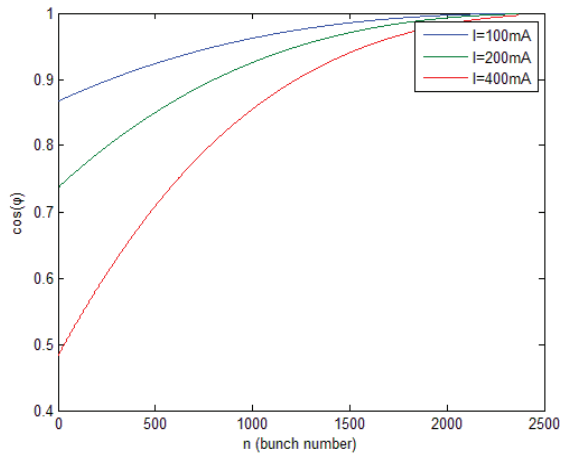

Figure 6: cosφ *vs* n

In Figure 8 the blue line (100mA modulated) is nearly coincident with the red one (100mA un-modulated). It shows that when the beam intensity is lower, the phase difference between bunches is so small that the vector superposition is similar to the direct superposition. In this case the bunch phase can simply calculated by

$$\cos\varphi_n = \frac{U_{rf} - U_b(T_F)}{U_{rf} - U_b(nT)} \tag{8}$$

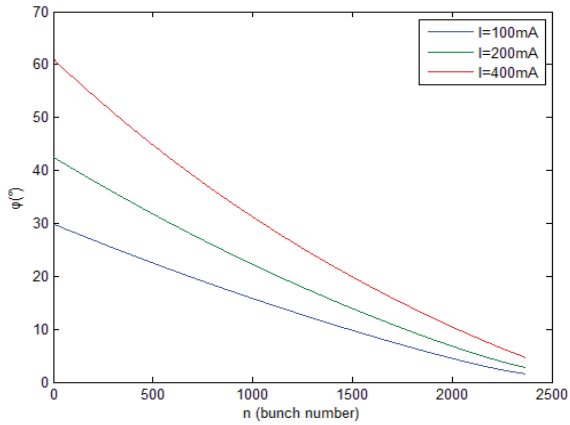

Figure7: bunch phase distribution.

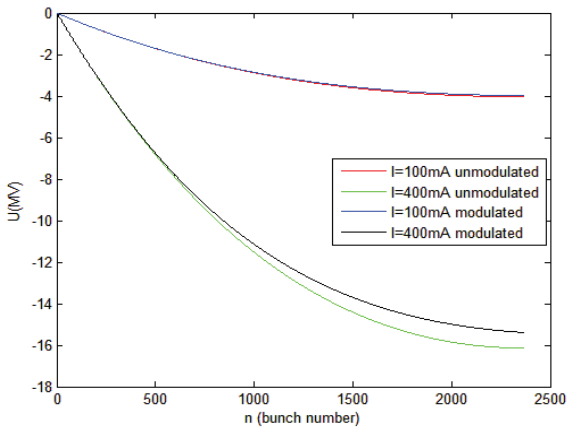

Figure 8: modulated and un-modulated beam loading.

CONCLUSIONS

The bunch by bunch phase modulation is a very interesting method to compensate the transient beam loading. The advantage of this method is that the compensation is global. If all of the accelerating sections in a linac adopt the identical structure, their beam loading will be compensated simultaneously. It would be a simple and cheap resolution for the larger linac such as linear collider. But how to realize the bunch phase modulation is a very complicated problem. At present we are developing a bunching system with the low-Q and wide-band cavity, the rf phase modulated signal can apply fast on it, the bunch phase will be modulated in the bunching procession.

RF CHARACTERISTIC STUDIES ON THE WHOLE ACCELERATING STRUCTURE FOR THE BEPCII LINEAR ACCELERATOR

S. Pei#, J. Zhang, M. Hou, X. Li, IHEP, Beijing 100049, P. R. China
B. Wang, SINAP, Shanghai 201800, P. R. China

Abstract

An accelerating structure is one device to boost the particle energy. 2856 MHz 3 m long travelling wave disk-loaded accelerating structure is applied in BEPCII linac, its RF characteristics are mainly determined by the 84 regular cells located between the input and output couplers. Input and output couplers need to be included when the whole structure RF characteristics are simulated before fabrication; otherwise it would be difficult to obtain the travelling wave fields excited in the whole structure. If the real 3D couplers are modelled during the design process, a large amount of computer resources and time need to be used. However, if the redesigned azimuth symmetric coupler is used to replace the real 3D one during the simulation process, much less computer resources and time are required. With this method proposed here, the simulation results agree well with the theoretically calculated and experimentally measured ones.

INTRODUCTION

The travelling wave (TW) disk-loaded accelerating structure is one of the key components in normal conducting (NC) linear accelerators, such as the BEPC and BEPCII linacs [1, 2], and has been studied for many years. Usually after the dimensions of each cell and the two couplers are finalized, the structure is fabricated and tuned, and then the whole structure RF characteristics are measured by using a vector network analyzer. Before the fabrication, the whole structure RF characteristics are less simulated. This is because of the structural scale (couples of meters long and centimeters in diameter at S-band) and also the personal computer capability limitations.

Because the RF characteristics of the TW structures with several tens of cells are mainly decided by the regular cells, one method to use redesigned power couplers with azimuth symmetry to replace the original 3D waveguide ones in finite element analysis (FEA) can be used. Then the whole structure RF characteristics, such as the electric field amplitude distribution along the structure's axis and the VSWR curve, can be analyzed by using the multi-physics software package ANSYS [3] with much less computer resources required.

In BEPC and BEPCII linear accelerators, 56 units of 3 m long constant gradient disk-loaded accelerating structure are employed. Table 1 shows the main specifications. Fig. 1 shows the schematic of the input/output coupler. To balance the electromagnetic field asymmetry existed in this kind of single feed input/output coupler, appropriate eccentricity offset is applied. If this real coupler shape shown in Fig. 1 is used to simulate the whole structure RF characteristics, at least 1/2 model (180^{o} azimuth angle) needs to be created, which is impossible to do with only one PC.

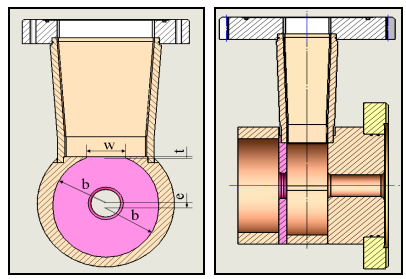

Figure 1: Schematic of the input/output coupler for the accelerating structure of the BEPCII linac. *b*—radius; *e*—eccentricity offset; *w*—coupling aperture width; *t*—coupling aperture thickness.

Table 1: Main Specifications of the TW Structure for BEPCII Linac

Parameters	Units	Values
Operating frequency	MHz	2856
Operating temperature	°C	45.0±0.1
Number of cells		84 regular cells 2 coupler cells
Section length	mm	3009 (86 cells)
Phase advance per cell		2π/3
Cell length	mm	34.99
Disk thickness	mm	5.84
Iris diameter (2*a*)	mm	26.231–19.243
Cell diameter (2*b*)	mm	83.460–81.781
Shunt impedance (r_0)	MΩ/m	54.6–63.9
Q factor		13990–13836
Group velocity	v_g/c	0.0208–0.0070
Filling time	ns	830
Attenuation coefficient	Np	0.57

ANSYS SIMULATION METHODOLOGY

The high frequency modal and harmonic solver modules in ANSYS can be used to perform the numerical finite element analysis on the whole structure RF characteristics. By using one program for all of the simulations any problems of meshing inconsistency between different types of software were eliminated.

#peisl@mail.ihep.ac.cn

A complete RF analysis on the whole TW disk-loaded structure requires 3 steps, as outlined below. Currently, the ANSYS high frequency modal and harmonic solver modules have the limitation that only 3D elements can be used. To minimize the CPU time and memory use, an axis-symmetric 3D model with a 1° azimuth angle (1/360 model) can be created to carry out the analysis. Otherwise, the azimuth angle of the model needs to be adjusted correspondingly.

1) With an HF119 high frequency tetrahedral element, modal analysis was performed in the vacuum part of each accelerating cell, the cell diameter 2*b* was varied to tune the 2π/3 mode resonating at the nominal operating frequency (2856MHz for the BEPCII linac) by fixing the iris diameter 2*a*.

2) By using the obtained dimensions of the first/last cells in Step 1, the redesigned axis-symmetric vacuum models of the input/output coupler as shown in Fig. 2 can be defined. To minimize the reflection coefficient at the input/output coupler port to the level of 10^{-2} to 10^{-3}, all of the dimensions shown in Fig. 2 except those related with the middle two cells can be adjusted. Once a flat electric field amplitude distribution along the redesigned coupler's axis is obtained and the phase difference between the middle two cells is ~120° (2π/3), the coupler's dimension can be finalized.

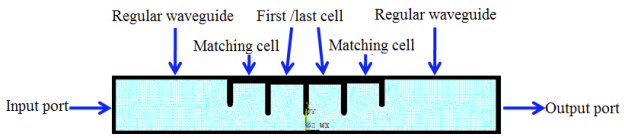

Figure 2: Schematic of the redesigned input/output couplers with azimuth symmetry.

3) Now the vacuum part of the whole structure can be modeled with the obtained cell and coupler dimensions from Steps 1 and 2. Harmonic analysis was carried out by defining the two redesigned couplers in Step 2 as input and output ports, respectively. Impedance boundary condition of copper was applied to the other outer boundary surfaces. Using the built-in macro 'SPARM' and 'HFPOWER', the scattering (*S*) parameters and the total time averaged losses can be calculated. If a harmonic response over a frequency range is performed, the *S* parameters at each frequency step for each port will be calculated, the structure's bandwidth (VSWR≤1.2) can then be known by checking the S11/VSWR data.

It is worth to point out that the mesh size consistency in all of the above analysis steps is the key for acquiring the correct simulation results. Only in Steps 1 and 2, the corresponding model dimensions need to be adjusted.

THE BEPCII LINAC STRUCTURE

By using the structural dimensions listed in [1] and the method proposed in last section, the whole structure RF characteristics on the accelerating structure of the BEPCII linac were studied.

Figure 3 shows the ANSYS model and meshing of the 43rd accelerating cell. Fig. 4 shows the corresponding electromagnetic field distributions of the 2π/3 mode operating at 2856MHz.

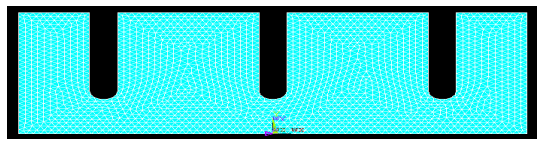

Figure 3: ANSYS model and meshing of the 43rd accelerating cell.

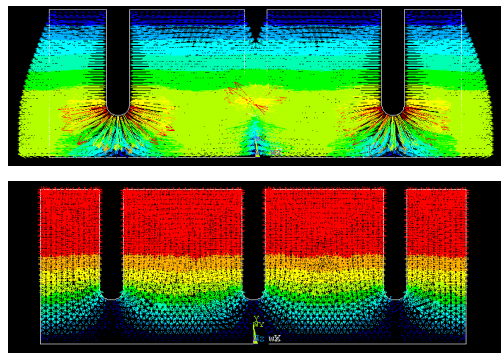

Figure 4: Electromagnetic field distributions of the 2856MHz 2π/3 mode in the 43th accelerating cell

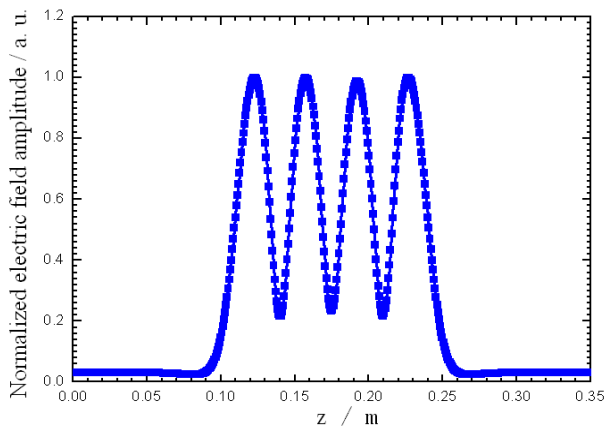

Figure 5: On-axis electric field amplitude distribution in the redesigned input coupler with azimuth symmetry.

Figure 5 shows the on-axis electric field amplitude distribution in the redesigned input coupler with azimuth symmetry of the accelerating structure for the BEPCII linac. This coupler includes two matching cells and two regular accelerating cells; the calculated phase shift between the middle two accelerating cells is ~119.4°. Correspondingly, the dimensions of the output coupler can be obtained with the same method.

The 1/360 model of the accelerating structure for the BEPCII linac is shown in Fig. 6. By appropriately defining the input and output ports in ANSYS, the amplitude distribution of the electric field along the whole structure's axis of the BEPCII linac accelerating structure can be obtained, which is shown in Fig. 7.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

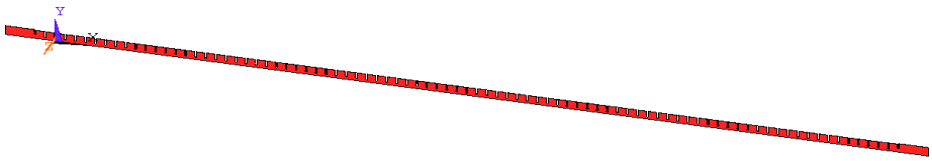

Figure 6: The 1/360 model of the accelerating structure for the BEPCII linac (total 84 regular cells and 2 coupler cells).

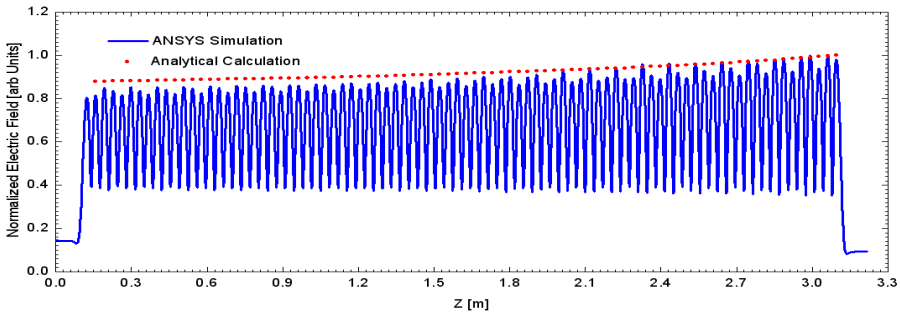

Figure 7: The electric field amplitude distribution along the structure's axis of the BEPCII linac accelerating structure.

In Fig. 7, one can see that there are 86 peaks for the ANSYS simulation result. The 1st and 86th peaks correspond to the matching cells of the input and output couplers, respectively. The middle 84 peaks correspond to the 84 regular accelerating cells. The ANSYS simulation result is consistent with the analytical one, which can be calculated with the analytical formulae listed in [4] after obtaining each cell's RF parameters such as the frequency, the quality factor Q, the shunt impedance R and the group velocity v_g. Usually, the former three ones can be calculated with SUPERFISH [5], and the last one with MAFIA [6].

With –34 dB reflection coefficient at the input port, the ANSYS simulated power attenuation coefficient to the output port is 0.56 Np (~4.85 dB), which is very close to the experimentally measured (0.57 Np) and the analytically calculated (0.54 Np) ones. By using the averaged value of the ANSYS calculated quality factor Q, which is ~13750, the corresponding filling time can be estimated to be 856 ns, which is only 26 ns longer than the experimentally measured value of 830 ns.

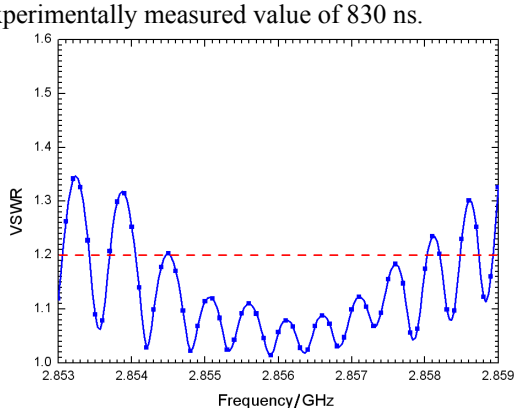

Figure 8: The ANSYS simulated VSWR curve.

Figures 8 and 9 show the ANSYS simulated and the experimentally measured VSWR curves, respectively. It can be clearly seen that the simulated frequency bandwidth is 2858.05–2854.5=3.55 MHz, while the measured one is 2858.3–2853.6=4.7 MHz. In Fig. 8, the VSWR at 2854.5 MHz is exactly 1.2, if it is not considered to be the lower limit of the bandwidth, then the ANSYS simulated bandwidth would be 2858.05–2854.05=4 MHz. Consequently, the difference of the bandwidth results between ANSYS and experiment would go from 1.15 MHz to 0.7 MHz.

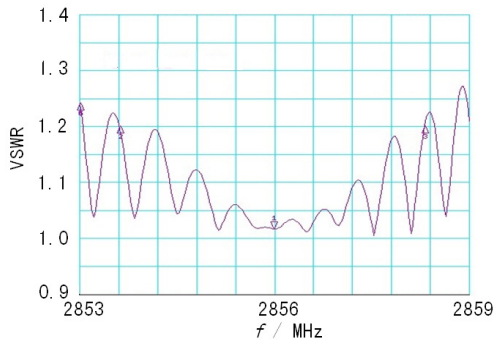

Figure 9: The experimentally measured VSWR curve.

CONCLUSION

By replacing the real 3D waveguide coupler with an axis-symmetric on-axis coupled one in ANSYS, the whole structure RF characteristics on the TW disk-loaded accelerating structure can be done with much less computer time and memory. The consistency between the simulation and experimental results of the BEPCII linac accelerating structure shows the validity of the method proposed in this paper.

Abstract

IHEP in China is designing and constructing a 100 MeV / 100 kW electron linac for NSC KIPT, which will be used as the driver of a neutron source based on a subcritical assembly. Recently, the physical design has been finalized. The chicane scheme instead of the RF chopper one has been selected. The mechanical design is on-going and will be finished in the very near future. The injector part of the machine has been installed in the experimental hall #2 of IHEP and is being commissioned and tested. The progress on the machine design and construction are reported, initial testing and commissioning results of the injector are also presented.

INTRODUCTION

One 100 MeV / 100 kW electron linac in NSC KIPT is being constructed, which will be used to drive a neutron source based on a subcritical assembly. This neutron source is a joint project between ANL (USA) and NSC KIPT (Ukraine), and IHEP in China is responsible for the linac (including the transport line to the target) design and construction. Due to the high average beam power of 100 kW and the low beam loss of ~3 kW (including intended and unintended) along the entire linac, the whole machine is being designed and constructed elaborately. Table 1 shows the main parameters of the NSC KIPT linac.

Table 1: Main Parameters of the NSC KIPT Linac

Parameters	Values	Units
RF frequency	2856	MHz
Beam energy / power	100 / 100	MeV / kW
Beam current (max.)	0.6	A
Energy spread (p-to-p)	±4	%
Emittance	5×10^{-7}	m-rad
Beam pulse length	2.7	μs
RF pulse length	3	μs
Pulse repetition rate	625	Hz
Klystron	6×30MW / 50kW	Units
Accelerating structures	10×1.336m	Units
Gun high voltage	~120	kV
Nominal gun beam current	~1–1.2	A

#peisl@mail.ihep.ac.cn

The beam energy spread at the linac exit has been changed to ±4% for peak-to-peak rather than 1% for 1σ [1] [2]. This is determined by the energy spread acceptance of the beam transport line with 90° bending angle located at the linac end. With ±4% peak-to-peak energy spread, the beam power losses along the transport line can be reduced to less than 1 kW with ±0.2 mm alignment error, ±2° phasing jitter, ±0.15% modulator voltage jitter, ±0.5% gun high voltage jitter and ±1% RF pulse flatness.

Figure 1 shows the mechanical layout of the linac including the beam transport line. The klystron gallery is located at the downstairs of the accelerator tunnel.

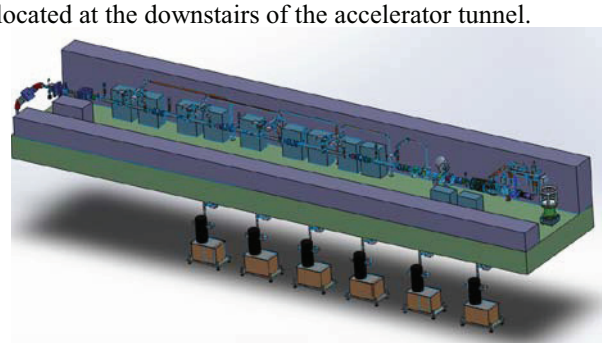

Figure 1: Mechanical layout of the linac including the beam transport line.

INJECTOR DESIGN AND TEST

To get a clean bunch without any satellite electrons in each RF period downstream the chicane system, the phases of all the RF structures (the prebuncher, the buncher and the 1st accelerating structure A0) and the solenoid field distribution in the injector are re-optimized. Finally one can obtain the phase and energy spectrums as shown in Fig. 2, which are appropriate for the beam collimation process with the chicane system to eliminate all particles with very large energy and phase spreads relative the reference particle located at the 0° phase. By this way, the beam power losses along the transport line can be minimized to the largest extent.

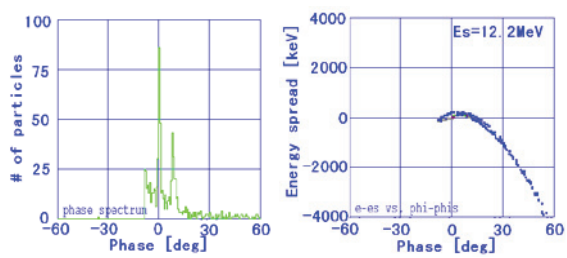

Figure 2: Phase and energy spectrums at the injector exit.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Fig. 3 shows the absolute energy spread distribution along the linac with all error and jitter effects considered.

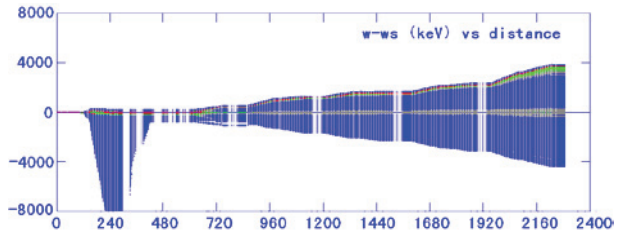

Figure 3: Absolute energy spread distribution along the linac with all error and jitter effects considered (unit: cm).

The injector part has been installed in the experimental hall #2 of IHEP, which is shown in Fig. 4. The commissioning and testing were started two months ago. For beam pulse length of 2.7 μs, the maximum current obtained at the injector exit is ~2 A, which is limited by the electron gun emission capability. No BBU effect in the injector was observed, which means the threshold current of the accelerating structure is higher than 2 A. Many effective measures are adopted in the linac design to cure the BBU effect as described in [1].

Figure 4: Injector testing facility installed in IHEP.

Fig. 5 shows the signals of BCT1 (gun exit) and ACCT1 (A0 exit, upstream the 37.5° energy analyzing magnet used temporarily for injector test). Here the beam current indicated by the ACCT1 signal is ~770 mA. The bunching efficiency is not known yet because the BCT1 is not calibrated; however, the estimated value is ~70% according to the gun current calibration before installation. The waveforms' swing up and down along the pulse is because of the interference from the old grounding system of hall #2, which was constructed more than 20 years ago.

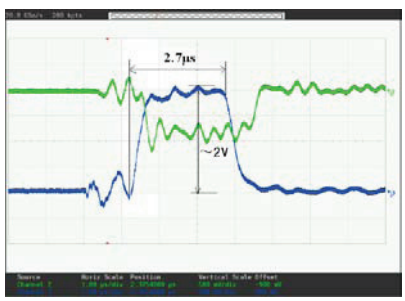

Figure 5: Signals of BCT1 and ACCT1.

Figure 6 shows the corresponding beam profile (downstream the analyzing magnet) at the energy and energy spread measurement line. It can be seen there is no high energy tails, but only low energy ones, which is consistent with the simulated energy spectrum in Fig. 2. The low energy tails will be collimated by the collimator located between the bending magnets CB2 and CB3 of the chicane system, and then a clean beam of ~600 mA without satellite electrons in each bunch can be obtained.

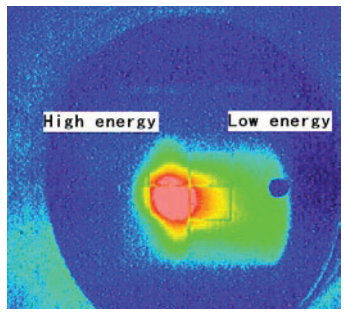

Figure 6: Beam profile at the energy measurement line.

CHICANE SYSTEM DESIGN

The chicane system is located downstream the injector but upstream the 2nd accelerating structure A1. There are 4 bends in the chicane system， mechanical layout of which is shown in Fig. 7. The bending magnets CB1 and CB4 are sectors, while CB2 and CB3 are rectangles. The 1st bending magnet CB1 was specially designed to have two functions. One is for the nominal beam collimation process with a bending angle of 10°; another is to be used as an energy analyzing magnet (AM) with 45° bending angle for measuring the beam energy and energy spread of the electron beam at the injector exit, then the RF phases seen by the beam in the prebuncher, the buncher and the 1st accelerating structure A0 can be optimized in real operation. The vacuum chambers for CB1, AM and CB2 are integrated together for saving space. Similarly, the chambers for CB3 and CB4 are also integrated.

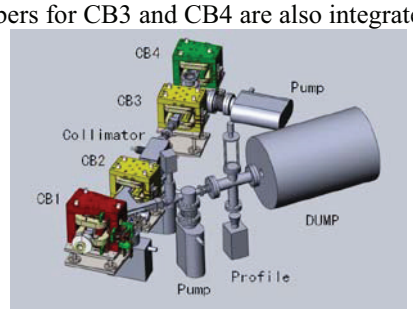

Figure 7: Layout of the Chicane system.

MAIN SYSTEMS AND COMPONENTS

Based on the decision to adopt the chicane scheme instead of the RF chopper one because of technology difficulty caused by the high beam current, construction and commissioning of all main systems are on-going.

The electron gun with Y824 cathode assembly has been in normal operation with high voltage (HV) of 120 kV (conditioned to 135 kV) for couples of months in the injector testing facility. The emitted current exceeded the design requirement of 2A. Fig. 8 shows the gun system setup in the tunnel.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

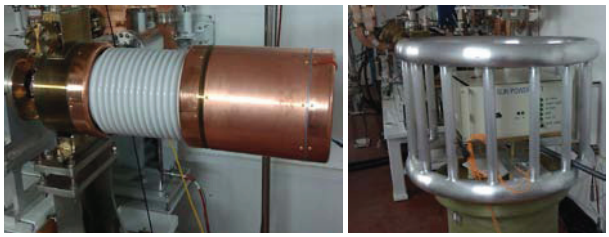

Figure 8: The electron main body and the HV station.

Figure 9 shows the modulator and the Toshiba E37311 klystron. ~400 Hz rep. rate (less than the design goal of 625 Hz) with 3μs RF pulse width has been reached because of the electrical capability of the experimental hall. Higher rate to 625 Hz will be conditioned after the electrical network upgrade. Fig. 10 shows the klystron output at 100 Hz. 30 MW peak power has been obtained.

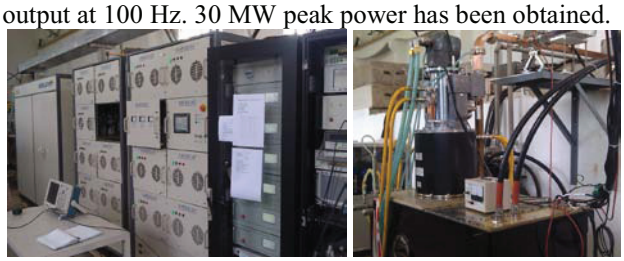

Figure 9: The modulator and Toshiba E37311 klystron.

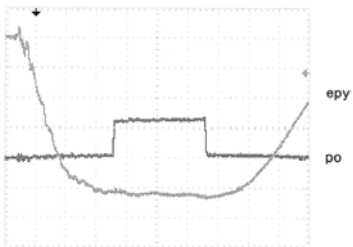

Figure 10: The klystron output at 100 Hz.

Most of the beam instrumentation devices are being fabricated and tested. Fig. 11 shows the ACCT with electromagnetic shielding and the BPM.

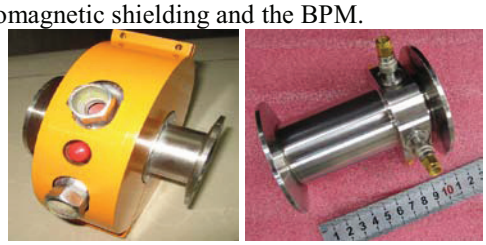

Figure 11: ACCT and BPM

The 1st accelerating structure A0 has been installed in the injector testing facility and is running well at couples of Hz rep. frequency. In the near future, it will be tested to run at 625 Hz with the nominal input power. If the result is positive, another 9 structure will be fabricated.

The LLRF system is being tested in this month. As shown in Fig. 12, the klystron drive waveform is optimized to obtain the desired pulse shape with minimized fluctuation. The testing of the firmware for digital signal processing including feed-forward and feedback control algorithms has been finished.

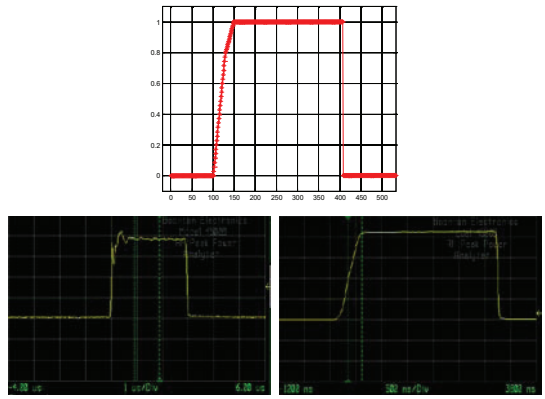

Figure 12: The klystron drive (upper), amplifier output before (lower left) and after (lower right) optimization.

The control system is based on EPICS, which includes all front-end controller, driver and operator screen as shown in Fig. 13. Currently, the design has been finished; most components are in the purchasing and tuning stage. The injector control system is being in operation stably.

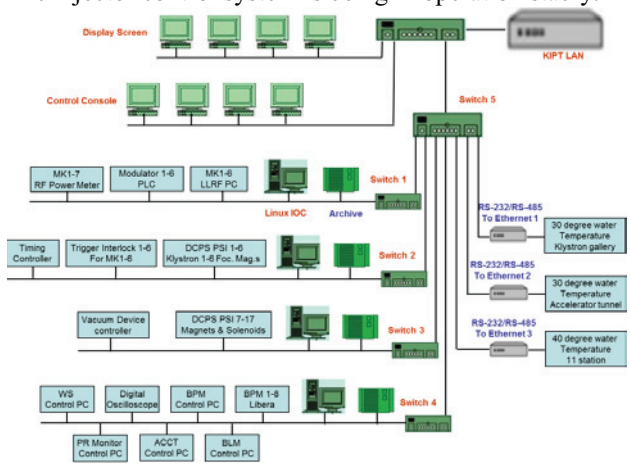

Figure 13: The control system architecture.

The water cooling system is designed to be composed by 3 subsystems: 1) first loop of 30 (max.) ±1°C for the tunnel devices; 2) first loop of 30 (max.) ±1°C for the klystrons gallery devices; 3) 40±0.2°C constant temperature system for the accelerator. The prototype is in well operation for the injector testing facility.

SUMMARY

The design and construction scheme of the 100 MeV / 100 kW linac for NSC KIPT neutron source has been finalized. The injector testing facility is being in operation to test the related systems / components. Currently, the testing results are acceptable. However, further work still need to be done to improve the machine performance including test of the beam loading compensation online.

Abstract

In the first phase of ongoing collaboration between VECC (India) and TRIUMF (Canada) a 10 MeV superconducting (SC) electron linac injector will be installed at VECC. This will constitute a 100 keV DC thermionic gun with grid delivering pulsed electron beam at 650 MHz. Owing to low beam energy from the gun, a capture cryomodule (CCM) consisting of two beta=1, 1.3 GHz single cell elliptical cavities will be installed for pre-acceleration of electron beam to around before it enters an Injector Cryomodule (ICM). The ICM consists of one 9-cell beta=1 elliptical cavity that will provide acceleration to 10 MeV. The present paper depicts the beam dynamics simulation and optimization of different parameters for the injector with a realistic simulated beam emittance from the electron gun.

INTRODUCTION

The proposed electron linac would eventually accelerate 10mA CW electron beam (16 pC/bunch) to 50 MeV with 1.3 GHz superconducting RF cavities. The e-Linac consist of a thermionic gun with 650MHz RF modulated grid followed by a buncher and the two cryomodules. The injector cryomodule (ICM) consisting of a single 9-cell 1.3 GHz niobium cavity followed by an accelerator cryomodule (ACM) having two 9-cell cavities [1]. Systematic optimization of the beam line with wide range of objectives and constraints has been carried out for this e-Linac. The TRIUMF machine would also be used in ERL or RLA mode [3]. Keeping this in mind, option of accelerating high brightness beam of 100pC/bunch charge with better longitudinal beam quality has been kept in the base-line design considering a 300 keV thermionic gun [2].

However, for the VECC facility a 100 keV electron gun would be developed for initial tests of the injector [1] because the present site has several limitations. The ICM would be identical to the TRIUMF machine and would be built and tested at TRIUMF and will be shipped to VECC. Since the 100 keV beam with a $\beta \approx 0.55$ is ill suited to be directly injected into the ICM, some pre-acceleration of the beam to an energy $\geq$ 300 keV will be needed. To achieve this, a capture cryo-module having two independently phased β =1 single cell cavities will be added before the Injector Cryo Module (ICM). The beam dynamics optimization of the 10 MeV injector for the VECC e-Linac facility will be presented.

sdc@vecc.gov.in

ELECTRON GUN SIMULATION

The electron gun consists of a cathode with a grid placed 150 micron away from the electron emitting surface, on which the modulating voltage would be applied. First the electrostatic field between electron emitting surface and grid and finally up-to anode was simulated using SIMION [4]. The electric field distribution thus generated was then used in GPT [5] for estimating the longitudinal and transverse emittance of 100keV electron beam. GPT simulation was done for different geometries essentially varying the cathode angle and cathode-anode distance. An optimum gap of 9.5 cm was chosen between the anode and cathode for good beam quality and a robust solution [6].The conduction angle of the gun was varied in order to estimate the beam structure both longitudinally and transversely for $\pm 16^0$ and $\pm 20^0$ beam.

For both the cases the bunch charge was 16pC which yields 10mA average current for conduction angle of $\pm 20^0$. Two factors are expected to influence transverse emittance growth - temperature of electron emitting surface (1400 K~ 0.13eV) and influence of grid due to the lens action of the micro holes in the mesh. It can be seen analytically that grid induced emittance dominates over the thermal effect. The "*Reiser model*" [7] for grid induced emittance cannot be used since the angle is not << 1. The analytically calculated grid effect was therefore included in the simulation.

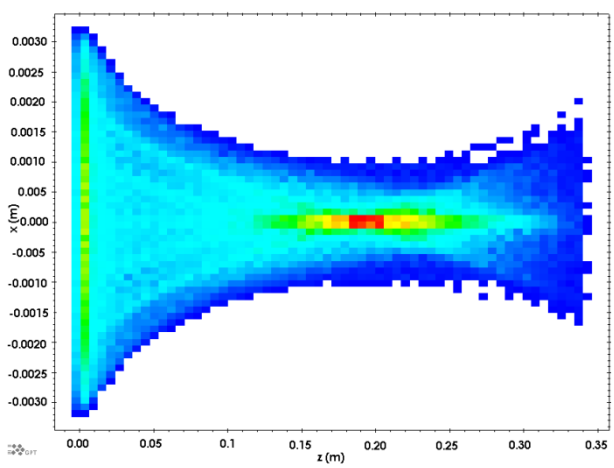

Figure 1: GPT simulated density distribution of 100 keV electron beam with 16pC, conduction angle of $\pm 20^0$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The normalized emittance of electron beam was taken to be 19 mm mrad (4 times RMS emmittance) assuming a transverse spread same as that of the longitudinal energy spread [8]. GPT simulated beam for 16 pC, ± 20^0 conduction angle, cathode-anode distance of 9.5cm is shown in Figure 1. Maximum electron density at the axis occurs at a distance of 200 mm from the electron emitting surface. The simulated parameters for the 100 keV electron beam for ±16^0 and ± 20^0 conduction angles are listed in Table 1.

Table1: Parmeters of 100 keV electron beam (simulation)

Conduction Angle	±16^0	± 20^0
εn,rms (X) π mm mrad	5.02	4.85
εn,rms (Y) π mm mrad	5.01	4.84
εn,rms (long.) π keV mm	0.92	1.694
Bunch Charge (pC)	15.5	16

BEAM LINE CONFIGURATION

The 100 keV electron beam simulated from GPT with realistic features was used for optimization of the base-line configuration for the VECC injector. The beam tracking was carried out in ASTRA [9], where the input fields for elliptical cavities, buncher and solenoids was created using SUPERFISH [10]. In order to test for robustness of the baseline configuration, multivariate optimization technique involving genetic algorithm was utilized as described in reference [2]. In continuation with work carried out earlier, the base line configuration starts with a 1.3 GHz normal conducting buncher after the gun. Earlier it was already established that compared to 650 MHz buncher, the present buncher perform better in terms of bunching the beam without substantial tail longitudinally.

In the next stage two β = 1 single cell elliptical cavities were used. The acceleration is achieved in the first single cell cavity whereas the second cavity essentially only bunches the beam. The additional bunching in the capture section comes with the cost of transverse defocusing. The required transverse focusing is achieved with a solenoid placed between the CCM and ICM. A 10mm virtual aperture is defined through the cavities and any solution where the electron hits this aperture is discarded. This in other words takes care of electron hitting the superconducting cavity. Layout of the proposed beam-line is shown in Figure 2. The last solenoid is redundant for 10 MeV case but would be needed if we would like to further enhance the energy to 30 MeV in subsequent two 9-cell cavities. Also at 10 MeV the last solenoid would be needed as a part of diagnostic equipment.

A genetic algorithm was used to find the above optimized layout by using variables as field strength of solenoids, electric field and phases of cavities to achieve particular sets of constraints and objectives. This algorithm was useful to search for robust solutions against near singularities in the modeling process. Distances have been kept considering required space for hardware as well as space constraints in mind. The solution sets for which the objectives of minimizing EmitX and energy width ΔE (rms) and constraint of achieving final energy greater than 10 MeV with ±16^0 GPT simulated beam were achieved are shown in Figure 3 and the same for ±20^0 case are shown in Figure 4.

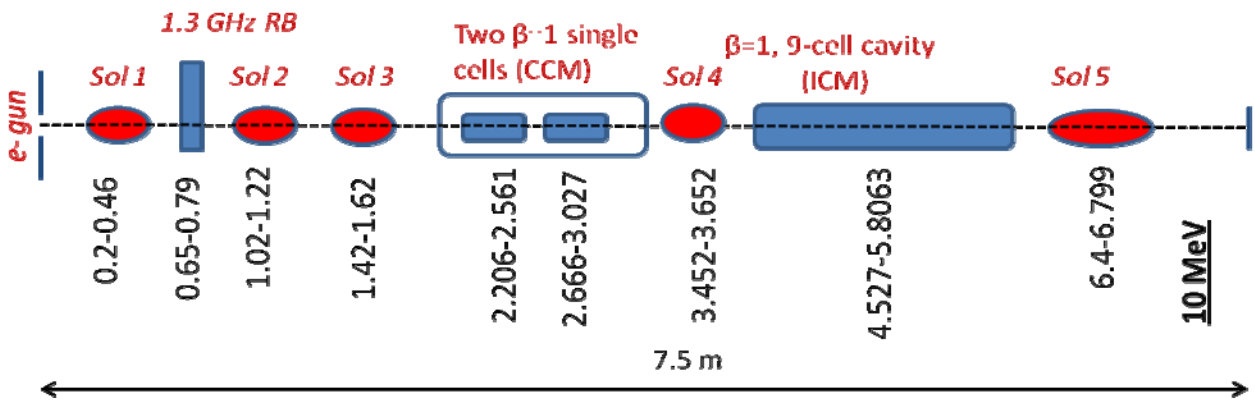

Figure 2. Layout of 10 MeV injector for VECC e-Linac

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The optimized beam dynamics parameters for one of the solution with $\pm16^0$ GPT simulated beam are shown in Figure 5. The first single cell cavity accelerates the 100 keV electron beam to 600 to 800 keV while the second cavity acts as mainly as a buncher with energy at its exit of around 1 MeV. The required solenoid fields are in the range of 300 to 400 Gauss. The required acceleration gradient E_{acc} in the first and second capture cavity is around 4.5 MV/m and 0.5 MV/m respectively. The rms bunch width at 10 MeV for most of the solution is less than 6mm going down to as low as 1-2mm, while transverse and longitudinal emittance are found to be within acceptable limits.

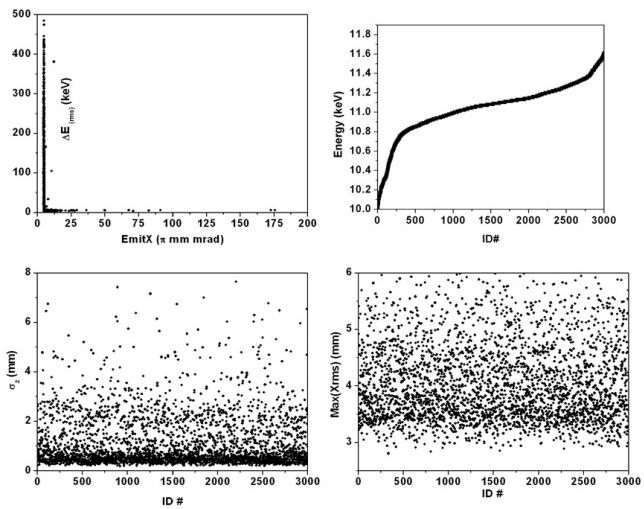

Figure 3. Solution sets with $\pm16^0$ GPT simulated beam

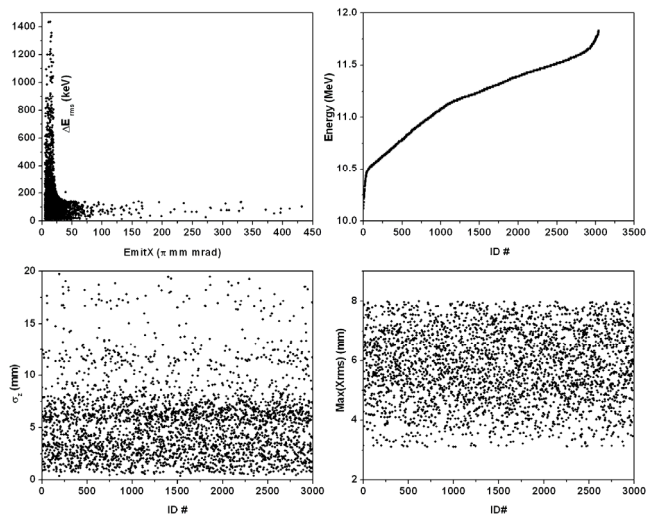

Figure 4. Solution sets with $\pm20^0$ GPT simulated beam

For most of the solutions the maximum value of Xrms is less than 6-8mm. The beam does not develop appreciable longitudinal tail. As far as acceleration upto 10 MeV, both $\pm16^0$ and $\pm20^0$ perform in similar fashion in terms of longitudinal and transverse beam quality. Just out of academic interest, optimisation was extended upto 50 MeV with both type of GPT simulated beam. $\pm16^0$ beam does not develop appreciable longitudinal tail thus not creating problem when accelerated to 50 MeV. This is not the case with 20 degree beam which is although comparable to 16 degree beam upto 30 MeV. But it seems to perform inferior in terms of number of solutions and also in terms of value of end parameters at 50 MeV. This is due to increase in number of particles in tail part of longitudinal structure of beam.

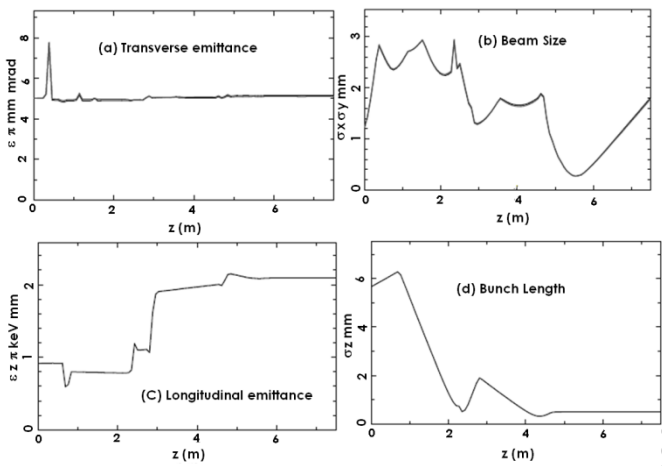

Figure 5. Optimised beam dynamics parameters with $\pm16^0$ beam;(a) transverse emittance, (b) beam size, (c) longitudinal emittance, (d) bunch length variation along the length.

Abstract

KEK-STF (Superconducting Test Facility) has been constructed to establish super-conducting accelerator technology for ILC (International Linear Collider). This facility is also used to demonstrate a high-brightness quasi-monochromatic X-ray generation by inverse laser Compton scattering. For the both purposes, high intensity electron beam in multi-bunch and long macro-pulse formats is important. The beam commissioning has been started since February 2012. 1 ms macro pulse train is successfully generated and 40 MeV acceleration was confirmed. We report the progress of the beam commissioning including the basic beam properties.

INTRODUCTION

Aim of KEK-STF(Superconducting Test Facility)is establish the super-conducting accelerator technology for ILC(International Linear Collider) which is a future project of high-energy physics. In STF, a beam acceleration test will be performed with parameters almost equivalent to those in the real ILC, 8.7 mA average current in 0.9 ms length macro-pulse. In super-conducting accelerator, the input RF power and phase should be well controlled by monitoring RF field of the cavity for stable beam acceleration which can be examined only with a real beam. In ILC beam format, the 3.2 nC bunch is repeated with 369 ns spacing up to 0.9 ms. Total number of bunch is 2625 in a macro pulse. We call this operation mode as ILC mode.

Another purpose of STF is MEXT Quantum Beam project, generating high brightness and quasi-monochromatic X-ray by inverse Compton Scattering[1]. In this case, 62 pC bunch is repeated each 6.15 ns up to 1 ms macro pulse. We call this mode as Q-beam mode.

These high-average and long macro pulse beam formats are generated by a normal conducting 1.3 GHz photo-cathode RF gun. It was originally developed by DESY for FLASH/XFEL[2]. The Gun cavity fabricated by FNAL was installed at KEK-STF. The design peak field of the gun is 50 MV/m at 4.5 MW RF power. Cs_2Te photo-cathode is employed for beam generation. It is prepared as thin-film by evaporation on Mo cathode block in a vacuum chamber (preparation chamber)[3].

* Work supported by Quantum Beam Project of MEXT, Japan.
† mkuriki@hiroshima-u.ac.jp

By switching laser systems, the macro pulse in ILC mode and Q-beam mode are produced with this RF gun system. A laser system for ILC mode was developed as a collaborative work between KEK, Hiroshima Univ., IAP, and JINR in Russia in 2010[4][5]. This system is based on 3 MHz Yb fiber oscillator. The pulse train is amplified by Nd:YLF laser pumped by flash lump. 266 nm UV pulse train up to 0.9 ms was obtained as 4th harmonics of the fundamental mode. Another laser system based on 162.5 MHz mode-lock oscillator with MOPA system was developed for Q-beam mode[6]. UV laser pulse train was obtained as FHG by LBO and BBO. Typical UV laser energy per bunch is 500nJ or less.

The STF beam line setup for Q-Beam mode is schematically shown in Fig. 1. The beam properties are observed by various beam monitors set in the beam line, FC(Faraday Cup), ICT(Integrated Current Transformer), BPM(Beam Position Monitor), etc. SC accelerator boost up the beam energy up to 40 MeV. The beam size at IP (Interaction Point) for laser-Compton scattering after acceleration is designed to be 10μm[7].

In this article, we report successful generation and acceleration of 1 ms macro pulse by this photo-cathode RF gun and super-conducting accelerator.

STF INJECTOR

The injector is based on 1.3 GHz L-band normal conducting RF gun originally developed by DESY for FLASH/XFEL[2]. The design peak field is 47 MV/m with 4.0 MW input RF power. To generate 1 ms long macro pulse with RF gun, suppressing dark-current, i.e. field-emission from the cavity wall, is an important issue. The dark-current should be well below the average beam current in the macro pulse for a stable operation and clear X-ray signal detection from the laser-Compton scattering. The gun cavity conditioning was performed with nominal high power RF processing and ethanol rinse. The detail of the conditioning was explained elsewhere[8][9][3].

The cavity processing was performed in three stages. Between the first and second stages, ethanol rinse for the cavity was performed. The summary of the cavity conditioning was given in Fig.2; The dark current is shown as a function of accelerating field. The dark current was decreased roughly more than an order of magnitude by the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

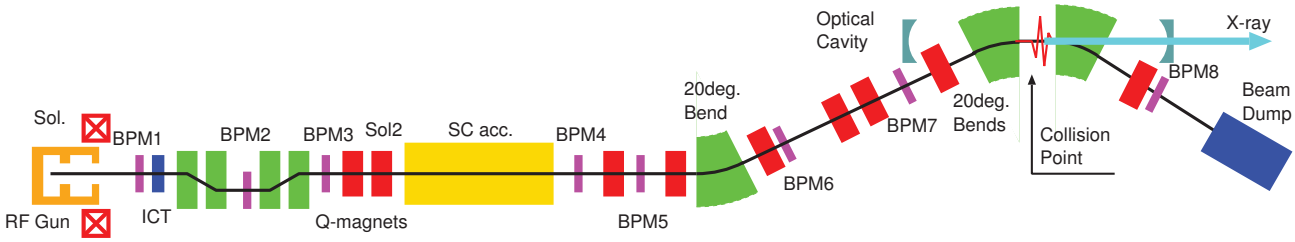

Figure 1: Schematic view of STF beam line. Beam current and position are measured by ICT(Integrated current Transformer) and BPM (Beam Position Monitor). After acceleration by a couple of SC cavities, the beam is focused on IP (Interaction Point) down to 10μm for efficient laser Compton scattering.

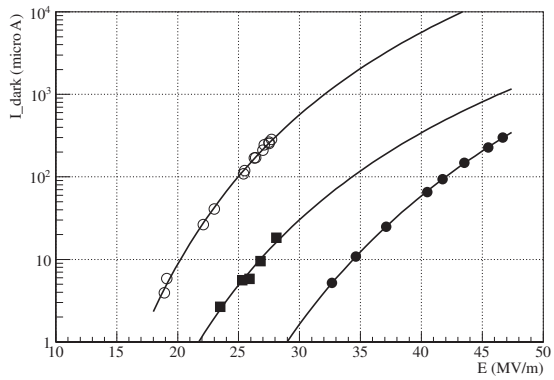

Figure 2: Dark current as a function of field, after first processing(open circle), second processing (filled square) and third processing (filled circle). Lines are expected dark current based on Fowler-Nordheim theorem.

ethanol treatment. Further reduction was observed by high power RF processing. Lines in Fig. 2 show the expectations according to Fowler-Nordheim theorem[10] assuming 4.7 eV work-function of Cu as cavity material. The expectation at 40.2 MV/m was 5.9 mA for first processing, 0.36 mA for second processing, and 0.062 mA for third processing which corresponds to 0.6% of the beam current. The dark current was suppressed by two orders of magnitude by the cavity conditioning.

The laser system for Q-beam mode was developed by Waseda Univ. and KEK for the Quantum Beam mode[6]. IR pulse train is generated by $\mathrm{Nd:YVO_4}$ mode lock oscillator in 162.5 MHz. The pulse train is amplified by a couple of two path Nd:YLF amplifiers. The CW IR pulse train is then clipped by Pockels cell to form the macro pulse structure, i.e. 1 ms pulse train in 5 Hz. The IR laser energy 17μJ / bunch is achieved. UV pulse train is generated by conversion from IR to UV with non-linear crystals, LBO for SHG and BBO for FHG, respectively. Finally, more than $500nJ$/bunch UV laser is obtained.

Cs_2Te cathode was made on Mo plug by evaporation in another vacuum chamber (preparation chamber) connected to the RF gun cavity. After the evaporation, the cathode plug is transferred and inserted to the gun cavity from backside without breaking vacuum. QE (Quantum Efficiency) of Cs_2Te was measured in preparation chamber by UV light from Xe lump and was typically more than 5% at the

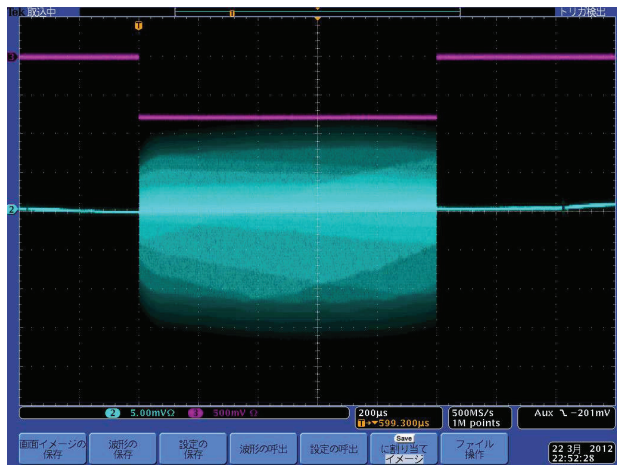

Figure 3: Beam temporal profile taken by BPM2 sum signal.

evaporation, but it was rapidly decreased down to less than 1%. QE in real operation is enhanced by the strong surface field in RF Gun giving more than 2 % QE[11].

1 ms BEAM GENERATION

1 ms beam generation test has been started since February 2012. Up to this period, 4.0 MW RF was successfully fed into the RF gun cavity, but the commissioning was performed with 2.0 MW RF for lower trip rate. Starting from 40μs, 1 ms pulse generation from the RF gun was examined. During the experiment, the field in the cavity was typically 33 MV/m. Detail of the tuning was given in Ref.[11]. After the basic beam tuning, number of bunches was gradually increased. After several iterations of the tuning and the bunch number increments, 1 ms macro pulse generation was achieved. Figure 3 shows the temporal profile of the 1 ms macro pulse. The shaded area shows sum of BPM signals which consist in 162450 bunches, but it is a shaded area due to limited resolution. Square pulse shown above it is the gate signal for laser pulse and has 1 ms duration. The bunch intensity was slightly less than 60 pC measured by ICT output. According to these measurements, it was confirmed that the multi-bunch electron beam with 1 ms pulse duration and very close to 10 mA average current was successfully generated by the photo-cathode RF gun.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

1 ms BEAM ACCELERATION

The beam is accelerated by the SC accelerator. It consists from a couple of 1.3 GHz 9 cells cavities made from Nb with its length 1 m. These cavities are installed in a super-fluid He cooled cryomodule operated in 2 K. The acceleration field is 14.5 and 24.0 MV/m for each cavities[7], respectively. After the injector tuning, the acceleration test was performed with a shorter pulse length. The horizontal beam orbit after the first bending magnet was observed at BPM6 by scanning RF phase of the SC accelerator. The result is shown in Fig. 4. A clear dependence of the horizontal beam position on the RF phase was observed. According to a beam optics design, the crest beam position corresponds to 40.2 MeV/c[12]. The beam acceleration more than 40 MeV was confirmed.

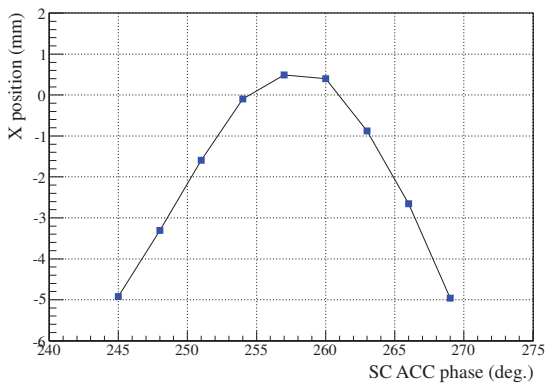

Figure 4: The horizontal beam position by BPM6 is plotted as a function of RF phase of SC accelerator. The maximum position corresponds to 40.2 MeV/c[12].

The final goal of Quantum Beam experiment at STF is demonstrating a high flux quasi-monochromatic X-ray generation by laser-Compton scattering with a compact system. The target value is more than $1.0 \times 10^{10} Photon/sec/1\%BW$. To realize this number, not only amount, but also quality like low-emittance and small spot size at IP are important. The design beam emittance at IP is $0.5\pi\mathrm{mm.mrad}$ and the beam size is $10\mu\mathrm{m}$ in rms for efficient X-ray generation. The bunch length is 12 ps and the bunch charge is 60 pC. The laser pulse stored in the optical cavity has the same 12 ps bunch length with 50 mJ energy per bunch.

The beam size and beam emittance was measured with tungsten wire scanner $10\mu\mathrm{m}$ in radius. This scanner is set at IP on a retractable mount. The emittance was qualified with Q-scan method in horizontal and vertical directions, respectively. The results were 0.82 and 1.34 $\pi\mathrm{mm.mrad}$ for horizontal and vertical directions, respectively. The bunch charge was 35 pC which is almost one half of the designed value. The RF power for RF gun was 3.5 MW giving 40 MV/m peak field . The field gradient of SC accelerator was 14.5 and 24.0 MV/m giving 40.2 MeV beam energy. The measured beam emittance is still twice bigger than the designed value. The beam size was measured directly with the same wire scanner. The results were 36.2 and 36.1 $\mu\mathrm{m}$ in horizontal and vertical directions, respectively. These numbers are still more than three times larger than the designed value, 10 $\mu\mathrm{m}$.

The both beam emittance and beam size are way from the designed numbers. It means that the emittance tuning and the beam optics tuning have to be carefully done. For example, the beam size at cathode should be optimized to minimize the emittance growth by the space charge effect. Solenoid strength should be adjusted for the emittance compensation at the given bunch charge and size. The beta matching should be made at the exit of SC accelerator including the focusing effect.

Although we have demonstrated the quantitative design parameters of the beam, e.g. bunch charge, average current, macro pulse length, and energy, these numbers were achieved not at once. Up to now, the maximum intensity of 1 ms pulse accelerated up to 40 MeV was 6.5 mA corresponding to 40 pC bunch charge. Demonstrating the beam satisfying the all requirements at once is another important mile-stone.

SUMMARY AND FUTURE PROSPECT

At KEK-STF, the beam test to generate 1 ms and 10 mA pulse was successfully carried out. The basic beam parameters such as beam current, macro pulse length meet the requirements. The beam was accelerated by SC accelerator and more than 40 MeV energy was confirmed, but the intensity was 60% of the designed value. The beam emittance was measured as 0.8 and 1.3 $\pi\mathrm{mm.mrad}$ for horizontal and vertical axes, respectively. The beam size at IP was 36 $\mu\mathrm{m}$ which is more than three times larger than the designed value. For efficient X-ray generation, these properties should be improved by progress of the beam and optics tuning.

Abstract

TRIUMF is collaborating with VECC on the design of a 10 MeV injector cryomodule to be used as a front end for a high intensity electron linac. A electron gun and low energy beam transport (LEBT) have been installed in a test area to act as the injector for the cryomodule test. The LEBT includes a wide variety of diagnostics to fully characterize the beam from the gun. A series of beam tests are being conducted during the stage installation. The test configuration details and results of beam tests will be presented.

INTRODUCTION

TRIUMF is now preparing a new high intensity (10mA) 50MeV superconducting electron linear accelerator [1], e-Linac, as a key element of the ARIEL project. In brief the e-Linac consists of five 1.3GHz nine-cell niobium cavities each providing 10MV acceleration with two 50kW power couplers supplying the required beam loaded rf power. The five cavities are housed in three cryomodules, with a single cavity in an injector cryomodule, EINJ, and two identical accelerating cryomodules EACA and EACB with two cavities in each module.

TRIUMF began developing EINJ in 2010 in collaboration with the VECC laboratory in Kolkata. As part of the collaboration two EINJs will be fabricated and beam tested at TRIUMF. One EINJ will be shipped and installed at VECC and the second will be installed in the e-Linac. The initial EINJ is presently in fabrication [2].

A beam test area is being installed in the ISAC-II building to eventually test the two injector cryomodules with beam. The site utilizes the existing ISAC-II cryogenics infrastructure and enables testing of the cryomodules well before the expected availability of the e-Linac cryogenics in 2014. The schedule calls for accelerated beam tests in early 2013. Moreover, the injector test facility provides an ideal proving ground for e-linac design and operation strategies. It duplicates the front-end of the e-linac up to the exit of the injector cryomodule with enhanced diagnostics capability for benchmarking both the performance of the gun but also of the various diagnostics themselves. In addition the test installation allows early demonstration and troubleshooting of various e-Linac sub-systems including MPS, controls, beam modes, safety, LLRF, HPRF, cryogenics and important feedback on beam quality, halo formation and high intensity operation. Commissioning this facility began Nov 2011.

INJECTOR LAYOUT

The test layout, shown in Fig. 1 includes an electron gun, a low energy beam transport (LEBT) complete with a beam diagnostics leg, the EINJ cryomodule, a medium energy beam transport and diagnostic end station (MEBT) and beam dump. Two guns are envisaged. In the first phase (present) a 100kV thermionic gun with rf modulated gridded cathode bias is utilized. The cathode rf drive is at 650MHz providing rf bunches for one of every two accelerating buckets. This will soon be replaced by a 300kV gun also with rf modulated gridded cathode bias at 650MHz. The higher energy is needed to achieve efficient capture in the EINJ while the 100kV gun is perfectly sufficient to characterize the rf modulation and commission the LEBT and diagnostics. In both cases the specified peak current is 10mA, with a bunch length of $\leq \pm 20^0$ of 650 MHz (170 ps), a bunch charge of 15.3 pC, an energy spread of $\leq \pm 1$ keV and a transverse emittance of ≤ 30 μm normalized to a 2σ x 2σ cylindrical beam.The rf modulation can also be pulsed to provide a macro duty cycle varying from 0.1% to 99.9% duty cycle at various macro periods.

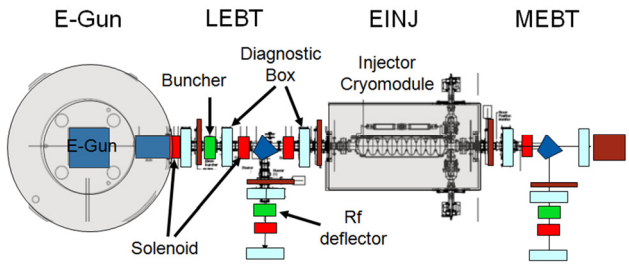

Figure. 1: TRIUMF/VECC beam test configuration.

The LEBT straight section is designed to prepare the beam for acceleration. Three solenoids are used to provide transverse matching and transportation. An initial solenoid provides a waist at the buncher while the two downstream solenoids match the beam to the cryomodule. A 1.3GHz room temperature buncher provides longitudinal matching to the EINJ. An analyzing diagnostic line includes a 90^0 bending spectrometer, diagnostic boxes and a 1.3GHz rf deflector for bunch length measurements.

DIAGNOSTICS

The diagnostics used in the LEBT are shown in Fig. 2. The diagnostics fit in multi-port custom chambers machined out of solid stainless steel bulk material. The

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

diagnostic chamber has eight transverse ports, four on the horizontal and vertical axis and four on the 45 degree axis. Two ports are occupied with an ion pump and turbo-pump roughing system respectively leaving six available for diagnostics.

The diagnostics comprise devices for a wide range of beam intensities. More details can be found in [3]. A standard water cooled Faraday cup (FC) can dissipate beam powers up to 200W. A high power Faraday cup (HPFC) is designed to take the full 1kW and is positioned at the end of the beamline. A high power slit (HP-Slit or Linear profile monitor (LPM)), shown in Fig. 3, consists of a water cooled copper plate with two 1mm slits cut at 45 degrees to the plate and 90 degrees from each other.

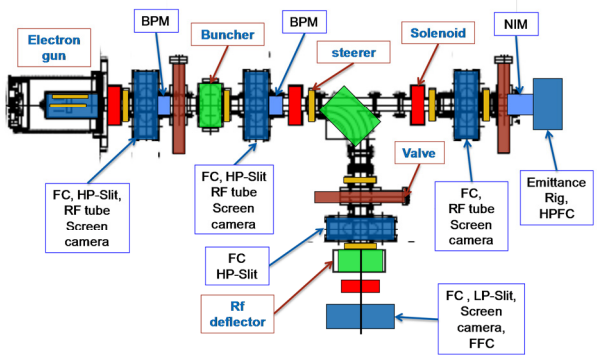

Figure 2: LEBT beam diagnostics, optical elements and rf devices.

The HP-Slit can absorb about 200W. An identical low power device, LP-Slit, has no water cooling provision and can dissipate a few watts only. The slit device is positioned on a 45 degree diagnostic port and when scanned in front of a Faraday cup gives beam x and y profile information. The device also doubles as an emittance defining slit when fixed in the beam. In longitudinal analysis mode the HP-slit in the box upstream of the analyzing dipole is used as an object slit and the HP-slit in the box upstream of the rf deflector is used to select an energy slice. The rf deflector is then used to analyze the time width of the selected beam. The slit plate also has a 2mm collimator to be used in a fixed mode to define the beam shape.

Several scintillator screens are used in the line. Each monitor includes two or three targets, optics and a camera. Possible target options are a 0.5 mm thick piece of gold-plated Yttrium Aluminium Garnet (YAG) scintillators, Chromox scintillators and a calibration target. An Optical Transition Radiation (OTR) screen is available for the MEBT. The screens can only dissipate a few Watts of beam power. A third type of profile device is the Allison type high power emittance scanner [4]. The device is designed to take up to 1kW with power densities up to 20W/mm^2. In brief the device consists of a front plate that selects a slice of the beam and a set of steering plates that scan the beamlet across a back slit to a Faraday cup to define the beam divergence. Quadrant button-type BPMs are also used for non-intercepting beam position information.

In the time domain an intercepting 50Ω co-axial fast Faraday cup (FFC) is used to measure bunch characteristics with a lower limit resolution of ~100ps. A non-intercepting monitor (NIM) capacitive pickup is used to record beam phase information. Higher resolution timing information is available from an rf deflector.

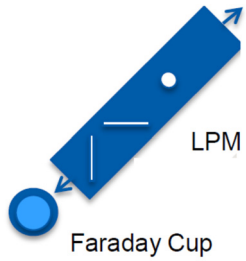

Figure 3: The LPM scanning slit profile monitor and collimator.

RF DEVICES

There are two rf devices installed in the LEBT; a 1.3GHz buncher operating in TM010 mode and a 1.3GHz deflecting cavity operating in a TM110-like mode.

Buncher

The bunching cavity is manufactured by Niowave and is identical to cavities designed and fabricated for the EMMA FFAG project at Daresbury [5]. Beam dynamics set the maximum required peak electric field on axis to 0.5MV/m and this corresponds to an integrated voltage defined by $V_0 = \int E_z dz = 30\,\mathrm{kV}$ based on a field profile from CST. The effective voltage of the cavity for β=1 φ=0 particle is normalized by T_0≅0.78 to V_{acc}=23.4kV. The measured shunt impedance, $R_{sh}=V^2/2P$, of the buncher cavity is 3.3MΩ. This converts to a linac shunt impedance ($R=2R_{sh}T_0^2$) of R=4.0MΩ for Q_0=20000 and R/Q=200Ω. The normalized transit time factors ($T_n=T/T_0$) at 100keV and 300keV are 0.64 and 0.89 respectively.

Deflector Cavity

The deflector cavity is designed after a Cornell deflecting cavity [6] but with simplifications to ease manufacturing. A TM110 pillbox vertically deflecting mode cavity is modified with entrance and exit nose cones that generate a concentrated magnetic deflecting field at entrance and exit and provide an on-axis vertical dipole field (Fig. 4) to enhance the effective perpendicular shunt impedance given by $R_\perp = \frac{(V_\perp)^2}{P} = \frac{(V_\perp)^2 Q}{\omega U}$ where $V_\perp$ is the effective perpendicular voltage gain from the magnetic and electric dipole components, Q is the quality factor of the mode and U is the stored energy. The vertical deflection is given by $y' = \frac{dy}{dz} = \frac{1}{\beta^2}\frac{V_\perp}{E}$ where E is the total energy of the electron. For β=1 CST gives $\frac{R_\perp}{Q} = 940\Omega$ while at β=0.78 (300keV) and β=0.55

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

(100keV) $\frac{R_\perp}{Q} = 480\Omega$ and $\frac{R_\perp}{Q} = 160\Omega$ respectively with an expected Q of 10000.

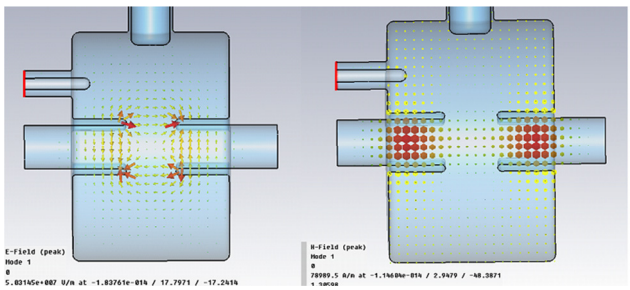

Figure 4: Electric and magnetic components of deflector field.

INSTALLATION AND BEAM TESTS

The equipment is being installed in stages. Presently the 100kV gun, complete LEBT and analyzing station are installed. The EINJ is in fabrication [2] and the MEBT station has components both in fabrication and in final design including a 30kW beam dump. The equipment is pre-cleaned in ultrasound and assembled in a clean room as major sub-assemblies. Each sub-assembly is then transported to the test area and installed into the system. When joining the new equipment to the existing equipment the open volume is slightly pressurized with filtered N_2 to reduce the risk of particulate contamination. The sealed line is evacuated and baked at ~150C for 48 hours. Typical vacuum is in the low 10^{-9} Torr range.

A series of beam tests have been organized with the installed equipment. These tests are designed to measure the properties of the beam but most importantly to establish techniques and procedures, qualify and characterize diagnostics and troubleshoot and evaluate sub-systems all well in advance of the e-Linac final installation. Initial beam tuning confirms the beam dynamics modeling for the solenoid and correctors. The emittance scanner has been characterized over a wide range of beam intensities with emittances recorded for peak power densities up to 100W/mm^2[4]. Measurements demonstrate an emittance of 90% of the beam within 30µm. The horizontal beam emittance as a function of bunch charge selected from the 100kV gun is shown in Fig. 5.

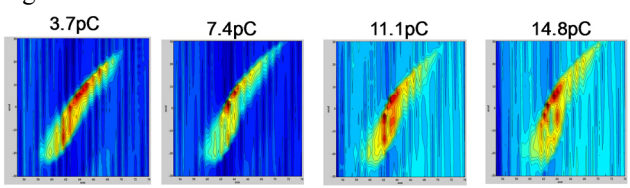

Figure 5: Horizontal emittance scan at various bunch charge settings.

The gun rf has been successfully used to provide a variable duty factor beam to adjust the beam intensity for different tuning regimes near the peak bunch charge. Typical low intensity operation is at 1kHz repetition rate with 1µsec macro-pulses (0.1% duty) with 10µA average beam current. All diagnostics including LPMs, FCs, FFCs and NIM have been characterized with beam and function as designed. The BPM and electronics have been characterized by scanning the beam with steering correctors. Both Chromox and YAG screens have been characterized. Charging up of YAG screens has been mitigated by depositing a thin gold coating on the surface.

The two rf devices are installed and commissioned. The measured installed Q of the buncher is 18500. The measured values on deflector transverse shunt impedance is $\frac{R_\perp}{Q} = 400\Omega$ for β=0.78 with a measured Q of 5400. The shunt impedance is slightly down from initial estimates due to a slight difference in actual nose positions compared to that of the simulations. The Q of the deflector was 8700 during the bench test before final cleaning so we suspect some surface pollution. Both buncher and deflector have been phase locked to the gun rf and first beam tests have been completed. The buncher effective voltage has been verified in beam based TOF tests. Fig. 6 shows the first demonstration of rf deflection of the beam on a scintillator screen. Future tests will involve characterizing the longitudinal emittance at various gun conditions.

The 300kV gun is being prepared for installation starting in Oct. 2012. The EINJ is in fabrication for installation and accelerated beam tests in early 2013.

COMMISSIONING OF THE X-BAND TEST AREA AT SLAC[#]

C.G. Limborg-Deprey*, C. Adolphsen, M. Dunning, S. Gilevich, C. Hast, K. Jobe, D. McCormick, A. Miahnahri, T. Raubenheimer, A.E. Vlieks, S. Weathersby, and D. Walz, SLAC, Menlo Park, California, R. Marsh, LLNL, Livermore, California, USA

Abstract

The X-Band Test Area (XTA) was installed in the NLCTA tunnel at SLAC over the spring and summer of 2012. The first gun to be tested is an upgraded version of a 5.5 cell, 200 MV/m peak field X-band gun designed at SLAC in 2003 for a Compton scattering experiment run in ASTA [1]. The first photo-electron beam was generated at the end of July. We report on the results of the first eleven days of commissioning.

X-BAND TEST AREA

The X-Band Test Area (XTA) is a gun test facility located in the SLAC NLCTA tunnel that uses exclusively X-Band technology. In its initial configuration, a 5.5 cell photo-rf gun is followed by a 1-m long accelerator structure (denoted T105) that had been built for NLC rf breakdown studies. Both are driven by a single klystron whose power is compressed (x4 in magnitude) with a SLED-II system. A combination of high power phase shifters and 3 dB hybrids allows the phase and amplitude of the gun and accelerator to be controlled independently.

Simulations [2] have shown that such a photoinjector has great potential to be a compact driver for X-ray FELs [3], for a compact Compton-generated photon source [4] and for Ultra-Fast Electron Diffraction. The main challenges of this technology were expected to be alignment and high dark current levels. Early operation of the facility indicates that these issues are manageable. Detailed tuning and full beam characterization will continue this year.

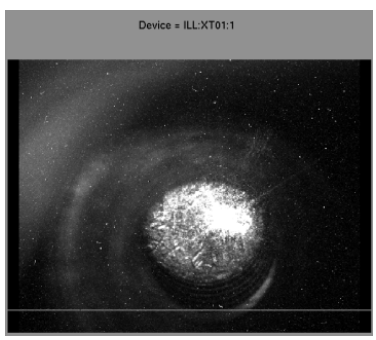

Figure 1: Green alignment laser striking the cathode.

LASER SYSTEM

Photo-Injector Laser

A Spectra Physics Tsunami oscillator locked at 79.3 MHz to the rf master clock provides a 305 mW, 65 nm bandwidth seed to a Coherent Elite regenerative Ti:Sapphire amplifier. The regenerative amplifier produces 600Hz, 3.5 mJ pulses of IR. This amplifier is shared with another experiment so pulses are sent to the XTA line at 300 Hz. The stretched IR pulses are transported through 26 m of vacuum pipe via relay imaging, yielding 2.6 mJ of IR at the XTA laser table. The IR is then compressed to 70 fs pulses of 1.7 mJ each. A non-linear tripling of the frequency with two 0.3 mm thick BBO crystals yields 120 uJ UV pulses. Finer tuning should provide a higher conversion efficiency, up to 10%, which this is not required initially.

Alignment Laser

A green laser was used to align the optics to the cathode – the image of this laser on the cathode is shown in Fig. 1. This procedure had to be implemented for two reasons: the rf gun does not have a removable cathode and the laser injection chamber was installed after the gun had already been positioned. The UV pulse follows the path defined by the green laser. A leakage of 10% before entering the injection chamber is sent to a virtual cathode camera as shown in Fig. 2.

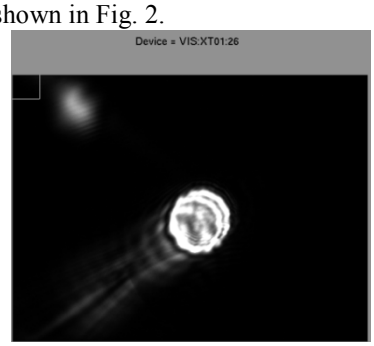

Figure 2: Virtual cathode image (4x6 mm): the main spot is the non-attenuated UV and the upper left spot is the green laser attenuated with filters.

Injection Chamber

The gun irises are 4 mm in radius which translates into a laser half-opening angular aperture of 45 mrad from the last adjustable mirror. Optimum emittance compensation requires having the first accelerator positioned as close as possible to the gun exit. However the injection mirror, which is located in between, has to be far enough away from the cathode to allow a reasonable beam stay-clear. As a compromise, the ~ 45 degree injection mirror was located 53 cm from the cathode plane. It is a 12.7 mm diameter Al substrate mirror with a UV protected Al coating. An extraction mirror for viewing the cathode is located symmetrically opposite of the injection mirror with a 7 mm gap between them. The injection chamber also accommodates a YAG screen combined with a

Faraday cup. A shadow of the two mirrors is visible on the dark current imaged on the YAG screen as shown in Fig. 3.

X-BAND GUN

After transport to the XTA area from the SLED II compression system, the rf is split via a 6 dB H-plane hybrid. A quarter of the power feeds the gun and three quarters feeds the T105 accelerator. The gun power is split, sent through the two phase shifters and recombined. Each phase shifter has a 110-deg range and the relative phase can be adjusted remotely to vary the combined power from zero to 100% of the input power. The linac line is also equipped with a 110-deg phase shifter to adjust the relative gun-to-linac phase (although this can also be done by changing the gun shifters in common). With 76 MW from the SLED II system and the 20% attenuation that occurs during transport, the gun input power is 15.2 MW, which should produce a cathode peak field of 186 MV/m after 200 ns.

Gun Exit Energy

The bunch energy was measured by recording the beam excursion on a YAG screen as a function of corrector strength (see Fig. 3). A bunch energy of 6.85 MeV +/- 0.15 MeV was observed with 76 MW from SLED II. Both vertical and horizontal measurements are consistent. This beam energy corresponds to a cathode peak voltage of at least 180 MV/m and depends on the rf-to-beam phase at the cathode (see Fig. 4), which was not known for this experiment.

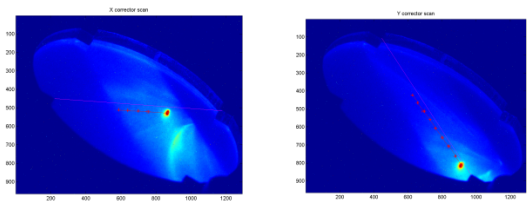

Figure 3: Beam centroid displacement as a function of (left) horizontal corrector and (right) vertical corrector settings.

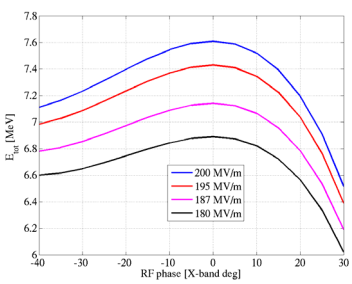

Figure 4: ASTRA-calculated energy at the gun exit for four cathode voltages:

Gun Tuning

To maximize the field in the gun, the reflected power was minimized by adjusting the gun temperature (the rf frequency is kept constant at 11.424 GHz). The gun operating temperature had been anticipated to be around 53 degC from design and cold test tuning. The minimization of reflected power indeed occurs at 53 degC as can be seen from the waveforms in Fig. 5. Systematic beam energy measurements as a function of temperature will be performed during the next run.

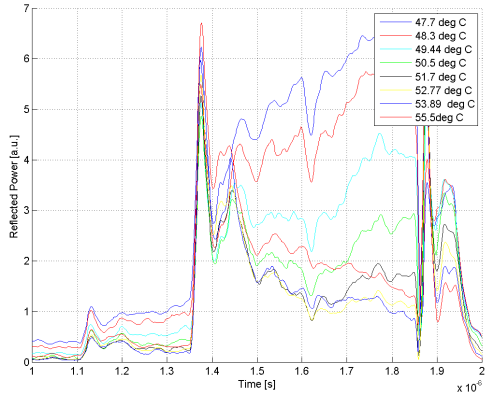

Figure 5: Reflected power waveforms from the gun for cathode temperatures between 47.7 degC and 55.5 degC.

Dark Current

The integrated dark current per pulse was measured as a function of the cathode temperature for 76 MW, 200 ns rf pulses from SLED II. The dark current was observed to increase as the temperature was lowered from the value that gives minimum reflected power (see Fig. 6). At the operating temperature of 53 degC, the dark current is about 150 pC, which should be manageable. The fluctuations in the dark current were of the order of 13%, and since the dark current increases as a high power (n > 10) of the peak voltage ($I \sim V^n$), the field stability appears to be at the 1% level or smaller.

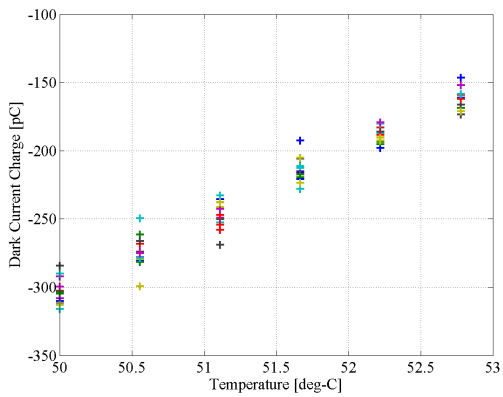

Figure 6: Gun dark current versus cathode temperature.

Beam Based Alignment

The laser should strike the cathode at the electromagnetic center of the rf gun and the electromagnetic axis of the gun should coincide with the magnetic axis of the solenoid. Preliminary measurements were made to establish a procedure to optimize the centering of the laser on the cathode. An rf phase scan was performed and the centroid of the photo-electron beam recorded on the first YAG screen. For the data shown in Fig. 7, the laser center is estimated to be offset from the gun center by 200 μm horizontally and 2.2 mm vertically.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Quantum Efficiency

Low energy (~7 μJ) laser pulses were used initally to avoid damage during laser alignment. This produced bunch charges of up to 15 pC. The quantum efficiency was thus around 10^{-5}.

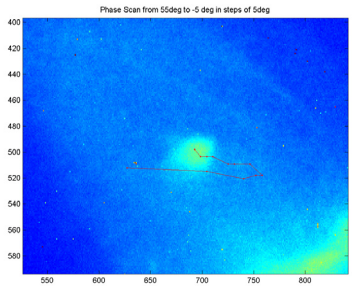

Figure 7: Electron beam centroid position on first YAG screen for various rf-to-beam phases.

HIGH ENERGY

Energy Measurement

The beam was accelerated in the linac and transported to the spectrometer at the end of the beamline. The gun-to-linac distance was not set precisely, and with the limited range of the phase shifters with full gun power operation, on-crest operation could not be achieved, although the phase offset was probably about 15 deg. The electron beam energy was measured to be 50 MeV. An appropriate positioning of the gun phase shifters should allow us to reach crest and 70 MeV. The T105 structure presently installed cannot be conditioned above about 65 MV/m due to pulse heating limits in the couplers. A new T105 structure with racetrack couplers will be installed next year and should allow up to100 MV/m acceleration.

Energy Jitter and Energy Spread

Large bunch energy jitter was measured at the spectrometer, about 2% at 50 MeV beam energy as shown in Fig. 8. This corresponds to excursions of +/- 3 deg X-band. Jitter levels of 3 deg could be traced back to the Low Level RF system. A new LLRF electronics system with higher initial power levels [5] will be installed and should lower this jitter. The additional jitter comes from the laser oscillator phase locking. The Tsunami oscillator is rated for 500 fs timing jitter, i.e., 2 deg X-band. However, we suspect that a larger oscillator phase jitter was present at the time of our experiment which would explain the +/- 3 deg total excursion. Acquiring a lower timing jitter (< 60 fs rms) oscillator is presently being considered.

Correlated energy spreads smaller than 50 keV were observed on the YAG screen of the spectrometer line. The YAG thickness and blurring effects hide the true beam size values. An OTR screen will be available for the next run.

Transverse Beam Characterization

The beam emittance was measured on a YAG screen as the OTR station was not equipped with appropriate lenses for capturing large cones of light. Small and intense spots were nevertheless observed on the OTR screen.

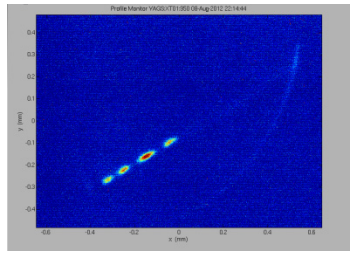

Figure 8: Five, 50 MeV pulses on the spectrometer YAG screen.

CONCLUSION

First photo-electron beam was successfully produced at the XTA facility after only 18 months of design, construction and installation. The rapid turn-on of this facility owes a lot to the expertise of various SLAC departments and the many years of X-band technology development. The results reported here cover only 11 days of commissioning and thus more work will be needed to fully optimize and understand the beam characteristics. However the early results look promising. In particular, the dark current levels and cathode QE are acceptable.

For the next run, an X-Band transverse deflector will be installed that will allow bunch length and slice emittance measurements. Many tools developed for optimizing the LCLS injector will be reused here. The OTR modules will be equipped with appropriate imaging systems for high resolution beam size determination. A peak brightness three to four times higher than that achieved at LCLS is expected with bunch lengths three times shorter than those obtained from S-Band guns.

ACKNOWLEDGMENT

We wish to thank E. Colby, R. Hettel and N. Holtkamp for their support and encouragement for this project and members of the many SLAC departments (alignment, magnetic measurement, mechanical engineering, laser, software and controls) for their valuable contributions

PERFORMANCE OF THE FIRST C100 CRYOMODULES FOR THE CEBAF 12 GeV UPGRADE PROJECT*

M. Drury, A. Burrill, G. K. Davis, J. Hogan, L. King, F. Marhauser, H. Park, J. Preble, C. E. Reece, R. Rimmer, A. Reilly, H. Wang, and M. Wiseman,
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606 USA

Abstract

The Thomas Jefferson National Accelerator Facility is currently engaged in the 12 GeV Upgrade Project. The goal of the 12 GeV Upgrade is a doubling of the available beam energy of CEBAF from 6 GeV to 12 GeV. This increase in beam energy will be due primarily to the construction and installation of ten "C100" cryomodules in the CEBAF linacs. The C100 cryomodules are designed to deliver an average 108 MV each from strings of eight seven-cell, electropolished, superconducting RF cavities operating at an average accelerating gradient of 19.2 MV/m. The new cryomodules fit in the same available linac space as the original CEBAF 20 MV cryomodules. Cryomodule production started in September 2010. Initial Acceptance Testing started in June 2011. Four C100 cryomodules were installed and tested from August 2011 through July 2012. The first two of these cryomodules were successfully operated during the last period of the CEBAF 6 GeV era, which ended in May 2012. This paper will present the results of Acceptance Testing and Commissioning of the C100 style cryomodules to date.

INTRODUCTION

Since July 2011, six C100 cryomodules have been delivered to the Cryomodule Test Facility (CMTF) for Acceptance Testing. Four of these cryomodules have been installed in the South Linac of CEBAF and commissioned. Two of these, C100-1 and C100-2, have been operated with beam during the final 6 GeV operations period for CEBAF which started in November 2011 and ended in May 2012.

Each cryomodule goes through two testing cycles, acceptance testing prior to installation in the linac and a final commissioning after installation.

Acceptance testing is generally a more comprehensive set of tests than the final commissioning and is meant to uncover any major problems before delivery to the linac. An example of such a problem would be the failure of an instrumentation feedthru during cooldown that leads to the loss of insulating vacuum. Such problems are more easily addressed while the cryomodule is in the CMTF.

During acceptance testing, each cavity is tested to insure proper operation of the mechanical and piezo tuners. Low power measurements using a network analyser are made to characterize the seven passbands of each cavity once the cavities have been tuned to 1497.000 MHz. The higher order modes of each cavity are also characterized at low power. Each cavity is then characterized in terms of maximum gradient, field emission, and unloaded Q (Q_0). Measurements of microphonics, pressure sensitivity, static Lorentz coefficients and static heat loads are also conducted.

Once the cryomodule has been installed in a linac, it is commissioned. Commissioning consists of a subset of the acceptance tests. The focus for commissioning is determining stable operating gradients, measuring field emitted x-ray production, Q_0 and microphonics.

MICROPHONICS

The measurement of cavity detuning due to external vibration sources is conducted in both the CMTF and in the tunnel. The results of these measurements, however, are location and time dependent. We now know that the CMTF has a large number of vibration sources that are not present in the tunnel environment. This paper will focus on measurements made on installed cryomodules.

A maximum peak detuning of 25 Hz was budgeted for the C100 cavities. Microphonics testing of the first unit (C100-1) met design goals, but results were higher than expected based on prototype testing. C100-1 as measured during operation in the CEBAF tunnel ranged as high as 21 Hz peak detuning during a 500 second sample time period [1]. While within the specification, the results were higher than predicted. These results led to a modification of the mechanical tuner system in order to gain margin. The tuner modification was first installed on the cavities in C100-4. Thicker plates at either end of the tuning structure led to an average reduction in peak detuning of 42% [1].

TUNING SENSITIVITY

Two other properties related to cavity detuning are measured during Acceptance testing. These are pressure sensitivity and the static Lorentz coefficient. As Tables 1 and 2 illustrate, these properties were also affected by the tuner modifications.

Table 1: Pressure Sensitivity (Hz / torr)

	C100-1	C100-2	C100-3	C100-4	C100-5
1	435	404	420	**250**	**254**
2	322	323	352	**226**	**234**
3	300	357	323	**215**	**203**
4	252	321	355	**200**	**188**
5	273	356	323	**205**	**183**
6	314	338	325	**230**	**203**
7		379	355	**213**	**214**
8		399	426	**243**	**243**

Table 2: Static Lorentz Hz/(MV/m)^2

	C100-1	C100-2	C100-3	C100-4	C100-5
1	-2.35	-2.23	-2.27	**-1.59**	**-1.60**
2			-2.18	**-1.58**	**-1.68**
3	-1.98	-2.08	-2.04	**-1.62**	**-1.43**
4	-1.95	-2.08	-2.14	**-1.63**	**-1.58**
5	-2.05	-2.11	-2.01	**-1.46**	**-1.55**
6		-2.19	-2.16	**-1.54**	
7	-1.94	-2.32	-2.18	**-1.61**	
8	-2.48	-2.36	-2.30	**-1.47**	

These two tables show that the tuner modification has led to a 37% reduction in pressure sensitivity and a 28% reduction in the static Lorentz detuning coefficient.

GRADIENT PERFORMANCE

The C100 cavities are required to have an average maximum usable gradient equal to or greater than 19.2 MV/m in order to meet the design goal of 108 MeV per cryomodule. The maximum gradient of each cavity is determined first in the CMTF and again after the cryomodules are installed in the linacs.

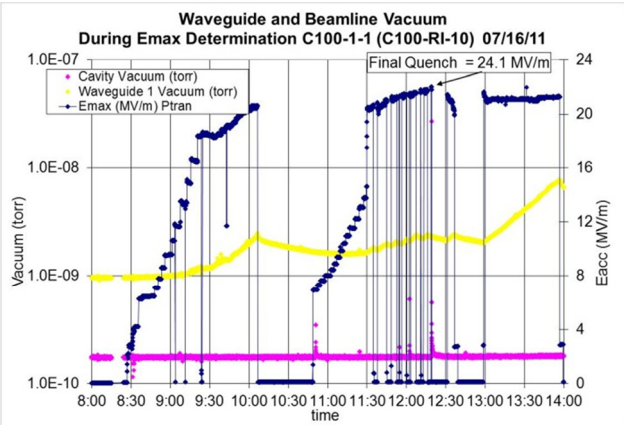

Figure 1: Maximum Gradient Determination

Figure 1 illustrates the process of raising a cavity to its maximum gradient (Emax) for the first time in a cryomodule along with the effects on both beam line and waveguide guard vacuums. This process can take as long as eight hours. Note that this cavity experienced multiple non-repeating quenches as the gradient was raised to its final maximum gradient at 24.1MV/m. This is typical behaviour for a cavity during this procedure.

In theory, there are a number of conditions that may limit the maximum gradient. These include, arcing in the waveguide vacuum space, vacuum degradation, rf window temperature, quenching, high dynamic (rf) heat load and an administrative limit of 25 MV/m. In practice, the cavities are limited by quenching, high rf heat load or the administrative limit. For single cavity operation, a dynamic heat load in the range of about 50–60 W would be considered to be too high for stable operation. Heat loads in this range will most likely cause "boiling" in the helium bath. This behavior manifests as large swings in the helium bath level and an increase in the helium bath pressure.

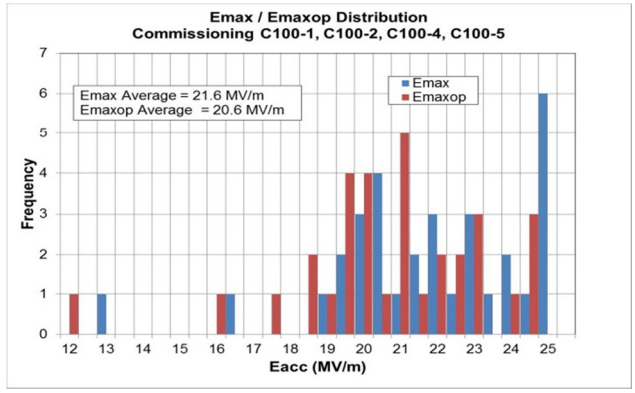

Figure 2: Emax / Emaxop Distribution.

Once the maximum gradient is known a determination must be made of the maximum stable operating gradient (Emaxop). This is done by lowering the gradient below Emax by an amount generally between 0.5 MV/m and 1.0 MV/m. The cavity is then operated at this new gradient for at least one hour. If no faults or cryogenic instabilities (such as boiling) occur, this gradient is designated as Emaxop for single cavity operation.

Figure 2 shows the distribution of maximum gradients for the first four installed C100 cryomodules. Note that there are three outliers in this distribution. The lowest gradient at 12.5 MV/m was the result of the beamline being vented to air during assembly, the next lowest suffered a quench induced field emitter during vertical test and was not reprocessed as would normally be done. The last of the three had a misadjusted stub tuner which led to waveguide vacuum problems. The stub tuner problem was later corrected after commissioning had been completed.

Field Emission

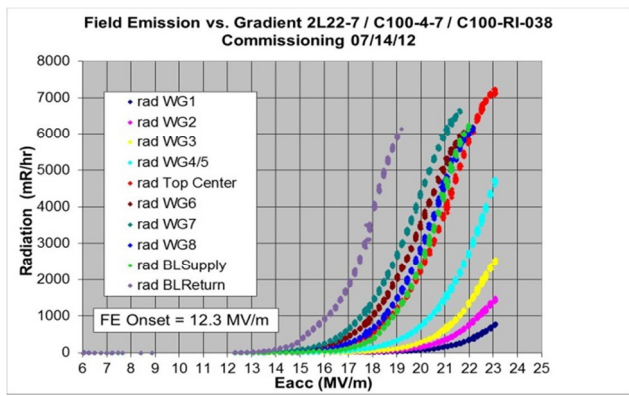

Figure 3: Typical Plot of X-Ray Production by Field Emission

After the Emaxop determination is completed, a measurement of x-rays produced by field emission as a function of gradient is made. A set of 10 Geiger –Mueller (GM) tubes are placed on the cryomodule at several locations including the beamline at either end of the cryomodule and at the Fundamental Power Couplers

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

(FPC's). Figure 3 shows the results for a typical cavity. Note that the GM tubes used saturate at approximately 7 R/hr. Figure 4 shows the distribution of field emission induced x-ray onset gradients for the four installed cryomodules.

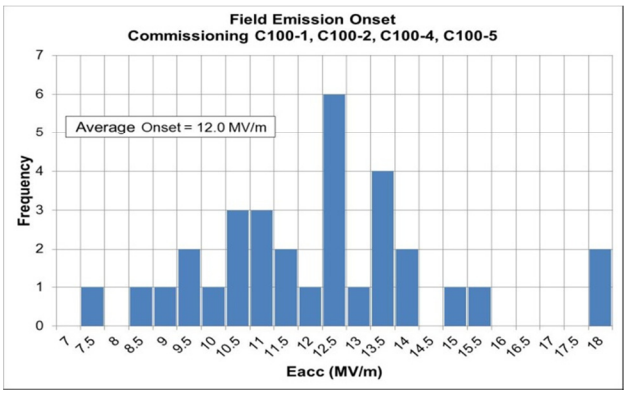

Figure 4: Field Emission Induced Onset of X-rays

Q_0 AND HEAT LOAD

After the operating gradients have been determined, Q_0 vs. E_{acc} is measured for each cavity. Q_0's are measured calorimetrically. The cryomodule is isolated by closing the JT and RT valves and the rate of rise of the helium bath pressure is used to determine the rf heat load [2]. Figure 5 shows a typical Q_0 vs. E_{acc} curve. Figure 6 shows the values of Q0 at Emaxop and at 2.07 K for the four installed cryomodules.

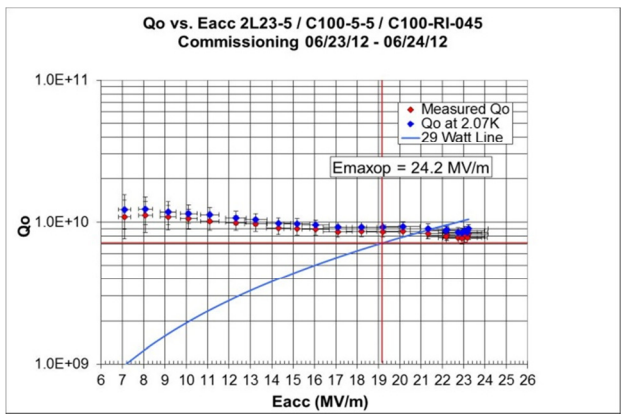

Figure 5: Typical Q_0 Plot

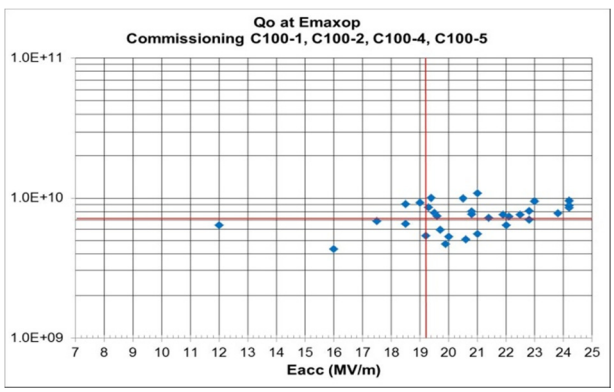

Figure 6: Q_0 at Emaxop

The Q_0 measurements are used to calculate a set of gradients at which the rf heat load equals 29 W but does not exceed Emaxop for a particular cavity. The 29 W value is based on a dynamic heat load budget for each cryomodule of 250 W that includes waveguide losses. If this budget is exceeded, boiling in the helium bath will begin and stable operations will not be possible. In cases where a cavity or cavities do not reach the 29 W heat load level due to other gradient restrictions, the gradients of other cavities in that cryomodule may be adjusted upwards. The final commissioning step is to attempt to operate all eight cavities simultaneously at these gradients for at least one hour. The average of these "ensemble" maximum operating gradients is 19.5 MV/m.

Table 3: Cryomodule Energy Gain (MeV)

	Acceptance	Commission	Ops
C100-1	111.7	104.3	94.5
C100-2	117.5	109.6	108
C100-3	118.7		
C100-4	115.1	105.8	106.2
C100-5	108.2	109.9	109.3

Table 3 lists energy gain for the first five cryomodules. It should be noted that the Acceptance test numbers are only predictions as the CMTF set up only allows for single cavity operation. Furthermore, only the first two cryomodules have been operated with beam. C100-1 has not yet been pushed to its maximum gradients with beam as efforts during the last physics run were focused on bringing C100-2 up to its maximum gradients with beam. On May 18, 2012, C100-2 was operated at 108 MV for over an hour at 465 µA, the design current for CEBAF [3].

SUMMARY

Five C100 cryomodules have been tested in the CMTF. Four of these have been installed in the CEBAF linacs, two of which have been operated with beam. In testing, all five have met or exceeded the specifications necessary for successful operation in the 12 GeV CEBAF accelerator. One of the five cryomodules has been shown to be operable at the design energy and beam loading.

VIBRATION RESPONSE TESTING OF THE CEBAF 12 GeV UPGRADE CRYOMODULES*

K. Davis, J. Matalevich, T. Powers, and M. Wiseman
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA

Abstract

The CEBAF 12 GeV upgrade project includes 80 new 7-cell cavities to form 10 cryomodules. These cryomodules were tested during production to characterize their microphonic response *in situ*. For several early cryomodules, detailed (vibration) modal studies of the cryomodule string were performed during the assembly process to identify the structural contributors to the measured cryomodule microphonic response. Structural modifications were then modelled, implemented, and verified by subsequent modal testing and *in-situ* microphonic response testing. Interim and latest results from this multi-stage process will be reviewed.

VIBRATION TEST PROGRAM

A vibration test program was conducted during construction of the first C100 cryomodules, with the goal of improving the operational vibration response of the cryomodules. Beginning with C100-4, a simple modification was introduced that reduces the peak microphonic detuning to less than one-half of the original project design requirements.

The 12 GeV project "budgeted" for 25 Hz peak total detuning (4 Hz static plus 21 Hz dynamic) based on the available klystron power (13 kW), the design Q_{ext} (3.2×10^7) for the fundamental power couplers, and maximum beam load (465 μA) [1]. Tuner performance allowed the static detuning budget to be reduced, allowing the full 25 Hz for the peak dynamic detuning. Operational experience in CEBAF has established a 6× rule-of-thumb between standard deviation to peak detuning, giving us approximately 4.2 Hz rms detuning (one σ, assuming a Gaussian distribution).

Commissioning of the cryomodules in CEBAF includes measurement of the ambient microphonic response of each cavity in the cryomodule using established procedures and test equipment [2]. Microphonics testing of the first unit (C100-1) met design goals marginally, but results were higher than expected based on prototype testing. C100-1, as measured during operation in the CEBAF tunnel ranged as high as 21 Hz peak detuning over a 500 second time period. Early measurements taken in the cryomodule test facility were even higher, but were eventually attributed to anomalous local driving sources in that facility. The last full upgrade-style pre-production cryomodule ("Renascence") measured less than 15 Hz peak detuning for all cavities in the cryomodule test facility (historically, half this amplitude would be expected in the CEBAF tunnel due to the different vibration environment found there). The most relevant design changes between the two modules comprised removal of the stiffening rings from the cavity design and a completely different tuner design.

A typical spectrum from one of the noisier cavities in the first production cryomodule (C100-1) is shown in Figure 1. The spectrum is dominated by the peak at approximately 10.5 Hz. This peak shows up in the spectrum of all eight cavities, and is typically highest in amplitude in the middle of the string (cavities 4 and 5), becoming lower in amplitude as you move out to the ends of the string (cavities 1 and 8).

Vibration testing of the CEBAF 12 GeV upgrade cryomodules comprised FEA modelling, modal testing of cryomodule components, and operational RF testing of the completed, cold cryomodules. The end goal was to improve our understanding of the vibrational response of the cryomodule to the extent that it affects RF performance, and to improve that performance with minimal risk to the 12 GeV project.

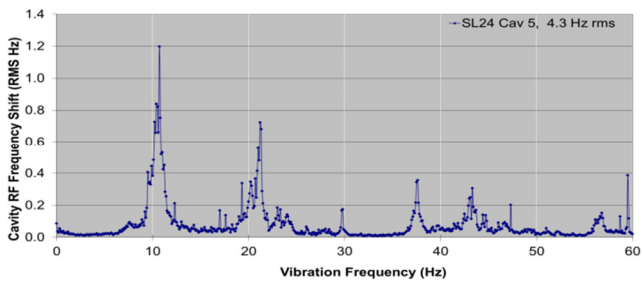

Figure 1: Spectra of Baseline (C100-1) Design

FEA Modelling

ANSYS™ finite element analysis software was used to create a 1-D simplified model of the string assembly. Once the model was validated against the modal test data, the model was used to vet various proposed design modifications including stiffening inside the cavity helium vessels, adding damping to the cavity string assembly, and changes to the cavity tuner. The conclusion of this analysis was that the tuner pivot plates were the least stiff component in the tuner assembly. Stiffening the pivot plate was judged to present low schedule, budget, and technical risk.

Modal Testing

The second production cryomodule (C100-2) was instrumented with triaxial accelerometers during the assembly process [Figure 2]. Hammer impact testing was performed at various stages during the assembly process, beginning with the completed string of eight cavities suspended in its space frame, and ending with the finished cryomodule prior to cool-down. Because a complete cryomodule is such a complex mechanical assembly with limited internal access, waiting until the module is completed before testing makes it difficult or impossible to determine how individual components and subassemblies influence the vibration response of the completed cryomodule. Because of the extreme temperatures inside an operating cryomodule, cool-down marked the last opportunity to collect data from accelerometers on the cold-mass.

A parallel set of modal tests was performed using a single C100 cavity mounted to its tuner in a stand-alone test stand (the tuner test stand) [Figure 3]. The goal for this set of modal tests was to understand how these components contributed to the overall vibration response of the cryomodule, and to test various engineering solutions intended to improve the vibration response.

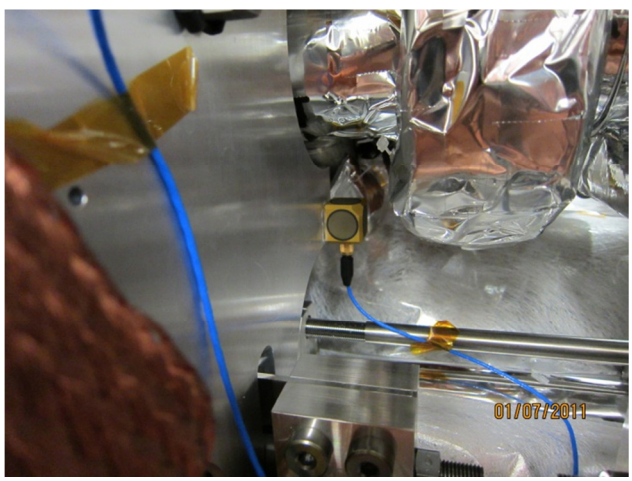

Figure 2: Accelerometer mounted to a tuner pivot plate during final assembly of the cryomodule.

TEST RESULTS

Results of String Modal Analysis

The following modes were identified as contributing to the operational microphonics:

1) First axial (10 Hz, beamline orientation) rigid body mode of the string: Center cavities have higher overall microphonics, most of which is accounted for by this mode. This effect is caused by the center axial nitronic rods, which impose a nearly fixed boundary at one end of cavity 4 and cavity 5. The warm tuner stacks actively participate in this mode, providing possible "hooks" to easily insert damping into the system.

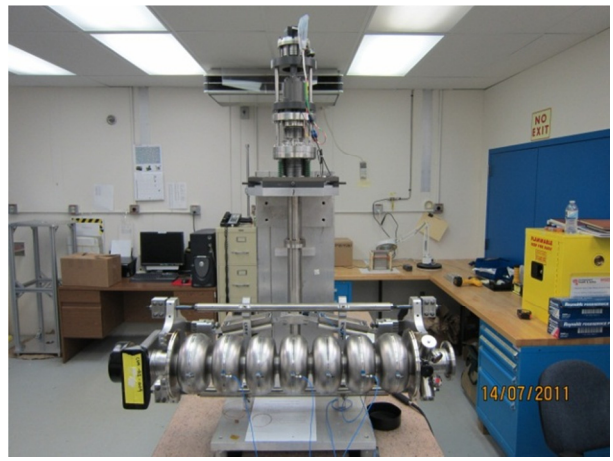

Figure 3: C100 Cavity in the Tuner Test Stand

2) Second axial modes of the string (20 to 25 Hz, varies with cryomodule): Each half-string (cav 1-4 or cav 5-8) has a mode where the four cavities move together, primarily in the axial (beamline) direction. The other half-string usually resonates at a slightly different frequency from cryomodule to cryomodule. The warm tuner stacks move very little in this vibration mode, any damping would involve changes to the cryomodule cold mass.
3) First bending mode of each individual cavity (40 to 45 Hz, varies cavity-to-cavity): The warm tuner stacks actively participate in this mode, providing possible damping "hooks" into the system.

Modified (stiffer) tuner plates were installed beginning with C100-4. The modal test of the cavity string was repeated during the assembly of C100-5. The results showed a decrease in the response at 10 Hz and between 40-45 Hz. The results also predicted a slight increase in response amplitude and frequency in the rage of 20-25 Hz.

Results of Tuner Test Stand Modal Analysis

In support of the investigation into microphonics on C100 cryomodules, a series of bench measurements were collected utilizing the tuner test stand [Figure 3]. The bench setup consisted of a bench-mounted C100 tuner, cavity, and in some test configurations, a helium vessel as well. The intent was to: perform a head-to-head comparison of several potential design modifications, experimentally define the vibrational modes of the system, and determine at what level measurements acquired on this fixture translated into actual performance of the tuner/cavity system in a fully assembled cryomodule. Because the boundary conditions on the bench are different than in the cryomodule, it was fully expected that the vibrational response would be different. But it was expected that at least portions of the system response would be similar enough that the results would prove useful to the overall study. The modifications that were studied include 1) a retrofit cell support device between the helium vessel and the cavity (both with and

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

without a cryogenic damping mesh material installed), and 2) stiffened tuner pivot plates.

The vibrational response of the cavity with and without the support devices was substantially the same with only modest reduction in amplitude with the support device. The results of the testing with and without the stiffened tuner pivot plates showed more promise. The overall modal response between the two configurations was similar as far as mode shapes and resonant frequencies. The configuration with the stiffened arms resulted in reduced vibrational amplitudes for several modes and a significant reduction in amplitude for a lateral bending mode of the cavity.

Operational Testing of the C100 Cryomodules

As of July, 2012, four C100 cryomodules have been installed and commissioned in CEBAF. Two of these cryomodules (C100-1 and-2, baseline tuner design) have been used to deliver beam to physics experiments during the final 6 GeV run. C100-2 demonstrated the ability to meet the 12 GeV design goals of 108 MeV per cryomodule with 465 μA of beam loading. Two more cryomodules (C100-4 and -5, modified tuner design) were installed at the beginning of the 12 GeV Long Shutdown. They have not been used to accelerate beam [3].

Since all of the cryomodules have not completed their construction, it was especially valuable to perform a validation test of the design modification: to compare the vibration response of a baseline cryomodule and a modified cryomodule. Because microphonic response is somewhat variable as a function of time and position in the linac, direct comparison of existing microphonics data (measured weeks or months apart) was not ideal. A baseline cryomodule and a modified cryomodule were operated in adjacent zones in the CEBAF tunnel with all sixteen cavities simultaneously at 10 MV/m, using the normal accelerating operating mode (constant frequency, fixed gradient regulation). The results are summarized in Table 1. Comparing the spectra of this data for C100-1 vs. C100-5, the dominant frequencies are similar; the relative contribution of the 10 Hz and 40-45 Hz components has been substantially reduced, at the expense of a moderate increase in the 20-25 Hz components. The overall ambient microphonic response of the cavities improved (decreased) by an average of 42%. This data is consistent with commissioning microphonics data measured independently on C100-1 through 5.

Table 1: Operational Microphonics in the CEBAF Tunnel, Baseline vs. Modified Design (peak detuning, Hz)

Cryomodule	C100-1 (baseline)	C100-5 (modified)	% Improved
Cavity 1	11.8	5.1	57%
Cavity 2	12.8	6.7	48%
Cavity 3	13.7	5.6	59%
Cavity 4	13.5	7.4	46%
Cavity 5	18.0	9.6	46%
Cavity 6	9.1	8.5	8%
Cavity 7	9.7	5.6	42%
Cavity 8	8.9	5.8	35%

Other Operational Issues

CEBAF accelerator operations group have had six months experience with first two C100 cryomodules. During this time, operations worked closely with the Low-Level RF group to define and improve the control system parameters and user interface [4]. One remaining issue that may be related to vibration response and/or controls: when operating at or near the limits of klystron power (high gradient and high beam loading), a single cavity trip can lead to a cascade that trips some, or all, of the other cavities in the zone. When a cavity trips, the associated loss of Lorentz force causes a step detuning of that cavity. Such trips contain substantial high frequency mechanical energy that travels through the string detuning other cavities (all eight cavities are rigidly coupled to each other). In some cases, all eight cavities trip within a few seconds. The root cause of these trips and how to control them are operational issues that are still being studied. Thus far, this has not proven to be a significant factor reducing beam availability. We are studying control system changes to reduce these trips, and to improve the associated recovery time once a trip happens.

SUMMARY

The first four C100 cryomodules have been commissioned; the first two were used to deliver beam to the CEBAF physics program over a six-month period. The microphonic response of the first two modules was within design requirements, but higher than expected. A vibration test program was performed. Various proposed changes were analysed, resulting in production changes to the cavity tuner. The first two cryomodules incorporating these modifications have been commissioned and tests show, on average, a 42% improvement in operational microphonic response (less than half of the original 12 GeV design envelope). This tuner modification will be included in the last seven C100 cryomodules, scheduled to be complete by the end of 2012.

STABILIZATION OF THE BEAM INTENSITY IN THE LINAC AT THE CTF3 CLIC TEST FACILITY

A. Dubrovskiy, JINR, Dubna, Russia
F. Tecker, CERN, Geneva, Switzerland

Abstract

A new electron beam stabilization system has been introduced in CTF3 in order to open new possibilities for CLIC beam studies in ultra-stable conditions and to provide a sustainable tool to keep the beam intensity and energy at its reference values for long term operations. The stabilization system is based on a pulse-to-pulse feedback control of the electron gun to compensate intensity deviations measured at the end of the injector and at the beginning of the linac. Thereby it introduces negligible beam distortions at the end of the linac and it significantly reduces energy deviations. A self-calibration mechanism has been developed to automatically configure the feedback controller for the optimum performance. The residual intensity jitter of 0.045% of the stabilized beam was measured whereas the CLIC requirement is 0.075%.

INTRODUCTION

CTF3 is a test facility, which is extensively used to uncover new frontiers of the Compact Linear Collider (CLIC) and to develop new technologies of normal conducting linear accelerators [1, 2]. In spite that the feasibility of most of the critical CLIC components has been demonstrated the demands on the beam with parameters closer to the CLIC ones are only rising [3]. The quality, the performance and the relevance to CLIC of each beam shot reduces with the beam deviation from the nominal parameters. In CLIC the beam stability and reproducibility are essential properties and they are required in order to keep the maximum luminosity up to 5.9×10^{34} $cm^{-2}s^{-1}$ at energies from 500 GeV to 3TeV during 20 years of high energy experiments [4]. The beam stability in CTF3 needs to be improved in order to meet CLIC requirements.

DRIVE BEAM GENERATION

In CTF3 an electron beam with the intensity of 4.5 A and the pulse length of 1.5 μs is created by a thermionic gun, bunched at 1.5 GHz or 3 GHz in the bunching system and then pre-accelerated up to 20 MeV (see Fig. 1). After the injector the beam passes through the cleaning chicane, where low energy particles are eliminated and the bunch length is reduced. The beam of 4.0 A with a low energy spread is injected into the linac. It is accelerated in the fully loaded mode at the average gradient of 7 MV/m up to 125 MeV. Then the beam goes through the stretching chicane, where the bunch length is increased. After that the beam goes around the delay loop and combiner ring, where the intensity is increased by the factor four or eight. The generated high-intensity, high-energy beam is delivered to the tests lines, where the beam is most required to be stable.

BEAM STABILITY OUTLINES

Beam current variations and drifts at the level of 10^{-4} in CTF3 cannot be associated with any one particular device as dominant source of influence. Apparently, it is a combination of imperfections of all components together: the electron gun, RF sources and the current control of magnets. On top of this each of components changes its properties due to fatigue processes, temperature variations and unknown sources. This study is limited to the consideration of the treatment of integrated deviations only in the linac.

The intensity and energy stabilities are the main properties of the beam, which are responsible for the stable pulse-to-pulse beam combination and delivery to the tests areas. In the fully loaded operation the beam energy deviation at the end of the linac can be approximated as follows:

$$\Delta E \propto -\frac{1}{2} I_L \Delta\varphi_L{}^2 - \Delta I_L + \frac{I_L}{E_L}\,\Delta E_I, \qquad (1)$$

where I_L and φ_L – the intensity and phase at the beginning of the linac and E_I is the energy at the end of the injector. The beam phase and intensity deviations propagate from the injector to the linac and they are coupled through the energy deviation in the cleaning chicane:

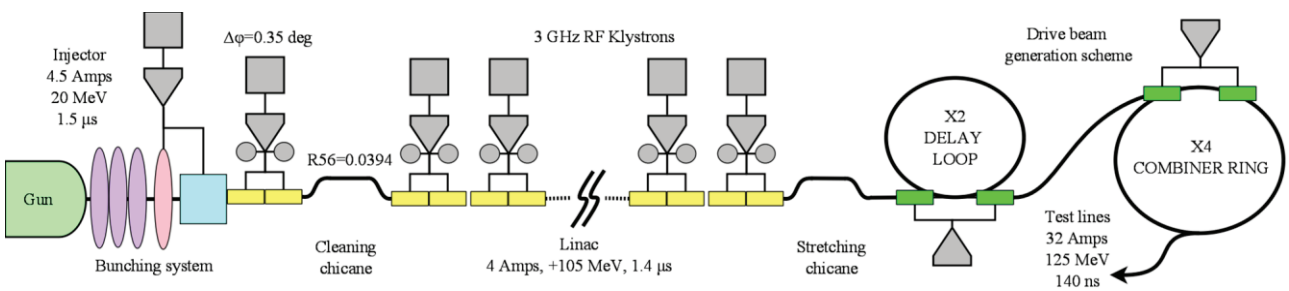

Figure 1: CTF3 layout.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

$$\Delta I_L \approx \Delta I_I \frac{I_L}{I_I} - k\, I_L \frac{\Delta E_I}{E_I}, \quad (2)$$

$$\Delta\varphi_L \approx \Delta\varphi_I + R_{56} f_{RF}/c \frac{\Delta E_I}{E_I}, \quad (3)$$

where I_I and φ_I are the intensity and phase before the chicane, k is the cleaning sensitivity constant corresponding to a ratio of the relative current change through the chicane with a fixed R_{56} to the relative energy deviation, f_{RF} is the linac RF frequency and c is the speed of light. By eliminating the relative energy deviation in the injector $\frac{\Delta E_I}{E_I}$ and substituting Eq. 2 and 3 into Eq. 1 the beam energy deviation ΔE scales with a function of beam current deviations before and after the cleaning chicane.

One option to improve the stability is to keep the intensity stable in the injector ($\Delta I_I = 0$):

$$\Delta E \propto -\frac{\Delta I_L}{I_L}\left(I_L + \frac{E_I\, I_I}{E_L k}\right) - \frac{I_L}{2}\left(\Delta\varphi_I - \frac{R_{56} f_{RF}}{c\, k}\frac{\Delta I_L}{I_L}\right)^2. \quad (4)$$

This option is favourable when the beam energy and phase remain unchanged in the injector. Another alternative option is to keep the intensity stable right after the chicane ($\Delta I_L = 0$):

$$\Delta E \propto \frac{E_I\, I_I}{E_L k}\frac{\Delta I_I}{I_I} - \frac{I_L}{2}\left(\Delta\varphi_I + \frac{R_{56} f_{RF}}{c\, k}\frac{\Delta I_I}{I_I}\right)^2. \quad (5)$$

The second option copes with small energy and intensity variations and it keeps the intensity stable at the end of the linac. An option can be chosen that has the smallest absolute energy deviation. The preference shall be given to the second one if $|\Delta E|_{\Delta I_L=0}| < |\Delta E|_{\Delta I_I=0}|$ (Eq. 4 and 5), where the intensity deviations are linked through the Eq. 2. The condition can be resolved for negative deviations only when the phase deviation is small:

$$2|\Delta\varphi_I| < \left|\frac{c\, k}{R_{56} f_{RF}}\right|. \quad (6)$$

When the phase deviation is significantly smaller in the above equation and while keeping the linac intensity stable the total compensation must meet one of the following requirements:

$$-{\Delta\varphi_I}^2 \gtrsim \frac{\Delta I_L}{I_L} \gtrsim -\left(\frac{c\, k}{R_{56} f_{RF}}\right)^2 \quad \text{or} \quad \frac{\Delta I_L}{I_L} > 0. \quad (7)$$

The third option is to keep the total energy stable $\Delta E = 0$. An approximated solution from Eq. 4 and 5 is to compensate the sum of weighted deviations such that:

$$s\frac{\Delta I_L}{I_L} - (1-s)\frac{\Delta I_I}{I_I} = 0,$$
$$s \approx 1 - \frac{E_I I_I}{kE_L I_L + 2E_I I_I}. \quad (8)$$

Since $\frac{1}{2} < s < 1$ intensity deviations in the linac should also be significantly compensated.

CTF3 BEAM STABILITY

The CTF3 parameters used for the following estimations are shown in the Fig. 1. The cleaning sensitivity k can be estimated from the injector beam energy distribution function as a derivative at the cut-off energy level. It can also be measured as a ratio of the beam loss after the chicane to the injector energy change by the control of the RF field level in the last two accelerating structures. The cleaning sensitivity $k = 0.5$ was measured in a setup with a high energy acceptance, in the nominal setup the value is supposed to be higher.

The lower injector phase error is bound by the RF phase stability. All RF phases in accelerating and bunching cavities are locked by RF phase loops, which are stabilizing phases at the level of the minimum RF phase shifters step $\Delta\varphi_{RF}$ [5]. Thereby the injector phase error should be at least as $2\Delta\varphi_{RF} < \sup\Delta\varphi_I$. For the same reason the current reference can be established with an error given by the phase. Taking into account the above the criteria to compensate the intensity variations in the CTF linac can be derived from Eq. 7 as:

$$\left|\frac{\Delta I_L}{I_L}\right| \gtrsim 0.015\%. \quad (9)$$

The upper compensation limitation is restricted naturally by the performance of the thermionic gun and transient losses.

One of the current CTF3 goals is to establish a highly stable combined beam in terms of the energy and intensity at the same time: $\left|\frac{\Delta I_L}{I_L}\right| < 0.075\%$ and $\left|\frac{\Delta E}{E}\right| < 0.1\%$. For this type of operation an intermediate option should be chosen between the stable intensity (Eq. 5) and the stable energy with $s \approx 0.769$ (Eq. 8), where residual energy deviations should come only from beam phase deviations.

The proposed three options to keep the beam intensity stable give different energy deviations at the end of linac (see Fig. 2). Medium term observations of intensities showed very small deviations in the injector while the deviations in the linac were up to $\pm 0.4\%$. Thus the first option with the stable injector represents the current status with no compensation, where the energy deviation proportionally grows with the intensity deviation reaching levels over 0.6%. The second option with the stable linac should bring intensity deviations in the linac to zero and reduces energy deviations down to 0.2%, which is above the required value. The third option with the stable energy

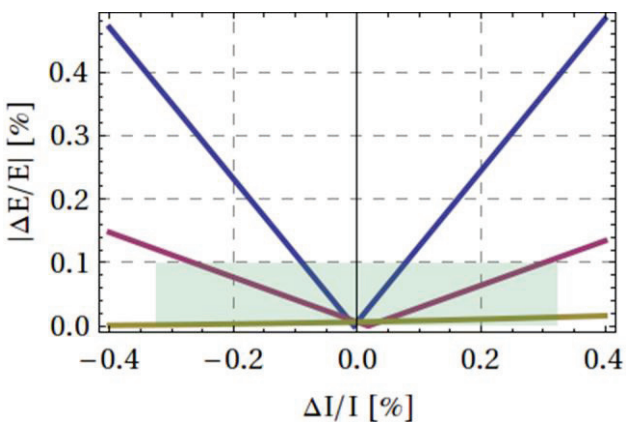

Figure 2: Total energy deviations at the end of the linac with corresponding intensity changes in the linac: blue line - stable injector, purple line – stable linac and yellow line – stable energy. The parts of the lines lying in the shaded area satisfy the stability goal.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

at the end of the linac should bring deviations close to the requirements for both parameters.

DEVELOPED SOLUTION

In order to apply different intensity compensation options a beam feedback software system has been developed and integrated into the control system in CTF3. In all cases the actuator of the intensity compensation is the grid voltage control in the thermionic gun. The gun control allows modifying the beam intensity in the order of 10^{-5} Amps, which is sufficiently small. The beam intensity is measured by Beam Position Monitors (BPM) with a resolution of only 5.8 mA, which is more than 0.1%. The integration over the pulse length up to 1.4 μs and averaging over several consecutive BPMs improve the resolution and reduce the noise down to 0.3 mA, which is below 0.01%. For each mode of operation a set of BPMs and their weights are predefined, and they are used to calculate the weighted mean intensity. The calculated intensity is compared with the reference value specified by operators. Based on this information the controller estimates the needed gun voltage correction and applies it on the next pulse (see Fig. 3). In order to prevent strong or unnecessary influence on the beam energy the upper and lower deviation thresholds are respected (for example see Eq. 9). The best and sustainable feedback performance has been achieved by applying exponential moving average filter on the weighted mean intensity, which also prevents from undesirable additional high-frequency fluctuations.

CALIBRATION

A self-calibration process of the feedback controller has been implemented to automatically compute most of the controller parameters. It provides an accurate calibration for the optimum performance. Inaccurate settings may lead to oscillation around the reference value, a large correction time or overshoots of the beam current. In the calibration mode the gun voltage is applied in a predefined pattern and the beam current is logged to determine the beam response, the noise impact, control limitations, setup correctness and the best filter parameter. It can be carried out at any time after significant modifications in the injector setup or in the cleaning chicane or when the controller is losing its efficiency due to some slow processes.

CONCLUSIONS

The intensity stabilization system has been successfully developed in a way to minimize energy deviations by keeping the intensity stable. It was tested and used during the normal operation and during the night operation in CTF3. The implemented self-calibration process allows operatively adapting to new setups with the best performance. Using the developed system the beam intensity has been stabilized in the injector down to 0.045%, which improves the earlier result of 0.05%. The intensity stabilization in the linac successfully transfers

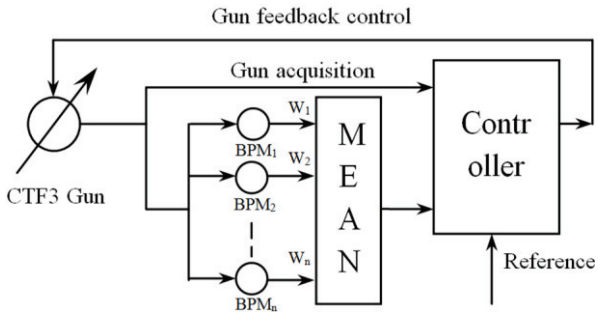

Figure 3: Intensity control layout.

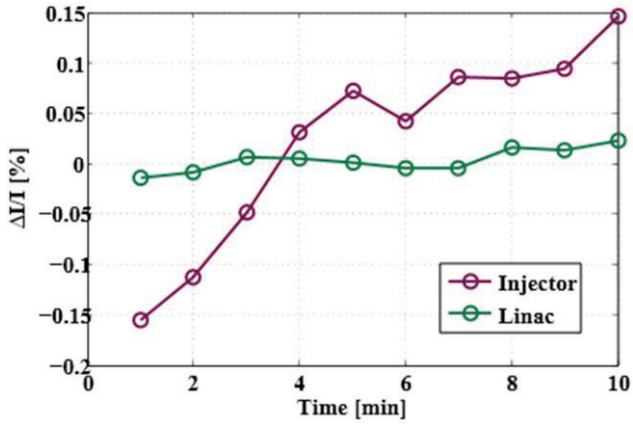

Figure 4: Illustration of the stabilization of the intensity in the linac by adjusting the intensity in the injector.

intensity variations over 0.15% from the linac into the injector within a small and preserved range of gun adjustments (see Fig. 4). Thereby it keeps the intensity stable at the end of the linac and it notably reduces energy deviations.

The effect of the stabilization system on possible changes of the emittance and bunch length must be additionally studied. Explicit energy correlation measurements will be performed soon.

The approach to cure integrated beam errors has been demonstrated to be a feasible and efficient technique at the cleaning chicane in CTF3 by transferring intensity variations from the linac into the injector.

TRIUMF, 4004 Wesbrook Mall, Vancouver, BC, Canada, V6T 2A3

Abstract

TRIUMF has been funded to build an electron linac with a final energy of 50 MeV and 500 kW beam power using TESLA type 9-cell superconducting cavities operating at 1.3 GHz at 2 K [1]. The e-linac consists of an electron gun, buncher cavity, injector cryomodule (ICM), and two accelerator cryomodules (ACMs). The ICM has one 9-cell cavity whereas each of the ACMs contains two 9-cell cavities. One ICM and one ACM are scheduled to be installed by 2014. Six power couplers, each rated for 60 kW CW, have been procured for three cavities. The ICM will be fed by a 30 kW CW Inductive Output Tube (IOT) and each ACM will be powered by a 290 kW CW klystron. Before installing the power couplers with the cavities, they are to be assembled and conditioned with a high power RF source. A power coupler test station has been built and tests of two power couplers have begun. A 30 kW IOT has been commissioned to full output power and it will be used for the power coupler tests. In this paper, test results of the RF conditioning of the power couplers in pulse and CW mode will be described.

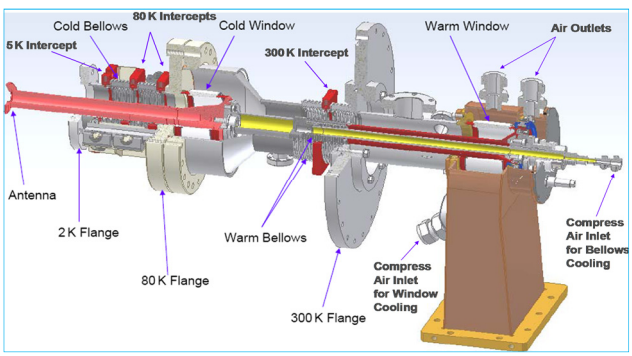

Figure 1: The CPI coupler is based on the Cornell 60 kW TTF-III coupler design.

INTRODUCTION

The power couplers that are being tested are manufactured by CPI, USA and have been adapted from the Cornell coupler shown in figure 1. The couplers, prior to installation with the accelerating cavities, are to be fully RF conditioned. A 30 kW IOT amplifier has been tested to full power and it will be used for RF conditioning of the couplers in both CW and pulse mode. Two couplers are mounted on to a waveguide box which has been designed such that RF power can be transmitted from the input coupler through the waveguide box and out through a second coupler to a 50 Ω waveguide load with minimum standing wave [2]. The coupler station is shown in figure 2. Each coupler has two ceramic windows, one cold and one warm. The cold window is the barrier for the ultra high vacuum pressure inside the SRF cavities which is on the order of 10^{-9} mbar and the warm window is a safeguard in the event of a failure of the cold window. Since the waveguide box and the couplers are at room temperature, the CW power applied to the couplers is kept to a level < 10 kW so as to limit the temperature of the inner conductor to 80 °C maximum. The couplers have Mega Industries WR650 coaxial to waveguide transitions which are at atmospheric pressure.

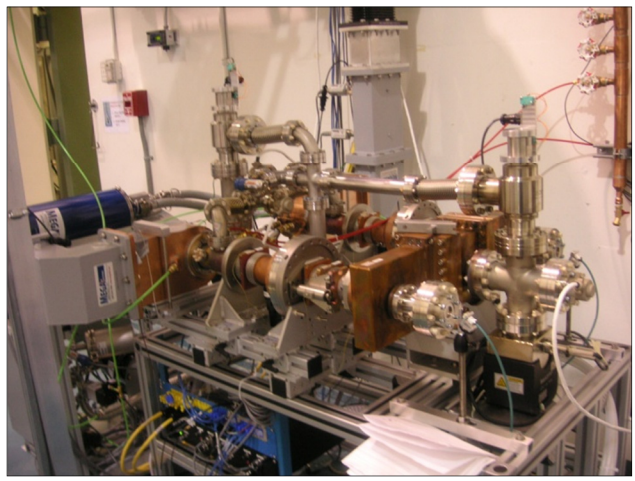

Figure 2: The power coupler test set up.

HIGH POWER TEST OF COUPLERS

The waveguide box was baked and found to be leak tight. The cold windows and the waveguide box were assembled in a clean room environment and leak checked. The warm window and waveguide to coaxial transition were assembled on the coupler test stand and all monitoring and instrumentation were attached.

Signal Level Measurement

The strength of the coupling to the waveguide box can be varied by moving the inner conductors of the couplers. Both couplers are adjusted for best matching (minimum VSWR). Measured values of S11 and S21 are 1.065:1 and 0.166 dB respectively. From the S21 measurement, the power loss in the two couplers and the waveguide box in total will be 39 W for an input power of 1 kW. Hence no cooling is required. However for 10 kW input power, the power loss increases to 390 W which requires cooling if run for a long time.

Interlocks and Monitoring

The vacuum system for the coupler test stand uses two systems; one vacuum common to the cold windows of the couplers and the waveguide box and the second system common to both of the warm windows of the couplers.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

A hardware interlock system was built to protect the power couplers during RF conditioning, figure 3. A sample of the IOT output power is derived from a 60 dB directional coupler and a four way splitter. This signal is brought to the protection electronics ZX47-40LN-S+ logarithmic power detector module using Andrew Heliax cable. The log detector output and a reference level set by a potentiometer drive a comparator to generate a trip. When a trip occurs, the 1.3 GHz drive signal to the linear IOT RF power amplifier is cutoff by a Mini-Circuits ZASWA-2-50DR+GaAs switch with ~65 dB of isolation. This switch has no latching problems and it is designed in fail-safe mode. The response time of the system, a few μs, is fast compared to the RF pulse widths used for conditioning and thus trips on peak rather than on average power. It has been found to be very stable and not to cause false trips when operating just below the trip level.

The fast trip system includes vacuum cold cathode gauges and photomultiplier (PMT) arc detectors. A trip is generated if the pressure in the warm space exceeds $5{\cdot}10^{-6}$ Torr or the pressure in the cold space exceeds $5{\cdot}10^{-7}$ Torr [3]. One Hamamatsu H10722-01 PMT attached to each power coupler is sensitive to light generated by multipacting in the region between the warm and cold RF windows. Ten thermocouples are attached at various points to the exterior of the couplers and the waveguide box. PT100 temperature sensors are attached inside the inner conductor of the couplers near the warm window bellows. Two Raytek MI series IR sensors measure the temperature of the cold window ceramics through viewing windows in the waveguide box. The ion pump current for both cold and warm sections, air cooling of the coupler inner conductors and water cooling of the external parts of the waveguide to coaxial transitions are monitored.

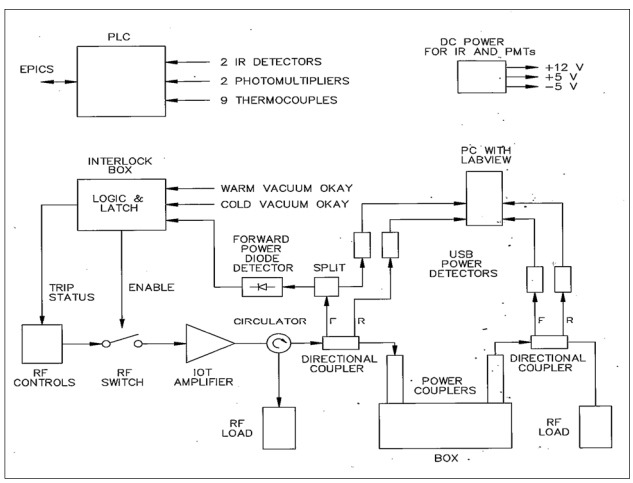

Figure 3: A block diagram of the RF set up.

RF Power Measurements

The couplers will be RF conditioned both in travelling wave mode and standing wave mode. The 30 kW IOT transmitter will be used for these tests. RF power will be initially pulsed with low duty cycle to allow high voltage conditioning of the coupler inner surfaces. Once no evidence of multipacting is observed and low pressure is established, < $1.0{\cdot}10^{-7}$ Torr, it will be driven in CW mode.

Travelling Wave Test

The RF drive power was pulse modulated, with a 200 ms period and pulse width varying from 100 μs to 10 ms. The duty ratio will eventually be changed to 10%, 20%, 50% and 100% and RF power reduced accordingly to stay within temperature and pressure limits.

Table 1: Travelling Wave Test in Pulse Mode

Width (ms)	Period (ms)	Duty Ratio (%)	Peak Power (kW)	Cold Vac (Torr)	Warm Vac (Torr)
0.1	200	0.05	7.50	1.19E-08	1.00E-07
0.2	200	0.10	10.00	1.70E-08	2.30E-07
1	200	0.50	9.00	2.30E-08	3.30E-07
2	200	1.00	7.60	2.50E-08	5.00E-08
10	200	5.00	7.20	1.48E-08	2.60E-08

Table 1 shows the vacuum pressure in the cold and warm sections for varying duty ratio and peak power ranging from 7 to 10 kW. There was no noticeable increase in temperature in the couplers or in the waveguide box. The results of a CW RF test are shown in figure 4 where the RF power was increased slowly from 0 to 9 kW over 2 hours. The pressure in the cold section remained unchanged whereas the pressure in the warm section deteriorated as the power was increased. The temperature increased from 22.6 to 29 °C for TCM-1 TC7 (the outer conductor of the coupler) and from 23.6 to 33.8 °C in TCM-2 TC3 (the inner conductor of the coupler). At 10 kW CW, the vacuum tripped and since then it has been difficult to condition at more than 1 kW CW. Both low level (<1 kW) pulse and CW RF conditioning were undertaken and severe multipacting was observed in the input coupler.

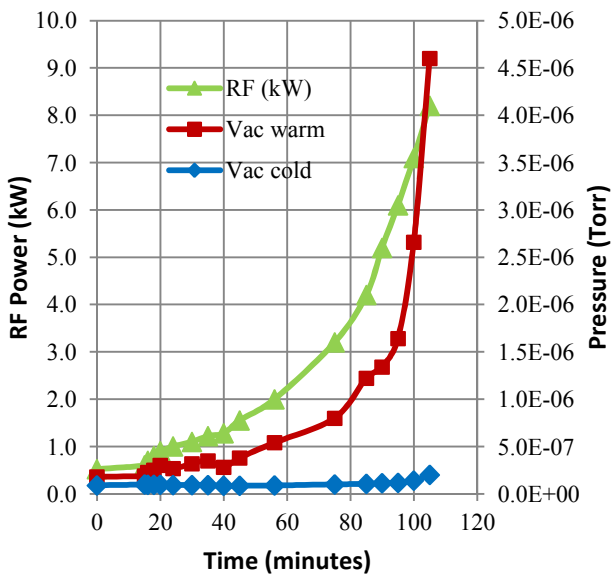

Figure 4: A travelling wave test in CW mode

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Standing Wave Test

Standing wave mode will be used to establish higher peak power in the couplers using a movable waveguide short instead of the 50 Ω waveguide termination. The waveguide box is made in-house, figure 5. A variation of a half guide-wave length can be achieved by moving the shorting plunger by 180 mm. High standing wave was established near the vacuum side of the input coupler's warm window by observing the vacuum bursts as the shorting plunger was moved.

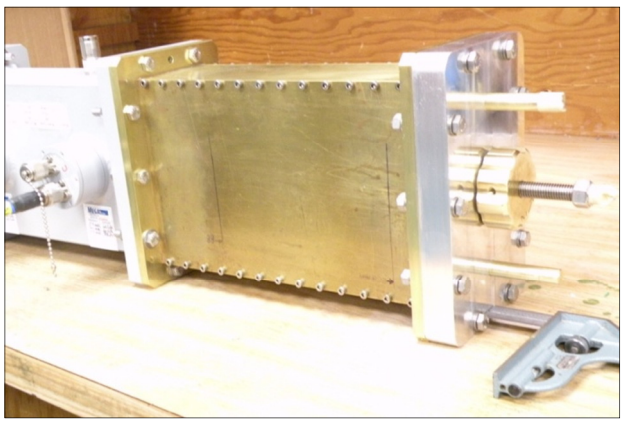

Figure 5: Movable WR650 waveguide short

A 500 W solid state amplifier was used in CW and pulse mode under standing wave conditions to locate the region of multipacting. Figure 6 shows the vacuum bursts as the waveguide shorting plate is adjusted to get high standing wave in the warm window region. The RF drive and the waveguide short were interchanged and the same cw and pulse tests were carried out. It was found out that coupler 2 vacuum settled to a steady, low value as shown in figure 7. It was concluded that the coupler 1 warm window shows signs of multipacting. Further investigation is to be carried out with higher power and higher duty ratio.

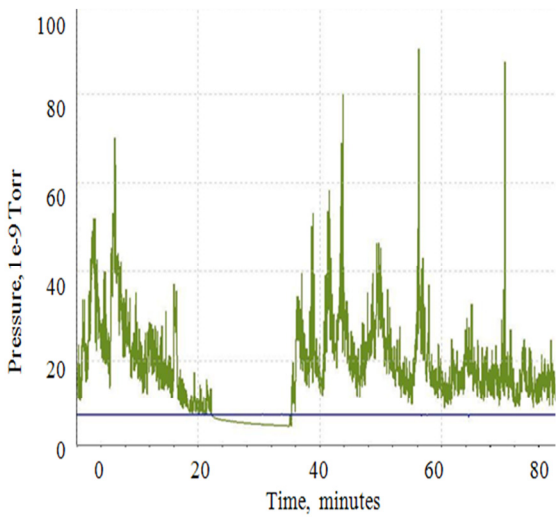

Figure 6: RF power applied to coupler 2 with the waveguide short at coupler 1.

CONCLUSION

The CW and pulse coupler tests were successful to a power level of 8 kW. However, after a vacuum trip at the warm window of the input coupler (coupler 1) at 8 kW, multipacting was observed at the 1 kW CW level. Afterwards, a solid state amplifier with 500 W output and a variable waveguide short were used to carry out coupler conditioning in standing wave mode in order to find the reason and location of the multipacting inside the coupler. The IOT transmitter will be used (it's going through some high voltage issues at present) again for conditioning after the low power test is concluded. It was observed that the warm window reacts to pulse conditioning much more than the cold window, hence another turbo pump and ion gauge will be installed so that the pressure at both of the warm windows can be observed simultaneously. The IR sensors which look at the cold windows are very helpful but their alignment is sensitive since their 20° field of view is partially obstructed and covers a small fraction of the ceramic. With improved cooling of the inner conductor of the coupler, possibly at liquid nitrogen temperature, it is envisaged to reach the final target of RF conditioned to 30 kW CW and 60 kW pulse. The RF conditioning of the coupler test is vital for the e-linac project since two such couplers are required to be installed with the ICM by mid 2013.

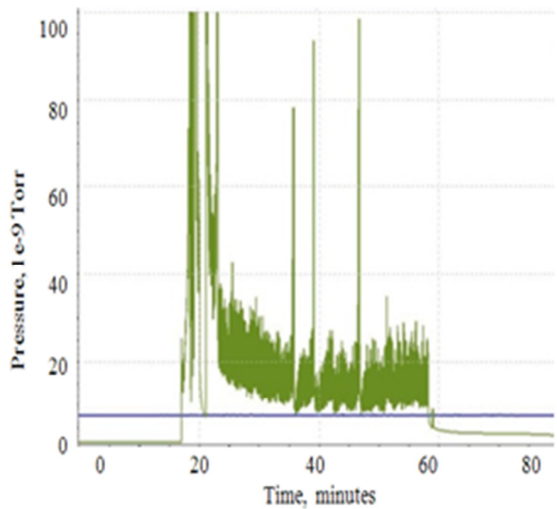

Figure 7: RF power applied to coupler 1 with the waveguide short at coupler 2.

NOVEL TECHNIQUE OF SUPPRESSING TBBU IN HIGH-ENERGY ERLS*

Vladimir N. Litvinenko #, Brookhaven National Laboratory, Upton, NY, USA
Department of Physics and Astronomy, Stony Brook University, Stony Brook, NY, USA

Abstract

Energy recovery linacs (ERLs) is an emerging generation of accelerators that promise to revolutionize the fields of high-energy physics and photon sciences. These accelerators combine the advantages of linear accelerators with that of storage rings, and augur the delivery of electron beams of unprecedented power and quality. However, one potential weakness of these devices is transverse beam break-up instability that could severely limit the available beam current. In this paper, I propose a novel method of suppressing these dangerous effects using the chromaticity of the transverse motion.

In this short paper I am able only to touch the surface of the method and a complete description of the method with all relevant derivations can be found in [1].

INTRODUCTION

Energy-recovery linacs (ERLs, see Fig.1) belong to a family of recirculating linacs (RLs) that accelerate a beam of charged particles multiple times in the same linear accelerator, accumulating the beam's energy on each pass.

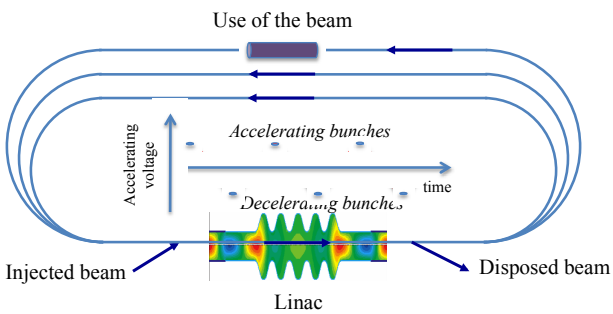

Figure 1: A sketch of a three-pass ERL.

One main challenge for these accelerators is the transverse beam break-up instability (TBBU) that especially is severe for SRF recirculating linacs. Early experiments with recirculating SRF accelerators at Stanford [2] and Illinois [3], where this instability occurred at a few microamperes of the average beam current, highlighted this problem. Dipole high-order modes (HOMs) of the SRF cavities were identified as the culprits driving this instability [4-5], and several remedies were developed for raising this threshold [6].

Detailed theoretical approaches and TBBU simulation programs were developed in the late 80s [7-9]. The renewed interest also stimulated refinements of the TBBU theory, simulation programs [10-12] and their experimental verification [13] all are driven by the need for high current ERLs, and also by the rewards of resolving this complex problem. Nevertheless, strong damping of HOMs in SRF linacs while maintaining high accelerating gradients remains one of the major unsolved issues. In the general ERL case, we can write a complete matrix of dispersion relations [7-12], but an analytical solution of the TBBU's instability threshold can be derived only for a single HOM mode, and a single-pass ERL, and as detailed in [5]:

$$I_{th} = \frac{2c^2}{e\,R_g \cdot Q \cdot \omega} \cdot \frac{1}{T_{12}\sin(\omega t_r)} \qquad (1)$$

where c is the speed of the light, e is the elementary charge, $R_g \cdot Q$ is the HOM's impedance (measured in Ω), ω is its frequency, and t_r is the beam's travel time through the returning loop. Since there are many HOM modes in the cavities encompassing a large range of the spectrum, there can be modes with $|\sin(\omega t_r)| \sim 1$; then, the only meaningful way of increasing the threshold is by reducing the values of Q and the $|T_{12}|$. As shown in [10], eq. (66), in an ERL with N passes through its linac, we can estimate the TBBU threshold by

$$I_{th} = \frac{2c^2}{e\,R_g \cdot Q \cdot \omega} \cdot \frac{1}{\sum_{J=1}^{2N}\sum_{I=J+1}^{2N} T^{IJ}\sin\omega(t_I - t_J)}, \qquad (2)$$

where $T^{IJ} \equiv T_{12}(s_J|s_I)$ is the element of transport matrix between the J^{th} and I^{th} pass through the linac. Analyzing eq. (3) the authors of ref. [10] offered their natural conjecture that the TBBU threshold scales as follows:

$$I_{th} \propto \left(R_g \cdot Q \cdot N^2 \left\langle \left|T^{IJ}\right| \right\rangle\right)^{-1}. \qquad (3)$$

The unfavorable scaling discussed above may have major implications on the cost of a high-energy ERL. Since an SRF linac usually more expensive than magnetic elements, cost-effective solutions [14-16] lead to three- to six-pass ERLs. If the current in such ERL designs suffer from severe beam current limitation, then the extent of their use and their energy reach will be restricted.

One way of resolving these confines lies in reducing the Q of all dangerous HOMs by developing complex HOM-damping schemes, and in addition, circumscribing the number of cells per linac module so to avoid trapping high-Q HOMs.

The other way of increasing the threshold current is by lowering $\left\langle \left|T^{IJ}\right| \right\rangle$. The latter is the topic of this paper.

SUPPRESSION OF THE BEAM'S RESPONSE USING CHROMATICITY

Since the bunch is an ensemble of particles, its transverse response to the kick will be the average if the responses of the individual particles are

$$\langle x_r \rangle = \langle T_{12} \rangle \cdot x', \tag{4}$$

where $\langle a \rangle$ signifies the average value of a parameter, a. I suggest using the chromaticity of the returning loops and an energy spread in the beam (induced by an RF chirp, if needed) beam to reduce $\langle T_{12} \rangle \to 0$.

For a particle with a small energy-deviation $p = p_o(1+\delta);\ |\delta| << 1$, the envelope function $\beta_o \equiv \mathrm{w}_o^2$ and the phase advance can be extended as

$$\begin{aligned} \mathrm{w}(s,\delta) &\cong \mathrm{w}_\mathrm{o}(s)\left(1+\delta\cdot\upsilon(s)\right); \\ \psi(s,\delta) &\cong \psi_\mathrm{o}(s)+\delta\cdot\phi(s), \end{aligned} \tag{5}$$

where the subscript "o" indicates the values for particles with the designed energy. The straightforward perturbation theory (see [1]) yields the following expression:

$$\begin{aligned} \varphi(s) &= -\frac{1}{2}\int_0^s K(z)\mathrm{w}_\mathrm{o}^2(z)\left(1+\cos 2\left(\psi_o(z)+\phi_o\right)\right)dz; \\ \upsilon(s) &= -\frac{1}{2}\int_0^s K(z)\mathrm{w}_\mathrm{o}^2(z)\cdot\sin 2\left(\psi_o(z)+\phi_o\right)dz. \end{aligned} \tag{6}$$

One important (and well known) feature of this solution is that the phase deviation (i.e., the chromaticity of oscillations) is defined by a monotonic function with average rate of $-\langle K(z)\mathrm{w}^2{}_\mathrm{o}(z)\rangle_z/2$, while the envelope deviation is a fast oscillating function with double-betatron frequency. Hence, in a large accelerator system, chromaticity grows steadily, and can reach significant values $C(s) = \phi(s)/2\pi >> 1$, and, even for a modest deviation in relative energy, phase variation can be large, while the relative variation in the envelope function remains small $\delta\cdot\upsilon(s) << 1$.

Naturally, the level of suppression of the beam's response (transfer function, $\langle T_{12} \rangle$) depends on the energy-distribution function; Table 1 gives a few examples. Smooth bell-shape energy-distribution functions (Gaussian, Lorentzian, $\kappa - 2$) assure the strong suppression of $\langle T_{12} \rangle$ whose value falls fast with the increase of $|X| \equiv 2\pi|C|\sigma_\delta$; sharp-edged distribution functions (such as rectangular- or triangular-ones) cause the oscillating behavior of $\langle T_{12} \rangle$ which declines more slowly with the growth of $|X|$. In all cases, a highly chromatic lattice resulting in $|X| >> 1$ effectively suppresses the beam's response to transverse kicks.

In the TBBU theory [7-12], the low-energy passes through the linac are considered to be the ones most vulnerable to TBBU instability. Specifically, the conclusions are that the TBBU threshold is proportional to the lowest energy in the recirculating path, and also inversely proportional to number of the recirculating passes. The examples described in this paper as well in ref. [1] show that this rule is not applicable to an ERL wherein the accumulated chromatic phase spread is significantly larger than unity.

Examples

eRHIC's low-emittance ERL lattice has chromaticities $C_{x_t} \cong -175;\ C_{y_t} \cong -125$ per turn. The LHeC low emittance lattice has $C_{x_t} \cong -510;\ C_{y_t} \cong -460$ per turn. Hence, an induced correlated Gaussian energy spread of $\sigma_\delta = 5\cdot 10^{-3}$ will suppress $\langle T_{12}(s|s+C\rangle$ 3,000 –fold in vertical direction and by astronomic $3.7\cdot 10^6$ in horizontal direction. In LHeC ERL $\sigma_\delta \cong 1.3\cdot 10^{-3}$ will suffice for suppressing a single-turn response 1,000-fold.

Table 1. Suppression of the Beam's Response on a Transverse Kick by the Chromaticity: $X = \phi\sigma_\delta;\ Y = \upsilon\sigma_\delta$.

$f(\delta)$	Suppression factor $\langle T_{12} \rangle / \mathrm{w}_{\mathrm{io}}\mathrm{w}_\mathrm{o}$	Type
$\frac{1}{\sqrt{2\pi}\sigma_\delta}\exp\left(-\frac{\delta^2}{2\sigma_\delta^2}\right)$	$e^{-X^2/2}\cdot\left(\sin\psi + X\cdot Y\cos\psi\right)$	Gaussian
$\frac{1}{\pi\sigma_\delta}\left(1+\frac{\delta^2}{\sigma_\delta^2}\right)^{-1}$	$e^{-\lvert X\rvert}\cdot\left(\sin\psi + Y\cdot sign(X)\cos\psi\right)$	Lorentzian
$\frac{2}{\pi\sigma_\delta}\left(1+\frac{\delta^2}{\sigma_\delta^2}\right)^{-2}$	$e^{-\lvert X\rvert}\cdot\left((1+\lvert X\rvert)\sin\psi + X\cdot Y\cos\psi\right)$	$\kappa - 2$
$\frac{1}{2\sigma_\delta}\left(\theta(\delta-\sigma_\delta)-\theta(\delta+\sigma_\delta)\right)$	$\frac{\sin X}{X}\sin\psi + Y\frac{\sin X - X\cos X}{X^2}\cos\psi$	Rectangular

Numeric example

Some higher order effects can, in principle, reduce or at least, significantly modify the predictions given in Table 1. To address this concern, I tested the concept by directly calculating the response of the beam with a Gaussian energy-distribution propagating through a beam-line encompassing 1024 FODO cells. Each FODO cell comprises one focusing- and one defocusing-quadrupole. Hence, I use the exact analytical expression for the transport matrix of the FODO cell for an ultra-relativistic particle with arbitrary momentum $p = p_o(1+\delta)$: $T_{FODO}(\delta)$. The matrix is multiplied by the necessary number of times

$$T_{total}(\delta) = \left[T_{FODO}(\delta)\right]^{1024} \qquad (7)$$

to form the exact matrix of the beam-line. The beam's displacement at the end of the beam-line to an angular kick, θ, at its entrance entails a simple convolution:

$$\langle x \rangle = \langle T_{12\ total} \rangle \cdot \theta; \quad \langle T_{12\ total} \rangle = \int_{-\infty}^{\infty} T_{12\ total}(\delta) f(\delta) d\delta$$

where $T_{12\ total}(\delta)$ is an exact, analytical, nonlinear function of δ. For comparison, I define the suppression factor of the transverse response as

$$S = \max\left(\left|T_{12\ total}(\delta)\right|\right) / \left|\int_{-\infty}^{\infty} T_{12\ total}(\delta) f(\delta) d\delta\right|.$$

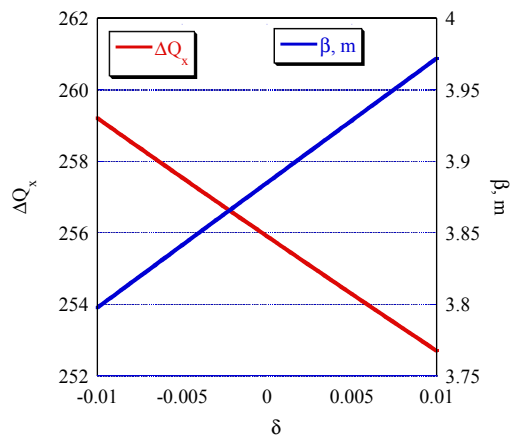

Figure 2. The FODO beam-line optics parameters as function of the particle momentum.

The exact matrix function was used to convolve it with Gaussian energy-distribution with $\sigma_\delta = 2 \cdot 10^{-3}$. I did not observe any significant deviations from the expected theoretical behavior either at a small values (as expected), or at large values of the of total beam-line's chromaticity. For example, the beam-line with tune advance of 0.22285 per cell has chromaticity of $C = -276.68$, and the calculated suppression factor of 428-fold that compares favorably with the theoretical estimation of 422-fold. Increasing the chromaticity further to $C = -328.51$ by increasing the tune advance per cell to 0.2499 increased the calculated suppression factor to $5.93 \cdot 10^3$. This also is reasonably close to the theoretical estimation of $5.02\ 10^3$.

CONCLUSIONS

I have shown in this paper that using the natural chromaticity of the arcs in ERLs affords an opportunity of suppressing the beam's transfer function (its response to transverse kicks), and either suppressing TBBU instability or significantly increasing allowable operating currents.

In an ERL comprising of a sequence of linacs and arcs, with the product of the chromaticity and the energy spread in the arcs $|\phi\sigma_\delta| >> 1$, the electron beam forgets the kick it received in the linacs while traveling through an arc. Then, the traditional ERL TBBU excitation scheme falls apart, and each linac effectively sees fresh electron beams.

ACKNOWLEDGMENT

The author would like to thank Ilan Ben-Zvi, Yue Hao, Dmitry Kayran (BNL) and Eduard Pozdeyev (FRIB) for fruitful, in-depth discussions of the methods, and Georg Hoffstaetter (Cornel University) and Frank Zimmermann (CERN) for their interest in the prospects of suppressing TBBU in high-energy ERLs.

THE LINEAR ACCELERATING STRUCTURE DEVELOPMENT FOR HLS UPGRADE *

K. Jin, S. C. Zhang, Y. L. Hong, G. R. Huang, D. C. Jia
National Synchrotron Radiation Laboratory, NSRL USTC,
P.O. Box 6022, Hefei Anhui 230029, China

Abstract

Hefei Light Source (HLS) is mainly composed of an 800 MeV electron storage ring and a 200 MeV constant-impedance Linac functioning as its injector. A new Linac is developed in view of the Full Energy Injection and the Top-up Injection scheme will be adopted in the HLS upgrade. In this paper, an 800MeV linear accelerating system construction, the constant-gradient structure design and the symmetry couplers consideration will be described in detail. The manufacture technology, the RF measurement, the high power test results and the accelerating system operation are presented.

INTRODUCTION

In order to ensure the low-emittance focusing parameters steady operation in the HLS Storage Ring, it's necessary to increase the injector energy to 800MeV. After realize Full Energy Injection, each system of Storage Ring can keep single operation state, the light source stability will be improved eminently. A new Linac is developed in view of the Full Energy Injection and the Top-up Injection scheme will be adopted in the HLS upgrade. An 800MeV Linac layout is shown in Fig.1.

The project is proceeding as planned at present. In this paper, an 800MeV linear accelerating system construction, the constant-gradient structure design and the symmetry couplers consideration will be described in detail. One section of accelerator structure has been fabricated successfully. The manufacture technology, the RF measurement, the high power test results and the project schedule are presented.

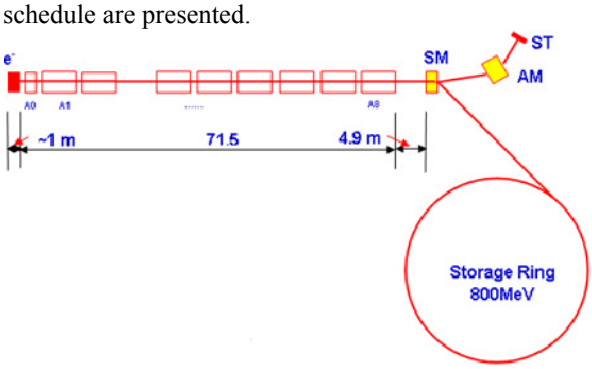

Figure 1: HLS 800MeV Linac layout

800MEV LINEAR ACCELERATING SYSTEM DESIGN

HLS accelerating system consists of a pre-buncher, a buncher and eight units of constant-gradient accelerating structures (6m accelerator unit). Total length is about 73meter. The electron beam energy can be achieved to 800MeV~1GeV. In general, seven such as units is in operation condition and another one is in standby state so that to assure storage-ring stability running (Fig.2).

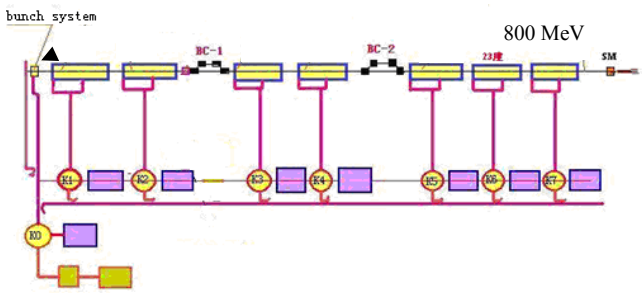

Figure 2: 800MeV electron Linac energy, phase and microwave System

Pre-buncher

Pre-buncher or velocity modulation cavity is a cylindrical reentrant resonator. Its resonance frequency is 2856 MHz, working at TM_{010} mode. Cavity dimensions and physical parameters are calculated with SUPERFISH. To reduce the errors of resonance frequency caused by temperature, beam loading etc., stainless steel is selected to make this cavity to reduce Q (~ 500), the cavity shunt impedance is Rs/Q = 220. So when 2kW power is feeding in, it will produce about 15kV microwave voltage in the cavity. According to beam dynamics calculation, bunching parameter is selected r = 1.92. The beam waist of electron beam from gun is focused at the center of pre-buncher. Through the preliminary bunching cavity and drift 35 cm, its phase width will be focused from 260°to 90°. The work was finished in a HLS phase I project. It is in good condition still. So it will continue to use after upgrading.

The fundamental mode buncher

The bunching system work frequency is 2856 MHZ, including pre-buncher and fundamental mode buncher. The beam from the gun is focused initially in the pre-buncher, then electron beam get into buncher to further complete beam phase bunching process, and further increase the beam energy. The fundamental mode buncher is constant gradient disk load accelerating structure. Solenoids are used to focus in the transverse direction. The length of fundamental mode buncher is 1.63 m, the accelerating gradient is about 8.2 MV/m, and beam energy is about 13.1 MeV after bunching section.

In order to optimize bunching effect, pre-buncher voltage is optimized to 15kV and the distance between buncher and pre-buncher is optimized to 35 cm. The

buncher adopts traveling wave electron accelerating structure. It totally has 45 cavities; the first five cavity is vary phase velocity period structure. The phase velocities are 0.70, 0.88, 0.95, 0.98, 0.99, the others are relativistic accelerating section. The results are in the Table.1.

Accelerating Section

The constant-gradient structure can produce higher energies than an optimized constant-impedance structure when both are operating at the breakdown limit of electric field strength. Considering such structure reduces ration of maximum to average field strengths and increases some advantages [1], the constant-gradient structure was thus adopted for the HLS Linac upgrade.

The cavity type of constant-gradient disk-loaded structure was selected in HLS accelerating section. Operating frequency of 2856MHz, phase shit per cavity of 2π/3, i.e. cavity length of 34.989mm and disk thickness of 5.8mm is set. The optimum cell geometer and its EM performance, calculated with MAFIA-Code [2], are listed in Table 2. The curves of field strength and energy vs. axial distance z are shown in fig.3. Here the power range is 32.0 Mw to 10.1Mw in such accelerator section, the field strength E_z of 20.7Mv/m is acquired and the energy gain is about 62MeV.

In order to realize Full Energy Injection, one klystron of 80Mw provides power to a pre-buncher and a buncher as well as to a 6m accelerator unit which is constructed by two 3m standard sections. Another one of 80Mw and six klystrons of 50Mw with SLED technology will provide

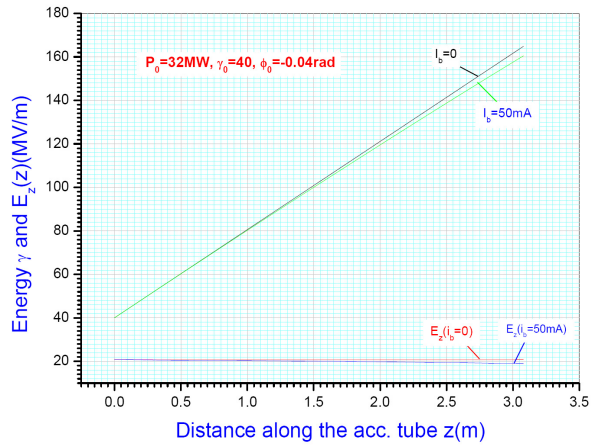

Figure 3: The field strength and energy gain in the 3m accelerating section.

power to each 6m accelerator unit individually.

The average accelerating gradient of 20Mv/m can be obtained in such away. The electron beam energy can be achieved to 800MeV~1GeV. In general seven 6m accelerator units are in operation condition and the other one is in standby state so that to assure storage-ring stability running. The electron beam energy gain in all accelerating structures is shown in Table 3.

HLS STANDARD 3M SECTION DEVELOMENT

According to the above-mentioned design, an 800MeV traveling wave linear accelerator is being developed. A standard 3m section of accelerator structure has been fabricated successfully. It consists of 86 disk-loaded accelerating cavities. The phase velocity of β_p=1, the operation mode of 2π/3 and the constant-gradient structure are considered.

The RF coupler is an important component for an accelerator structure. It consists of a tapered rectangular waveguide and a coupling cavity with a coupling aperture. It must be well matched to the feeding waveguide and has synchronous frequency for the proper phase advance in the structure so that ensure the input power is fed effectively and an excellent travelling wave is transmitted in the accelerating cavities train. Therefore the sizes of the coupling cavity and the coupling iris aperture should be designed exactly at operation frequency so that the optimum transmission parameter S21 and scattering parameter S11 are obtained. In order to compensate the amplitude asymmetry and the phase shift, offsetting the coupler cavity was adopted. The value of the offset was found by means of microwave perturbation measurement, for the input cavity, it is 1.8mm, and for the output cavity, 1.0mm. The amplitude asymmetry of the order of 1.58%, and the phase shift of the order of 1.0°was obtained over the beam aperture.

In our project, the numerical simulation design of RF coupler assembly was considered. In the wake of the computer program development, special the MAFIA-code [2], it made the three dimensions (3D) S-parameters calculation in time domain becoming possible and the change in dimensions can be easily implemented on the computer. Revising the sizes step by step in such a way, in conjunction with microwave measurement by Kyhl method [3], the optimal matching and tuning results is acquired finally.

The cavities were machined high-precisely in a constant temperature room. It was assembled with the input coupler and the output coupler. Also the external water pipes are used so that the structure can be cooled and keep constant operating temperature. Finally the module was brazed in a hydrogen furnace.

Then each cell of the accelerating structure was tuned to the phase shift φ=120°/cell. The RF parameters are measured with the Network Analyzer Agilent E5071C. The voltage standing wave ratio, VSWR=1.019, was achieved at the operation frequency and VSWR is less than 1.2 in a frequency-bandwidth of 4 MHz, which is shown in Fig.6 for the typical structure.

The high-power test of the 3m accelerator section was processed in May. 2012. The pulse length of 1uS, maximum input power to the section is approximately 50Mw peak; Steady operation of pulse length of 5uS, input power of 40MW peak for such section was obtained. The test results satisfied the design which input power to the section is 32Mw peak. It means that accelerating gradient of 20Mv/m can be achieved in HLS Linac. It is a basic guarantee of the 800MeV Linac upgrade project success.

CONCLUSION

At present a Buncher and all 16 standard 3m sections has been manufactured successfully in NSRL. Microwave measurement and cavities tuning will be finished end of Sep. The HLS Linac Ⅱ will be installed in Oct. and will be operated end of 2012.

ACKNOWLEDGMENT

We would like to thank all the members of the collaboration for their contributions. Special thanks are given to J. Wang, J. F. Gao, Y. Z. Liu, J. Y. Zhang, W. Wei, F. Hu, S. Y. Jiang, X. Y. He and Y. J. Pei, who were heavily involved in the HLS Linac Ⅱ fabrication.

FEASIBILITY STUDY OF SHORT PULSE MODE OPERATION FOR MULTI-TURN ERL LIGHT SOURCE*

T. Atkinson†, A. V. Bondarenko, A. N. Matveenko, Y. Petenev,
Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (HZB), Germany.

Abstract

The optic and simulation group at HZB are designing a light source based on the emerging Energy Recovery Linac superconducting technology, the Femto-Science-Factory (FSF) will provide its users with ultra-bright photons of angstrom wavelength at 6 GeV. The FSF is intended to be a multi-user facility and offer a wide variety of operation modes. A low emittance $\sim 0.1\,\mu$m rad mode will operate in conjunction with a short-pulse ~10 fs mode.

INTRODUCTION

This paper continues on from a recent introductory study[1] and highlights the physical limitations when trying to offer interchangeable modes and preserve beam quality. The paper concentrates on the short bunch mode, introducing the multi stage compression schemes in a general manner and presents the first results of the start-to-end beam simulations.

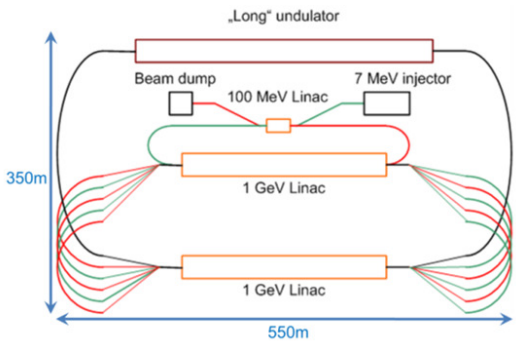

Figure 1: Schematic of the FSF Multi-Turn ERL.

The main design parameters of the FSF are listed in Table 1 and Fig. 1 shows the layout of the light source.

A SRF injector based on the design parameters of the BERLinPro[2] project delivers the 100 MeV electron beam into the main accelerator. Here two 1 GeV linacs are continually traversed until 6 GeV beam energy is reached. Each Arc contains straight sections for undulators and the final energy Arc permits a long straight section for 5000 period undulators.

The beam quality delivered to the long undulators and hence the photon brilliance attainable depends on the machine operating mode.

Table 1: Main design parameters of FSF

Parameter	High Brilliance Mode	Short Bunch Mode
Energy (GeV)	6	6
Charge (pC)	15	4
Bunch Length (fs)	>200	~10
<B> (ph/s/mm^2/mrad^2/0.1%)	10^{22}	10^{21}
B_{peak} (ph/s/mm^2/mrad^2/0.1%)	10^{26}	10^{26}

SHORT BUNCH MODE

Single pass machines do not suffer the same fate as storage rings as equilibrium is never reached. A design based on linear uncoupled optic, helps address a proof-of-principle for the short pulse mode, which is later then tested using a realistic input beam distribution from the BERLinPro injector project.

Compression in the Injector

Producing a femto-second pulse of low energy spread starts at the Gun, Table 2. Here the longitudinal electron beam properties are restricted by the photo-injector laser pulse and the superconducting RF acceleration. The primary subtle compression in the Merger between the Booster and linac minimizes transverse emittance growth.

Table 2: Injector ASTRA[3] simulations

Component	Bunch Length (mm)	Emittance (keV mm)	Energy (MeV)
Gun	0.7	0.3	1.8
Booster	1.0	2	6.6
Linac	0.45	2.2	50

The injector Arc is then used to prepare the beam for the main accelerator. The combination of a second linac to increase the beam energy to 100 MeV and the R_{56} in the Arc compress the beam to $\sigma_t \sim 660\,fs$ with a correlated energy spread of $\Delta E/E \sim 1.5 \cdot 10^{-4}$.

Telescopic Compression

The main acceleration stage uses a scheme based on telescopic compression. In this regime the combination of the linac chirps and the R_{56} in the Arcs are described as a simple focusing (F) and defocussing (f) lens, Eq. 1. The shortest pulse achievable from a multi-turn isochronous structure is with full compression in the final arc. This is however at the expense of a correlated energy spread, blue in Fig. 2.

$$\begin{pmatrix} z \\ \Delta E/E \end{pmatrix}_1 = \begin{pmatrix} f/F & F-f \\ 0 & F/f \end{pmatrix} \begin{pmatrix} z \\ \Delta E/E \end{pmatrix}_0 \quad (1)$$

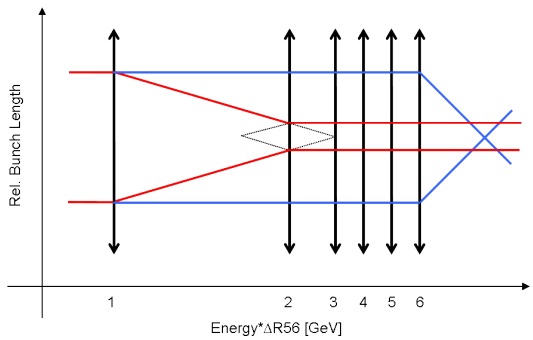

Figure 2: Telescopic bunch compression to preserve energy spread.

In order to remove the correlated energy spread and still produce a short pulse consider an alternative solution based on a telescopic lattice, red in Fig. 2. Implementing the first two arcs as achromats and accelerating either side of on-crest in each linac, the two "lenses" can share the same focal plane, just like in a telescope, to maximize the magnification and recover the energy correlation properties of the injector.

The minimal bunch length of the final beam into the long undulators is restricted by the requirement of an rms energy spread given by $\Delta E/E \sim 1/\text{UndulatorPeriods} \sim 10^{-4}$, to be $\sigma_t \sim 10\, fs$ when implementing purely linear optic.

Simulation Codes

Starting from previous calculations using ASTRA[4] up until the 50 MeV injector linac exit, the beam distribution was converted and tracked onwards through the FSF using Elegant[5].

Short Bunch Simulations

The first 50 m shown in Fig. 3 is the initial bunch compression in the injector Arc to prepare the beam for the first 1 GeV FSF linac of phase $\phi_1 = +8^\circ$ off crest . What follows this a step like bunch compression in the first Arc with $R_{56} = 20\, cm$ till the second 1 GeV linac at $\phi_2 = -20^\circ$ (placed at $s \sim 500\, m$). The second Arc of $R_{56} = 5\, cm$

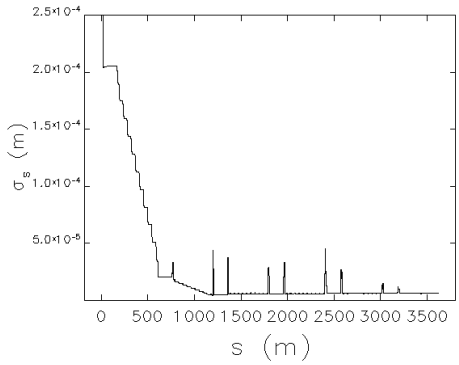

Figure 3: Bunch length variations in the FSF.

then completes the full bunch compression. These longitudinal bunch parameters are then preserved in the remaining isochronous Arcs, with some "spiking" shown due the vertical spreaders.

With the present optic a bunch length $\sigma_t \sim 20\, fs$ and energy spread $\Delta E/E \sim 1 \cdot 10^{-4}$ is achievable at the long undulator entrance Fig. 4.

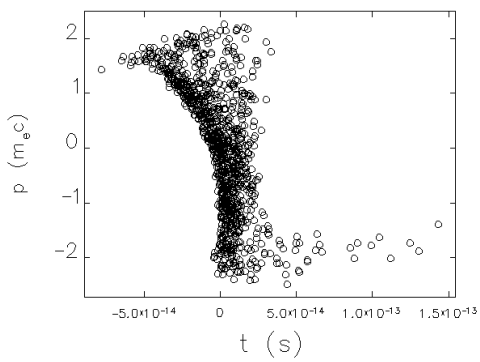

Figure 4: Phase space at long undulator entrance.

Large cumulative distortions due to radiation effects are not envisaged in this two stage process to achieve full compression as the energy after the first main linac is 1 GeV and the bunch charge is reduced for the short pulse mode.

LONGITUDINAL EMITTANCE

The longitudinal emittance can be described as an ellipse occupying a density of particles in $(c\Delta t, \delta)$ phase space. The non-linear properties of RF curvature acceleration can alter the phase distributions varying the normalized emittance.

2nd Order Aberrations

An emittance compensation scheme using higher order magnetic terms created in the Arcs is described here.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Using the linacs relative energy Eq. 2 and the Arcs bunch length Eq. 3 variations respectively one can calculate the emittance variation across the two stages as follows.

$$
\begin{aligned}
&LINAC \\
&\delta_1 = \delta_0 + R_{65} c\Delta t_0 + T_{655}(c\Delta t_0)^2 \quad (2) \\
&c\Delta t_1 = c\Delta t_0 \\
&+ARC \\
&\delta_2 = \delta_1 \\
&c\Delta t_2 = c\Delta t_1 + R_{56}\delta_1 + T_{566}\delta_1^2 \quad (3)
\end{aligned}
$$

Keeping only second order terms, assuming $\delta_0 = 0$ and substituting Eq. 2 and Eq. 3 the emittance can be approximated as Eq. 4

$$
\begin{aligned}
\epsilon^2 &= <(c\Delta t_2)^2><\delta_2^2> - <(c\Delta t_2 \delta_2>^2 \quad (4) \\
\epsilon^2 &\simeq <(c\Delta t_0)^4><(c\Delta t_0)^2> \left(T_{566}R_{65}^3 - T_{655}\right)^2
\end{aligned}
$$

Emittance Correction

One can interpret Eq. 4 as a useful tool to control the normalized emittance. The accelerating phase determines both the R_{65} and T_{655} terms and sextupoles in the Arc can adjust T_{566} to compensate for them.

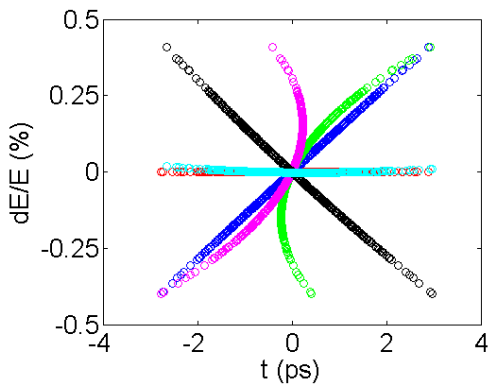

Figure 5: Correction of the 2nd order aberrations.

Fig. 5 demonstrates this concept, showing anticlockwise the variation of the beam phase space from an uncorrelated low emittance flat beam (red) through a non-linear RF chirp (blue). Then the introduction of first and second order magnetic correction, rotating and deforming the phase space (green - magenta - black) before finally a second linac is used to approximately recover the original distribution (cyan).

Emittance Correction Simulations

This scheme was adapted for the two stage telescopic bunch compression in the FSF machine simulations Fig. 6. The second order terms from the off-crest RF acceleration for the short bunch mode were optimized so that they would be fully compensated for by the T_{566} term created in the dipoles in the achromat Arcs.

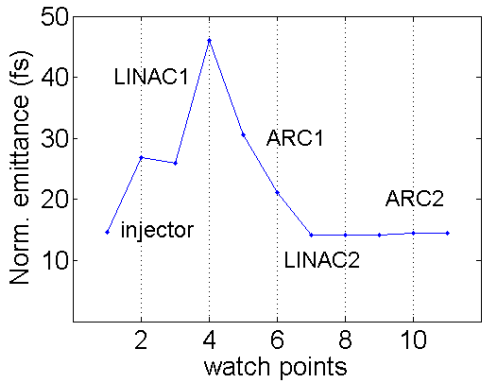

Figure 6: Recovering the injector properties.

Additional correction using sextupoles will be considered for future calculations as an essential tool for the recovery of the injectors longitudinal beam properties.

CONCLUSION

A two stage linear bunch compression scheme for the FSF light source has been presented and simulated using realistic beam parameters from the BERLinPro injector. A compensation scheme to recover the normalized emittance of the injector has been proposed.

LINAC OPTICS DESIGN FOR MULTI-TURN ERL LIGHT SOURCE*

Y. Petenev#, T. Atkinson, A.V. Bondarenko, A.N. Matveenko, HZB, Berlin, Germany.

Abstract

The optics simulation group at HZB is designing a multi-turn energy recovery linac-based light source. Using the superconducting Linac technology, the Femto-Science-Factory (FSF) will provide its users with ultra-bright photon beams of angstrom wavelength at 6 GeV. The FSF is intended to be a multi-user facility and offer a variety of operation modes. In this paper a design of transverse optic of the beam motion in the Linacs is presented. An important point in the optics design was minimization of the beta-functions in the linac at all beam passes to suppress beam break-up (BBU) instability.

INTRODUCTION

In this document we present a design of a Linac optics for a new 3 pass ERL-based LS with 6 GeV maximum energy of electron beam. This future facility is named Femto-Science Factory (FSF) [1].

The schematic layout of the facility is presented in Fig. 1. A beam is created in 1.3 GHz SRF gun with photo cathode. We consider an SRF injector with similar parameters to the B*ERL*inPro injector under development at HZB [2, 3]. Then it passes a 100 MeV Linac and is accelerated to 6 GeV after passing 3 times through each of two 1 GeV main Linac's. In the arcs between the acceleration stages it is assumed to have undulators with 1000 periods. In the long straight section (see Fig.1) a long undulator with 5000 periods is assumed. The main design parameters of FSF are presented in Table 1.

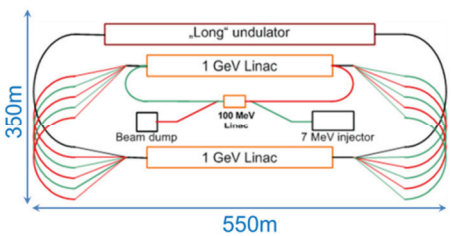

Figure 1: The scheme of FSF.

One potential weakness of the ERLs is transverse beam breakup instability, which may severely limit a beam current. If an electron bunch passes through an accelerating cavity it interacts with dipole modes (e.g. TM_{110}) in the cavity. First, it exchanges energy with the mode; second, it is deflected by the electro-magnetic field of the mode. After recirculation the deflected bunch interacts with the same mode in the cavity again which constitutes the feedback. If net energy transfer from the beam to the mode is larger than energy loss due to the mode damping the beam becomes unstable.

The actuality of this problem was recognized in early experiments with the recirculating SRF accelerators at Stanford [4] and Illinois [5], where threshold current of this instability was occurring at few microamperes of the average beam current. In the works of Rand and Smith in [6] dipole high order modes were identified as a driver of this instability. In late of the 80's the detailed theoretical model and simulation programs had been developed [7, 8]. Nowadays the interest to this problem was renewed. The requirements for more detailed theory and simulation programs [9-11] are given by the needs of high current (~100 mA) ERLs.

The threshold current for the transverse beam breakup may be estimated for the case of a single cavity and single mode for a multipass ERL in the form as [11]:

$$I_{th} \approx I_0 \frac{\lambda\!\!\!^{-2}}{Q_a L_{eff} \sqrt{\sum_{m=1}^{2N-1} \sum_{n=m+1}^{2N} \frac{\beta_m \beta_n}{\gamma_m \gamma_n}}}, \qquad (1)$$

where I_0- Alfven current, Q_a is the quality factor of HOM, $\lambda\!\!\!^{-} = \lambda/2\pi$, λ is the wavelength corresponding to the resonant frequency of the TM_{110} mode, γ_m is the relativistic factor at the m-th pass through the cavity, β_m – is the Twiss parameter, L_{eff} – is the effective length of the cavity, N is the number of passes during acceleration. It should be noted that (1) gives more realistic estimation of the BBU threshold current than a similar expression in [9] with a 1/N(2N-1) dependence on the number of passes. This is the result of an assumption in [9] of integer tunes in every turn of the ERL.

Table 1: Main Design Parameters of FSF

Parameter	High brilliance mode	Short bunch mode
E, GeV	6	6
<I>, mA	20	5
Q, pC	15	4
τ, fs	200-1000	~10
<B>, ph/s/mm2/mrad2/0.1%	$8 \cdot 10^{22}$	$\sim 4 \cdot 10^{21}$
B_{peak}, ph/s/mm2/mrad2/0.1%	10^{26}	$\sim 10^{26}$

Eq. 1 shows that it is preferable to have low β-functions at low energies. Therefore, the design was optimised to minimize beta functions of the beam in the Linac to increase the threshold current of BBU instability from one

point of view and to decrease the beats of the beta functions in the spreaders from another.

As it was shown in [1], for a scheme of FSF, presented in Fig. 1, BBU instability will develop in the 1st cavity of the 1st 1 GeV linac.

In this paper we analyze the influence of the energy gain in the preinjection linac (100 MeV) and two main linacs (1 GeV) on the BBU threshold and propose an optimized solution.

Preinjection Linac Pattern

In this part we would like to discuss BBU instability in the preinjection linac, which is coming after the merger section. In Fig. 1 it is suggested to have a 100 MeV linac. Therefore we have acceleration from 7 to 107 MeV, or deceleration for the same amount of energy. Therefore it is required to have one cryomodule with an acceleration gradient of the cavities of G = 15.5 MeV/m.

Now we would like to analyse model with a linac consisting of two cryomodules with acceleration up to 250 MeV and with a triplet of quadrupole magnets in between them, which role is to change the sign of the twiss parameter α of the beam. Let us find the initial injection twiss parameters to have the equal threshold currents for the entrance and for the middle of the linac. To find that we will use eq. 1 and a model of the linac with one dipole HOM, which we locate at different positions in the linac. In this case we assume that the 1st cryomodule is a long cavity with a transfer matrix M given by [12]:

$$\begin{pmatrix} \cos(\alpha)-\sqrt{2}\sin(\alpha) & \frac{\sqrt{8}\gamma_0 L\sin(\alpha)}{\Delta\gamma} \\ -\frac{3}{\sqrt{8}}\frac{\Delta\gamma\sin(\alpha)}{L\gamma_1} & \left(\cos(\alpha)+\sqrt{2}\sin(\alpha)\right)\frac{\gamma_0}{\gamma_1} \end{pmatrix}, \quad (2)$$

where $\alpha = \frac{1}{\sqrt{8}}\ln\left(\gamma_1/\gamma_0\right)$, $\gamma_{1(0)}$ is the final(initial) normalized energy of the particle, L – the length of the cavity (cryomodule). Also we assume that there is a symmetrical β-functions on acceleration and deceleration in the linac.

Therefore we can transfer the beta function through the 1st cryomodule as:

$$\beta_1 = \frac{\gamma_1}{\gamma_0}\left(\beta_0 m_{11}^2 - 2\alpha_0 m_{11}m_{12} + \frac{1+\alpha_0^2}{\beta_0}m_{12}^2\right) \quad (3)$$

.

The RF focusing in the second cryomodule is quite weak and we represent it with a cavity without RF focusing for simplicity. So the beta function at the end of the linac might be found as:

$$\beta_2 = \frac{\gamma_2}{\gamma_1}\left(\beta_1 - 2\alpha_1 L + \frac{1+\alpha_1^2}{\beta_1}L^2\right) \quad (4)$$

.

The minimum of the $\beta_2 = 2L^2/\beta_1$ is given, when

$$\alpha_1 = \frac{\beta_1}{L} \quad (5)$$

.

Now we can proceed with an equation for the thresholds:

$$\sqrt{\frac{\beta_0\beta_2}{\gamma_0\gamma_2}} = \frac{2\beta_1}{\gamma_2-\gamma_0} \quad (6)$$

.

To find the solution we will vary the initial twiss parameters and look for a maximum value of the thresholds. The numerical solution is presented in Fig. 2.

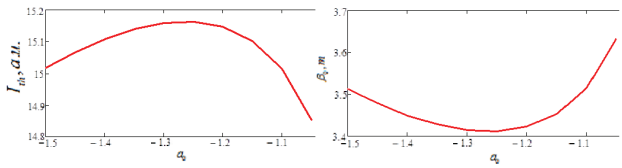

Figure 2: Threshold current, calculated using eq. 1 (without constants, which are the same for all cavities) and initial twiss parameters for preinjection Linac, consisting of two long cavities with a triplet in between.

One can see from Fig. 2 that the maximum threshold current is achieved at α_0 ~ -1.26 and β_0 ~ 3.41.

Different Acceleration Pattern

In this paragraph we would like to discuss an improvement of the present scheme of FSF, where we have 100 MeV preinjection and then two 1 GeV Linacs (Fig. 1), for the scheme, presented in Fig. 3.

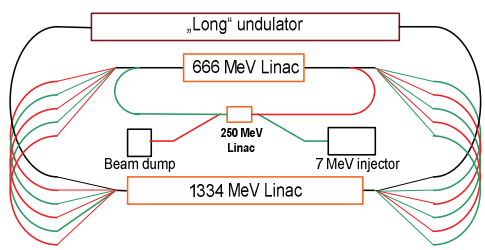

Figure 3: The improved acceleration scheme of FSF.

One of the motivations of this improvement was BBU instability. The new scheme gives roughly 1.7 times better threshold current for the 1-st cavity in the 1-st linac see Table 2, where the instability develops in the first scheme.

The easiest way to see the reason of rebalancing of the energies in the two main linacs is to analyse the eq. 1, specifically the square root in the denominator. We would

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

like to find a balance between the energy gains in two main linacs to have equal threshold currents for them. To do that, we will analyse a model with linacs, when a focusing from a triplets is neglected for the second and the third passes. In this model with the injection energy of about 250 MeV the transverse focusing inside the cavities can be neglected. So, we assume that the beta functions of a beam at the exit and at the entrance to the linac are about the length of the linac for the second and the third passes and for the end of the linacs at the first pass and it is about the length of the one cryomodule [1] at the entrance for the first pass.

Let's introduce G as a gradient of the cavities in MeV/m, $L= 2000$ [MeV] $/G$ is a length of the cavity structure, required to accelerate to the final energy of 2 GeV, x is the length of the first linac and, therefore, L-x is the length of the 2-nd. Now we can find energies $\gamma_{1(2),n}$ for each pass and as we said before $\beta_{1,1(6)} = \beta_{2,1(6)} \sim 12.57$ m and $\beta_{1,n} = x$ or $\beta_{2,n} = L$-x for the first and the second linac respectively and for n=2..5.

We can proceed with the following equation:

$$\sqrt{\sum_{m=1}^{2N-1}\sum_{n=m+1}^{2N}\frac{\beta_{1,n}\beta_{1,m}}{\gamma_{1m}(x)\gamma_{1n}(x)}} = \sqrt{\sum_{m=1}^{2N-1}\sum_{n=m+1}^{2N}\frac{\beta_{2,n}\beta_{2,m}}{\gamma_{2m}(x)\gamma_{2n}(x)}}, \quad (7)$$

when the threshold currents have the same values for the 1-st and last cavities in both linacs. This equation can be solved numerically and gives the result that x ~ L/3 with injection energy – $\gamma_{1,1} = 480$. This explains why we propose a new acceleration pattern in Fig. 3.

Now we proceed with a modeling of the linac optics in Elegant program [13]. Optics for all three passes through the first 666 MeV linac is presented in Fig. 4.

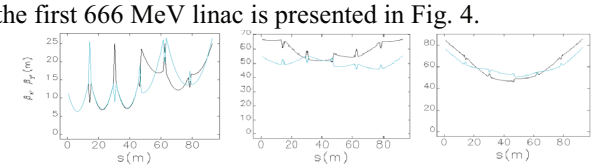

Figure 4: Optics design of the first 666 MeV linac. 3 passes with 250, 2.250 and 4.250 GeV beam injection energy from left to right correspondingly.

Also the optics was designed for the second 1334 MeV Linac and it is presented in Fig. 5.

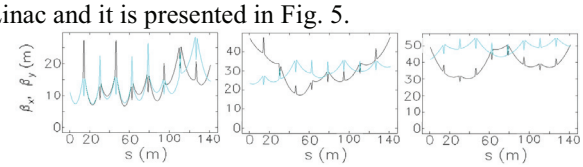

Figure 5: Optics design of the second 1334 MeV linac. 3 passes with 916, 2916 and 4916 MeV beam injection energy from left to right correspondingly.

The threshold currents for the schemes of FSF in Figs. 1 and 3 are presented in Table 2. For the estimations we used the following equation (which is a combination of eq. 1 and [9]):

$$I_{th} = \frac{2mc^3}{e\omega\left(\frac{R}{Q}\right)_d Q_d}\frac{1}{\sqrt{\sum_{m=1}^{5}\sum_{n=m+1}^{6}\frac{\beta_m\beta_n}{\gamma_m\gamma_n}}}, \quad (8)$$

and we took a mode with $(R/Q)_d \cdot Q_d = 6\cdot 10^5$ Ω, $\omega = 2\pi\cdot 2\cdot 10^9$ Hz.

Table 2: Threshold Currents for Different Schemes

Linac scheme	I_{th}, A		
	Preinjector	1st Linac	2nd Linac
0.100 + 1 + 1GeV	1.26	0.88	3.73
250 + 666 + 1334MeV	1.21	1.46	3.58

One can see from the Table 2 that the value of threshold current for the 1st main linac was improved. It was also slightly decreased for the 2nd linac and for the preinjection.

CONCLUSION

In the new proposed scheme BBU instability will develop in the preinjection Linac. In the future work we should find a way how to increase the thresholds in the preinjection linac and in the 1st by decreasing the threshold current value in the 2nd linac.

SINGLE SHOT BUNCH-BY-BUNCH BEAM EMITTANCE MEASUREMENT OF THE SPRING-8 LINAC

Yoshihiko Shoji# and Kouji Takeda, NewSUBARU/SPring-8, University of Hyogo, Japan

Abstract

The bunch-by-bunch emittance of a single shot beam from the SPring-8 electron linac was measured utilizing phase rotation in an electron storage ring. The linac beam was injected into the ring and the beam profiles of several revolutions were recorded using a dual sweep streak camera. The fast sweep separated the linac bunches in 1 ns macro pulse and the slow sweep separated the profiles at different turns. The bunch emittances were reconstructed from the profiles. The stability of the linac beam was evaluated from the recorded shot-to-shot fluctuation. We also identified differences in the orbit and the emittance of different bunches in a pulse.

INTRODUCTION

The SPring-8 linac has been operated as an injector to the electron storage ring, NewSUBARU. However, fine parameter tuning is required for stable top-up injection because of the small ring acceptance. In that process, single shot linac beam monitors were necessary to understand the shot-to-shot fluctuation of the injection. A single shot bunch-by-bunch emittance monitor would be a powerful tool to understand the shot-to-shot fluctuation of the injection efficiency.

We used the visible light profile monitor of the electron storage ring as a diagnostic for the linac beam. The dual sweep streak camera recorded multiple profiles of the injected beam in a single camera frame. The fast sweep separated linac bunches in a macro pulse and the slow sweep separated profiles of different turns. The betatron oscillation in the ring produced phase rotation allowing the reconstruction of the beam emittance. It was possible to fully optimize the ring parameters for our measurements since beam storage was not required.

A stability of the linac beam was evaluated from the shot-to-shot variation. We could also see differences in the bunch at the front of a macro pulse compared to the bunch at the rear.

PARAMETERS OF DAILY OPERATION

Averaged Beam Parameters

Figure 1 shows the layout of the SPring-8 linac, the booster synchrotron, and NewSUBARU storage ring. Table 1 shows the main parameters for the linac. The macro pulse width of the linac beam is normally 1 ns, which contains 3 linac bunches. The rf synchronization system between the linac and the ring [1] enables an injection to a single rf bucket of the ring with rf frequency of 500 MHz.

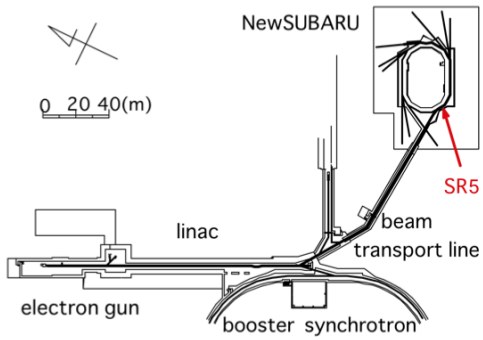

Figure 1: Layout of the 1 GeV SPring-8 linac, the booster synchrotron, and the NewSUBARU storage ring.

Table 1: Main Parameters of the Linac

Electron energy	1 GeV
Rf frequency	2856 MHz
Common pulse rate	1 Hz
Common pulse width	1 ns
FWHM bunch length; front/middle	10 ps / 14ps
Full energy spread; front / middle	0.4% / 0.6%
Transverse emittance (FWHM^2)	100 π nmrad.

The listed transverse emittance was calculated from the average over many shots, measured by Q-scanning at the beam transport line. The longitudinal parameters were obtained from the measurements of the synchrotron oscillation in the ring just after injection [2]. The listed bunch length and the energy spread were calculated from the average of 10 shots.

Bunch Structure and Injection Efficiency

The bunch structure was fluctuated by a jittering of the gate pulse of the electron gun. Figure 2 shows six typical dual sweep images of the streak camera with six typical bunch structures. The vertical axis in the images is the ring rf phase and the horizontal axis the revolution. The time structure at 1/4 of the synchrotron oscillation period (41 μs) gives the energy profile.

Figure 3 shows the injection efficiency with the ring parameters characteristic of daily operation. Shots with images A and B had comparatively worse efficiency. A separated data shows that the ring has a large enough longitudinal acceptance for the injected beam, suggesting that dependence on transverse parameters caused fluctuations in the injection efficiency.

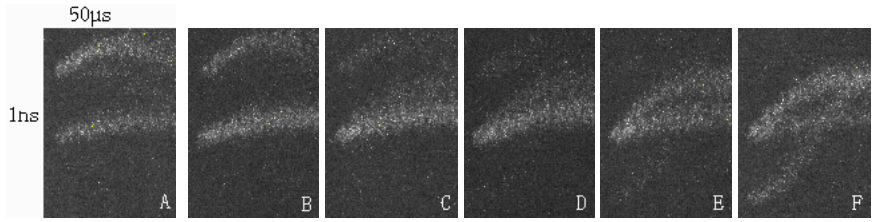

Figure 2: Typical dual sweep images.

SHOT-TO-SHOT MEASUREMENTS

Setup for the Measurement

Figure 4 shows the schematic layout near the injection point and the monitor line, named SR5. The dove prism on the line switches transverse measurement axis, in this case we selected the vertical with 90 degrees rotation.

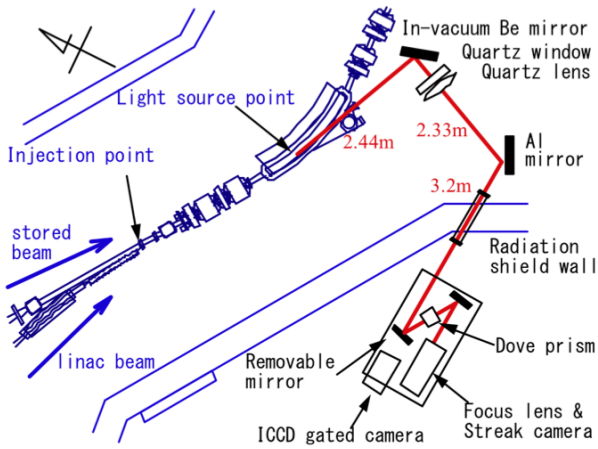

Figure 4: Layout of the visible light monitor line SR5.

The ring parameters were different from those of daily operation. The injection pulse bump was optimized so that the injected beam had a small dipole oscillation and maintained almost 100% injection efficiency. The vertical chromaticity was reduced to 0 in order to eliminate the betatron phase spread over multiple revolutions. The linear H/V coupling was reduced to less than 1%. The very small beam size of the stored beam was used to calibrate the vertical spatial resolution: 0.3 mm FWHM at the light source point with $\beta_y = 17$ m.

Data Analysis of a Typical Shot

Here we demonstrate our method of analysis using a representative shot (#12) as an example. Its total charge, measured by fast CT on the beam transport line, was 0.23 nC.

Figure 5 shows the dual sweep image of the streak camera frame and the projection to the fast sweep axis. The vertical axis is the horizontal position in space and the ring rf phase in time. The upper part of the figure corresponds to the head of the linac pulse with the tail in the lower part of the figure. The horizontal axis is the vertical position in space and the ring revolutions in time. The six spots correspnd to profiles from the 4th through 9th turns after the injection. Profiles at the initial 3 turns were out of the camera slit because of a large horizontal displacement. The horizontal profile in the figure of each spot corresponds to the vertical spatial profile in the experimental frame.

Figure 6 shows profiles of the 6 turns of the two respective bunches. They were fitted with Gaussian functions. We derived the peak position y and a divergence σ^2 as a function of the revolution number N.

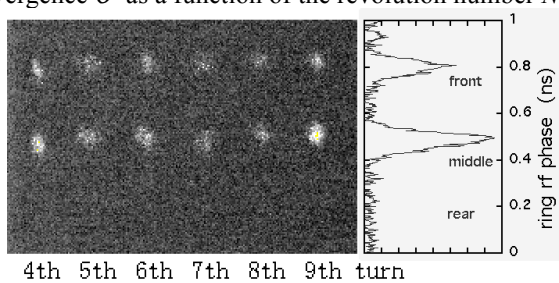

Figure 5: Dual Sweep image of the injected beam of the shot #12.

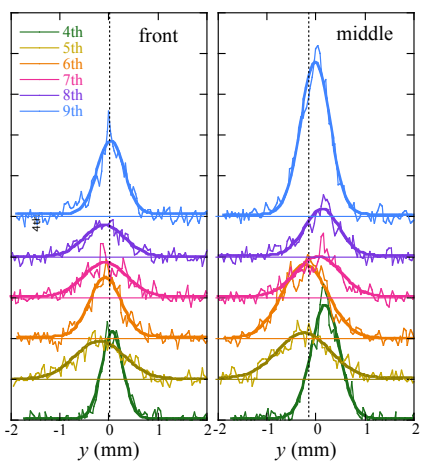

Figure 6: Vertical beam profiles from turns 4 through 9 of the front bunch and the middle bunch.

As shown in Figure 7, the data were fitted with the following sinusoidal functions

$$y = A_0 + A_S \sin(2\pi\Delta\nu_y N) + A_C \cos(2\pi\Delta\nu_y N) \quad (1)$$

$$\sigma^2 = B_0 + B_S \sin(4\pi\Delta\nu_y N) + B_C \cos(4\pi\Delta\nu_y N) \quad (2)$$

Here $\Delta\nu_y$ =0.224 is the sub-integer part of the vertical betatron tune. The dipole oscillations of two bunches were obviously different. The oscillations of the widths

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

were almost the same except for one data point, the 6th turn of the middle bunch.

The beam ellipse at the injection point is calculated using the phase advance to the light source point, 0.15 rad. Figure 8 shows the extrapolation of the fitted wave and the beam ellipses at the injection point.

The transverse emittance ε_y was obtained from

$$\varepsilon_y = \sqrt{(B_0 - \sigma_R{}^2)^2 - (B_S{}^2 + B_C{}^2)}/\beta_y. \quad (3)$$

Here $\sigma_R{}^2$=0.02 mm^2 is the spatial resolution.

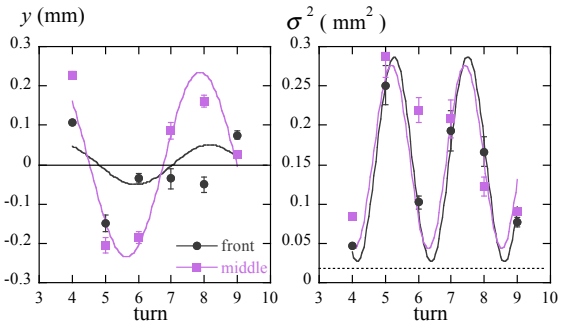

Figure 7: The dipole oscillation of the peak position (left) and the quadrupole oscillation of the divergence (right). The dotted line on the right indicates the spatial resolution.

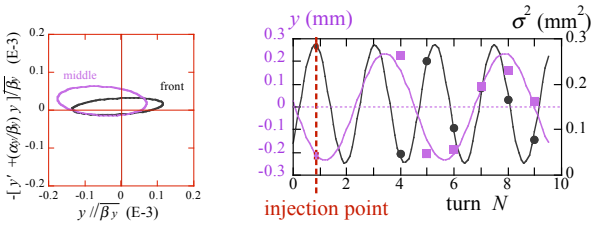

Figure 8: Extrapolation of the fitted waves and the calculated beam ellipses at the injection point.

Shot-to-Shot Fluctuation

We recorded the profiles of 20 shots in order to see the shot-to-shot fluctuation. Figure 9 shows the bunch charge for the 20 shots. They are grouped A-E, according to the charge of the front bunch.

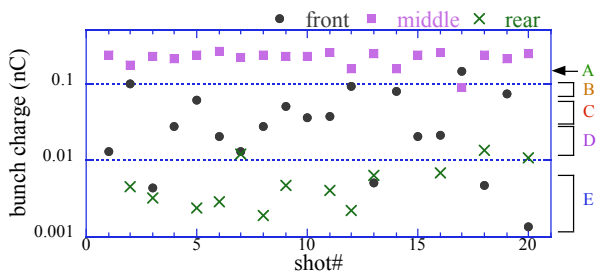

Figure 9: Bunch charge for the highlighted 20 shots.

The parameters quantifying the dipole oscillation, A_C and A_S, of the middle bunch are plotted in Figure 10. The fluctuation was correlated with the group and took place at the phase $\Delta A_S/\Delta A_C$ = 1.3. We added data points of the front bunch of groups A–C to the plot. The differences in the same pulse were roughly of the order of the fluctuation in phase.

The parameters for the quadrupole oscillation, B_C and B_S, of the middle bunch are plotted in Figure 11. No clear dependence on the group was observed. However, it seems to be no accident that the difference of two bunches satisfied $2\Delta B_S - \Delta B_C > 0$ for all 8 shots.

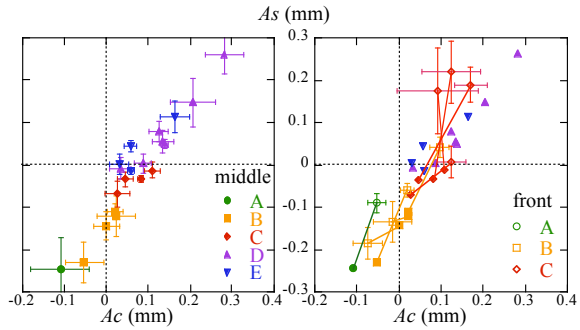

Figure 10: Shot-to-shot fluctuation of the dipole oscillation of the middle bunch (left) and those of the front bunch (right). The oscillations of different bunches in the same shot are connected with lines.

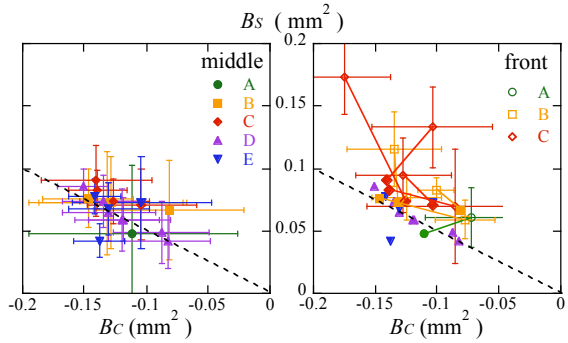

Figure 11: Shot-to-shot fluctuation of the quadrupole oscillation of the middle bunch (left) and those of the front bunch (right).

SUMMARY AND DISCUSSION

We succeeded in measuring the shot-to-shot, bunch-by-bunch fluctuations of the vertical emittance of the SPring-8 linac beam. A measurement of the horizontal parameter would be necessary to identify the mechanism that causes the correlation with the injection efficiency.

ACKNOWKEDGEMENT

We thank operators of NewSUBARU, Dr. Minagawa, Mr. Shinomoto, and Mr. Takemura for their help with the measurement. We thank members of the SPring-8 linac group for many helpful suggestions. We acknowledge technical and financial support by KEK on the construction of SR5 according to the "comprehensive support program for the promotion of accelerator science and technology".

Abstract

Diamond is being evaluated as a dielectric material for dielectric loaded accelerating structures. It has a very low microwave loss tangent, high thermal conductivity, and supports high RF breakdown fields. We report on progress in our recent beam tests of the diamond based accelerating structures of the Ka-band and THz frequency ranges. Wakefield breakdown test of a diamond-loaded accelerating structure has been carried out at the ANL/AWA accelerator. The high charge beam from the AWA linac (~70 nC, σ_z ~ 2 mm) was passed through a rectangular diamond loaded resonator and induce an intense wakefield. A groove is cut on the diamond to enhance the field. Electric fields up to 300 MV/m has been generated on the diamond surface to attempt to initiate breakdown. Wakefield effects in a 250 GHz planar diamond accelerating structure has been observed at BNL/ATF accelerator as well. We have directly measured the mm-wave wake fields induced by subpicosecond, intense relativistic electron bunches in a diamond loaded accelerating structure via the dielectric wake-field acceleration mechanism. A surface analysis of the diamond has been performed before and after the beam test.

INTRODUCTION

Diamond has been proposed as a dielectric material for dielectric loaded accelerating (DLA) structures [1-3]. Dielectric Loaded Accelerator structures using ceramics or other materials and excited by a high current electron beam or an external high frequency high power RF source have been under extensive study for many years [4-7]. Low loss microwave ceramics, fused silica, and CVD polycrystalline and single crystal diamonds [11] have been considered as materials for dielectric based accelerating structures to study of the physical limitations encountered in developing field strengths > 100 MV/m at microwave [4-6] and > GV/m at THz frequencies in a dielectric based wakefield accelerator [6,7,11,12]. THz radiation has been generated recently by a short ~10 GV/m pulse within a 100 μm diameter quartz fiber [7]. A planar diamond-based DLA structure was proposed recently by Omega-P, Inc., where the dielectric loading of this structure was to be made of diamond slabs fabricated using CVD (chemical vapor deposition) technology [2].

Our choice of CVD (Chemical Vapor Deposition) diamond as a loading material will allow demonstration of high accelerating gradients; up to 0.5-1.0 GV/m as long as the diamond surface can sustain a 0.5-1.0 GV/m short pulse (~ 10 ns) rf field without breaking down. Diamond has the lowest coefficient of thermal expansion, highest thermal conductivity (2×10^3 Wm^{-1} K^{-1}) and extremely low loss tangent ($<10^{-4}$) at Ka-W frequency bands. Secondary emission from the CVD diamond surface can be dramatically suppressed by diamond surface dehydrogenation or oxygen termination [3,6,8-12]. The CVD process technology is rapidly developing, making the CVD diamond fabrication process fast and inexpensive. Given these remarkable properties, diamond should find numerous applications in advanced accelerator technology [3]. Planar diamonds are available commercially in various grades including single crystal diamonds. The goal of this research is to perform a wakefield acceleration experiment using a diamond loaded structure and to test diamond for breakdown.

Euclid Techlabs had performed two wakefield experiments with diamond loaded accelerating structures: a 25 GHz structure at the Argonne Wakefield Accelerator of ANL and a 250 GHz structure at the Accelerator Test facility of BNL [9].

BEAM EXPERIMENTS WITH THE DIAMOND BASED DLA STRUCTURES

Significant progress has been made in the development and testing of high gradient dielectric accelerating structures (DLA) [1]. As various engineering challenges (breakdown, dielectric losses, efficient RF coupling) have been overcome, the technology of high gradient RF or wakefield driven dielectric loaded structures appears increasingly attractive as a viable option for high energy accelerators. Typical DLA considered in experiments is a cylindrical, dielectric tube with an axial vacuum channel inserted into a conductive sleeve or a rectangular waveguide loaded with planar dielectric pieces. In this paper we will focus on the latter structure. The dielectric constant, thickness of dielectric and the size of a vacuum gap are chosen to adjust the phase velocity of the fundamental mode at certain frequency to the beam velocity ~ c. In the application to particle acceleration, the dominant TM_{01} mode is of main interest.

We report here the results of a wakefield breakdown test of single crystal diamond-loaded rectangular accelerating structure [10]. The high charge beam from the AWA linac (~70 nC, σ_z = 2 - 2.5 mm) was transported through a rectangular diamond - loaded resonator and induced an intense wakefield [12]. A deep (200 μm) and narrow (20 μm) groove is cut on the diamond surface to enhance the field (by approximately a factor of ε). Electric fields at least of 300 MV/m were present on the diamond surface in the groove (decay time ~ 35 ns). A surface analysis of the diamond was performed before and after the beam test. No breakdown-type damage was observed on scanning electron microscopy images [10].

Structure design was presented earlier in [10], Fig.1. Parameters of the structure were determined via parametric simulations with constraint on the thickness of commercially available diamond plates, and the minimal gap size was determined by beam dynamics [11].

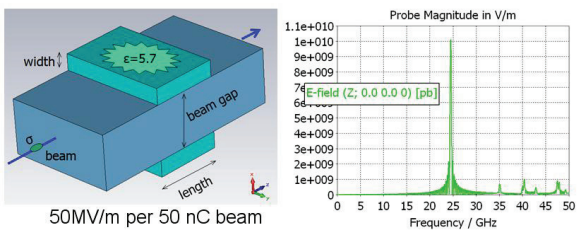

Figure 1: Left: geometry of the diamond resonator: length = 4mm, width = 1.2mm, beam gap = 4mm and overall width = 8mm. Right: spectrum of the wakefield (simulation).

To achieve stronger fields on the surface of the diamond two small 20 and 25 micron – wide, 220 micron deep grooves were laser cut on the diamond surface transverse to the beam propagation direction. There is a large field enhancement in these grooves: the field at the entrance to the groove is higher by a factor of ~ ε (5.7) than it would be in its absence [10] – a five time field enhancement because of the boundary conditions for the electric field at the surface of dielectric. For deep and narrow scratches (aspect ratio of 10 and higher) such enhancement is practically ε. As the groove becomes wider and shallower the field enhancement drops.

Diamond laser cutting is not a trivial procedure. Multistage cleaning was used to get rid of partial conductivity from carbon deposits. Special technology has been used that allowed removing practically all remaining carbon. SEM measurement confirmed that the laser cutting was successful as well as that target values of groove widths were achieved [11], Fig. 2.

In the experiment we manage to transport 72 nC charge through the structure, which corresponded to at least 300 MV/m on the surface of the groove. The bunch length measurement was not available, so for this estimate we used maximum value of 2.5mm. Shorter bunch length yields higher gradient.

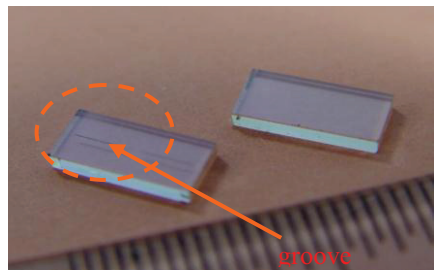

Figure 2: Field Enhancement groove machined in a planar diamond sample.

We used scanning electron microscopy to analyze the condition of the diamond surface before and after the experiment. Besides the presence of lint the surface did not undergo noticeable changes, Fig.3.

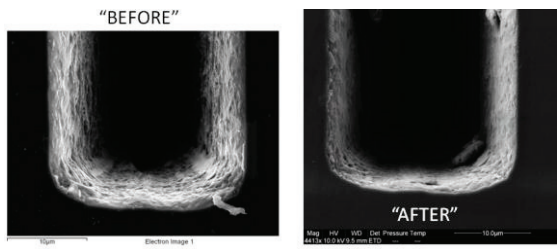

Figure 3: SEM measurement of the groove: right – before, left – after the test.

WAKEFIELD ACCELERATION IN A 250 GHZ DIAMOND STRUCTURE

Recently, we have directly measured THz wakefield acceleration/deceleration in a diamond loaded dielectric accelerating structure.

Proof of principle experiments at BNL/ATF [9] have studied wakefields in diamond structures in the 250 GHz regime. It should be noted especially that in this experiment diamond was for the first time used as a loading material for a wakefield dielectric based accelerating structure [9]. Fields produced by a leading (drive) beam were used to accelerate a trailing (witness) electron bunch, which followed the drive bunch at a variable distance. The energy gain of a witness bunch as a function of its separation from the drive bunch describes the time structure of the generated wakefield. By sweeping the separation between the drive beam and the witness beam and energy measurements of the witness beam a 0.25 THz frequency wakefield was directly sampled at the scale of about one wavelength [9,13].

The general experimental methodology is the following: a pair of beams is generated: - a high charge drive beam, followed by a smaller witness beam at a variable distance *d*. The drive beam generates a wake there and the witness beam is accelerated or decelerated depending on the delay between the two beams. We record the witness beam energy change, ΔE as a function of *d*.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

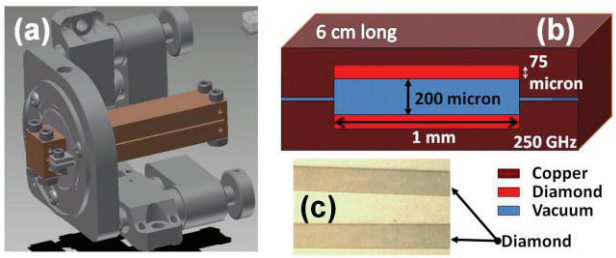

Figure 4: (a) 250 GHz structure mounted on a positioning holder; b) structure dimensions; c) photo of diamond after the experiment exhibiting no visible damage.

In the experiment we used 75 micron thick polycrystalline diamond plates loaded in a 6 cm long waveguide, Fig.4. The beam gap was 200 microns. This structure yields a wakefield dominated by a TM_{11} – like mode with 1200 micron wavelength (0.25 THz). The ATF drive beam is very short and also excites higher order modes, hence the wake is not a pure sine wave [9].

The subpicosecond drive and witness beams are produced by the technique described in [9]. A beam accelerated off-crest hence having a linear energy chirp (the head of the beam having lower energy than the tail) passes through a a dispersionless translating section. A mask is placed between the dogleg dipoles where the beam transverse size is dominated by the correlated energy spread. After the second dipole magnet the transverse pattern introduced by the mask becomes the longitudinal charge density distribution. In our case the mask was motorized and allowed creation of a drive beam followed by a witness beam at a variable delay [9].

Calibration is done via coherent transition radiation (CTR) interferometry. We fitted the recorded transverse profile by a gaussian distribution with σ_x = 50 μm, σ_y = 350 μm. The longitudinal wakefield produced by a beam with this current distribution was numerically calculated and compared with the experimental results.

The relative change in witness beam energy depending on the drive – witness separation is measured on the spectrometer. Compared to the beam energy, when it does not go through the structure, we observe energy gain and loss in the interval from -0.6 to +0.65 MeV for the witness beam following a drive beam through the DLA structure. This yields a 10.8 MV/m gradient for a 6 cm structure. The measurement accuracy was limited by the spectrometer resolution (σ = 0.028 MeV), estimated using the sharpest features obtained on the spectrometer by measuring the FWHM (full width half maximum) and dividing it by 2.355 to obtain the equivalent Gaussian width. Fig. 5 shows the measured energy change (diamonds) as a function of drive – witness separation with error bars. The shape of the experimentally mapped wake (diamonds) agrees well with the theoretical (scaled) prediction (circles) based on the wakefield (solid line) calculated for the drive beam current distribution (dashed line).

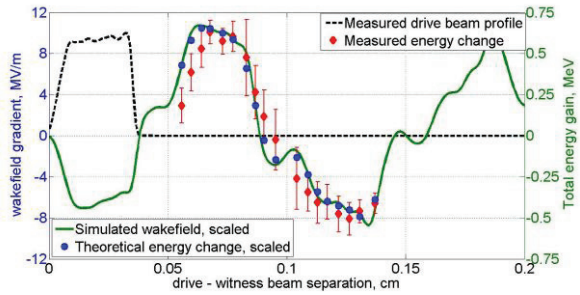

Figure 5: Energy gain of the witness beam as a function of separation from the drive beam.

SUMMARY

The emphasis of this paper is to present progress on development and fabrication of new types of diamond waveguides to be used for high gradient dielectric accelerating structures. We reported the results from development of a diamond DLA of GHz frequency range and wakefield tests of diamond-loaded rectangular accelerating structures at THz frequencies. We have directly measured THz wakefield acceleration and deceleration in a diamond loaded dielectric accelerating structure in an experiment where diamond was used for the first time in a wakefield dielectric based accelerating structure. In the 25 GHz frequency range, we achieved field levels on the order of 300 MV/m (35 ns pulse) in the structure using the 72 nC, 15 MeV beam at the Argonne Wakefield Accelerator Facility. Single crystal diamond plates produced by chemical vapor deposition (CVD) were used in the structure. A surface analysis of the diamond has been performed before and after the beam tests.

ON-LINE DISPERSION FREE STEERING FOR THE MAIN LINAC OF CLIC

J. Pfingstner*, D. Schulte, CERN, Geneva, Switzerland

Abstract

For future linear colliders as well as for light sources, ground motion effects are a severe problem for the accelerator performance. After a few minutes, orbit feedback systems are not sufficient to mitigate all ground motion effects and additional long term methods will have to be deployed. In this paper, the long term ground motion effects in the main linac of the Compact Linear Collider (CLIC) are analysed via simulation studies. The primary growth of the projected emittance is identified to originate from chromatic dilutions due to dispersive beam orbits. To counter this effect, an on-line identification algorithm is applied to measure the dispersion parasitically. This dispersion estimate is used to correct the beam orbit with an iterative dispersion free steering algorithm. The presented results are not only of interest for the CLIC project, but for all linacs in which the dispersive orbit has to be corrected over time.

INTRODUCTION

Linear colliders and light sources often require very small beam emittances and beam sizes to reach their goals. This fact makes these machines inherently sensitive to ground motion effects. For short time scales orbit feedbacks can be used to mitigate these effects by steering the beam with the help of beam positioning monitors (BPMs) (see [1] for the CLIC case). For longer time scales, this steering is not sufficient to preserve the beam quality as can be seen in Fig. 1. To be able to operate CLIC over longer time periods, it is essential to correct this remaining emittance growth. The development of such an algorithm is the topic of this paper.

The main reason for the remaining emittance growth is that the BPM positions itself will drift from their original position, which results in a dispersive beam orbit. The according chromatic dilutions decrease the beam quality over time. In the literature, a technique named dispersion free steering (DFS) can be found, which has been developed to correct similar chromatic dilutions (see [3] and [4]). In this paper we modify and extent this basic DFS method, such that it can be used to correct long term ground motion effects in an on-line mode. On-line means in this case that the DFS correction is applied during the normal accelerator operation in a parasitic way, without stopping the physics program. The methode will be explained an evaluated on the example of CLIC, but can be easily utilised for other accelerators.

* juergen.pfingstner@cern.ch

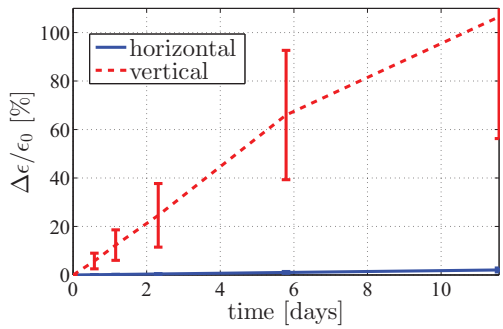

Figure 1: Simulations of the relative emittance growth over long time scales with orbit feedback in the main linac of CLIC. The used ground motion is generates according to the ATL law [2] with a constant A of $0.5\times10^{-6}\,\mu m^2/m/s$, which is the baseline for CLIC. The results have been averaged over 10 random samples of ground motion. For the initial horizontal and vertical emittance 600 nm and 10 nm have been used. The action of the orbit feedback was assumed to be perfect and therefore simulated by applying one-to-one steering without BPM noise, which is an optimistic approximation. It can be seen that already after 1 day the emittance has increased by about 10%.

ON-LINE DFS ALGORITHM

In this section, we will first introduce the basic DFS algorithm. After that the modifications necessary to apply this algorithm in an on-line mode will be discussed.

Basic DFS Algorithm

The DFS algorithm consists of two steps. In the first, the dispersion $\boldsymbol{\eta}$ at the BPMs is measured by varying the beam energy. This energy change can be created by changing the acceleration gradient, scaling the magnet strength and/or changing the initial beam energy. In the second step, corrector actuations $\boldsymbol{\theta}$ are calculated such that at the same time the measured dispersion $\boldsymbol{\eta}$ as well as the beam orbit $\boldsymbol{b}$ are corrected. Such actuations can be calculated by solving the following system of equations for $\boldsymbol{\theta}$ (see [5] for more details)

$$-\begin{bmatrix} \boldsymbol{b}-\boldsymbol{b}_0 \\ \omega(\boldsymbol{\eta}-\boldsymbol{\eta}_0) \\ \boldsymbol{0} \end{bmatrix} = \begin{bmatrix} \boldsymbol{R} \\ \omega\boldsymbol{D} \\ \beta\boldsymbol{I} \end{bmatrix}\boldsymbol{\theta}, \qquad (1)$$

where $\boldsymbol{b}_0$ and $\boldsymbol{\eta}_0$ are the reference beam orbit and target dispersion respectively. The third set of equations in Eq. (1) with the unity matrix $\boldsymbol{I}$ on the right side is used to damp too high corrector actuations. The weights ω and β can be

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

chosen to minimise the emittance, which is easiest done in simulation via a parameter scan. The matrices $\boldsymbol{R}$ and $\boldsymbol{D}$ are the orbit and dispersion response matrix.

To increase the robustness, this DFS algorithm is usually applied sequentially to overlapping sections of the accelerator. In the case of CLIC, the main linac is partitioned into 36 fully overlapping sections each consiting of about 28 FODO cells. Note that after the correction of one section, the dispersion of the sections downstream has changed as well. It is therefore necessary to re-measure the dispersion after each DFS correction of one section.

Problem of Low Energy Variations

The primary difference between the basic and the on-line DFS algorithm is that the dispersion cannot be measured straight forward. In the basic method, a large energy deviation will be used to create large dispersive offsets in the BPMs to increase the measurement accuracy. This is however not possible for an on-line algorithm, since only tiny energy variations can be tolerated due to the energy acceptance of the final focus system of CLIC. For the simulations in this paper an energy variation of only 0.5 per mill is used.

Two main problems arise from these small induced energy variations. First of all, the induced orbit variations will be small and the necessary accuracy of the dispersion measurement has to be recovered by combining many measured orbit samples in a stochastic way to filter the noise. This dispersion estimation will be discussed in the next section. The second problem due to the small energy variations comes from the fact that the used energy deviations are so small that they are in the order of the beam energy spread, which is strongly influenced by wakefields. Therefore, changes of wakefields due to the change of beam orbits or cavity positions start to influence the dispersion measurement. This problem can be resolved by an initial cavity alignment (see [6]) before the on-line DFS, which reduces the wakefield effects for the current beam orbit. It is also beneficial to perform a cavity alignment after each full DFS correction of the linac.

Dispersion Estimation

The dispersion is measured in this paper by changing the acceleration gradient, which can be accomplished for the main linac of CLIC by a modulation of the beam intensity of the drive beam. Additionally, the initial beam energy is varied with the help of a bunch compressor. Since the induced energy variations have to be small, the individual dispersion measurements will be disturbed strongly by the influence of BPM noise and the usual jitter of the initial beam energy and the accelerating gradients. Therefore, the dispersion is determined by using many measurements and combining them to a least squares (LS) estimate to ensure the necessary accuracy. Instead of determining the LS estimate via the usual calculation of the pseudo-inverse, a very efficient recursive version of the algorithm can be derived, if the induced energy variations are chosen to be the sequence $\{-\Delta E, +\Delta E, -\Delta E, +\Delta E, \dots\}$. In this case the LS estimate of the dispersion η_N at a BPM at time step $N \in 2\mathbb{N}$ can be written as

$$\eta_N = \left(\boldsymbol{E}^T\boldsymbol{E}\right)^{-1}\boldsymbol{E}^T\boldsymbol{b} = \frac{T_N}{N\Delta E} \quad \text{with} \qquad (2)$$

$$\boldsymbol{E} = \begin{bmatrix} -\Delta E \\ +\Delta E \\ \vdots \\ -\Delta E \\ +\Delta E \end{bmatrix} \quad \text{and} \quad T_N = \sum_{i=1}^{N} (-1)^i b_i,$$

where $\boldsymbol{b} \in \mathbb{R}^N$ is the vector of previous BPM measurements. The so obtained estimate η_N can subsequently be used to calculate corrections θ for the next accelerator section according to Eq. (1). The question how many samples N have to be used to create an accurate enough estimate will be answered in the results section of this paper.

Integration of On-Line DFS and Orbit Feedback

When using the on-line DFS algorithm in combination with the orbit feedback, the interaction of the two subsystems has to be considered. At the dispersion estimation the beam energy changes induced by the on-line DFS will create orbit offsets that will couple to the action of the orbit feedback. By choosing the excitation to be a constant value with alternating signs, the induced disturbances are of the highest resolvable frequency of the orbit controller. Due to its design, the orbit controller frequency response demagnifies this frequency component strongly and the orbit feedback will couple only very weakly to the induced orbit offsets.

Another modification to the basic DFS algorithm is necessary, since the orbit controller will react on the changed beam orbits due to the on-line DFS corrections. The orbit feedback would aim to steer the beam back on its previous orbit. Therefore, the BPM centres of the corrected section have to be shifted electronically to the new reference orbit after the DFS correction.

If a section would be DFS corrected without considering the beam orbit in the rest of the downstream linac, the beam would be steered far from its reference orbit. This would lead to an unacceptable emittance growth. Also the orbit feedback would react strongly on the large offsets, which would also decrease the accuracy of the next dispersion estimate. Therefore, the expected beam orbit change $\hat{\boldsymbol{b}}$ in the BPMs after the current section has to be corrected with the correctors after the current section. Simulation showed that it is sufficient to use only the correctors of the next section, which reduced the necessary calculation time of the performed all-to-all steering. The according corrector actuations $\hat{\theta}$ can be calculated by solving

$$-\begin{bmatrix} \hat{\boldsymbol{b}} \\ \boldsymbol{0} \end{bmatrix} = \begin{bmatrix} \hat{\boldsymbol{R}} \\ \beta_0 \boldsymbol{I} \end{bmatrix} \hat{\theta}, \qquad (3)$$

where β_0 is a damping factor for the corrector actuations.

RESULTS

To test the on-line DFS algorithm proposed, it was integrated in the simulation framework described in [1], which include the beam tracking in the main linac of CLIC, ground motion generation and the action of the orbit controller. The algorithm was tested on a beamline that was misaligned with about 11 days of ATL ground motion, followed by a one-to-one steering.

To determine how many samples are needed to estimate the dispersion sufficiently well, a simplified procedure was used. Instead of using full-scale simulations, the real dispersion was determined in simulations and corrupted with artificial BPM noise. The influence of the BPM resolution on the on-line DFS correction result is shown in Fig. 2. The effective BPM resolution in the estimate has to be about 5 nm to not worsen the average on-line DFS correction by more than 2%. Assuming a BPM resolution of 100 nm, the noise has to be reduced by a factor of 20. Since the averaging reduces the remaining noise by the factor $1/\sqrt{N}$, where N is the number of used samples, N has to be 400, which corresponds to 8 s of CLIC operation. Considering further that this procedure is repeated for 36 linac sections over two iterations, the full correction time needed is about 10 minutes not including the time needed for the cavity alignment. Additionally to the influence of noise, also the DFS algorithm itself cannot correct the chromatic dilutions fully. With perfectly known dispersion, the initial vertical emittance growth of 107.6% was reduced to 2.5% on average.

The long time periods necessary for the averaging cannot be simulated directly in reasonable time. We therefore only performed full-scale simulations with an N of 100, which corresponds to a real-time operation of about 2 minutes. Different imperfections were applied and on average the emittance growth could be reduced after two iterations to 2.8% with no imperfections, 3.7% with orbit feedback turned on and 10.4% with realistic BPM resolution.

The results for one particular ground motion sample are shown in Fig. 3. It can be observed that at the corrections of the final sections the emittance grows for a short time period. We believe that this behaviour is due to a worse steering and an improvement is subject to future work. Simulations were also performed including short-term ground motion (model B [1]) in combination with the orbit feedback for the dispersion estimation. The observed effect due to the ground motion was seen to be negligible. Another tested imperfection is the jitter of the acceleration gradients. Also here no significant degradation was observed for the maximal specification of 0.5%.

CONCLUSIONS

In this paper an on-line DFS algorithm was presented. Simulation results show that it is capable of correcting dispersive beam orbits due to long term ground motion misalignments efficiently. Two iterations of the algorithm have found to be enough to reduce the according beam emittance growth very efficiently, which takes for CLIC about 10 min. Since the time constant of the correction is much smaller than the emittance growth, there is no need to run the algorithm continuously. The mutual interaction of the algorithm with the orbit feedback was found to be small. Also the influence of ground motion and decelerator gradient jitter can be neglected. The presented algorithm is therefore an essential contribution for the successful operation of CLIC over longer time periods.

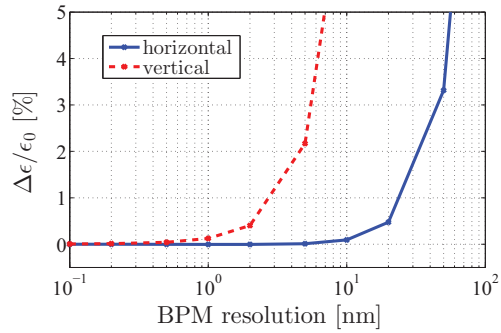

Figure 2: Relative emittance growth due to BPM resolution when using on-line DFS averaged over 20 random samples.

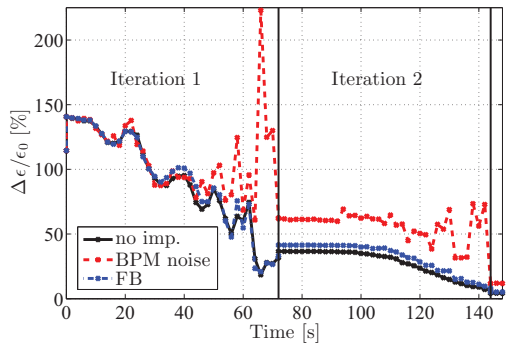

Figure 3: Relative vertical emittance during two iterations of the on-line DFS correction for one particular sample of ground motion. No imperfections are applied for the black curve (4% emittance growth). For the blue curve, the orbit feedback is turned on during the dispersion estimation. The mutual influence of the two subsystems is seen to be small (5% emittance growth). For the red curve a BPM resolution of 100 nm is used (12% emittance growth).

DETAILED ANALYSIS OF THE LONG-RANGE WAKEFIELD IN THE BASELINE DESIGN OF CLIC MAIN LINAC

V.F. Khan and A. Grudiev
CERN, Geneva, Switzerland.

Abstract

The baseline design of the accelerating structure of the CLIC main linac relies on strong damping of transverse higher order modes (HOMs). Each accelerating cell is equipped with four damping waveguides that causes HOM energy to propagate to damping loads. Most of the HOMs decay exponentially with a Q-factor of about 10, however there are modes with higher Q-factors. Though the amplitude of the high Q modes is nearly two orders of magnitude smaller than the dominating lowest dipole mode, their cumulative effect over the entire bunch train may be significant and dilute the beam emittance to unacceptable level. In this paper we report on an accurate calculation of the long-range wakefield and its overall effect on beam dynamics. We also discuss possible measures to minimise its effect in a tapered structure.

INTRODUCTION

The CLIC baseline design of the main linac operates at 12 GHz [1]. Preserving the beam quality in linacs operating at high frequencies is primarily limited by the beam induced fields known as wakefields [2]. Inadequate suppression of wakefields may result in emittance dilution; hence it is essential to employ a damping mechanism. In the first section of this paper we present detailed calculation of the wakefields in the CDR [1] baseline design of the CLIC accelerating structure (CLIC AS) [3], which is based on strong waveguide damping of HOMs. We also investigate the presence of so called persistent wakefield [4] in this structure. In the CLIC scheme, the bunch train consists of 312 bunches [1]; in such multi-bunch acceleration, wakefield generated by a bunch often leads to kicking the following bunches. An analytical estimate of the effect of multi-bunch long range wakefields on the beam profile is presented in [5]. However, in [5], by considering the strong damping of the HOMs, it is assumed that only the first trailing bunch experiences a kick due to an off-axis driving bunch. Herein we calculate the very long range wakefields in CLIC AS which allows HOM kicks to be considered on all trailing bunches by applying the analytical model to estimate the long range multi-bunch wakefield effect. These results are discussed in the second section.

WAKEFIELDS IN CLIC AS

The CLIC AS is designed with tapered irises so as to keep the accelerating gradient (nearly) constant. The wakefield is strongly damped by means of four waveguides attached to each accelerating cell [1, 3]. The time domain code GdfidL [6] was utilised to calculate the long-range wakefields excited in the structure. The wakefield can also be reconstructed using the frequencies, kicks and Q factors of the dominating modes. The lowest dipole mode has the strongest impact on the off-axis beam as it contains the largest kick factor. The damping waveguides are carefully designed, in particular to damp this mode with a Q ~10 [3]. The envelopes of transverse wakefields of the sample cells, namely the first, middle and last are illustrated in the Fig. 1, and a disc of the CLIC AS is also shown inset. Beyond 1 m wake-length it is clear that only one mode dominates, which has low amplitude but high Q-factor. However, modes with high group velocity (v_g) and poor damping via these waveguides travel along the structure and are damped by means of evacuation from the structure volume through the input and output power couplers. Whereas the wakefield in the last cell does not seem to be affected by

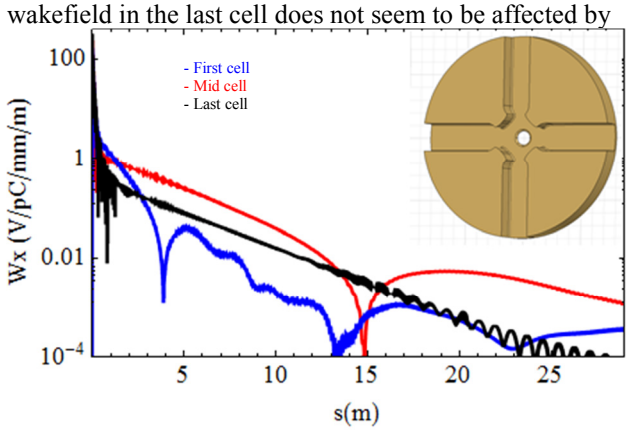

Figure 1: Envelope of transverse wakefield in single cells of CLIC AS.

the group velocity of the mode, the wakefields in the first and the middle cells are, resulting in reduction of the wakefield envelope at about 4 m and at about 15 m respectively. In this case, the wakefield is calculated including the group velocity term (β) as [1, 2]

$$W_{\perp}(s) = 2\sum_{p} K_p Exp\left[i\frac{\omega_p s}{c}\left(1+\frac{i}{2(1-\beta_p)Q_p}\right)\right]\left(1-\frac{\beta_p s}{L(1-\beta_p)}\right) \quad (1)$$

where K_p and ω_p are the frequency and kick factor of the mode p respectively, L is the structure length and $\beta=v_g/c$. The modes with non-negligible β_p travel rapidly through the structure which expedites wake suppression, hence it is necessary to include this term in the calculation. In order to understand the modal contribution in the wake beyond 1 m, we study the transverse impedance (Fourier transform of the wake) in these cells. The impedance of these cells is shown in Fig. 2. As can be seen, the first mode around 17 GHz has the largest impedance (i.e. kick factor) and better damping (width of the peak) compared to the other modes. The modes at 21 GHz, 26 GHz, 40

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

GHz and 55 GHz have non-negligible kicks. Among these, the mode at 21 GHz is poorly damped. Detailed Fourier analysis of the wakefield beyond 3 m indicates that only the 21 GHz mode contributes to the wakefield due to its poor damping. The impedance of the single cells beyond 3 m wake-length is shown in the inset of Fig. 2.

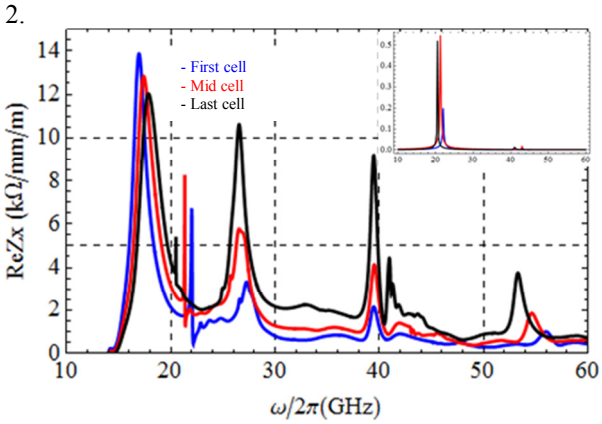

Figure 2: Transverse impedance in single cells of CLIC AS. Impedance for a window of 3m to 7m wake-length is shown inset.

The mode at 21 GHz has a detuning of ~1.5 GHz which assists in non-coherent addition of the wakefield. The wakefield excited in the CLIC AS is indicated in Fig. 3. The various modes contributing to the wakefield

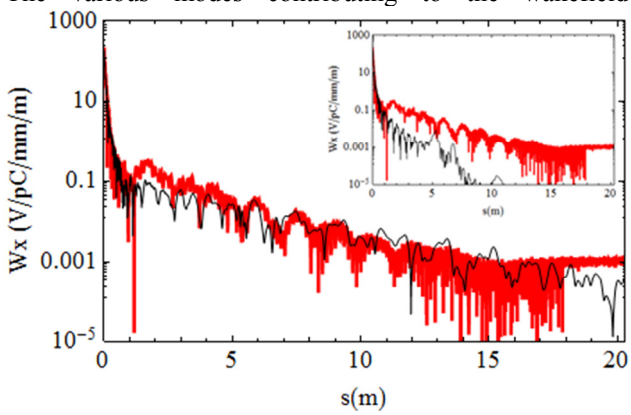

Figure 3: Comparison of the envelope of transverse wakefield in CLIC AS using GdfidL (red curve) and reconstruction using single cell modes (black curve). Inset compares the reconstruction excluding the 21 GHz mode.

are visualized in detail in Figs. 1 and 2. From these modes we reconstruct the wakefield (eq. 1) of the CLIC AS. We learned that the 21 GHz mode has a Q of few hundreds (it varies from cell-to-cell) and v_g ranging from 10% c in the first cell, 2.8% c in the middle cell and down to 0% c in the last cell. The reconstruction of the wake using single-cell modes is compared with the GdfidL simulation in Fig. 3. As the 21 GHz mode travels through the structure, it couples from cell to cell. We utilised single band of circuit model [7] to compute the coupled mode frequencies of this mode. Very good agreement has been found between the reconstructed and GdfidL wakefields. If we artificially remove this mode (using reconstruction), the wakefield does reduce for s > 1 m, which is indicated in the inset of Fig. 3.

If a mode is excited in a structure close to the cut-off frequency of the waveguide, then it does not travel through the waveguide, hence it cannot be damped. The wakefield pertaining to this mode is defined as persistent wakefield which does not decay exponentially [4]. Lingering of such a wakefield-tail is not acceptable from the beam dynamics point of view. We investigated the possibility of persistent wakefield in the CLIC AS. We observe that the modes contributing significantly to the wakefield decay exponentially. The reconstruction plot for a sample (mid) cell is presented in Fig. 4.

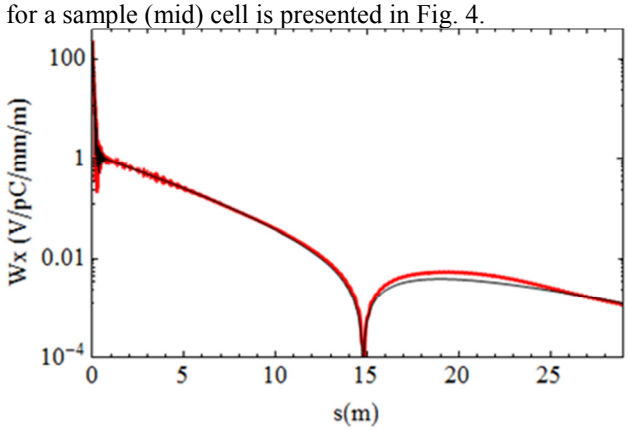

Figure 4: Reconstruction of wakefield in the middle cell using modal sum method. The black curve represents reconstruction, the coloured curve GdfidL simulation.

The only mode that does not decay rapidly is the 21 GHz mode. Detailed study of the e.m. fields in this mode using HFSS revealed that this is a TE-type dipole mode concentrated near the iris of the cell; the fields in this mode are far away from the damping waveguide aperture, hence this mode is poorly damped. The wakefield of this mode can be reconstructed using eq. 1. It is clearly visible that the wakefield decays exponentially with a Q of a few hundred. The reconstruction of this mode confirms the fact that there is no visible persistent wakefield in the CLIC AS. The multi-bunch wakefield effect causing beam amplification is discussed in the next section.

MULTIBUNCH WAKEFIELD EFFECT

In the CLIC scheme, the beam dynamics study defines an upper limit of 7 V/pC/mm/m wake on the first trailing bunch [1]. However, in multi-bunch acceleration, an off-axis driving bunch can cause serious deflections of the trailing bunches. In order to understand an overall effect of the wakefield on a multi-bunch beam profile, a matrix formulation was studied and is presented in [5]. This formulation involves two effects: an off-axis driving bunch deflecting a trailing bunch (direct effect), due to the deflection of this trailing bunch and, subsequent deflection of trailing bunches (indirect effect). In [5] it is assumed that every driving bunch exhibits wake only on the first trailing bunch. With this model a beam

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

amplification factor was calculated which is caused by coherent jitter (F_c ~1), r.m.s of jitter (F_{rms} ~4.9) and a worst case amplification factor (F_w ~20). Herein we extend this calculation to consider a more realistic case of very long range wake including the kicks on all trailing bunches even though the kicks have small amplitudes. For illustration a case of 3 bunches is assumed. The direct effect (a) and direct-indirect effect (A) matrix formulation in this case is [5]

$$a=\begin{pmatrix}0 & 0 & 0\\ ia_1 & 0 & 0\\ ia_2 & ia_1 & 0\end{pmatrix};\ A=Exp[a]=\begin{pmatrix}1 & 0 & 0\\ ia_1 & 1 & 0\\ \frac{i^2a_1^2}{2}+ia_2 & ia_1 & 1\end{pmatrix}. \quad (2)$$

In matrix a, a_1 and a_2 are the kicks experienced by the first and second trailing bunch respectively due to an off-axis leading bunch; which is nothing but a direct effect. Whereas $(ia_1)^2/2$ is the indirect effect on the second trailing bunch as is shown in matrix A. The aforementioned amplification factors are defined as [5]

$$F_c=\frac{1}{n}\sum_k\left|\sum_j A_{kj}\right|^2;\ F_{rms}=\frac{1}{n}\sum_{k=0}^{n-1}\sum_{j=1}^{k}A_{kj}A_{kj}^{*} \quad (3)$$

$$(u,\lambda,v)=\mathrm{SVD[A]};\qquad F_w=\lambda_1^2 \quad (4)$$

where SVD is the singular value decomposition of the matrix A. Using the matrix formulation, the amplification factors in CLIC AS are calculated and the results are presented in Fig. 4. Beyond 100 bunches (50 ns) the F_c does not change. This means a driving bunch kicks about 100 trailing bunches and beyond this its contribution is negligibly small. The consequence is that simulation over the time of an entire bunch train (47 m) is not needed. In Fig. 5 it can be observed that F_c does not change alarmingly compared to the previously calculated value [5] and the difference is about +5% which is within the beam dynamics limit [8]. The other two amplification factors are also within the acceptable limits [8]. In order to understand the sensitivity of the amplification factors we introduce +/-1% random errors in bunch spacing (r.m.s ~0.6%). Though this error changes the kicks on the bunches, the amplification factor F_c changes by only 1%. This is illustrated in Fig. 6.

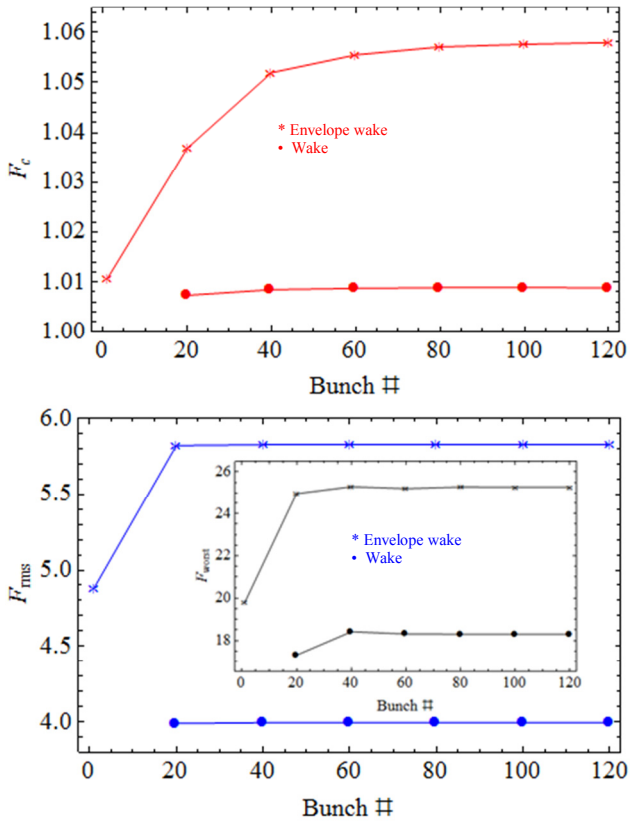

Figure 5: Amplification parameters of CLIC AS

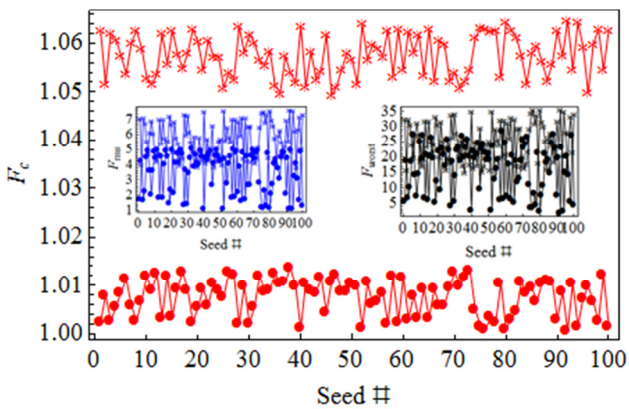

Figure 6: Amplification parameters of CLIC AS with random errors of +/- 1% in bunch spacing.

FINAL REMARKS

The baseline design of the CLIC AS for the CDR meets the beam dynamics criterion of damping HOMs. The maximum amplification of the beam due to coherent jitter considering the multi-bunch long range effect is about 6% which is within the acceptable limit.

ACKNOWLEDGEMENTS

The authors would like to thank D. Schulte and A. Latina for valuable discussions on beam dynamics constraints and multi-bunch matrix formulation as well as W. Wuensch for stimulating discussions and support for this work.

Abstract

The longitudinal phase stability of the CLIC main and drive beams is a crucial element of the CLIC design. In order to measure and control the phase a distributed phase monitoring system has been proposed. The system measures the beam phase every 900 m. The relative phase between the measurement points is synchronized with an external reference system via a chain of reference lines. This paper presents the simulations of error propagation in the proposed distributed monitoring system and the impact on the drive and main beam phase errors and the luminosity. Based on the results the error tolerances for the proposed system are detailed.

INTRODUCTION

The Compact Linear Collider (CLIC) is a proposed 3 TeV center-of-mass energy e^+e^- collider. It is designed to extract the RF energy from high-current low-energy drive beams and use this energy for acceleration of the low-current high-energy main beams that are brought into collision.

Since the main beam acceleration is performed by the RF power extracted from the drive beam, the stability of the relative phasing of the drive and main beams is crucial for the preservation of CLIC's luminosity. A relative phase error of 0.2° @ 12 GHz between the drive and the main beam will cause a luminosity loss of 1% if the error is coherent between the 24 decelerator segments. The same luminosity loss can be caused by an incoherent error of 0.8°. [1]
Additionally to these requirements on the relative drive beam - main beam phase, the phase tolerance between the two main beams at the interaction point (IP) has been set to 0.6° @ 12 GHz [2]. Hence, in order to align the main beam phase a global phase reference over 50 km is needed.

The stated tolerance requirements have to be met on the timescale of ≈50 ns, since this is the beam loading time of the main beam accelerating structures and errors on the shorter time scale will be (at least partially) filtered out by the structures.

PROPOSED DISTRIBUTED TIMING SYSTEMS

The distributed timing system is required to establish the correct beam phase at each turn-around of the linac. This allows to measure and correct the main and drive beam phases along the main linac. There are two approaches for the design of such a system.

The first approach (A) is to use the outgoing main beams to transmit the phase information to a number of local oscillators (Fig. 1, top). These can maintain the phase accurately enough until the main beam returns on the way to the interaction point. This system requires accurate phasing between the outgoing main beams at the first booster linac near the interaction point (Fig. 2).
In the other approach (B) the master clock near the interaction point (IP) would define the nominal phase and distribute it as a signal cascade from one 900 m long decelerator segment to another (Fig. 1, bottom). This system would establish the relative phase of the local timing clocks by an optical connection independently of the beams.

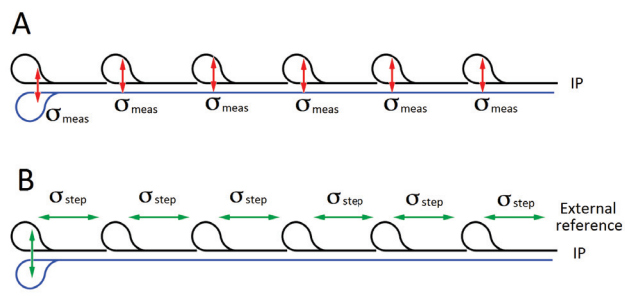

Figure 1: Phase signal propagation for the reference based on the main beam (A) and chained distribution of master clock signal (B).

Approach A has the advantage of having a relatively small error between the main and the drive beams, since the phase measurement at each drive beam decelerator is performed locally and hence no additional error is introduced during the distribution process (see Fig. 3, left). Approach B allows the correction of the main beam at its final turn-around, giving the possibility to reduce the jitter between the e^+ and e^- main beams (Fig. 3, right). However, if the drive beam correction signal is transported from the master clock via the distribution system, the noise introduced by this system would reduce the effectiveness of the phase correction. In the final CLIC design these approaches could be potentially combined.

The proposed timing distribution system is based on state of the art technology for signal distribution via optical fibers tested at XFEL (DESY, Hamburg) [3], [4]. This system is proven to provide <10 fs stability over the distance of several kilometers.
The following analysis determines the specifications of the

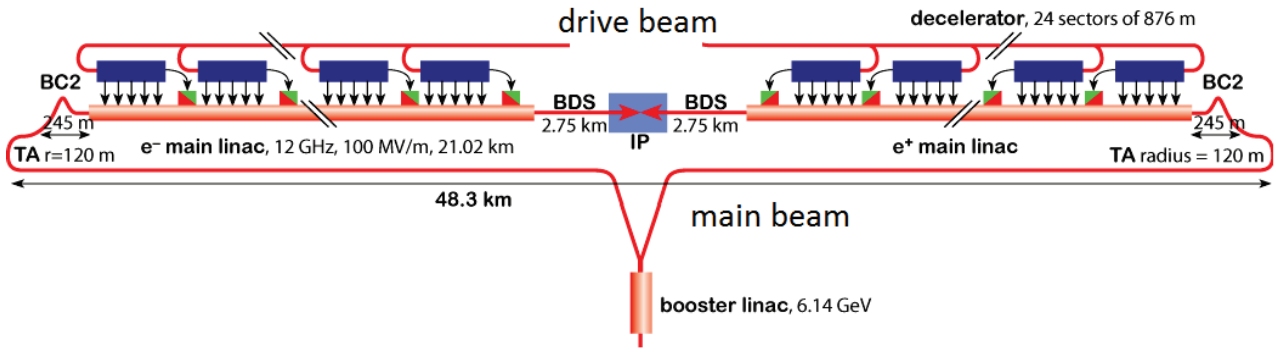

Figure 2: CLIC layout at 3 TeV.

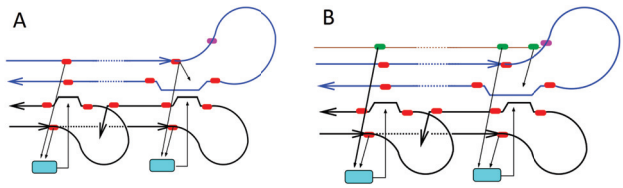

Figure 3: Phase correction system based on the main beam phase measurement (A) and on the external master clock (B) [2].

second approach (distributed timing system) and sets the requirements for the tolerances of this system.

ANALYSIS OF SPECIFICATIONS FOR THE DISTRIBUTED TIMING SYSTEM

Principle of time distribution and phase correction

As shown in Fig. 3 B, the signal from the master clock is used as the synchronization signal for the local oscillators. The master clock itself has a particular noise spectrum [5]. The impact of the noise on the local oscillators can be reduced by integrating the signal over the time intervals longer than the beam propagation time through the machine (≈ 0.2 ms).
The correction of the main beam is performed at the final turnaround with help of a kicker chicane, which can change the path length of the main beam bunches and hence their longitudinal position. The drive beam phase is also corrected via a chicane to the nominal value defined by the master clock at the turnarounds at each of the 24 decelerator modules.

The phase measurements on the main and drive beam after the chicanes ensure that the provided correction had the right value. If it is not the case, this could mean that the path length of the beams in the chicane is not as predicted, the chicane has the wrong R_{56} value or that the waveguide length has changed (e.g. due to temperature variation). To correct for these changes, a pulse-to-pulse feedback system can be introduced. Provided the changes are slow enough, the measured value of the correction error can be used to adjust the relative definitions of the monitors' nominal phase. The new definitions will ensure that the correction for the next pulse will set the drive beam bunches closer to their nominal position relatively to the main beam bunches. Hence, high stability of the local oscillator clocks must be ensured on a timescale of 20 ms, which is the pulse-to-pulse interval of CLIC.

In order to calculate the phase tolerance for signal transfer between the two subsequent decelerators, σ_{step}, (Fig. 1, B), one must calculate the impact of this error on the total phase error. We will assume a random walk of the phase error, which starts from the master clock at the IP and propagates along the machine step by step from one drive beam decelerator segment to another.

e^+ and e^- main beams phase tolerance

For the incoming main beams the relative phase tolerance at the IP is $0.6°$ @ 12 GHz $\hat{=}$ 42 μm $\hat{=}$ 140 fs [2] which corresponds to 1% of luminosity loss. Hence, one must assure that the total phase error introduced by the distributed timing system σ_{dts} is below $(140\text{ fs})/\sqrt{2}$ for each of the main beams.
Additionally to the 24 decelerator modules, each about 900 m long, we must consider that the beam delivery system of each main beam is about 2.75 km long [8]. To simplify the calculation it will be assumed that the distributed timing system for the main beam is 27, instead of 24, sectors long, hence about 2.7 km longer. One can consider the errors at each of the segments as linearly independent. Hence, the tolerance for the phase error introduced in each segment is given by

$$\sigma_{step,mm,1\%} = \frac{140\ fs}{\sqrt{27}\times\sqrt{2}} = 19.05\ fs \hat{=} 5.72\ \mu m. \quad (1)$$

The stated correction system error would cause a luminosity loss of 1%. However, in reality the largest part of the tolerance budget will be reserved for the beam itself and not for the reference jitter. Hence, the calculation only determines the upper limit for the distribution error but not

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

the effective system requirement, which will depend on the expected beam phase jitter. Defining the distribution system requirement to causing max. 0.1% luminosity loss, one obtains $\sigma_{step} = 5.72\ \mu m/\sqrt{10} = 1.81\ \mu m$
An advantage of the distributed timing system is that it allows to loosen the phase tolerances on the outgoing main beam by a factor of 7, since the phase correction at the final turnaround of the main beam can reduce the phase error [1], [7]. Also, the phase correction can compensate for the change in the main beam path length, given the path length change is slow enough ($\ll 20\ ms$ pulse interval).

Main beam - drive beam phase tolerance

The error σ_{step} causing 1% luminosity loss can be calculated from the main beam - drive beam relative phase error tolerance. The total error σ_{tot} introduced by the phase correction system at each decelerator must be below 0.8° @ 12 GHz for uncorrelated errors.

We assume a random walk of the distribution error segment by segment. The impact of each error is given by $\sum_{j=1}^{i} \sigma_{step}$ with i being the number of the segment counted from the IP. The total error introduced by the distributed timing system σ_{dts} is given by the sum of the errors in all segments. One should also consider that the main beam bunches are positioned at 30° of the RF wave in the four segments nearest to the IP and at 8° in other 20 segments. Hence σ_{dts} is given by

$$\sigma_{dts}^2 = \sum_{i=1}^{4}\left(\sum_{j=1}^{i}(\sigma_{step}\times\sin 30°)\right)^2 + \sum_{i=5}^{24}\left(\sum_{j=1}^{4}(\sigma_{step}\times\sin 30°)+\sum_{j=5}^{i}(\sigma_{step}\times\sin 8°)\right)^2$$

Normalising σ_{dts}^2 by the RMS value of the stated sine functions and calculating the sums, one obtains

$$\sigma_{step,md,1\%} = 0.059° \triangleq 4.12\ \mu m \qquad (2)$$

This value is of the same order of magnitude as the tolerance given by the main beam - main beam phase error consideration ($\sigma_{step,mm,1\%} = 5.72\ \mu m$) calculated in the previous sub-section. Defining as above the maximal 0.1% luminosity loss as a specification of the distribution system, the requirement for the reference stability will be $4.12\mu m/\sqrt{10} = 1.30\ \mu m$.

The 1% luminosity loss from the reference jitter has been calculated independently for main beam - main beam and main beam - drive beam phase error tolerances. In reality the same reference jitter σ_{step} would cause a luminosity loss via both channels,

$$\Delta\mathcal{L}_{total} = \Delta\mathcal{L}_{md} + \Delta\mathcal{L}_{mm} = 1\% \times \left(\left(\frac{\sigma_{step}}{\sigma_{step,md,1\%}}\right)^2 + \left(\frac{\sigma_{step}}{\sigma_{step,mm,1\%}}\right)^2\right)^2$$

Solving this equation for $\Delta\mathcal{L}_{total} = 1\%$ yields $\sigma_{step} = 3.34\ \mu m$. However, $\Delta\mathcal{L}_{total} = 0.1\%$ defines the specification of $\sigma_{step} = 1.06\ \mu m$ average error introduced by the distributed timing system at each decelerator segment.

CONCLUSIONS AND OUTLOOK

The phase jitter of the distributed timing system at each decelerator segment is calculated to be 3.34 μm for 1% luminosity loss from both the main to main and main to drive beam tolerances.This value is met by demonstrated performances [3], [4], which proves the feasibility of the distributed timing system. However, ideally the specification would be tighter - 0.1% luminosity loss, which requires a distribution system stability of 1.06 μm per segment. Hence, it has to be investigated whether the noise can be significantly reduced.

The demonstrated performance of the signal distribution includes the transformation of the optical signal into electrical and vice versa. One solution could be chaining the distribution by splitting the optical signal at each decelerator, using one part of the signal as a reference and amplifying the other part and sending it to the next decelerator. This would help to avoid transformation noise and might allow to reach the specified target. A dedicated approach would be needed to prove this concept experimentally.

It will be also necessary to demonstrate the reliability of the signal distribution technology to operate unattended in the tunnel.

Abstract

The electron linear accelerator has wide applications, and the demands for the irradiation applications are keeping growing in China. A high beam power 10 MeV L-band Linac has been developed recently as a joint venture of Institute of High Energy Physics (IHEP) and Wuxi EL-PONT Company in China. The Thales TH2104U klystron, 2 A thermionic electron gun and 3 m long L-band disk-loaded constant impedance RF structure were adopted. A stable electron beam of 10 MeV / 40 kW has been obtained in the last April. In this paper the detailed design issues and beam commissioning results are reported.

INTRODUCTION

IHEP in China has very rich experience in the electron linac design and development. When requested to transfer the technology to industry, many S-band electron linacs have been developed for medical and irradiation applications. For the S-band irradiation linac, the beam power is limited to be ~20 kW because of the RF structure heating/cooling issues. Due to the scaling law of $P \sim f^{1}$ between the RF power consumption of the accelerating structure and the frequency, L-band structure [1][2] is usually adopted for the nature extending to much higher beam power up to ~100 kW level. For any high beam power machines the power efficiency is a concern. According to Eq. (1), the maximum conversion efficiency η_{max} of the RF power to the beam power dependents only on the attenuation factor τ [3], and smaller τ is preferred.

$$\eta_{\max} = \frac{1}{2}\left[\frac{\left(1-e^{-2\tau}\right)^2}{\left(1-e^{-2\tau}\right)-2\tau e^{-2\tau}}\right] \quad (1)$$

However, there is a compromise among power efficiency, power dissipation as well as heating, peak beam current and beam energy. It is known that τ is independent of frequency, and for SLAC type 3m long disk-loaded TW structure τ is ~0.57. Suppose a 3 m long L-band structure of 34 cavities is used, τ can be roughly estimated to be 0.57*34/86=0.225. With SUPERFISH simulation and cold test, τ is shown[4] to be 0.22, which is in good agreement with the simple scaling. By putting 0.22 into Eq. (1) one can get an efficiency η_{max} of 90%, which is very excellent. In this condition, the beam current is ~900 mA according to Eq. (2).

$$i_{\eta_{\max}} = \left(\frac{P_T}{rl}\right)^{1/2}\left[\frac{\left(1-e^{-2\tau}\right)^{3/2}}{\left(1-e^{-2\tau}\right)-2\tau e^{-2\tau}}\right] \quad (2)$$

Table 1 shows the design parameters for the 10 MeV / 40 kW L-band linac. The linac is a machine with very heavy beam loading; the beam energy range of 8 to 12 MeV can be easily controlled by simply adjusting the gun bias voltage (i.e. the gun emitting beam current), but above 10 MeV is not recommended for prevention of the neutron production.

Table 1: Design parameters for the 10MeV L-band linac

Beam energy (MeV)	10
Beam power (kW)	40
RF frequency (GHz)	1.3
Peak beam current (mA)	530
Duty cycle (%)	0.75
Klysron peak power (MW)	10

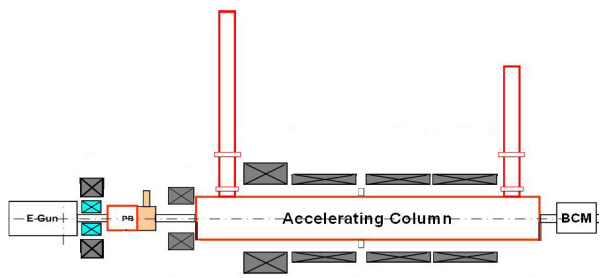

Figure 1: The schematic of the L-band linac.

DETAILED DESIGN AND SIMULATION

Figure 1 shows the schematic of the high power 10 MeV L-band linac, which mainly consists of an electron gun, an RF power source and an accelerating column. The electron gun is the 80 kV BEPC type [5] gun with 2 A Y646B cathode grid assembly. The gun system is separated from the other subsystems, which makes it easy for maintenance. The gun emitting current and the beam energy are adjustable. The RF power source is a 10 MW Thales TH2104U klystron with 130 kW average power, and the modulator was designed to make it work at 100 kW. Fig. 2 shows the Thales TH2104U klystron and its parameters.

Figure 2: Thales TH2104U klystron and its parameters.

With 10 MW TH2104U klystron and a 3 m long L-band RF structure, a 10 MeV / 40 kW electron beam with a beam current of 530 mA as listed in Table 1 can be obtained. Except for the klystron, the RF structure is a key issue for the high power electron linac. The simple constant impedance structure with the cell dimension scaled from the 3 m long SLAC type disk-loaded TW structure was used, but the first 6 cells are β changed for the beam bunching requirement. Simulations with the EGUN and PARMELA codes have been conducted [6], and the simulation results were confirmed by measuring the beam performance in later commissioning. Even without the pre-buncher, a proper beam with more than 40% transmission efficiency was obtained, which is also confirmed with the machine commissioning. Fig. 3 shows the simulated beam energy spread and beam size, which are good enough for an irradiation machine.

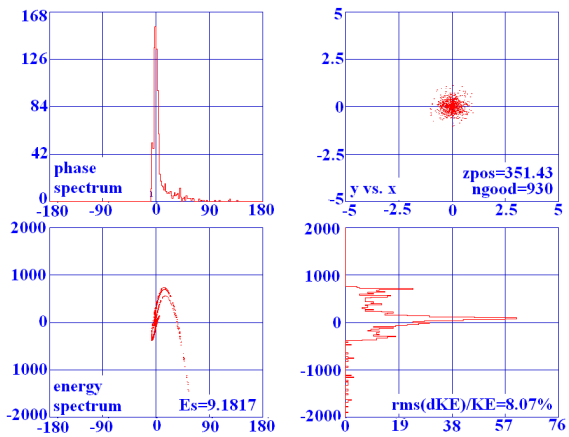

Figure 3: The simulated beam phase space.

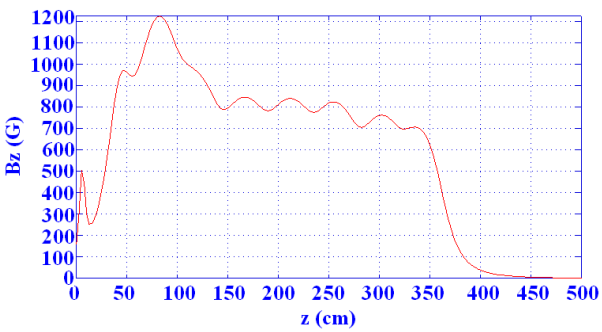

Figure 4: The solenoid magnetic field distribution along the 10 MeV / 40 kW linac.

Fig. 4 shows the designed solenoid magnetic field distribution along the whole linac. As the RF structure heating is a concern for the design of the high power electron linac, the structure iris temperature rise and its deformation were also simulated [7] and shown in Fig. 5, which indicates the maximum temperature of 62 °C under the design parameters and a tolerable deformation of ~17 μm. The cooling system is a simple water jacket around the accelerating column; A special cooling design is required if even higher beam power up to 100 kW is needed.

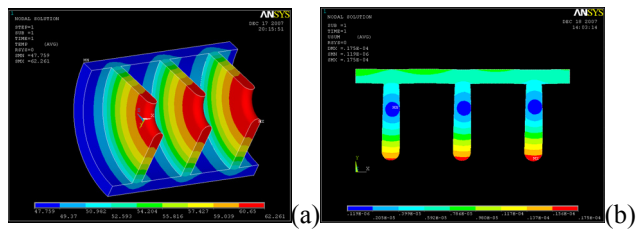

Figure 5: ANSYS results for the structure heating under the design parameters: (a) the iris temperature rise; (b) the structure deformation.

COMMISSIONING AND BEAM TEST

The machine was installed at EL PONT Company in 2009; the machine processing and commissioning were started right after the entire subsystems ready. The first beam was obtained on November 3rd, 2010. Fig. 6 is the picture of the whole linac, and Fig. 7 shows the modulator.

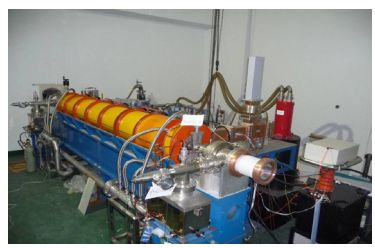

Figure 6: Picture of the L-band linac.

Figure 7: Pictures of the modulator.

Table 2 shows the milestones of the high power L-band electron linac development and commissioning progress. Almost two years were taken to get the first beam, and the main time consuming task is the klystron purchase, which takes one year and a half with almost 6 months delay. From the first beam @ 5Hz to the 40kW stable beam almost half year was taken to reach the design goal. During the high power processing process, many lessons have been learnt, such as beam instability, beam duct heating and degassing, beam loss and so on.

Fig. 8 is the beam testing results with the beam energy of 11.2MeV at 600mA beam current shown in (a) and the beam current profile measured with BCT shown in (b), which is better than the design prediction.

Table 2: Milestones of the L-band linac development

Date	Activity
October, 2007	Proposal and design
Auguest, 2008	Manufacture, purchase
September, 2009	Assembly at EL PONT
November 3rd, 2010	First beam
November 6th, 2010	Beam at 5 Hz
March 31st, 2011	30 kW
April 24th, 2011	40 kW

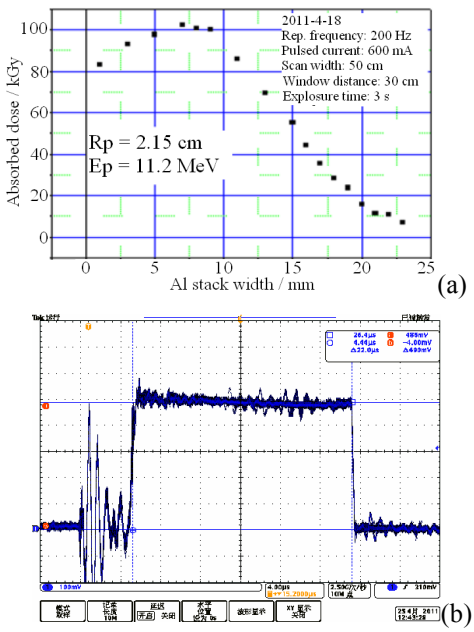

Figure 8: The beam testing results. Time-scale is 4 μs/division.

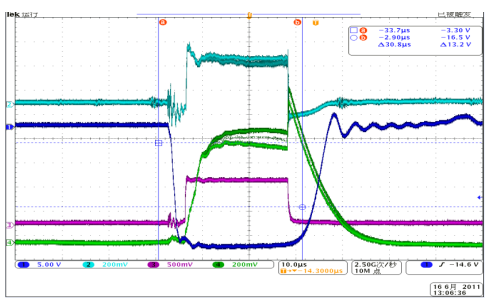

Figure 9: Machine status: blue line is the modulator high voltage waveform, turquoise the beam current from BCT, pink forward RF, and green reflected RF. Time-scale is 10 μs/division.

Many problems have been encountered during the beam testing and the machine commissioning; in particular the beam instability has very strong impact on the beam quality, the beam duct heating and the vacuum degradation, so systematic investigations were conducted for more than two months. Finally the RF driven source problem was found by monitoring the voltage standing-wave ratio (VSWR) as shown in Fig. 9, in which channel (1) in blue is the modulator high voltage waveform, channel (2) in turquoise the electron beam current from BCT, channel (3) in pink the forward RF, and channel (4) in green the reflected RF. It can be seen that the beam instability is correlated with the reflected RF (not the arcing but the VSWR change), which means the frequency is not correct even the indicator still shows 1300 MHz. After the problem was fixed, the beam instability was gone. In addition, the bunching effect of the pre-buncher was found not so strong, and taking out it would make the machine architecture much simpler.

SUMMARY

The high power 10MeV L-band electron linac is the first 40 kW irradiation linac developed and constructed in China. The first beam was obtained on November 3rd, 2010, which confirmed the design and the simulation predictions. After a few months machine processing, the designed beam parameters were achieved on April 24th, 2011. The formal beam testing was conducted by the National Institute of Metrology on December 26th, 2011, and the testing beam current is 720 mA with energy of 9.9 MeV. If the machine works at a duty cycle of 0.7% as already processed, the beam power can reach 50 kW. The conversion efficiency η from the RF power to the beam power is ~72%, a little bit lower than the theoretical prediction, which is partially because the RF power into the accelerating structure is lower than 10 MW, and/or the beam loss. Nonetheless, 72% is not bad. Now the machine has been put into operation at EL PONT Company.

ACKNOWLEGEMENT

The high beam power 10 kW / 40 MeV electron linac facility is a joint venture of IHEP and EL-PONT Company in China. Many works not mentioned here were accomplished by EL-PONT, such as infrastructure, power supply, cooling system, beam scan or deliver system and so on. Many thanks to all EL-PONT staffs for their contributions to the machine design, development, commissioning and operation.

APPLICATIONS OF COMPACT DIELECTRIC BASED ACCELERATORS*

C. Jing#, S. Antipov, P. Schoessow, and A. Kanareykin, Euclid Techlabs LLC, Solon, OH, USA

Abstract

Important progress on the development of dielectric based accelerators has been made both experimentally and theoretically in the past few years. One advantage of dielectric accelerators over their metallic counterparts is their compact size, which make them attractive for industrial or medical applications. In this article, we discuss the design of dielectric based accelerators focusing on those technologies relevant toward these needs.

DIELECTRIC LOADED ACCELERATOR

The first studies of using RF driven dielectric-loaded circular waveguide for particle acceleration can be traced back to the early 1950's [1]. In recent years, because of its geometrical simplicity and availability of low loss dielectrics, theoretical and experimental investigations on dielectric based accelerators have been intensively revived. Among them, externally powered Dielectric-Loaded Accelerators (DLA), dielectric wakefield accelerators, and dielectric laser accelerators have attracted the most attention. In this paper, we concentrate on externally powered DLA technologies and possible application.

DLA structures can be made as simple as a dielectric tube surrounded by a conducting cylinder. Most of them use uniform, linear ceramic tubes so that they work as constant impedance accelerating structures. The TM_{01} mode (traveling wave accelerator) or TM_{01n} mode (standing wave) are the fundamental accelerating modes. Unlike conventional metallic accelerating structures, DLA structures do not require any structure periodicity to slow the phase velocity of the guided wave below the speed of light. For a given radius, the phase velocity of each guided wave mode in a DLA structure is governed by the dielectric constant of the material and its wall thickness. In general, for the same a/λ, where a is the radius of the beam opening and λ is the wavelength, the DLA structure can be made much smaller than a disk-loaded accelerating structure due to the high dielectric constant of the material used. This small size may be favored for applications with tight space requirements. It also facilitates the use of quadrupole lenses or a permanent solenoid around the structure to prevent the beam from breaking up in the case of high current beam acceleration. For example, for an X-band structure, given $a/\lambda=0.156$, the diameter of a cell of a 120-degree traveling wave disk-loaded accelerating structure is larger than 2 cm, but the outer diameter of the dielectric tube in a DLA structure is only 1 cm if the dielectric constant of the tube is 20.

However, the choice of dielectric constant should be considered as far more complicated than the requirement of a reduced transverse dimension. It is strongly linked with other accelerating parameters as well. A very good estimate of the group velocity of a traveling wave DLA structure is given by $V_g/c \approx 1/\varepsilon_r$ (where c is the speed of light and ε_r is the relative dielectric constant of the loaded material) when a/λ is less than 15%. The quality factor of a DLA structure can be roughly estimated as $Q \approx 5.22\times10^4/\{\sqrt{[f<GHz>\times(\varepsilon_r-1)]}+5.22\times10^4\times\tan\delta\}$, where f is the frequency of the TM01 mode in units of GHz and $\tan\delta$ is the loss tangent of the loaded material.

PARAMETER CHOICE

DLA structures are generally preferred for use in a short structure powered by short, high frequency RF pulses, which reduces the probability of RF breakdown but needs a short filling time to achieve a high RF-to-beam efficiency [2]. Consider the rough design of an X-band travelling wave DLA structure. From the group velocity estimate, we choose $\varepsilon_r=10$ for a structure with $V_g=10\%$ c. Then Q can be estimated to be 3400. Since the size of the beam opening (2a) is independent of Q but tightly related to the R/Q (figure of merit of an accelerating structure) and shunt impedance R (they both increase as the beam opening decreases), we can choose a as small as the beam emittance allows to obtain both a large R/Q and R. Meanwhile the filling time (defined as L/V_g, where L is the length of the structure) remains short since the group velocity is unrelated to the beam opening. It should be pointed out that a/λ of DLA structures cannot be chosen too small since it will increase the wakefield and thus the risk of beam break-up.

Transverse wakefield damping in DLA structures has been well studied [3]. Its implementation is rather simple: an axially slotted copper jacket filled with RF absorber or metallized strips on the outer surface of the dielectric tube surrounded with RF absorber. The low Q of the DLA structures also helps the damping of long range wakefields.

Figure 1 shows a few parameters of X-band (11.7GHz) travelling wave DLA structures. Three different dielectric constants are used in the plots, representing three commonly used low loss materials: Alumina ($\varepsilon_r=10$, $\tan\delta=1\times10^{-4}$), MgCaTiO ($\varepsilon_r=20$, $\tan\delta=1\times10^{-4}$) and Quartz ($\varepsilon_r=3.8$, $\tan\delta=6\times10^{-5}$). Figure 1(a) clearly shows that the group velocity is bounded by the reciprocal of the dielectric constant as the beam opening decreases. The quality factor of a DLA structure is the combined contribution of metal wall losses and dielectric losses, but

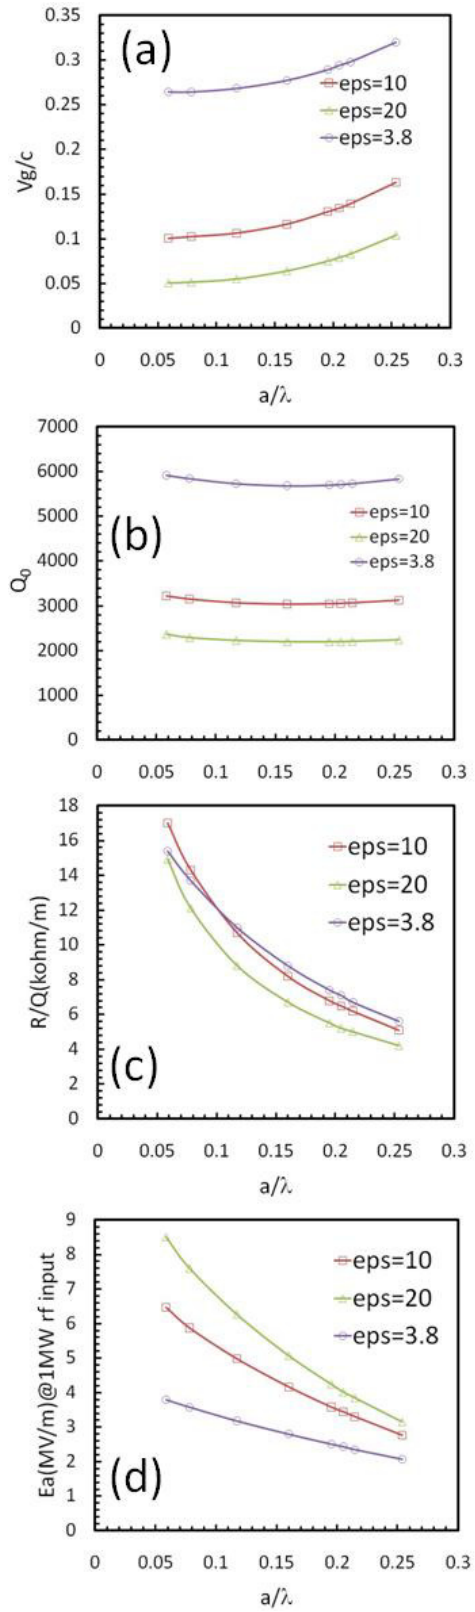

Figure 1: Dependence of parameters in DLA structures on the scaling parameter a/λ: (a) group velocity; (b) quality factor; (c) R/Q; (d) accelerating gradient.

it remains nearly constant across different size of beam channel (Fig. 1b).

From Fig. 1(c) and 1(d) we can see that the R/Q values for different dielectrics can approach or cross each other for small beam channels but the gradient in a higher ε_r DLA structure is always higher. This is because of the strong dependence of the gradient E_a on the group velocity, $E_a^2=[R/Q]\times 2\pi f\times P/V_g$, where P is the input RF power. Again, the low V_g leads to a long RF filling time which then requires a longer RF pulse to power the structure and accelerate the beam. The strong pulse length dependence of the RF breakdown rate will limit the accelerating gradient. However, in an application that does not need to operate with the gradient at a high risk level, a high dielectric constant material should be preferred since it will provide a higher gradient for a given RF power.

MULTIPACTOR

One principal effect that has limited further advances in DLA technology in the past is the problem of multipactor. The fraction of the power absorbed at saturation in the DLA structure was found to increase with the incident power, with as high as 30% of the incident power per unit length being absorbed if the dielectric material has a high Secondary Electron Yield (SEY). A thin film TiN coating, which reduces SEY, can reduce the multipactor loss below 10%. Using geometric factors, particularly the introduction of surface grooves to reduce the multipactor in DLA structures is also under investigation. However, lessons from other work show that one challenge to the success of this approach is the strong dependence upon a few critical dimensions of the groove design, which leads to a very tight machining tolerance and in turn increases the fabrication difficulties and costs.

In fact, the most effective approach to completely terminate multipactor is to use an external solenoid field. Analytical models, numerical simulations, and practical example in other applications have successfully demonstrated its effectiveness [4, 5]. In DLA structures, an external DC magnetic field in the longitudinal direction can continuously reduce the period for secondary electrons hopping on the dielectric surface (and thus spoil the resonance condition) when the ratio of the gyro-frequency to RF frequency is in the range of 0.7 to 1 (The gyro-frequency, Ω, is a plasma parameter; for electrons it is defined as $\Omega=eB/m_ec=1.76\times10^7B$ rad/s, where B is the magnetic field component perpendicular to the electron motion plane). It is equivalent to a solenoid field range from 2.8 kG to 4 kG for an X-band DLA structure. This approach is more attractive than other techniques since it can maintain all the advantages of regular DLA structures, and it is independent of the accelerator parameters other than the operating frequency.

TUNING

The need for frequency tuning (or phase velocity adjustment) of any accelerating structure arises from the fact that the phase velocity of the assembled accelerating

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

structure will, in general, differ from the design phase velocity due to various sources of error. In a DLA structure, these errors can be caused by machining tolerances of the dielectric dimensions, thermal expansion of the structure, dielectric constant heterogeneity, etc. The common way of tuning all-metal structures is using temperature variation or slight mechanical deformation of the accelerating structure walls. The DLA structure does not admit this possibility because the ceramic loading is usually made of a brittle microwave thermostabilized ceramic that does not allow any noticeable mechanical adjustment of its geometrical parameters. At the same time, the permittivity of BST ($Ba_xSr_{1-x}TiO_3$) ferroelectric has a strong temperature dependence. If a thin, low loss ferroelectric layer having relatively high dielectric constant (ε_r>100, tanδ<5×10^{-3}) is introduced, the DLA structure can be easily tuned by controlling its temperature. Introducing a relatively thin ferroelectric layer does not change the basic accelerating structure parameters significantly but it makes the overall average permittivity of the dielectric loaded resonator tunable in the range from tens of kHz to tens of MHz depending on the thickness of ferroelectric material [6].

RF COUPLING

Besides the dielectric loaded section, a DLA structure requires a RF coupler to feed in the high power RF signal. A well designed coupler should possess a high mode conversion efficiency (e.g. TE_{10} mode in rectangular waveguide to TM_{01} mode in DLA structure), and be less susceptible to high power breakdown. Figure 2 show three coupling schemes commonly used in DLA structures. In Fig. 2(a), the metallic RF coupler is separated from the DLA section. The tapered dielectric matching section is a part of the DLA structure that matches the impedance of the TM_{01} mode between the empty and dielectric-loaded waveguide. This coupling method can reach a very broad bandwidth at a cost of the extra length of the dielectric taper. It is worth pointing out the importance of fabricating the entire dielectric tube in a single piece. Any micro gap caused by a dielectric joint is subject to RF breakdown due to the strong field enhancement. Figure 2(b) shows a coaxial type coupling, where the impedance matching is accomplished in the coupler section so that the DLA section remains a simple straight tube. This design is very effective and compact, but the beam hole in the inner conductor of coaxial coupler may limit its usefulness in high gradient applications (i.e. where a/λ is small). Figure 3(b) shows a variation of the side coupling configuration, which is simple in fabrication but generally exhibits a smaller bandwidth than the axial coupling.

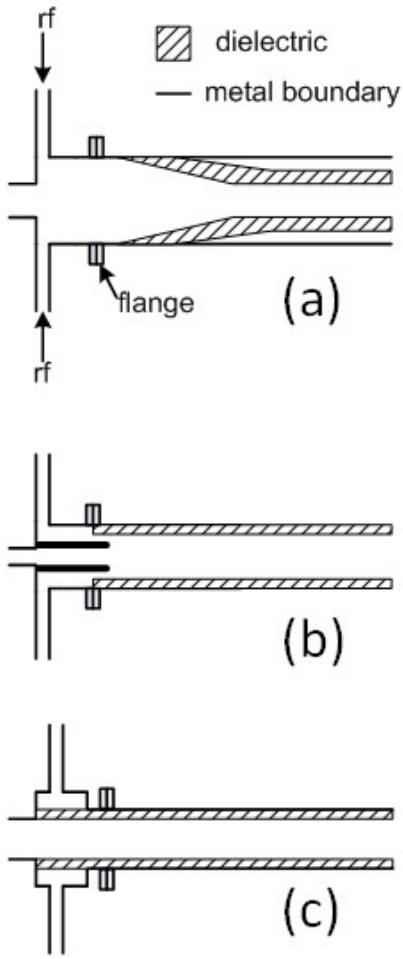

Figure 2: Three commonly used RF coupling schemes in DLA structures; (a) mode launcher; (b) coaxial coupler; (c) side coupling.

REMARKS

DLA technologies have seen significant progress for a decade. At present, it is possible to build and use a practical DLA structure. We expect that its compactness and low cost will eventually make it broadly useful in many applications.

Abstract

Linear accelerator based on parallel coupled accelerating structure and RF-controlled electron gun is developed and produced. The structure consists of five accelerating cavities. The RF power feeding of accelerating cavities is provided by common exciting cavity which is performed from rectangular waveguide loaded by reactive pins. Operating frequency is 2450 MHz. RF-controlled Electron gun is made on the basis of RF triode. Linear accelerator was tested with different working regimes. The obtained results are following:

- energy is up to 4 MeV, accelerating current is up to 300 mA with pulse duration of 2.5 ns on the half of the width,
- energy is up to 2.5 MeV, accelerating current is up to 100 mA with pulse duration of 5 μs,
- energy is up to 2.5 MeV, accelerating current is up to 120 mA with pulse duration of 5 μs and beam capture of 100%.

The descriptions of the accelerator elements are given in the report. The features of the parallel coupled accelerating structure are discussed. The results of the measuring accelerator's parameters are presented.

INTRODUCTION

Compact linear electron accelerators have wide scientific and industrial applications. The more often linacs are used with energy up to 10 MeV, average beam power up to several kilowatts. In present there are two type of accelerating structures with travelling wave and standing wave. But all of these structures have sequential RF power feeding of the accelerating cells. This is cause of some problems. To supply the accelerating structure total RF power has to go from the first accelerating cell. As the power is attenuated along these structures the initial value of the power must be very high, therefore, there are breakdowns and thermal surface damage in the first accelerating cell. When the breakdown is happened in one of the accelerating cell the operating RF pulse is terminated because of all storage energy of the structure is dissipated in it. Developing of *accelerating structure with given distribution of the power along the cavities is very difficult task. Also there is problem of high order modes, vacuum pumping and etc.

The linear electron accelerator based on new type accelerating structure is developed and produced by Budker Institute of Nuclear Physics of SB RAS, Institute of Chemical Kinetics and Combustion of SB RAS and Institute of Catalysis of SB RAS [1]. The main elements of accelerator are parallel coupled accelerating structure, injector, waveguide track with vacuum RF window, focusing system and klystron KIU-111. The klystron's frequency is 2450 MHz, average power is 5 kW with pulse power of 5 MW [2]. The main goal of our efforts is to test new ideas and devices which are used in the accelerator. The mass of these elements are used in such accelerator for the first time and have some advantages.

PARALLEL COUPLED ACCELERTING STRUCTURE

The scheme of parallel coupled accelerating structure is shown in the Fig. 1 and Fig. 2. RF power from a klystron feeds the exciting cavity (1) through inductive coupling window (7). The exciting cavity supplies the accelerating cavities (2). The RF connection of the exciting cavity with the accelerating cavities is provided by magnetic field through coupling slots (5). The focusing alternative magnetic field is created along the beam axis by periodic permanent magnets (3) with radial magnetization inserted in the iron yoke (4). This kind of focusing provides large enough magnetic field while keeping the weight of the focusing system considerably small. The cupper pins (6) are used to tune the exciting cavity (1) at the resonance frequency.

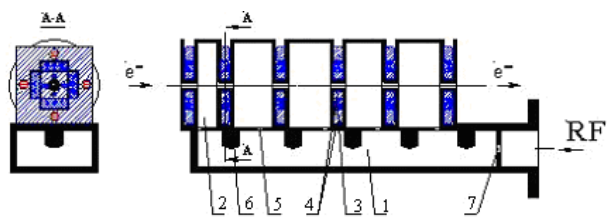

Figure 1: Scheme of the parallel coupled accelerating structure.

Due to the scheme of RF power supplying this accelerating structure has some advantages versus structures with sequential power feeding. There is no need to have a high power in the first accelerating cavity. So the overvoltage and breakdown problems, thermal surface damage near the coupling slots are absent. The design of parallel coupled accelerating structure allows us to create compact periodic permanent magnet focusing system based on the permanent magnets with radial magnetization (see Fig. 1). The accelerating cavities are not connected with each other by electric field therefore aperture of the drift tubes between cavities is limited only by the beam focusing. By changing the coupling factor between exciting and accelerating cavities it is possible to make the free power distribution along the structure. If breakdown is happened in one of the accelerating cavities the storage energy only this cavity is dissipated, and only in this cavity. So the working RF pulse is not terminated but only amplitude of reflected signal is slightly changed, as it is presented on the Fig. 3.

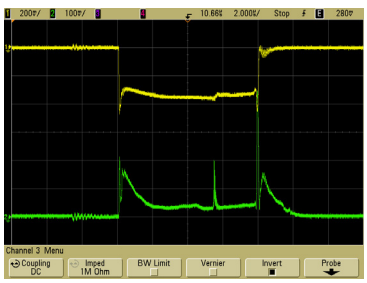

Figure 3: Breakdown in one of the accelerating cavities: 1 - signal from klystron; 2 - reflected signal from accelerating structure.

The accelerating structure can be used as for high average current with high average power as for short nano- and picoseconds duration current pulses with high amplitudes.

INJECTOR

Injector is the electron gun with DC voltage of 50 kV and pulse current up to 1 A. It is based on RF triode GS-34 and shown on the Fig. 4.

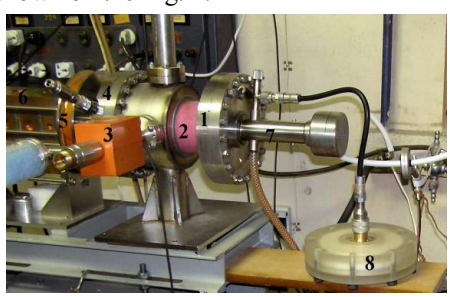

Figure 4: Injector: 1- cathode-grid unit, 2 – ceramics, 3 – vacuum pump, 4 – bunching cavity, 5 – matching solenoid, 6 - accelerating structure, 7 – coaxial cavity for RF beam control, 8 – antenna type RF lead.

Injector can work with following regimes: short pulses with duration of about nanoseconds, long pulses with duration of microseconds and long pulses with RF control for a beam π-chopper. Under using RF control the beam is modulated by coaxial cavity on bunches with length equaled to half wavelength of RF field. Due to this feature, the beam capture can be achieved up to 100%.

The cathode-grid unit 1 (see Fig. 4) is under potential of -50 kV. So, to feed the coaxial cavity 7 the antenna-type coaxial lead (8) was developed and produced. It is shown on the Fig. 5. The antenna-type lead consists of two symmetrical parts of coaxial half-wave resonator. The resonator is cut along perpendicular to the longitudinal axis plane of symmetry. The solid dielectric disk is located between the halves.

The Fig. 6 shows the measured bandpass characteristics. The reflection coefficient S_{11} at the operating frequency is 0.098 and the transmission coefficient S_{21} is 0.976. Bandwidth at the attenuation level of -3 dB is more than 1800 MHz (73%).

Figure 5: Antenna type RF lead.

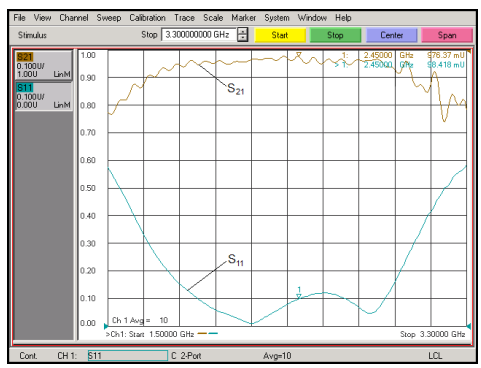

Figure 6: The transmission S_{21} and reflection S_{11} coefficients of the lead.

ACCELERATOR MEASUREMENTS

Accelerator was tested under three regimes.

The first regime is characterized by short beam pulse with duration of 2.5 ns on the half of width (see Fig. 7). The beam energy is about 4 MeV, beam current amplitude is about 300 mA. The Fig. 8 shows the cross section of the beam profile.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

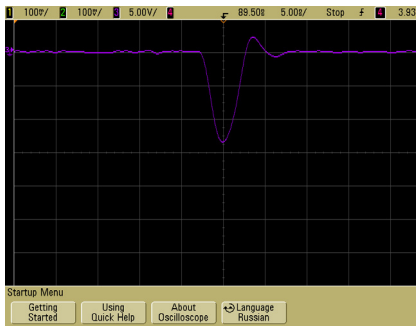

Figure 7: Oscilloscope of the accelerated beam current with duration of 2.5 ns (100 mA per cell).

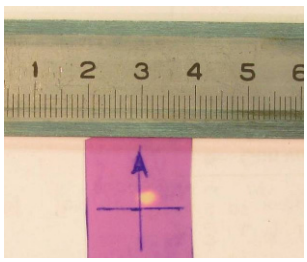

Figure 8: Cross section of the beam profile with pulse duration of 2.5 ns.

In the second regime the beam duration is 4 μs, energy is 2.5 MeV, beam capture is about 50%. Oscilloscope of the beam current and cross section of the beam profile are shown on the Fig. 10 and Fig. 11 correspondingly.

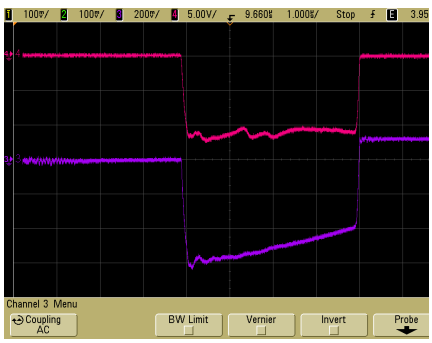

Figure 9: Oscilloscope of the accelerated beam current with duration of 4 μs: 3 – emission beam current (180 mA per cell), 4 – beam current in the end of accelerating structure (100 mA per cell).

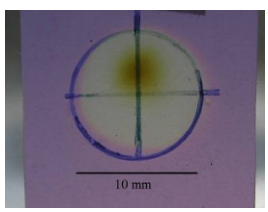

Figure 10: Cross section of the beam profile with pulse duration of 4 μs.

In the third regime the injector operated with RF control. The energy is equaled to 2.5 MeV. The feature of this regime is beam capture of 100%. Oscilloscope of the beam current and cross section of the beam profile are shown on the Fig. 12 and Fig. 13 correspondingly

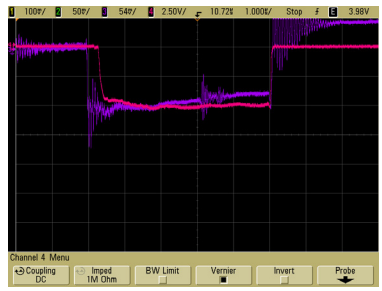

Figure 12: Oscilloscope of the accelerated beam current with RF control: 3 – emission beam current (50 mA per cell), 4 – beam current in the end of accelerating structure (50 mA per cell).

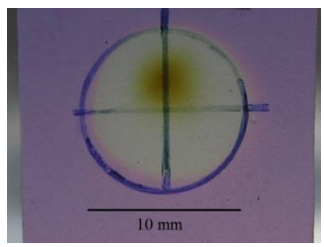

Figure 13: Cross section of the beam profile with RF control.

CONCLUSION

Linear electron accelerator based on parallel coupled accelerating structure and injector with RF control for a beam π-chopper is made, tested and measured. The beam energy is 2.5-4 MeV with total power of 2.4 MW, accelerated beam current is 100-300 mA. These values depend on the beam loading effect. The durations of the beam pulse were changed from 2.5 ns to 5 μs. With RF control the beam capture was achieved 100%. The diameter of cross section of the beam profile was about 3 mm. The beam loading effect is studying.

Abstract

We design a C-band standing-wave accelerator for an X-ray and electron source of medical radiotherapy. The accelerator system is operated two modes, using the X-ray and electron beams. Since two modes require different energy, the accelerator is capable of producing 6-MeV, 100-mA pulsed electron beams with peak 2-MW RF power, and 7.5-MeV, 50 mA electron beams with peak 2.5-MW RF power. The beam is focused by less than 1 mm without external magnets. The accelerating structure is a bi-periodic and on-axis-coupled structure with a built-in bunching section, which consists of 3 bunching cells, 14 normal cells and a coupling cell. It is operated with the π/2-mode standing-wave. The bunching cells are designed to enhance the RF phase focusing. Each cavity is designed by the MWS code within 3.5% inter-cell coupling. In this paper, we present design details of RF cavities and the beam dynamics.

INTRODUCTION

The electron accelerator is widely used for industrial and medical applications: a contraband detection, material processing, a medical diagnosis and therapy, sterilizing food, and environmental processing [1, 2]. For the medical applications, the electron beam with 3 ~ 15 MeV, pulsed tens mA is required. These applications require the small beam spot size at the X-ray conversion target for reducing the penumbra [3]. In order to achieve such a small beam spot size, the RF focusing effect is maximized instead of the magnetic focusing with external magnets for a compact accelerator system.

We are developing a C-band standing-wave electron accelerator for an X-ray and electrons source of medical radiotherapy. This accelerator system is operated two modes, using the X-ray and electron beams. The X-ray beam is used to irradiate the viscera, and the electron beam is used to irradiate the inner and outer layers of skin. There is energy loss by two scattering foils which are between the accelerating column and the affected area in the electron mode, as shown in Fig. 1 [4]. The beam energy at the end of column has to be higher than irradiated energy in the affected area, 6 MeV which are widely used in the medical radiotherapy [5]. For such reasons, the accelerator is designed to produce 6-MeV, pulsed 100-mA electron beam with peak 2-MW power in the X-ray mode, and 7.5-MeV, pulsed 50-mA electron beam with peak 2.5-MW power in the electron mode. It is operated with a pulse length of 4 μs and with a pulse repetition rate of 250 Hz. The bunching cells are designed with beam dynamics simulation for enhancing the RF phase focusing. We design the RF cavities in the bi-periodic and on-axis-coupled accelerating structure with the MWS code. The beam dynamics simulations are conducted with PARMELA codes.

ACCELERATOR OVERVIEW

The accelerator uses a 5712-MHz magnetron as an RF source. It is capable of producing a max. 2.5 MW RF with a 4-μs pulse length and a 250-Hz repetition rate. It is supplied pulsed 2.0 MW RF in the X-ray mode, and pulsed 2.5 MW RF in the electron mode, as shown in Table 1. The RF power is transmitted to the accelerating column through the WR187 waveguide network, as shown in Fig. 2. Since there is a transient reflection during an RF filling time in the standing-wave accelerating structures, a circulator with the matched load is inserted in the waveguide network. The pulse modulator supplies a max. 65-kV and a 90-A pulsed power to the magnetron with a 4-μs pulse length. It also supplies a max. 20-kV pulsed voltage to an E-gun.

The E-gun is a diode-type thermionic DC gun with a dispenser cathode. Although the E-gun is capable of emitting electron beam of maximum 560 mA, the gun emits 80-mA electron beam with 20-kV pulse in the electron mode, and 180-mA e-beam with 19-kV pulse in the X-ray mode. The beam radius is 0.6 mm at the beam waist which is 15.2 mm from the anode. The direction of the beam is adjusted by the steering coils in the upstream and downstream of the accelerating column, as shown in Fig. 3.

The accelerating column is attached to the E-gun directly, as shown in Fig. 3. For a compact structure, it has a built-in bunching section without a pre-buncher, and any focusing magnet is not used, because the beam is focused enough by the enhanced RF phase focusing with the design of the bunching cells [6]. A bi-periodic and an on-axis coupled structure is adopted for the π/2-mode standing-wave structure [7]. The first three cells, in Fig. 3, are the bunching cells with phase velocities (βph) of 0.3, 0.5, and 0.85. The number of normal cells with βph = 1 is 14 units, and after these, the coupler cell is attached to the tapered C-band waveguide.

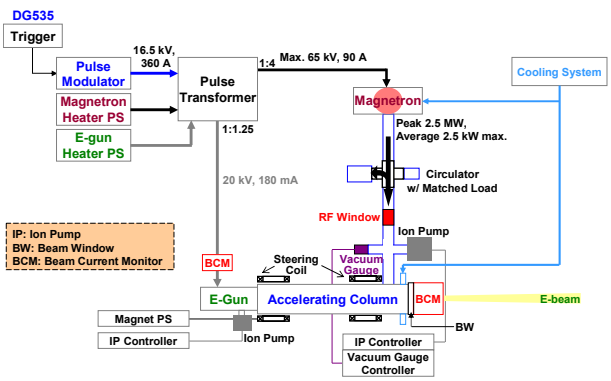

Figure 2: Schematic diagram of the accelerator system.

BEAM DYNAMICS

Beam dynamics simulations in the accelerating column are conducted by using the PARMELA code. The emittance of input beams is 20 mm-mrad and other parameters of input beams are described in the previous section. The phase velocities of bunching cells, and the asymmetric geometry of the first and second bunching cells are optimized to enhance the RF phase focusing, as shown in Fig. 3 [6]. In the electron mode, since the beam is scattered at two foils, the small beam spot is not required. Therefore, the efforts to enhance the RF phase focusing are optimized in the X-ray mode.

Fig. 4 is the phase trajectories of the X-ray and electron modes, and Fig. 5 is the beam envelopes of two modes. In the X-ray mode, the accelerating field is lower compared with that of the electron mode, because of the lower input RF power. Since the RF focusing is proportional to the square of the accelerating field, the beam is less focused in bunching cells, as shown in Fig. 5 [6]. However, since the beam is less accelerated in bunching cells, the average phase of the bunch is higher than that of the electron mode, as shown in Fig. 4. Then, the RF phase focusing is increased in normal cells [7]. Since these two effects cancel each other out, the beam spot size is almost the same in two modes. With effective RF focusing, the beam spot sizes of both are less than 1 mm at the end of column, as shown in Fig. 5.

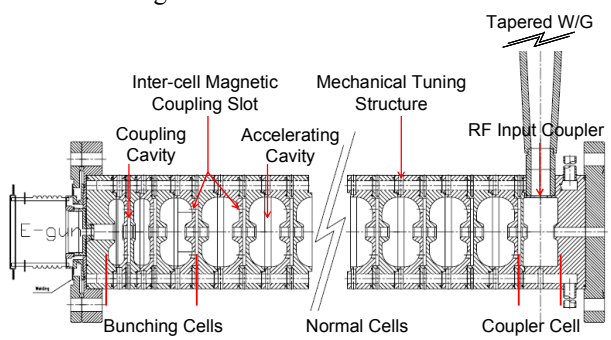

Figure 3: Cross-sectional view of the accelerator structure.

The output beam parameters of two modes are in Table 2. Since there is a lot of beam loss in the conversion target, collimator, and the flatfilter, as shown in Fig. 1, the beam current in the X-ray mode is higher than that of the electron mode, in order to obtain a lot of radiation. In the electron mode, the beam is accelerated near the crest, and more bunched, as shown in Fig. 4. Therefore, the beam energy spread is 10% less than that in the X-ray mode. It affects the increasing of the energy uniformity of beam in the electron mode.

RF CAVITY

Each cell in the accelerating column consists of the accelerating cavity and the coupling cavity, as shown in Fig. 3. Magnetic coupling slots are bored on the side wall between the accelerating cavity and the coupling cavity for the inter-cell coupling. The inter-cell coupling constant becomes 3.5%, restricted by the decrease of the shunt impedance. Due to these slots, the 3-D electro-magnetic simulation is conducted with the MWS code to obtain the resonant frequency for the π/2-mode of each cavity, as shown in Fig. 6. In the case of the coupling cavity, the transverse mid-plane can not be a symmetric boundary due to the magnetic coupling slots. To estimate an accurate resonant frequency for the coupling cavity,

the end cells are detuned for the frequency of the detuned cell to be lower than 3 GHz, as in Fig. 6(b) [8]. From the simulation result, the resonant frequencies of each cavity is obtained, 5711.5±0.5 MHz.

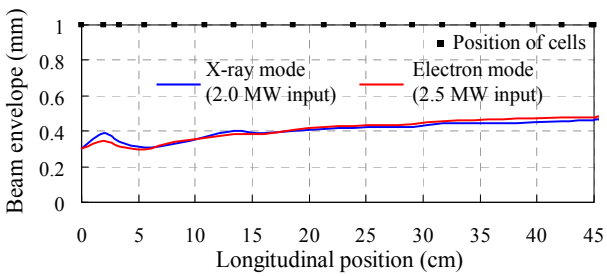

Figure 5: The beam envelopes of the X-ray and electron modes.

Table 2: The output beam parameters of the X-ray and electron modes

Beam parameters	X-ray Mode	Electron mode
Average Energy	6 MeV	7.5 MeV
Pulsed Beam Current	100 mA	50 mA
Energy spread	37%	27%
Beam spot size	~ 1 mm	~ 1 mm

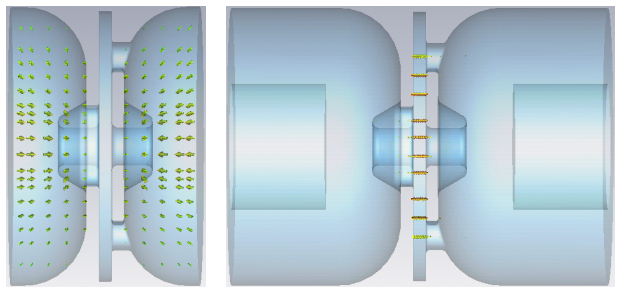

Figure 6: Simulation model to find the resonant frequency for (a): the accelerating cavity, (b): the coupling cavity.

SUMMARY

The C-band standing-wave accelerator is developed for the X-ray and electron source. This accelerator is capable of producing 6-MeV, 100-mA pulsed electron beams with an RF power of 2.0 MW for the X-ray source, and 7.5-MeV, 50-mA pulsed electron beams with an RF power of 2.5 MW for the electron source. In order to enhance the RF phase focusing, the phase velocities of bunching cells and the geometry of the first and second bunching cell are adjusted with beam dynamics simulations. Under these conditions, the beam is focused by less than 1 mm at the end of accelerating column in both of conditions. Since the beam is accelerated near the crest and more bunched in the electron mode, the beam energy spread 27% which is 10% less than that in the X-ray mode. The bi-periodic accelerating structure with on-axis coupling is designed. The cavity dimensions are determined for the π/2-mode frequency to be 5712 MHz with 3.5% inter-cell coupling by the MWS code simulation.

CHANGING ATTITUDE TO RADIATION HAZARDS AND CONSEQUENT OPPORTUNITIES FOR LINAC APPLICATIONS

Y. Socol, Falcon Analytics, POB 82 Netanya 42100, Israel

Abstract

High-energy LINACs unavoidably yield ionizing radiation. This fact makes them subject to strict regulations and considerably limits their possible applications. During the last two decades the attitude to ionizing radiation hazards seems to become more balanced, as opposed to "radiophobia" of the Cold-War era. Scientifically, the Linear No-Threshold (LNT) model of radiation damage is more frequently questioned. Moreover, the hypothesis of radiation hormesis – beneficial effect of low-dose radiation – is studied. While this scientific debate has not yet given fruit in terms of changes in radiation regulation policy, we may expect this to happen in the near to middle term. Namely, the ALARA (as low as reasonably achievable) demand is anticipated to be substituted by some tolerance level, which in turn is anticipated to be very high according to the present standards. The presentation will review the present status of the radiation-hazard debate, and outline anticipated opportunities for LINAC applications, like compact designs and wider industrial outreach.

TOLERANCE LEVEL VS. LINEAR NO-THRESHOLD

High-energy LINACs unavoidably yield ionizing radiation. Adverse effects of high doses of ionizing radiation were discovered nearly immediately after the discovery of X-rays and radioactivity back in the XIX century. However, it took about two decades before early medical practitioners began to control their exposures to ionizing radiation. For example, the British X-ray and Radium Protection Committee was formed in 1921. In 1924, at a meeting of the American Roentgen Ray Society, Arthur Mutscheller recommended "tolerance" (permissible) dose rate for radiation workers, a dose rate that could be tolerated indefinitely. This rate was 0.2 roentgen per day (R/day), based on applying a factor of 1/100 to the commonly accepted average erythema dose of 600 R (not accidentally – lethal dose in case of acute whole-body irradiation), spread over 30 days [1]. The International Commission on Radiological Protection (ICRP), established in 1928, accepted in 1931 this tolerance dose rate as a universal recommendation that was in effect for more than quarter of a century. This level corresponds to 70 R/year or about 700 mSv/year – 35 times higher than the present-day occupational (professional) exposure limit, and 700 times higher than the present-day public one. It was assumed that no harm will be caused by radiation below this tolerance level. To illustrate the extent of public confidence in the usefulness and safety of ionizing radiation we will remind that until after the Second World War X-ray machines were typical equipment of shoe shops (this fact was mentioned in passing in Rudolf Peierls' book from 1956 [2]).

It should be stressed that until now nobody succeeded to disprove the assumption of tolerance level (while it is clear that high dose is harmful: acute dose of 100 R leads to radiation sickness and 200 R may be already lethal). For example, a study of British radiological society members [3] reveals that while the pre-1921 radiologists (who had not controlled their exposure and therefore received high doses of ionizing radiation) had a 75% (4σ of the expected value) higher cancer mortality than other medical practitioners, the post-1920 radiologists had an insignificant 5% (0.4σ) excess. Furthermore, the studies of radium dial-painters, exposed to huge cumulative doses (mostly at low rates), revealed that no cancer excess was observed below the life-time dose of about 1000 rad [4]. For α-particles, emitted by radium, the radiation weighting factor w_R=20, i.e. 1000 rad = 10 Gray correspond to 200,000 mSv!

However, geneticists strongly believed the theory that the number of genetic mutations is linearly proportional to radiation dose just like the number of ionized atoms, that mutagenic damage was cumulative and therefore no tolerant (safe) dose for radiation could be set. According to this view, there is no absolute radiation safety, so that the safety level should only be weighed against the cost to achieve it [1].

After the bombing of Hiroshima and the start of the nuclear arms race, geneticists greatly amplified their concerns that exposure to radiation of atomic bomb fall-out would likely have devastating consequences on the gene pool of the human population. Hermann Muller was awarded the Nobel Prize in 1946 for his discovery of radiation-induced mutations. In his Nobel Prize Lecture, he argued that the dose-response for radiation-induced germ cell mutations was linear and that there was "no escape from the conclusion that there is no threshold" [5].

There was great controversy and extensive arguments during the following decade. Probably, both super-powers became interested in exaggerating the nuclear fall-out hazard. Ultimately all kinds of ionizing radiation became connected in public perception with nuclear apocalypse. As a result of (or at least in the wake of) this change in public perception, the ICRP and the national regulators changed their radiation protection policies in the mid-1950s. They rejected the tolerance dose concept and adopted the ALARA (as low as reasonably achievable) policy, i.e., to keep the radiation exposure ALARA. The accepted model for low-dose radiation-induced health damage became the so-called Linear No-Threshold (LNT) model. In LNT, the acute exposure, high-dose cancer

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

mortality data from the study on Hiroshima-Nagasaki survivors [6] was taken as the basis for extrapolation to low doses of radiation. (We should also mention in brackets, that the Life Span Study of the survivors, though dealing with vast amount of data, is performed by single organization that grants only a very limited access to its raw data for the scientific community). The ICRP has been progressively tightening its recommendations for occupational and public exposures, from 50 and 5 mSv/year in 1958 [7] to 20 and 1 mSv/year in 1990 [8], and national regulators usually followed. And probably even more importantly, these stringent norms were (and to a large extent are still being) considered unsafe by the general public.

NEW TRENDS

While the Linear No-Threshold (LNT) view is commonplace for the present regulation and for the public perception, it has never been a subject to scientific consensus. The absence of consensus has been always officially acknowledged – see e.g. the 1979 report of the US Congress Office of Technology Assessment [9]. Towards the end of the Cold War, the LNT model becomes more and more challenged.

In simple terms, the concept of a cumulative no-threshold damage to living organism by *any* possible factor contradicts most of the existing scientific evidence. E.g., for paracetamol – a widely used non-prescription medicine – the lethal dose LD_{50} is about 2 g/kg, i.e. below 200 g for a normal person (few weigh above 100 kg). Following the LNT logic, each caplet of paracetamol (0.5 g) has lethal probability of 50%×0.5/200=0.125% – i.e. a caplet should kill on average 1 out of 800 patients! Clearly, the LNT logic is completely inapplicable here, which is typical for biology. In more professional terms, an enormous amount of research has been underway on genetics and on the effects of radiation on DNA throughout the XX century. A very important review of this subject, as pointed by Jerry Cuttler [1], was published in 1990 by Daniel Billen in the Radiation Research Journal [10].

The above review points out that "DNA is not as structurally stable as once thought. On the contrary, there appears to be a natural background of chemical and physical lesions introduced into cellular DNA by thermal as well as oxidative insult. In addition, in the course of evolution, many cells have evolved biochemical mechanisms for repair or bypass of these lesions."

Billen points that spontaneous DNA damage occurs at a rate of about 10,000 natural events per cell per hour. Let us compare this with the damage caused by ionizing radiation. The number of DNA damaged sites per cell per roentgen (R) is estimated to be below 100 [10]. A radiation level of 0.2 R (or 2 mSv) per day (ICRP 1931 recommendation) would cause on average less than 20 events per cell per day, or below 1 event/cell per hour. This is 10,000 times lower (!) than the natural rate of DNA damage that occurs in every person. The above numbers have been known for more than 20 years, verified by numerous investigations and considered to be a solid scientific evidence.

Moreover, one can even suggest that low doses of X-rays and nuclear radiation are beneficial to human health ("hormesis" hypothesis) – just as the ultraviolet radiation (also a form of ionizing radiation) is clearly beneficial in low doses (sun tanning) while high doses are certainly harmful (sunburns and skin cancer). In that context it is worth mentioning that the healing properties of radon spas have been utilized for centuries before people heard the word "radiation", and that radon treatment is definitely not considered to be an "alternative therapy" by the mainstream medicine in Europe (as opposed to the US) [11]. Another fact worth mentioning is that in most of the nuclear industry workers studies, the rate of cancer mortality (as well as overall mortality) among the radiation workers is substantially lower than in the reference population [12]. These little-spoken facts and many others [11,13] comprise emerging (though not yet conclusive) scientific support for the hormesis hypothesis. The very idea of radiation hormesis and the term itself appeared back in 1920-s, but since 1950-s were missing in the scientific literature for decades till re-appearance in 1982. Since then, the scientific interest to hormesis steadily grows, as shown in Fig. 1.

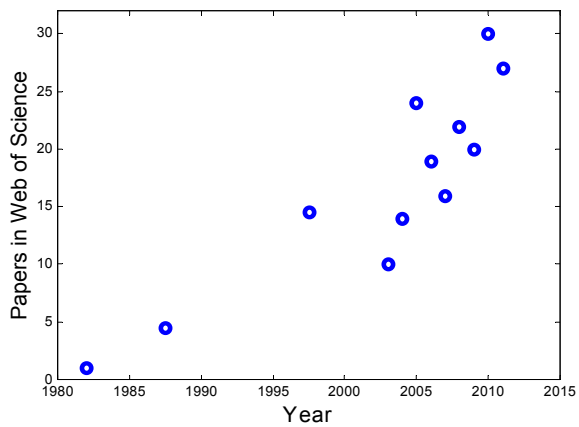

Figure 1: Growing number of scientific papers dealing with *radiation hormesis* (beneficial effects of low-dose ionizing radiation). The term "hormesis" appeared in 1920-s, but since 1950-s was missing in the scientific literature for decades till re-appearance in 1982. Source: Science Citation Index Expanded [14].

While this scientific debate has not yet given fruit in terms of changes in radiation regulation policy, we may expect this to happen in the near to middle term. For example, after the Fukushima accident it was publicly announced – probably for the first time after 1950-s – that no positive scientific evidence (besides extrapolation from high acute dose) supports carcinogenic or other harmful effect of radiation dose below 10 R (100 mSv). While the above understanding did not prevent the Japanese authorities from performing large-scale (and in our opinion unjustified) evacuation [1], it was still

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

essential in *ad hoc* setting higher radiation limits for the radiation workers, which led to ultimate solving of the damaged reactors' issues.

Instead of the ALARA (as low as reasonably achievable) demand, "as high as reasonably safe" AHARS approach was suggested [15]. Reasonably safe tolerance level is anticipated to be very high according to the present standards, probably orders of magnitude higher than the present limits, as discussed in the first part of this paper.

APPLICATIONS

Below we discuss how different applications of LINACs may benefit from the more realistic attitude to radiation hazards.

Food industry

Electron LINACs may be used for food sterilization, leading to the reduction in supply-chain losses and to extended shelf life. Since the irradiated food does not become radioactive, the main obstacle to the spread of this technology seems to be related to the public perception of radiation hazards. With more realistic attitude to radiation hazards, the market for LINAC-irradiated food is anticipated to considerably grow.

Manufacturing of plastics

Irradiation leads to intensification of important chemical processes, such as polymerization or curing in composites. In high-volume production, the radiation doses for the workers are relatively high. Since the plastics industry is generally regarded as low-tech with relatively cheap labour, upgrading the employees officially to a status of "radiation workers" does not seem to be a viable option in the present situation. However, the situation will change dramatically with easing of the radiation regulations and changing of the public perception of radiation hazards.

Other applications

All LINAC applications, especially compact Free-Electron Lasers still to be designed, will benefit from easing the radiation regulation and elimination of radiophobia. However, other applications seem to be less affected. For example, in medical applications (radiotherapy and end-point sterilization of equipment) there seems to be virtually no radiophobia whatsoever. It is as if these were different types of X-rays, electrons and isotopes being used for the different applications – harmless in medicine, yet extremely dangerous in all other fields of human endeavour. This topic by itself is worth of serious research, however more in relation to psychology and sociology than to physics.

CONCLUSIONS

During the last two decades the attitude to ionizing radiation hazards seems to become more balanced, as opposed to "radiophobia" of the Cold-War era. We may expect in the near or the middle term future a decline of radiophobia and easing of the radiation regulations. The ALARA (as low as reasonably achievable) demand is anticipated to be substituted by some tolerance level, which in turn is anticipated to be very high according to the present standards. The main anticipated opportunities for LINAC applications belong in our opinion to the food industry and plastic production technologies.

ACKNOWLEDGMENT

The author wishes to thank Dr. Jerry Cuttler (Cuttler & Associates Inc.) for drawing attention to his excellent recent publication [1], which provided a significant part of the historical background in the current publication.

FERMILAB 1.3 GHz SUPERCONDUCTING RF CAVITY AND CRYOMODULE PROGRAM FOR FUTURE LINACS*

C.M. Ginsburg#, Fermilab, Batavia, IL 60510, USA

Abstract

The proposed Project X accelerator and the International Linear Collider are based on superconducting RF technology. As a critical part of this effort, Fermilab has developed an extensive program in 1.3 GHz SRF cavity and cryomodule development. This program includes cavity inspection, surface processing, clean assembly, low-power bare cavity tests and pulsed high-power dressed cavity tests. Well performing cavities have been assembled into cryomodules for pulsed high-power tests and will be tested with beam. In addition, peripheral hardware such as tuners and couplers are under development. The current status and accomplishments of the Fermilab 1.3 GHz activity will be described, as well as the R&D program to extend the existing SRF pulsed operational experience into the CW regime.

INTRODUCTION

Work by the International Linear Collider (ILC) [1,2] community, which includes Fermilab, has motivated substantial world-wide infrastructure development and cavity performance progress. At Fermilab, this has translated to a very large commitment of resources for infrastructure and personnel development. The developed capability has led to the possibility to use the 1.3 GHz infrastructure for development of Project X [3,4], although the performance requirements are somewhat different [5]. The Project X 3 GeV CW linac requires high Q_0 at gradients (E_{acc}) in the range $15<E_{acc}<20$ MV/m; 1.3 GHz cavities can be used to investigate high Q_0. In addition, the Project X 3-8 GeV pulsed section operates at 1.3 GHz and requires ILC-like cavities with E_{acc}~25 MV/m. The status of Fermilab 1.3 GHz infrastructure, accomplishments and plans are described.

INFRASTRUCTURE

The cavities are fundamentally of the Tesla design [6], made of high RRR niobium with an elliptical cell shape, for superconducting operation at 2K. Cavity qualification has been described in detail elsewhere [7] and includes cavity inspection, surface processing, clean assembly, and one or more cryogenic qualification tests which typically include performance diagnostics. Cavities which reach the performance requirement in vertical (bare) qualification test, typically $E_{acc}>35$ MV/m, are dressed and horizontally tested. Cavities which reach the performance specification in horizontal (dressed) qualification test, also typically $E_{acc}>35$ MV/m, are assembled into cryomodules.

The joint ANL/FNAL facility is the primary infrastructure [7] for surface processing of 1.3 GHz cavities, and includes electropolishing (EP). New infrastructure at Fermilab includes two high temperature furnaces for hydrogen degassing, see Fig.1. In addition, a centrifugal barrel polishing (CBP) machine for 1-cell and 9-cell 1.3 GHz cavities has been introduced for R&D and may be used for production cavity preparation in the future, see Fig.2. CBP may be used in place of the standard bulk electropolishing step, to reduce acid use. CBP has been demonstrated to be a useful repair technique [8], and may have other benefits as well, such as reducing cavity performance sensitivity to minor manufacturing or material defects; these studies are not yet complete. A new R&D surface processing facility [9] is now fully operational for the full suite of standard EP processing for 1-cell 1.3 GHz cavities. The R&D EP tool is shown in Fig.3.

ILC AND CONSIDERATIONS FOR CW

ILC R&D contributed substantially to cavity gradient performance. A worldwide effort by participating laboratories, including Fermilab, to optimize cavity processing and to develop new cavity vendors for high gradient cavities was implemented. As part of this work, a systematic analysis of cavity vertical test data was performed [10]. The data set is comprised of cavities fabricated by established vendors (ACCEL/RI, AES, MHI, Zanon), and processed by established laboratory surface processing (JLab, DESY, KEK), including electropolishing. If a cavity does not reach 35 MV/m after the initial EP processing stage, we assume it would be re-processed. Standard 2nd pass processes may include EP, HPR, or 120C bake, and are selected based on 1st pass performance at the discretion of the laboratory. There are 51 cavities in the 1st pass plot, and 35 in the 2nd pass plot. The difference in number of cavities reflects the fact that the 2nd pass may not have take place yet, or may have been done with a non-standard process. The gradient distribution of cavities which are not included in the 2nd pass yield is the same as those which are included. The ILC gradient yields, representing percentage of cavities reaching either 25 MV/m (blue points) or 35 MV/m (red points) are shown in Fig.4. ILC cavities reach 35 MV/m more than half the time after one or two EP processing cycles. For Project X, the gradient yield at 25 MV/m is of interest. In 1st pass, (69±6)% of all 51 cavities achieve >25 MV/m; and (86±13)% of 7 cavities achieve >25 MV/m considering only cavity tests taking place in 2012. In 2nd pass, (80±7)% of all 35 cavities achieve >25 MV/m; and (92±7)% of 13 cavities achieve >25 MV/m considering only cavity tests taking place in 2010-2012.

Ongoing efforts to improve cavity performance yields, either 1st pass or 2nd pass, include applying localized grinding (pioneered by KEK) to performance-limiting defects, and CBP. Many (~12) cavity repairs have been achieved through these two methods; however, at this time, cavity performance after these repairs has not been included in yield plots.

Two approaches for Q_0 optimization for Project X are being pursued at Fermilab now: venting cavities after hydrogen degassing in a nitrogen atmosphere [11], and using a hydrofluoric acid rinse as the final processing step [12]. Both approaches show promising results.

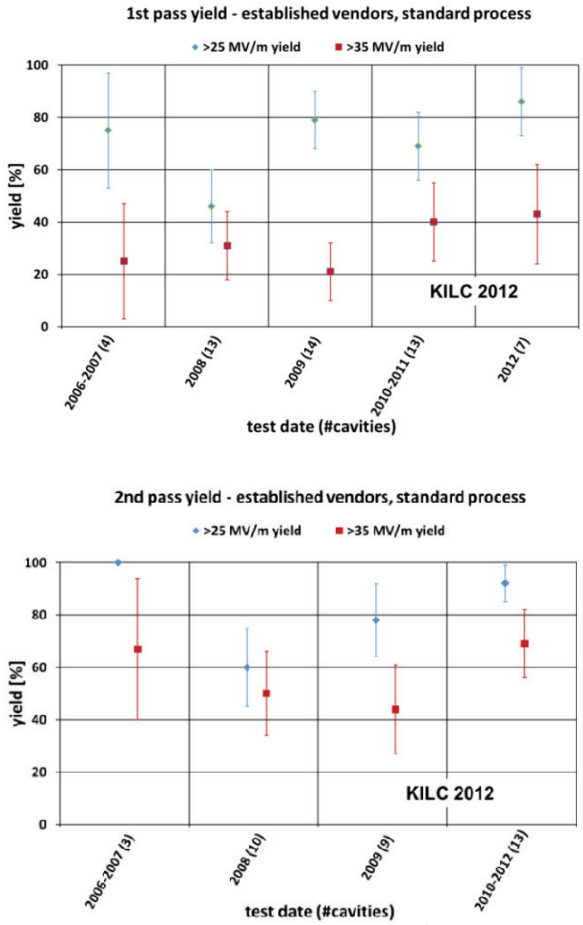

Figure 4: ILC cavity gradient yields: 1st pass (top) and 2nd pass (bottom), as a function of time. Blue points are >25 MV/m yield and red points are >35 MV/m yield.

ACCOMPLISHMENTS

Fermilab provides stewardship for 80 9-cell cavities for the ILC/Americas region. The status of these cavities is shown in Table 1. The bare cavities are processed and tested in strong collaboration with JLab, Cornell and ANL; see Fig.5 for vertical test performance.

Table 1: 9-cell Cavity Status August 31, 2012

ordered	80
received	69
processed	47
vertically tested	47
dressed	22
horizontally tested	19
CM2 installed	8

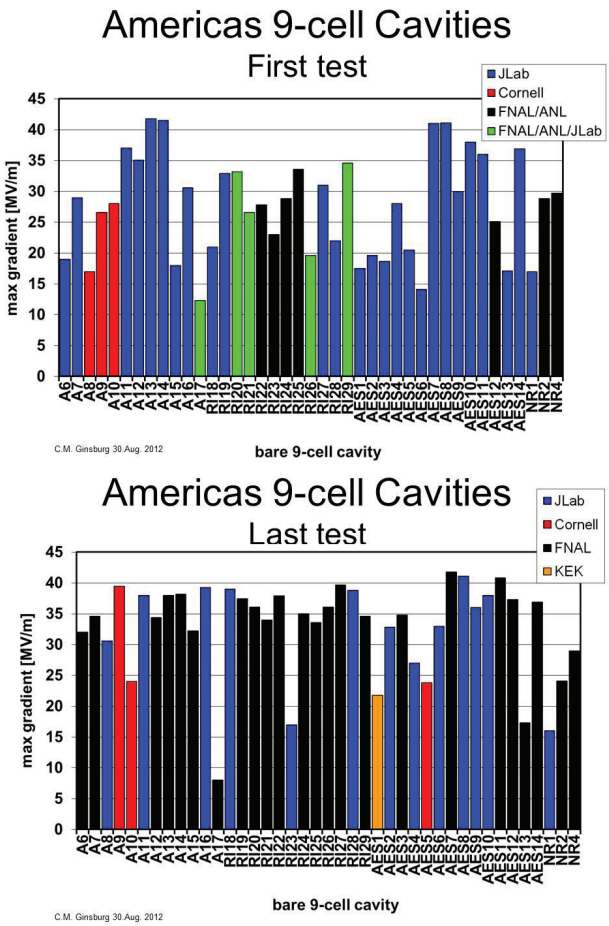

Figure 5: Gradient performance of all Americas cavities in first test (top) and last test (bottom). The test location is designated by the histogram bar color. An overall improvement is seen after additional process and test.

Two 1.3 GHz cryomodules have been assembled at Fermilab: CM1 and CM2. CM1 was built from a DESY "kit" containing parts from DESY and INFN, including surface processed, dressed, tested cavities. The magnet position is occupied by a "dummy" magnet. CM1 has been tested cold with excellent results [13]. CM2 is an 8-cavity string with a quadrupole package. CM2 is comprised of cavities which were surface processed and reached 35 MV/m in vertical test at JLab. These cavities were dressed and horizontally tested at Fermilab, then assembled into CM2. The summary of final cavity performance before CM2 assembly [14] is shown in Fig.6. CM2 will be tested at NML first without beam and then with beam within a year. All components are available for the assembly of CM3, which is expected to proceed within about a year.

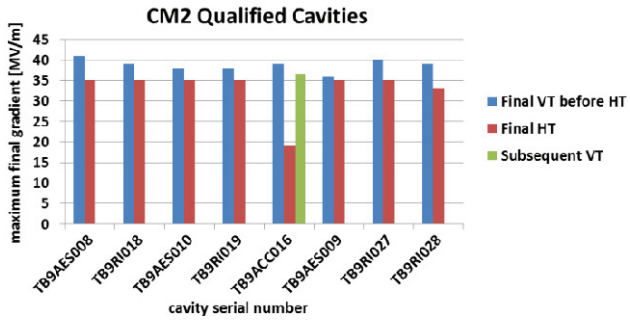

Figure 6: Gradient performance of CM2 cavities in vertical (blue) and horizontal tests (red). In one case, a subsequent dressed-cavity vertical test was performed after failed horizontal test.

Abstract

Starting from the high-resolution camera for inspection of the cavity inner surface – so-called Kyoto Camera, high resolution T-map, X-map and eddy current scanner have been developed. R&D for radiography techniques is also going on to detect small voids inside the Nb EBW seam, where the target resolution is 0.1 mm. Some radiography tests with X-rays induced from an ultra short pulse intense laser were carried out. The local treatment technique on the found defects is also realized by the Micro-Grinder.

INTRODUCTION

Non-destructive Inspections play important roles in improving yield on production of high performance SC Cavities. Starting from the high-resolution camera for inspection of the cavity inner surface [1], high-resolution T-map, X-map and eddy current scanner [2,3,4,5,6] have been developed. We are also investigating radiography to detect small voids inside the Nb EBW seam, where the target resolution is 0.1 mm. We are carrying out radiography tests with X-rays induced by irradiations of an ultra short pulse intense laser on a target metal sheet. Defects found by the inspection technique can be locally treated by the Micro-Grinder.

CAVITY CAMERA UPDATE

In order to inspect the SPL cavity at CERN, whose frequency is about a half of ILC cavity and the diameter is about twice larger, the illumination system has been enhanced to illuminate the wider surface area (see Fig. 1). Although the iris diameter is about twice larger than that of ILC's, the bore diameter at the flange position is limited (just below ø80mm). This limits the camera cylinder diameter is ø70mm. Fig. 2 shows the modification on the illumination system to illuminate the wider area with enough strength. While the former system used two LED's for each strip, the new system uses 14 LED chips on a line and two lines consist one strip. Thus 28 LED chips are used for a strip. Furthermore, the LED chip has three LED's in a package. This illumination system should provide enough light for the wider cavity surface area. Because of the larger cavity size, the working distance is longer than former model and a bigger lens system is adopted. Fig. 3 shows the overview of this system. The illumination plate on the cylinder is shown in Fig. 4. The camera cylinder can be rotated to see the annular area in a cavity without movement of the cavity, while the cavity table can rotate the cavity if it does not wear its He jacket around. The table has a function to move the cavity in its axial direction.

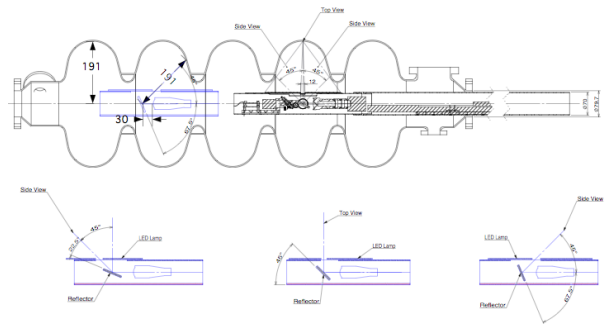

Figure 1: CavCam3 in SPL cavity.

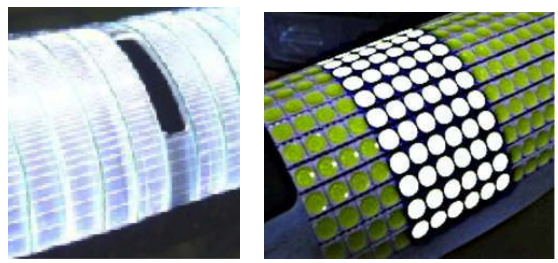

Figure 2: Enhanced illumination for wider surface area (Armadillo Illumination). 28 LED chips (right) instead of 2 LED's per strip (left) are installed.

Figure 3: Latest CavCam-3 for SPL cavity at CERN.

Figure 4: All the LED's are lighten. A diffusing panel will be install on the LED's to form the light strip. 14 chips/line x 2 lines/strip x 10 strips/side x 2 sides = 560 chips are used.

HIGH DENSITY T-MAP & X-MAP

The high density Temperature mapping system (T-map) and X-ray mapping system are under development. These systems utilize multiplexing technique to reduce the number of lines from the sensors to the measurement circuits. The temperature sensors are put on a Nb cavity surface during the vertical test to detect the temperature rise from the quench phenomena due to a defect on the inner surface, if any. Since one temperature sensor / cm^2 is assumed for the surface density, 1024 sensors will be installed on a cell and about nine thousands of sensors will be need to be connected to the measurement circuit. The number of lines needed for these connections is reduced by multiplexing the analog signals in the cryogenic area. The reduced lines include the three power supply lines (0V, ±5V), one clock line, one reset line, and two signal lines for each type of system (t-map and X-map) as shown in Fig. 5. T-sensors are installed on the inner side and X-sensors are located on the other side. T-sensors contact on the cavity surface (see Fig. 6). As shown in Fig. 7 the leaves can be instantly attached on a cell, which helps to reduce the installation time for a vertical test.

A dedicated X-map system for installation under the stiffener ring is also developed (see Fig. 8). Only X-sensors are installed on the PCB, which can slide into the space under the stiffener ring as shown in Fig. 9.

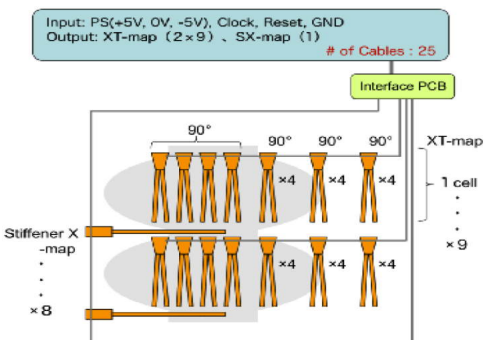

Figure 5: The inter-connection for the XT-map system.

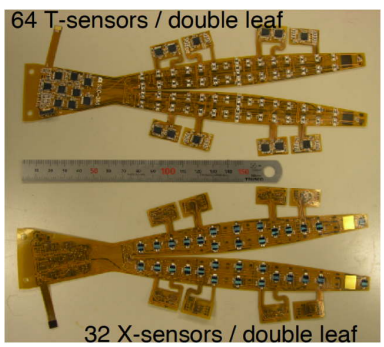

Figure 6: Leaf shaped flexible PCB.

HIGH RESOLUTION EDDY CURRENT SCAN

A Nb sheet before the press to form the cup will be inspected by a Eddy current scan [7]. Using a multi-frequency Eddy current probing system, a small void just under the surface, which may appear after surface treatments such as electropolishing (EP), would be detected. The depth information would be obtained from the three different frequency data simultaneously acquired during the measurement. The detected hole size is currently ø100µm x 50µm depth (see Fig. 10).

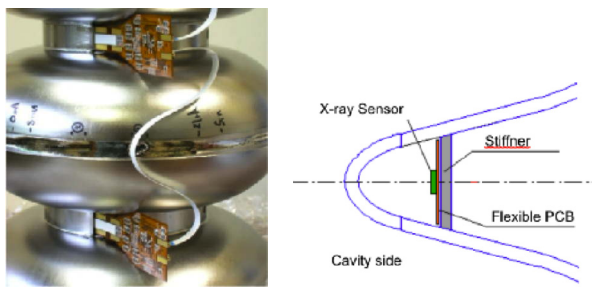

Figure 9: Installed stiffener X-map ribbons. The ribbons go under the stiffer ring.

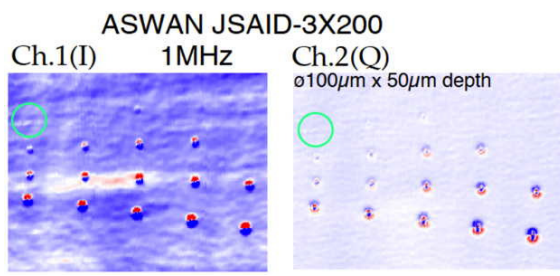

Figure 10: The high resolution eddy current scanner can detect the drilled holes on the Nb sheet down to ø100µm x 50 µm depth.

RADIOGRAPHY EFFORT

In order to inspect the EBW seam especially for possibly buried defects under the surface, various radiography techniques have been investigated such as

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

X-ray CT, and neutron CT. Since Nb has larger atomic number, high energy X-rays tend to be preferred for a better transmission. The contrast, however, becomes worse for high energy X-rays. Although the phase contrast techniques should have better contrast even in this case, it is not a handy way. After some trials, laser induced X-ray radiograph is under investigation (see Fig. 11). Fig. 12 shows the obtained radiography images for targets of Zr and Ag, where Zr is supposed to be better because of the X-ray energy just below the K absorption edge of the Nb. Further study is needed for better visibility and practical applications.

LOCAL REPAIR TECHNIQUE

Using the inspection devices, defects on the surfaces can be identified and analyzed. For those defects judged as harmful, the local repair technique should be applied. The micro-grinder can be inserted into the cavity, while the grinding head is retracted (see Fig. 13)[8]. After its positioning, some amount of water is applied to the area and the head with abrasives can start to grind. The grinding time can be limited by a timer up to 99 minutes. Additional EP and following processes are applied to the treated cavity to bring the cavity back to the line. Several cavities have been already repaired and show satisfactory results (see Fig. 14).

TEST RESULTS OF TESLA-STYLE CRYOMODULES AT FERMILAB *

E. Harms#, K. Carlson, B. Chase, D. Crawford, E. Cullerton, D. Edstrom, A. Hocker, M. Kucera, J. Leibfritz, O. Nezhevenko, D. Nicklaus, Y. Pischalnikov, P. Prieto, J. Reid, W. Schappert, P. Varghese, Fermilab, Batavia, IL 60510 USA

Abstract

Commissioning and operation of the first Tesla-style Cryomodule (CM-1) at Fermilab was concluded in recent months. A second Tesla Type III+ module, RFCA002, will be replacing it. CM-1 is the first 8-cavity ILC style cryomodule to be built at Fermilab and also the first accelerating cryomodule of the Advanced Superconducting Test Accelerator (ASTA). We report on the operating results of both of these cryomodules.

INTRODUCTION

An electron Linac based on Superconducting RF technology has been proposed and is under construction at Fermilab. This Advanced Superconducting Test Accelerator (ASTA) has as its main components a Cs-Te 1-1/2 cell Photoinjector gun, two Capture cavities, and Tesla–style SRF cryomodules as well as low (40 MeV) and high energy user beam lines. This facility has been described previously [1]. It currently serves as the only test bed for multi-cavity cryomodules at Fermilab until a dedicated facility, the Cryomodule Test Facility (CMTF), now under construction is completed.

The setup for testing cryomodules at ASTA contains all of the necessary infrastructure including:

- 5MW 1.3 GHz klystron capable of pulsed operation at 10 Hz
- Cryogenics plant capable of providing 120 Watts of refrigeration at 2 Kelvin
- Interlock/protection systems
- Low Level RF (Feedforward & Feedback) system
- Vacuum system
- Controls integrated to Fermilab's Accelerator Controls system, ACNET.

CRYOMODULE 1

CM-1 was the first Tesla Type III Cryomodule to be placed into operation in the United States and the first multi-cavity cryomodule of any type to become operational at Fermilab. It was provided to Fermilab as a 'kit' from DESY in exchange for a 4-cavity 3.9 GHz module, ACC39, which was designed and assembled at Fermilab and is now in operation at DESY's FLASH facility. Table 1 highlights the major steps in bringing CM-1 into operation and completing the test program.

The test plan for CM-1 has been described previously as has been the performance characteristics of individual cavities [2]. Typical operating conditions were:

- 5 Hz repetition rate
- 700 μs fill time
- 500 μs flattop
- 2 Kelvin / 23.4 Torr temperature
- 3.9 MW peak Klystron power.

Table 1: CM-1 Commissioning Milestones

Milestone	Date
Cryomodule moved into final position and aligned	22 January 2010
5 MW RF/Klystron commissioning	June - July 2010
Warm coupler conditioning - one cavity at a time (4 - 14 days/cavity)	August – October 2010
Cool down from room temperature to 4 then 2 Kelvin	17 – 22 November 2010
Individual Cavity cold conditioning and evaluation	December 2010 – June 2011
Installation of Waveguide Distribution system and Water System upgrade	13 June - 5 July 2011
First powering of the entire module	6 July 2011
Long Pulse (9ms) tests	December 2011
Thermal cycling and lN_2 leak repair	January - February 2012
Cease operation/Removal	March 2012

Figure 2 provides a comparison of peak cavity gradients during qualification tests at DESY as well as during CM-1 full module operation while Table 2 summarizes individual cavity performance in CM-1. On average, the cavities' peak gradients in CM-1 are 85% of that measured previously.

Module Evaluation

The previous report [2] on CM-1 indicated some outstanding measurements to be performed including

- Demonstration of Lorentz Force Detuning Compensation on the entire module,
- Additional processing to attempt to improve the performance of deficient cavities,

*Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.
#Harms@fnal.gov

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

- Possible thermal cycling to improve performance/uncover additional field emitters,
- Readjustment of VTO's to better match cavity pair outputs.

In large measure this was all carried out as was a Dynamic Heat Load measurement to determine the overall cryomodule Q_0 vs E.

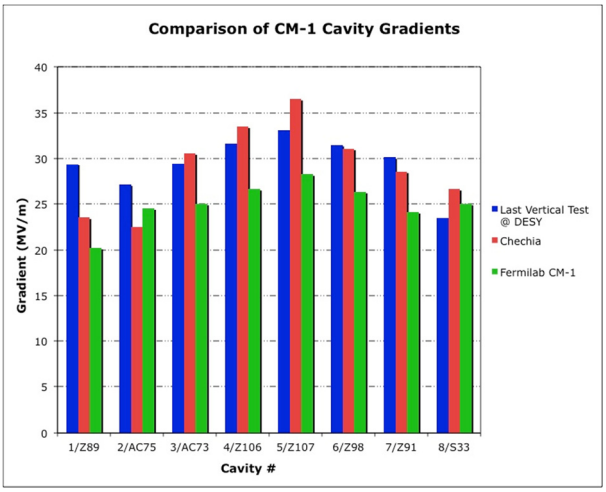

Figure 1: Comparison of cavity peak gradients – DESY single cavity vertical (blue), horizontal/Chechia (red), and the complete CM-1 at Fermilab (green).

Lorentz Force Detuning Compensation

Adaptive Lorentz Force Detuning Compensation (LFDC) measurements made on single cavities are documented elsewhere [3] prior to when all cavities were simultaneously powered and corrected. In this state gradients in the cavities ranged between approximately 8 and 27 MV/m. Without compensation, the highest gradient cavities would detune by up to 400 Hz during the flattop. With adaptive compensation on the detuning was negligible in all the cavities except for Cavity 1 which detuned by approximately 10 Hz during the RF pulse. Even for the cavities operating at the highest gradients, Lorentz force detuning could be compensated using relatively modest voltages to drive the piezoelectric tuners, approximately ±20V, and the waveforms did not exhibit fast transients that could potentially damage them.

Low Level RF

Development work on the Low Level RF system (LLRF) was a constant throughout the running period. By the end of the run it was possible to control the RF amplitude and phase over 50 pulses to a RMS magnitude error of $2.5X10^{-4}$% and RMS phase error of 0.005° as measured in-loop.

9 Millisecond Test

Once the cryomodule was well characterized a 'long pulse' study in support of an R&D program for Fermilab's proposed Project-X SRF Linac was performed. This proof-of-principle study entailed operating the two best-performing cavities (5 & 6) at a pulse length of up to 9 milliseconds and determining the LLRF and resonance control capabilities at various input powers and Q_L values. Operating parameters in this mode were:

- RF power limitations: 80 kW; 100 kW, 120 kW per two cavities,
- Use of the 'CC2' klystron capable of producing long pulses,
- External Q_L: 3 X 10^6; 6 X 10^6; 1 X 10^7,
- Gradient: 15MV/m; 20 MV/m; 25 MV/m,
- Pulse Width: up to 9 ms.

Table 2: Individual Cavity Performance Characteristics

Cavity	Peak E_{acc} (MV/m)	Estimated maximum Q_0 (E09)	Limitation/ Comments
1/Z89	20.2	11	'Soft' quench
2/AC75	22.5	12	Quench
3/AC73	23.2	0.43	'Soft' quench
4/Z106	24*	2.3	*RF-limited
5/Z107	28.2	39	Quench
6/Z98	24.5	5.1	Quench
7/Z91	22.3	4.7	'Soft' quench
8/S33	25	18	Tuner motor malfunction

This study proved to be a good first pass test. LFDC at the nominal parameters, Q_L= 1 X 10^7 and 25 MV/m, was demonstrated. LLRF feedback worked with phase stability good to ± 4°. The total range of detuning was found to be of order ±10 Hz peak-to-peak with comparable contributions from residual LFD and microphonics. The measured microphonics level was in range 2-4 Hz, similar to what was measured for short (1ms) pulses. Areas requiring further work were uncovered. Input power limitation for the low Q_L case (~3 X 10^6) limited the peak gradients to less than 20 MV/m. The system also proved to be less stable under dynamic conditions. Nearly constant attention was required under these conditions to maintain stable operation especially when adjusting the power.

Thermal Cycling

Additional processing of lower performing cavities did not noticeably alter their performance. The module was warmed up to room temperature and cooled also with no significant change in performance. During cooldown a

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

leak on the liquid nitrogen circuit appeared. In situ investigation revealed a failed feed-through on an in-line temperature sensor which was subsequently capped off and replaced with an externally mounted one. This experience proved to be valuable in both making diagnosis and repair without removing the cryomodule.

Summary of CM-1

Although issues with a tuner motor prevented all eight cavities from operating on resonance together and a subset of cavities exhibited sub-par performance, CM-1 did operate for an extended time stably and near the peak achievable gradients with both LLRF feedback enabled and LFDC. Valuable experience was gained and a larger cadre of staff was exposed to this type of operation.

As appropriate, components such as low performing cavities, tuner motors, and the like will be scrutinized and subjected to further testing once CM-1 is disassembled.

RFCA002

The second cryomodule planned for ASTA was delivered in March 2012 and installation work begun immediately. This device known as RFCA002 or CM-2 is also a Tesla Type III+ device. All cavities were fabricated by industry. Vertical testing was carried out at both Jefferson Lab and Fermilab and horizontal tests of the dressed cavities at Fermilab's Horizontal Test Stand. All facets of testing and assembly have been under the supervision of Fermilab staff. Since CM-2 is being installed in place of CM-1 the necessary infrastructure is already in place.

Expectations for the cryomodule are high as individual cavity testing results for these cavities met or exceeded the ILC design specification of 31.5 MV/m. These results are described previously [4]. Figure 3 summarizes the performance.

A final leak check of the 2-phase helium circuit gave indications of a leak, so the module has been returned to its assembly building, partially disassembled, and attempts to identify the source of the leak are in progress. The current expectation is for the cryomodule to be returned to ASTA late in 2012 with full warm and cold checkout completed in the first half of 2013.

LESSONS LEARNED

Operating experience with CM-1 in recent months is proving valuable in anticipation of bringing CM-2 and other cryomodules destined for this facility on-line in the near future as well as in preparation for possible future SRF facilities such as Project-X. Already the suite of instrumentation has been reviewed and modified for RFCA002 based on CM-1 experience. The sequence of commissioning steps has been reviewed and modified in light of the initial operating experience and will no doubt lead to faster and more efficient start-up of future modules.

Tuner motor issues with CM-1 led to a review of the motor controller circuitry, which led to modifications realizing a more robust and fail-safe system.

The Controls user interface system is also under regular updating as more experience is gained.

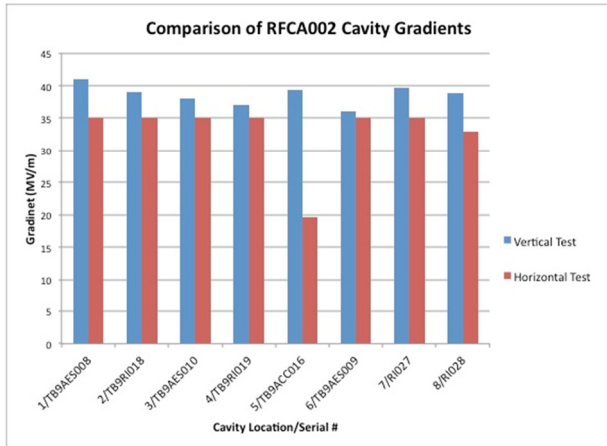

Figure 2: CM-2 peak cavity gradients as measured vertically (blue) and at Fermilab's HTS (red).

SUMMARY

Testing of the first Tesla-style SRF module at Fermilab has been successfully completed and preparation for installing and bringing a second module, capable of meeting ILC specifications, is well underway. With these achievements as well as operation of other SRF facilities, Fermilab is demonstrating its maturity in this field.

ACKNOWLEDGEMENTS

The achievements to date would not have been possible without the hard work and effort of many people in Fermilab's Technical and Accelerator Divisions. Shared expertise and contributions of hardware etc. from collaborators from many institutions around the world especially Argonne National Laboratory, DESY, INFN/LASA, Milano, Jefferson Lab, and SLAC, are noted and appreciated.

DEVELOPMENT OF SUPERCONDUCTING RADIO-FREQUENCY DEFLECTING MODE CAVITIES AND ASSOCIATED WAVEGUIDE DAMPERS FOR THE APS UPGRADE SHORT PULSE X-RAY PROJECT*

J. Holzbauer†, A. Nassiri, G. Waldschmidt, G. Wu
Argonne National Laboratory, Argonne, IL 60439, U.S.A.

Abstract

The Advanced Photon Source Upgrade (APS-U) is a Department of Energy (DoE) funded project to increase the available x-ray beam brightness and add capability to enhance time-resolved experiments on few-ps-scale at APS. A centerpiece of the upgrade is the generation of short pulse x-rays (SPXs) for pump-probe time-resolved capability using SRF deflecting cavities [1]. The SPX project is designed to produce 1-2ps x-ray pulses for some users compared to the standard 100ps pulses currently produced. SPX calls for using superconducting rf (SRF) deflecting cavities to give the electrons a correlation between longitudinal position in the bunch and vertical momentum [2]. The light produced by this bunch can be passed through a slit to produce a pulse of light much shorter than the bunch length at reduced flux. The ongoing work of designing these cavities and associated technologies will be presented. This includes the design and prototyping of higher- (HOM) and lower-order mode (LOM) couplers and dampers as well as the fundamental power coupler (FPC). This work will be given in the context of SPX0, a demonstration cryomodule with two deflecting cavities to be installed in APS in early 2014.

INTRODUCTION

The SPX project calls for the use of an RF deflecting-mode cavity to chirp electron bunches, giving the electrons a correlation between their longitudinal position in the bunch and their vertical momentum. Synchrotron light produced from this bunch can then be passed through a physical slit to create a shorter light pulse at the proportional sacrifice of total flux. This scheme was first proposed by Zholents [1]; the scheme can be seen in Figure 1.

A significant amount of design work has gone into the RF cavities required for this project, details of which can be found in [2, 3, 4, 5, 6, 7]. This cavity application has many specific challenges including the need to heavily damp all non-operational modes to preserve beam quality for other APS users.

CAVITY DESIGN

The current design is a squashed elliptical dipole-mode cavity with a Y-shaped end group and an on-cell damping

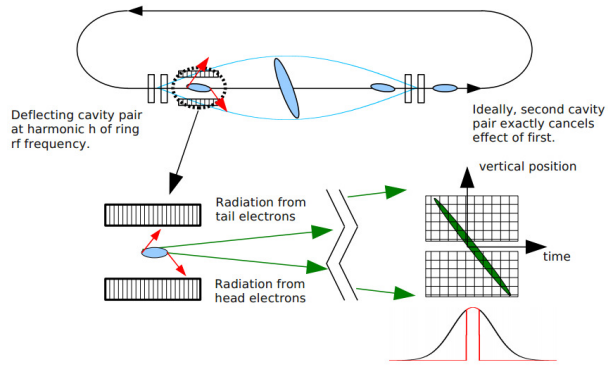

Figure 1: Schematic of Zholent's short pulse x-ray generation scheme. Image credit to [3].

port which can all be seen in Figure 2. Two of the waveguides from the Y end group will be used for damping of higher-order modes (HOMs) while the third will be primarily used as the forward power coupler. The on-cell damper is used primarily to damp the fundamental mode, called the lower-order mode (LOM). A list of the cavity parameters can be seen in Table 1.

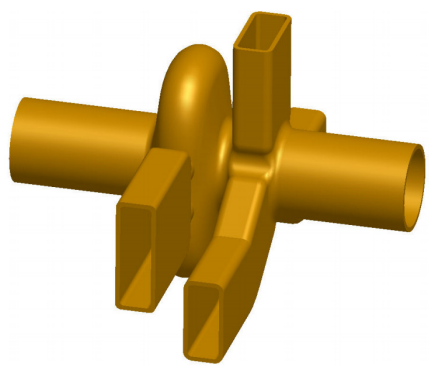

Figure 2: Schematic of a deflecting mode cavity for SPX. The LOM waveguide can be seen on-cell with the Y-end group (HOM dampers and FPC) to the right. Image credit to [3].

At this point, it is expected to use a BCP etching during cavity processing. Given the cavity parameters and this processing technique, 120 mT is the maximum expected reliable peak magnetic field. Given this and the requirement that each deflecting section have a total of 2 MV of

deflecting voltage to achieve 2-ps x-ray pulses [3], each cavity will be run at 0.5 MV deflecting voltage or 100 mT. In order to increase the operational margin, the possibility of electropolishing these cavities is being investigated.

HIGHER-ORDER MODE DAMPING

Because of the tight beam requirements, strong damping of non-operating modes was a focus of the overall cavity design. The squashed elliptical cavity geometry is meant to break the degeneracy of the dipole modes, increasing the frequency of the undesired dipole polarization as was done at KEK in the design of a similar deflecting mode cavity [8]. Significant work has been put into modeling of the cavities' broadband impedances [4], as well as the design of the HOM waveguides and dampers [7]. While the HOM waveguide design has been investigated in concept [9], their detailed design and packaging had not been considered until recently.

HOM Transitional Waveguide

Design of the SPX prototype cryomodule (SPX0) is well underway at JLab. Because of the broadband HOM damping requirements, it was decided to not use a window for the HOM dampers. This meant that all components of the HOM dampers would have to be assembled on the cold mass and had to fit inside the space frame for assembly. This is further complicated by the attachment of the tuner to the cavity very near to one of the HOM waveguide ports, making the HOM transitional waveguide (the waveguide running from the cavity to the damper itself) a very complex shape. This shape can be seen in Figures 3 and 4.

Despite these logistical requirements, the broadband transmission of this waveguide must not be compromised. The sizing of the HOM waveguide leading out of the cavity was chosen to have it's cutoff frequency between the operational frequency (2.815 GHz) and the first higher-order mode (estimated at 2.94 GHz). The waveguide must connect this custom sized waveguide to the HOM dampers which are based on WG340 waveguide. The placement and geometry of this taper was carefully considered to both give adequate attenuation of the operational mode and decent broadband transmission of HOM power.

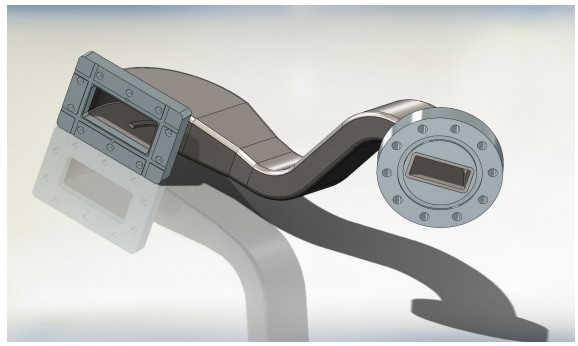

Figure 3: HOM Transitional Waveguide. Flange on the left connects to the cavity while the flange on the left connects to the damper assembly.

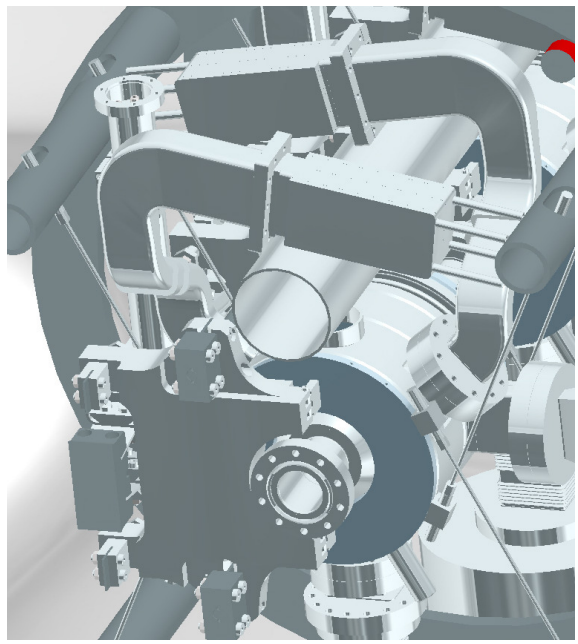

Figure 4: Section view of the SPX0 cryomodule space-frame mock-up. Cavity in helium vessel can be seen at the bottom of the image with tuner attached on the right side of the vessel. The HOM transitional waveguides and dampers can be seen crossing at the top of the image.

Given the space available, it was not possible to make the taper gradual enough to provide adequate broadband transmission because the first HOM (2.94 GHz) was still relatively close to cutoff. A ridge was added to this taper to improve transmission through the transition. The ridge was run through the taper on the wide wall and extended both toward the cavity into the S-Bend section and away from the cavity into the final, large radius bend. While this ridge improved transmission at 2.94 GHz, it also reduced transmission at some higher frequencies (3.0 GHz and 3.2 GHz) due to reflections off of the beginning of the ridge. The length of these ridge extensions was optimized to give the best broadband performance, the results of which can be see in Figure 5. The length of the ridge extension into

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

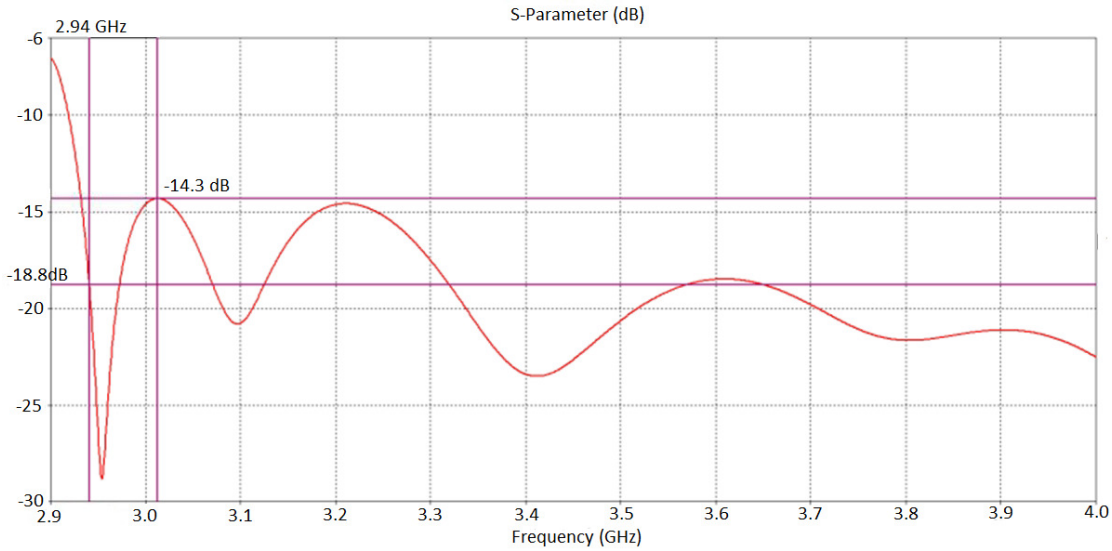

Figure 5: S11 parameter for the HOM Transitional Waveguide with optimized ridge. Reflection at the first HOM (2.94 GHz) is better than -18dB while the additional reflection cause by the ridge at 3.0 and 3.2 GHz is kept better than -14dB.

the S-Bend had the largest effect on performance. Longer ridges improved transmission at the first HOM frequency (2.94 GHz) but reduced performance at the higher frequencies. Without a ridge, S11 at 2.94 GHz was roughly -7dB, an unacceptably high reflection. Unfortunately, any reasonable ridge created the reflection at the higher frequencies which cannot be completely suppressed.

It is desired to keep the evanscant power from the operational mode reaching the HOM damper to below 10 W at full field to reduce total load on the damper. Simulations indicate that this traveling wave power should be 4.5 W, an acceptable number.

Waveguide Fabrication

When fabricated, the waveguide must be both mechancially robust and an adequate thermal barrier to keep the 2K heat load low. The HOM damper is water-cooled at room temperature outside the thermal shield and separated from the HOM transitional waveguide by a bellows, providing thermal resistance. The damper-end flange of this waveguide is expected to be strapped to the 80K cooling circuit. With a 1/8" wall of stainless steel and 10 microns of copper plating to improve RF performance, it is expected that this waveguide will contribute about 1.4 W (dynamic) to the 2 K heat load. Most of this comes from the evanescent fields in the beginning of the waveguide. Several fabrication methods are being considered for this complex geometry including fabrication from stainless steel sheet in parts, forming, and solid casting.

CONCLUSIONS

A credible design has been advanced for the HOM transitional waveguide. Prototyping is expected to begin in the coming months to validate the design and chosen fabrication process. SPX0 will provide an excellent test bed for this design and its interface with the cavity and HOM dampers. Results from this testing will be used to improved this design if necessary for the final SPX cryomodules.

Abstract

Some of the advantages of superconducting spoke cavities are currently being investigated for the high-velocity regime. When determining a final, optimized geometry, one must consider the possible limiting effects multipacting could have on the cavity. We report on the results of analytical calculations and numerical simulations of multipacting electrons in superconducting spoke cavities and methods for reducing their impact.

INTRODUCTION

Superconducting multi-spoke cavities for frequencies of 325, 352, 500, and 700 MHz and velocities of β_0 = 0.82 and 1 have been designed and optimized [1, 2, 3] for a variety of possible applications. These applications include, but are not limited to, compact machines such as future light sources and high-energy proton or ion linacs. Here we focus on what regions of these resonators are most susceptible to multipacting events.

When the internal surface of a rf cavity is exposed to the high fields maintained in a superconducting cavity, electrons (known as primary electrons) can be emitted from the metal. The kinetic energy and trajectory of these electrons is determined by the electromagnetic fields, and in many cases, they will come in contact with another part of the surface with a certain amount of impact energy. If this energy falls within the secondary emission yield (SEY) range, then additional electrons, known as secondary electrons, will be ejected [4]. Figure 1 shows a generic SEY curve. The parameters E^I_{oc}, and E^{II}_{oc} are known as the crossover energies for which δ = 1. E_{om} marks the electron energy for which δ is maximum. These parameters can vary greatly between materials. Even for a given material, these parameters can vary widely based on both the bulk properties and surface condition.

For well prepared niobium cavities, the crossover energies are around 150 eV and 1050 eV, while E_{om} is around 375 eV [5]. We have presented preliminary results for crossover energies of 150 eV and 2000 eV previously [2]. When secondary electrons are in resonant trajectories, and each impact energy is in the range for which $\delta > 1$, then a cascade can occur generating excessive heat, thus leading to thermal breakdown. These regions are commonly called barriers, and they are classified as either "soft" or "hard." Soft barriers are those that can be conditioned through and thereby passed. It is believed conditioning occurs because multipacting electrons actually clean the surface to a point where the secondary emission yield is below unity [7]. Hard barriers are those which persist resulting in a limited achievable gradient and quenching.

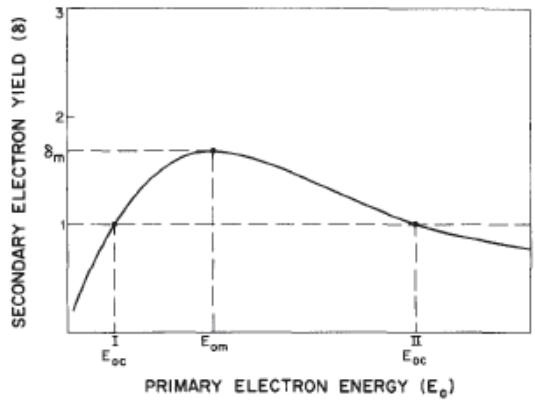

Figure 1: Definition of secondary-electron yield-curve parameters [6]

By improving the quality of the surface, the soft barriers on the gradient can be eliminated. On the other hand, hard barriers can only be overcome by changing the cavity geometry in such a way as to avoid resonant trajectories all together.

Multipacting is also characterized, most commonly, as either one-point or two-point. One-point multipacting occurs when the time of flight of the electron between two impacts is an integer number of rf cycles and that the electron's impact site is approximately the same as it's ejection site. This condition can be described in terms of the cyclotron and rf frequencies as [8],

$$\frac{f}{n} = \frac{eB}{2\pi m} \tag{1}$$

In the case of two-point multipacting, the time of flight is an odd number of half rf cycles and the impact site is not the same as the ejection site. The former condition can be described with the same parameters as (1) [9],

$$\frac{2f}{2n-1} = \frac{eB}{2\pi m} \tag{2}$$

MULTIPACTING ANALYSIS

In order to analyze the multipacting conditions in our optimized multi-spoke cavities, the 3D parallel tracking code Track3P contained in the ACE3P code suite developed by SLAC was used [10]. The cavity was divided into three regions as seen in figure 2. The regions labeled 1 and 3 include the end caps, half of one spoke, and the outer conductor enclosing the end accelerating gaps. The region labeled 2 includes half of each spoke and the outer conductor enclosing the middle accelerating gap. Due to the symmetry, regions 1 and 3 give similar enough results that we will only discuss 1 and 2.

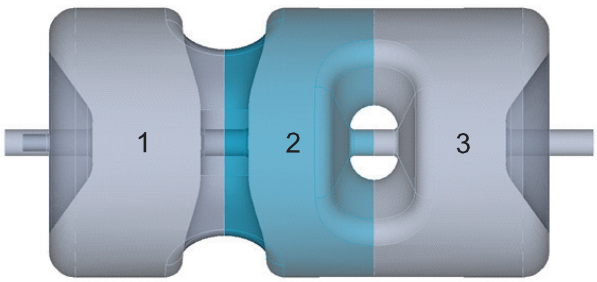

Figure 2: 325 MHz, β_0 = 0.82 cavity divided into three regions for multipacting analysis.

End cells

Figure 3 shows the resonant electrons surviving 50 rf cycles in region 1, along with their impact energies.

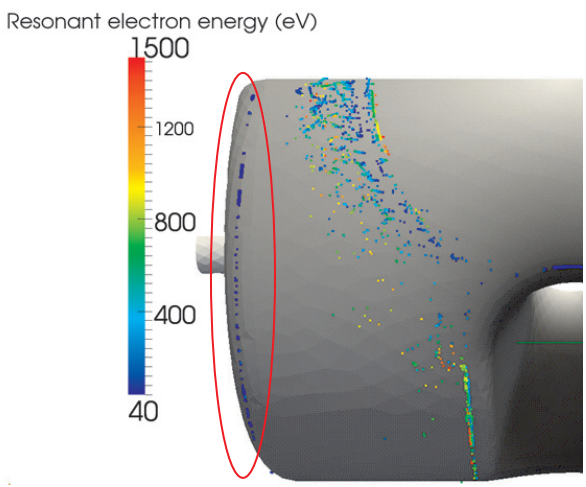

Figure 3: Resonant electrons and their impact energies surviving after 50 rf cycles as simulated by Track3P.

Figure 5 shows a plot of the resonant energies shown in figure 3. Upon inspection of figure 5, there are two observations to take note of. First, it appears that there are possible hard barriers between around 0.4 - 2 eV. Secondly, there are stable multipacting electrons at high field gradients. These electrons are found to be two-point, first order, and reside in the end cap area identified in figure 3. An example of these particle's trajectory is shown in figure 4.

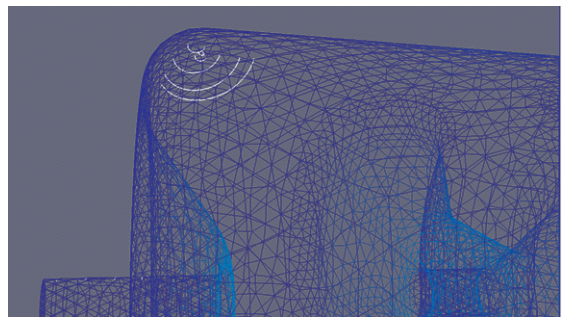

Figure 4: Two-point resonant electron trajectories in the end cap of the cavity.

The question of whether hard barriers exist has recently been tested on a similar cavity operating at 700 MHz, β_0 = 1. The cavity was designed and built in a collaboration between ODU and Niowave [3]. Multipacting analysis of that cavity showed a similar potential for hard barriers at low field gradients, but recent tests at 4.2 K have shown this not to be the case.

To address the question of soft barriers at high field gradient, the inset of figure 5 shows the multipacting electron energies present at 6 MV/m - 10 MV/m for this region of the end cap. The plots are for two different rounding radii at the outer edge, and the picture is of the end cap itself. A more subtle rounding (shown in black) has electrons with resonant impact energies of up to about 250 eV, although most fall below 150 eV. On the other hand, a larger rounding radius (shown in red), results in virtually all of the electron energies being below 100 eV.

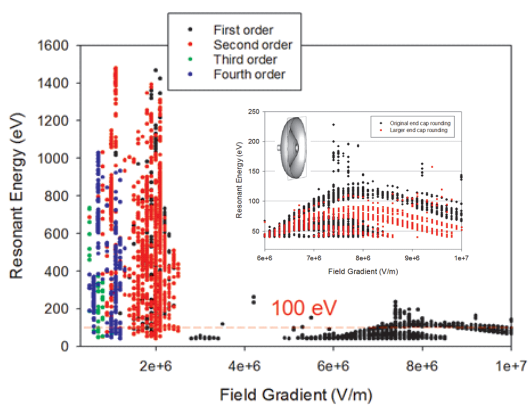

Figure 5: Resonant electron impact energy in region 1 for gradients up to 10 MV/m. The inset shows the impact energies for stable multipacting electrons for two different end cap outer rounding radii.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Center cell

The main regions of stable multipacting electron trajectories in the center accelerating gap are shown in figure 6. The low energy electrons (dark blue in color) are, as in the end caps, the ones that are still present even at high gradients. The energy of these electrons is shown in figure 7, and is similar, but slightly less than that of their counterparts at the end caps. These are also two-point, first order electrons which get trapped in the curvature where the spoke base meets the cylindrical outer conductor. As such, varying the curvature in this region can effect the electron's trajectory and impact energy. The inset of figure 7 is an example of this. For a smaller rounding radius (shown in black), there are a number of resonant electrons with energies between 100 and 120 eV for a field gradient of 7-9 MV/m. By increasing the rounding radius (shown in red), the maximum impact energy is now below 100 eV.

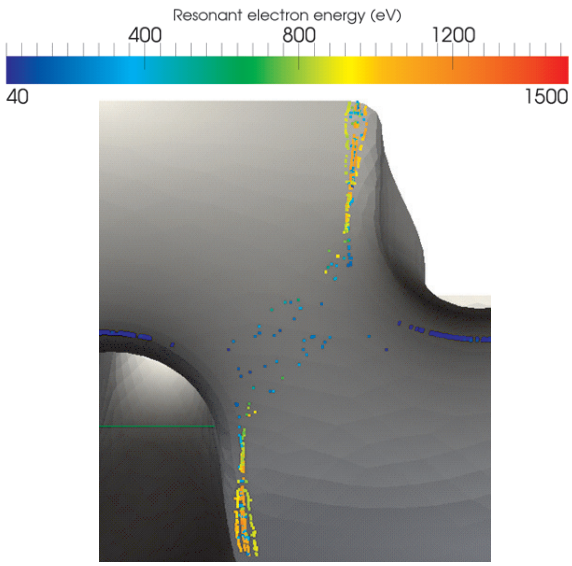

Figure 6: Resonant electrons and their impact energies surviving after 50 rf cycles as simulated by Track3P.

CONCLUSION

Multipacting simulations for multi-spoke cavities show that there is a potential for hard barriers at low field gradients and stable multipactors at high field gradients. However, recent prototype tests of an ODU designed, Niowave fabricated two-spoke cavity operating at 700 MHz has shown that these potential barriers should be able to be processed through.

Additionally, the soft barriers present at high gradients can be minimized by slightly altering the geometry in specific areas of the cavity. Both the end cap and spoke base rounding radius can be increased to a point where the stable, two-point, first order multipactors in these regions are likely to be conditioned away. Experiments at high gradients will have to be done in the future to verify this.

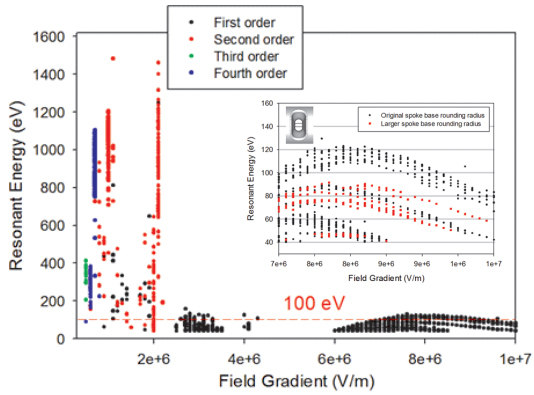

Figure 7: Resonant electron impact energy in region 2 for gradients up to 10 MV/m. The inset shows the impact energies for stable multipacting electrons for two different rounding radii where the spoke base meets the outer conductor.

ACKNOWLEDGMENT

We would like to thank Cho-Kuen Ng and Lixin Ge of SLAC for their helpful discussions on the Track3P code. We also thank Rocio Olave for her multipacting analysis of the 700 MHz cavity.

MECHANICAL STUDY OF FIRST SUPERCONDUCTING HALF-WAVE RESONATOR FOR INJECTOR II OF CADS PROJECT*

Shoubo He#, Yuan He, Weiming Yue, Shenghu Zhang, Ruoxu Wang, Cong Zhang, Mengxin Xu, Fengfeng Wang, Shichun Huang, Yuzhang Yang, Shengxue Zhang, Hongwei Zhao
Institute of Modern Physics, Chinese Academy of Sciences, Lanzhou, Gansu 730000, China

Abstract

Within the framework of the China Accelerator Driven Sub-critical System (CADS) project, institute of modern physics (IMP) has proposed a 162.5MHz half-wave resonator (HWR) Superconducting cavity for low energy section (β=0.09) of high power proton linear accelerators. For the geometrical design of superconducting cavities structure mechanical simulations are essential to predict mechanical eigenmodes and the deformation of the cavity walls due to bath pressure effects and the cavity cool-down. Additionally, tuning analysis has been investigated to control the frequency against microphonics and Lorentz force detuning. Therefore, several RF, static structure, thermal and modal analyses with three-dimensional code Traditional ANSYS have been performed [1]. In this paper, we will present some results about mechanical analysis of the first superconducting HWR cavity in order to further optimization in the near future.

INTRODUCTION

The cavity geometry has been optimized to reach the design frequency 162.5MHz and β=0.09 and also we want to minimize value of peak electrical and magnetic field on the cavity surface relative to the accelerating electrical field on the cavity axes (Bpk/Eacc and Epk/Eacc) [2]. So the fabrication technology and resonator structural properties including cooling down, vacuum, etching and so on, also should be taken into account at the beginning of design. SC HWR cavities are highly sensitive to mechanical deformations due to the small loaded bandwidth of some SCRF applications. So accordingly for HWR the stability of the cavity structure against any external distortions is the primer design goal. In order to improve df/dP for a low Beta HWR cavity, the typical approach is to add some stiffening ribs on the cavity, but it will not be discussed in this paper. Here, we will investigate this type of structure and then we will improve it in the future. Primarily structural analysis was completed to determine the locations of the model that were beyond yield strength.

Since CADS accelerator will work in CW regime, the main goal of our cavity structural design is a minimization of the resonant frequency dependence on the external pressure fluctuations. The general basics of the cavity structural design are to avoid using the plane surfaces as illustrated in Figure 1. Besides, four access ports at each cavity (two at the bottom, two at the top) guarantee draining off of the chemical etching and easy access to the inner surfaces during the high pressure water rinsing (HPR).

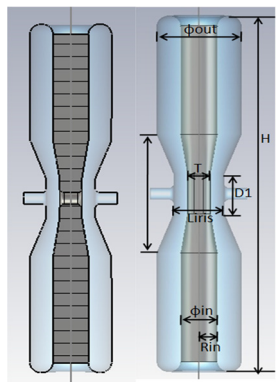

Figure 1: The cross section of HWR cavity with the main geometric parameters: Liris-iris to iris length, T-inner conductor thickness, D1-cavity diameter.

Table 1: Some Properties of HWR Cavity

Para.	Frequency	β	Diamater	Uacc	Epeak	Bpeak
Value	162.5	0.093	40	0.78	25	50
Unit	MHz	---	mm	MV	MV/m	mT

STRUCTURAL ANALYSIS

Injector II of CADS is composed by an ECR ion source, LEBT, RFQ and superconducting accelerating section. And in superconducting accelerating section, there are two cryomodules and each cryomodule is composed of 8 superconducting Half-Wave-resonator cavities and 9 superconducting solenoids. The proton beam will be accelerated from 2.1 MeV to 10MeV. Before structure analysis the geometry of HWR cavity was taken from a sat. model that was generated in software CST Microwave Studio and represented one cavity structure. The ANSYS RF results were compared to CST and to HFSS models of the same cavity for final verification. And the difference among these code result is only about 0.065%.

During mechanical analysis of HWR cavity, the variation of RF Eigen frequency was calculated, including pressure sensitivity, Lorentz force detuning, tuning sensitivity and resonant vibration and etc.. The

relationship between changes in RF frequency and mechanical deformations is given by the Slater Perturbation Theorem as the following equation 1, where E_0 and H_0 are the unperturbed electric and magnetic fields respectively, U_0 is the stored energy, f0 is the original cavity frequency, and Δf is the frequency shift:

$$\frac{\Delta f}{f_0} = \frac{\int_{\Delta v} (\mu_0 \left|\vec{H}_0(\vec{x})\right|^2 - \varepsilon_0 \left|\vec{E}_0(\vec{x})\right|^2) d^3x}{4 \cdot U_0} \quad (1)$$

PRESSURE SENSITIVITY

A sequential coupled field analysis RF-Structural-RF is used to predict the frequency shift due to cavity deformations under external pressure using codes ANSYS. As the cavity stiffening environment is hard to determine when cavity design, it is necessary to provide this research under two cavity beam port boundary conditions: fully fixed and completely free. The same meshed model was used for all types of simulations and that is very important as we can evaluate the frequency shift at the same scale.

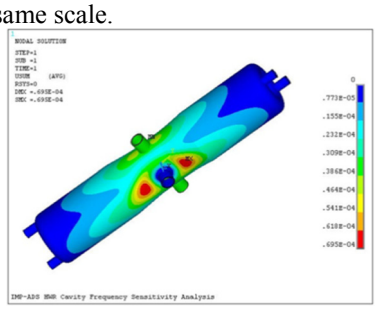

Figure 2: Structural analyses results of HWR with beam pipes fixed (cavity deformation).

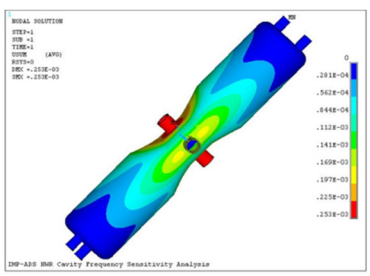

Figure 3: Structural analyses results of HWR with beam pipes free (cavity deformation).

Table 2: Pressure Sensitivity under 1 Atm

Boundary	Displacement	Stress	Δf	df/dp
fix	0.0695	5.786	17.892	23.54
free	0.252	19.066	110.773	145.6
Unit	mm	ksi	kHz	Hz/torr

From the above results we can see that the main frequency shift is caused by the beam port displacements. Although in this analysis the cavity has been simulated without helium vessel. While the helium vessel adds rigidity to the beam ports and in other words it is equivalent approximately to the fully constrained conditions. Whatever the different boundary condition, the cavity seems to be too soft so we need add some ribs on it for strength the cavity. And recently we just explore how to add these stiffening ribs.

Lorentz Force Detuning (LFD)

Since the superconducting HWR cavity will work in cw mode, so it will be static Lorentz force on the cavity walls. The pressure results in a deformation of the SC HWR cavity walls with changing the cavity volume by ΔV. And it creates the frequency shifts, which may be approximated as a perturbation using Slater's Theorem[3]. This shift is usually quantified by KL which is defined as

$$K_L = \frac{\Delta f}{(E_{acc})^2} \quad (2)$$

The numerical coupled analysis for LFD effect has been done and also an initial simulation of the cavity under beam pipes full constrain can be showed. From this formula, we can see that the frequency shift is proportional to the accelerating gradient. With the increase of accelerating gradient, the resonant frequency also decreases. Figure 4 shows the deformation of the cavity with LFD effect .

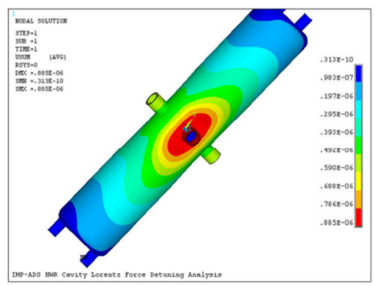

Figure 4: Deformation of the cavity wall (fix boundary condition)

From the above simulation the final fitting curve of the Δ f and E_{acc} is

$$\Delta f = -4.657 E_{acc}^2 - k \quad (3)$$

Finally according to the equation 2, the obtained Lorentz force detuning coefficient K_L is -4.657Hz/(MV/m)^2.

Modal Analysis

Generally speaking, it is difficult to eliminate vibrations in cavities because the situation around the cavity and the helium vessel is extremely complicated. In practice the structural modal analysis need to be provided with helium vessel fixed at the supports and tuner fixed by the tuner stem. While here the results is obtained from naked HWR cavity. And then we have the lowest frequency of modal analysis is 188Hz, which is far from the dangerous frequency obviously. Certainly it is need to

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

be further tested for all the accelerator with helium vessel, coupler, tuner and cryomudule etc. to verify the analysis.

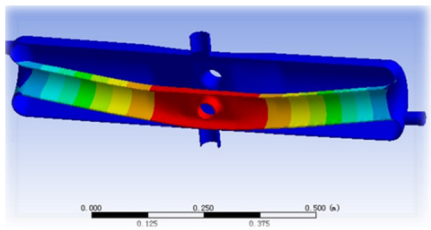

Figure 5: One of Model analyses results of HWR cavity with cleaning pipes free (cavity deformation).

Tuning Sensitivity

The role of the tuner is to ensure that the cavity resonance frequency will match the desired accelerator operating frequency. Tuners are generally made an active part of a complete RF control system which fulfills several functions. It stabilizes the frequency, amplitude, and phase variations induced by sources such as the RF drive, beam current variations, LFD, and microphonics. The usual tuning method for SC cavities is to change the length of the cells by mechanical adjustment of the overall length of the cavity. This method will not only bring in new HOM, but also not cause a big change for previous HOM[4].

The main factors that may be needed at the design of tuner are as follows:

- The tuning sensitivity of HWR cavity is 180KHz/mm;
- The spring constant of the HWR cavity is 2.2KN/mm;
- The limited space available (tuning range) is about 2mm.

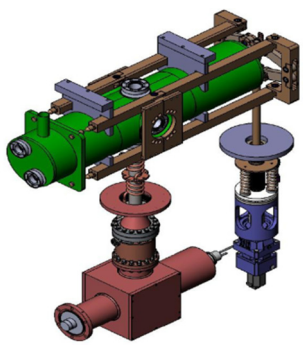

Figure 6: The IMP mechanical tuner: tuner(dark gray), helium vessel (green), and coupler (red).

Considering the fabrication tolerances for the cavity, the tuner may be able to retune the cavity over a range of 150 kHz cantered on the nominal operating frequency of 162.5 MHz.

Figure 7: Mechanical Tuner of HWR cavity test with copper HWR prototype .

CONCLUSION

We Mechanical analysis has been developed for 162.5 MHz SRF HWR cavities for the proposed CADS at IMP. The design of the tuner has been described and results of the static performance of the first copper HWR prototype have been got recently. In view of the mechanical results we find obviously that the SRF HWR cavity is much too sensitivity. So Some stiffening ribs must be added on the cavity wall. Besides, the coupled field analysis is in progress with more realistic boundary conditions ,including helium vessel.

ACKNOWLEDGMENT

We would like to thank Prof. Haipeng Wang and Dr. Gary Cheng of JLAB for the idea of simulations and helpful discussions.

Abstract

The Cross-Bar H-type (CH) cavity is a multi-gap drift tube structure operated in the H21 mode [1]. The Institute of Modern Physics (IMP) has been doing research and development on this type of superconducting CH cavity which can work at the C-ADS (accelerator driver sub-critical system of China). A new geometry CH cavity has been proposed which have smaller radius. It's suitable in fabrication, and it's can reduce cost too .Detailed numerical simulations with CST MicroWave Studio have been performed. An overall surface reduction of 30% against the old structure seems feasible. A copper model CH cavity is being fabrication for validating the simulations and the procedure of fabricating niobium cavity.

INTRODUCTION

C-ADS project with ambitious requirement regarding beam power and quality need new superconducting linac development. Superconducting Crossbar-H-Mode (CH)-cavities have two important features meet with the requirements of C-ADS. Superconducting CH cavity have high real estate gradients compared to conventional low-beta ion linacs, this feature will reduce the amount of cavity prominent. For the cross bar structure, CH cavities are more rigidly. This feature satisfy the harsh requirements of C-ADS about reliable. As this reasons, superconducting CH cavities have been choose as a backup cavity type for the C-ADS(see Fig.1). With respect to C-ADS actual application, one prototype of superconducting CH cavity (f=162.5MHz, beta=0.067, 6 cells) is presently being development in IMP.

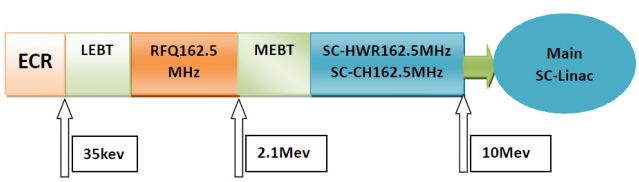

Figure 1: Layout of Injector-II for C-ADS.

NEW SHAPE SUPERCONDUCTING CH CAVITY

The superconducting CH cavity has electric and magnetic field structure similar with combine the 4-vane RFQ and DTL's. We can use a semi-analytical approach to estimate basic parameters like frequency. The parameter Rt and r1 are represent the radius of CH cavity and the tube radius of CH cavity respectively. Using this equivalent, we can get the resonance frequency with the radius Rt as following [1]:

$$\omega \approx c\left(\frac{0.73}{Rt^2\left(\frac{25}{144}+\frac{25}{72}Ln\left(\frac{Rt}{r1}\right)-0.2\right)}\right)^{1/2} \quad (1)$$

In case of the superconducting CH cavity of IMP, the frequency is 162.5MHz, r1 was 0.03m. Using the formula (1) can give radius Rt of the CH cavity is 0.29 meter. We have using the software CST to simulation. The radius of CH cavity is 0.32 meter [2].

The superconducting CH cavity is a complex cavity. With the radius of 0.32 meter, there are big surface. This means a large amount of high pure niobium needs and a more chance to come across defects. As in superconducting cavity, perfect surface is important for the cavity quality [3]. This size of CH cavity is not easy to protect from defects and contaminates or not suitable in the vacuum chamber of electric beam welding machine.

We try to cut a part of the girder called undercut [4] (see Fig.2).This undercut will increase inductance in the end of cavity, as this will increase the length of current flow. Increased inductance will lower the resonance frequency that we can get a smaller cavity structure in the same frequency (see Fig.3).

When we change the size of undercut in the girder of CH cavity, the radius will reduce with the width of girder liner. At most, we can reduce the radius of cavity by 20% (see Fig.4). As the radius reducing, the surfaces of the cavity reduce by 30% (see Fig.5).

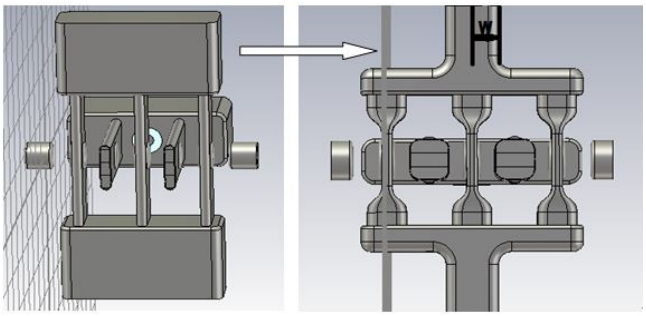

Figure 2: The copper CH cavity structure (left) and the CH cavity of use undercut in girder (right).

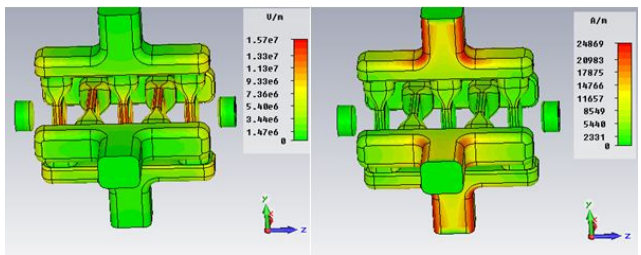

Figure 3: The electric field of use undercut CH cavity (left) and the magnet field of use undercut CH cavity.

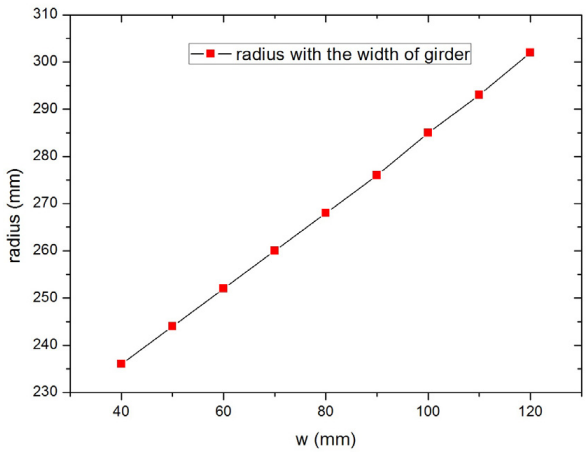

Figure 4: The radius of CH cavity with the width of girder.

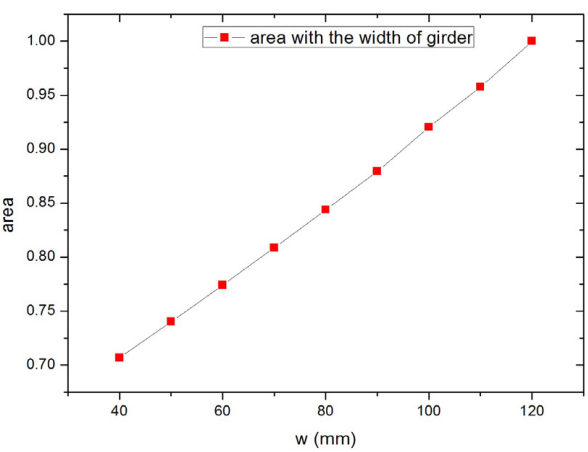

Figure 5: The surface of CH cavity with the width of girder.

This reduction has such advantages: as the cavity size became smaller, deep drawing dies became smaller too. It's easy to hand; the last electron beam welding joint have smaller length, less risk to burn a hole, easy to change position at the EBW; smaller use of high purity niobium, lower cost; less chance to come across defect in surface [4].

Field distribution variation with different undercut girder

The usage of undercut girder leads to a more homogeneous field distribution along the beam axis because the volume for the magnetic field is increased (see Fig.6).

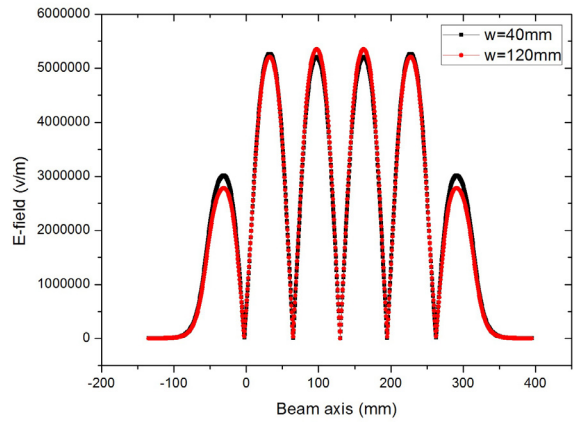

Figure 6: Field distribution of CH cavity with the different width of girder.

Frequency variation with different undercut girder

The frequency tuning is by compress and pulling the two side of cavity along beam axis. Different undercut girder influence the F/l (see Fig.7).

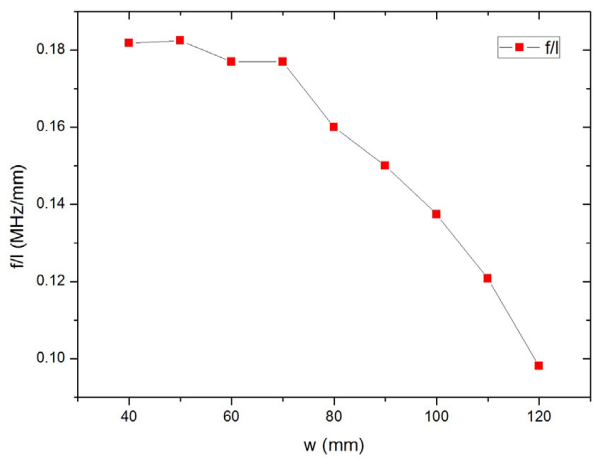

Figure 7: F/l of CH cavity with the different width of girder.

Copper prototype CH cavity fabrication

A copper prototype CH cavity has been built (see Fig.8) to validate the electromagnetic simulations, such as frequency (see Table1), field distribution along the beam axis, coupler size and position, tuning ability. And the CH cavity structure is complicate, need to check the design of dies and the path of electron beam weld in the fabrication.

Table 1: The EM parameters of the copper CH cavity

Parameter	Value	Unit
Frequency	162.5	MHz
Beta	0.067	
Ra/Q0	670	Ω
G	47	Ω
Epeak /Eacc	5.3	
Bpeak /Eacc	6.37	mT/ MV/m

OUTLOOK

We have design a superconducting CH cavity with smaller size. The future optimization will focus on lower the E_{peak} /E_{acc} and B_{peak} /E_{acc} , that it should be possible to reach higher effective voltages . The normal copper CH cavity will be finish at the end of 2012.

Abstract

In the development of new superconducting materials for possible use in SRF-based accelerators, it is useful to work with small candidate samples rather than complete resonant cavities. The recently commissioned Jefferson Lab RF Surface Impedance Characterization (SIC) system [1] can presently characterize the central region of 50 mm diameter disk samples of various materials from 2 to 40 K exposed to RF magnetic fields up to 14 mT at 7.4 GHz. We report the recent measurement results of bulk Nb, thin film Nb on Cu and sapphire substrates, Nb_3Sn sample, and thin film MgB_2 on sapphire substrate provided by colleagues at JLab and Temple University.

INTRODUCTION

SRF accelerating cavities for particle accelerators made from bulk niobium materials are the state-of-art for particle accelerators. Other materials, like thin film Nb on Cu, Nb_3Sn, and MgB_2 are of interest because of their potential cost and performance benefits in SRF applications. In this paper, we report the measurement results from bulk Nb, thin film Nb on Cu substrates and thin film MgB_2 on sapphire provided by colleagues at JLab and Temple University.

DESCRIPTION OF APPARATUS

The sample has been put at the open end of a TE_{011} cylindrical Nb cavity with a sapphire rod inside, described in [1] . The system provides a resonant field at 7.4 GHz. The cavity body, from which the sample is thermally isolated, is surrounded by liquid helium during the test, which differs from the previous measurements [2-4] by making the RF effect on sample the only contribution to the induced heat and resonance frequency change. Heat can be conducted from the sample only via the calorimeter. The effective surface impedance of the sample is derived by directly substituting heater heat for RF heat under controlled RF field and temperature conditions. This system can detect as little as 1 μW dissipated on the sample, enabling the resolution of surface resistance as low as 1.2 nΩ at 5 mT peak magnetic field. A cross-section of the SIC system is shown in Figure 1.

The effective surface impedance can be calculated from:

$$Z_s = \frac{E_Z}{H_Y} = \frac{P_{rf}}{\frac{1}{2}\int H^2(S)dS} + i\omega\mu_0\lambda = \frac{P_{rf}}{kB_{pk}^{\ 2}} + i\omega\mu_0(\lambda_{ref} + \frac{f - f_{ref}}{M})$$

with: $k = \frac{1}{2}\int B^2(S)dS \Big/ (\mu_0 B_{pk})^2$

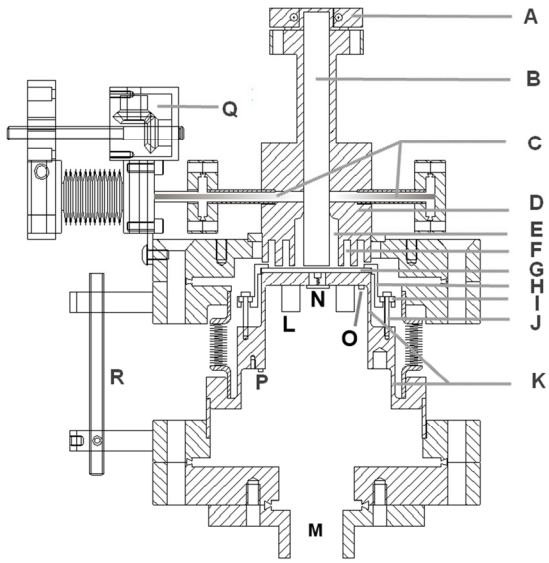

Figure 1: SIC system cross-section. A. Cap for sapphire rod, B. Sapphire rod, C. RF coupler, D. Nb cavity body, E. TE_{011} cavity, F. Double choke joints, G. Sample on top of copper sample holder, H. Stainless steel sample clamp, I. G-10 washer, J. Aluminium bolt, K. Upper and lower thermal insulators, L. Ring heater, M. Port for vacuum and wires. (Vacuum port of the cavity is not shown), N. Thermal sensor mounted on spring, O&P. Thermal sensor, Q. Coupler tuning mechanism, R. Gap tuning mechanism (1 of 3).

The real part is the effective surface resistance and imaginary part is the effective surface reactance. P_{rf} is the RF induced heat, $B(S)$ is the magnetic field distribution on the sample, M is the tuning sensitivity that represents the ratio between frequency change and penetration depth change. k and M are geometry dependent coefficients and ω is the resonant circular frequency. The RF induced heat is calculated from the difference between the power from the heater required to keep a constant sample temperature without RF fields in the cavity and the power from the heater required to keep the sample's equilibrium temperature unchanged when RF fields are present, so called power compensation technique. The change of effective surface reactance is proportional to the change of penetration depth. It may be discerned from the

frequency dependence of the TE_{011} mode as a function of sample temperature.

EXPERIMENT

A set of commissioning measurements (Fig. 2) have been accomplished using bulk niobium, thin film niobium grown by energetic condensation (EC) on polycrystalline copper substrates, a Nb_3Sn film on niobium, and MgB_2 films on single crystal sapphire. The EC film samples were drawn from a batch produced by extracting niobium ions from an ECR plasma onto a biased and heated substrate [5].

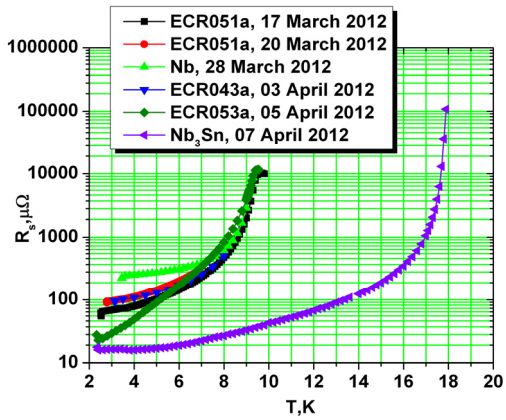

Figure 2: Measured surface resistance of several EC films, bulk Nb sample and Nb_3Sn sample.

Assuming 5% error in power measurement, 1% in current and voltage and 10% in loaded quality factor, the R_s measurement error is estimated to be ~ 20% (not shown). The measurements show high and inconsistent residual resistance at low temperature which is not yet understood.

Several EC samples were characterized with SIC the system. All samples show BCS resistance similar to that of bulk niobium. From the RF surface resistance at ~ 9.5 K in the normal conducting state, surface RRR of the films was estimated and is presented in Table 1 together with DC RRR measurements of co-deposited films. The difference between RF and DC measurement suggests variation in RRR values across the film.

Table 1: Transition temperatures, superconducting transition widths and surface RRRs of measured samples estimated from the data close to the transition temperature.

	RRR_{RF}	RRR_{DC}	T_c, K	ΔT, K
Bulk Nb	~ 60	>250	9.24	0.01
ECR051a	~ 40	54	9.30	0.30
ECR053a	~ 35	182	9.31	0.05
ECR043a	~ 50	289	9.29	0.20
Nb_3Sn			17.80	0.20

A Nb_3Sn sample that was produced at Jefferson Lab by a vapor deposition method was measured in the SIC system directly after the deposition. The R_s measurement shows the transition temperature of about 18 K, consistent with DC magnetization measurements. The film shows high RF surface resistance at the transition temperature suggesting a suboptimal film. This is consistent with the measurements done at Wuppertal University, which indicated that up to 0.5 μm needed to be oxypolished in order to achieve optimal RF performance. We plan to oxypolish the sample and measure the change in low temperature surface resistance as a function of removal.

MgB_2 on Sapphire

The principles of the HPCVD system used to produce the MgB_2 samples were described in references [6, 7]. Three 5 cm diameter samples were fabricated for SRF property characterization, two 200 nm thick (labelled MgB_2-200-I and MgB_2-200-II) and one 350 nm thick (labelled MgB_2-350). Small samples with 1×1 cm^2 size and 350 nm thickness have been fabricated for surface characterization.

The transition temperatures of MgB_2-200-I and MgB_2-200-II were both 39.3±0.2 K, while that of MgB_2-350 was 39.5±0.2 K.

The penetration depth λ_s may be derived from the effective penetration depth of thin films using the expression $\lambda_{eff} = coth(d/\lambda_s)$ [8] with d the film thickness. The results are plotted in Figure 3. The measurement errors of penetration depth and sample temperature are 5% and 0.01 K, respectively. Theoretical value based on BCS theory and Mattis-Bardeen's anomalous skin effect of a superconductor may be calculated using a code SRIMP, written by Halbritter [9]. Using the fitting routine developed by Ciovati [10], we find the suggested BCS model parameters for these MgB_2 samples $\Delta/kT_c = 1.08$, London penetration depth = 180 nm, coherence length = 6 nm, and mean free path = 38 nm.

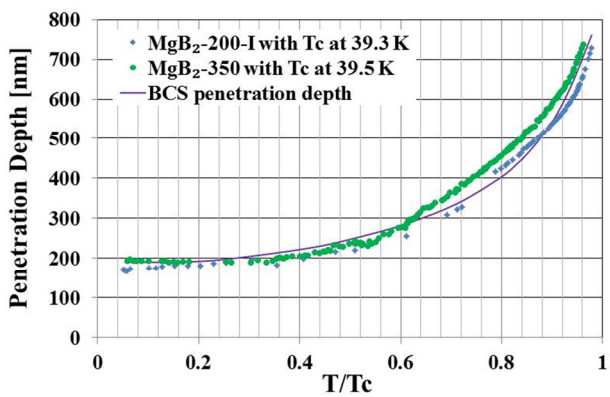

Figure 3: ◆MgB_2-200-I with T_c 39.3 K ● MgB_2-350 with T_c 39.5 K penetration depth versus sample temperature of MgB_2 on sapphire substrate – BCS penetration depth.

Figure 4 shows the effective surface resistance at 7.4 GHz of the MgB_2 samples, measured at temperatures between 2.1 K and 40 K, with peak fields between 0.6 mT

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

and 3.7 mT. The surface resistance of a large-grain Nb sample prepared by BCP etch, measured using the same apparatus, is plotted as a reference. At temperatures above 4 K, the MgB_2-350 sample has a lower surface resistance than Nb. At 2.2 K, the effective surface resistance decreased from 20 μΩ to 9 μΩ with the film thickness increase from 200 nm to 350 nm. The lowest effective surface resistance measured was 9±2 μΩ at 2.2 K, which is consistent with the previous best reported results [4, 11, 12] (using the f^2 rule for normalization) and with smaller systematic errors. We note that the 350 nm sample is less than two penetration depths thick at low temperatures and much less at higher temperatures. This must be taken into account when interpreting the effective surface resistance with respect to a BCS model. The microstructural defects or impurities revealed by XRD might explain why the samples' SRF performance <4K is not yet better than that of a near-perfect single crystal bulk Nb. These XRD measurements have been reported elsewhere [13] and suggest that the crystal quality of the epitaxial films may yet be improved. For the MgB_2-350 sample, the effective surface resistance versus magnetic field was measured with fields up to 10 mT at 3 K sample temperature. Results are shown in Figure 5. Effective surface resistance increased from 10 μΩ to 35 μΩ with increased fields from 0.5 mT to 10 mT.

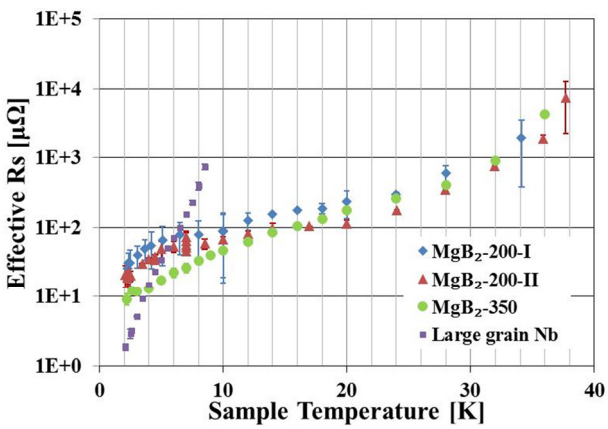

Figure 4: ◆MgB_2-200-I ▲MgB_2-200-II ●MgB_2-350 Effective surface resistance of MgB_2 on sapphire substrate ■Surface resistance of large grain Nb sample.

SUMMARY

The surface impedance characterization (SIC) system at Jefferson lab has been used to measure a variety of thin films on different substrates. In some circumstances the system appears to indicate anomalously high residual resistances that remain yet to be understood. From the data surface RRR values of the films were estimated. The first RF measurement of Nb_3Sn film produced at Jefferson Lab by the vapor diffusion method shows critical temperature of about 18 K consistent with DC magnetization measurements, but also suggests that the film performance may be improved by oxypolishing.

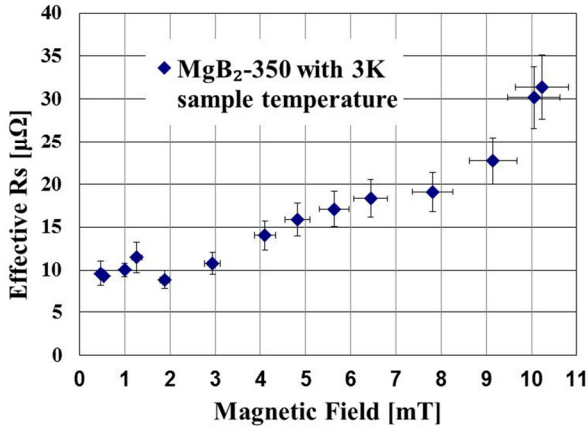

Figure 5: Effective surface resistance of MgB_2-350 versus magnetic field at 3 K.

Quality surface impedance characterization of MgB_2 films of two thickness has been accomplished. Extensive use of the SIC system for SRF material development is anticipated in the future.

THE NEW 2ND-GENERATION SRF R&D FACILITY AT JEFFERSON LAB: TEDF*

C. E. Reece and A. Reilly
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA

Abstract

The US Department of Energy has funded a near-complete renovation of the SRF-based accelerator research and development facilities at Jefferson Lab. The project to accomplish this, the Technology and Engineering Development Facility (TEDF) Project has completed the first of two phases. An entirely new 3,100 m^2 purpose-built SRF technical work facility has been constructed and was occupied in summer of 2012. All SRF work processes with the exception of cryogenic testing have been relocated into the new building. All cavity fabrication, processing, thermal treatment, chemistry, cleaning, and assembly work is collected conveniently into a new LEED-certified building. An innovatively designed 800 m^2 cleanroom/chemroom suite provides long-term flexibility for support of multiple R&D and construction projects as well as continued process evolution. The detailed characteristics of this first 2nd-generation SRF facility are described.

JLAB SRF FACILITY HISTORY

In 1987 the construction of CEBAF began on a green-field site in Newport News, Virginia. Since CEBAF was to be the first major research institution fully dependent on superconducting RF (SRF) technology in the US, a self-contained set of facilities using then-current technology were setup to support construction of CEBAF. To assure project success and on-going support capability, investments were made in chemical, cleanroom, assembly, and testing facilities that have served multiple needs for the subsequent +20 years.

These facilities enabled the construction of the 42 cryomodules for CEBAF, two cryomodules for the JLab FEL, 24 cryomodules for SNS, rework with upgraded techniques of the ten weakest cryomodules from CEBAF as part of the "C50 program" to establish a 6 GeV program, several prototype cryomodules, and most recently ten "C100" cryomodules for the CEBAF 12 GeV Upgrade project. These projects plus additional R&D programs accumulated over 4200 cavity preparation and vertical cryogenic testing cycles.

Participation in the SNS construction project and the ILC R&D program provided opportunities to make some improvement to the cavity cleaning and testing capabilities. The evolution and aging of the infrastructure resulted in adequate, but constrained capabilities and significant on-going maintenance challenges.

DOE SLI PROGRAM

The US Department of Energy has a program designed to upgrade existing substandard facility infrastructure within the Office of Science laboratory system. Jefferson Lab won a competitive award from this system, the Science Laboratory Infrastructure (SLI) program, to build the Technology and Engineering Development Facility Project (TEDF). The project allows elimination of substandard structures and provides improved:

- Energy efficiency
- Life-safety code compliance
- Work-flow efficiency
- Facility sustainability
- Human work environment
- Technical quality of facilities for future work

The completed TEDF project will provide new homes for members of several Jefferson Lab organizational units, including the SRF staff, most of the Engineering Division, and Physics Division instrumentation groups. The new building set will meet the "green building" standards of LEED Gold™.

TEDF CONCEPTUAL DESIGN

The architectural engineering firm EwingCole was retained to integrate user requirements into a coherent package. The firm took a blank-page approach to facility design, seeking to incorporate improved safety, energy efficiency, and work flow for SRF cavity development, fabrication, processing, assembly, testing, and provide increased build-out space for cryomodule assembly. Replacement of the cryomodule test facility and cavity vertical dewar test facility was briefly considered, but even simple duplication would have been much too expensive.

Lessons learned over the past +30 years of SRF cavity preparation were folded into facility requirements, as was equipment and support systems expertise from the semiconductor industry. This new facility was composed so as to strengthen our support of four parallel missions:

- Reliable on-going support for the CEBAF nuclear physics research program
- Research on performance-limiting aspects of SRF technology to push the net system costs down
- Development of new accelerating structures, improved SRF cavity processing methods, and prototype cryomodules for new applications
- Construction and delivery of SRF-based accelerator modules for Jefferson Lab and partner laboratories.

Anticipating the continued evolution of the designs, materials, and processes used in SRF cryomodules, the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

new purpose-built facility was designed with flexibility of use in mind.

NEW FACILITY DESCRIPTION

The Technology and Engineering Development Facility Project has completed the first of two phases. A new 3,100 m^2 SRF technical work facility has been constructed and occupied in the summer of 2012. This new structure was appended to the south end of the existing Test Lab building, home to all previous SRF work at JLab. Each of the SRF work processes with the exception of cryogenic testing has been relocated into the new building.

The second phase of the TEDF project is now underway, fully renovating the existing Test Lab building. All internal structures and utilities are being demolished and removed with the single exception of the SRF cryogenic test areas, the vertical test area (VTA) and the cryomodule test facility (CMTF). A fully reconstructed office wing will reoccupy areas that were formerly technical work areas. A large concrete shielding wall originally constructed in the 1960s for the NASA synchrocyclotron has been removed from the center of the high bay to allow growth of the VTA staging and support areas. During this second phase construction period SRF staff are temporarily located in a new multi-use building that was also constructed during phase one. A schematic layout of the new facility is presented in Figure 1.

Chemroom/Cleanroom Suite

A unique feature of the new TEDF SRF facility is the ~800 m^2 chemroom/cleanroom suite. Two separate chemrooms are provided, one for larger components and more production-style cleaning and chemical processing activities, the other for developmental and research activities. Both of these rooms are outfitted with acid-compatible exhausted wet benches, ultrasonic cleaners, and robust safety systems. To minimize manual handling of acids, supply of standard BCP and EP electrolytes will be provided directly to use locations from a nearby external building. The existing JLab horizontal electropolish cabinet has been relocated into the production chemroom. The air supply to both chemrooms is 100% HEPA filtered. Both chemrooms also have cleaning stations and pass-throughs that connect to the 380 m^2 cleanroom. All material enters the cleanroom via one of these routes. The cleanroom is ISO Class 5 and meets International Standard 14644. It has 100% HEPA filter coverage with at-grade perforated floor return.

When complete, an appendage from the cleanroom will extend into the Test Lab and under the existing bridge crane. From this horizontal-flow cleanroom SRF cavity vertical dewar test inserts will be assembled and transferred via the crane to the VTA for cryogenic testing.

Adjoining both chemrooms and one wall of the cleanroom is the Process Support Area (PSA). The PSA contains all process piping for the chemrooms and the cavity processing equipment/tools that are accessed from inside the cleanroom.

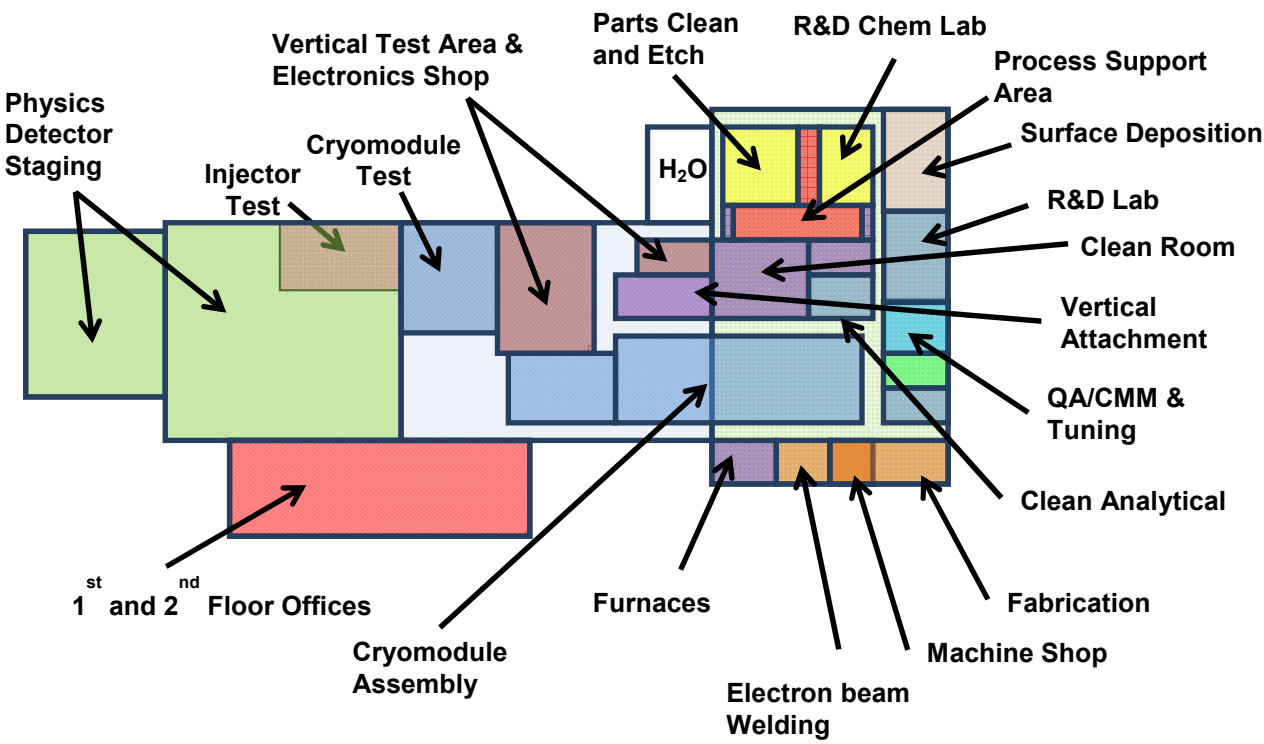

Figure 1: Overview schematic of new Test Lab/TEDF SRF facilities at Jefferson Lab, to be complete summer 2013.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The process tools are bulk-headed into the cleanroom from the PSA. Because of the actual and potential presence of hazardous acids, all effluent drains from the chemrooms and PSA, as well as any potential spills, gravity drain through the PSA to an external collection tank. A new acid neutralization system draws from this tank and increases the pH to an acceptable level before discharge to the sanitary system. The acid waste neutralization system has a capacity of 60 gpm.

The TEDF project provides new infrastructure, but not new equipment. The BCP acid etch cavity processing tool, high pressure cavity rinse tool, and vertical electropolish development tool have been relocated into the PSA, with front face open into the new cleanroom. (See Figure 2.) Hook-up and commissioning of the process tools are underway. The horizontal electropolish system, used for the 12 GeV Upgrade cavities and ILC cavity R&D, has been relocated into the production chemroom and is being recommissioned.

Figure 2: BCP and HPR tools bulk-headed into new cleanroom.

Water System

The new SRF ultrapure water (UPW) system has a makeup water capacity of 60 gallons per minute (gpm) and a polish water capacity of 120 gpm (90 gpm ambient loop and a 30 gpm hot UPW loop @ 60ºC). The UPW system is designed to produce microelectronics grade water with a resistivity of 18.2 Mohm-cm, total silica less than 3 ppb, total oxidizable carbon (TOC) below 2 ppb and an overall quality equivalent to type E-1.1 as specified in ASTM D5127-07, with the exception of dissolved gases and boron. This water is plumbed to all chemroom work locations and to each tool in the PSA.

Materials Research and Development

Within the large cleanroom an interior room is allocated to analytical equipment focused primarily on particulates that can generate field emission inside of accelerator cavities. The scanning electron microscope/scanning field emission microscope (equipped with EDS and EBSD) and field emission viewer systems have been relocated here.

The several JLab surface deposition systems have been collected into a common lab in the new facility. These include the general-purpose sputter coating system, the ECR plasma niobium energetic condensation research system, the UHV multi-technique deposition system, and a fledgling niobium HIPIMS deposition system. The infrastructure in this lab was also laid out to accommodate eventual addition of thin film coating systems for multi-cell cavities as those techniques mature.

Cavity Fabrication Facilities

The TEDF project has enabled JLab to retain and strengthen its SRF cavity development and prototyping capability. The sheet metal forming and machining equipment have been consolidated. The electron beam welder was relocated into a dedicated room in the new facility and its vacuum system was upgraded. The set of brazing and high temperature vacuum furnaces were collected into a common room. The cavity tuning and inspection stations were also collected together conveniently.

Cryomodule Assembly Facilities

As a result of the need to accommodate the concurrent assembly of 12 GeV cryomodules for CEBAF during the TEDF realization period and also address on-going maintenance and future construction projects, the cryomodule assembly facility is laid out as four parallel assembly lines. During the second phase of the TEDF project, when access to the Test Lab high bay is unavailable, only half of these four lines are available, and two are dedicated to completion of the remaining 12 GeV “C100” cryomodules. These extended assembly rail systems will create the opportunity to serve up to four independent activities/projects simultaneously in 2014 and beyond.

SUMMARY

Realization of a new state-of-the-art SRF facility is in progress at Jefferson Lab. Its purpose is to provide high-quality support to local, national, and international needs for SRF accelerator system development and construction.

A NEW INTERNAL OPTICAL PROFILOMETRY SYSTEM FOR CHARACTERIZATION OF RF CAVITY SURFACES – CYCLOPS*

C. E. Reece[1], A. D. Palczewski[1], H. Tian[1], J. Bearden[2], and L. Jacobs[2]
[1]Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA
[2]MicroDynamics Inc., Woodstock, GA 30189, USA

Abstract

Jefferson Lab has received and is commissioning a new interferometric optical profilometer specifically designed to provide internal surface mapping of elliptical rf cavities. The CavitY CaLibrated Optical Profilometry System – CYCLOPS – provides better than 2 μm lateral resolution and 0.1 μm surface height resolution of programmatically selected locations on the interior surface of multi-cell cavities. The system is being used to provide detailed characterization of surface topographic evolution as a function of applied surface treatments and to investigate particular localized defects. We also intend to use the system for 3D mapping of actual interior rf surface geometry for feedback to structure design model and fabrication tooling. First uses will be illustrated. CYCLOPS was developed and fabricated by MicroDynamics Inc., Woodstock, GA, USA.

INTRODUCTION

The performance of superconducting resonant rf structures used for particle acceleration is quite often limited by localized surface defects. Developing an understanding of the nature of such defects and their origin is critical to confidently avoiding their occurrence. The surface of interest is the interior of a complex three-dimensional object, which presents a major impediment to the development of such an understanding.

External thermometry during cryogenic rf testing provides confident localization of anomalous heating to within ~1 cm. Use of such thermometric mapping has been followed up with visual inspection by careful non-contacting insertion of a camera and illumination system such as that developed at Kyoto University [1], and by use of long-range microscopes with mirror and lighting inserted into the cavity [2]. Such visual inspection provides valuable information about the morphology of the defect region, but is very difficult to interpret quantitatively. In addition to characterization of defects, quantitative topographical information is needed to refine the understanding of cavity surface topography evolution as a function of applied processing steps, whether mechanical or chemical, to optimize those processes for both effectiveness and economy.

One route to obtain quantitative topographic information from a location of interest is by forming a replica mold of the region which may then be examined with external profilometry tools. This has been successfully accomplished for a few defect spots in multi-cell cavities [3, 4], and even accomplished without affecting the performance of the cavity. Such technique, however, can hardly be envisioned for extensive use.

A more attractive solution would be provided by optical interferometric profilometry accomplished on the interior of the finished cavity. Though perhaps conceptually straightforward, the realization of such a system presents significant motion control challenges.

MicroDynamics Inc. [5] has developed such a system, called CavitY CaLibrated Optical Profilometry System (CYCLOPS) and delivered it to Jefferson Lab. Commissioning of the CYCLOPS is underway.

SYSTEM DESCRIPTION

This unique system provides optical inspection and quantitative profilometry of the interior surface of cylindrically symmetric structures that have axial clearance of at least 48 mm diameter. The system can accommodate structures up to 1.5 m in length and diameter up to 34 cm. See Figure 1.

Figure 1: CYCLOPS setup at Jefferson Lab.

The system is oriented vertically with the non-contacting optical probe traveling down the cylindrical axis. The probe consists of two concentric hollow cylinders, an outer probe which positions a lower mirror,

and an inner probe which moves vertically with the balance of the optical system, including the reference leg of the interferometer. The displacement between the inner and outer probes establishes the distance of the focal plane away from the bottom mirror. The bottom mirror has a precision tilt control. The range of motion of the mirror provides a view 80º up to 30º down from horizontal.

Because the system is optimized for a very narrow depth of field for interferometric measurements, the cavity interior surface is best observed with the height of the bottom mirror and its tilt angle set to provide normal incidence on the surface of interest. A cavity to be inspected is mounted from below on a fixed-height rotary stage.

The four position control parameters of CYCLOPS are accessed via a computer interface and together establish a unique location in the 3D coordinate frame of the system to a precision of typically about 1 μm.

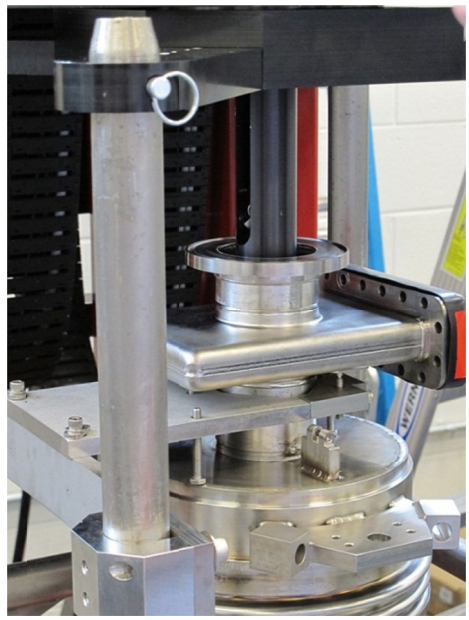
Reflections from the cavity surface return to a CCD camera. Surface profile data is derived by tracking the interference fringes from a blue LED through a series of acquired digital (1600 × 1200) optical images from an area approximately 2.6 × 2.0 mm. The focal plane is incremented through the surface during this series. Optical element position resolution is 78 nm, roughly $1/6^{th}$ of the optical wavelength. A non-interferometric, lower magnification mode provides a ~ 5 × 4 mm field of view for manual scanning operations.

OPERATION

A cavity to be examined may either be flange-mounted directly to the rotary headstock or aligned in a standard JLab cavity handling frame, which in turn is mounted to a spider fixture attached to the rotary table as in Figure 2.

Because best results are obtained when the surface is viewed with near-normal incidence, a CAD file of the cylindrically-symmetric design contour of the cavity is loaded as an input to CYCLOPS. Registration of the system's vertical coordinate, $z = 0$, to the design is accomplished by manual control and observation. Subsequently, the operator may specify the elevation of interest and request an auto setup of the system parameters so as to view that location in space with normal incidence to the design surface. Such setup is available except when the slope of the cavity wall is too steep to obtain normal incidence.

The operator then adjusts the position of the focal plane to the real surface and adjusts the field of view to the region of interest. The focus is then further refined to observe interference fringes. A series of digital images is acquired as the focal plane is scanned through the surface. Image processing then tracks the fringes between images and infers topographic information, finishing with a profilometry array for graphical display and further analysis, such as cross-section display, statistical characterization, etc.



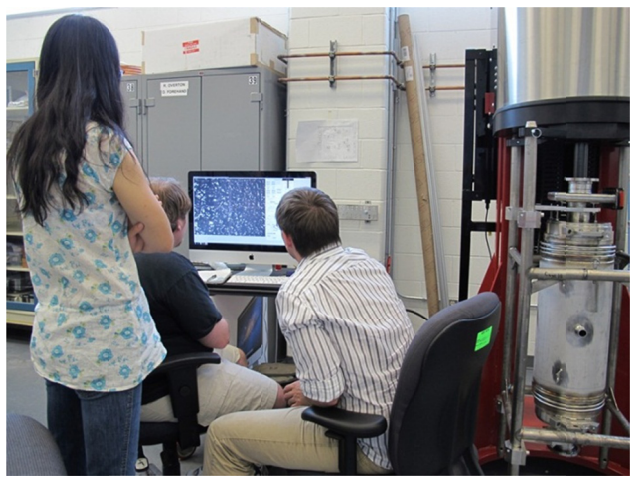


Figure 2: CEBAF upgrade cavity mounted on CYCLOPS for inspection.

Figure 3 shows the user interface while inspecting an intentionally drilled hole in a single cell test cavity. The right-most panel gives the operator graphical feedback on the location being viewed. The left panel is the live digital image. In between is the motion control panel for use by the operator.

Figure 4 is a rendering of the resulting profilometry scan for this defect. Due to the extreme depth of the hole, no interference fringes were observed there, so this region remains unresolved.

At present, operation is limited to user driven analysis of specific locations. Our intent is to continue to develop the user interface and to gradually increase the degree of automation in surface characterization and defect recognition.

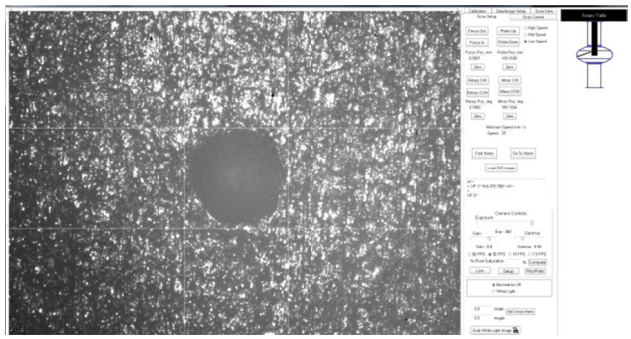

Figure 3: CYCLOPS user interface inspecting a 680 µm diameter drilled blind hole.

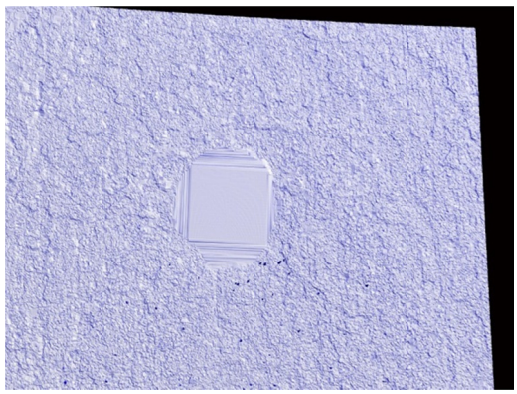

Figure 4. Interferometrically reconstructed surface profile from the surface imaged above.

Another intended use for CYCLOPS is as a tool for mapping the actual internal surface of multicell cavities for comparison with the theoretical design surface. Creating a 3D point cloud mapping of the actual surface will be valuable feedback to both the cavity sheet metal and welding fabrication processes. The feedback is also valuable for RF modelling, which is increasingly called upon to anticipate the field configurations of multiple higher-order modes as well as the fundamental accelerating mode. Subtle shape deviations from designs can have significant effects on the field configuration of such modes in multi-cell cavities. The CYCLOPS software to accomplish this mapping mission has not yet been commissioned.

SUMMARY

A new system for inspecting and characterizing the interior surface topography of cylindrically symmetric RF accelerating cavities has been developed. The system provides a helpful bridge between *ex situ* material studies and *in situ* visual inspections of "normal" and "defect" surfaces. Further automation of CYCLOPS is planned for the near future.

Abstract

eRHIC will collide high-intensity hadron beams from RHIC with a 50-mA electron beam from a six-pass 30-GeV Energy Recovery Linac (ERL), which will utilize 704 MHz superconducting RF accelerating structures. This paper describes the eRHIC SRF linac requirements, layout and parameters, five-cell SRF cavity with a new HOM damping scheme, project status, and plans.

INTRODUCTION

The proposed electron-ion collider eRHIC will collide ions from one of the rings of the existing heavy-ion collider RHIC with electrons from a new accelerator to be installed in the RHIC tunnel [1, 2]. eRHIC will utilize several superconducting RF accelerators. Layout of the SRF systems in the RHIC tunnel, their description, and main parameters were presented elsewhere [3]. The main electron accelerator, the subject of this paper, is a six-pass ERL with two 2.45-GeV SRF linac sections. After six re-circulations, the electron beam energy will be as high as 30 GeV.

SRF LINAC

Each SRF linac section will be 200-meters long. Due to rapid increase of the synchrotron radiation power at high energies, the beam current will be lowered at energies above 20 GeV to keep the total power loss below 10 MW. Thus, the highest luminosity will be achieved at 20 GeV. Parameters of the SRF linac are listed in Table 1.

Installing a shorter linac first and then gradually adding more SRF cryounits will stage the energy of the machine. The initial energy of the main ERL will be 10 GeV with three or four re-circulations. Only one linac section will be installed at this stage of the project.

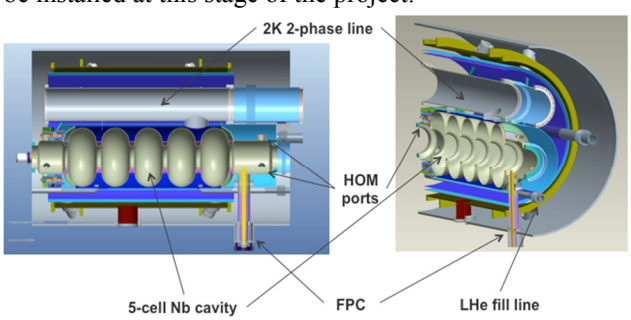

Figure 1: Preliminary layout of a cryounit for eRHIC.

Table 1: Parameters of the Main ERL Linacs

Energy gain per linac section at 30 GeV	2.45 GeV
Beam current per pass (E ≤ 20 GeV)	50 mA
Bunch frequency	14.1 MHz
Bunch length	2 mm rms
RF frequency	703.8 MHz
Linac length	2×200 m
No. of cavities per linac	2×120
Filling factor	0.64
Cavity type	Elliptical, 5-cell
E_{acc} at 30 (20) GeV	19.2 (12.7) MV/m
Peak detuning due to microphonics	6 Hz
Q_{ext} FPC	5.9×10^7
RF power per cavity	10 kW
Total heat load at 1.9 K	5,700 W
Total heat load at 50 K	12,000 W

The SRF linac utilizes five-cell, 704-MHz cavities, described in the next section. Each cavity will be housed in an individual cryounit (Figure 1). A series of such cryounits will form one long cryomodule per section of the linac, with one-meter long transitions to room temperature at each end. The linac's accelerating gradient will reach 19.2 MV/m when operating at the highest energy. At 6 Hz peak detuning due to microphonic noise, the RF power is under 10 kW per cavity. The cavities will be powered from individual solid-state RF amplifiers.

FIVE-CELL CAVITY AND OTHER COMPONENTS

Cavity and HOM Damping

A superconducting cavity for high-current applications [4-6] is shown in Figure 2. The cavity, named BNL3, has an optimized geometry that supports strong damping of higher order modes (HOMs) while maintaining good properties of the fundamental mode. The damping is accomplished via six antenna-type couplers attached to the large diameter beam pipes [7]. The simulations show that this HOM damping scheme provides sufficient suppression of the parasitic impedance to satisfy eRHIC requirements. The cavity parameters are listed in Table 2.

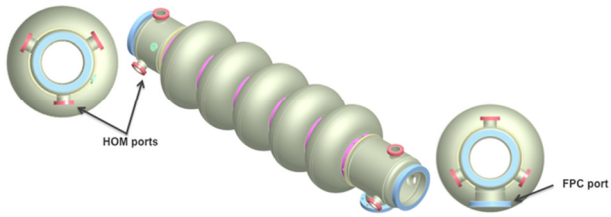

Figure 2: Five-cell 704-MHz SRF cavity for eRHIC.

Table 2: Parameters of the BNL3 Cavity

R/Q	506.3 Ohm
Geometry factor	283 Ohm
Cell-to-cell coupling factor	3.02%
Cavity loss factor (at σ_z = 2 mm)	3.96 V/pC
Cavity Q_0	4×10^{10}
E_{peak}/E_{acc}	2.46
B_{peak}/E_{acc}	4.27 mT/(MV/m)
Lorentz force detuning coefficient	0.45 Hz/(MV/m)^2
HOM power per cavity	7.3 kW
Operating temperature	1.9 K

Structural and thermal analysis, the cavity mechanical design, fabrication of a copper model and the first niobium cavity were done by AES, Inc. as part of collaboration with Stony Brook University and BNL. The full-scale copper model was designed and built with detachable end groups to provide more flexibility in studies of its HOM properties [6]. Because of a large cell-to-cell coupling, the initial field flatness was already very good at 90% right after manufacturing. It was improved to ±1.2% after tuning. The copper cavity is shown in Figure 3. A copper prototype of the HOM coupler is fabricated, and the HOM studies on this cavity are in progress [6].

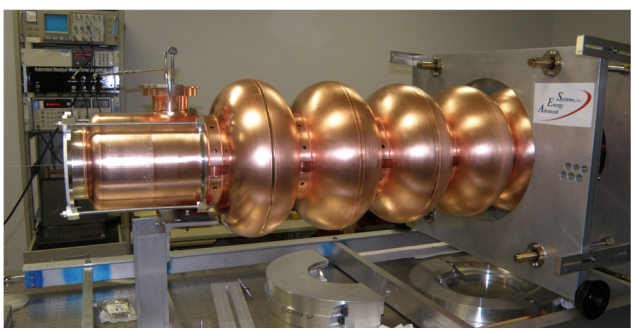

Figure 3: BNL3 cavity copper model undergoing frequency tuning at AES.

Fabrication of the first niobium cavity, BNL3-1, was completed recently at AES (Figure 4). It was made using 3-mm thick high-RRR material. All flanges are Conflat. RF measurements showed field flatness of ±3% and the resonant frequency within the specification so no cavity tuning was necessary after fabrication. The cavity is now being prepared for BCP, 600ºC vacuum bake and HPR. It will be tested at the BNL's vertical test facility in late 2012/early 2013.

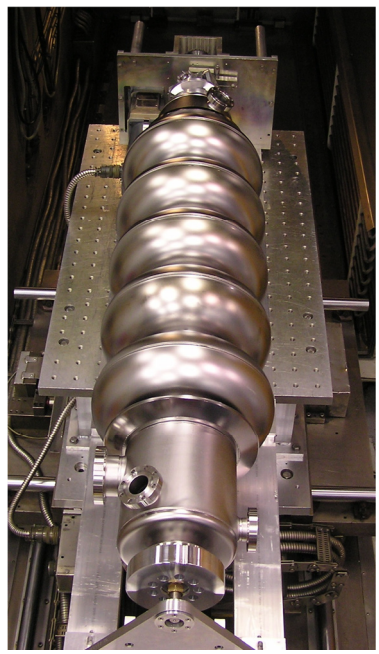

Figure 4: The first niobium BNL3 cavity (courtesy of AES).

Fundamental Power Coupler

As the RF power requirement for the eRHIC ERL cavities is relatively low (10 kW), the main emphasis of the fundamental power coupler (FPC) design is on minimizing its heat leak to 2 K system. Preliminary considerations [8] show that with a proper heat intercept the heat load at the cavity end is less than 0.4 W.

CRYOMODULE FOR COHERENT ELECTRON COOLING EXPERIMENT

The BNL3 cavity was chosen to provide an energy boost of 20 MeV to electrons in the Coherent electron Cooling Proof of Principle (CeC PoP) experiment in RHIC [9]. The new cavity (BNL3-2) and a single-cavity cryomodule are on order from Niowave, Inc. In addition to serving as the CeC PoP linac, it will provide valuable information for designing future eRHIC cryounits.

The BNL3-2 cavity will be fabricated from a 2.8-mm thick high-RRR niobium and will have a few design differences w.r.t. BNL3-1, while being interface-compatible with it. BNL3-2 will undergo processing similar to BNL3-1. The vertical testing at BNL is expected in mid-2013. Based on their vertical test

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

performance, one cavity will be chosen for incorporating in the cryomodule.

SUMMARY

A 30-GeV ERL is proposed for the future electron-hadron collider eRHIC. The main ERL linac is based on five-cell, 704 MHz elliptical SRF structures. The cavities will have to accommodate high average beam currents and will have to be strongly HOM-damped to satisfy requirements imposed by BBU. The optimized cavity shape has been developed and the design of the HOM coupling scheme is in progress at BNL. The first cavity, BNL3-1, has been fabricated by AES and is being prepared for vertical testing. The second cavity is on order from Niowave. One of these prototype cavities will be used for the CeC PoP experiment.

Abstract

BNL is developing several superconducting RF guns for different applications. The first gun is based on a half-cell 1.3-GHz elliptical cavity. This gun is used to study generation of polarized electrons from GaAs photocathodes. The second gun, also of a half-cell elliptical cavity design, operates at 704 MHz and is designed to produce a high average current electron beam for the R&D ERL from multi-alkali photocathodes. The third gun is of a quarter-wave resonator type, operating at 112 MHz. This gun will be used for photocathode studies, including a diamond-amplified cathode, and to generate a high charge, low repetition rate beam for the coherent electron cooling experiment. In this paper we describe the gun designs, present recent test results, and discuss future plans.

INTRODUCTION

Developing superconducting RF (SRF) photoinjectors is a part of the SRF program that is important for several projects in progress or under consideration at the Collider-Accelerator Department of BNL. The SRF photocathode guns promise to generate high-bunch-charge, high-average-current, low-emittance electron beams. The three SRF guns described in this paper address different issues, from generating polarized electrons, to experimenting with different photocathodes, to producing high-intensity beams for energy recovery linacs and electron coolers.

1.3 GHz SRF PLUG GUN FOR GaAs PHOTOCATHODES

SRF guns, which combine excellent vacuum conditions of DC guns and high accelerating gradients of RF guns, potentially can generate very low emittance polarized electron beams from GaAs photocathodes with long lifetime. Our simulations show that a SRF gun can exceed the ILC's requirement for vertical beam emittance by a factor of two, if an ellipsoid charge distribution is used. There will be no need for a damping ring.

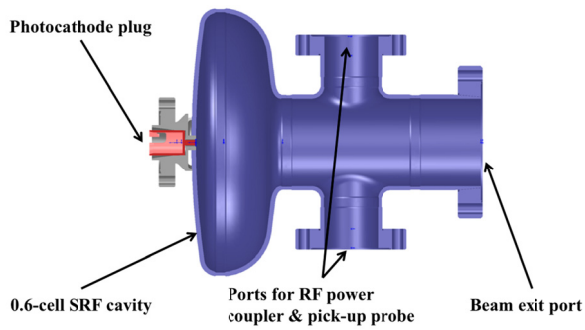

Figure 1: BNL 1.3-GHz plug SRF gun cavity.

Table 1: Parameters of the 1.3 GHz SRF gun

RF frequency	1300 MHz
Cavity active length	0.6 cell
Energy gain	0.6 MeV
Maximum field at the cathode	15 MV/m
e^- emission RF phase at 2.5 MV	20º
Cavity Q_0 at 2 K	7×10^9
Cavity operating temperature	2 K
Bunch repetition frequency	81.25 MHz
Bunch charge	0.12 pC
Bunch length	10 ps
Cathode spot size	2 mm dia.

We are using a 0.6-cell 1.3-GHz SRF plug gun to test the quantum efficiency (QE) and lifetime of a GaAs photocathode. It has got its name from a removable niobium plug holding a cathode and located at the back of the gun. The gun and cathode transfer system were

*Work is supported by Brookhaven Science Associates, LLC under contract No. DE-AC02-98CH10886 with the US DOE. The work at Niowave is supported by the US DOE under SBIR contract No. DE-FG02-07ER84861.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

designed and fabricated by AES, Inc. [1]. Figure 1 illustrates the cross section of the gun and Table 1 lists its main parameters. The Q_0 of 3×10^8 was obtained in a vertical test of the gun with a GaAs photocathode at JLab [2]. With our improved photocathode holder design, the Q_0 of the gun is estimated to be higher than 5×10^8.

A beam line for the beam test has been assembled and leak checked. A high temperature vacuum bake of the gun is necessary to achieve 10^{-11} Torr vacuum. Nb-Ti flanges began leaking during the bake. We plan to replace Nb-Ti flanges with two Conflat flanges, which can hold the high temperature easily. The refurbishment of the gun will be finished soon, and the final photoemission measurements are expected to take place in a few months.

The VTA test of the gun with the new holder and cathode is scheduled for mid-October of 2012. The goal of this is to test heat generating mechanism of the heavily doped GaAs in RF field. We successfully activated the bulk GaAs in a preparation chamber. The highest QE was 10% at 532 nm, which dropped to 0.8% after passing the photocathode through a transfer section to the gun [3].

704 MHz SRF GUN FOR R&D ERL

The R&D ERL at BNL is a facility dedicated to develop accelerator technologies for future energy recovery linac applications [4]. The project will be commissioned in several stages with an eventual goal to demonstrate operation with beam currents as high as 500 mA. A 704 MHz elliptical half-cell SRF gun was designed by BNL [5, 6] and fabricated by AES, Inc. Its main parameters are listed in Table 2.

Table 2: Parameters of the 704 MHz SRF gun

RF frequency	703.5 MHz
Cavity active length	8.5 cm (0.4 cell)
Maximum energy gain	2.5 MeV
Maximum field at the cathode	33.4 MV/m
E_{acc} at 2.5 MV	29.4 MV/m
e^- emission RF phase at 2.5 MV	33.4°
Energy gain at 500 mA	2.0 MeV
e^- emission RF phase at 2.0 MV	29.9°
Beam power at 500 mA	1 MW
R/Q	96.2 Ohm
Cavity geometry factor	112.7 Ohm
Cavity Q_0 at 2 K	3×10^{10}
Cavity operating temperature	2 K
Cavity RF losses (2 K) at 2.0 MV	1.4 W
Cathode operating temperature	80 K
Copper cathode RF losses (80 K) at 2.0 MV	226 W

The actual length of the nominally half-cell cavity is 0.4 cells. A copper cathode stalk is connected to the cavity via a specially designed quarter-wave choke joint. All surfaces of the choke joint are grooved to prevent multipacting [7]. The gun has two fundamental RF power couplers allowing delivery of 1 MW to a 500 mA electron beam. HOM damping is provided by a beamline ferrite load with a ceramic break [8]. A high temperature superconducting (HTS) solenoid is located inside the cryomodule near the beam exit.

The gun cryomodule was designed and fabricated by AES. Fundamental power couplers were manufactured by CPI/Beverly and were conditioned with maximum RF power of 250 kW pulsed and 125 kW CW in a full standing-wave mode [9]. The gun cavity was chemically etched, cleaned and vertically tested at Jefferson Lab. It reached accelerating gradient of 35 MV/m when tested without a cathode stalk.

The cryomodule was assembled at BNL, including its hermetic string (Figure 2) preparation in the clean room. It is installed in the ERL blockhouse for cold testing in Fall 2012 and subsequent beam operation. This gun will use a CsK_2Sb photocathode and is expected to operate with a gap voltage up to 2.5 MV and eventually generate a beam current of 500 mA at 2 MV.

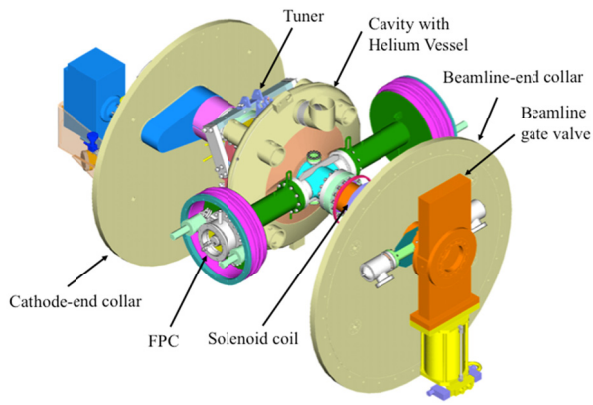

Figure 2: Hermetic string assembly of the 704-MHz SRF gun for R&D ERL.

112 MHz SRF GUN FOR COHERENT ELECTRON COOLING EXPERIMENT

A superconducting 112 MHz quarter-wave resonator (QWR) was developed for photocathode studies and electron gun experiments by collaborative efforts of BNL and Niowave, Inc. [10]. The low frequency was chosen to take full advantage of QWR benefits. The long wavelength allows generating long bunches and thus reducing space charge effects. A short, w.r.t. the wavelength, accelerating gap makes transit time factor close to unity and the gap field practically constant.

The gun will operate at 4.5 K with liquid helium provided from a quiet helium source via the cryomodule

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

cryogenic tower. Assuming a residual surface resistivity of 10 nOhm and a residual magnetic field of 60 mG, we expect to achieve the cavity quality factor of 1.8×10^9.

The QWR's center conductor geometry naturally accommodates a half-wavelength choke joint and allows mechanical decoupling of the cathode assembly from the niobium cavity [11]. A low RF loss photocathode stalk operates at room temperature. It is hollow, allowing inserting a small photocathode pack via a load lock system. Experiments are planned with multi-alkali and diamond-amplified photocathodes. The gun cryomodule is shown in Figure 3 and the gun parameters are listed in Table 3.

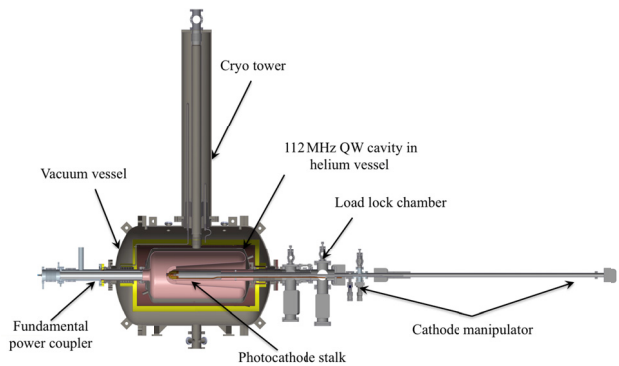

Figure 3: 112 MHz SRF gun cryomodule.

Table 3: Parameters of the 112 MHz QWR SRF gun

RF frequency	112 MHz
Maximum energy gain	2.0 MeV
Bunch charge	1 to 5 nC
Bunch repetition frequency	78 kHz
R/Q	127.3 Ohm
Geometry factor	38.5 Ohm
Cavity Q_0 at 4.5 K	1.8×10^9
Cavity RF losses at 2.0 MV	17 W
RF losses in the cathode stalk at 2.0 MV	38 W
Frequency tuning range	78 kHz
Frequency tuning with FPC	3 kHz
Q_{ext} of FPC, min.	1.25×10^7
Available RF power	2 kW

The 112 MHz gun will be equipped with a double-purpose fundamental RF power coupler/fine frequency tuning assembly [11]. The fine frequency tuning with a range of 3 kHz will be used for remote frequency adjustment. It will complement a larger range (78 kHz) tuner, which will be used only for an initial frequency set up. A focusing solenoid is placed on top of the FPC close to the cryomodule flange.

The cavity was chemically etched, high-pressure rinsed at Niowave, and first cold test of the gun was successfully performed there in December of 2010. The cavity Q of greater than 10^9 was measured and maintained up to ~0.5 MV accelerating voltage, and the pressure sensitivity of the fundamental mode was measured at 10 Hz/mbar [9]. At present, the gun cryomodule is undergoing modifications for compatibility with installation in RHIC tunnel, where it will become a part of the Coherent electron Cooling Proof-of-Principle (CeC PoP) experiment [12]. The first cool down of the modified gun at BNL is scheduled for 2013. The gun is expected to operate at an accelerating voltage up to 2 MV and generate electron beams with a charge per bunch from 1 to 5 nC.

SUMMARY

The superconducting RF photoemission sources of electron beams promise to provide high-quality electron beams for a variety of accelerator applications. At BNL, we are pursuing several design options. The 704 MHz gun for R&D ERL is assembled and its commissioning will begin soon. The other two guns are at different stages of modification with the goal to begin experiments in 2013.

IMPACT OF TRAPPED FLUX AND SYSTEMATIC FLUX EXPULSION IN SUPERCONDUCTING NIOBIUM

J. Vogt, O. Kugeler, J. Knobloch, Helmholtz-Zentrum für Materialien und Energie (HZB)

Abstract

The intrinsic quality factor Q_0 of superconducting cavities is known to depend on various factors like niobium material properties, treatment history and magnetic shielding. To study trapped flux in Niobium we constructed a test stand at Horizontal Bi-Cavity Test Facility (HoBiCaT) at HZB using niobium rods equipped with thermal, electrical and magnetic diagnostics. The focus in this study was on the behaviour of the trapped flux when the sample is slowly warmed up towards the critical temperature T_c. Besides the (incomplete) Meissner effect we observed additional flux expulsion starting at ≈0.1K below T_c. The reduced level of trapped flux is maintained when the sample is cooled down again and can even be improved by repeating the procedure. Possible explanations for the effect are discussed.

INTRODUCTION

We already reported on the impact of temperature gradients during the cool-down on the obtained Q_0 [1]. In the quest for minimization of RF losses in SRF cavities the impact of trapped vortices is one main topic. The vortices have a normal conducting core with a surface resistance about 6 orders above that of superconducting Niobium. This surface fraction is proportional to the trapped magnetic flux. The surface resistance was determined to be 2.2nΩ per μT for a 1.5GHz cavity [2]. A crucial step in avoiding trapped flux is an improved understanding of flux trapping behaviour of Niobium.

The energetically most favourable state of bulk Niobium at 1.8K (4.2K) is the Meissner phase, in which all magnetic field present in the normal conducting state is expelled. However, expulsion of flux can be incomplete, yielding a remaining magnetization of the material even after removing the external field source. The dynamics of this trapped flux is still not well understood. One approach was the investigation of flux that is permitted to penetrate a marginal type II superconductor in the mixed state. Here, the flux tubes form a lattice and several studies [3, 4] indicate a phase transition from localized (solid, fixed regular lattice) flux tubes towards moveable (liquid) flux tubes when the superconductor exceeds certain temperature / magnetic field combinations as indicated by the black dotted "melting line" in Figure 1.

The behavior of flux that is trapped in the Meissner state is uncertain. A continuation of the melting line in this phase is conceivable, so that flux lines in the check region (Figure 1) may be able to exit the Niobium below T_c. In our study, we examine the properties of the trapped magnetic flux in the Meissner phase when the rod is slowly warmed up.

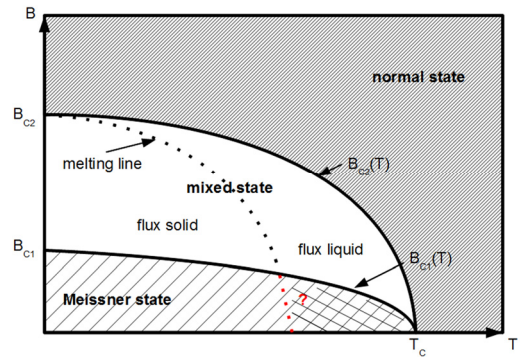

Figure 1: Magnetic phase diagram of marginal Type II superconductor [5]. The added red dotted line indicates a possible extension of the liquid/solid flux interface into the Meissner state. The size of the check region is exaggerated.

EXPERIMENTAL SETUP

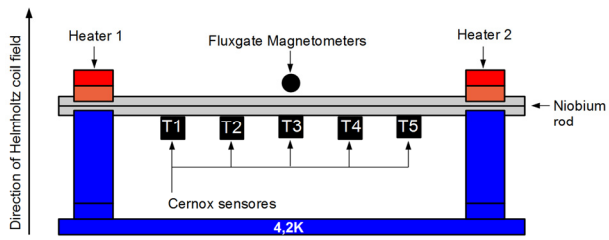

Figure 2: Experimental setup

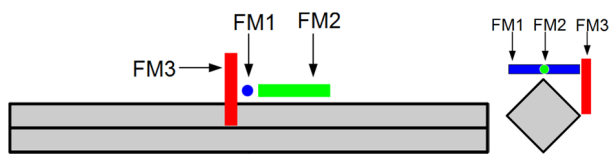

Figure 3: Positions of fluxgate magnetometers (FM): Longitudinal view (left) and cross section (right) of FM1 (black), FM2 (green) and FM3 (red)

For the experiments, a RRR=300 niobium rod (8.4x8.4x300mm) was positioned inside HoBiCaT [6]. It was conduction cooled through the posts to 4.2K. In order to reduce heat transfer into the Helium, heat conductivity was reduced by introducing a kapton foil between rod and support stands. Both ends of the rod were equipped with a resistive heater. They could be individually regulated to control the temperature of the rod with 10mK accuracy. Five Cernox temperature sensors with mK resolution and three fluxgate magnetometers with 1nT resolution (Bartington Mag-01H), one for each spatial direction,

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

were attached along the rod. A Helmholtz coil (HC) for the generation of a vertical magnetic field up to ±300μT enclosed the whole construction. The setup and the positions of the instruments are displayed in Figures 2 and 3.

MANIPULATION OF TRAPPED FLUX

In each of the performed experiments a magnetic field is applied using the HC while the Nb rod is cooled through T_c. Afterwards, the rod is smoothly warmed by manually adjusting the two heaters and the change in the magnetic field is observed by three fluxgate magnetometers (FM). Precise temperature control was exercised to ensure that at no time T exceeded T_c.

Manipulation without applied field

In the first set of experiments the HC is turned off after the rod has reached the minimum temperature. Hence, the signal registered subsequently by the FMs roughly corresponds to the frozen flux inside the rod. Referring to Figure 4, this is position (A).

When the rod is warmed up again, the magnetisation observed by the FMs stays constant until a temperature of T≈9.1K (<T_c) is reached. At this point the amount of trapped flux suddenly starts to drop (B) until a minimum level is reached (C). When the warming is stopped during the decrease and the rod is cooled, the level of trapped flux at the instance of stopping remains - even upon subsequent cooling.

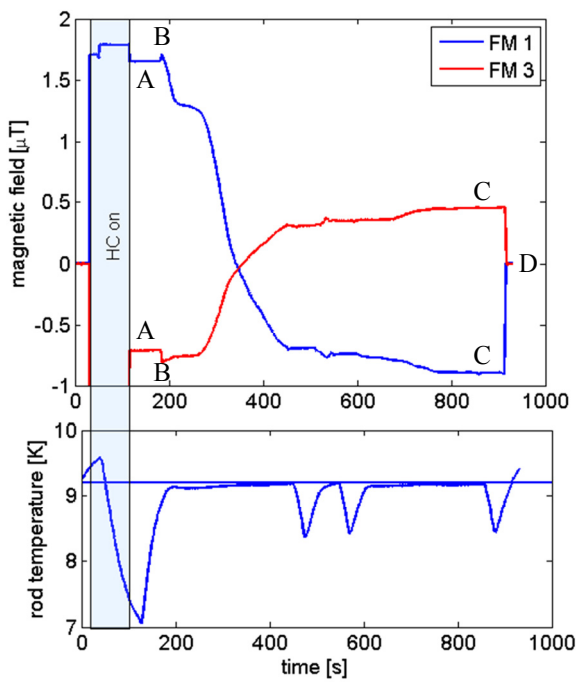

Figure 4: Behaviour of trapped flux and temperature when a HC field of 33μT is applied and trapped: Initially trapped flux (A), minimal trapped flux (C) and level of flux ambient in HoBiCaT ≈3μT (D). This value has been subtracted from all data points.

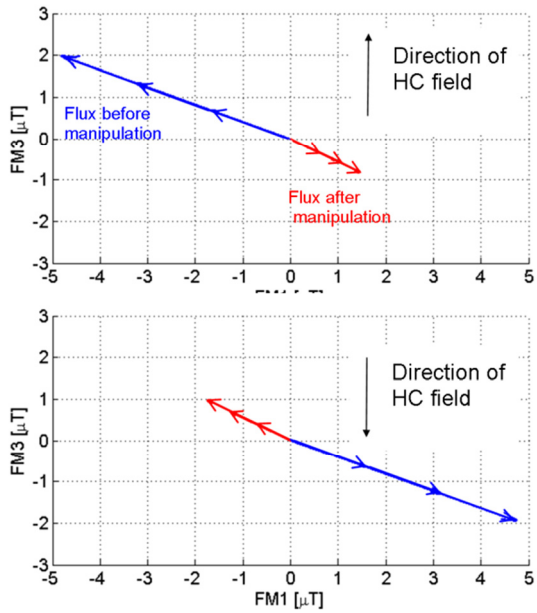

Figure 5: Trapping for HC fields: 33μT, 65μT, 97μT (above) and -32μT, -66μT, -98μT (below). The initially trapped field is blue and the field after additional expulsion is red.

The signals obtained by FM1 and FM3 are displayed in Figure 4. For better visualization their values can be combined to a vector indicating the spatial orientation of the trapped flux, see Figure 5. The signal of FM2 is more than one order of magnitude smaller than the signals of FM1 and FM3 due to the orientation of HC and rod and therefore is not displayed here.

The change in the trapped flux indicates that the warming enables the trapped flux lines to move. A possible explanation could be that the thermal energy exceeds the pinning potential and the pinning potential barrier does not hinder the movement of flux lines anymore ("liquid flux state"). Driving force for the movement could be the strive for approaching the energetically most favourable state – the complete Meissner state – given by a minimum of sc/nc interface area. Not all flux is expelled because different pinning centres have different pinning potentials [7] and not all of them can be exceeded by the thermal activation. Also the driving force reduces, the less flux remains in the sample. We observe:

(1) A redistribution of flux lines (here even change in sign due to geometry) and
(2) A reduction of the absolute amount of frozen flux

The latter is evident from the shortening of the vectors in Figure 5. Table 1 displays the values of the initially trapped field and the minimal trapped field in the end of the procedure for different HC fields. We achieved an expulsion of up to 75%.

Table 1: Magnetic field before and after expulsion

B_{HC} [µT]	$\lvert B_{trapped}\rvert$ [µT]	$\lvert B_{minimised}\rvert$ [µT]	Expulsion [%]
33	1.98	0.50	75
65	3.91	1.19	70
97	5.84	1.88	68
-32	1.87	0.88	53
-66	3.80	1.57	59
-98	5.73	2.26	61

Manipulation with applied field

These investigations raise the question how the flux tubes behave when an external field is not turned off during warm up as opposed to the above experiment, where an external field was trapped but only the ambient field remained during warm up.

Figure 6 displays a typically obtained signal of FM1. In the beginning the rod is normal conducting (A). It is cooled below T_c where flux is expelled by Meissner effect (B). The magnetic field probe measures an increase in the field density outside the rod. Afterwards the rod is slowly warmed using the heaters. Starting at a temperature of (9.08±0.01)K we observe a sudden decrease in expelled flux (C) which coincides with the onset of Paramagnetic Meissner Effect (PME) reported by Thompson [8]. The onset temperature does not depend on the applied field strength in the range of ±300µT tested here. The PME is a phenomenon observed in some high temperature superconductors and in Niobium. These materials exhibit a paramagnetic phase between the perfect diamagnetic behaviour in the Meissner state and the normal conducting state. Note the difference to classical frozen flux which is a topological coexistence of normal conducting and Meissner-like areas.

When the rod is warmed up further, a second effect occurs. When T_c is approached an additional expulsion of flux is evident (D) resulting in a lower level of residual frozen flux (i.e. a higher level of expelled flux). Subsequent repetition of cooling and heating leads to a minimized level of trapped flux (E) and each time we observe the PME. Further repetition leads only to the jumps in magnetisation due to PME but no further change in the level of trapped flux.

A possible explanation for this systematic flux expulsion could be an increased mobility of flux lines in a temperature regime close to T_c consistent with the data obtained in the first set of experiments.

In this set of experiments, HC fields of up to ±300µT were applied leading to expulsion pattern that were all similar to Figure 6. Hence, systematic flux expulsion works under these conditions.

CONCLUSION

The amount of trapped magnetic flux can be manipulated and systematically minimized while the material remains superconducting. The complete Meissner state is thus being approached.

If one could apply such a procedure to SRF cavities, this effect could lead to higher Q_0 values and operation close to the BCS-limit. In addition, the major impact of the cooling dynamics in the temperature range between 9.08K and T_c on the flux trapping behaviour could explain the impact of temperature gradients during the cool-down on the obtained Q_0 values as described in [1].

ACKNOWLEDGMENT

We would like to thank A. Frahm for the design of the testing apparatus and S. Klauke and M. Schuster for help with setting up the experiment.

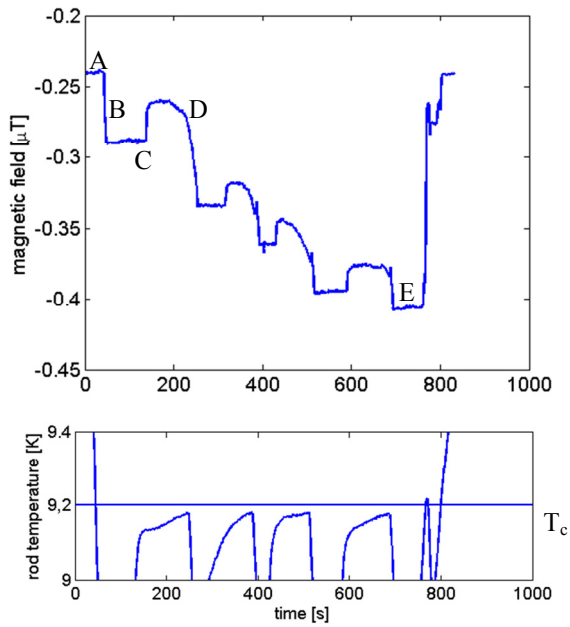

Figure 6: Behaviour of trapped flux (FM1) and temperature upon heating in ambient field (background field trapped and partially expelled)

ALTERNATIVE APPROACHES FOR HOM-DAMPED CAVITIES*

Bernard Riemann†, TU Dortmund University, Dortmund, Germany
Axel Neumann, Helmholtz-Zentrum Berlin, Berlin, Germany
Thomas Weis, TU Dortmund University, Dortmund, Germany

Abstract

In this paper, we present two different ideas that may be useful for design and simulation of (superconducting) radio frequency cavities.

To obtain longitudinal and transverse voltages resp. shunt impedances in cavities without rotational symmetry, one or two integration paths are often used to get an approximate difference relation for the transverse voltage of higher order modes (HOMs). The presented approach uses a multipole decomposition that is valid in vicinity of the central axis to compute voltage multipole decomposition directly for paths of arbitrary number and position.

Elliptical cavities have been a standard in SRF linac technology for 30 years. We present another approach to base cell geometry based on Bezier splines that is much more flexible in terms of optimization, while reaching equal performance levels.

POLAR PATH INTEGRAL ANALYSIS

In the following section, the longitudinal and transverse voltages are expressed using a multipole decomposition. By pseudo-inversion of the resulting equation system (similar to polynomial interpolation), one can calculate the corresponding coefficients directly from an arbitrary number and position of integration paths.

This method also allows to check a) if the position and number of paths is appropriate to extract the desired coefficients, b) if there is any "noise" in the voltage paths that stem from computational errors or from a too large distance of the path from the central axis.

Signed Effective oltages

The effective longitudinal and transverse acceleration voltages can be written as complex Fourier integrals

$$\tilde{V}_{\parallel} = \int E_s(s) \exp\left(ik_\beta s\right)\, \mathrm{d}s \in \mathbb{C}, \tag{1}$$

$$\tilde{\vec{V}}_{\perp} = \frac{1}{q} \int \vec{F}_{\perp}(s) \exp\left(ik_\beta s\right)\, \mathrm{d}s \in \mathbb{C}^2, \tag{2}$$

where $\vec{F}_\perp$ is the total transverse Lorentz force, and E_s is the longitudinal electric field at the path position s. The complex angle $\Psi_0 = \arg(\tilde{V}_\parallel)$ corresponds to an optimal acceleration phase, and its magnitude to the acceleration voltage for this phase (see [6] for a special derivation of this relation with a fixed $\Psi_0 = 0$).

For each mode, the phases of $\tilde{V}_\parallel$ on all paths are equal up to an additional shift by π, corresponding to a sign change (deceleration). Using a fixed phase Ψ_0 that is one of the two possible optimal phases, we may define a real acceleration voltage for the optimal phase by

$$V_\parallel := \tilde{V}_\parallel \cdot e^{-\mathrm{i}\Psi_0} \in \mathbb{R}. \tag{3}$$

and, using the Panofsky-Wenzel theorem, a corresponding real transverse voltage may be defined by

$$\frac{\partial}{\partial t}\tilde{\vec{V}}_\perp = i\omega\tilde{\vec{V}}_\perp = -\vec{\nabla}_\perp \tilde{V}_\parallel \tag{4}$$

$$\vec{V}_\perp = \begin{pmatrix} V_x \\ V_y \end{pmatrix} = -i\tilde{\vec{V}}_\perp \cdot e^{-\mathrm{i}\Psi_0} \in \mathbb{R}^2. \tag{5}$$

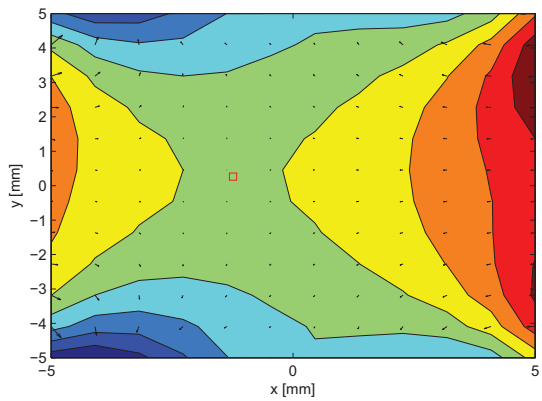

Figure 1: Reconstruction of the transverse (arrows) and longitudinal (isolines) voltages in the beam area with contributions from different multipole components. The corresponding coefficients were computed from voltages on circularly arranged integration paths at 5mm offset from beam axis for an eigenmode of the B*ERL*inPro main linac cavity. The red square marks the transverse forceless point z_0 which deviates from the axis by more than 1 mm.

Holomorphic Multipole Expansion

By using a complex analytic multipole decomposition

$$F(z) \approx \sum_p c_p\, z^p, \tag{6}$$

where $z = x+iy = re^{i\phi}$ is the transverse position of the integration path, and $c_p = a_p + ib_p$ are complex numbers that

* this work is supported by BMBF contract 05K10PEA
† bernard.riemann@tu-dortmund.de

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

describe the magnitude and orientation of different multipoles, the signed longitudinal and signed transverse voltages can be expressed as

$$V_{\parallel}(z) := \Im F(z) = \sum_p r^p [b_p \cos(p\phi) + a_p \sin(p\phi)] \quad (7)$$

$$\Rightarrow X(z) := \frac{\mathrm{d}}{\mathrm{d}z} F = -\omega(V_y + iV_x) = \sum_p p c_p \, z^{p-1} \quad (8)$$

Multiple Path Equation System

Assuming there are N numerical integration paths at transverse positions z_n set up for the computation, they can be combined into a vector thus summarizing the problem into two matrix equations.

$$\vec{V}_{\parallel} = \Im \left[\mathbf{M} \begin{pmatrix} c_0 \\ \vdots \\ c_{P-1} \end{pmatrix} \right] \quad , \quad \vec{X} = \mathbf{M} \begin{pmatrix} 1c_1 \\ \vdots \\ Pc_P \end{pmatrix} \quad (9)$$

where $\mathbf{M}$ denotes the $N \times P$ Vandermonde matrix defined by $M_{n,p} = z_n^{p-1}$.

The matrix equation for $\vec{V}_{\parallel}$ is sufficient to solve for the coefficients. On the other hand, the possible occurance of numerical errors in the path integral computation and the limited validity of the multipole decomposition, which only holds for small $|z|$, enforces cross-checking with the transverse data. To get the best results, information of all V should be used simultaneously. To do this, rectangular matrices $\mathbf{G}$ are defined by

$$\begin{pmatrix} c_0 \\ \vdots \\ c_{P-1} \end{pmatrix} = \mathbf{G}_1 \vec{c} \quad , \quad \begin{pmatrix} 1c_1 \\ \vdots \\ Pc_P \end{pmatrix} = \mathbf{G}_2 \vec{c}, \quad (10)$$

where $\vec{c}$ is a $P+1$-dimensional vector containing all c_p from 0 to P. The imaginary part of the bracketed term in (9) can be expressed in terms of the real and imaginary components $\vec{a}, \vec{b}$.One must now also separate $\vec{X}$ into its real and imaginary multipole components. Furthermore, the resulting matrix equation is still complex, since $\vec{X}$ is a complex vector, but $\vec{V}_{\parallel}$ must be real (which leads to inversion problems). To resolve this, the final equation system can be written as

$$\begin{pmatrix} \vec{V}_{\parallel} \\ \Re\vec{X} \\ \Im\vec{X} \end{pmatrix} = \begin{pmatrix} \Im\mathbf{M}\,\mathbf{G}_1 & \Re\mathbf{M}\,\mathbf{G}_1 \\ \Re\mathbf{M}\,\mathbf{G}_2 & -\Im\mathbf{M}\,\mathbf{G}_2 \\ \Im\mathbf{M}\,\mathbf{G}_2 & \Re\mathbf{M}\,\mathbf{G}_2 \end{pmatrix} \begin{pmatrix} \vec{a} \\ \vec{b} \end{pmatrix}. \quad (11)$$

To solve this equation system for $\vec{a}, \vec{b}$, singular value decomposition

$$\begin{pmatrix} \vec{V}_{\parallel} \\ \vec{X} \end{pmatrix} := \mathbf{u}\mathbf{\Sigma}\mathbf{v}^* \begin{pmatrix} \vec{a} \\ \vec{b} \end{pmatrix} \Rightarrow \begin{pmatrix} \vec{a} \\ \vec{b} \end{pmatrix} = \mathbf{v}\mathbf{\Sigma}^{-1}\mathbf{u}^* \begin{pmatrix} \vec{V}_{\parallel} \\ \vec{X} \end{pmatrix} \quad (12)$$

is used. For voltages of a number of eigenmodes Q to be processed, their column $2N$ vectors can be concatenated to form a $2N \times Q$ matrix.

Since multipole expansion of the longitudinal voltage is used, there must be at least one extremal point if components higher than dipolar are included. In fact, if the field is dominated by quadrupolar modes, one is interested in the exact position of this extremal point z_0, since the transverse voltages included in $X(z)$ cancel out for this path. The extremal point z_0 is given by

$$X(z_0) = \sum_p p c_p \, z_0^{p-1} \stackrel{!}{=} 0, \quad (13)$$

which can easily be solved numerically for z_0 by finding the roots of the given polynomial.

To check if the number and position of paths for the given multipole order is sufficient, one should check for the ratio σ_1/σ_P to be not too large. To check if the multipole decomposition method is valid for the integration path region, one should investigate if the components larger than P of the vector $\mathbf{u}^* \begin{pmatrix} \vec{V}_{\parallel} \\ \vec{X} \end{pmatrix}$ do vanish.

Preliminary Results and Outlook

Figure 1 shows a reconstructed area around the central axis path for the B*ERL*inPro main linac cavity for a mainly quadrupolar mode, and the forceless path position. The irregular isolines at the outer edge indicate a mixing with higher order multipole field components. For more results on the B*ERL*inPro main linac, see [1].

The obtained information is important in the consideration of coupler kicks that do not stem from the operational mode, but from quadrupolar or higher order modes (HOM coupler kicks). The question whether to include mainly quadrupolar modes into HOM damping considerations may be answered using such studies, especially the z_0 position distribution along all HOMs of the cavity. Such a study may also help to answer questions regarding alignment tolerances of cavities and cavity strings.

For including more distant points from the axis into the equation, one may consider to relax the multipole conditions and to include Bessel function terms into the modal decomposition basis, thus allowing for two or more different complex coefficients to describe each multipole. As an extreme case for all points of a cylindrical mesh, this would be equivalent to a waveguide mode-like decomposition of the generalized path voltages on an electric boundary plane with $V_{\parallel}, \mathrm{i}V_{\perp}$ instead of $\vec{E}_{\parallel}, \mathrm{i}\vec{H}_{\perp}$.

BEZIER SPLINE CAVITIES

In modern accelerator facilities, high acceleration gradients and duty cycles are achieved using SRF cavities. To protect these cavities from quenching and RF breakdown, sufficiently small peak surface electric fields in comparison to acceleration gradient $E_{\mathrm{surf}}/E_{\mathrm{acc}}$ are necessary. Therefore, the cavity shapes must be constructed from smooth profile curves.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

From the disk-loaded cavity, design of such cavities has evolved from first rounding off the edges, and then substituting them by elliptical shapes, leading to modern SRF "re-entrant", "low-loss" and "TESLA-shape" [5] cavities which suppress resonant multipacting of secondary electrons. While elliptical shapes have shown superior performance, this parameterization is qualified by historical developments, as to the authors' knowledge, no other parameterizations of similar smoothness have been systematically researched for ultra-relativistic particles. The spline cavity geometry is such an alternative shape with additional desirable properties [2].

Figure of Rotation Parameters

A Bezier spline is a parameterized curve [3]

$$\vec{s}(t) = \vec{a}_0 + \vec{a}_1 t + \vec{a}_2 t^2 + ... = \sum_{n=0}^{N} \vec{s}_n b_{n,N}(t) \qquad (14)$$

with Bernstein polynomials $b_{n,N}$ and $t \in [0,1]$. The $N+1$ points $\vec{s}_n$ define the so-called control polygon and contain the free parameters of the spline. Let us consider the simplest possible case of a cubic ($N = 3$) Bezier spline as shown in Fig. 2. The geometry parameters are reduced by cell periodicity conditions and elementary RF constraints to a set of only three parameters [2], compared to five for an elliptical cavity. These parameters can be optimized according to the specific purpose of the cavity.

Implementation and Results

For the single cell computations with periodic boundary conditions, we used the well-known 2d code SUPERFISH [4]. Since the SUPERFISH mesher cannot use spline curves, a small wrapper for MATLAB was developed. The spline geometry was discretized by calculating a 200 point (halfcell) polygon from its parameters (Fig. 2), which was then used as input in SUPERFISH, also specifying a special localized mesh that matches the polygon discretization accuracy.

A parameter sweep for a given iris radius and an external equator tuning procedure were also implemented to tune all cavity sets to a π-mode frequency of 1.3 GHz [2]. The scan of the $(v_1, v_2)/L$ parameter space was processed in a spiral pattern to fully exploit the similarities between spline shapes with only slight parameter differences. A second scan with given radii for the 0-mode was performed, obtaining the corresponding frequency needed for the intercell coupling constant κ [6]. The procedure for a fixed iris radius took approx. 3.5 hours on a standard PC [2].

Figure 3 shows the results for a typial iris radius of 35 mm. It can be seen by comparison e.g. with [5] that the cubic spline shape geometry performance is in roughly the same range as the standard elliptical cavity geometries, although as stated, the cubic shape has two less free parameters. By inspecting the map, the trade-off between different figures of merit in the design process becomes visible (see e.g. red and black lines).

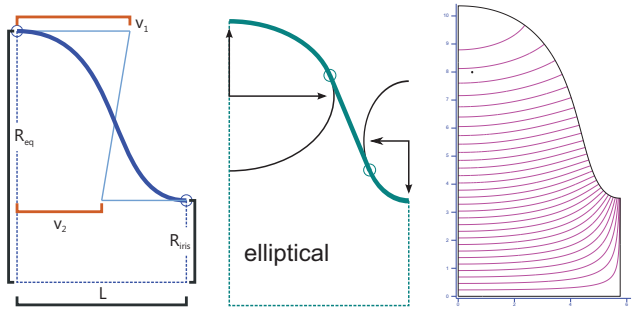

Figure 2: Parameterization for cubic Bezier shape (left), elliptical parameterization (center) and exemplary result for electric field lines ($v_1 = 0.9, v_2 = 0.65, R_{\mathrm{iris}} = 35\,\mathrm{mm}, R_{\mathrm{eq}} = 103.60\,\mathrm{mm}$, right)

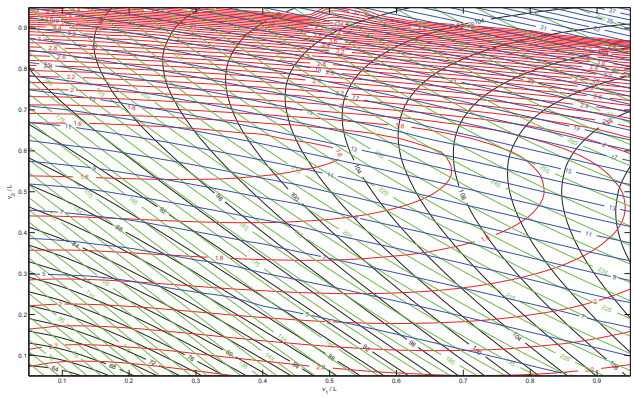

Figure 3: Cubic Bezier map for a 1.3 GHz cavity with iris radius 35 mm. The map shows the cubic interpolated isolines of $R/Q\,[\Omega]$ in black, $E_{\mathrm{surf}}/E_{\mathrm{acc}}$ in red, the Geometry factor $[\Omega]$ in green, and the intercell coupling constant $[10^{-3}]$ in blue.

Abstract

The Berlin Energy Recovery Linac Project (B*ERL*inPro) is designed to develop and demonstrate CW LINAC technology for 100-mA-class ERLs. High-current operation requires an effective damping of higher order modes (HOMs) of the 1.3 GHz main linac cavities.

We have studied elliptical seven cell cavities damped by five waveguides at the adjacent beam tubes. Eigenmode calculations for geometrical figures of merit show that the present design should allow successful cw linac operation at the maximum beam current of 100 mA / 77pC bunch charge.

In this paper the progress in HOM calculations to avoid beam-breakup instabilities for the favored cavity structure is presented.

INTRODUCTION

B*ERL*inPro will be a CW driven ERL machine with a maximum current of 100 mA beam and a maximum energy of 50 MeV, while preserving a normalized emittance of better than 1 mm mrad at a pulse length of 2 ps [1]. The main linac cavity has strong HOM damping requirements since it is passed by two 100 mA beams that both resonantly interact with transverse deflecting (e.g. TM_{110}) cavity modes, leading to beam break up (BBU) [2].

An ERL cavity design must minimize the HOM's $R/Q_\perp$ and external quality factors Q_{ext} [8]. The mid-cell design influences the HOM spectrum, dispersion relation and operational mode acceleration performance (see [8] for op. mode parameters of the tuned structure). By proper end-cell tuning that preserves field flatness for the fundamental TM_{010}-π mode, mode localization (trapping) can be avoided and the Q_{ext} can be recuced to a sufficient extent.

In this paper updated HOM calculations of the main linac cavity using new methods are presented [8], and an outlook on ongoing activities to decompose the cavity structure into smaller parts is given [5] [9].

STRUCTURE EIGENMODE CALCULATIONS

The design under consideration is a seven cell structure using the Cornell ERL mid-cell design [6] and combining it with JLab 3-fold symmetric waveguide HOM couplers [7] (see Figure 1). Flexible input power coupling is enabled by replacing one waveguide with a TTF-III type coaxial fundamental power coupler (thus breaking the 3-fold symmetry). The design aims at combing the peak field properties of the Cornell design with the advantage of waveguide couplers having a natural cutoff above the fundamental, and further limiting the possibility of dust intruding from ferrite beam tube absorbers into the cavity.

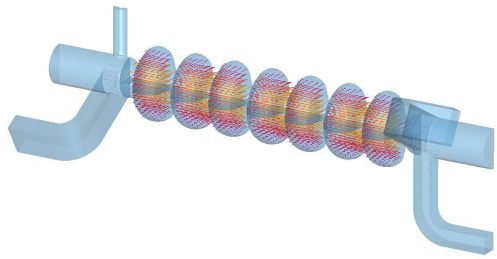

Figure 1: Rendering of the cavity design under consideration for B*ERL*inPro with a cut through the symmetry (FPC) plane and electric field magnitude of the operational mode.

	ERL shape Cornell U.	**Spline shape** TU Do, v4 / v5
$E_{\text{surf}}/E_{\text{acc}}$ (π mode)	2.07	2.08 / 2.07
$R_\parallel/Q$ (π mode)	111 Ω	113 Ω / 112 Ω
intercell coupling κ	2.1 %	1.7 % / 1,9 %
Geometry factor G	272.7 Ω	- / 269.5 Ω

Table 1: Cavity mid-cell figures of merit comparison.

Base cells

In parallel to periodic boundary mid-cell calculations, such calculations were also performed using Spline-based cells [4]. Table 1shows a preliminary comparison between 36 mm radius mid-cells for both designs. At the moment, development concentrates on the Cornell ERL mid-cell. Further development and degree elevation of the spline design may lead to a mid-cell shape with higher performance.

Transverse shunt impedance

The final goal will be to minimize the product $R/Q_\perp \cdot Q_{\text{ext}}$ for all HOMs. $|\vec{V}_\perp|^2 \propto R_\perp/Q$ can be computed di-

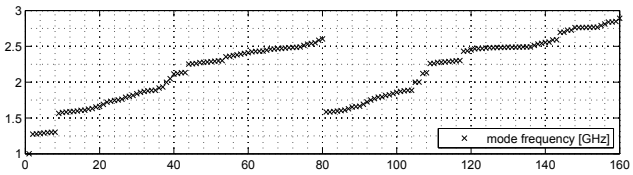

Figure 2: Frequency of all modes up to 2.85 GHz, about the lower range of the 4th dipole band. All modes were computed using the JDM eigenmode solver of CST MWS™.

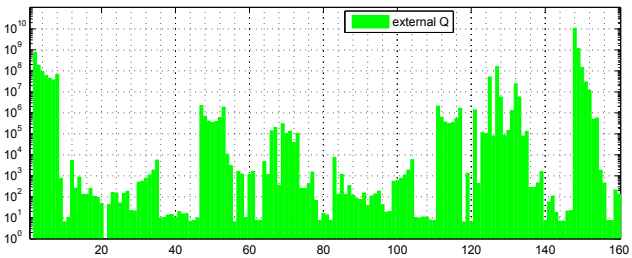

Figure 3: External Q of all TM/TE modes up to 2.85 GHz. While the dipole modes are sufficiently damped, some quadrupole modes exhibit large $Q_{\text{ext}} > 1 \cdot 10^6$.

rectly from the fields on the central axis by

$$\vec{V}_\perp = \frac{1}{q} \int \vec{F}_L(s) \exp\left(ik_\beta s\right)\, \mathrm{d}s \cdot \exp(-\mathrm{i}\Psi_0) \in \mathbb{R}^2 \quad (1)$$

simultaneously with its polarization and additional information about optimal phase relations in Ψ_0 [3]. The resulting $R/Q_\perp$ is shown in Figure 4. Again the dipole modes seem sufficiently damped while some quadrupole modes due to their high Q_{ext} and a small, but finite non-zero shunt impedance on axis show to be the most harming modes concerning BBU.

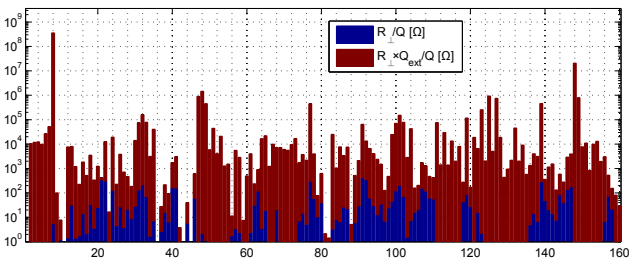

Figure 4: Transverse $R/Q_\perp$ and $R/Q_\perp \cdot Q_{\text{ext}}$ for all TM and TE modes up to 2.85 GHz (beginning of 4th dipole band). The arrow marks the coupler kick by the TTF-III power coupler at the fundamental mode.

Polar path analysis

The action of seemingly small voltages from mainly quadrupolar modes, giving rise to large instabilities, leads to the question if and to which extent quadrupole mode damping should be considered in realistic cavity designs, based on the influence of higher order mode coupler kicks and imperfections in beam path position and construction issues. Due to the broken rotational symmetry, any eigenmode may consist of different multipole components. A scheme named polar path analysis was developed [3] to extract the voltage components a_p, b_p of the longitudinal (and equivalently, transverse) voltage

$$V_\parallel(r,\phi) \approx \sum_p r^p [b_p \cos(p\phi) + a_p \sin(p\phi)] \quad (2)$$

from all available longitudinal and transverse voltages on an arbitrary number of integration paths N (the different paths are comprised into vectors of the respective voltages) by constructing and pseudo-inverting a rectangular matrix $\mathbf{A}$ in an equation system of the form [3]

$$\begin{pmatrix} \vec{V}_\parallel \\ \omega\vec{V}_x \\ \omega\vec{V}_y \end{pmatrix} = \mathbf{A} \begin{pmatrix} \vec{a} \\ \vec{b} \end{pmatrix}. \quad (3)$$

To investigate the possible shift of quadrupole modes a calculation of $R_\perp/Q$ along circular distributed integration paths at an arbitrary offset of 5mm was performed. Fig. 5 shows the results of the eigenmode computation for a mode with a dominating quadrupole component. Fig. 6 is a plot of the reconstructed transverse area with the result coefficients $|a_0 + \mathrm{i}b_0| = 3,5 \cdot 10^4$ V (monopole), $|a_1 + \mathrm{i}b_1| = 1.28 \cdot 10^5$ V/mm (dipole) $|a_3 + \mathrm{i}b_3| = 4.6 \cdot 10^4$ V/mm^2 (quadrupole) and $|a_4 + \mathrm{i}b_4| = 5.6 \cdot 10^2$ V/mm^3 (sextupole).

For quadrupolar modes, we are interested in the shift of the transverse forceless path. Fig. 6 also shows the marked forceless point given as a solution of the complex polynomial $X(z) \stackrel{!}{=} 0$ [3].

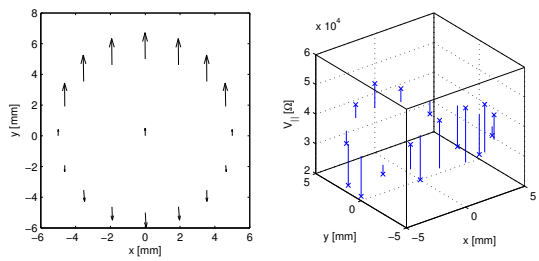

Figure 5: Polar plot of transverse (left, arrows) and longitudinal (right) voltages determined on circularly arranged integration paths at 5mm offset from beam axis for a mainly quadrupolar mode.

Most modes of these quadrupole bands are shifted more than the expected vertical beam size in the linac and thus mainly quadrupole modes may exhibit a non-neglectible dipole component. This effect needs to be investigated in more detail and it has to be understood how much the coupler's position influences this effective dipole component of the quadrupole modes.

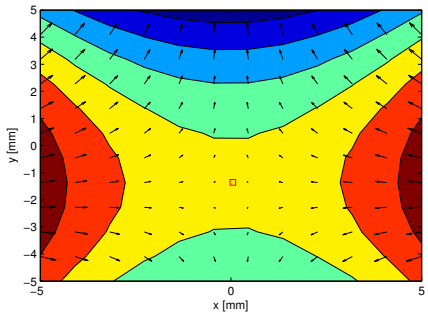

Figure 6: Reconstruction of the transverse (arrows) and longitudinal (isolines) voltages in the beam area from the data shown in Fig. 5. The red square marks the transverse forceless point.

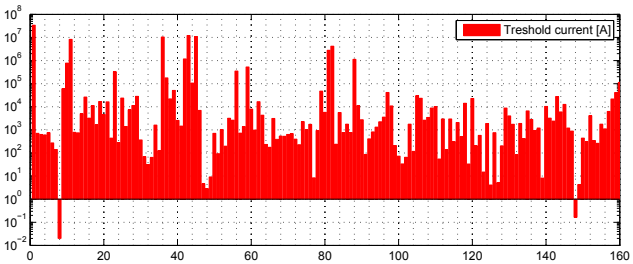

Figure 7: Approximate (orders of magnitude) calculations for the treshold current based on Eq. 4.

Treshold current

To evaluate and optimize the cavity, we use a simpflied equation for the treshold current

$$I_{\mathrm{th}} \approx \frac{2c}{e} \frac{E_0}{R_\perp/Q\, Q_{\mathrm{ext}} \omega} \qquad (4)$$

for one cavity HOM that still depends on the mode's transverse shunt impedance $R/Q_\perp$, its external quality factor Q_{ext} and frequency ω and the beam's energy E_0, but neglects the influence of recirculation time and the recirculation arc linear beam optics ("worst phase" assumption).

The results of our preliminary treshold current calculation for all modes are shown in Fig. 7. The seemingly smallest current value is not valid due to being equivalent to a coupler kick of the operational mode which is externally driven and cannot be described by the treshold current formula.

OUTLOOK

Full 3d structure eigenmode computations using several million mesh cells for hundreds of modes need too much computational resources to implement them as iteration steps into an optimizer routine for end-cell tuning (to lower the Q_{ext} for the dangerous HOMs). Thus, the next steps in B*ERL*inPro main linac cavity design will either consist of using Coupled S-parameter Calculations [11] of the segmented structure (see Fig. 8) with 2d eigenmode calculations of the rotationally symmetric cavity, or using a state-space equation system with a similarly separated structure [9] to find a set of end-cells with field-flat op. modes that are then optimized for maximum overall HOM damping ($R_\perp/Q \cdot Q_{\mathrm{ext}}$) [5]. The sufficient cavity sets will then be concatenated to the full three cavity string, as already the lowest order dipole modes propagate along the beam tube and couple to the neighboring rf structures.

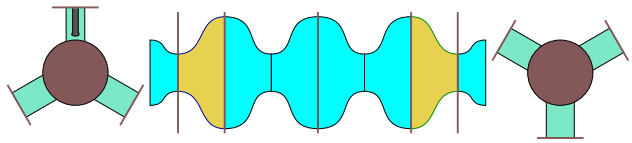

Figure 8: Cavity separation planned for CSC. The rotationally symmetric structure is decomposed along the equator radii, with an additional separation at the outer endcell iris. The resulting structure is concatenated with the 3d FPC/waveguide damping structure and the 2d (cartesian) 3-fold symmetric waveguide damping structure.

STUDY OF HPR CREATED OXIDE LAYER AT Nb SURFACES

P. V. Tyagi#, GUAS, Tsukuba, Japan
T. Saeki, M. Sawabe, H. Hayano, S. Kato, KEK, Tsukuba, Japan

Abstract

The performance of superconducting radio frequency (SRF) niobium (Nb) cavities mainly depends on final surface condition therefore the surface preparation of these SRF cavities becomes very important. The preparation of surface includes two steps; surface chemistry (in order to get a smooth surface) and cleaning/rinsing (in order to remove contaminants left after the surface chemistry). As high pressure rinsing (HPR) with ultra pure water (UPW) is most commonly used surface cleaning method after the surface chemistry, it's very interesting to characterize the Nb surfaces after HPR. The surface characterizations show the presence of a thicker oxide layer at Nb surface as an outcome of HPR. In this article, we report the production of oxide layer (FWHM thickness) based on different conditions such as high pressure and doses. The surface characterization was done by XPS (x-ray photoelectron spectroscopy) with depth profiling.

INTRODUCTION

Final surface preparations [1] of niobium (Nb) superconducting radio frequency (SRF) cavities play a critical role in order to achieve high performances. Final surface preparation includes mainly two steps 1) surface chemistry in order to make surface smoother and 2) post cleaning processes in order to remove chemical residues left after the surface chemistry. As a step two, the High Pressure Rinsing (HPR) with ultra pure water/deionized water (UPW/DI), is most commonly used surface cleaning procedure worldwide [2,3]. The HPR seems to be a most effective cleaning procedure and HPR treated cavities have shown high field gradient with a high Q value. For the last two decades, HPR has been successfully used on SRF cavity surfaces and became an integral part of the final surface preparation of Nb SRF cavities. In order to make HPR more effectively for removal of the contaminants from cavity surface, the HPR operating parameters such as high pressures and doses should be carefully determined.

In this paper, we report our efforts towards finding of the optimized pressure and doses for HPR. In this regard, three samples were initially buffer chemical polished (BCPed) and subjected to HPR with three different pressures and two doses. For the HPR experiments, a commercial high pressure washer machine was used which can reach to a maximum pressure of 15 MPa. After the experiments, sample surfaces were analyzed by XPS (x-ray photo-electron spectroscopy).

Work was conducted in KEK, Tsukuba Japan.

EXPERIMENTAL DETAILS

Surface Analysis

After the experiments, all the samples surfaces were analysed by XPS and a depth profile can be obtained. Our surface analysis system contains one main chamber along with three loadloack mechanism. The main chamber is equipped with an electron energy analyzer, an ion mass spectrometer, a x-ray source, an electron gun, an ion gun for depth profiling, an extractor gauge, and a residual gas analyzer. The analysis system is capable of executing Auger electron spectroscopy (AES), secondary ion mass spectrometry (SIMS) with argon ion etching, and XPS with probing area of 2 mm. Fig. 1 is the overview of our surface analysis system. The main chamber is maintained at extremely high vacuum [4].

The three loadlock mechanism provides the facility to transfer the samples from vacuum environment to main chamber without exposing them in to air. A vacuum suitcase (maintained at UHV) can be attached to one of the loadloak chambers with it and sample can be transferred from the suitcase to the analysis chamber keeping in vacuum. A sample storage chamber, which maintains the base pressure of 10^{-8} Pa, is also connected to one of the loadlock chambers to keep remaining samples in the carousel in UHV. Also, samples can be mounted to one of the loadlock chambers directly from the atmosphere and can be transferred to main chamber after achieving UHV.

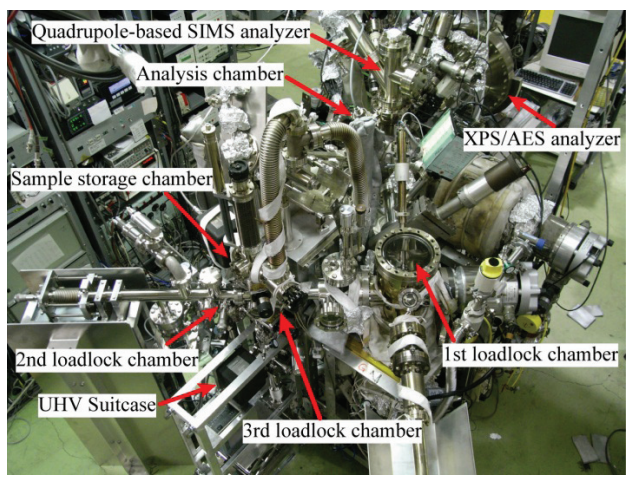

Figure 1: Overview of the surface analysis chamber.

HPR Experiments

We have conducted a series of HPR experiments on three Nb samples with three different pressures and two doses. The dose can be defined as the total injected

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

quantity of water/area. The aim of the experiment was to explore the effect of different parameters of HPR on contaminants removal after the surface chemistry.

A commercial Kranzle high pressure washer machine was used for the HPR experiments which can attain the pressure up to 15 MPa. The nozzle of the lance was made of ceramic with the diameter of 1 mm. For the experiments, three Nb samples (rectangular type: 20x14x2.8mm^3) were initially BCPed and a depth of 20 µm was removed. The sample (one by one) was mounted on a base plate which was fixed on a slide rail and can be slid during the HPR. We used one separator which separates the sample in two parts, to avoid the effect of rinsing of another position by side-streams of the water beam. Each sample was subjected to two doses at different places for each pressure. In order to keep the same dose as of other HPR facilities, we had calculated the total scanning time of the sample during the HPR was 1 second corresponding to a dose of 0.79l/cm^2. The other dose of 7.9l/cm^2 corresponding to a scanning time of 10 second was selected to compare the effect of different doses. During the HPR, each sample was manually scanned. Totally, six experiments were conducted with two doses for three different pressures. The distance between sample and nozzle was kept 50 mm to get highest pressure and to avoid the spreading of water beam. The experiment was conducted in class 1000 clean room. After the HPR experiment, all the samples were analyzed by XPS and a depth profile was obtained for each experiment.

EXPERIMENTAL RESULTS

XPS results of the BCPed sample followed by UPW rinsing only, showed that a huge amount of fluorine (up to 7 at. %) was found at top surface.

Table 1: The atomic composition present at top surface of the samples after HPR with different pressures as a function of dose

Elements	Atomic Composition Present at Samples Surface (Atomic %)						
	Dose=0.79l/ cm^2			Dose=7.9l/ cm^2			UPW rinsing
	8 MPa	10 MPa	15 MPa	8 MPa	10 MPa	15 MPa	
Nb	19	20	16	18	22	19	24
C	17	17	28	17	21	19	23
O	62	54	55	63	57	62	45
F	1.5	1.2	1	1.2	0.3	0.3	7

As it can also be encountered from the table 1 that the HPR was quite effective to mitigate the fluorine from the sample surfaces. The lowest fluorine was found on the surfaces treated with the higher dose. According to XPS results, it is evident that not only the higher pressure is effective in order to mitigate the chemical contaminants from the surface but higher dose is more advantageous over the high pressure.

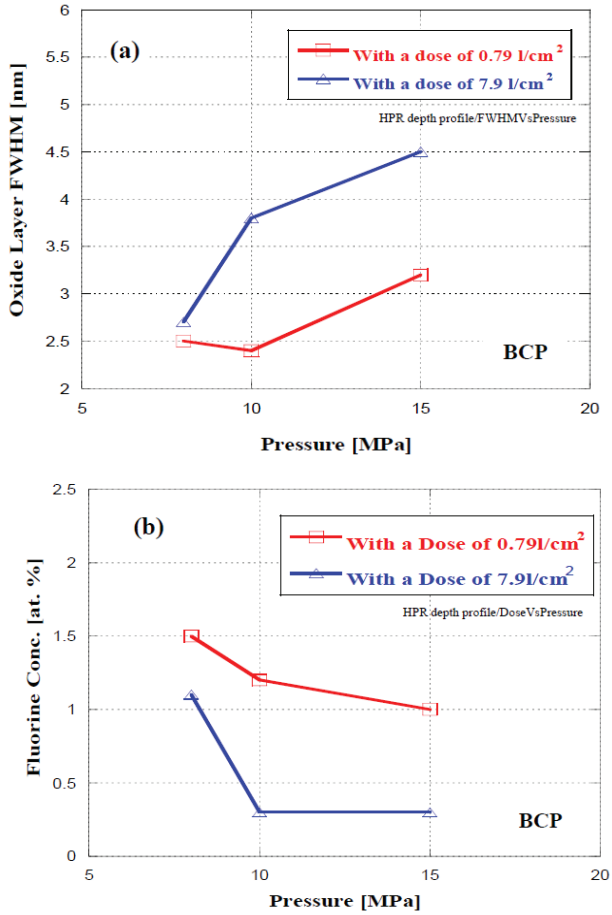

Figure 2: (a) Variation of oxide layer FWHM as a function of pressure and dose. (b) Reduction in fluorine concentration based on pressure and dose.

The depth profiles of all the samples showed a great increment in the thickness of oxide layer after the HPR. It can be seen from the fig. 2 (a) and (b) that the fluorine was reduced to same amount (up to 0.3 at.%) in case of the HPR with 10 MPa and 15 MPa with a high dose but a thicker oxide layer was produced by HPR with 15 MPa and a high dose. The FWHM oxide layer was found 0.7 nm thicker in case of 15 MPa than 10 MPa with a high dose (see table 2).

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Table 2: The FWHM oxide layer thickness of after the HPR.

Pressure (MPa)	FWHM oxide layer thickness (nm)	
	Dose=0.79l/ cm^2	Dose=7.9l/ cm^2
8	2.5	2.7
10	2.4	3.8
15	3.2	4.5

It is also noticed that the amount of fluorine was increased at 1 nm depth and was similar in all the cases which shows that the HPR is effective to mitigate the contaminants from top layer of surface (<0.5 nm) only.

DISCUSSIONS

After the surface chemistry of Nb SRF cavities, the chemical residues such as fluorine and sulfur left after the process are expected to be the measure source of field emission during the operation of Nb SRF cavity. The HPR with optimum parameters will provide the better performance of SRF cavities ultimately a significant reduction in the production cost of Nb SRF cavities. Our surface analysis results of the HPR experiments showed that the HPR with high pressure and high dose was quite effective to remove contaminants after the surface chemistry. The depth profiles of the samples showed that the HPR with high pressure and dose produces a thicker oxide layer which might be a concern from SRF point of view. As it can be seen from our results, one side HPR with high pressure and dose seems to be very effective in order to mitigate the contaminants, another side it produces a thicker oxide layer. Therefore, in order to use HPR effectively, the balance in all the operating parameters should be carefully determined.

CONCLUSIONS

We have conducted a series of HPR experiments with three different pressures of 8, 10 15 MPa and two doses of 0.79l/cm^2 and 7.9l/cm^2. The experimental results showed that the fluorine was reduced to same amount after the HPR with high pressures of 10 and 15 MPa and a dose of 7.9l/cm^2 while a thicker oxide layer was created in case of the sample treated with 15 MPa and 7.9l/cm^2. Therefore it can be concluded from our experiments that the HPR with high pressures and doses is very effective to mitigate the contaminants after the surface chemistry but produces a thicker oxide layer.

ACKNOWLEDGMENT

The authors express their special thanks to Mr. T. Noguchi and Mr. V. Chouhan for their support in the experimental work.

Abstract

Quality control is a key factor in the SRF cavity mass production. This paper summarizes ongoing research at the facility of Rare Isotope Beams (FRIB) to validate the quality assurance of SRF cavities while optimizing processing procedures for mass production. Experiments are conducted to correlate surface cleanliness for niobium surfaces with high pressure rinse time using β=0.085 quarter-wave resonators (QWR) cavities. Diagnostic devices, a liquid particle counter, a surface particle detector and a total organic carbon (TOC) analyzer are used to monitor key parameters for quality control. Rinse water samples are collected during high pressure rinsing to measure liquid particle counts. The SLS 1200 Sampler is used to detect the presence of liquid particles of 0.2µm and up to 1µm to set standards for acceptable cleaning thresholds and optimize high pressure rinse time. The QIII+ surface particle detector is used to scan the high electric field region of the β=0.085 QWR to ensure high pressure rinsing efficiency. The β=0.085 QWR RF testing data are analyzed and results are presented to investigate the correlation between attained acceleration gradients and surface cleanliness.

INTRODUCTION

A quality control (QC) system is in place for cleanroom processing of SRF cavities at FRIB. The FRIB QC system embeds diagnostic tools and stringent cavity processing procedures to control particle contamination, increase field emission onset level and attain high acceleration gradients. The e-traveler system is launched to document procedures and to provide a reporting tool for data mining and decision-making. This paper presents the findings of the commissioning and use of the liquid particle counter during the high pressure rinsing process. The paper also focuses on the QC steps for the clean assembly of β=0.085 QWR, and investigates the potential of predicting the cavity attained gradient (E_{acc}) at field emission onset based on its QC data collected during processing.

QUALITY CONTROL FOR CLEANROOM PROCEDURES

High Pressure Rinsing (HPR)

HPR is a key step that precedes the final SRF cavity assembly for RF vertical testing. HPR is proven the most effective tool as a final surface treatment to remove particles and to reduce field emission [1]. The FRIB HPR tool for production is still under development. The current HPR tool resides in an ISO5 cleanroom. Cavities are high pressure rinsed by rotating the cavity on a rotary aluminum cylinder flange as illustrated in Figure 1. A stainless steel spray nozzle wand with 8 jets moves in and out from below the rotating cavity. The HPR system utilizes a 3HP CAT pump and a final 0.1µm filter; both of which are located outside the cleanroom. The CAT pump pressurizes the ultra-pure water to ~ 8300 kPa.

Figure 1: β=0.085 QWR on high pressure rinse in ISO5 cleanroom

Ultra-pure Water (UPW) Quality Control

A reliable ultra-pure water system is essential to the successful operation and process quality of the HPR system. The current ultrapure water system is fed by a 7.6 l/m reverse osmosis system (RO). The resistivity of the ultrapure water system ranges between 17.2-17.6 MΩ-cm. The resistivity is monitored by an inline resistivity meter. The TOC is measured routinely for all points of use on the UPW distribution line using a TOC analyzer. The UPW TOC levels are consistently below 50 ppb. The microbiological quality of the system is analyzed every year to detect any bacterial buildup and assess the need for the system sterilization. Ultimately, a well-defined maintenance schedule is followed to replace critical system components. [2]

Another integral component for monitoring the UPW and the HPR process is the liquid particle counter. The Liquid particle counter (SLS-1200) is a device that pressurizes the water sample using a built in pump and a syringe. The device is capable of detecting 0.2µm size particles and up to 1µm. A ¼" stainless steel national pipe tapered thread (NPT) fitting was installed on HPR system tray to collect drain water samples during cavity HPR.

Liquid Particle Counter Commissioning Experiments

An experiment was set up to HPR one β=0.085 QWR (SC246X) and commission the liquid particle counter. The cavity was high pressure rinsed for 140 minutes per standard operating procedure. Rinse water samples were collected off the NPT fitting with tygon tubing that fed directly into a glass beaker. Another set of samples was collected directly off the NPT fitting without the tygon tubing. Samples were analyzed for liquid particle counts to display a descending trend with time as the cavity gets cleaner (see Figure 2). Athough the tygon tubing was ultrasonic cleaned, the cumulative liquid particle counts in rinse water samples collected with the tubing attached were extremely higher than those collected without the tubing. It was concluded that liquid particle counts samples should be collected directly off the NPT fitting.

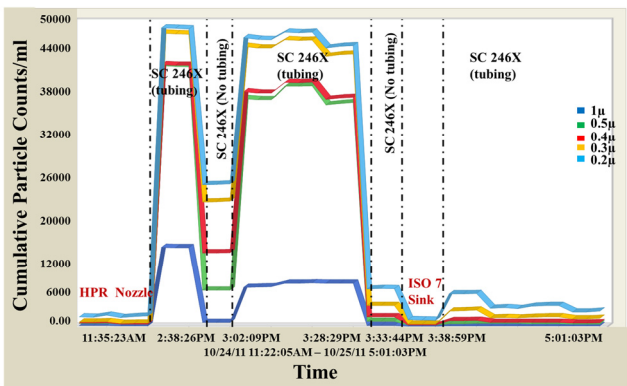

Figure 2: β=0.085 QWR (SC246X) HPR liquid particle counts time chart 10/24/2011

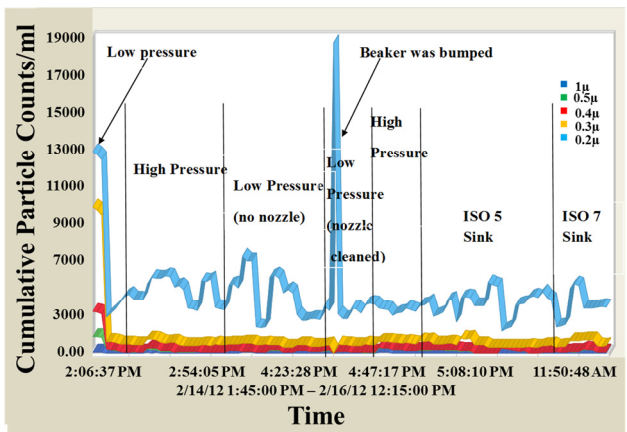

Figure 3: Liquid particle counts time chart for the UPW baseline experiment 02/14/12 - 02/15/12

Figure 3 displays the results for the baseline water quality experiment. This experiment was performed to investigate the water quality of the UPW system and to determine the HPR system baseline particle counts.

High and low pressure water samples were collected from the HPR wand with and without the spray nozzle. Samples were also collected from the ISO7 and ISO5 cleanroom sinks. Then the nozzle was disassembled from the wand, inspected, ultrasonic cleaned and re-installed to collect low and high pressure samples. UPW samples were also collected from ISO5 and ISO7 cleanroom sinks. Results were plotted for comparison (see Figure 3). TOC and resistivity were recorded for each sample with values of 58 ppb and 17.2 MΩ-cm respectively. It was concluded that UPW from HPR spray nozzle has the same quality as the cleanroom sinks. The 0.3µm cumulative liquid particle counts ranged between 400-500 particles/ml.

It was noted that on one of the samples the beaker was accidently bumped, creating a lot of bubbles. A sharp peak was recorded on the 0.2µm size counts (Figure 3), probably counting air bubbles as particles. Thus we will only report the 0.3µm cumulative liquid counts for all subsequent cavity processing and experimental work.

Components Preparation, Cleaning & Assembly QC Steps

Components used on cavity assembly undergo QC checks for residual magnetic field using a magnetometer. A demagnetizer is used to demagnetize components with residual field levels greater than 50 mG for ReA3 and greater than 15 mG for FRIB. The residual magnetic field is re-checked to ensure the acceptable threshold was attained. Components are prepared for the cleanroom using the following standard operating procedure: degrease with acetone, scrub using 1% solution of Micro-90®, rinse in deionized water, and wipe with ethanol. Components ultrasonic cleaning takes place in the ISO7 cleanroom for 30 minutes in a 1% solution of Micro-90® in UPW at 37.8°C, followed by a final ultrasonic rinse in UPW at 60°C for 40 minutes [3]. In the ISO5 cleanroom components are set to dry for assembly on the next day.

QC checks are performed on cleaned, dried components prior to their assembly to the cavity. The QIII+ surface particle counter is used to scan the seal surface on blanks, flanges, tuning plates, input and output couplers. The device is capable of detecting the presence of 0.3µm particles and up to 10µm. The surface particle detector uses a destructive sampling technique; as particles are removed from the surface, therefore the component gets cleaner. Surface particle counts are performed inside the cavity beam ports and RF ports. The inner surface of the outer conductor is also scanned for surface particle counts in the region below the beam and RF ports. These counts are illustrated as Q1, Q2, Q3 and Q4 in Figure 5. The surface particle count threshold for qualifying assembly components is set at 0.05 particles/cm^2 for the 0.3µm cumulative counts.

Air particle counts are performed at the cavity beam line before assembly to detect the 0.5µm particle size counts. The QC threshold of less than 1333 particles/m^3 must be attained for the clean assembly to take place.

CAVITY PROCESSING QC DATA & TEST RESULTS

Three β=0.085 QWR production cavities have passed the vertical Dewar testing at 4.3K and have been certified and assembled toReA3 coldmass string. During the tests, the amount of X-rays emitted from the cavity is measured

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

with an ion chamber approximately 1 meter from the cavity. Figure 4 shows that the acceleration gradient for SC251, 256 and 252 production QWRs had a large margin above the ReA3 goal of 3.4 MV/m. The figure also shows test results for two prototype cavities (SC246 & SC247).

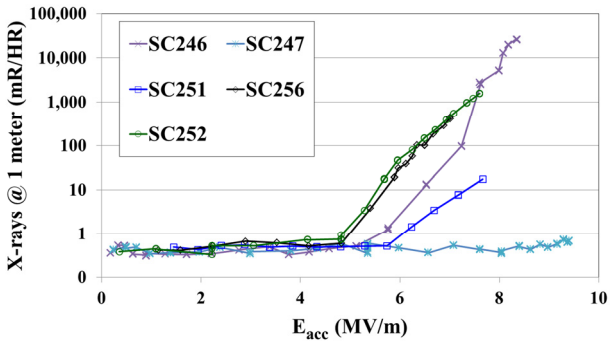

Figure 4: Field emission vs. E_{acc} for β=0.085 QWRs

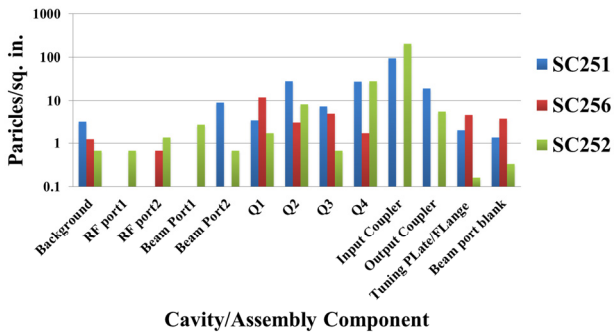

Figure 5: 0.3µm cumulative surface counts for β=0.085 QWR production cavities

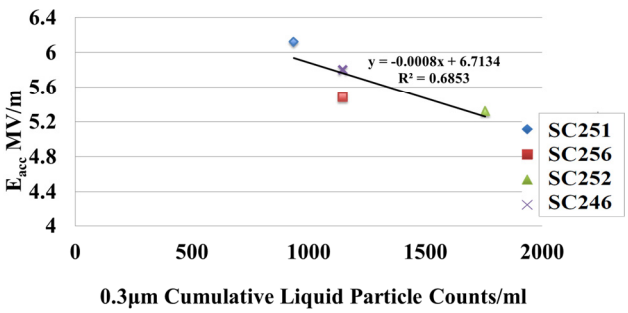

Figure 6: E_{acc} vs. 0.3µm cumulative final HPR liquid particle counts for β=0.085 QWR cavities

All cavities were processed per standard operating procedures; liquid particle counts were sampled every 20 minutes during HPR. QC checks and surface particle counts were performed on the cavities and assembly components to quantify cleanliness as in Figure 5.

Figure 6 is a plot for the 0.3µm cumulative liquid particle counts at the end of the β=0.085 QWR HPR vs. the cavity accelerating gradient at initial field emission onset. The figure illustrates a trend for an acceleration gradient at initial field emission onset of less than 5.9 MV/m if the cumulative liquid particle counts at the end of HPR is greater than 1000 particles/ml. We reported SC247 test results with no field emission and with the implementation of the QC system we recorded its final HPR cumulative liquid particle counts to be equal to the baseline particle counts of the UPW at HPR point of use.

CONCLUSION

FRIB cleanroom procedures have improved with the contribution of the QC system to ensure reproducibility of processing & clean assembly for mass production. The liquid and surface particle counters have been successfully commissioned and used. Acceptable cleaning thresholds have been identified. The overall surface cleanliness of cavities and assembly components has improved. The performance of β=0.085 QWR cavities that have been tested over the past year has improved; all production cavities were certified for ReA3. The processes are being optimized as this work paves the way for FRIB mass production through systematic procedures involving liquid, surface particle counts, field emission onset and acceleration gradient measurements. We reported findings on cavity liquid particle counts data during the HPR process that correlated to RF test results. Preliminary results show a trend for the acceleration gradient at FE onset that decreases as the 0.3µm cumulative liquid particle counts in cavity rinse water increases at the end of HPR. However many more cavity processes and tests are necessary to build a reliable statistical database and to define the right processing scheme for each cavity type.

AKNOWLEDGMENTS

The authors would like to thank all the members of the NSCL and FRIB for their significant contribution to this paper in particular Matthaeus Leitner, Steve Bricker, Chris Compton, Ken Witgen, Douglas Miller, David Norton, Andrew Wisniowiecki, Dan Victory and Nicholas Putman. We also would like to acknowledge and thank Bob Laxdal, John Mammosser and Peter Kneisel for their contributions and fruitful discussions.

Abstract

The Facility for Rare Isotope Beams (FRIB) will utilize over 330 superconducting radio frequency (SRF) low beta cavities for its heavy ion driver linac. The SRF department will process and test all cavities prior to string assembly in the cleanroom. The baseline processing procedures have been established. The methods are being optimized for production rate benchmarking. Additional processes are being developed to increase flexibility and reduce technical risks. This paper will describe developments and experimental results. Topics include high temperature heat treatment for hydrogen degassing, selective chemical etching for cavity frequency tuning, low-temperature bake out and process quality control.

INTRODUCTION

The ReAccelerator (ReA) and FRIB projects at MSU both utilize a 80.5 MHz β=0.085 quarter wave resonator (QWR) design [1]. For the ReA3 project eleven cavities have been fabricated and eight need to be certified, while for the FRIB project, 126 cavities need to be fabricated with 94 qualified for use in a cryomodule. The ReA project allows for the chance to gain valuable production experience. To meet the ReA3 cavity frequency specifications a differential etching technique with Buffered Chemical Polish (BCP) was developed for post fabrication tuning. The technical risks regarding cavity performance for ReA linac operation were reduced by establishing a low temperature bakeout method and a high temperature heat treatment - both of which improved cavity Q_0 values. The process steps for the ReA3 cavities are shown in Table 1. The process procedures will be optimized from lessons learned during the ReA cavity production.

Table 1: Summary of process steps for ReA3 cavities.

Step	Cavity Process Steps
1	Degrease, bulk BCP, dry, frequency measurements
2	Differential BCP, dry, frequency measurement
3	Degrease & hydrogen degas
4	Degrease, light BCP, High Pressure Rinse (HPR)
5	Clean assembly, evacuation, 120°C low temperature bake
6	*Test preparations and RF Dewar testing*
7	Clean removal from test stand and install to coldmass

In preparation for FRIB production, a comprehensive program is in place to improve process quality control and documentation. Innovative diagnostic tools allow for the quantification of process and assembly parameters for quality control [2]. The cavity fabrication, processing and vertical test parameters are recorded in a computer database (electronic traveler system), for cavity characterization and analysis. The database is accessible through a web-based interface, and will ease the analysis of 50 cavities before FRIB production.

HYDROGEN DEGASSING

The risk of Q-disease has been mitigated by implementing a hydrogen degassing step to the cavities after the bulk chemistry. The cavities are fired in a high temperature vacuum furnace for 10 hours at 600°C, while maintaining vacuum less than $5X10^{-6}$ Torr. The heat treatment removes much of the hydrogen from the bulk niobium material. Multiple QWRs and half wave resonators (HWRs) have been heat treated, using furnaces at Jefferson Lab and Fermilab, in an effort to quantify the benefits of the treatment both at 4.2 K and 2 K. The furnace design and heat treatment cycle have been optimized for production, considering both mechanical impacts to the cavity structure and overall schedule constraints. The current FRIB cavity furnace cycle is about 40 hours and includes pump down, temperature ramp up, steady state bake at 600 °C and cool down.

Figure 1: T-M Vacuum® high temperature vacuum furnace commissioned and being used to heat treat cavities at MSU.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The FRIB baseline calls for all SRF cavities to receive heat treatment. A high temperature vacuum furnace, shown in Figure 1, was procured from T-M Vacuum® in 2011 and installed and commissioned at MSU in 2012. The furnace fits two FRIB cavities per cycle.

DIFFERENTIAL REMOVAL AND TUNING

In an effort to compensate for frequency shifts during β=0.085 QWR fabrication, a program of frequency tuning by targeted material removal was undertaken. Removing material from the magnetic field region of the β=0.085 QWR will reduce the cavity frequency, while removing material from the electric field region (Fig. 2) will increase the cavity frequency. The process used to remove material from the RF surface must be reproducible, in order to accurately tune to the desired frequency goal after fabrication.

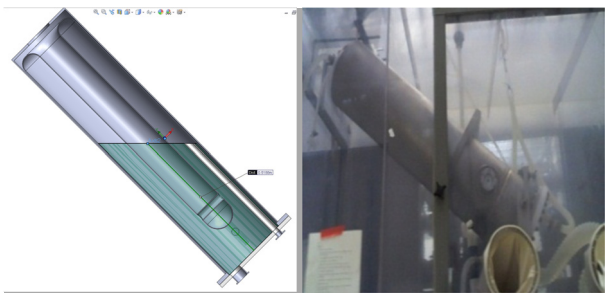

Figure 2: Differential etching setup for removal in high electric field region of the β=0.085 to increase frequency.

Etching with BCP was chosen to remove material because it was most likely to be uniform and repeatable. Simulations were performed to predict the expected amount of frequency shift per micron of niobium removed from the surface. The simulation predicted the cavity frequency would shift by 0.9 kHz/μm when etched in the high electric field region. A custom flange was fabricated to allow BCP circulation, while maintaining a specific fill height. After three trials an empirical tuning factor, kHz/μm, was calculated. The factor is recalculated after each custom etch for increased accuracy (Fig. 3).

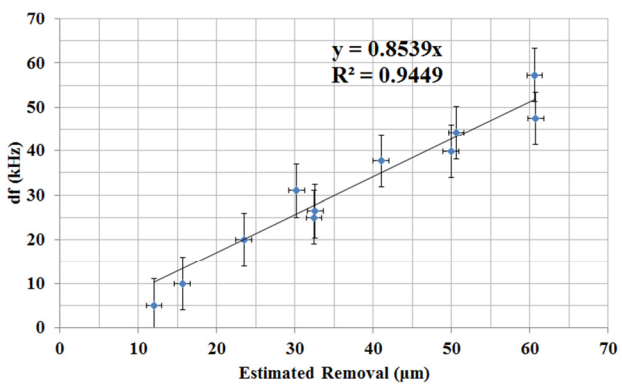

Figure 3: Measured frequency shift (kHz) versus the estimated material removal (microns).

Eight of the β=0.085 QWRs for ReA3 required a frequency increase and have been successfully tuned with this method. The current tuning factor is 0.8539 kHz/μm for removal in the electric field region. The average error is within 6 kHz of the desired frequency before the degassing procedure, which can cause unpredictable shifts up to 7 kHz. After degassing, the final frequency is set, to within 5 kHz (well within the operational fine tuning range) by attaching a custom length "puck" to the demountable niobium tuning plate with an e-beam weld which does not disturb the prepared cavity.

LOW TEMPERATURE BAKEOUT

Performing a 48-hour long 120ºC bakeout procedure, prior to cavity testing, has proven to be beneficial in improving the performance of the β=0.085 QWR at 4K (Fig. 4).

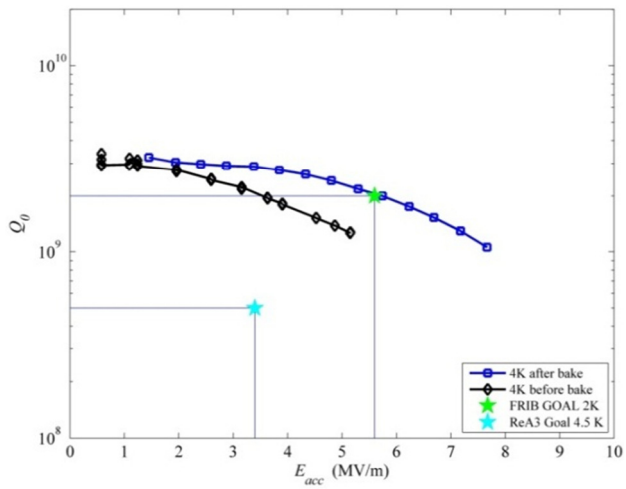

Figure 4: Q_0 versus E_a showing improvement in cavity performance after low temperature bakeout application.

After clean cavity assembly to the test stand and evacuation, the stand is removed from the cleanroom. The cavity is then wrapped in fiberglass heat tape and a gas heater is attached to the helium return flange on the vessel. Twelve thermocouples, five of which are connected to controllers, monitor the internal and external cavity temperatures to ensure that the temperature does not exceed 120ºC. Especially important to monitor is the bottom flange of the cavity, which cannot exceed 156ºC, the temperature at which the indium wire used in the vacuum seal will begin to melt. The cavity is wrapped in foil for insulation, and the temperature is slowly ramped up to 120ºC and then monitored for 48 hours. Residual gas analyzer scans are taken during the baking cycle to monitor the pressure in the cavity and to allow for the presence of any potential contaminants to be determined. The gradual stabilization of the pressure over time is indicative of the removal of water and other low-boiling contaminants in the vacuum space. The bakeout process has proven itself to be a low cost method by which to quickly improve the low field quality factor and somewhat recover the higher field Q-slope in an underperforming cavity. The bake application is being

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

considered as an optional process step for FRIB cavities exhibiting slightly low Q_0 during vertical test. A test stand bake oven is under development which will minimize the process time.

PROCESS QUALITY CONTROL & DOCUMENTATION

Overall cavity performance and certification rate in both the vertical Dewar and final cryomodule testing is improved by continuous documentation and aggressive quality control. Diagnostic tools are used to monitor and quantify the process data [2] and to discover problems quickly so they can be corrected. Documented process parameters include: water quality identifiers, niobium concentration in BCP, High Pressure Rinse (HPR) liquid particle counts, and surface particle counts of cavity RF surfaces and associated vacuum hardware. An inclusive process and maintenance management system, the electronic traveler (e-traveler), is used to record fabrication, process and test data for various devices (Fig. 5) and control process steps. The data can be searched, extracted, and analysed for correlations and post failure analyses (Fig. 6). Scheduled reports can be produced for various data fields or parameters and specified devices, being helpful to track trends and provide feedback.

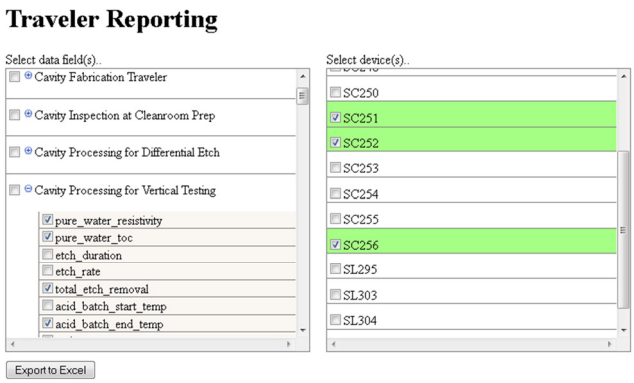

Figure 5: Screenshot of the reporting function which quickly exports any selected data field and device to an Excel® file.

Device SN	nb_concentration_solution	particle_count_end	spc_tuning_plate	initial_field_emission	low_field_q0	q0_120	xray_count_120
SC251	2.1	936	0	6.12	2.60E+09	1.50E+09	0.5
SC252	13	1775	0	5.32	2.80E+09	1.30E+09	0.8
SC256	13.3	1146	1.33	5.48	5.00E+09	3.25E+09	0.52

Figure 6: Sample of an e-traveler report for selected data fields and devices (in this case ReA3 cavities).

The initial release of the e-traveler system allows for its use during the ReA3 coldmass production. This has been beneficial to streamline the system and move toward production operations. The e-traveler reporting function reduces the time to identify the correlations between cavity process parameters and the cavity RF test results. These trends guide the optimization of the process procedures to ensure that they are effective, yet efficient.

Device routers, assembly work instruction and standard operating procedures are written and controlled as FRIB documents by the FRIB Manufacturing Engineering group and will eventually be embedded as links in each e-traveler form.

CONCLUSION

The recently developed procedures presented here have been applied to ReA3 cavities. Three of the cavities have been successfully RF tested, certified and installed to the coldmass string. The processing procedures and quality control techniques have proven to be effective at producing the required performance specifications for ReA3 cavities during vertical Dewar testing (Fig. 7).

MULTIPOLE EXPANSION OF THE FIELDS IN SUPERCONDUCTING HIGH-VELOCITY SPOKE CAVITIES *

R. G. Olave, J. R. Delayen, C. S. Hopper, Center for Accelerator Science, Old Dominion University
and Thomas Jefferson National Accelerator Facility, VA, USA †

Abstract

Multi-spokes superconducting cavities in the high-beta regime are being considered for a number of applications. In order to accurately model the dynamics of the particles in such cavities, knowledge of the fields off-axis are needed. We present a study of the multipoles expansion of the fields from an EM simulation field data for two-spokes cavities operating at 325 MHz, $\beta = 0.82$, and 500 MHz, $\beta = 1$.

INTRODUCTION

In recent years there has been considerable progress in the optimization and characterization of accelerating multi-spoke cavities in the high-velocity regime ($\beta_0 = v_0/c > 0.6$). Multi-spokes cavities have several advantages over the more traditional multi-cell elliptical cavities [1, 2], such as increased longitudinal acceptance, lower superconducting surface resistance and therefore lower heat load allowing for operation at 4K, and a cavity diameter on the order of half the rf wavelength, which allows for lower operating frequencies for a given size.

The lack of cylindrical symmetry of the multi-spokes cavities might result in the presence of non-negligible higher order multipole components of the operating mode. In order to study the impact of the cavity fields on the beam dynamics, it is necessary to characterize off-axis fields. To this end, we present a study of the multipoles expansion of the fields for the operating (fundamental) cavity mode for spokes operating at 325 MHz, $\beta = 0.82$, and 500 MHz, $\beta = 1$.

MULTIPOLAR RF KICKS AND FIELD EXPANSION

It has recently been demonstrated that surface fitting of field data around a virtual cylinder in the proximity of the beamline can be used to compute high-order transfer maps, interior fields, and non-linear beam dynamics including high-order multipole effects [3, 4].

From the interpolation of the electromagnetic fields on the surface of a virtual cylinder of radius R through the length of the cavity in a region with no charge, a general complete solution to the fields can be found. The accelerating electric field can then be expressed as:

$$E_{acc}(r,\phi,z) = E_z e^{i\omega t} = E^{(0)}_{acc-c} + \Big(\sum_{n=1}^{\infty} r^n \big(E^{(n)}_{acc-c} cos(n\phi) + E^{(n)}_{acc-s} sin(n\phi)\big)\Big) e^{i\omega t} \quad (1)$$

Where E_{acc} is the accelerating electric field along the beamline direction z and ω is the rf frequency. If the field $E_{acc}(R,\phi,z)$ is known, then the coefficients $E^{(0)}_{acc-c}$, $E^{(n)}_{acc-c}$ and $E^{(n)}_{acc-s}$ can be found via inverse Fourier integration of the surface fitted field.

Inserting this series into the Panofsky-Wenzel theorem we may then calculate the transverse change in momentum (kick) of the particles as a series of multipolar RF kicks:

$$\Delta p_{\perp} = \Big(\frac{e}{\omega}\Big) \int_{-\infty}^{+\infty} (-i)\nabla_{\perp} E_{acc}|_{t=z/v_z} dz \quad (2)$$

To get an idea of the impact of the nonlinear effects of the higher order field multipoles, it is useful to compare the strength of the multipolar RF-kicks with that of magnetic multipoles [7]. It is usual to express the magnetic potential and static magnetic kick to incoming particles as a Taylor series expansion [5, 6]. In magnets, the a_n and b_n terms are determined by the orientation of the magnet, such that a_1 corresponds to a vertical bend of the particle trajectory, b_1 to a horizontal bend, and in general a_n correspond to skew oriented magnets and b_n to normal oriented magnets. For simplicity we will continue to use this nomenclature. Obviously, the b_0 or monpole term is not dependent on the orientation of the cavity and corresponds to the accelerating voltage across the cavity. Following this idea, we find:

$$b_0 = \int_{-\infty}^{+\infty} E^{(0)}_{acc-c}(z)dz, \propto V_{acc}$$
$$b_n = \int_{-\infty}^{+\infty} \frac{ni}{\omega} E^{(n)}_{acc-c}(z)dz, (n = 1, 2, ...) \quad (3)$$
$$a_n = \int_{-\infty}^{+\infty} \frac{ni}{\omega} E^{(n)}_{acc-s}(z)dz, (n = 1, 2, ...)$$

Additionally, the rf multipole strength depends of the rf phase of particles traversing the cavity; so we can express them as complex numbers, where the real part corresponds to particles on crest, and the imaginary part corresponds to particles off-crest.

RF CAVITIES

We are in the process of design and characterization of a 325 MHz, $\beta = 0.82$ cavity; the optimization procedure, multipacting, and higher-order mode analyses have been presented elsewhere [8, 9, 10]. The 3D electromagnetic fields were obtained using CST Microwave Studio® 2012 (CST MWS). Table 1 lists the cavity's relevant RF parameters.

Table 1: RF Parameters of the 325 MHz cavity (At E_{acc} = 1 MV/m and reference length $\beta_0\lambda$)

Parameter		Units
Frequency	325	MHz
β_0	0.82	
R/Q	629	Ω
$(R/Q) * (QR_s)$	99200	Ω^2
E_p/E_{acc}	2.8	
B_p/E_{acc}	5.3	mT/(MV/m)
Bp/Ep	1.9	mT/(MV/m)
Energy Content	0.445	J

In order to get a better understanding of the beam dynamics, we present in Fig. 1 a plot of the transverse voltage (in the x and y directions) as a function of transverse offset from the design beamline. It is clear that focusing would occur in one direction while defocusing would occur in the other. This behavior is characteristic of quadrupole fields, so we may conclude that the dominant higher order multipole is a quadrupole. The transverse voltage due to higher-order multipoles is less than 1% with respect to the accelerating voltage. An open picture of the cavity with the electric surface fields is shown as well.

The results of the calculation of the multipole strength numbers are presented in table 2, up to the octupole terms. The numbers have been normalized to simulation field data such that V_{acc} = 1 V; notice that the deviation from this value gives us a measure of the error in our surface fitting calculation.

Table 2: RF Multipole components, normalized from simulation field data to $V_{acc} = 1V$, of the 325 MHz, $\beta = 0.82$ cavity.

Multipole component		Units
V_{acc}	0.89	V
V_x	0	V
V_y	0	V
b_2	-0.01 - 1.09 i	nT
a_2	0.003+0.22 i	nT
b_3	0	nT/m
a_3	0	nT/m
b_4	23.8 - 128.7 i	nT/m^2
a_4	-9.9 + 53.3 i	nT/m^2

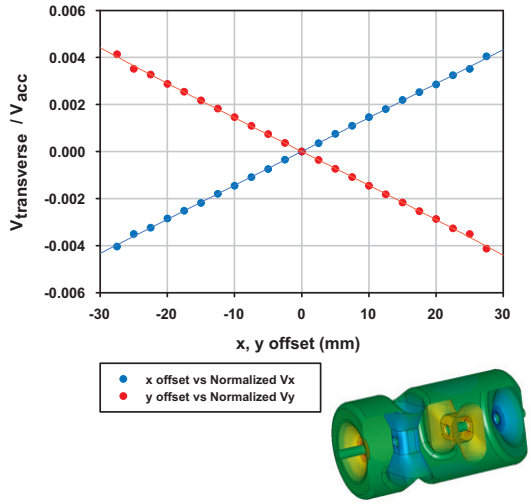

Figure 1: Normalized transverse voltage as a function of transverse offset, for the 325 MHz, $\beta = 0.82$ cavity. A CST MWS picture of the surface fields of the open cavity is shown for reference.

We have designed cavities operating at an rf frequency of 500 MHz, β = 1, optimized with racetrack-shaped spokes. It has recently been observed that there may be geometries in which the quadrupole effects can be minimized, specifically ring-shaped spokes, which exhibit more symmetry about the beamline [11]. Table 3 presents the relevant RF parameters for a cavity with racetrack shaped spokes, and for a cavity with ring spokes. This latter geometry has not been fully optimized yet for high shunt-impedance and/or low surface-fields, however it already exhibits promising rf characteristics.

Table 3: RF Parameters of the 500 MHz cavities (At E_{acc} = 1 MV/m and reference length $\beta_0\lambda$)

Parameter	Racetrack spokes	Ring spokes	Units
Frequency	500	500	MHz
β_0	1	1	
R/Q	725	737	Ω
$(R/Q) * (QR_s)$	124000	118000	Ω^2
E_p/E_{acc}	3.5	3.9	
B_p/E_{acc}	5.4	7.1	mT/(MV/m)
Bp/Ep	1.6	1.8	mT/(MV/m)
Energy Content	0.158	0.155	J

Picures of the cavities with racetrack-shaped spokes and ring-shaped spokes are presented in Figs. 2 and 3 respectively. Also presented are a plot of the transverse voltage field with respect to spatial offset from the design beamline. It is clear that there is a noticeable reduction in the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

quadrupole strength, and an increase in effects from higher order multipoles, as evinced by the slightly oscillatory behavior. The same can be concluded from the multipole strength numbers presented in table 4, while we observe that the octupole term has indeed increased.

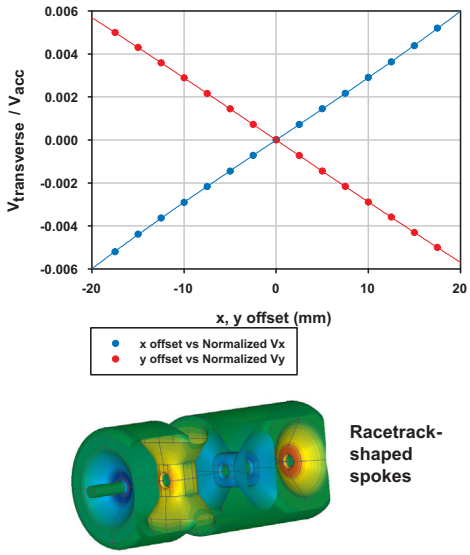

Figure 2: Normalized transverse voltage as a function of transverse offset, for the 500 MHz, $\beta = 1$ cavity with wide racetrack-shaped spokes. A CST MWS picture of the surface fields of the open cavity is shown for reference.

Table 4: RF Multipole components, normalized from field simulation data to $V_{acc} = 1V$, of the 500 MHz, $\beta = 1$ cavities.

Multipole component	Racetrack-shaped spokes	Ring-shaped spokes	Units
V_{acc}	1	1	V
V_x	0	0	V

COLD TESTING OF SUPERCONDUCTING 72 MHz QUARTER-WAVE CAVITIES FOR ATLAS

M. P. Kelly, Z. A. Conway, S. M. Gerbick, M. Kedzie, T. C. Reid, R. C. Murphy,
P. N. Ostroumov, Argonne National Laboratory, Argonne, IL 60439, U.S.A.

Abstract

A set of seven 72 MHz β=0.077 superconducting quarter-wave cavities for a beam intensity upgrade of the ATLAS heavy-ion accelerator has been completed. Cavities have been fabricated using lessons learned from the worldwide effort to push the performance limits for niobium cavities close to the fundamental limits. Key developments include the use of electropolishing on the completed cavity. Polishing parameters, including temperature, are better controlled compared to the standard horizontal electropolishing systems for elliptical cavities. Wire EDM, used instead of traditional niobium machining, looks well suited for preparing weld joints that are, with respect to quench, defect free. Hydrogen degassing at 625 C has been performed after electropolishing, removing the need for fast cool down in with 2 K or 4 K operation. Tested cavities have useful accelerating voltages of >3 MV/cavity at 4 K, as for ATLAS, and 5 MV or more per cavity at 2 K with B_{PEAK}>130 mT in 3 of 4 cases.

INTRODUCTION

The essential components of the ATLAS Efficiency and Intensity Upgrade [1] are a new CW radio frequency quadrupole injector and one new cryomodule of 7 SC cavities for β=0.077, scheduled to replace three existing cryomodules of split-ring resonators in the middle portion of the ATLAS SC ion linac. This upgrade follows upon the 2009 β=0.15 ATLAS Energy Upgrade cryomodule, presently the world leading cryomodule for low velocity ions, providing 14.5 MV accelerating voltage over 4.5 meters.

The new cryomodule will nominally provide 17.5 MV of accelerating potential at a lower beta of 0.077 in a 5 meter cavity string (see Figure 1). ATLAS beam transport efficiency for both stable and radioactive ion beams will be improved dramatically by increasing overall acceptance and reducing emittance growth inherent in the split-ring designs.

Figure 1: Initial mock up of the 72 MHz cavity clean room assembly.

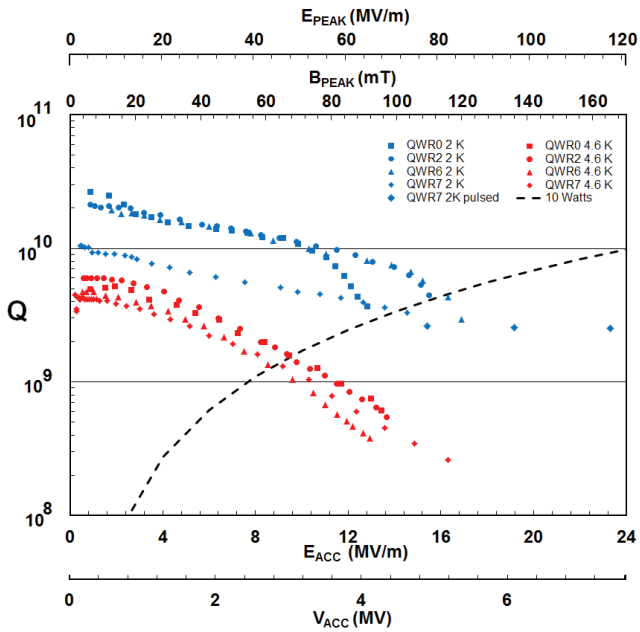

Figure 2: Quality factor versus accelerating gradient, voltage and surface fields at 2 and 4 K (l_{eff}=βλ=0.32m)

The planned cavity operating voltage of V_{ACC}=2.5 MV/cavity is roughly two times higher than for the present state-of-the-art at this beta, however, cavities and subsystems, including power couplers and cryogenics are all designed for operation with at least V_{ACC}~3 MV/cavity. Several improvements have been made since 2009 to achieve this performance, however, the two critical pieces are the improved rf design [2] and the unique capability to electropolish complete quarter-wave cavity/helium jacket assemblies [3].

CAVITY PERFORMANCE

Cold tests at 2 K and 4 K for four out of eight new 72 MHz cavities are complete and test results are shown in Figure 2. Seven of these cavities will be installed into ATLAS as part of the intensity upgrade and the eighth is for R&D and intended to advance the performance for this class of cavity [4]. Of the seven ATLAS cavities, four will be tested individually in the ANL test cryostat while the remaining three will be tested in the full cryomodule before installation into the ATLAS beamline. If a cavity requires a second round of cleaning, it can be removed

from the cryomodule string using the previously developed up-to-air system [5].

Electropolishing

A key processing step for the cavities was the heavy, 150 μm, electropolishing on the complete cavity. Two separate rounds of polishing are performed. First, after fabrication, the cavities were electropolished on consecutive days, removing 65 μm of niobium each day. Total polishing time was about 12 hours. The cavities were then baked under vacuum at Fermilab for 14 hours at 625°C in order to degas hydrogen. Last, the cavities were returned to Argonne for a final light 20 μm electropolish.

Fundamentally, the ANL low-beta cavity electropolishing system and associated polishing parameters are similar to those for horizontal systems used with 1.3 GHz cavities for the global international linear collider effort. There is one major improvement, however. Since quarter-wave cavities do not require field flatness tuning or direct access to the niobium surface after polishing, final heavy electropolishing can be performed with the complete cavity with liquid helium jacket. The helium jacket is used to directly cool the niobium surface with chilled (22+/-0.5 °C) water in order to maintain a stable and uniform temperature over the entire cavity surface. As for elliptical cells, the cavities are rotated during the procedure at a speed of 1 rpm, however unlike with most e-cells, the maximum temperature on the niobium surface never rises above 32°C at any time during the rotation period.

4 Kelvin Performance

In ATLAS cavities are operated with 4.5 K helium from the ATLAS refrigerator. The nominal accelerating gradient is 7.9 MV/m ($l_{eff}=\beta\lambda=31.75$ cm) or 2.5 MV/cavity with a quality factor of $Q=1x10^9$ and a corresponding total surface resistance of 26 nΩ. At least 10 Watts of cryogenic cooling per cavity will be available.

In four cavities tested so far, achieved cw cavity accelerating gradients at 4.6 K range between E_{ACC}=12.4-16.2 MV/m, or double the requirement for ATLAS. Most cavities had approximately 3 hours of low-level (E_{ACC}=0-1.5 MeV) multipacting conditioning and one half to 1 hour of short pulse conditioning with 4 kW peak power in order to achieve the measured performance shown in Figure 2. Based on recent cavity results for Spiral-2 [6], an 'in-situ' bake at 110-120°C for 48 hours was performed for QWR0 by circulating warm helium gas through the cavity helium vessel. In this case, cold testing before and after showed no measureable difference from baking. This is not considered to be definitive since the temperature variations of 10°C both in time and over the cavity surface were larger than desirable.

2 Kelvin Performance

ANL is also pursuing the developments needed in order to demonstrate practical 2 K operation, the likely operating mode for future large SRF linacs. The high practical cavity field gradients possible at 2 K, combined with the compact lattice of the Argonne cryomodule design, can provide 'real-estate' gradients of 7 MV/m (at B_{PEAK}=120 mT), or about 2-3 times higher than for today's state-of-the-art at 4 K. This would make feasible the construction of a compact proton linac that would be extremely attractive for the next generation of high-power accelerators in areas of energy, national security, and medicine.

The four cavities tested to date support this goal. Cavities reach magnetic surface fields in the range B_{PEAK}=98-165 mT. In two of four cases, the thermal magnetic breakdown was extracted from pulsed 5% duty cycle measurements in order to limit x-ray radiation at very high fields. These points are not included on the Q curve for QWR's 2 and 6. The lowest quench at 98 mT for QWR0 is due to breakdown on the central conductor, based on second sound measurements. The location corresponds to that of a known welding defect, where contamination on the center conductor weld preparation is strongly suspected. At the other end, the QWR7 never quenched (B_{PEAK}=165 mT) and was administratively limited due to x-ray emission at the very high field of E_{PEAK}=115 MV/m, a regime that the present test cryostat shielding was not designed for. QWR7 was also fabricated from RRR 300 niobium, rather than RRR 250, and received particularly careful attention during fabrication [4]. Quench locations for the other two QWR's, numbers 2 and 6, were not measured.

Generally, each of the four tested cavities is much more efficient at 2 K, even considering the additional cost of refrigeration. The 2 K residual resistance, ranging from 1-2.5 nΩ comes directly from low field decay time measurements. Values of 5 nΩ for accelerating gradients up to 12 MV/m in three out of four cavities are, indeed, low for any cavity of any type. A goal for future cryomodules of B_{PEAK}=120 mT with R_s=5 nΩ and V_{ACC}=5 MV/cavity at T=2 Kelvin is within reach based on these results.

Other Performance Considerations

Improvements other than electropolishing have been made since the 2009 upgrade. Electromagnetic (EM) optimizations of the 72 MHz QWR accounts for about 20% of the performance increase relative to the previous 109 MHz ATLAS Energy Upgrade cavities. The design has been presented previously [2], however, the most substantial new feature is the conical-shaped outer

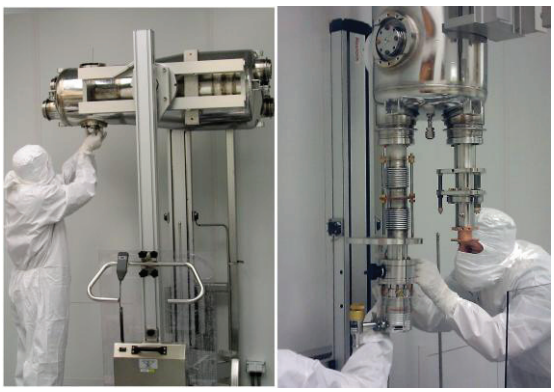

Figure 4: Clean room assembly for the 72 MHz QWR's.

housing which reduces B_{PEAK}/E_{ACC} by 20% compared to a straight cylindrical housing. No additional beam-axis space is needed since the expanded volume occupies the empty space already needed to join cavities together.

High values for E_{PEAK} in Table 1 are possible due to improved clean room fixturing. All of the assembly onto the six cavity ports is performed with the workers located well below the open cavity port (Fig. 4). Final rinsing of the cavities was performed for 1 hour through each of six ports in a class-100 clean room adjacent to the existing 1.3 GHz cavity rinsing area. The sequence for rinsing and assembly, as for e-cell cavities, includes mounting pickup probes, and blanks before the final rinse.

It is noted that wire electric discharge machining (EDM) was used to perform essentially all cutting on niobium subcomponents. The technique should, in principle, give similar results as for traditional mill machining, however, in practice it requires much less fixturing and technical skill with niobium and reduces the likelihood for embedding inclusions. Hydrogen contamination from EDM is not a major drawback since cavities require degassing anyway to achieve optimal performance at either 2 K or 4 K.

MICROPHONICS

Design and fabrication techniques for these quarter-wave cavities that nearly eliminate microphonic detuning include; (1) reduction of pressure sensitivity by EM design, (2) mechanical centering of the central conductor during fabrication, and (3) a passive mechanical damper to reduce the intrinsic mechanical Q of cavity vibrations. We show in Figures 5 and 6 early measurements of the effect of mechanical centering of the center conductor. Data is for QWR0 after all mechanical fabrication and electropolishing. Centering is done by inserting a long stainless bar into the center conductor through a 50 mm port in the top of the helium jacket and then inelastically bending the center conductor while monitoring the frequency on a network analyzer. The total bending was approximately 1 mm with a final accuracy of +/- 100 microns. The beneficial effect (Figure 5) is large, with a reduction in the peak-to-peak amplitude by a factor of 7, even before mechanical damper installation.

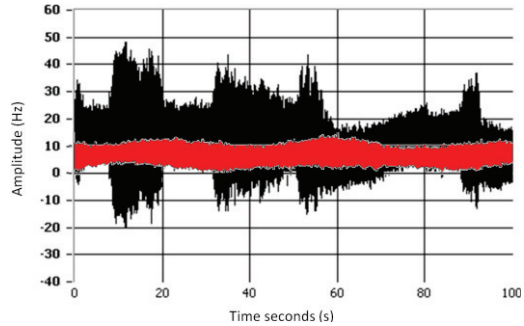

Figure 5: Microphonic amplitude reduction in a quarter-wave cavity due to centering the central conductor

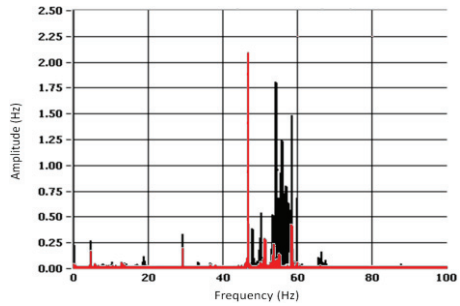

Figure 6: Fourier spectrum for data in previous Figure. Microphonics are lower (red) but the mechanical Q remains high when no mechanical damper is used.

CONCLUSION

The fabrication of eight quarter-wave cavities for β=0.077 and 72.75 MHz is complete and four of these have been tested. Horizontal electropolishing on the completed cavities was performed for the first time. Initial results at both 2 K and 4 K show remarkably good performance, easily exceeding the ATLAS requirements. Performance ranges from B_{PEAK}=98-165 mT, E_{PEAK}=70-120 MV/m, with practical acceleration at V_{ACC}>3 MV/cavity at 4 K and V_{ACC}>5 MV/cavity at 2 K.

THERMO-MECHANICAL SIMULATIONS OF THE FREQUENCY TUNING PLUNGER FOR THE IFMIF HALF-WAVE RESONATOR

N. Bazin, P. Bosland, S. Chel, G. Devanz, N. Grouas, P. Hardy, J. Migne, F. Orsini, F. Peauger,
CEA, F-91191, Gif-sur-Yvette, France

Abstract

In the framework of the International Fusion Materials Irradiation Facility (IFMIF), which consists of two high power CW accelerator drivers, each delivering a 125 mA deuteron beam at 40 MeV [1], a Linear IFMIF Prototype Accelerator (LIPAc) is presently under design for the first phase of the project. A superconducting option has been chosen for the 5 MeV RF Linac, based on a cryomodule composed of 8 low-beta Half Wave Resonators (HWR), 8 Solenoid Packages and 8 RF couplers. The initial solution for the frequency tuning system of the HWR was an innovated system based on a capacitive plunger located in the electric field region, allowing a large tuning range of ±50 kHz, while keeping the cavity rigid enough to fulfill the Japanese regulations on pressurized vessel. Following the cold test results obtained on HWR equipped with the first design of plunger in 2011 [2], the project decided to change the tuning system by a more conservative solution based on the HWR wall deformation.

Nevertheless RF and thermal simulations were realized to understand the previous test results and the conceptual design of a new plunger in niobium was proposed to resolve the issue. The mechanical constraint is to sufficiently deform the plunger to tune the cavity while staying in the elastic range of the niobium material. For the thermal simulations, all the non-linear properties of the materials and the effects of the RF fields are taken into account: thermal conductivity and surface resistance are depending on the temperature, RF fields computed with dedicated software are leading to thermal dissipations in the materials and the vacuum seal.

FIRST DESIGN OF THE HWR PROTOTYPE TUNING SYSTEM

The low-β HWR prototype, whose RF and mechanical design has already been presented in [3] is made of niobium with a titanium helium vessel and niobium-titanium alloy flanges.

The tuning system is based on a capacitive plunger located in the electric field region of the HWR, perpendicular to the beam axis. This plunger, filled with liquid helium, is connected to a thin membrane – 1.7 mm thick – via a 5 mm stem where the tuning force is applied. In order to clean the cavity, the whole tuning system is dismountable from the cavity body and a Garlock Helicoflex joint is used for the vacuum tightness.

For mechanical reasons, the membrane was made of niobium-titanium alloy, whereas the stem and the plunger are made of pure niobium. The membrane can be deformed in the range of ±1 mm which is sufficient to achieve the required tuning sensitivity of ±50 kHz.

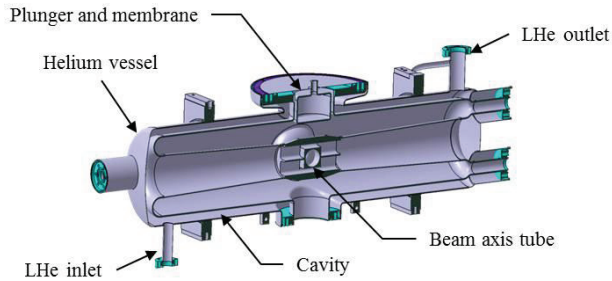

Figure 1: the IFMIF HWR prototype.

Vertical Test Results

After a proper preparation at IPN Orsay (BCP treatment, high pressure rinsing and assembly in an ISO 4 clean room), the prototype equipped with the tuning system was tested in a vertical cryostat at 4.2K.

Several multipactor barriers were observed starting at very low accelerating field (fist barrier at 12 kV/m) and up to 500 kV/m. To pass these barriers, the input power was increased on the incident antenna but the consequence was a quench of the NbTi membrane at the $E_{acc} \geq 1$ MV/m.

According to RF simulations, the magnetic field distribution over the membrane shows a maximum value of ~20% of peak field located on the centre of the membrane, which represents ~ 2.5 mT (Figure 2). This value may be sufficient to heat the membrane until its critical temperature.

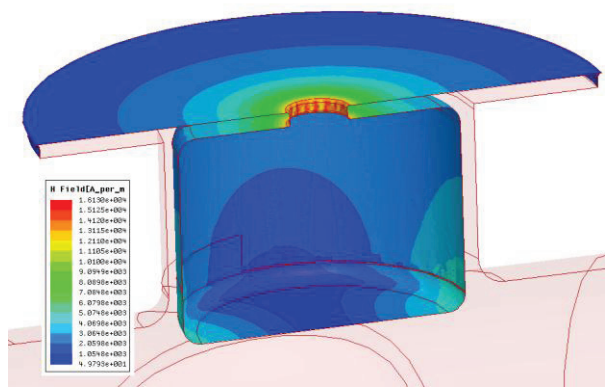

Figure 2: H-field in the plunger region.

Thermal Model of the Tuning System

In order to understand the behaviour of the tuning system, a thermal model has been developed taking into account all the non-linear properties of the materials and the effect of the RF field.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The thermal phenomena in the tuning system are:

- Convection with liquid helium inside the plunger and on the niobium-titanium flange
- Heat flux generated by the H-field on the RF surfaces of the membrane, the plunger and the flange, and
- RF dissipation in the seal (Figure 3).

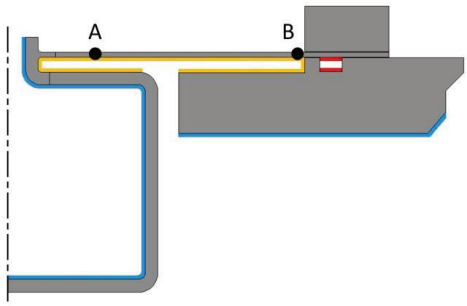

Figure 3: thermal loads on the 2D axis symmetrical model: in blue, the convection with the liquid helium, in orange, the RF losses, in red, the seal dissipation.

To determine the heat flux on each RF surface, the surface resistance of the niobium and the niobium – titanium alloy between the working temperature (4.2 K) and the critical temperature (9.2 K) at the cavity frequency must be introduced in the model. For both materials, the R_{BCS} was calculated using Halbritter's model [4], the parameters for the niobium can be found in [5] and the ones for the niobium-titanium alloy in [6].

As the thermal conductivity of the niobium is strongly dependent of its residual resistance ratio (RRR), the model developed in [7] was used to calculate this parameter between 4 K and 9.2 K. For the niobium-titanium alloy the temperature dependent thermal conductivity was given by the materials thermal properties database CryoComp.

In theory, the gasket placed in a groove on the niobium-titanium flange of the cavity does not produce RF dissipation. The plunger membrane is pinched between two flanges and so its contact with the rim of the cavity flange forbids the penetration of the field inside the gasket groove. In practical, the flatness of the contact surface of the two pieces is not perfect, and a gap may exist. The H-field value on the gasket is not calculated with the 3D software HFSS because of the scale difference between the gap flange (sub-millimeter scale) and the cavity (meter scale). Simulations on a simplified geometry made with 2D code Superfish show that whatever the size of the gap, 90% of the field on the rim penetrate on the gasket (Figure 4).

As the gasket is made of normal conducting material, its surface resistance is in the order of several milli-ohms at 175 MHz. In the worst case (i.e. half of the surface of the seal affected by the field) up to 25 W are dissipated at the nominal accelerating field.

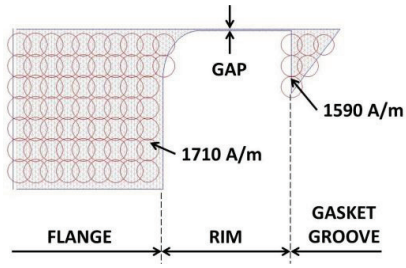

Figure 4: 2D simulation results of the influence of the gap between the membrane and the flange of the cavity on the gasket (H-field values are given for 4.5 M/m, the nominal accelerating field).

The thermal model was implemented in the finite element software Cast3M. The non-linear resolution procedure PASAPAS was modified and a new sub-procedure that redefines the RF heat load at each iteration has been introduced. For each boundary element, there is a surface resistance value attached at each element of the mesh. At each iteration this value is updated depending on the temperature of the element.

Simulation Results and Analysis

First, some simulations were done with no dissipation in the seal, heat load coming only from the RF field. For several values of the accelerating field, the peak temperature of the NbTi membrane (point A on Figure 3) is recorded. The result is presented in Figure 5: the higher the accelerating field, the warmer is the membrane. Above E_{acc} = 4.2 MV/m, the peak temperature is above the critical temperature of the niobium-titanium alloy.

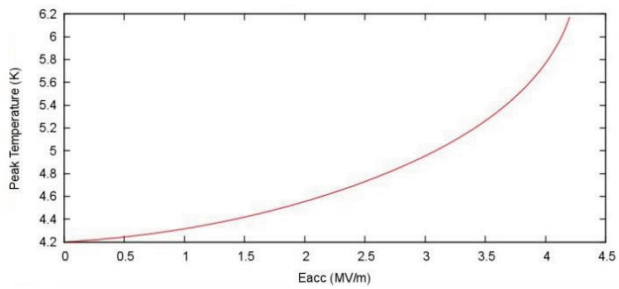

Figure 5: peak temperature of the membrane versus the accelerating field in the cavity (no dissipation in the seal).

The simulations show that even with the optimistic case of no dissipation in the seal, the RF losses lead to self-heating of the membrane due to the poor thermal conductivity of the niobium-titanium alloy.

Then the accelerating field was set at 1 MV/m, and simulations were done with several values for the power dissipated in the seal. Like before, the peak temperature of the membrane (point B on Figure 3) is recorded. Only 1.1 W is needed to reach the critical temperature of the material. The cause is the poor thermal conductivity of the niobium-titanium alloy which does not allow a good propagation of the heat in the material.

ALL-NIOBIUM PLUNGER TUNING SYSTEM

The previous thermal simulations have shown that the combination of the dissipated power in the seal, the poor thermal conductivity of the material and the high field due to the stem of the plunger can lead to a thermal quench of the membrane. These points were taken into account when designing a new all-niobium plunger tuning system.

Mechanical Design

The all-niobium tuning system was designed considering the following constraints:

- The overall dimensions are similar to the previous system in order to test it without modifying the cavity prototype.
- The displacement of the bottom surface of the plunger must be ±1 mm to achieve the frequency cavity tuning requirements.
- The system must sustain the atmospheric pressure with vacuum inside the cavity at room temperature.
- At room and helium temperatures, the stress must stay under the elastic limit of the niobium.

The resulting geometry is presented on Figure 6. There is no more liquid helium inside the plunger, the stem which was needed for manufacturing and was the cause of the field reinforcement has been suppressed. But as the length of the membrane is reduced and its flexibility is consequently limited, a flexible element similar to a wave was introduced.

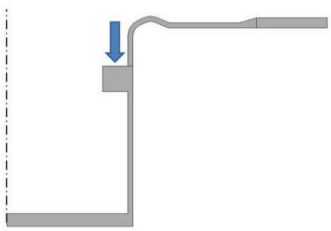

Figure 6: geometry of the niobium plunger. The arrow represents the force applied by the actuator.

The actuator force is no longer applied in the centre but on the side wall of the plunger. To achieve the ±1 mm displacement, a force of 4300 N is needed which can be easily delivered by the actuator designed for the first tuning system and slightly modified to be adapted to this system.

Thermal Design

The previously described thermal model was used to simulate the new plunger tuning system. First, RF simulations were done on the new geometry which showed that the field amplitude has marginally changed on the rim of the cavity flange. Indium seal is used instead of Helicoflex seal. The surface resistance is about the same (indium is superconducting under 3 K), but the surface of the indium seal affected by the RF field is much smaller. The dissipated power is estimated at 1.5 W at the nominal accelerating field.

A first simulation was carried out with no liquid helium cooling except the existing one on the bottom of the niobium-titanium flange of the cavity. At the nominal accelerating field, the plunger temperature is homogenous at 8.2 K, too close to the critical temperature to be acceptable.

We also observe that the dissipated power in the indium seal in the predominant heat source. It is necessary to prevent this heat to propagate along the niobium plunger. A second simulation was carried out with helium cooling on one side of the anchor piece of the actuator system. The plunger temperature is reduced to 5 K for the coolest part to 5.8 K for the warmest part (Figure 7).

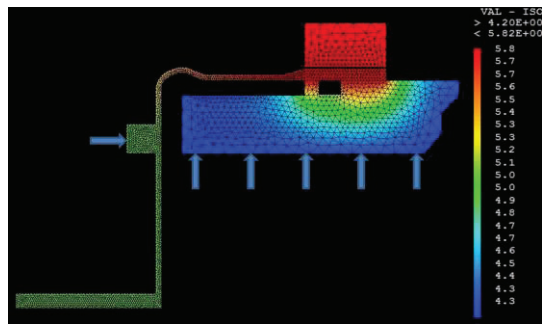

Figure 7: thermal simulation result. The blue arrows represent the liquid helium cooling.

CONCLUSION

The RF and thermal simulations made on the first tuning plunger allowed to understand the vertical test results and the limitations of the design.

In parallel of the design studies of the all-niobium plunger, the principle of tuning the cavity with a capacitive plunger was abandoned by the project and replaced by a more conservative solution of HWR deformed by beam noses compression. According to the project decision, a new tuner design is in progress.

LORENTZ FORCE DETUNING COMPENSATION STUDIES FOR LONG PULSES IN ILC TYPE SRF CAVITIES

N.Solyak, G.Cancelo, B.Chase, D. Crawford, D. Edstrom, E. Harms, Y.Pischalnikov, W.Schappert,
Fermilab, Batavia, IL 60510, USA

Abstract

Project-X 3-8 GeV pulsed linac is based on ILC type 1.3 GHz elliptical cavities. The cavity will operate at 25 MV/m accelerating gradient, but in contrast with XFEL and ILC projects the required loaded Q is much higher (Q~10^7) and RF pulse is much longer (~8ms or even 26ms). For these parameters Lorence force detuning (LFD) and microphonics should be controlled at the level <30 Hz to minimize power overhead from the klystron. A new algorithm of LFD compensation, developed at Fermilab for ILC cavities was applied for Lorentz force compensation studies for 8ms pulses. In these studies two cavities inside TESLA-type cryomodule at Fermilab NML facility have been powered by one klystron. Studies done for different cavity gradients and different values of loaded Q demonstrated that required level of LFD frequency compensation is achievable. Detuning measurements and compensation results are presented.

INTRODUCTION

For the proposed second stage of Project X at Fermilab a 1mA H^- beam will be accelerated from 3 to 8 GeV in pulsed linac, based on XFEL/ILC technology. Each of 28 cryomodules with 8 cavities and one quadrupole will be powered by one RF power source. Efficient operation of the linac requires cavities operating at 25 MV/m with a higher loaded Q_L driven by longer pulses, (4ms fill and 4.3ms flattop) than has typically been used with Tesla style cavities until now. The period of the dominant mechanical modes of the cavities is typically several milliseconds and if left uncompensated, the Lorentz force at the planned gradient of 25MV/m can drive the cavities several bandwidths off resonance during the pulse. The RF power required to drive a detuned cavity for different values of Q_L is shown in Figure 1. Since detuned cavity requires extra power, it is critical to have LFD compensated to 30 Hz or better to keep RF power below 50 kW, enough to cover cavity detuning, RF distribution losses and provide overhead for LLRF control. The chosen value $Q_L=10^7$ is a compromise between cavity bandwidth and required power.

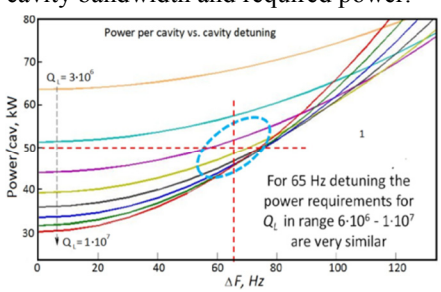

Figure1: Required power per cavity vs. cavity detuning

The feasibility of actively compensating Lorentz force during long pulses to the levels required for efficient operation of the linac under consideration for Project X was assessed during recent studies using two cavities from CM1 at the Fermilab SRF Test Facility.

EXPERIMENTAL SETUP

CM1 is a DESY Type II cryomodule containing eight 9-cell elliptical superconducting Tesla style cavities operating at a frequency of 1.3 GHz [1] , see Fig.2.

Figure 2: Cryomodule in NML at Fermilab

Following the successful commissioning of the cryomodule, the RF distribution system and modulator were reconfigured to drive only the two highest gradient cavities, C5 and C6, with 9 ms pulses from a 120 kW klystron at repetition rates of up to 1 Hz. These two cavities can operate at accelerating gradients, E_{acc}, of 25MV/m and 27MV/m respectively. The vector sum of the two cavities was controlled using an Esecon digital controller and the LFD compensation system developed for CM1 was adapted to handle the modified cavity configuration. The loaded Q_L of both cavities can be varied between 10^6 ($f_{1/2}$=650 Hz) and to 10^7 ($f_{1/2}$=65 Hz) by adjusting the ratios of the power couplers. Cavity baseband waveforms were recorded for the following matrix of operating conditions:

- Q_L: $3\cdot10^6$; $6\cdot10^6$; $1\cdot10^7$;
- E_{acc}: 15MV/m; 20 MV/m; 25 MV/m;
- RF power per cavity: 40 kW; 50 kW; 60 kW.

Current plans for the candidate Project X linac call for the cavities to operate with $Q_L=10^7$ at a gradient of 25 MV/m while driven by 50 kW of RF power required for RF distribution losses, control overhead and compensation of residual frequency detuning from LFD and microphonics.

ADAPTIVE COMPENSATION OF THE LORENTZ FORCE DETUNING

The CM1 LFD control system employs an adaptive feed-forward algorithm developed at FNAL to tailor the piezo drive waveform for each individual cavity [2]. This algorithm has been used successfully at FNAL [3] and KEK [4] to control LFD in a variety of SRF cavity designs and operating conditions.

In contrast to the approach commonly used, driving the piezo with a simple half-sine impulse with bias, width, amplitude, and timing adjusted to compensate detuning during the flattop of a short RF pulse, the FNAL algorithm measures the detuning response of the cavity to a series of piezo impulses timed to arrive between 10ms and 0ms in advance of the RF pulse. A least squares fit is then employed to determine the linear combination of impulses needed to cancel the detuning of the cavity by the Lorentz force. As the length of the RF pulse becomes comparable to the period of dominant mechanical mode of the cavities a more complex piezo waveform such as that produced by the FNAL algorithm is required to damp out mechanical oscillations.

An earlier test of adaptive algorithm for 8 ms pulse for dressed ILC-type cavity with blade-tuner in Horizontal Test Cryostat (HTS) at 22 MV/m the demonstrated LFD compensation at the level below 100 Hz peak-to peak [4]. This short test was performed at the end of routine testing of the cavity for short 1.3 ms pulses without optimizing of algorithm and cavity parameters. In current studies with two cavities at CM1, the main focus has been optimization of algorithm for long pulse operation.

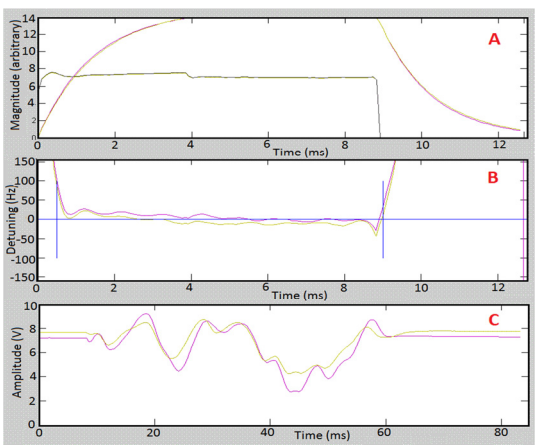

Figure 3: LFD compensation in C5 and C6 during a 9ms RF pulse at E_{acc}=25 MV/m. (A): Baseband envelopes of the forward and cavity field probe signals. (B): Residual detuning using following compensation by adaptive LFD algorithm. (C): Piezo drive waveforms.

Figure 3 shows a sample screenshot of the LFD controller online display. Compensation is applied over the window set by the two blue lines in Panel B. The piezo drive pulse begins 30msec prior to the arrival of the RF pulse and continues for the duration of the 9ms RF pulse. The LFD compensation algorithm was first tested and tuned for the modest set of cavity parameters Q_L~$3\cdot10^6$ (typical value for ILC cavity) and cavity gradient 18 MV/m. Large bandwidth provides robust operation in this regime.

RESULTS

The recorded baseband waveforms were analysed offline to determine the peak detuning during the flattop, pulse-to-pulse variation of detuning, and the phase and amplitude stability of both the vector sum and of the two individual cavities.

With an available RF power of 120 kW (~60 kW per cavity) the gradient was limited by 18 MV/m for Q_L=3.10^6. For higher values Q_L=6.10^6 and Q_L=10^7 the gradient ~25 MV/m was achieved.

Figure 4(left) shows the superposition of C6 detuning of 1800 pulses collected over a period of 30 minutes during operation at Q_L=10^7 and E_{acc} =24.5 MV/m. The red curve shows the detuning averaged over all the pulses while the white curve shows the std deviation of the sample at each point in time. The peak detuning during the flattop is 10Hz. Figure 4(right) shows a histogram of the average detuning for the same sample of pulses. The peak pulse-to-pulse variation during the flattop under these operating conditions is better than ±10 Hz peak-to-peak and 2.27Hz RMS. For all other operating conditions standard deviation of detuning was in range 2-4 Hz.

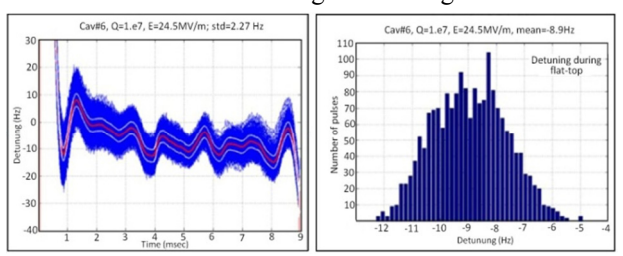

Figure 4: Residual detuning over 30 minutes during operation at Q_L=10^7 and E_{acc} =24.5 MV/m. (A) shows the detuning waveforms of 1800 pulses collected over (B) histogram of the average detuning for the same sample.

Figure 5 shows the closed loop amplitude and phase stability of the C5, C6 and of the vector sum of the two cavities during operation at 25 MV/m. While the individual cavities show pulse-to-pulse amplitude and phase variations of up to 0.2 MV/m and 4 degrees respectively, the variations of the two cavities is strongly anti-correlated (right plot) and the vector sum is stable to 0.01 MV/m (0.04%) in amplitude and 0.2° in phase.

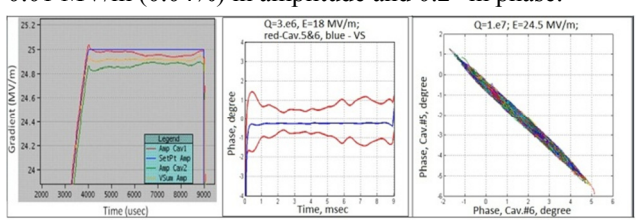

Figure 5: Ampitude (left) and phase (middle) waveforms of C5, C6 and VS. Cavity phase correlation plot (right).

The phase of the vector sum consistently shows a sinusoidal modulation at a frequency close to 1 kHz. This

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

modulation is not present when compensation is off. This modulation is almost certainly an artefact induced by the compensation algorithm but there was not sufficient time during these studies to adequately investigate it. Suppressing this component might allow compensation be further improved.

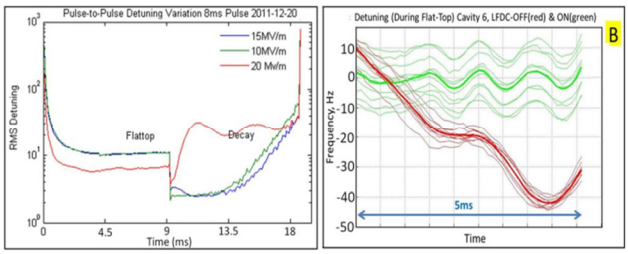

Figure 6: (A): RMS detuning for E_{acc}=10; 15; 20 MV/m. (B): Detuning (during 5ms flat-top) for the 10 RF pulses with LFDC system ON (green) and OFF (red). Thick line is average of 10 pulses.

An attempt was made to investigate the source of the pulse-to-pulse variations. Figure 6(A) shows the RMS detuning during and after of the RF pulse. During these measurements the adaptive portion of the compensation algorithm was turned off so that the compensation pulse did not change. The pulse to pulse variation drops dramatically when the RF feedback ends following the flattop. This may indicate that some of the pulse to pulse variation is due to pulse-to-pulse variations in the RF drive waveforms. Figure 6(B) compares the pulse-to-pulse detuning variation with compensation OFF and compensation ON while the RF controller was operating with feedback turned off. Although compensation is able to reduce the average detuning, the pulse-to-pulse variation becomes somewhat larger.

In these studies the settings for the shape of the cavity probe signal during filling time was optimized for Q_L=6.10^6. Some overhead in the forward power for Q_L=10^7 during the filling time can be seen in the Figure 7 (right).

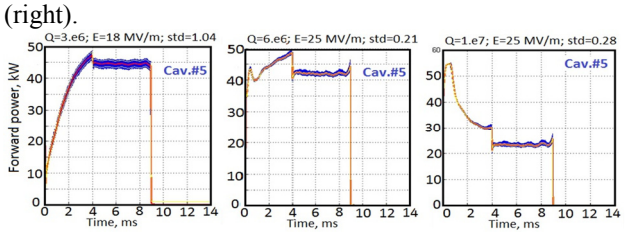

Figure 7: Forward power for Q_L=3.10^6 and E_{acc}=18 MV/m (left); Q_L=6.10^6 and E_{acc}=25 MV/m (centre); Q_L=10^7 and E_{acc}=24.5 MV/m (right)

DISCUSSIONS AND FUTURE PLANS

In these studies it was found that for a lower value of Q_L< 6.10^6 the tuning to operation regime was robust. The adaptive LFD compensation algorithm was able to react quickly enough during the period where gradient in cavity increases. Large bandwidth provides robust operation in this regime.

The tuning process for high Q_L=1.10^7 and E_{acc}=25 MV/m operation was more tricky in part of narrow bandwidth and because of operating gradient was close to the quench limit for C5. Also, in this regime klystron power was close to saturation (see Fig.7) complicating LLRF control. Additional difficulties for tuning of the cavity from low to high gradient arose from limitation in the drive signal applied for piezo-tuner. The later should be in range 0-200 Volts to ensure linear response. At high gradient the bias and voltage variation are increases and push required drive signal out of acceptable range. To put it back, it is required detune the cavity at intermediate gradient by using a mechanical frequency tuner, which complicates the tuning process due to hysteresis and non-linear response. As a result, after a quench it takes some time to tune cavity back to 25 MV/m again. This behavior depends on tuner design (Sacley-type tuner in these tests). The next long-pulse studies planned will involve on CM2 using two high gradient ILC cavities with blade-tuners. By that time we should have fixed known limitations of LFD compensation algorithm and LLRF system.

CONCLUSION

The results of the studies described here can be summarized as follows:

- Active compensation is able to limit LFD during long pulses in cavities operation with Q_L=10^7 and E_{acc}=25 MV/m to ±10 Hz peak-to-peak or better. This is comparable to the pulse-to-pulse detuning variations due to non-deterministic sources.
- The residual detuning is consistent from pulse-to-pulse and is dominated by a single deterministic sinusoidal component with a frequency near 1kHz. Compensation might be improved further if this component can be suppressed.
- Microphonics levels of 2-4 Hz were observed during long pulses. This is similar to the levels measured during 1 ms pulses.
- The detuning responses of the two cavities tested were different prior to compensation, but the levels of residual detuning following compensation were similar. The compensation algorithm is able to adapt the piezo waveform to the detuning response of each individual cavity.

While further improvements may be possible these studies clearly demonstrate that a pulsed linac employing active compensation of Lorentz force detuning could already meet the phase and amplitude stability requirements for Project X.

Two normal conducting deflecting structures are currently being developed at the Cockcroft Institute, one as a crab cavity for CERN linear collider CLIC and one for bunch slice diagnostics on low energy electron beams for Electron Beam Test Facility EBTF at Daresbury. Each has its own challenges that need overcome. For CLIC the phase and amplitude tolerances are very stringent and hence beamloading effects and wakefields must be minimised. Significant work has been undertook to understand the effect of the couplers on beamloading and the effect of the couplers on the wakefields. For EBTF the difficulty is avoiding the large beam offset caused by the cavities internal deflecting voltage at the low beam energy. Prototypes for both cavities have been manufactured and results will be presented.

INTRODUCTION

Transverse deflecting cavities are required for many applications on accelerators, including crab cavities, bunch separators, emittance exchange and for bunch length diagnostics. These cavities usually operate in a TM_{110}-like mode. The Cockcroft Institute in the UK is participating in the design of several deflectors for a range of applications including crab cavities for ILC [1], CLIC [2] and LHC [3] and a bunch length diagnostic for EBTF [4]. In this paper we concentrate on the normal conducting rf deflectors for CLIC and EBTF.

CLIC CRAB CAVITY

CLIC requires a crab cavity to rotate the bunches prior to the interaction point (IP) to achieve an effective head-on collision. As the bunch size at the IP is very small (~5 nm) the luminosity is very sensitive to the crab cavities RF phase and amplitude. This means that the beamloading must be minimised and correction applied. The beamloading is dependent on the longitudinal electric field experienced by the bunch. In crab cavities the longitudinal electric field is zero on axis but has a linear variation as the bunch goes off axis. This means the beamloading could be positive or negative depending on the beam offset. As the bunch train for CLIC is short (~200 ns), the beamloading cannot be compensated for in a single bunch train, the feedback would occur over several trains. Unless the jitter on the beam offset is much less than the bunch size the compensation will not be successful, hence the beamloading must be minimised instead [5]. In order to reduce the effect of beamloading the cavity is designed with a large power flow so that any power induced by beamloading is smaller in comparison. This is achieved by using a high group velocity travelling wave structure.

Another issue affecting beamloading is the perturbation of the input and output couplers. Couplers break the symmetry of the cavity and can give rise to monopole components to the deflecting field. A dual feed coupler keeps the symmetry of the structure and avoids monopole components but is more complex coupling arrangement requiring splitters. A single feed is the simpler coupling arrangement however this gives the end cells a large monopole component of the rf field. We have investigated methods of single feed coupling without inducing monopole component.

Single-feed Couplers

In order to minimise the monopole component of rf field in the end cells while using a single-feed coupler a number of options were investigated. Initially cancelling the monopole kick from the two end cells was studied. Consider particle moving at the speed of light. If the cell is rotated the monopole component has the sign of the real part of the voltage flipped. Hence if the input and output couplers are mounted on opposite side the real parts should cancel. If the lengths of the cells are adjusted so that the voltage is entirely real then the entire monopole component is cancelled. This however is not sufficient in travelling wave deflecting structures as the power put into the output cell will be extracted through the output coupler while the power in the input cell will travel down the structure. Hence it is necessary to cancel the beamloading in each cell individually.

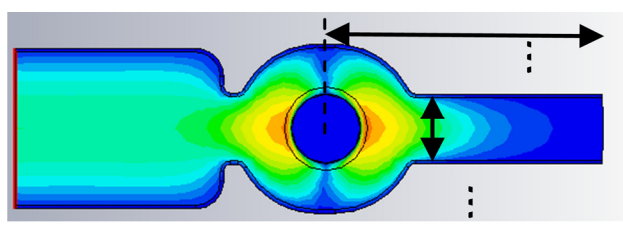

Figure 1: Dummy waveguide and input coupler on the CLIC crab cavity

In order to restore the symmetry of the cell a dummy waveguide opposite the coupler was studied. Using a

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

dummy waveguide was found to significantly reduce the monopole component but not reduce it to zero. The real part is reduced to zero, but the imaginary component is not and hence gives the minimum voltage. The reason for this is because there must be a power flow across the cell, from the coupler to the dummy waveguide. This means that there cannot be a full standing wave in the cavity and there must be a travelling wave component.

Another method of symmetrising the cell is to couple from the side with a TE_{02} mode coupler. This allows an equal power flow to each side hence avoiding a monopole component. However the cavity is now vertically asymmetric and hence there is a small vertical kick. However this symmetry can be recovered by adding a dummy waveguide. The TE02 mode splitter must carefully be designed to avoid excitation of a TE01 mode which gives rise to a monopole component to the fields.

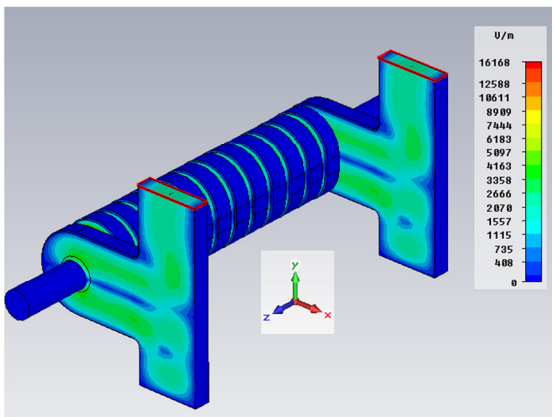

Figure 2: TE_{02} mode coupler

Wakefield Damping

As the cavity is close to the final focus magnets, where the beta function is large, it is very sensitive to transverse wakefields. It is necessary to damp any long-range wakefields within a few bunches to avoid large transverse offsets at the IP. The vertical wakefield is the most sensitive, due to the small vertical beam size, and is dominated by the opposite polarisation of the crabbing mode, known as the same order mode (SOM). As the wake is dominated by a single mode it is proposed to have this modes frequency at the zero-crossing, where the mode frequency is a half integer harmonic of the beam frequency. This means that each bunch induces a voltage 180 degrees out of phase with the previous bunch hence cancelling each other. For CLIC it is proposed that the cell has an elliptical cross-section such that the crabbing mode is at 11.99 GHz while the SOM is at 12.98 GHz. However the SOM still requires significant damping due to the very tight tolerances on vertical kicks. Choke damping and waveguide damping were both considered. Choke cavities are difficult for deflecting cavities as the choke must be polarised to damp one polarisation but not the other. Options are to use an elliptical cavity, an elliptical choke or a slotted choke [6]. The slotted choke achieved the best performance; however widening the slot to achieve better damping also reduces the Q of the crabbing mode which could be problematic due to enhanced heating. For this reason a waveguide damper was chosen for CLIC, as shown in Fig.3, as a waveguide coupler shows strong damping of the SOM without affecting the crabbing mode.

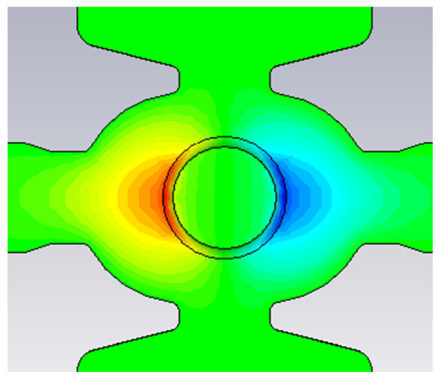

Figure 3: Damped elliptical cell of the CLIC crab cavity

Cavity Prototype

Two prototype cavities have been manufactured. One has been made by Shakespeare Engineering, a UK company, to be tested at SLAC and the other has been made at VDL, to be tested at CERN. The CERN cavity has had the parts machined and is due to be brazed soon. The SLAC cavity, shown in Fig. 4, has been fully manufactured and is currently undergoing tests at Cockcroft before shipping to SLAC.

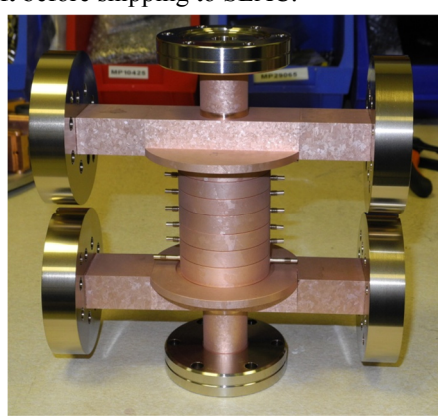

Figure 4: CLIC crab cavity prototype manufactured by Shakespeare Engineering.

EBTF TRANSVERSE DEFLECTING CAVITY

The Electron Beam Test Facility (EBTF) at Daresbury Laboratory will deliver low energy (5/6 MeV) short bunches (down to 40fs RMS) to a number of industrial experimental stations and for fundamental scientific research. In order to measure the longitudinal profile of the bunch an S-band transverse deflecting cavity will be inserted into the beamline. A transverse kick of around 5 MV is required, hence a 9 cell design has been chosen. The design of the transverse deflecting cavity has been influenced by the competing demands of high RF efficiency [7] and minimising the equal and opposite

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

unwanted transverse kick at the entrance and exit of the cavity which causes the low energy electrons to be displaced while traversing the cavity [8]. The coupler has a dummy waveguide to minimise the on-axis longitudinal electric field.

Minimising transverse offset

As a transverse deflecting cavity has a finite size the beam experiences a range of phases as it crosses the cavity. This means for a zero-crossing it experiences a finite force, initially in one direction and then in the other such that the net transverse momentum at the centre of the bunch is the same at the start and end of the cavity. However this does result in a transverse offset as the beam travels transversely inside the cavity. It was found that due to the beampipe the electrical centre of the end cell was not at the geometric centre. This resulted in an uneven kick producing a net transverse momentum when leaving this cell, which wasn't removed until experiencing the opposite force at the other end cell. This gave a much larger transverse offset in the cavity, of 4 mm, due to the low energy of the bunch. As the beam was offset the beamloading was much higher which significantly altered the beam energy. For ultra-relativistic beam this offset is small and typically ignored. For low energy beam of EBTF is could not be ignored and has to be minimized.

In order to counteract this effect the end cells were made much shorter such that transverse kick in the end cells for a zero-crossing particle was minimised. The final cavity is shown in Fig. 5. The particle tracking simulations in GPT [9] show the transverse offset inside the cavity is minimised, shown in Fig. 6.

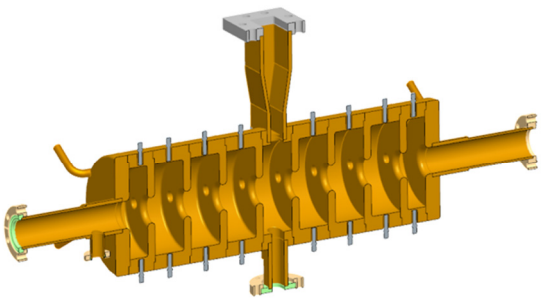

Figure 5: EBTF Transverse deflecting cavity with shortened endcells.

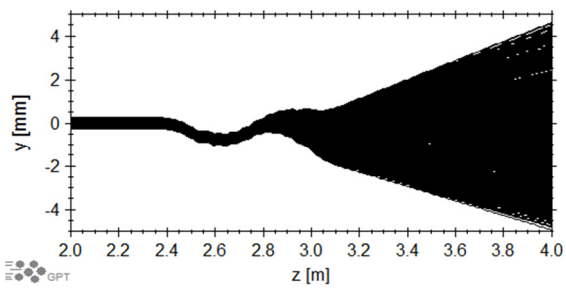

Figure 6: GPT tracking simulation of EBTF transverse motion.

Prototype Cavity

A 3-cell prototype has been produced by Research Instruments (shown in Fig. 7), to verify brazing procedure, and a contract has been placed with them for a full 9-cell structure.

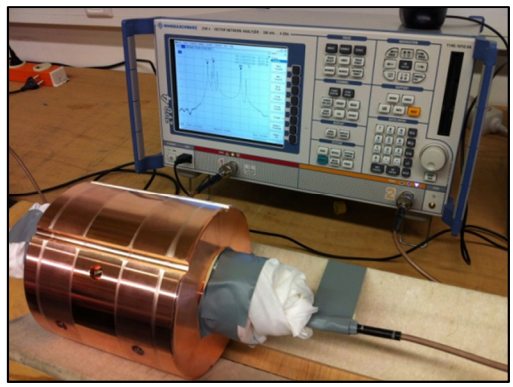

Figure 7: 3-cell prototype of the EBTF Transverse deflecting cavity.

SUMMARY

The Cockcroft Institute has a proven track record of designing deflecting cavities for numerous applications. High power testing is expected to be done on both cavities in the next few months.

ACKNOWLEDGEMENTS

This work has been supported by STFC via the Cockcroft Institute core grant and the EU through the EUCARD grant.

STATUS OF THE C-BAND RF SYSTEM FOR THE SPARC-LAB HIGH BRIGHTNESS PHOTOINJECTOR*

R. Boni, D. Alesini, M. Bellaveglia, G. Di Pirro, M. Ferrario, A. Gallo, B. Spataro,
INFN-LNF, Frascati, Italy
A. Mostacci, L. Palumbo, ULRS, Rome, Italy

Abstract

The high brightness photo-injector in operation at the SPARC-LAB facility of the INFN-LNF, Italy, consists of a 150 MeV S-band electron accelerator aiming to explore the physics of low emittance high peak current electron beams and the related technology. Velocity bunching techniques, SASE and Seeded FEL experiments have been carried out successfully. To increase the beam energy so improving the performances of the experiments, it was decided to replace one S-band travelling wave accelerating cavity, with two C-band cavities that allow to reach higher energy gain per meter. The new C-band system is in advanced development phase and will be in operation early in 2013. The main technical issues of the C-band system and the R&D activities carried out till now are illustrated in detail in this paper.

THE SPARC-LAB AT FRASCATI LNF

The SPARC-LAB is a research facility of the INFN Frascati Laboratory (LNF) whose purpose is to conduct advanced research in the field of high brightness, low emittance electron beams [1]. The facility, able to operate also in the velocity bunching configuration, feeds six 2m. long undulators and integrates the 150 MeV S-band photo-injector with a 220 Terawatt, Ti:Sa ultrashort laser system. FEL radiation in the SASE, Seeded and HHG modes have been performed from 500 nm down to 40 nm wavelength. The photo-injector SPARC, a single bunch electron accelerator, consists of a laser driven RF Gun followed by three traveling wave (TW), constant gradient, $2\pi/3$ accelerating cavities, with the first two immersed in a solenoidal field to keep down the beam emittance growth. A second beam line has been also installed and is now hosting a narrow band THz radiation source.

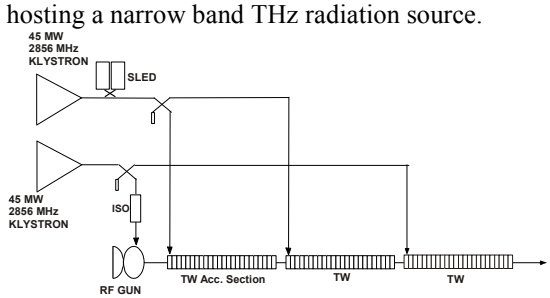

Figure 1: the SPARC photoinjector present layout.

To improve the performances of the experiments and recuperate the energy that is lost in the velocity bunching configuration. it was decided to increase the beam energy by replacing the third S-band section with two, 1.4 m. long, C-band TW accelerating structures that allow to operate at higher gradient. The choice of a higher frequency, e.g. the X-band, was also considered but then discarded because more expensive and technically more challenging.

THE C-BAND RF SYSTEM

The C-band technology is relatively new in linear accelerators compared to the standard and widely used S-band systems. Nevertheless it can be considered sufficiently mature since it is already employed in other accelerator laboratories like the Spring8 (JP) and the PSI FEL (CH) facilities.

R&D of the Accelerating Structure

The third S-band accelerating section, that is a 3 m. long SLAC-type unit, shown in Fig.1will be replaced with two, 1.4 m., C-band sections supplied with a 50 MW, 5712 MHz Toshiba klystron through a SKIP-type pulse-compressor [2]. In order to ease design and construction, the C-band sections are constant impedance (CI) structures with large (14 mm) iris diameter to minimize the surface electric field on the iris edges and improve the pumping speed. Also, the group velocity increases and this reduces the filling time. It must be remarked that the typical exponential decay of the input compressed pulse is partially compensated by the RF losses of the CI structure, resulting in a quasi-constant field amplitude along the section. Input and output waveguides are coupled to the beam-pipe instead of to the end-cells. A 50 cm long prototype was designed at LNF and built by a local firm. Brazing and vacuum test have been made at LNF [3].

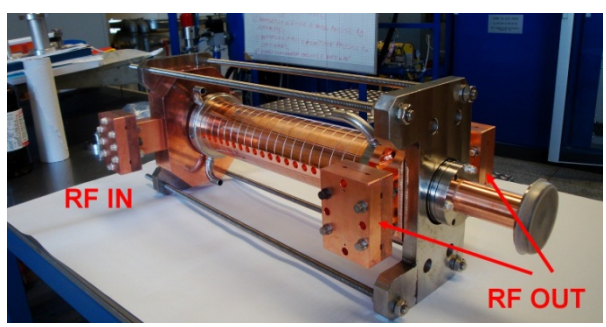

Figure 2: The C-band prototype tested at KEK.

The prototype, shown in figure 2, has been power tested at KEK, in the frame of a collaboration established ad hoc with the INFN.

The KEK RF station consists of a 50 MW - 2.5µsec Toshiba E37202 klystron, followed by a pulse compressor. The results of the power tests, reported in detail in the ref. [4], was very successful and well beyond our expectations. The C-band prototype was tested up to 110 MW peak - 200 nsec - 50 Hz to a maximum average gradient of 55 MV/m, with a breakdown rate of the order of 10^{-6} bpp/min after about 300 hours of RF conditioning. A picture of the prototype is shown in figure 2.

Following the positive results of the KEK power test, we started the construction of two 1.4 m accelerating sections. The next figure 3, shows the concept of the beam-pipe coupling. This type of coupling allows the first RF cell to be mechanically unperturbed, i.e. there are no slots on the cell outer wall that normally cause heating and degrade the performances.

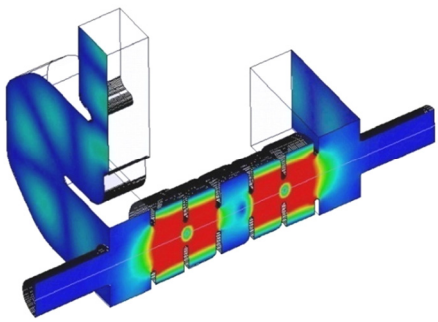

Figure 3: The waveguide beam-pipe coupling.

Further, the symmetric coupling guarantees low quadrupole components on the longitudinal axis [3]. The same concept of beam-pipe coupling is applied at the accelerating section output, with two opposite flanges without combiner. So we use 2 loads per section but the power dissipated by each load is halved.

The actual accelerating structures consist of 71 cells and are 1.4 m. long, to leave 20 cm for the insertion of a pumping unit in the 3 m. left available by the 3rd S-band section. The new C-band sections have been manufactured The cells and the waveguide couplers have been machined by a local firm; then, low power test and brazing of two halves have been made at LNF where a vacuum furnace of 80 cm of internal height is available. After joining mechanically the two halves, the first C-band section was tuned at LNF by adjusting the plungers on each cell wall. The last brazing will be made shortly by a local firm, where a 2 m. long vacuum furnace is available. The C-band actual section in shown in the next figure 4.

The figures 5 and 6 show the low power measurements made in laboratory with the bead perturbation technique. The following table 1 shows the main specifications of the C-band accelerating structures.

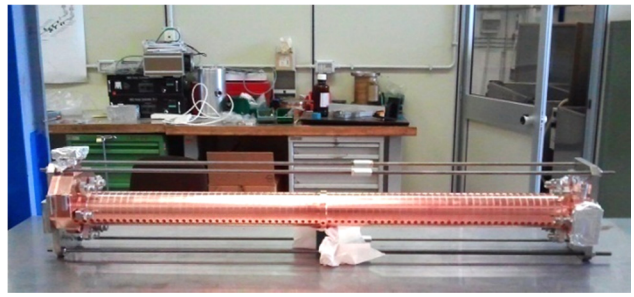

Figure 4: The two halves of one C-band section before the final brazing.

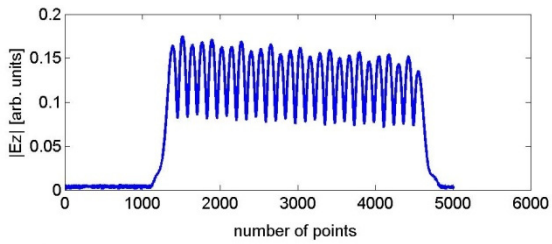

Figure 5: RF field profile of half C-band section.

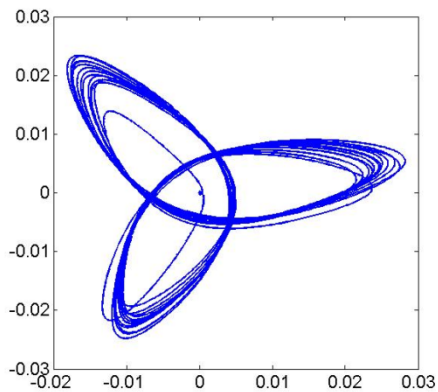

Figure 6: Phase advance per cell in the polar plane.

Table 1: C-band Structures Main Parameters

Frequency (MHz)	5712
type	TW, CI
structure	Disk loaded
Phase advance per cell	2π/3
n. of cells	71
Coupling type	beam-pipe
Iris radius (mm)	7.0
Group velocity/c	0.0283
Shunt impedance (MΩ/m)	82.9
Surf. peak E field/Acc. field	2.17
Filling time (nsec)	150
Total length with couplers (cm)	140

The RF power needed to produce the accelerating field is about 60% of input power. The residual 40% will be dissipated by two RF water-loads, supplied by CML-Engineering, connected to the output coupling ports of the accelerating sections.

The Power Transmission System

The layout of the complete C-band system is presented in figure 7. The RF power will be distributed to the accelerating structures by means of a network of rectangular WR187 waveguides (WG) made of OFHC copper. The total WG length from the klystron to the accelerating sections is about 10 m. and the RF losses are of the order of 10% since the attenuation is 0.035 dB/m.

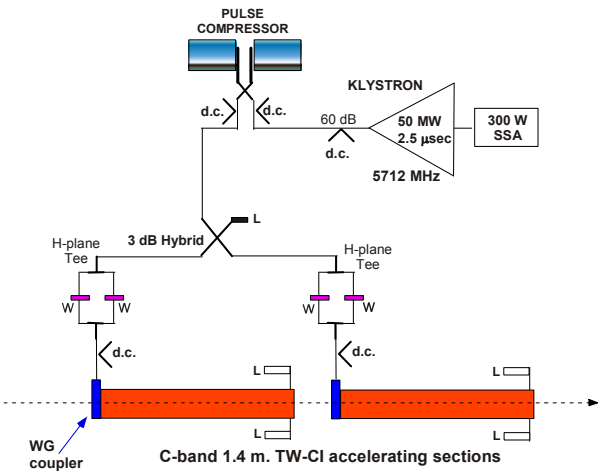

Figure 7: Layout of the SPARC C-band system

The C-band pulse compressor (PC) is under construction by the Division of Technology Development of the IHEP, Beijing, China. It is a double slot coupled cylindrical resonator system that follows the concept of the model "SKIP" developed by KEK. The PC output power is divided in two by a 3 dB hybrid junction and then delivered to the accelerating sections through two RF windows. The RF is split and recombined with two H-plane Tees. In this way the peak power through each RF window is halved as we are not sure of the actual capacity of them to handle power levels in excess of 100 MW peak.

The H-plane Tee s11 is -20 dB and the phase unbalance between outputs is about 1°. They have been designed and brazed at LNF. The machining was made by the local firm Comeb.

The RF Power Station

The RF power station consists of the Toshiba klystron E37202 driven by a solid state 400 W amplifier supplied by MitecTelecom. The pulsed klystron modulator is also a full solid state system made by Scandinova. The table 2 lists the main parameters of the RF power station. The klystron have been successfully RF tested on a dummy load up to 40 MW – 2 µsec – 10 Hz. The klystron RF conditioning is still ongoing.

Table 2: C-band Power Station Main Parameters

Frequency (MHz)	5712
Max klystron power (MW)	50
RF pulse width (µsec)	2.5
Klystron input RF power (W)	300
Klystron beam voltage (kV)	350
Max RF pulse rep. rate (Hz)	10

The Low Level RF System

The control of the C-band accelerating structures will be achieved by a digital low level RF (LLRF) system where all RF signals are down-converted to intermediate frequencies which are then digitized and processed with powerful digital processing platforms. The drive signal is finally up-converted to control the RF high power chain The schematic layout of the digital control system is shown in the figure 8..

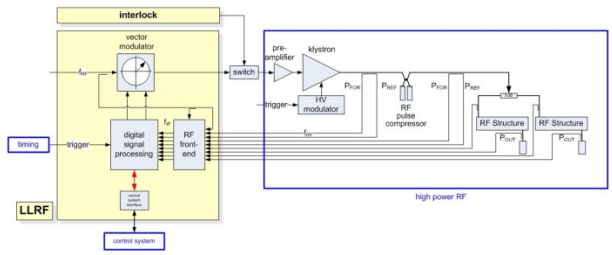

Figure 8: Schematic layout of the digital LLRF system.

A processing board based on VME64x is under development by the PSI laboratory (CH) in collaboration with INFN. It includes a multi-core PowerPC processor and a high performance field programmable gate array Xilinx Virtex-6 on the main board and provides a variety of I/O interfaces. The goal of the digital signal processing is to implement all static algorithms like the digital down-conversion from intermediate frequency to base-band, filtering, I/Q to amplitude/phase conversions and averaging calculations in firmware in the FPGA while using the PowerPC for more sophisticated high level applications like pulse-to-pulse feedback algorithms.

TRAVELING WAVE ACCELERATING STRUCTURES WITH A LARGE PHASE ADVANCE

V. Paramonov *, INR of the RAS, Moscow, 117312, Russia

Abstract

The Traveling Wave (TW) accelerating structures, operating with phase advance for the whole field more than 180^o per period (up to 1300^o) are considered in this report. To realize such phase advance, the structures should operate in higher branches of the Brillouine diagram for TM_{01} wave and have similar to TM_{01n} mode field distribution in the cell. RF parameters of the Disk Loaded Waveguide (DLW) cells are considered for such phase advance and some additions to improve RF efficiency are presented.

INTROSUCTION

There are a lot of papers, describing traveling wave structures with phase advance $\Theta \geq 180^o$ and particularities of particle acceleration. For example, see [1] and related references, higher current electron beams can be accelerated. If such structures operate in the first Brillouine zone for TM_{01} wave and field distribution in the cell corresponds to TM_{010} mode, it means acceleration with higher spatial harmonics. The subject of this paper is consideration of DLW structures, in which the main, dominating spatial harmonic has a phase advance $\Theta \geq 180^o$.

FIELD DISTRIBUTION

In Fig. 1 is shown well known formation of the DLW dispersion diagram from TM_{01} wave parabola in smooth waveguide, [2], and numbers of Brillouine zones are marked. For traveling wave the field distribution in the

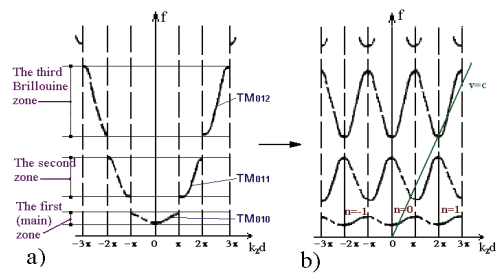

Figure 1: DLW dispersion diagram formation for TM_{01} wave.

aperture all time can be represented in complex form as:

$$E_j(r,z) = \Re E_j(r,z) - i\Im E_j(r,z) = \quad (1)$$
$$= e^{\frac{-i\Theta_0 z}{d}} \sum_{n\to-\infty}^{n\to+\infty} a_{jn}(r) e^{\frac{-i2n\pi z}{d}},$$

where d is the DLW period and $0 \leq \Theta_0 \leq 180^o$ is the phase advance. In the main zone, Fig. 1, the TM_{010} mode is implemented in DLW cell and expansion (1) starts with $n = 0$. For the second zone the field distribution is TM_{011}-like. For symmetrical DLW cell there is no $n = 0$ harmonic in the expansion (1), which starts now with $n = -1$, and field phase advance is in range $180^o \leq \Theta \leq 360^o$, including 180^o leap due to TM_{011} mode field structure.
So on, in higher zones with TM_{01N}-like field in the cell, we can provide field phase advance $N \cdot 180^o \leq \Theta \leq N \cdot 180^o + 180^o$.

DLW CELLS PARAMETERS

RF parameters of DLW cells in higher TM_{01} passbands investigated assuming operating frequency $3.0GHz$ in wide range of aperture radius a and Θ_0 similar to [3] with powerful 2D software. In each passband the cell length is defined from synchronism condition:

$$d_2 = \frac{\lambda(2\pi - \Theta_0)}{2\pi}, \quad d_3 = \frac{\lambda(2\pi + \Theta_0)}{2\pi}, \quad (2)$$

where d_2 and d_3 are the DLW cell length for the second and the third passband, respectively.
In Fig. 2 the surfaces of the group velocity β_g and effective shunt impedance Z_e are shown with parameters $\frac{a}{\lambda}$ and Θ_0 for the second and the third TM_{01} passbands.

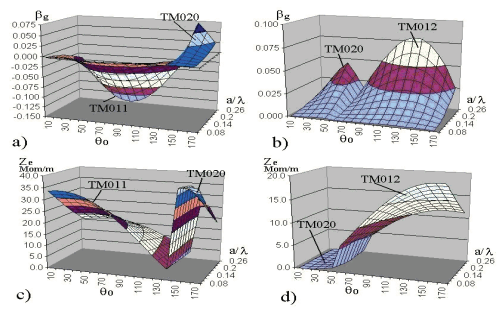

Figure 2: The surfaces $\beta_g(\frac{a}{\lambda}, \Theta_0)$, (a,b) and $Z_e(\frac{a}{\lambda}, \Theta_0)$, (c,d) for the second (a,c) and the third (b,d) passbands.

The regions of TM_{01} wave existence in each higher passbans are limited by interaction with TM_{02} wave, see Fig, 2. For the first and the second passbans possible Θ_0 values are in limits $0 < \Theta_0 < 140^o$ and $70^o < \Theta_0 < 180^o$, respectively. Outside these limits the cell radius R_c becomes large enough and TM_{02} wave comes in appropriate passband.
Without 2D investigations, these Θ_0 limitations were accepted and for appropriate higher passbands (the forth and so on).

The examples of phase and amplitude distributions along

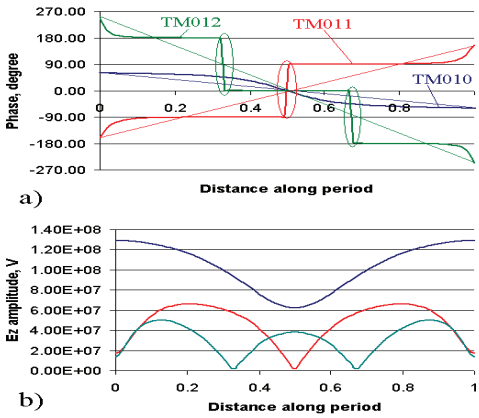

Figure 3: Phase (a) and amplitude distributions along DLW cell axis for the first ($\Theta = 120^o$), the second ($\Theta = 320^o$) and the third ($\Theta = 510^o$) passbands.

cell axis are plotted in Fig. 3 for several passbands, showing for the total field the phase advance per cell $\Theta > 180^o$ in higher passbands.

The relative dimensions of DLW cells for the first and the

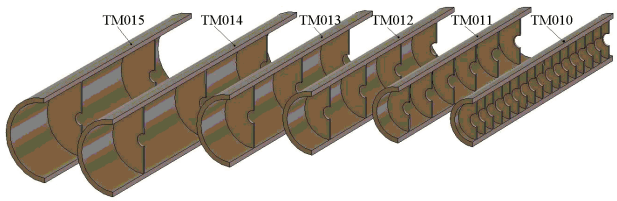

Figure 4: The relative DLW cells dimensions for operation in the first and in higher TM_{01} passbands.

higher TM_{01} wave passbands are compared in Fig. 4 and main RF parameters are listed in the Table 1.

As one can see from Fig. 4 and Table 1, the simple DLW

Table 1: The main RF parameters of DLW cells, $f_0 = 3GHz, a = 12mm$, for operation in the first and higher passbands.

Mode	Θ_0	R_c	$\beta_g \cdot 10^2$	$Q \cdot 10^{-3}$	Z_e
TM_{010}	120	39.49	2.19	14.1	60.86
TM_{011}	320	48.08	-1.36	18.7	24.93
TM_{012}	510	56.02	0.58	25.6	18.24
TM_{013}	680	65.51	-0.39	31.7	12.23
TM_{014}	840	70.73	0.22	36.4	9.48
TM_{015}	1040	79.55	-0.17	40.1	7.15
TM_{016}	1230	83.01	0.11	45.9	6.05

cells in higher passbands lose to classical DLW for the fist zone in transverse dimensions, group velocity and Z_e value.

EFFICIENCY IMPROVEMENT

Efficiency reduction of DLW cells in higher TM_{01} passbands is evident from the particularity in electric field distribution for TM_{01N} mode. In Fig. 5 electric field is shown in DLW cell for TM_{012} mode and one can see a strong E_r component along segments BE and CF.

Considering the balance

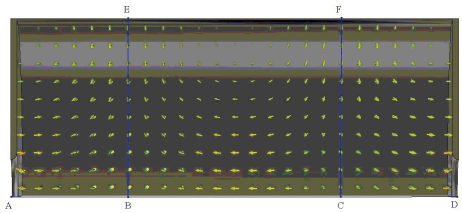

Figure 5: Electric field of TM_{012} mode in DLW cell.

$$\int_B^E E_r dr + \int_C^B E_z dz + \int_F^C E_r dr = \omega\mu\mu_0 \oint_S H_\varphi dS, \quad (3)$$

one can conclude - RF voltage along segments BE and CF spend magnetic flux, but doesn't takes a part in acceleration. It tells a way for RF efficiency improvement - we can substitute a part of segments BE and CF by conducting washers to reduce radial RF voltage part in (3). The maximum of E_r corresponds to minimum of H_φ and washers should not increase RF loss essentially.

Structures with washers in DLW cells are shown in Fig. 6 and main RF parameters are listed in the Table 2 for the same conditions as DLW cells in Fig. 3 and in the Table 1.

The washers lead to essential reduction in the cell radius

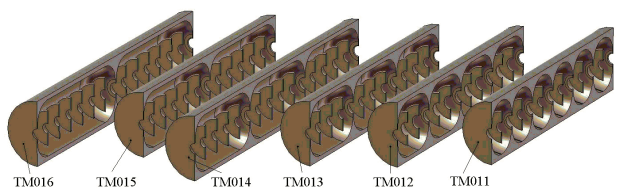

Figure 6: Structures with washers in DLW cells.

R_c, which is defined now mainly by washer diameter and for all structures in Fig. 6 $R_c \approx 65mm$. As one can see from the Table 2, the group velocity β_g and Z_e values are improved essentially due to stronger fields near axis. The DLW with washers is the structure with separated functions - β_g value for TW operations depends on the aperture radius in the disk. And Z_e value is defined by washers, which have similar to standing wave π mode field distribution - mostly effective with respect Z_e value. As one can see from the Table 2, Z_e value comes to saturation with increasing number of washers. The case $N = 3 \div 4$ (TM_{013}, TM_{014}) modes in the cell is a reasonable choice.

The accelerating structure with washers is known, [4], and further Z_e improvement is due to the drift tubes at washers. Such structure is shown in Fig. 7 and for the fifth passband,

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Table 2: The RF parameters of DLW cells with washers.

Mode	$\beta_g \cdot 10^2$	$Q \cdot 10^{-3}$	Z_e
TM_{010}	2.19	14.1	60.86
TM_{011}	-0.91	24.4	50.32
TM_{012}	0.87	33.5	60.29
TM_{013}	-0.83	37.4	61.91
TM_{014}	0.77	40.2	64.01
TM_{015}	-0.76	42.4	65.85
TM_{016}	0.73	43.6	65.56

TM_{014} - like mode in the DLW cell has for bore hole diameter in drift tubes $2 \cdot a_b = 24mm$ calculated parameteres $Q = 34300, \beta_g = 0.822 \cdot 10^{-2}, Z_e = 75.5MOm/m$ and $Q = 35800, \beta_g = 0.812 \cdot 10^{-2}, Z_e = 99.1MOm/m$ for $2 \cdot a_b = 10mm$, showing essentially higher Z_e value, as compared to classical DLW.

The dimensions optimization for DLW cells with washers and drift tubes for further Z_e increasing was not performed and Z_e values, listed in the Table 2 and given for the structure in Fig. 7 may be not maximal.

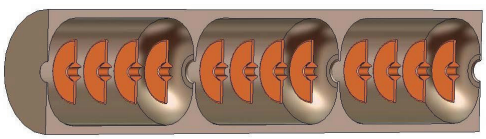

Figure 7: The structure with washers and drift tubes in DLW cell.

DISPERSION PROPERTIES

Due to the design idea, the operating branch of the dispersion diagram is not fundamental. Depending on the Θ value, below operating branch there are several lower branches of TM_{01j} modes and branches of modes with an azimuthal field variations. As an example, in Fig. 8 is shown the dispersion diagram for the structure with washers in the cell, operating with $\Theta = 510^o$ in the third TM_{01} passband with TM_{012}-like mode in the DLW cells. Instead of differences in details, there are common features for dispersion diagrams of all structures, considered in this report. All these structures are narrow band with strong dispersion and relatively small passband width for all branches.

The washers, or washers with drift tubes, do not change dispersion diagram significantly, as compared to diagrams for simple DLW cells, shown in Fig. 4. The lowest branch is all time for modes with one azimuthal field variation.

The line of synchronous interaction $v = c$ cross the lowest branch, and, therefore, upper branches, for $\Theta > 180^o$.

In the vicinity of operating point there are branches, with separation in frequency $(30 \div 100)MHz$, for modes with one and three azimuthal field variations. In this topic the situation with high order modes in the vicinity of operating point is the same as for the structure [4] and well known

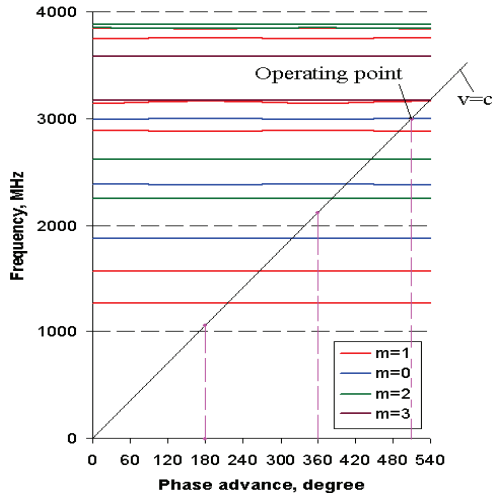

Figure 8: Dispersion diagram of DLW with washers, TM_{02}-like operating mode in the cell, $\Theta = 510^o$, m - number of azimuthal variations.

Disk And Washer (DAW) accelerating structure.

The density and placement of branches for high order modes in the vicinity of operating point is the limitation for washers number increasing in the cell.

SUMMARY

Traveling wave accelerating structures with the phase advance for the total field essentially larger than 180^o per period are possible using higher passbands of TM_{01} wave. It allows longer period length, but the simple DLW cell will lose to the classical case in RF efficiency. With washers and washers with drift tubes in DLW cells RF efficiency for higher passbands is improved in times, overlapping the classical case. The washer support, high order modes influence are the subjects for further consideration.

RF PARAMETERS OF A TE - TYPE DEFLECTING STRUCTURE FOR THE S-BAND FREQUENCY RANGE *

V. Paramonov †, L. Kravchuk, INR RAS, Moscow, Russia
K. Floettmann, DESY, Hamburg, Germany

Abstract

In [1]an effective compact deflecting structure has been proposed preferably for the L-band frequency range. RF parameters of this structure are now considered for S-band frequencies both for traveling and standing wave operation. Some methodical topics of the structure are discussed too.

INTRODUCTION

In [1] a deflecting structure was proposed with the original design idea to separate the functions of RF efficiency and RF coupling, which are coupled in the well known Disk Loaded Waveguide (DLW) by a single parameter - the aperture radius r_a. Two protrusions are introduces at the disk in order to concentrate the transverse electric field at the axis, Fig.1b. The magnetic field around the protrusions, Fig. 1d, provides the required flux for the transverse RF voltage. The structure has a small transverse diameter $2r_c \sim (0.6 \div 0.8)\lambda_0$, where λ_0 is the operating wavelength and looks promising at lower frequencies, including the L-band range. The structure dispersion is positive with a passband width $\Delta f \sim (0.10 \div 0.15) f_0$. It reaches a significant group velocity β_g for a Traveling Wave (TW) with a phase advance $0 < \theta < \pi$, which results in a significant power flow and thus suggest a Standing Wave (SW) operation, [2].

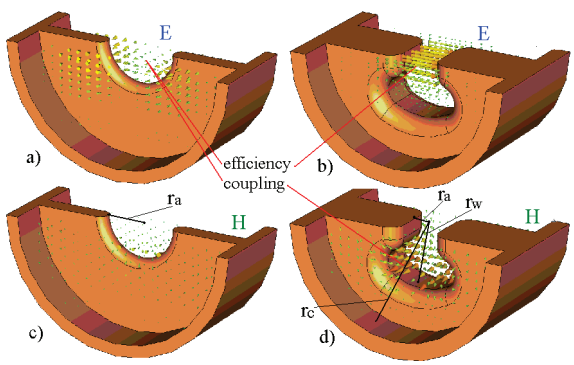

Figure 1: Electric (a, b) and magnetic (c, d) field distributions for the classical DLW structure (a, c) and the TE-deflector, (b, d).

The attractive features of the structure stimulate an additional study, including possible applications in the S - band frequency range.

FIELD DISTRIBUTION

The classification of a structure with a complicated field distribution is always rather conditional. In the field distributions, Fig. 1b,d, one can see a strong transverse electric field, providing an argument for a structure classification in the RF sense as TE - type. But for the description of a deflecting field at $\beta = 1$ the generating hybrid waves HM_n and HE_n are used, see [3] for explanations, both with simultaneously non vanishing E_z and H_z components. For the deflecting force - the transverse component of the Lorenz force - in cylindrical or Cartesian coordinates we have:

$$\vec{F}^L_{r,x} = e(\vec{E} + [\vec{v}, \vec{B}]) = e(E_r - \beta Z_0 H_\varphi) = \\ = e(E_x - \beta Z_0 H_y), \quad Z_0 = \sqrt{\mu_0}\epsilon_0. \tag{1}$$

In contrast to a DLW, the structure under consideration has the same phasing for both transverse components E_r, H_φ or E_x, H_y and the deflecting effect of the electric field is partially compensated by an opposite deflection of the magnetic field. The phasing of transverse E, H components defines also the sign of the group velocity, which is positive in our case. For a deflection of particles this structure can be described as HE_1-dominating structure.
The effective transverse shunt impedance Z_e in the structure,

$$Z_e = \frac{|\frac{1}{k}\int_0^L \frac{\partial E_z}{\partial z} e^{ikz} dz|^2}{P_s L}, \quad \beta = 1, \tag{2}$$

where L is the structure length and P_s is the dissipated RF power, depends mainly on the distance between the ends of the protrusions, i.e. the effective aperture diameter $2r_a$, Fig. 1d, Fig. 2.
The structure has no rotational symmetry, which removes

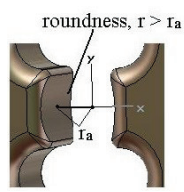

Figure 2: The structure shape near the axis for the reduction of multipole additions.

the problem of overlapping modes with perpendicular field orientation. But in the field distribution exist, together with the desirable dipole components $\sim cos(\varphi), sin(\varphi)$, multipole components $\sim cos(n\varphi), sin(n\varphi), n = 3, 5, 7, ..,$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

which provide non linear additions $\sim r^{(n-1)}$ in the deflecting field. The relative amount of multipole additions can be effectively reduced by a special shape of the ends of the protrusions, Fig. 2. The roundness radius $r > r_a$, Fig. 2 should be optimized for the chosen value of r_a thus compromising the linearity of the field in the specified vicinity of the axis $r < r_0$ and the RF efficiency Z_e.

TW OPERATION

For a constant impedance structure the deflecting voltage V_d, the attenuation constant α and the normalized deflecting field $\frac{E_d^0\lambda}{\sqrt{P_t}}$ relate as:

$$V_d = \frac{E_d^0}{\alpha}(1-e^{-\alpha L}), \alpha = \frac{\pi}{\lambda|\beta_g|Q}, \frac{E_d^0\lambda}{\sqrt{P_t}} = \sqrt{\frac{2\pi\lambda Z_e}{|\beta_g|Q}}, \quad (3)$$

where P_t is the input RF power and Q is the quality factor of the structure .

In Fig. 3 the calculated surfaces $\beta_g(r_a,\theta_0)$ and $Z_e(r_a,\theta_0)$ for aperture radii $0.06 \le \frac{r_a}{\lambda} \le 0.15$ and phase advance $20^o \le \theta_0 \le 179^o$ are shown for a TW operation. As can be seen from Fig. 3b, high values of $Z_e \sim 70$MOm/m can be realized for $60^o \le \theta_0 \le 140^o$ and $\frac{r_a}{\lambda} \sim 0.07$. For $\frac{r_a}{\lambda} \sim 0.15$ both TE deflector and DLW reach comparable shunt impedances Z_e but, as compared to a DLW, the considered structure is not restricted in β_g, Fig.3a.

For each phase advance θ_0 the structure has an inversion

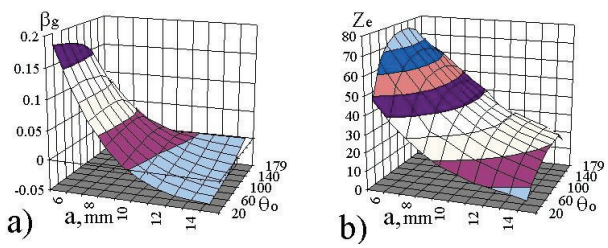

Figure 3: The surfaces of $\beta_g(r_a,\theta_0)$ (a) and $Z_e(r_a,\theta_0)$ for the TE-structure, $\lambda = 10cm$.

point at $r_a = r_{ai}$, where $\beta_g = 0$, as can be seen from Fig. 3a. The dependence $r_{ai}(\theta_0)$ is plotted in Fig. 4a as brown curve. The inversion point corresponds to the condition $H_y^0 = 0$, i.e. zero amplitude of the synchronous spatial harmonics in the transverse H_y component. In this report we consider the structure parameters for $r_a < r_{ai}$, assuming HE - domination. For $r_a > r_{ai}$ the components E_x and H_y have an opposite phasing. It is accompanied by a shunt impedance reduction, Fig. 3b.

For typical values of $\beta_g = 0.01, 0.02$ the dependencies of r_a, α and $\frac{E_d^0\lambda}{\sqrt{P_t}}$ on θ_0 are plotted in Fig. 4. Generally, the structure has a lower Q value, as compared to a DLW, especially for $\theta_0 < 60^o$ and the attenuation constant α for this region is rather high. But, in combination with the large value of $\frac{E_d^0\lambda}{\sqrt{P_t}}$ the structure reaches due to the higher Z_e a higher total deflecting voltage V_d. The deflecting field

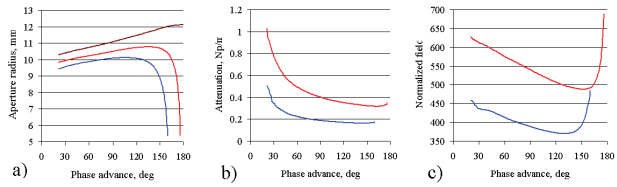

Figure 4: The dependencies of aperture radius r_a (a), attenuation α (b) and normalized field $\frac{E_d^0\lambda}{\sqrt{P_t}}$ (c)on θ_0 for $\beta_g = 0.01$ (red) and $\beta_g = 0.02$ (blue).

distributions for the TW mode are not considered in this report.

SW OPERATION

As can be seen from Fig. 3b, for SW operation, i.e. $\theta = 180^o$, the shunt impedance Z_e reaches not the maximal value. If an aperture radius r_a is specified, two parameters can be used to tune the operating frequency - the cell radius r_c and the window radius r_w, Fig.1. In Fig. 5 the dependence of Z_e on the aperture radius r_a is plotted for a fixed window radius r_w.

For small aperture radii the operating passband of the

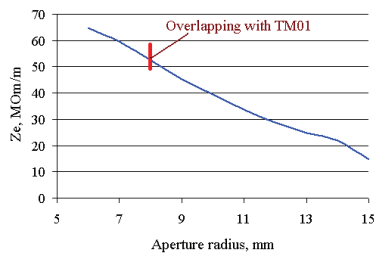

Figure 5: Z_e dependence on the aperture radius for $\theta_0 = 180^o, r_w = const$.

TE_{11}-like mode is the lowest band and the nearest TM_{01} passband is $\approx 500MHz$ higher. With increasing aperture the cell radius r_c increases too and the TM_{01} passband moves down. Due to the thick disk of approximately half a period length, modes of other types, except the operating mode, have a very weak coupling and a very narrow passband width of ($\sim 10MHz$). The vertical red line in Fig. 5 marks the range of r_a where the TM_{01} passband is closer to the operating frequency than $\pm 30MHz$.

Changing the window radius r_w both the operating frequency and the balance $\frac{Z_0 H_y^0}{E_x^0}$ in the deflecting field distribution are modified. A reduction of r_w simultaneously reduces both Z_e, and $\frac{Z_0 H_y^0}{E_x^0}$. The relative reduction of H_y^0 leads to a reduction of the operating passband width, which is just $\sim 16MHz$ for $H_y^0 = 0$. In Fig. 6 examples of deflecting field distribution are shown for different balance values $\frac{Z_0 H_y^0}{E_x^0}$, assuming the average deflecting field $10MV/m$. The plots of the amplitudes E_d are shown in

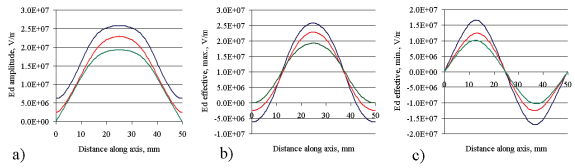

Figure 6: Distribution of the deflecting field amplitude (a), the effective field for bunch deflection (b) and bunch rotation (c) for harmonics balance $\frac{Z_0 H_y^0}{E_x^0} = 0.23$, (blue), 0.07 (red) and 0 (green) along the periodical axis.

Fig. 6a and $|E_d| \approx 0$ at the period ends for $\frac{Z_0 H_y^0}{E_x^0} = 0$. For bunch deflection the bunch center moves synchronously with the maximum of the total deflecting field, i.e. $\delta\psi = 0$. The effective deflecting field as seen by the particles is plotted in Fig. 6b. Sections with different sign of E_d can be seen, thus the deflected bunch will oscillate around the average deflected trajectory in this structure.

Today deflecting structures are widely used for another purpose, [4], related to bunch rotation. In this case the bunch center should move in a zero deflecting field, i.e. $\delta\psi = 90^o$, and the effective oscillating field becomes comparable to the amplitude of the average deflecting field, as shown in Fig. 6c. Thus together with the rotation, the bunch will oscillate as a whole along axis. Structure application for bunch rotation should hence be considered together with beam dynamics simulations. The high shunt impedance allows a higher deflecting voltage but large oscillations are not desirable from a beam dynamics point of view.

ADDITIONAL TOPICS

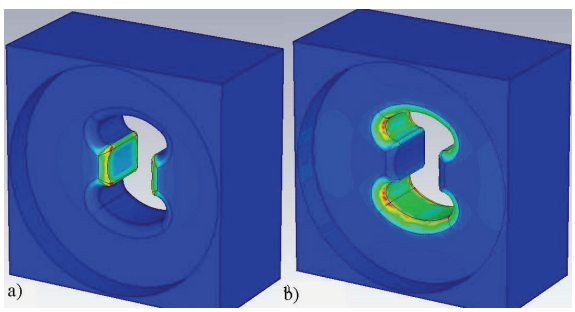

Figure 7: Electric (a) and magnetic (b) energy density distributions at the structure surface.

The somewhat more complicated structure shape, as compared to a DLW, presents no problem for modern numerically controlled tools. For the tuning after brazing the structure has an additional possibility: The distributions of the electric and magnetic energy densities at the structure surface are shown in Fig. 7 and a clear spatial separation can be seen. Four blind holes can be manufactured into the thick disk close to vicinity of the axis. After brazing of the structure small surface deformations in opposite holes, provide both positive and negative shift of the operating frequency.

With three independent parameters, $r_a < r_w < r_c$, the structure can be modified essentially. For $r_w \to r_a$ the structure transfers into the well studied DLW. Results for the opposite direction $r_w \to r_c$ are shown in Fig. 8.

The structure diameter becomes smaller, $2r_c \leq \lambda/2$ and

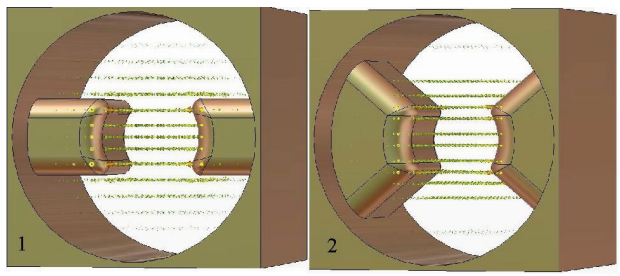

Figure 8: The structure modifications for $r_w = r_c$.

low frequency operation is possible. From an RF point of view the field distribution, can be considered either as for two transverse coaxial protrusions with opposite phasing or similar to a TM_{010} pillbox cavity with axis in x direction. For particle deflection along z-axis the structure remains HE_1 - dominated, with $\frac{Z_0 H_y^0}{E_x^0} \sim 0.4$, i.e. with stronger oscillations of the deflecting field, as shown in Fig. 6.

For manipulations of heavy ion beams, $\beta \ll 1$, [5], the magnetic component in the deflecting field (2) is negligible and the ions will see only the E_x component, similar to the case $\frac{z_0 H_y^0}{E_x^0} = 0$ in Fig. 6.

SUMMARY

RF parameters of a TE -type deflector are considered for the S - band frequency range. A higher shunt impedance, as compared to a classical DLW, can be obtained, leading to a higher deflecting voltage. Some methodical topics are considered too.

OPERATIONAL EXPERIENCE WITH THE FERMI@ELETTRA S-BAND RF SYSTEM*

A. Fabris#, P. Delgiusto, F. Gelmetti, M. Milloch, A. Milocco, F. Pribaz, C. Serpico, N. Sodomaco, R. Umer, L. Veljak, Sincrotrone Trieste, S.S. 14 – km. 163,5, in Area Science Park, 34149 Basovizza, Trieste, Italy

Abstract

FERMI@Elettra is a single-pass linac-based FEL user-facility covering the wavelength range from 100 nm (12 eV) to 4 nm (310 eV) and is located next to the third generation synchrotron radiation facility Elettra in Trieste, Italy. The machine is presently under commissioning and the first FEL line (FEL-1) will be opened to the users by the end of 2012. The 1.5 GeV linac is based on S-band technology. The S-band system is composed of fifteen 3 GHz 45 MW peak RF power plants powering the gun, eighteen accelerating structures and the RF deflectors. The S-band system has been set into operation in different phases starting from the second half of 2009. This paper provides an overview of the performance of the system, discussing the achieved results, the strategies adopted to assure them and possible upgrade paths to increase the operability of the system.

INTRODUCTION

The FERMI@Elettra FEL facility is based on a warm linac followed by a single pass seeded FEL [1]. Two FEL lines are foreseen: FEL-1 which produces fundamental output wavelength from 100 to 20 nm and FEL-2 which will extend the operation down to 4 nm applying High Gain Harmonic Generation schemes. The main parameters of the machine are reported in Table 1.

Table 1: Machine Parameters

Parameter	FEL-1	FEL-2	Unit
Wavelength	100-20	20-4	nm
Electron beam energy	1.2	1.5	GeV
Bunch charge	0.8	1	nC
Peak current	850	500	A
Bunch length (FWHM)	400	600	fs
Norm. emittance (slice)	0.8-1.2	1.0-2.0	mm mrad
Energy spread (slice)	150-250	100-200	keV
Repetition rate	10-50	50	Hz

The accelerator consists of an RF photocathode gun, an S-band linac, an X-band structure, a laser heater to control the uncorrelated energy spread and the beam transport system to the undulators. The machine is presently working at a repetition frequency of 10 Hz, which will be increased to 50 Hz in May 2013.

The commissioning of the facility is rapidly advancing and FEL-1 will be opened to external users at the end of the present year. Commissioning of FEL-2 will progress in the remaining time with the target of the first test experiment during 2013.

PRESENT STATUS OF THE S-BAND SYSTEM

Sixteen S-band accelerating structures are installed in the FERMI linac (Fig.1). The first nine structures are TW ones, while the last seven are BTW type and are equipped with SLED. Two more TW structures will be added in the future. They will replace the first two structures that will be finally relocated along the machine.

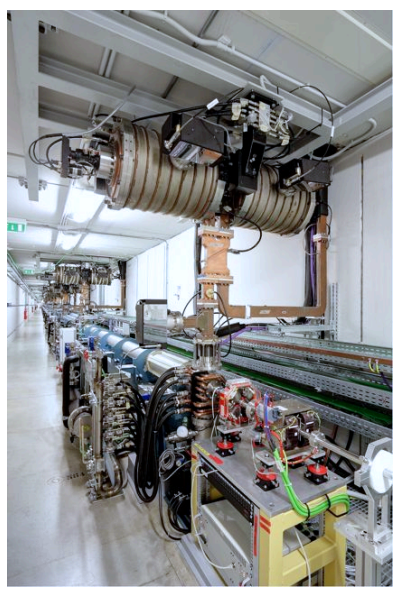

Figure 1: View of the linac from the high-energy end.

Fifteen 45 MW peak klystron (TH2132A) are installed, each one powered by pfn based modulators (Fig.2). Fourteen klystrons provide RF power to the accelerating structures, to the gun and to the low and high-energy RF deflectors. Two main power distribution schemes are used: one klystron feeding two TW structures or one klystron feeding one high gradient BTW structures. A spare power plant provides a backup solution to the first two, powering either the RF gun or the structures before the laser heater. The change of the operating mode is

*Work supported by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3

performed by an array of remotely controlled waveguide switches.

Each RF plant is equipped with a low level RF (LLRF) system that maintains the stability of the RF below 0.1 % and 0.1° at 3 GHz. The system now in operation is an intermediate system, which implements a commercial processing board instead of the one specifically designed for FERMI and now in construction. All the needed loops are implemented such as amplitude, phase, cable calibration and phase locking. SLED phase reversal and phase modulation have been also implemented by means of the LLRF.

Figure 2: One of the fifteen modulators

The S-band RF system has been gradually set into operation starting with the first installation of the plant for the gun in the second half of 2009 [2]. All the fifteen RF plants and sixteen accelerating structures are now in operation. The machine routinely operates on a 24 hours basis for the commissioning of the accelerator and of the beamlines. The operating energy of the machine is 1.2 GeV and the repetition rate is 10 Hz.

ENERGY AND REPETITION FREQUENCY UPGRADE

Two major goals are foreseen for 2013: the upgrade of the repetition rate, following the installation of the new RF gun designed for 50 Hz, and the commissioning activities of FEL-2. Besides the proof of the double stage HGHG scheme, the latter also implies the upgrade of the machine energy to 1.5 GeV.

The transition to 50 Hz requires an upgrade of the modulators operation. This is particularly important for the first six built that, for time constrains, were installed re-using the components of the previous Elettra injector and therefore are limited by the hardware to 10 Hz. The upgrade of these modulators implies an almost complete rebuild, since many of the main components, such as pfn, pulse transformers, etc. have to be replaced. In addition, the upgrade activities must not affect the commissioning calendar and therefore they can be generally done only in the already planned shutdowns. The process is advancing according to the schedule and it will be completed in May 2013.

The energy upgrade to 1.5 GeV will be mainly realized by increasing the energy gain in the BTW high gradient accelerating structures, increasing the RF power and the RF pulse length. For the remaining structures there will be no major changes since an increase in the energy gain is basically limited either by the available RF power and the constraints due the energy requirements at various points along the machine, like the bunch compressors and the laser heater. The RF conditioning will be done using the automatic software already developed and available via the machine control system.

Table 2 shows the energy budget on crest for the two operating energies for FEL-1 and FEL-2. This should be decreased by the effects of:

- the deceleration of the X-band cavity (20 MeV typically);
- the longitudinal wakefields when operating at high bunch current (expected 30 MeV at 1.5 GeV);
- the loss in energy gain if running some structures off-crest for beam dynamic optimization.

Table 2: Energy gain per structure and total energy budget

Type	Quantity	1.2 GeV	1.5 GeV
Gun	1	5 MeV	5 MeV
TW-Elettra	2	47 MeV	47 MeV
TW-LIL	7	57 MeV	57 MeV
BTW	7	110 MeV	154 MeV
Total energy		**1268 MeV**	**1576 MeV**

In order to achieve the required energy gain in the BTW structures, overcoming the limitations encountered in their operation as injector for Elettra, the SLEDs will be phase modulated. This feature has been already implemented in all the plants with SLED since it has in any case a beneficial effect on the reliability. A preliminary test was done on one plant to investigate the energy gain limits [3]. After a first optimization of the parameters of a linear phase modulation, in this structure an energy gain of 165 MeV was reached, corresponding to an accelerating gradient of 27 MV/m. The klystron was operating at 38 MW peak power and 4 μsec pulse width. These results give confidence in the reaching of the target energy for FEL-2. Further studies will be done to evaluate the advantages of using a non-linear phase modulation to get a flatter RF pulse.

NEXT IMPLEMENTATIONS

New Accelerating Structures

The layout of the machine allows for the installation of two more accelerating structures powered by the existing plants. This gives the opportunity to move the first two structures along the machine and replace them with structures optimized for the beam dynamics needs at low

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

energy and high charge. The specification of the two structures calls for minimized phase and amplitude asymmetries in the coupler cells, to minimize the induced kick to the beam due to the multipole field components. The input and output coupling cells shall be of the dual-feed racetrack type with diametrically opposed sidewall-coupling aperture. Symmetrical feed coupling should allow to erase the dipole transverse momentum on the beam due to the total phase and amplitude symmetries in the coupling iris plane, while racetrack geometry permits to minimize quadrupole field components [4]. Each of the two structures will contribute with 50 MeV to the energy budget. This will extend the energy margin or allow operation at higher energy.

LLRF

The processing board presently used is a commercial board (LLRF4) and will be replaced by a new board under construction. This will allow to extend the capabilities of the system due to the higher computing power, adding new functionalities, such as intra-pulse feedback or real rime communications between LLRF units.

The present feedbacks are inter-pulse feedbacks and correct the RF drive to the klystron between pulses. This corrects mainly drifts in phase and amplitude, but does not correct jitter contribution which could be generally associated with modulator instabilities, for example due to the HV power supply or the pfn. In an intra-pulse feedback the information at beginning of the pulse is acquired and the correction applied inside the same pulse. This implementation requires higher performance capabilities on the processing hardware that should be achieved with the new board. The main issue to be taken into account for an intra-pulse feedback is the latency time, which is due to different contribution, such as the structure filling time, the digital acquisition time and the digital processing time.

The structure filling time varies from 0.8 to 1.5 μsec depending on the structure type and is the main contributor to the latency time. Since in the FERMI case the RF pulses are 4 μsec width, this makes not efficient to include the structure in the loop. Therefore a sample of the RF field at the output of the klystron will be acquired and used, allowing also the advantage of shorter cables.

Due to the high acquisition accuracy of the LLRF (0.017°, 0.029%), there is no need of averaging so we do not expect problems due to the digital acquisition time. The new board features low latency ADCs, high FPGA clock frequency and double data rate DACs, so also the digital processing time issue should be very much under control. Finally, the measurements taken on FERMI show that the phase and amplitude trend of the RF pulse can be considered constant between pulses. This leads to the conclusion that single amplitude and phase correction can be used within pulse.

RELIABILITY ANALYSIS AND RELATED ASPECTS

In the last years the effort has been mainly concentrated on installation aspects. The completion of these activities is shifting the attention on reliability and availability aspects. Some of these issues were already considered during the design phase, for example leading to the construction of a spare modulator. Some other aspects are being analyzed based on the operational results.

Current availability of the S-band system is 93 %, which is sufficient for the commissioning phase and the first users' periods. Klystron-modulator systems are the main source of short resettable faults affecting the uptime. A testing program has been launched to understand these events and figure out how to reduce them. Similar analysis will be applied to the other parts of the systems.

Other availability aspects are being considered, such as the ones related to reduction of the time needed for klystron or thyratron replacement. The possibility of having other spare plants cannot be pursued due to space limitations, so the spares should be ready to use for replacement. This is especially valid for the klystron in order to reduce activation and HV conditioning time once installed.

CONCLUSIONS

The commissioning of FERMI@Elettra is progressing and FEL-1 will be opened to external users at the end of 2012. The S-band RF system has been gradually set into operation during these years and it is being upgraded for 50 Hz operation. Fifteen RF power plants and sixteen accelerating structures are in operation, allowing the reaching of the required electron beam energy. Stability of the fields is well in specification as confirmed by the measurements on the beam parameters, such as the beam time jitter. Continuous efforts on reliability aspects are pursued since these are key points a users' facility.

DESIGN OF A C-BAND DISK-LOADED TYPE ACCELERATING STRUCTURE FOR A HIGHER PULSE REPETITION RATE IN THE SACLA ACCELERATOR

Tatsuyuki Sakurai#, Takahiro Inagaki and Yuji Otake, RIKEN SPring-8 center, Hyogo, Japan
Hiroyasu Ego, JASRI/SPring-8, Hyogo, Japan

Abstract

It is expected that the high pulse-repetition rate of the SACLA accelerator provide a higher rate of X-ray laser pulses to expand ability of user experiments, such as simultaneously providing the laser to several beamlines and reducing a measuring time in the experiment. Therefore, we studied on a C-band accelerating structure for the higher pulse rate above 120 pps than the present rate of 60 pps. Since the higher repetition rate operation is inclined to increase vacuum electrical discharges, it is required to reduce the surface electric fields in the structure without decrease in accelerating voltage. We designed a cross sectional shape of ellipsoidal curvature, which reduces the maximum surface electric or rf field by 20%. The designed structure adopts a TM01-2π/3 mode disk-loaded type with a quasi-constant gradient. Since the high repetition rate also increases the heat load to the structure, in simulation, we optimized cooling channels. As a result of the design, an accelerating gradient of more than 40 MV/m will be expected, when an input RF power of 80 MW is fed into the structure.

INTRODUCTION

The SACLA (SPring-8 Angstrom Compact free electron LAser) facility succeeded to generate of the X-ray free electron laser (XFEL) with a wavelength of 0.12 nm in June, 2011[1]. Since March 2012, the X-ray laser is provided to the user experiments by mainly using one beamline.

To expend user experiment ability, SACLA has a space of five beamlines for the future expansion. The electron beam must be distributed to the beamlines by using a fast switching magnet in order to supply X-ray laser to many experiments users. However, the repetition rate of each beamline decreases inevitably. Therefore, we plan to operate SACLA with a repetition rate up to 120 pps for the upgrade of the beamlines.

Our present C-band (5712 MHz) accelerating structure to adopt multi-bunch operation has a choke-mode cavities [2] and an SiC absorbers outside of each cavity. The present structure generates an accelerator gradient of 37 MV/m to obtain a 8GeV electron beam and has a phase advance per cell of 3π/4 mode in order to machine the choke-mode cavity. Due to the heat dissipation, this complicated structure has distortions of the cavity, which leads large shifts of a resonant frequency and an RF phase. This distortion is a serious problem for 120 pps operation. Therefore, the newly designed accelerating structure does not have complicated choke structures and SiC absorbers. Furthermore, the simple structure gives reduction of the production costs and enable us high precise adjustment of the resonant frequency with the dimpling method after the brazed of the structure.

NEW STRUCTURE DESIGN

The designed disk-loaded structure has a phase advance per cell of 2π/3 for the accelerating TM01-mode and quasi-constant gradient. The highest shunt impedance for a travelling-wave structure occurs in the neighborhood of the phase advance. Therefore, an accelerating gradient of the new structure should be higher than the existing structure. Due to the compatibility of future replacement with the present choke-mode structure for future replacement, a structure length, a filling time and an attenuation parameter of new structure are designed to be the same as those of the choke-mode one.

We used the 3D electromagnetic field simulation codes, ANSYS-HFSS [3], in order to design the structure. By the simulation, the iris diameter (2a) of each cell is linearly changed over 100 cells and a quasi-constant gradient is obtained. The cell diameter (2b) was adjusted so that the resonance frequency for every cell is equal to the operation frequency of 5712 MHz. Table 1 shows the parameters of a new C-band disk-load type accelerating structure. Figure 1 shows variations of the 2a and the accelerating gradient at an input power of 80 MW. The averaged accelerating gradient is expected to be 43 MV/m, when an input RF power of 80 MW is fed into the structure.

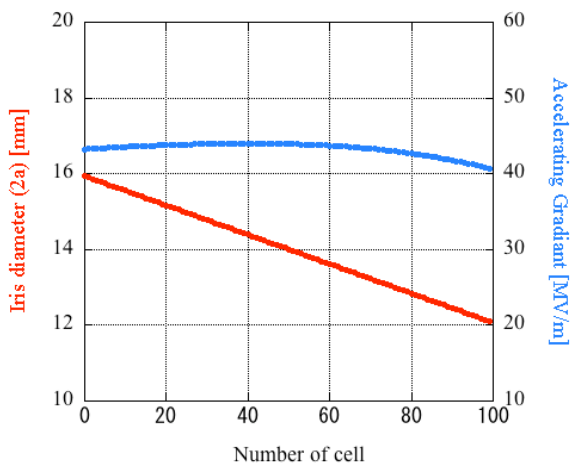

Figure 1: Variation of the iris diameters (red line/left axis) and an accelerating gradient at an input power of 80 MW (blue line/right axis).

The dipole HEM11 mode is the dominant source of beam wakefield instability [4] and hence the frequency and wakefield of the mode were also calculated. The variation of 2a was so determined that the wakefield of the HEM11 mode falls off in a few nsec and has drops within every bunch interval of 4.2 nsec in the which might be assumed as the minimum bunch-interval of multi-bunch operation in SACLA. Figure 2 shows the calculated envelope of the wakefield. It decreases sufficiently and drops at intervals of 4.2 nsec are less than 2% compare with peak value of the wakefield.

Table 1: Parameter of the new C-band accelerator

Operation frequency [MHz]	f_a	5712
Structure type		Quasi-Constant Gradient (quasi-CG) Disk-load type, Traveling wave structure
Resonant mode		TM01-2π/3
Total cavity length [m]	L	1.862
Unloaded Q factor	Q_0	8800
Group velocity	v_g/c	0.023
Filling time [nsec]	t_F	270
Attenuation parameter	τ	0.59
Average shunt impedance [MV/m]	r	66.0
Number of cell	N	100
Iris diameter [mm]	2a	15.941~12.109
Cell diameter [mm]	2b	43.761~42.451
Disk spacing [mm]	d	17.495
Disk thickness [mm]	t	4
Cross sectional shape of Iris		Ellipsoidal curvature

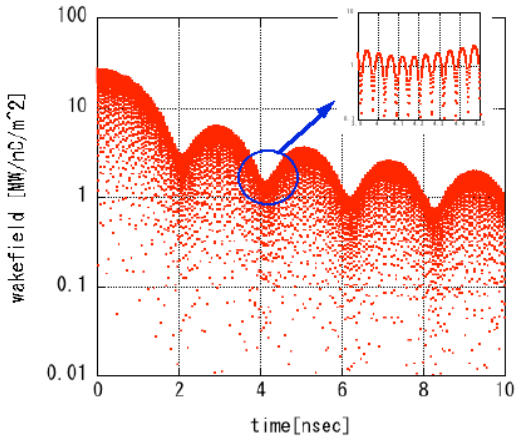

Figure 2: Wakefield envelope of HEM11 mode.

CROSS SECTIONAL SHAPE OF ELLIPSOIDAL CURVATURE

We designed a cross sectional shape of the iris as ellipsoidal curvature, which reduces the strength of surface electrical field. Figure 3 shows the cross sectional view of the ellipsoidal curved iris shape. We estimated the dependence of the maximum surface electrical field dependent on the axis ratio of major and minor axis of an ellipse iris (B/A), by using HFSS and decided the disk thickness (t) is 4.0 mm, as well as to maintain the compatibility to the existing choke-mode type accelerating structure. It is the same as the existing structure parameter in order to replace the choke-mode structure. Therefore, we fix A=2 mm and change the size of B. Figure 4 shows the ratio of the maximum surface electrical field to the on-axis electrical field (E_p /E_{acc}) depending on a ratio of B/A. E_p/E_{acc} becomes minimum at B/A = 2 and is 20% lower than that at B/A=1. Therefore, we adopted the cross sectional shape of the iris as ellipsoidal curvature of B/A = 2.

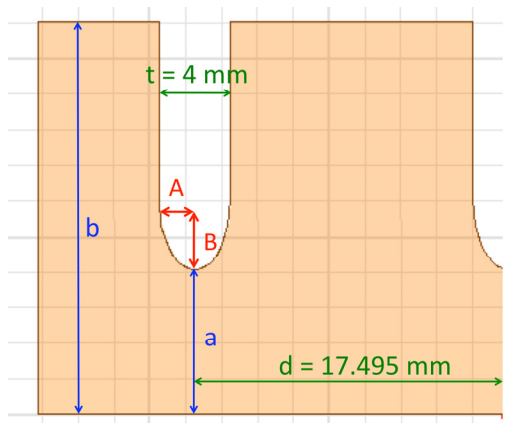

Figure 3: Cross sectional view of the ellipsoidal curved iris shape.

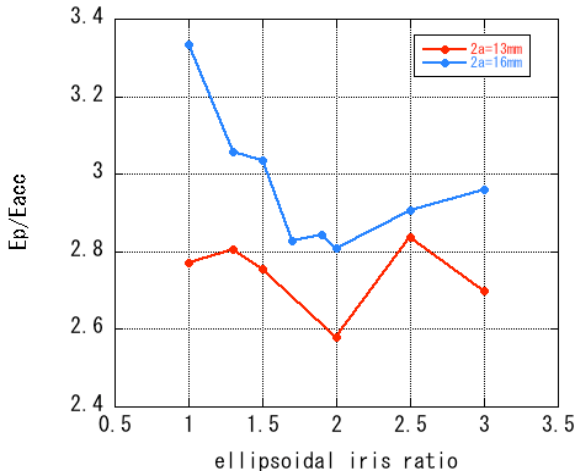

Figure 4: Ratio of maximum surface electrical field to the on-axis electric field (E_p /E_{acc}) depending on the ratio of B/A.

THERMAL EXPANSION EFFECT

The high repetition rate increases the heat load of the accelerating structure, which may causes the thermal expansion and the shift of the resonant frequency. Therefore we carefully optimized the cooling water channels of the accelerating structure. The heat load of the accelerating structure in 120 pps is educed to be 3.8 kW. The initial temperature of the cooling water from a cooling system is 26.5°C. We place eight water flow channels with an 8 mm in diameter as shown in Figure 5. A flow velocity of water is assumed to be 0.8 m/sec. A water flow rate per one channel and the total flow rate are assumed to be 2.5 L/min and 20 L/min, respectively. A counter-flow method is adopted the cooling of accelerating structure in order to make a temperature slope small. We employ a precise temperature-regulation system in order to stabilize the temperature of the accelerating structure by feedback control of the water heater [5]. A required temperature stability should be set at ±0.1°C.

To realize the above-mentioned conditions, we used the ANSYS thermal and structure analysis software to simulate the temperature distribution and expansion of the accelerating structure. Figure 5 shows the estimated temperature distribution of the accelerating structure operated at 120 pps. We designed the resonant frequency of the cavity is set at 5712 MHz with the cavity temperature at 33°C. When the cavity is heated with the heat load of 3.8 kW, 2b is expanded at about 2.8 μm from the original size, and the resonant frequency shifts at 430 kHz. The frequency shifts is compensated by lowering the water temperature by 4.4°C. The rise of the water temperature due to 3.8 kW is 2.7°C. Since we use the counter-flow method, the temperature of the input water temperature should be set at 33°C-4.4°C=28.6°C, which compensates the frequency shift. Since this input temperature is higher than 26.5°C of the initial temperature of the cooling water system, the precise temperature-regulation system can control the temperature by changing the heater power. On the other hand, when the repetition rate is low and the heat load is negligibly small, the temperature of cooling water can be controlled to be 33°C with a heater. Therefore, we can keep the resonant frequency at 5712 MHz for every operation rate by adjusting the heater power.

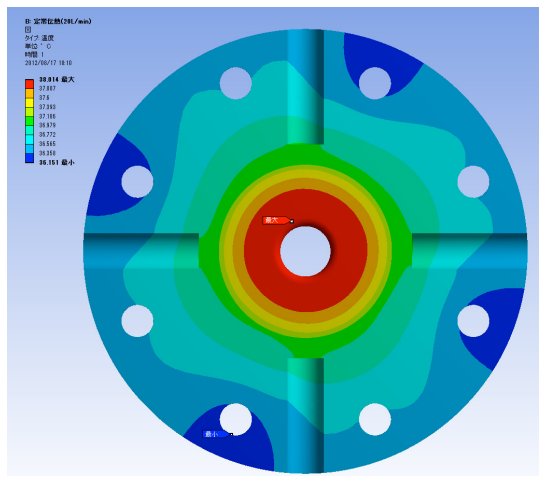

Figure 5: Temperature distribution of the accelerating structure in 120 pps operation

SUMMARY

We designed a new C-band accelerating structure adapted to a pulse repetition rate of 120 pps. The structure is a TM01-2π/3 mode disk-loaded type and has a quasi-constant accelerating gradient of 43 MV/m at an input RF power of 80 MW. Furthermore, the cross sectional shape of an iris having the ellipsoidal curvature decreases a surface electrical field by 20%. We confirmed that the new structure could be operated by 120 pps, by our thermal-expansion analysis. We will manufacture a prototype accelerating structure and perform a high power RF test in 2013.

THE NONRESONANT PERTURBATION THEORY BASED FIELD MEASUREMENT AND TUNING OF A LINAC ACCELERATING STRUCTURE *

W. C. Fang#, Q. Gu, Z. T. Zhao, SINAP, Shanghai, China
D. C. Tong, THU, Beijing, China

Abstract

Assisted by the bead pull technique, nonresonant perturbation theory is applied for measuring and tuning the field of the linac accelerating structure. The method is capable of making non-touching amplitude and phase measurements, real time mismatch feedback and field tuning. Some key considerations of the measurement system and of a C-band traveling-wave structure are discussed, and the bead pull measurement and the tuning of the C-band traveling-wave linac accelerating structure are presented at last.

INTRUDUCTION

The Shanghai soft X-ray Free Electron Laser test facility(SXFEL)is presently being planned and designed at the Shanghai Institute of Applied Physics, CAS [1]. This facility will be located close to the Shanghai Synchrotron Radiation Facility, which is the first 3rd generation light source in mainland China [2]and it requires a compact linac with a high gradient accelerating structure and high beam quality. As a key R&D item, a room temperature C-band (5712 MHz) accelerating structure has been developed [3, 4]. For fabricating the C-band structure with high performance, the bead pull measurement system based on nonresonant perturbation theory has been developed.

There are several methods for RF structure measurement or tuning, such as the resonant perturbation method [5] and the phase shift method, however several limitations appear when they are applied to a traveling-wave accelerating structure. The resonant perturbation method picks up the amplitude of the electromagnetic field, therefore it is limited in the measurement of the standing-wave accelerating structure and the phase shift method only shows the phase information in the RF structure. For the accurate and fast tuning of a traveling-wave linac RF structure, nonresonant perturbation theory is the preferable method, which can measure the electromagnetic field distribution with both amplitude and phase, and this method is capable of making non-touch measurement, which can maintain the clean inner surface of the accelerating structure and reduce its RF breakdown rate. Furthermore, this method is also very effective in performing an accurate and fast real-time tuning of the accelerating structure, which is economical for mass fabrication of accelerating structures.

In this paper we present a cold test application of nonresonant perturbation theory on a linac RF structure [6]. This method based on the bead pull technique can pick up the amplitude and phase distribution of a linac structure, particularly for a traveling-wave structure, and is a preferable and efficient method for accelerating structure cold testing and tuning. In the following we describe firstly the theory of nonresonant perturbation and the tuning procedure and then discuss the key considerations of our measurement system with the bead pull technique. At the end we give several experimental results of our newly developed C-band traveling-wave accelerating structure tuning, which verify the feasibility of this method.

NONRESONANT PERTURBATION THEORY AND TUNING PRINCIPLE

According to nonresonant perturbation theory, the variation of the reflection coefficient in the input port is measured with and without a perturbation bead, which is placed at different points along a line to pick up the amplitude and phase distribution of the electromagnetic field strength, a schematic drawing is shown in Figure 1. Based on the results and post-processing, RF tuning is processed with accurate and fast real-time feedback.

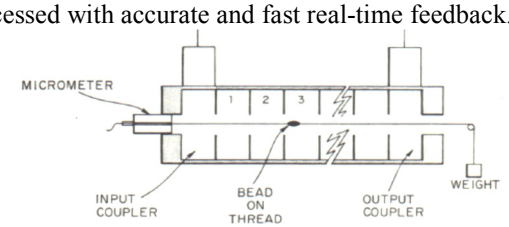

Figure 1: The field measurement based on nonresonant perturbation theory.

Nonresonant Perturbation Theory and Field Measurement

In nonresonant perturbation theory, the desired field strength is calculated as the following [6]:

$$2P_i(\Gamma_p - \Gamma_a) = -j\omega[k_e E_a^2 - k_m H_a^2] \quad (1)$$

For an accelerating structure, the TM mode is used for beam acceleration and the crucial longitudinal electrical field Ez is the unique field component on axis, thus the first equation of equation (1) is used for field measurement, and is renamed as equation(2) with reflected coefficient S11 of the Network Analyzer:

$$\Delta S11 = \Gamma_p - \Gamma_a = S11_P - S11_a = -\frac{j\omega k_e}{P_i} E_a^2 \quad (2)$$

whereS11p and S11a are acquired from the Network Analyzer, respectively corresponding to Γp and Γa in equation (1) above. In equation (2), Ea is complex data, its amplitude is the square root of the amplitude of ΔS11, and its phase is half of the phase ofΔS11. As the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

bead goes through the RF structure, the distribution of Ez on axis can be measured step by step.

Tuning Principle

With the bead pull measurement, the amplitudes and phases of the field can be measured, and after post-processing the local reflected coefficient can be calculated for the later tuning procedure. For the accelerating structure, the field of the center of the ith cell can be expressed by $E_i e^{j\varphi_i}$, which is the superposition of forward and backward waves $a_n e^{j(-2\pi/3(i-n)+\psi_n)}$ and $b_n e^{j(2\pi/3(i-n)+\phi_n)}$, where the center cell is the nth cell of the three cells in Figure 2.

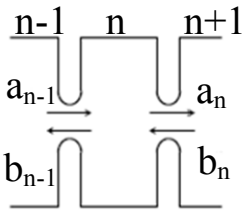

Figure 2: Forward and backward wave of nth cell.

It is supposed that the amplitudes in three adjacent cells are the same, according to [7],

$$a_n e^{j\psi_n} = E_{n-1} e^{j(\varphi_{n-1}-\pi/2)} + E_n e^{j(\varphi_{n-1}-\pi/6)}/\sqrt{3}$$
$$b_n e^{j\phi_n} = E_{n-1} e^{j(\varphi_{n-1}+\pi/2)} + E_n e^{j(\varphi_{n-1}+\pi/6)}/\sqrt{3} \quad (3)$$
$$b_{n+1} e^{j\phi_{n+1}} = E_n e^{j(\varphi_n+\pi/2)} + E_{n+1} e^{j(\varphi_{n+1}+\pi/6)}/\sqrt{3}$$

Based on equations (3), the local reflected coefficient of the nth cell is derived as equation (4)

$$\Gamma_{local,n} = \frac{b_n e^{j\phi_n} - b_{n+1} e^{j(\phi_{n+1}-2\pi/3)}}{a_n e^{j\psi_n}} = A + jB \quad (4)$$

where A and B represent the real and imaginary parts of the reflection respectively.

According to the conclusion in [8], the real part of the reflection coefficient in equation (4) is small and neglected relative to the imaginary part. The left imaginary part is dominated by the frequency detuning of each cell, which is shown in Equation (5).

$$\Gamma_{local} \approx -j\frac{2\beta Q_0 \Delta F}{(\beta+1)^2 + Q_0'^2(\Delta F)^2} \approx j\frac{Q_0' \Delta f_0}{f_0} \quad (5)$$

where f_0 is the eigenfrequency, $\Delta f_0 = f_0 - f$, and $Q_0' = c\varphi/vg$ is the eigen-parameter of each cell. In Equation (5), it is easy to find that the reflection coefficient Γ_{local} is more or less than zero respectively when f_0 is detuned above or below the operating frequency f. Based on this principle, every cell can be tuned independently according to the sign of Γ_{local}.

According to equation (5), in equation (4) A is neglected and B presents the frequency detuning. If B is more than zero, the frequency is more than the design value, and to the contrary, frequency is a little less. This is the rule for the automatic tuning process, and the process is not stopped until B reaches zero.

In equation (4), the left side represents the local reflection$\Gamma_{local,n}$of the nth cell, however in the automatic tuning process, only reflection coefficient Γ_{port} of the input port can be measured, which is the sum of the local reflection coefficients of all cells including coupling cells and periodic cells. Because of the attenuation and reflection of each cell, these reflections are added with different weight, and this is expressed as equation (6),

$$\Gamma_{port} = \sum_1^n C_n \Gamma_{local,n} \quad (6)$$

For a traveling-wave accelerating structure, the attenuated power for the nth cell is [9]

$$\left(\frac{dP}{dl}\right)_n = -2\alpha_n P \quad (7)$$

whereα_n is the attenuation factor of the nth cell and P is the power flow of the nth cell, and equation (7)can be solved as

$$P_n = P_0 e^{-2\sum_1^n \alpha_n} = P_0 e^{-2\tau_n} \quad (8)$$

so that the weight from attenuation can be expressed as

$$\Gamma_{port} = \sum_1^n e^{-2\tau_n} \Gamma_{local,n} \quad (9)$$

In equation (9), the global attenuation for all cells from the input waveguide should be added, and equation (9) is revised as

$$\Delta\Gamma_{port} = |S11| e^{-2\tau_n} \Delta\Gamma_{local,n} \quad (10)$$

where|S11|is the global attenuation factor from the input waveguide, which is equal to the reflection coefficient of the input port when detuning the input coupling cell.

Besides the effect of attenuation, the reflection of each cell also occupies some part of the weight C_n in equation (6),however the reflection of each cell is random. So the reflection of each cell cannot be derived analytically, however it can be calculated by the post-processing of the forward and backward waves in equation (3).

For a constant impedance traveling-wave accelerating structure, equation (10) is modified as

$$\Delta\Gamma_{port} = |S11| \left(\frac{a_n}{a_1}\right)^2 \Delta\Gamma_{local,n} \quad (11)$$

wherea_n is the same as that in equation (3), and $\left(\frac{a_n}{a_1}\right)^2$ includes both the attenuation factor in equation (10) and the reflection from each cell. The square represents the integrated effect of both forward and backward waves.

For a constant gradient traveling-wave accelerating structure, equation (10) is modified as

$$\Delta\Gamma_{port} = |S11| \left(\frac{a_n}{a_1}\right)^2 e^{-2\tau_n} \Delta\Gamma_{local,n} \quad (12)$$

where $\left(\frac{a_n}{a_1}\right)^2$ only represents the reflection factor, and $e^{-2\tau_n}$ is the attenuated factor, which can be calculated from design parameters.

TUNING EXPERIMENTS

Based on the design in [3], the 1.1m C-band traveling accelerating structure has successfully accomplished cold RF testing and tuning, which is shown in Figure 3. It is necessary to point out that a constant impedance structure is adopted for the 1.1m C-band structure at last, which is different from the preliminary one, for simplifying the fabrication process. The 1.1m C-band structure is tested vertically so that the pull-bead can be placed into the structure easily without touching the inner surface of the structure.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Figure 3: Vertical cold RF test for the 1.1m C-band traveling accelerating structure.

Before any tuning, the field distribution on axis is measured, which is shown in Figure 4 left. In Figure 4 left, the field distribution including amplitude and phase is very confused, and it predicts that there are complicated standing waves on axis in the accelerating structure. After the analysis by LABVIEW code in Figure4 right, apparently there are three peaks around the 15th, 22th and 50th cells and it is detuned severely. Similarly, the phase advance per cell has large fluctuation, which is expected to be about 120 degrees. Based on this severe detuning of the C-band accelerating structure, several tuning iterations are proceeded necessarily.

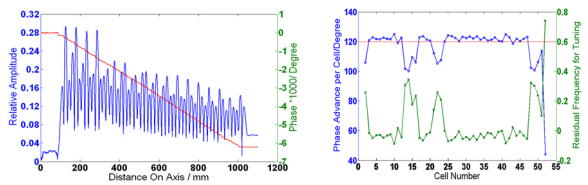

Figure 4: The field distribution and analysis before tuning

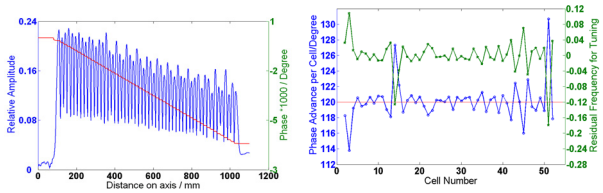

Figure: 5 The field distribution after 1st tuning.

After the first tuning phase, the field distribution and post-processing analysis are shown in Figure 5. In Figure 5 left the amplitude and phase on axis are distributed more smoothly with respect to that before tuning. In Figure 5 right, the phase advance mainly fluctuates between 118 and 122 degrees, and the amplitude of the residual frequency tuning per cell is mainly less than 0.05, which is within the permitted tolerance. However there is some slight detuning among cells, and after four water tubes are brazed, the last tuning phase eliminates the residual detuning finally.

After the final whole-structure tuning, the accelerating structure is almost matched, and the results are shown in Figure 6. According to the design target, the standing-wave ratio on axis is below 1.1 and the amplitude of phase advance fluctuation per cell is 2 degrees, corresponding to the baseline of 120 degrees per cell. In Figure 6 left, the field amplitudes in the center of cells are attenuated exponentially and the standing-wave ratio (SWR) on axis of the accelerating structure is below 1.1.In Figure 6 right, the phase advance per cell fluctuates between 118 and 122 degrees, and correspondingly the residual frequency detuning of all cells is from -0.04 to 0.04, which stays in the range of tolerance from -0.05 to 0.05. However on the both ends of accelerating structure in Figure 6 right, three cells on the each end are detuned out of the range above, which is used for the tuning of couplers.

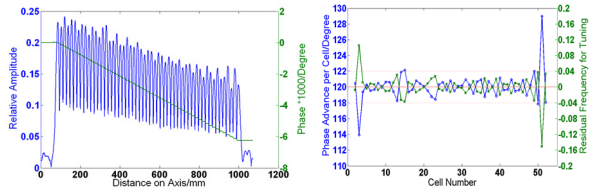

Figure 6: The field distribution after final tuning phase.

CONCLUSION

The nonresonant perturbation theory based on the bead pull measurement technique is an effective means for measuring and tuning a high gradient accelerating structure. The measurement system has been setup and successfully used in the R&D of a 1m long C-band traveling-wave accelerating structure for SXFEL. Now this prototype structure is ready for a high power RF test and since a 1.8 m long C-band constant gradient structure is under development, this measurement system becomes an indispensable tool in the accelerating structure developments.

ACKNOWLEDGEMENTS

We would like to thank Dr. Juwen Wang of SLAC for his helpful suggestion and useful discussion on the development of the measurement system, and appreciate our SINAP colleagues who join in the discussion on the nonresonant perturbation theory.

S-BAND LOADS FOR SLAC LINAC*

A. Krasnykh, F.-J. Decker, SLAC National Accelerator Lab, Menlo Park, CA 94025, USA
R. LeClair, INTA Technologies, Santa Clara, CA 95051, USA

Abstract

The S-Band loads on the current SLAC linac RF system were designed, in some cases, 40+ years ago to terminate 2-3 MW peak power into a thin layer of coated Kanthal material as the high power absorber [1]. The technology of the load design was based on a flame-sprayed Kanthal wire method onto a base material. During SLAC linac upgrades, the 24 MW peak klystrons were replaced by 5045 klystrons with 65+ MW peak output power. Additionally, SLED cavities were introduced and as a result, the peak power in the current RF setup has increased up to 240 MW peak. The problem of reliable RF peak power termination and RF load lifetime required a careful study and adequate solution. Results of our studies and three designs of S-Band RF load for the present SLAC RF linac system is discussed. These designs are based on the use of low conductivity materials.

INTRODUCTION

The original RF system setup of the SLAC linac (see Fig. 1) was based on an array of 24 MW peak klystrons [1].

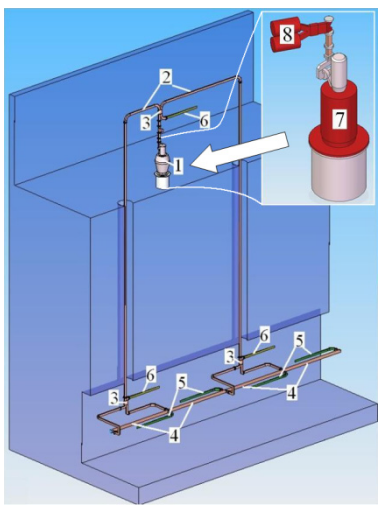

Figure 1: Original RF setup of the SLAC linac; 1 is XK-5 Klystron, 2 is WR284 Waveguide Branches, 3 is Power Dividers, 4 is Accelerating Sections, 5 is High Power RF Loads, 6 – Low Power RF Loads

Each RF station is equipped with a XK-5 klystron (1), feeding two branches of WR284 waveguide (2) and three 3dB power splitters (3) to supply four 10ft travelling accelerating sections (4). The residual klystron power after passing through the accelerator structure is absorbed by four high power loads (5).

* Work supported by the U.S. Department of Energy under contract number DE-AC02-76SF00515 and SBIR grant number DE-SC0007661

Three low power RF loads (6) absorb any mismatched (reflected) RF power. 240 such stations were in service of the original SLAC linac.

A high energy physics program (to reach 50 GeV output beam energy) was initiated and completed at the end of 1980 [2]. The original XK-5 klystrons were replaced by 5045 series klystrons with a 50 MW peak (subsequent production improvements the output power reached 65+ MW peak). SLED cavities were also introduced into the RF system thereby increasing the beam energy by a factor 1.7. The present typical RF setup is depicted in Fig. 1 where the new RF components (5045 klystron (7) and the SLED assembly (8)) are shown in right corner. A white arrow shows the location of the upgrade.

The residual power termination performance of the RF loads was not a concern during many years of service. For example, there were not any problems when the linac is used as the PEP-II injector. The RF absorption performance only became an item of concern after analyses of the LCLS RF phase stability issues [3].

It was found that the RF amplitude and phase of the reflected signals are unstable. It was shown also that these RF instabilities are associated with the processes inside of the load vacuum envelope. A detail of the RF structure layout that helps illustrate the high power load problem is shown in Fig.2.

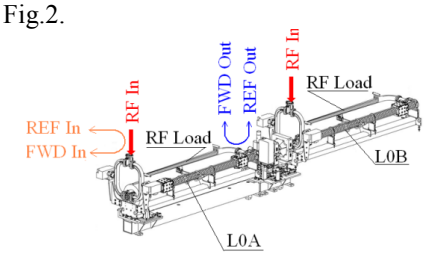

Figure 2: LCLS Injector layout

These two stations are working with detuned SLED cavities. The input and output couplers are employed for the monitoring of forward (FWD In and FWD Out) and reflection (REF In and REF Out) signals. The waveforms of these signals are shown in Fig. 3.

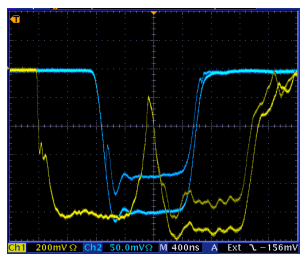

Figure 3: Waveforms of reflection signals

Ch1 (yellow trace) shows the reflection power from the input of the accelerating structure. Ch2 (blue trace) shows the reflection signal from the output of the accelerating

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

structure. One can see that the amplitude of the reflection signal from the input of the accelerating structure (the Ch1 trace) is stable in the beginning of the RF pulse, and after approximately 1600 nsec the amplitude is jumping between two stages. This is clear from the Ch2 trace, which corresponds to the signal from the output coupler on the end of the accelerating structure that has been terminated by the high power RF load.

The result of the activity inside of the RF load is also clearly seen in Fig. 4).

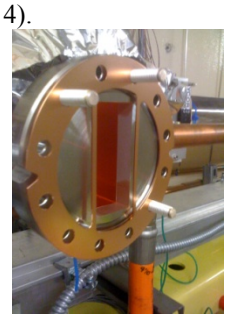

Figure 4: The grey area seen in copper waveguide

When the RF load was disassembled from the accelerating structure, a gray layer on a flange of the output coupler and waveguide wall could be seen. This gray area consisted of deposited particles that were created inside of the high power RF load and transported by a pumping gradient to the end of the accelerating structure. Due to coupler directivity limitation (approx. -25 dB) the RF instability can be seen on the FWD RF signal of many SLAC RF stations. We have no data on the lifetime of the original high power RF loads. Independently we tested dozen available (spare) original RF loads. The instability of the high power RF termination has been identified in all tested loads.

RESULTS OF STUDY

There was unsuccessful attempt to find (in national and world wide) vendors to purchase the needed vacuum load from industry. Two dry load designs were tested. One high power load was designed in BINP (Novosibirsk, Russia) and another S-Band dry load manufacturer was Nihon Koshuha Co. (NKC, Japan). The BINP load design does not meet the "*dry*" SLAC specification (i.e. with water leak proof) because the only brazing layer is the vacuum-water interface. It is not acceptable for 2 mile SLAC linac. The NKC loads cost and acceptance yield are not acceptable for SLAC (we tested five loads and only two were accepted).

SLAC's Designs and Results

The results above required find alternative solution for our linac within SLAC budget limitations. We are now working with a small business company that was granted a Phase I SBIRs to develop new S-Band RF loads for the SLAC linac. This work is being performed under a Cooperative Research and Development Agreement (CRADA) to design and build the RF load based on low conductive materials as a high power RF absorber. According to the CRADA, the high power load design will be performed by SLAC personnel. INTA will be a responsible for the technology and manufacting methodologies. Working together under the DoE SBIR support, the problem of high power RF load could be solved for the next 50 year linac service. A more detail decryption of SLAC RF load design will be published at SLAC.

The following RF load concepts are under consideration by INTA and SLAC:

- RF load design based on SiGraSiC group of composite materials
- RF load based on the bulk Kanthal APMT extruded tubing
- RF load based on the plasma deposition of ferritic FeCrAl alloy

Result of the RF Load Design Based on SiGraSiC Material. This is a rather new family of the carbon-carbon conductive materials and their composites. We contacted HITCO Carbon Composites, Inc. and realized that the manufacturing process allows us to tailor the conductivity based upon the constituents to some extent. Samples of this material was tested in a broadband power range (mW <P< 10 kW) range power. A design of the high power 3dB attenuator with SiGraSiC insertions was made and a prototype of the attenuator has been tested at 8 kW peak RF level. The 3dB prototype attenuator at test stand is shown in Fig. 5. Two black 12 inch insertions at H-planes of WR284 waveguide are made from SiGraSiC blocks.

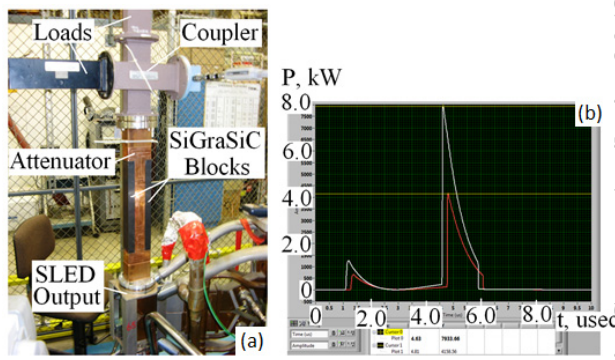

Figure 5: Experimental setup (a) and results (b)

shows input and output waveform of the RF power. White and red traces are the input and transmitted RF power though a device. We did not see any RF absorber degradations at kilowatt power levels. Attenuation rate with a special SiGraSiC shape is approx. 10 dB/m. A load (that possesses 10dB one-way-pass attenuation) will require two SiGraSiC blocks of a 40 inch length each. The technology of vacuum and heat transfer issues is under consideration.

Result of the RF Load Design Based on the Bulk APTM Kanthal Extruded Tubing. The Kanthal material is preferable because of its reasonable low electric conductivity, its stability under high temperature, and its good vacuum properties. Our discussion with experts from Kanthal indicated that a rectangular waveguide from the Kanthal material will require design of special

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

extruded tooling and a significant upgrade in technology. However extruded "cylindrical" tubing made from bulk Kanthal material is readily available. A proposed RF load concept is shown in Fig. 6.

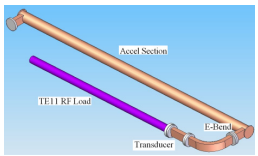

Figure 6: TE11 mode RF load concept

The RF load based on tubing will require a mode converter (transducer) because the RF mode from the output of the accelerating section is TE10 mode. For our experiments, we selected a tube with OD=75mm and wall thickness=4.5 mm because the wave length in this waveguide would be close to the critical wave length. In this case, we would expect a high attenuation of a propagated wave.

We evaluated two types of waveguide transducers. The first one is simply a rectangular-to-round waveguide with a conductive post (see HFSS half of model on Fig. 7a) and a smooth tapering transducer from rectangular-to-round waveguide is shown in Fig. 7 b).

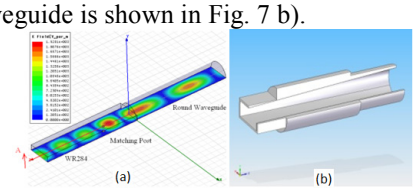

Figure 7: Mode converters with matching post (a) and rectangular-to-round transition (b)

A low level setup for a measurement of RF power attenuation of the APTM Kanthal extruded tube of 6 ft long is shown in Fig 8. We tested this load concept in a broadband power range too.

Figure 8: TE11 mode RF load under low power test

TE11 attenuation measurements of the bulk Kanthal APMT show approximately 2-2.5 dB/m attenuation rate. It is rather low compared to the attenuation rate of the original RF load [1] where a technology of "flame-spayed" Kanthal wire onto a stainless steel base was used. That fact confirms that both (1) a component matrix of absorber and (2) a technology of matrix deposition onto base material are important phases for the RF attenuation rates.

Result of the RF Load Design Based on the Plasma Deposition of Ferritic FeCrAl Alloy. A concept of the TE10 mode RF load can be seen from Fig. 9 where a cross section of modified WR284 waveguide is shown.

Figure 9: TE10 mode RF load concept

The modified WR284 waveguide is formed (extruded) from two identical parts made from aluminium alloy. Two halves are a base for the RF absorber layer. Both H-planes are with four thin vanes. A FeCrAl matrix is plasma sputtered onto the halves. Both coated halves are welded and a waveguide channel is formed. The RF load prototype was designed at SLAC and made by INTA Technologies. The RF load prototype had been conditioned and tested up to 30 MW peak power at SLAC high power test stand. Two power meter waveforms vs. time are shown in Fig. 10. Red and blue traces are forward and transmitted RF power.

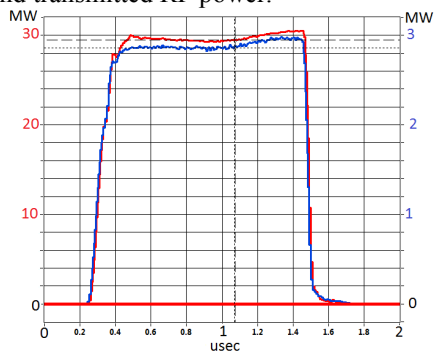

Figure 10: Input (red) and Output (blue) RF power wavforms

One can see that: (1) the RF load prototype runs at 30MW peak and 1 usec pulse width, and (2) one-way-pass attenuation is approx. 10 dB (~5.5 dB/m). No RF power instability was detected. More details of our studies and results will be published in SLAC-PUB-preprint.

CONCLUSION

There are indications that the present SLAC RF loads are near the end of their lifetime. SLAC and INTA Technology haves studied several alternatives for solving the RF load problem. The most promising results were obtained with the plasma deposition of ferritic FeCrAl alloy onto modified rectangular waveguide with vanes on H-planes. The technology achieved a 5.5 dB/m attenuation rate at 30 MW peak power and 1 usec pulse width with no evidence of breakdown activity in the vacuum envelope on the coated surfaces. We proposed a design and technology recommended for manufacture of a pilot series of the high power loads for the SLAC linac.

ACKNOWLEDGMENT

We thank Mr. R. Sviben and Mr. S. Schatz (Kanthal, SANDVIK) and Mrs. R. Hines (SiGraSiC, HITCO) for useful discussions.

FABRICATION TESTS FOR IMP 162.5 MHz RFQ*

Bin Zhang, Yuan He, Xiaofeng Jin, Jing Wang, Junhui Zhang, Aiming Shi, Xiaonan Du,
Zhouli Zhang, IMP, CAS, China
Derun Li, Matthew, D. Hoff, Steve Vireostek, Andrew Lambert, LBNL, USA

Abstract

The RFQ for one of front ends of C-ADS is designed. The frequency of the RFQ is 162.5 MHz and the energy is 2.1 MeV. The beam intensity is 15 mA and it works at CW mode. Because of low frequency, the four-wing structure is big size. It makes fabrication will take more risks. Therefore, four fabrication tests were planned and done to minimize the technic risks. The description about fabrication and testing results are presented .

STRUCTURE DESIGN

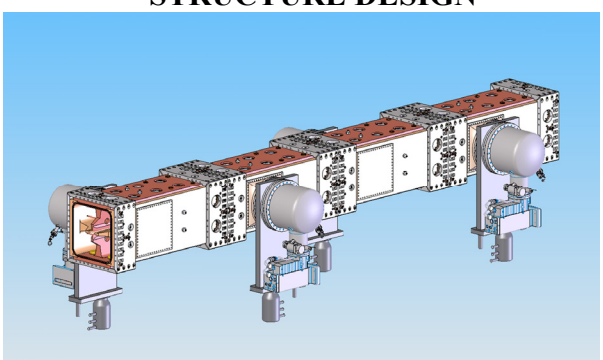

Figure 1: Structure of the ADS-Linac RFQ

Four 1.05 m long cavity modules were bolted together with a total length of 4.20 m, approximately 1000 kg for each complete module. All OFHC copper body were machined from solid billets, 4-vane cavity structure be choose with fly cut modulated vane tips. In this structure it includes 32 Pi-mode rods for mode stabilization, 20 fixed slug tuners/module 12 field sensing loops were designed per module. RF power feed through two loop couplers. 20 cooling channels per module will take the heat of RF power.

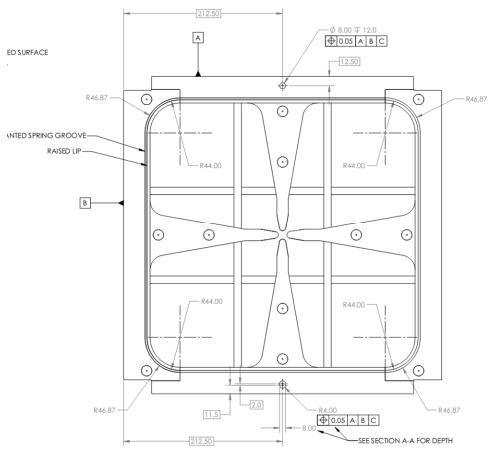

Figure 2: Section of RFQ

FABRICATION TESTS

Since the RFQ work in a low frequency, the four-wing structure is big size (425mm×425mm at section), four fabrication tests were planned and done to ensure fabricated process and minimize technic risks. It include fly cutting test, full length vane test, braze and clamp test and half-length test module. Two of them had finished the last one were rough machining now, as for hydrogen braze test, more tests were necessary before the last braze to take.

Flying cutting test

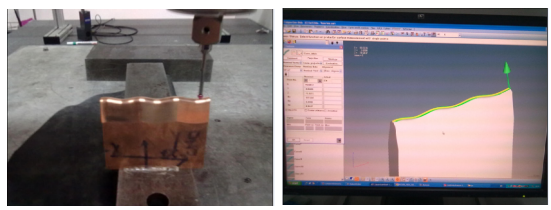

Figure 2: measurement vane

Flying cutting method were choice for RFQ modulation machined instead of ball drill. Two short pieces were cut and measurement with CMM. the result of measurement shows some point were out of tolerance ,some improvement with cutting tool will be take and the pieces will be measurement again in new CMM device.

Table 1: result of modulation measurement

	Max (mm)	Min(mm)
Profile tolerance	+0.0067	-0.0070
Section 1	+0.0056	-0.0097
Section 5	+0.0103	-0.0185
Section9	+0.0431	-0.0856
Radius of tip	8.5685	8.5315
Angle	19.9332	19.5164

Full length vane fabricated test

Full length of a single vane is about 1050mm, include all mechanic structure of RFQ, such as braze groove, cooling water deep hole, modulation of vane, vacuum seal groove etc. Main task were focused on the Gun-drill for deep hole, EBW for water plunger and the tolerance for vane pale. So far, it had been finished and all ports, holes and outside surface geometry tolerance will be checked by CMM this month.

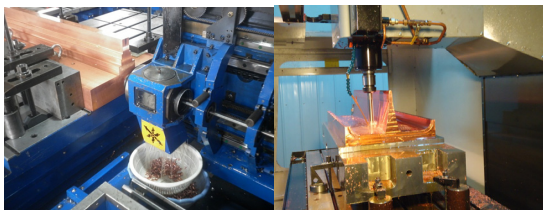

Figure 3: process of fabrication

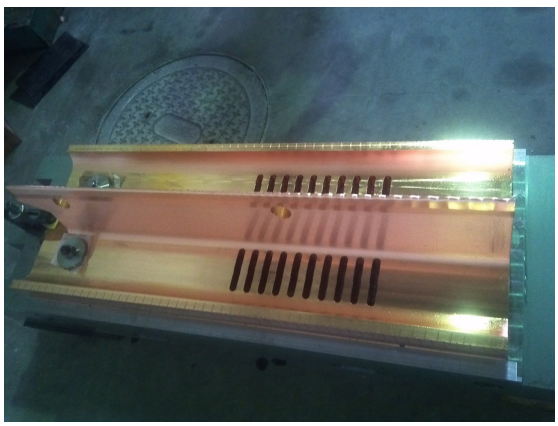

Figure 4: Single vane in full length

Braze and clamp test

Braze alloy is Ag-Cu28, and braze temperature is 790°C. Two braze test were carried out separately in hydrogen furnace and vacuum oven. The result shows braze in hydrogen has advantage attemperature uniformity. After checking with CMM the deformation of short braze pieces , nearly 0.8mm deformationwere be found. 3D ANSYS calculated were taken and it shows the same deformation trend. The reason is that OFC will get very soft at high temperature while braze clamp (SS) still keep intensity. Improved braze clamp had been redesign, and next test will be carry out later.

Figure 5: Short part were brazed in furnace

Half-length test module

The half-length module were rough machining now, however, fine machining will wait until braze test be finished.

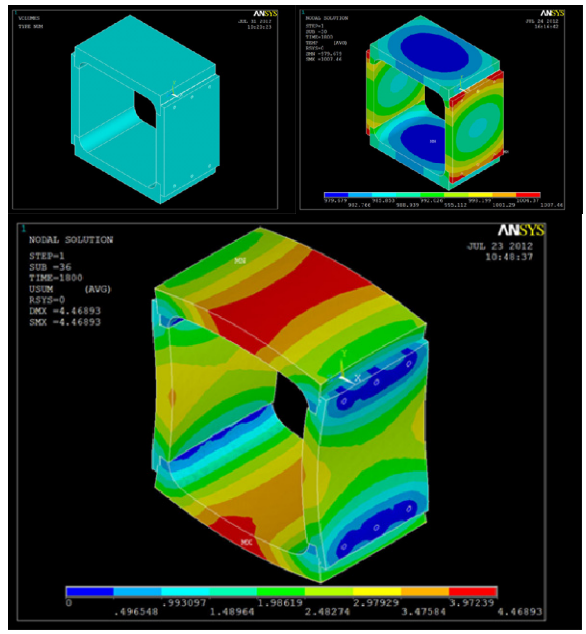

Figure 6 Deformation during brazing

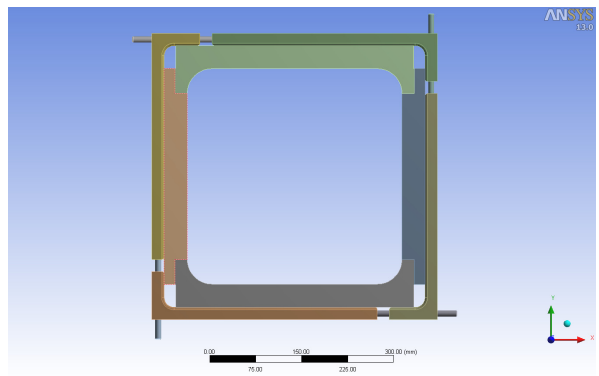

Figure 7 New structure of braze clamp

CONCLUSION

There are benefits in starting fabrication tests in parallel to the planned short module.

Gun drill (in addition to vane cutting test)

EB welding for the cooling channel

Inter-module assembly technique

Development of brazing for large copper components is critical.

Tooling and assembly procedures need to be discussed.

AKNOWLEDGEMENTS

We would like thank Xiaoqi Zhang and Guoping Sun (KTTJ)for their fruitful collaboration on the mechanic design and machining.

Abstract

Thomson scattering X-ray source, in which the TW laser pulse is scattered by the relativistic electron beam, can provide ultra short, monochromatic, high flux, tunable polarized hard X-ray pulse which is can widely used in physical, chemical and biological process research, ultra-fast phase contrast imaging, and so on. Since the pulse duration of X-ray is as short as picosecond and the flux in one pulse is high, it is difficult to measure the x-ray spectrum with traditional spectra measurement methods. In this paper, we introduce an iterative statistical algorithm (Expectation-Maximization) to reconstruct the spectra from the attenuation data, and the results of the X-ray spectrum measurement experiment on Tsinghua Thomson scattering is also presented.

INTRODUCTION

Thomson Scattering sources (also called Inverse Compton Scattering), which can be bright X-ray sources typically produce photons, have attracted a lot of interest as the technologies for producing low-emittance high-brightness relativistic electron sources and ultra-short high-power lasers have progressed. The X-rays that are generated by the interactions between laser and electron, exhibit high directivity, and have a polarized tunable quasi-monochromatic spectrum. The knowledge of the spectrum of an X-ray source is a key point for the development of any kind of application, for example in imaging both contrast and absorbed dose strongly depend on energy. However, direct methods performing a standard spectrometric measurement based on single photon energy measurement to detect the X-ray spectrum of Thomson Scattering sources have always been considered troublesome to implement because the beam is too intense to cause pulse pile up problems. Thomson Scattering source can produce up to 10^8 photons, bunched in 10ps long pulse [1]. An alternative way to measure the spectrum might request the measurement to be integral-type, which will not be affected by the high rate of incidence of photons. The analysis of attenuation data (transmission curves), which can provide some information about the spectral distribution of an X-ray source, as not affected by the rate of incidence of photons, is a good candidate to measure the X-ray spectrum of the Thomson Scattering X-ray source. Although there are several problems with this method, such as low accuracy, non-unique solution to ill-condition system and instability with different measurement error [2], this method can still give good estimation and reconstruction of spectra with some improvements based on the property of the measured spectra.

In this article, we introduce an iterative statistical algorithm (Expectation-Maximization) [3] to reconstruct the spectra from the attenuation data on simulated measurement. Results show that this method can give good approximations for the mean energy of the spectra, while it is not sensitive to the specific spectral distribution and the energy broadening. In order to reconstruct the shape of the spectra, especially the energy broadening, we present a new method based on the Expectation-Maximization algorithm. An preliminary experiment is also carried out on Tsinghua Thomson scattering X-ray source, the measured maximum X-ray energy is about 53keV, which is agreed well with the simulations.

OVERVIEW OF TTX

The scheme of TTX is shown in figure 1. This machine includes a 50MeV electron linac based on the photocathode RF gun and a Ti: Sapphire TW laser system. The laser system generates both the 266nm UV pulse for photocathode and the 800nm IR pulse for scattering interaction. The two pulses are derived from one 79.3MHz Ti:Sapphire oscillator in order to reduce the time jitter between the electron beam and the IR pulse. The linac system consists of a BNL/KEK/SHI type 1.6 cell S-band photocathode RF gun, a 3m S-band SLAC type travelling wave accelerating section, generates 40~50MeV ultra-short high brightness electron pulse for scattering interaction. The laser system is synchronized with the RF system through a timing circuit, with a timing jitter no greater than 0.5ps. The parameters of electron and laser were listed in the table 1.

In previous experiment, we succeed to generate and detect the X-ray signal with head-on colliding mode. The results from the MCP and X-ray CCD are shown in figure 2.

LOCAL ENERGY SPECTRUM MEASUREMENT

X-Ray Spectrum Measurement from the Analysis of Attenuation Data

The relative transmission function $T(x)$ responding to an attenuator of thickness x is related with the spectrum of an X-ray beam in the following way[1]:

$$T(x)=\frac{S(x)}{S(0)}=\int_0^{E_{\max}} e^{-\mu(E)x}F(E)dE \qquad (1)$$

where $S(x)$ is the signal measured with an absorber of thickness x, and $S(0)$ is the signal measured without any absorber. $\mu(E)$ is the total attenuation coefficient of the attenuator in which are included both photoelectric and Compton effects for photons of energy E. $F(E)=\phi(E)\bullet C(E)$, where $\phi(E)$ represent the spectrum distribution of photons and $C(E)$ represent the energy response determined by the way to measure the signal $S(x)$. $E_{\max}$ is the maximum energy of the spectrum.

When we treat the problem from its numerical point of view by discretizing the integral, the Eq.(1) turns out a linear system of the form

$$T=A\bullet F \qquad (2)$$

where $T\in R^M$ represent the attenuation curve as a function of the attenuator and $F\in R^N$ is the discretized spectrum. Generally, the linear system described by Eq.(1) translates, after the disctretization, into an ill-conditioning linear system in Eq.(2). Here the Expectation-Maximization (EM) algorithm is used to obtain an approximation to the exact solution of the system Eq.(2)[2]. Expectation -Maximization algorithm is an iterative statistical algorithm with the form [3][4]:

$$F_n^{(k+1)}=F_n^{(k)}f_n,\quad f_n=\frac{\sum_m A_{nm}{}^t\dfrac{T_m}{\sum_{n'}A_{mn'}F_{n'}^{(k)}}}{\sum_m A_{nm}{}^t} \qquad (3)$$

Numerical Simulation

A Monte Carlo numerical simulation experiment is carried out to verify the method first. During the simulation process, Monte Carlo method is used to simulate the Thomson Scattering and calculate the attenuation curve through silicon with different thickness to justify the reliability and feasibility of this method. Figure 3 shows the results for the reconstruction of local spectra for different two points in the X-ray spot.

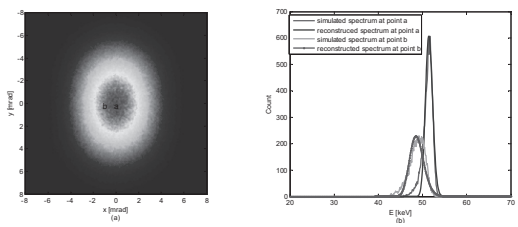

Figure 3: (a) X-ray profile simulated by CAIN and the two points selected to reconstruct local spectra. (b) Simulated and reconstructed spectra at two different points with 0.5 mrad collecting angles and 5% Gaussian random error.

It can be observed that the EM method performs well to reconstruct the local spectra of Thomson Scattering source. However, as the collecting angles increase, the X-ray spectra are not close to Gaussian distribution any more. To solve this problem, we propose an assumption that according to the spectral distribution features of Thomson Scattering, as the collecting angles increase, the right half of spectra remains almost unchanged. So we

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

can treat the right-half spectra of the small collecting angles given by EM algorithm as the right half for spectra of other angles within a certain range. Then we can reconstruct the spectra with the attenuation data more accurately as under this assumption, the mean energy will have direct and close relationship with the shape of spectra. Fig.4 shows the reconstruction result (top) and the simulation result (bottom) for Thomson Scattering spectra within the collecting angle range from 0.5mrad to 5mrad.

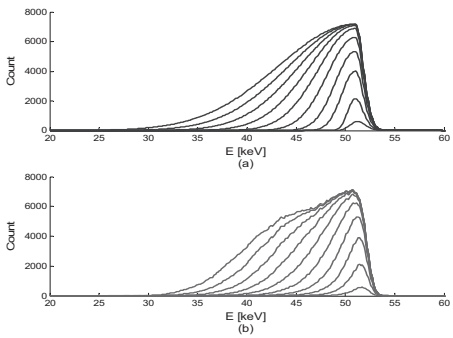

Figure 4: (a): Representative reconstruction results of spectra for collecting angles ranging from 0.5 mrad to 5 mrad with an equal interval of 0.5 mrad (b): The simulated spectra for the Thomson Scattering source with collecting angles of the same range with CAIN.

Experiment Results

A preliminary experiment is carried out on TTX to measure the X-ray spectrum. The scheme of the experiment is shown in figure 5. The silicon wafers with different thickness are used as attenuator, a CsI screen and CCD camera are used as the X-ray intensity monitor.

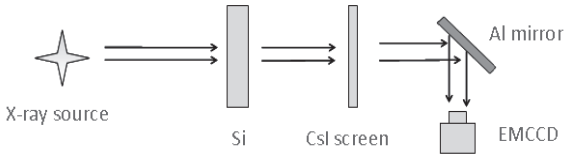

Figure 5: The scheme of the X-ray spectrum measurement.

The typical X-ray profile with attenuators is shown in figure 6. The sheltered part is used to obtain the attenuation curve and the unsheltered part is used to X-ray intensity normalization to cancel the jitter influence. The attenuation curves for point a, b, and c, the reconstructed X-ray spectrum from the attenuation curves are also shown in figure 6. The maximum X-ray energy at the center of profile is 53keV, which is agreed well with the theory expectation and simulations.

In Thomson scattering X-ray source, the X-ray energy is a function of scattered angle. In figure 7, the mean energy of the X-ray as a function of scattered angle is shown and compared with the theory and simulation expectations. The measured results are a little different to the theory curve but agreed well with the simulation results, since in theory curve the emittance effect of the electron beam is not included.

Reconstruction spectra results from measured attenuation for collecting angles ranging from 0.5mrad to 5mrad with an equal interval of 0.5mrad are shown in figure 8:The deposition efficiency of CsI screen is considered.

Abstract

A Technology Demonstration Cryomodule (TDCM) has been developed for a systems test of technology being developed for FRIB. The TDCM consists of two half wave resonators (HWRs) which have been designed for an optimum velocity of beta=v/c=0.53 and a resonant frequency of 322 MHz. The resonators operate at 2 K. A superconducting 9T solenoid is placed in close proximity to one of the installed HWRs. The 9T solenoid operates at 4 K. A complete systems test of the cavities, magnets, and all ancillary components is presented in this paper.

INTRODUCTION

The SRF Department at Michigan State University had developed and tested four cryomodules prior to the first demonstration cryomodule for FRIB. Two of the cryomodules are working reliably in the ReA3 linac at MSU [1]. The TDCM, shown in figure 1, is the first cryomodule that demonstrates FRIB specific technology and encourages a transition to large scale engineering and quality assurance methods [2].

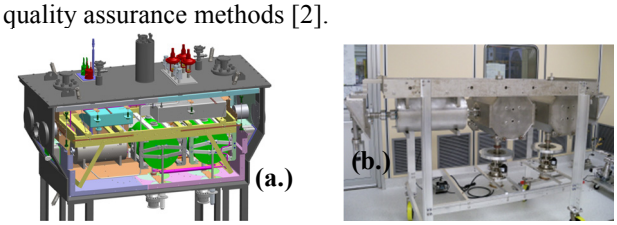

Figure 1: (a.) Rendering of TDCM in cryostat (b.) Cold mass assembly in cleanroom.

In developing the FRIB TDCM, a baseline cryomodule production method evolved for FRIB. The technical and schedule related setbacks encountered during the TDCM campaign eventually yielded reliable fabrication, processing, and certification techniques. SRF-related infrastructure and utility usage required for the TDCM assisted in finalizing planning for a new SRF high bay which will support FRIB cavity processing, vertical testing, cold mass assembly, and cryomodule bunker tests.

TDCM RELEVANCE TO FRIB

The TDCM is a developmental snapshot, and much of the technology improved as more detailed engineering analysis and sub component testing programs provided opportunities for design optimization [3- 5]. Some of the key differences are: a "bottom-up" style from the "top-down" TDCM style [4]; the rail system, support system, heat and magnetic shields assemblies were simplified; Improvements to alignment methods; an internal heat exchanger replaces the external heat exchanger; the 4K thermal intercepts will be parallel circuits as opposed the series connection in the TDCM.

With much of the cryogenic circuitry and alignment systems optimized in the baseline design before TDCM testing took place, alignment and continuous 2K operation aspects were not tested. The plumbing of the RF coupler 4K intercepts [6] required steady flow in the static state required continuous overfilling of the 4K header to ensure the couplers stayed cooled during RF conditioning.

TDCM DEVELOPMENT

Individual tests or more detailed engineering analyses conducted on the cavities, couplers, tuners, and cryogenic circuits used in the TDCM led to design optimizations and improved processing [7- 9].

Initial dunk tests showed low field emission onset values and thermal breakdown below the operating gradient; FRIB processing optimization for the HWR began during the TDCM campaign. The TDCM cavities were field emission-free [10] prior to the installation of the helium vessels.

Initial tests still showed signs of multipacting in the cavity. Repeated measurements on several cavities show a recurring barrier at 2 MV/m E_{acc}. This barrier self-conditioned as the RF power was raised, and in most tests only observed during initial 4K measurements.

During the initial dunk tests, it was discovered Q_0 was lower after a thermal cycle with no change otherwise. A closer investigation for Q-disease showed a strong reduction in the Q_0 after a 15 hour soak at 100K. The cavities were sent to JLAB for a furnace treatment to remove hydrogen from the bulk. Subsequent 'Q-soaks' and thermal cycles showed no signs of degradation. A 600°C furnace treatment was added to the baseline processing plan and a furnace has been installed at MSU [9].

After being jacketed with a helium vessel, the 1st cavity was certified using the vertical cryostat configuration [5], and no field emission was observed. This helium vessel design utilized a titanium bellows at the beamport to reduce the tuning force required for the scissor-jack tuner.

*This material is based upon work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661.
#popielar@frib.msu.edu

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

After this cavity had been installed on the TDCM cold mass, the next jacketed cavity developed a large leak from the helium to insulating space found at the titanium bellows. The bellows were removed from the already certified cavity, requiring additional machining and welding.

TDCM TESTING

RF Amplitude and Phase Control

The resonators in the FRIB linac will operate with a very narrow BW for amplitude and phase control. For the HWR, the 30 Hz RF bandwidth available for control presents a technical challenge and increasing the RF BW has a very large impact on cost. The low level RF controller was developed at MSU and employs an ADRC algorithm [11] which is required to ensure a dynamic stability within 2% (peak-to-peak) amplitude and 2 degrees (peak-to-peak) phase. The resonators do not have fast tuning implemented to cancel microphonics. Measurements were done using a fast (1.6 kHz) data acquisition of the RF signals. The results are shown in figure 2, where the measured cavity and amplitude stability is within the limits of the measurement uncertainty. During the measurements, the cavity field was kept just below a multipacting barrier in the cavity and with the slow tuning feedback to the scissor-jack mechanical tuner turned off.

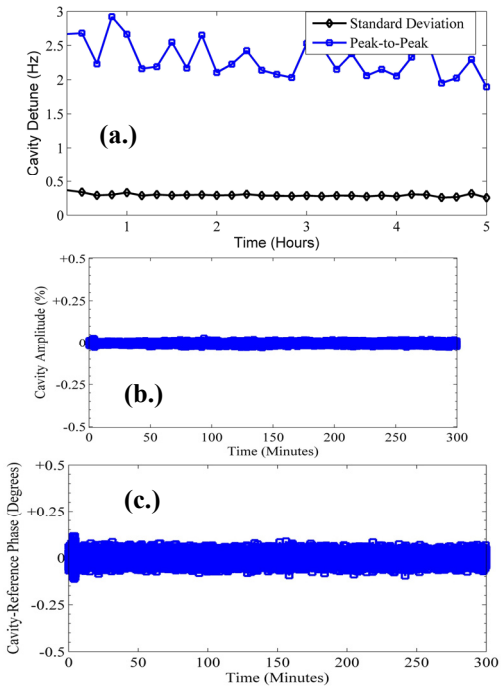

Figure 2: (a) Closed loop detuning, calculated from the forward phase changes while regulating with the cavity amplitude and phase (b, c) well within the design specification.

The 'cavity detune' (Δf) in Figure 2a is inferred from the changes in the forward phase ($\Delta\varphi_f$) and is calculated from $\Delta f = BW \times \Delta\varphi_f$. The closed loop detune inferred from the measurement agreed well with some shorter duration open loop measurements done a 2K. A slow drift of 8 Hz over five hours was measured, justifying the necessity of a slow tuner. During this measurement, the bath pressure was well regulated (less than 0.7 Torr peak-to-peak).

The next round of measurements was performed using the feedback to the slow tuner. The measured amplitude and phase stability was higher (1.4%, 0.6°, peak-to-peak), but still within the FRIB specification. It was noticed that the tuner drive was constantly moving, which created a mechanical oscillation at 110 Hz, causing a closed loop detune of 24 Hz peak-to-peak.

RF Couplers

The RF couplers had been conditioned for multipacting barriers prior to the installation into the cold mass [6]. The multipacting that was conditioned had returned after installation to and cooling of the TDCM, with similar onset levels. Coupler conditioning did not completely remove the multipacting from the coupler above 2 kW after 10 hours of RF pulses. The multipacting was suppressed by applying an external magnetic field through a coil winding around the coupler. Figure 3 shows a plot the current on the probe near the ceramic disk; 6.8 kW peak power was achieved with 4.5 kW average forward power while driving 1 MHz off-resonance. A detailed multipacting analysis [12] shows that the location of the two-point multipacting in the coaxial line depends strongly on the boundary condition at the cavity port. With the rf system 'detuned' from the cavity, the boundary condition at the coupler port is that of a short circuit, and a single two-point multipacting node exists at the voltage peak, which is approximately half way between the coupler port and the ceramic disk. However, when driving the cavity on resonance, two voltage peaks exist on the transmission line. The magnetic field suppression did not suppress the multipacting when locked to the cavity resonance.

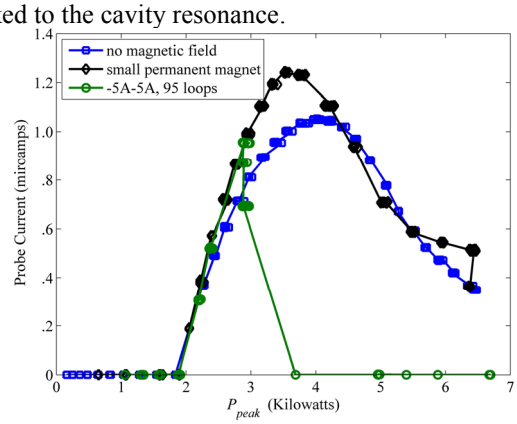

Figure 3: Multipacting suppression in the FPC while driving from the cavity off-resonance.

Tuners

The bellows used to reduce the force required to tune the cavity was replaced with a rigid connection to the helium vessel. A measurement of the tuning ratio of

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

360:1 greatly exceeds the expected 8:1 ratio showing that the scissor-jack mechanism was not performing as expected. This resulted in a reduced tuning sensitivity of the actuator controller (from 1.8 Hz/step to 0.03 Hz/step), which may explain the mechanical effects on the performance of the LLRF with the tuner engaged. Additional testing will be performed on an alternate tuning concept which utilizes a pneumatic drive.

Cryostat

Static load measurements on the TDCM cryostat were performed by recording liquid level as a function of time using the level sensor to infer the evaporation rate. This rate was calibrated by using a gas meter to measure the mass flow of the helium gas at room temperature. The mass flow measurement and nominal liquid volume boil-off from the header dimensions had roughly good agreement. Neither the level vs time nor the gas meter methods were calibrated with a known heat source. An evaporation rate of 2.85 W to the 2K header and 4.0 Watts to the 4K header was measured and repeated four times, with a spread of 0.22 W peak to peak.

Cavity Dynamic Load

The cavity dynamic loads, measured the same as the static load measurements described above, could not be accurately measured below the multipacting barriers (1.67 MV/m E_{acc}), since the resolution of this type of measurement is ~0.5 W. This resolution exceeds the heat load measured in the last Dewar test (0.10 Watts at 1.67 MV/m). With helium processing, a reasonable field level (4 MV/m) was reached. The dynamic load of 1.5W @ 4 MV/m yields a Q_0 of 1.2E10. This measurement was done in the last hours of the TDCM test. The load from the RF coupler at this field (850W forward power) was negligible considering a load measurement done with 4.5 kW forward power off resonance was less than the measurement resolution.

Magnets & Magnetic Field Interactions

The Earth's magnetic field is shielded from the cavities with a global mu-metal shield. Measurements on the shield showed an attenuation factor of at least 25 was achieved; however accurate measurements of the residual magnetic fields with the cold mass installed were not performed. Prior to energizing the magnets, the low field Q_0 (@1.67 MV/m) showed the possibility of high residual magnetic fields trapping fluxes up to 200 mG, but the Q drop at this field could also be explained as either measurement error or multipacting.

The 9T solenoid has a fringe field such that the flux at the nearest cavity surface is 250 Gauss. The revised FRIB specification for this fringe-field is 650 Gauss. The magnet was powered to full field; the cavities were warmed up to 30 K, and then re-cooled. The dynamic loads were measured again at 2K. The difference in the dynamic loads was less than the 0.5 W measurement resolution. A magnetic field cancellation procedure was performed by varying the power supply current, I, in a decreasing and alternating manner, e.g. a series, $\{(-0.9)^n I\}_{n=0}^{40}$ which took 5 hours to complete. The dynamic load measurement performed after this degaussing and further RF conditioning yielded a quality factor close to that measured in the vertical test.

TDCM Outlook and Future Tests

The TDCM test ended abruptly after taking only limited dynamic load data due to an unexpected cryoplant failure. A suspected helium leak in the transfer line that supplied the TDCM required mass flow rates of 3-5 g/s to maintain level in the liquid helium levels, though static load measurements indicate only 0.5 g/s is required. Therefore, running the TDCM test in parallel to NSCL experimental programs in impossible due to the unavailability of this LHe supply rate.

Though the TDCM completed a successful first round of testing in mid-2012, additional testing will be done by end of 2012. The next round of testing will focus primarily on the high power RF conditioning that commenced in the later stages of the TDCM measurements.

A new transfer line is being procured and installed to supply the TDCM from a refrigerator that is separate from the NSCL experimental program. While the transfer line is being built, the cryostat is being opened up to make some adjustments. Magnetic material found on the internal scissor jack tuning mechanisms is being removed. The RF couplers are undergoing an in-situ bake (~100-120C, 72 hours) in an effort to reduce the multipacting intensity. Additional measurement equipment will be installed to determine the dynamic load of the couplers to the intercepts and the remnant fields from the 9T solenoid before and after degaussing steps.

ACKNOWLEDGMENTS

The authors would like to thank Greg Velianoff, Jon Wlodarczak, Tom Russo, John Brandon, Mike Holcomb, and Jie Wei for their help in late night and evening shifts during RF conditioning; JLab for degassing the HWR's installed in the TDCM; Peter Kneisel, Curtis Crawford, and Bob Laxdal for their advice given regularly in weekly teleconference.

THE INJECTOR CRYOMODULE FOR THE ARIEL E-LINAC AT TRIUMF

R.E. Laxdal, N. Muller, A. Koveshnikov, W.R. Rawnsley, G. Stanford, V. Zvyagintsev
TRIUMF, Vancouver, Canada
M. Ahammed, M. Mondrel, VECC, Kolkata, India

Abstract

The ARIEL project at TRIUMF includes a 50 MeV-10 mA electron linear accelerator (e-Linac) using 1.3 GHz superconducting technology. The accelerator is divided into three cryomodules including a single cavity injector cryomodule (ICM) and two accelerating cryomodules with two cavities each. The ICM is being built first. The ICM utilizes a unique top-loading box vacuum vessel. The shape readily allows the addition of a 4K/2K cryogenic unit that accepts near atmospheric LHe and converts to 2K liquid inside the cryomodule. The cryomodule design is complete and in fabrication. The 4K/2K cryogenic unit has been assembled with tests scheduled next month. The paper describes the design and status of the cryomodule.

INTRODUCTION

TRIUMF is now preparing a new high intensity superconducting electron linear accelerator[1], e-Linac, as a key element of the ARIEL project. The e-Linac is specified to produce 10mA of 50MeV electrons as a powerful 0.5MW photo-fission driver to add a complimentary second source of radioactive ion beams for the existing ISAC experimental infrastructure. The e-Linac consists of five 1.3GHz nine-cell niobium cavities each supplying 10MV acceleration with two 50kW power couplers supplying the required beam loaded rf power. The five cavities are housed in three cryomodules, with a single cavity in an injector cryomodule, EINJ, and two identical accelerating cryomodules EAC1 and EAC2 with two cavities in each module. The fully funded first phase of the e-Linac includes the first two cryomodules for a final energy and intensity of 30MeV and 5mA for 150kW driver capability by 2014. The EINJ is presently being fabricated and will serve as the working prototype for EAC1.

TRIUMF began developing EINJ in 2010 in collaboration with the VECC laboratory in Kolkata. VECC requires a photo-fission driver for the proposed ANURIB[2] facility. TRIUMF and VECC have an agreement to jointly design the EINJ cryomodule. Two EINJs are being fabricated and beam tested at TRIUMF with one EINJ being shipped to VECC and the second installed in the e-Linac. The initial EINJ is presently in fabrication. A beam test area is being installed in the ISAC-II building to utilize the existing cryogenics infrastructure with beam tests scheduled for early 2013.

CONCEPTUAL DESIGN

Cryomodules for 1.3GHz elliptical cavities utilize typically round vacuum chambers with end loaded cold mass assemblies. In applications such as X-FEL involving long linac structures the gas return pipe in the cryomodule acts as both the support strongback for the cold mass and the helium cold return distribution line for the overall cryogenic system. Operation is at 2K with the 2K produced either in a central 2K cold box or in a JT expansion valve close to the cryomodule that transforms a typical 3 bar stream from a 4K cold box to He-II. Heavy ion linacs such as the ISAC-II 40MV linac[3] operate at 4K due to typically lower rf frequencies and hence lower BCS resistance and are typically designed as box cryomodules with the cold mass loaded from above due to the large transverse size of the low frequency low beta cavities.

Although non-standard a top-loading box design (Fig. 1) has some advantages for the e-Linac over an end-loading round variant. Firstly the modular and staged testing/installation sequence of the e-Linac suggests that each cryomodule be self-reliant to convert 4K atmospheric LHe available from dewars or ISAC-II cryogenic system into 2K He-II. To this end the box

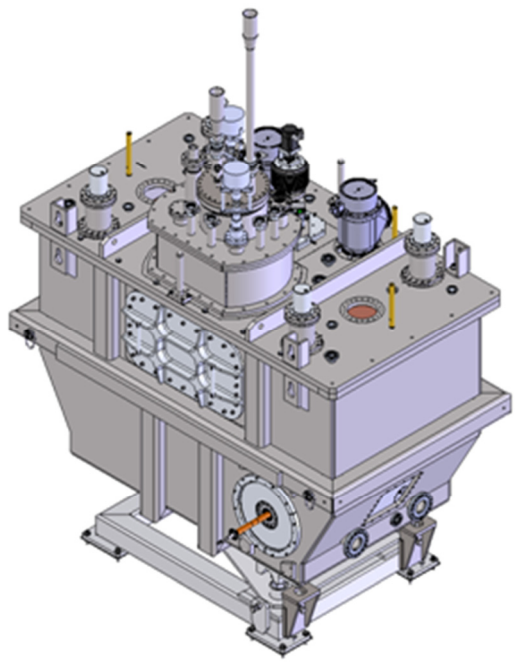

Figure 1: Model of the e-Linac Injector cryomodule.

cryomodule design has sufficient head room that makes possible the addition of a dedicated 4K/2K cryo-insert on each module. Secondly, incorporating features of the ISAC-II design reduces the engineering design effort within TRIUMF and takes best advantage of the existing infrastructure for assembly and test.

The basic concept of the e-Linac cryogenic system[4] replicates the ISAC-II system. A 4K cold box produces 4K liquid at 1.3Bar to a supply dewar that feeds LHe to a common delivery trunk with parallel 4K feed to each cryomodule. A 4K reservoir on board each cryomodule acts as phase separator and the 4K return vapor is sent back to the cold box. The 2K liquid is produced in each cryomodule by passing the 4K liquid through a heat exchanger in counterflow with the returning exhaust gas from the 2K phase separator and expanding the gas to 30 mbar through a JT expansion valve. The header pipe above the cavity string acts as a 2K phase separator and delivers cold gas back through the 4K/2K heat exchanger to the sub-atmospheric pumping system as a liquid load. A second on-board cryovalve delivers helium from the 4K phase separator to the bottom of the cavity string during cooldown. A siphon circuit from the 4K reservoir is used to cool the 4K temperature intercepts with vapour return back to the reservoir.

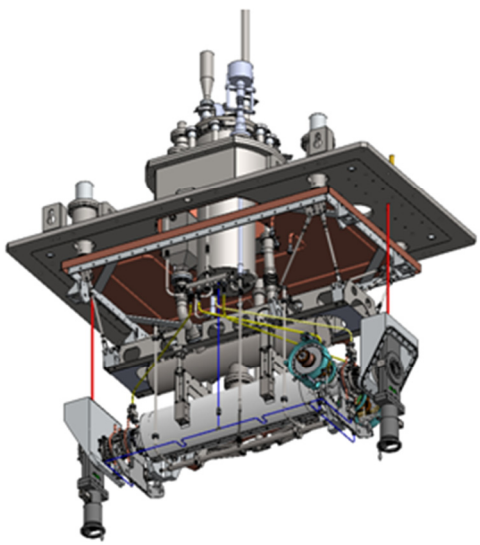

Figure 2: Top plate and cold mass assembly for EINJ.

DETAIL DESIGN

Vacuum Vessel

The vacuum vessel is a stainless steel vessel in a rectangular box shape with additional ribs welded on to strengthen against the vacuum load (Fig. 1). A warm layer of 1mm mu-metal sheet is placed in the vacuum space anchored to the vacuum vessel. The entrance and exit beam tube regions are angled to allow the installation of the cold mass as a hermetically sealed unit with warm isolation valves at either end.

The cold mass is supported from the top plate with the following minor exceptions. The beam pipe is connected at the warm isolation valve to the end flange. In addition each cavity is fed rf power through two couplers mounted horizontally and symmetrically opposed at the `coupler end' of the cavity. The cold part of the coupler is assembled with the cavity as part of the hermetically sealed unit. After the top assembly has been inserted into the cryomodule the warm end is assembled to the cold end through cutouts in the side of the cryomodule. Two Cornell/CPI 50 kW couplers will be used to feed rf power to each of the 9-cell cavities. The power couplers are on the downstream end to reduce coupler kicks. There are also flanges adjacent to the beam tubes for off-axis wire position monitors (WPM)[5] for alignment purposes. The top plate has a cut out opening to allow independent installation and removal of the cryo-insert (see below). In addition a side panel cut-out allows access to the cryo-insert connections to allow removal of the cryo-insert without pulling the cold mass.

Strongback and Cold Mass

The stainless steel strongback supports the cold-mass and forms a rigid assembly unit (Fig. 2). The cold-mass includes the cavity hermetic unit, cold mu-metal, tuner, 2K phase separator, lower cooldown supply pipe, and diagnostics. The strongback is supported from the top flange of the cryostat through struts. The support struts are equipped with spherical rod ends to avoid any mechanical stresses that may develop during thermal cycling. The hermetic unit consists of the niobium cavity and titanium helium jacket, the cold end of the power couplers, the warm-cold beam-pipe transition including HOM dampers, the cavity rf pick-up and isolation valves. The strongback and struts will thermally contract during cooldown though the reduced length of the module limits this to <4 mm. The vertical contraction does not affect the alignment since this can be compensated for during the initial set-up using the WPM and optical measurements and is repeatable.

4K / 2K Cryo-Insert

The 4K/2K cryo-insert is being built and tested as a separate package. The geometry of the cryogenic unit is chosen to be compatible with pre-testing in an existing cryostat. The insert, shown schematically in Fig. 3, includes a 4K phase separator, 4K/2K heat exchanger, JT expansion valve, 4K cooldown valve, LN2 cooled thermal shield, warm mu-metal layer plus siphon circuit for intercept cooling. The prototype heat exchanger is fabricated by DATE with an estimated capacity of 2.5 gm/sec. A dummy 2K phase separator and three dummy thermal intercept loads are added to the test unit. These are removed during installation to the cryomodules and replaced with the 2K phase separator and actual thermal intercept loads.

The 4K/2K test unit is assembled and tests are imminent. Tests will include (1) static load measurements (2) 2K production efficiency (3) thermal siphon circuit cooling capacity (4) cooldown procedure and (5) cryogenic diagnostics operation.

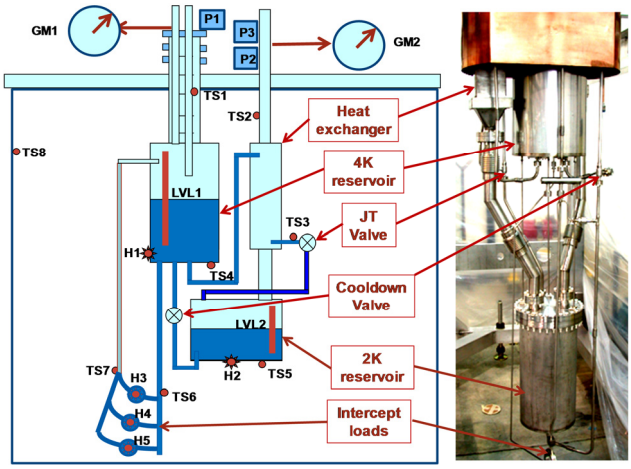

Figure 3: 4K/2K test unit with schematic and test diagnostics including temperature sensors (TS), variable heaters (H), gas meters (GM), pressure sensors (P) and level probes (LVL) and the actual unit as assembled prior to first cold test.

Alignment

A cavity alignment of ±0.5mm is specified. The alignment is done using a combination of Wire Position Monitor (WPM)[5] sensors and optical targets. Before final treatment of the cavity a WPM bracket is attached to the upstream and downstream cavity beam tube. The WPM holders on the bracket are indexed to the cavity center using beam tube reference targets. Each bracket is equipped with two WPM holders one right and one left of the beam center and two optical targets. The cavity is assembled in the clean room to form a hermetically sealed unit then assembled into the cold mass and supported from the lid resting on an assembly frame with for and aft features replicating the beam port and WPM and optical target positions. After the cold mass is inserted into the tank the support towers are adjusted using WPM and optical targets as reference to bring the cold mass on line. Later after cooldown and full thermalization the support towers are re-adjusted to final position.

Developments

Power coupler assembly mock-up: The alignment strategy requires that the cold mass be allowed to move during warm-up and cooldown without undo stress on components. Specifically the power couplers and warm-cold transition sections need sufficient flexibility. The coupler is flexibible through transition bellows and an internal universal coupling. An exoskeleton gymbal has been designed to allow the warm and cold end of the coupler to move while maintaining the concentricity of the inner to outer conductor and reduce stress build-up in the coupler windows. This gimbal was tested in a mock-up of the cavity and tank wall geometry. The mock-up is also useful to help establish the jigs and fixtures required to intall the warm- end of the coupler through the outer side wall.

Scissor tuner mock-up: A spare scissor tuner assembly has been loaned from J-Lab. A mock-up of the cavity tuning geometry is used to test the tuner using a mechanical spring with a force loading of 4500N/mm comparable to that of the cavity. The ISAC-II rotary servo motor with ball screw is being used to drive the tuner. The mock-up is useful in benchmarking the tuner motor under the typical loads and to test the rate, response and backlash in the mechanism (Fig. 4).

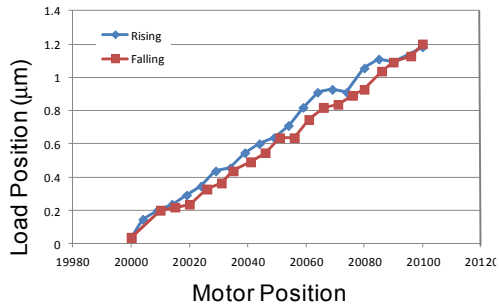

Figure 4: Correlation of mock cavity length with motor position for 1 micron cycling.

STATUS

The tank and lid are being manufactured by a local shop. The strongback and strut supports are being fabricated at TRIUMF. The cavity is being fabricated at PAVAC. A 7-cell replica cavity in copper has been fabricated and is being used for HOM studies. The first Nb cavity inner cells are nearing completion with coupler and tuner end groups to follow. Two 50kW couplers are being conditioned in a dedicated waveguide box station. The 4K/2K test stand will be tested first without MLI to check for cold leaks and function of diagnostics then wrapped in MLI for performance tests. The cold mu-metal has been designed and will be manufactured at Amuneal. The scissor tuner will be ordered from Incodema pending completion of performance tests at TRIUMF. The LN2 shield is in fabrication at TRIUMF. The warm-cold beam pipe transition section with HOM dampers is undergoing final studies to determine placement of HOM diagnostics.

Abstract

Electron beam driven wakefield acceleration is a bona fide path to reach high gradient acceleration of electrons and positrons. With the goal of demonstrating the feasibility of this concept with realistic parameters, well beyond a proof-of-principle scenario, the AWA Facility is currently undergoing a major upgrade that will enable it to achieve accelerating gradients of hundreds of MV/m and energy gains on the order of 100 MeV per structure. A key aspect of the studies and experiments carried out at the AWA facility is the use of relatively short RF pulses (15 – 25 ns), which is believed to mitigate the risk of breakdown and structure damage. The upgraded facility will utilize long trains of high charge electron bunches to drive wakefields in the microwave range of frequencies (8 to 26 GHz), generating RF pulses with GW power levels.

AWA FACILITY

The mission of the Argonne Wakefield Accelerator Facility (AWA) is to develop technology for future accelerator facilities. The AWA facility has been used to study and develop new types of accelerating structures based on electron beam driven wakefields. In order to carry out these studies, the facility employs a photocathode RF gun capable of generating electron beams with high bunch charges and short bunch lengths. This high intensity beam is used to excite wakefields in the structures under investigation.

The facility is also used to investigate the generation and propagation of high brightness electron beams, and to develop novel electron beam diagnostics.

The AWA high intensity electron beam is generated by a photocathode RF gun, operating at 1.3 GHz. This one-and-a-half cell gun typically runs with 12 MW of input power, which generates an 80 MV/m electric field on its Magnesium photocathode surface. A 1.3 GHz linac structure increases the electron beam energy, from the 8 MeV produced by the RF gun, to 15 MeV. The linac is an iris loaded standing-wave structure operating in the $\pi/2$ mode with an average accelerating gradient of 7 MV/m; it has large diameter irises to minimize the undesirable wakefields generated by the passage of high charge electron bunches.

The charge of the electron bunches can be easily varied from 1 to 100 nC, with bunch lengths of 2 – 2.5 mm rms, and normalized emittances of 3 to 100 π mm mrad.

The AWA laser system consists of a Spectra Physics Tsunami oscillator followed by a Spitfire regenerative amplifier and two Ti:Sapphire amplifiers (TSA 50). It produces 1.5 mJ pulses at 248 nm, with a pulse length of 2 to 8 ps FWHM and a repetition rate of up to 10 pps. A final KrF Excimer amplifier is optionally used to increase the energy per pulse to 15 mJ.

The generation of electron bunch trains (presently up to 16 bunches) requires each laser pulse to be divided by means of beam splitters into a laser pulse train. The charge in each electron bunch is determined by the energy in each laser pulse and the quantum efficiency of the photocathode material. Typically, single bunches of 100 nC can be produced (with a maximum of 150 nC occasionally reached).

WAKEFIELD ACCELERATION

The use of electron beam driven wakefields to achieve high gradient acceleration has received considerable attention. It offers the advantage of using a relativistic beam to transport the energy to the accelerating structures, decreasing the difficulties of generating and distributing RF power by conventional means; wakefields naturally constitute RF pulses that are of short duration and high peak intensity [1].

Research at the AWA facility has been exploring various types of wakefield structures, including photonic band gap structures, metallic iris loaded structures, and also more exotic schemes using metamaterials. The main focus of the facility, however, has clearly been the development of dielectric loaded structures. They offer the advantage of simple geometry and easy fabrication with accelerating properties that compare favourably with conventional iris loaded metallic structures: the axial electric field is uniform across the transverse cross section of cylindrical structures, and the uniform cross section of the structures presents no geometric features to cause field enhancement. The damping of the undesirable deflecting dipole modes seems to be more easily accomplished in dielectric loaded structures as well; planned experiments will explore the use of longitudinal slots on the metallic outer shell of dielectric structures, as a possible scheme to damp dipole modes. Dielectric structures also hold the promise of withstanding higher electric fields without material breakdown. A significant advantage offered by wakefield structures, in comparison

with other wakefield schemes, is the ability to accelerate positron bunches or electron bunches in basically identical fashion.

AWA FACILITY UPGRADES

The AWA Facility has several major upgrades presently underway, which will considerably enhance its capabilities.

A new one-and-a-half cell RF gun (Fig.1) has been commissioned, and it will replace the existing RF gun as the source of drive bunches. The new RF gun operates with a Cesium Telluride photocathode, and thus, due to the higher quantum efficiency of Cs_2Te, it will be able to generate longer bunch trains with high charge per bunch. We plan to generate trains with up to 32 electron bunches, each separated by one L-band RF period, and with up to 100 nC per bunch. (It should be noted that the two upper limits, i.e. 32 bunches and 100 nC per bunch, cannot be reached simultaneously, since this would load the accelerating fields in the RF gun to an unacceptable level.) These longer bunch trains will, of course, generate longer RF pulses when traversing the wakefield structures.

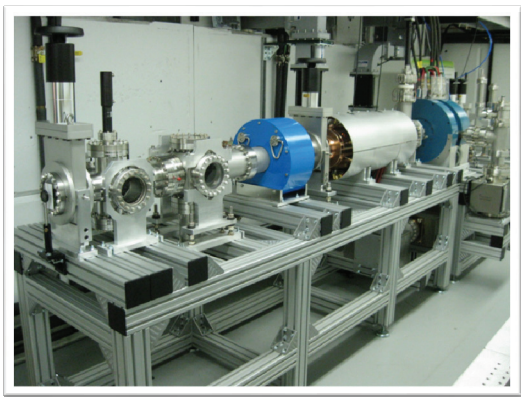

Figure 1: The new AWA RF gun (between the blue solenoids), followed by the first one of the six new linac tanks, another focusing solenoid, and two vacuum crosses for laser beam input and beam profile measurements (YAG screen). A combination of ICT and FCT (Integrating Current Transformer and Fast Current Transformer made by Bergoz) is installed in between the two crosses.

Three additional L-band RF power stations, consisting of one 30 MW Litton klystron and two 25 MW Thales klystrons, and their respective modulators, will power six new linac tanks in the drive beamline. These new klystrons have been commissioned to full power.

The new linacs [2] will be seven-cell standing-wave π mode structures, designed to operate with 10 MW of input power and 11.2 MeV energy gain. Thus, the operation of the six new linac tanks will increase the energy of the beam produced by the drive gun from 8 MeV to 75 MeV. This will, of course, allow significantly more energy to be extracted from the drive beam as it drives wakefields in the structures under test. The higher beam energy also implies a smaller physical transverse emittance of the bunches, facilitating their propagation through smaller aperture wakefield structures, and generating even higher wakefield amplitudes.

The fabrication of the first one of the six new linac tanks has been completed, and good field flatness across the cells has been achieved (Fig.2). It has been installed just downstream of the new RF gun (Fig.1). The fabrication of the remaining five linac tanks is under way, and their final brazing cycles are scheduled for October of 2012.

The commissioning of the new drive gun will free up the existing gun, which will then be used to generate a witness beam to probe the wakefields produced by the drive bunches.

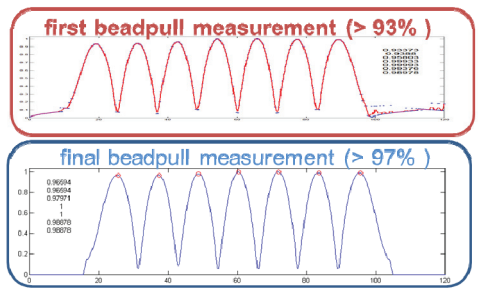

Figure 2: Bead-pulling RF measurement of first linac tank, showing good field balance across the cells.

A new beamline switchyard (Fig. 3) will be constructed to allow concomitant experiments: (a) collinear wakefield acceleration; (b) RF power generation and two beam acceleration; (c) phase space manipulation (emittance exchange, etc); (d) high brightness beam generation; (e) beam diagnostic development. This flexible beamline switchyard will allow a quicker and more efficient transition among several concurrent experimental setups.

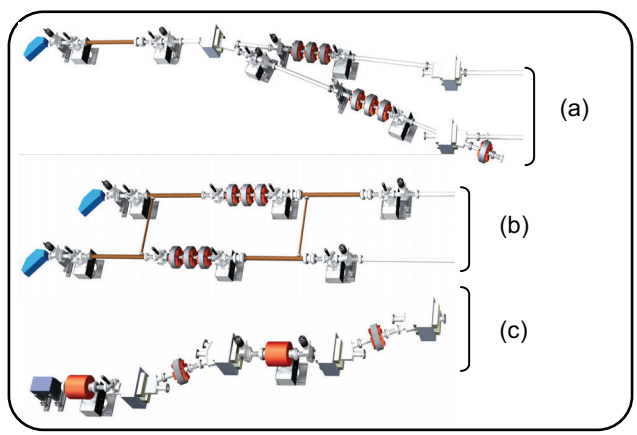

Figure 3: Different legs of the new AWA beamline switchyard will be dedicated to specific types of experiments: (a) collinear wakefield acceleration; (b) two-beam-acceleration and RF power generation; (c) phase space manipulation (emittance exchange) and beam diagnostic development.

In order to house the upgraded AWA Facility, the present bunker has been extended beyond the perimeter of the existing building, into a new annex. Figure 4 shows the interior and the roof of the expanded bunker.

(a)

(b)

Figure 4: The expanded AWA bunker: (a) plentiful interior space is now available for the installation of the new linac tanks and new beamline switchyard; (b) new RF power circulators and waveguides have been installed on the roof of the expanded bunker, ready to connect the new klystrons to the new linac tanks.

CONCLUDING REMARKS

In the past few years AWA has demonstrated high gradient fields (100 MV/m) in dielectric based wakefield structures [3]. Generation and extraction of RF power using beam driven dielectric structures has also been demonstrated [4 - 6]. Several experiments exploring new designs and new features of dielectric based wakefield structures will be conducted in the near future.

Concomitantly, AWA is undergoing upgrades that will enhance its capabilities. These upgrades will allow the generation of longer bunch trains with high charge per bunch. The higher beam energy will make it possible to excite high gradient wakefields in longer accelerating structures, thus generating hundreds of MV/m over meter scale structures. The second RF gun will provide "witness" bunches to probe the wakefields, demonstrating high gradient acceleration.

Once the upgrades are completed, the goal is to achieve accelerating gradients on the order of 0.5 GV/m in structures with approximately 3 mm apertures. The generation and extraction of RF pulses with power levels on the order of GW shall also be demonstrated. As an example, Table 1 shows the main parameters of a pair of structures that will be tested as soon as the upgraded AWA Facility becomes available. The actual hardware is seen in Fig. 5.

SIMULATION STUDY ON THE LONGITUDINAL BUNCH SHAPE MEASUREMENT BY RF CHOPPER AT J-PARC LINAC

T. Maruta*, J-PARC center, Japan Atomic Energy Agency, Tokai, Ibaraki, Japan
M. Ikegami, High Energy Accelerator Research Organization, Tsukuba, Ibaraki, Japan

Abstract

We propose to measure the longitudinal rms beam size by existing apparatuses in MEBT1 at J-PARC linac. The RF chopper cavity horizontally deflects beam particles at the frequency of 324 MHz, which is the same frequency as other accelerator cavities. By setting an adequate driving phase of the chopper, a horizontal deflection is proportional to relative phase difference from the centroid of a beam bunch. Then, the deflected beam distribution is measured by a wire scanner monitor. It is also possible to measure the longitudinal rms emittance by varying the amplitude of a buncher upstream. In this paper, we confirm the feasibility of the measurement scheme with particle simulation.

INTRODUCTION

The J-PARC linac is comprised from a 50 keV negative hydrogen (H^-) ion source (IS), a 3 MeV Radio Frequency Quadrupole (RFQ), a 50 MeV Drift Tube Linac (DTL), and a 181 MeV Separate-type DTL (SDTL). There is a medium energy beam transport section (MEBT1) between the RFQ and DTL. We place an RF chopper system in the middle of MEBT1 to shape a macro pulse configuration in accordance with RF frequency of following 3 GeV rapid cycling synchrotron (RCS).

In the J-PARC linac, a beam intensity upgrade project is currently underway. The project will replace the front end part (IS to RFQ) for the extension of the peak current to 50 mA in the next summer. A simulation study indicates that the longitudinal beam emittance in the 50 mA operation is 20 % larger than present one. The beam rejection power of the RF chopper system is inversely correlated to a beam width in phase direction, it motivated us to consider a reinforcement of the chopper. It is important to understand the current beam width for an inquest of the reinforcement. However, we have no monitors for the beam width measurement, and moreover, there is no space to install an additional monitors in MEBT1.

We devise a beam width measurement method only with an existing apparatus in MEBT1 to overcome the situation. Then we evaluate the feasibility with a three dimensional particle-in-cell code IMPACT [1].

MEBT1

MEBT1 is a 3 m long transport line between RFQ and DTL as shown in Fig. 1. There are two major issues. One is a matching of the beam to the DTL acceptance in both longitudinal and transverse phase space by eight quadrupole magnets and two buncher cavities while transferring the beam to DTL. To measure the beam qualitatively, we place beam current monitors (CT), beam position monitors (BPM) and wire scanner monitors (WSM) [2] throughout MEBT1. The other issue is a shaping of a macro pulse in accordance with the RF frequency of following RCS. The RF chopper system is involved in the shaping. It is comprised from an RF chopper cavity and a scraper which is located at 0.72 m downstream from the cavity. Unnecessary beam bunches are horizontally (x) deflected by the cavity and then they hit to the scraper.

RF Chopper Cavity

We employ an RF deflector (RFD) for beam chopping [3]. The RFD is operated in a TE_{11}-like mode with the frequency of 324 MHz, which is same as RFQ and DTL. The deflection angle of a RF gap is 6 mrad at the electric field of 1.6 MV/m of which an RF power is 22 kW. There are two RF gaps in the cavity at intervals of $3\beta\lambda$, where β is the velocity of beam normalized by the speed of light and λ is RF wave length. The two RF gaps are currently connected in series via a coaxial tube with length of 2λ to supply an RF from a single semiconductor amplifier. In this summer, we modify the configuration to individually supply an RF to each RF gap by introduction of an additional amplifier. It enable us to tune an asynchronous phase and an amplitude of each RF gap individually. The current amplifier stably supply an RF power up to 35 kW which corresponds a gap field of 2.0 MV/m. Moreover, we have a plan to upgrade the amplifier to 60 kW in the next summer.

MEASUREMENT METHOD

In the measurement, we use the RF chopper cavity, the upstream buncher and a WSM downstream of the chopper cavity. The measurement is comprised of two steps. In the first step, we measure the beam width in phase direction by the chopper cavity and the WSM. Then, the second step measures a longitudinal emittance and a Courant-Snyder parameter by adding the buncher to the beam width measurement. This measurement is similar to a transverse emittance measurement so-called "Q-scan" [4] in principle.

Beam Width in Phase Direction

In the nominal operation of J-PARC linac, the chopper is tuned to give a maximum deflection to a beam bunch. It is equivalent that we adjust the RF to be maximum when a beam bunch arrives at the middle of an RF gap as shown in Fig. 2(a). The integrated RF of a beam particle gradually attenuates in accordance with a phase difference from the

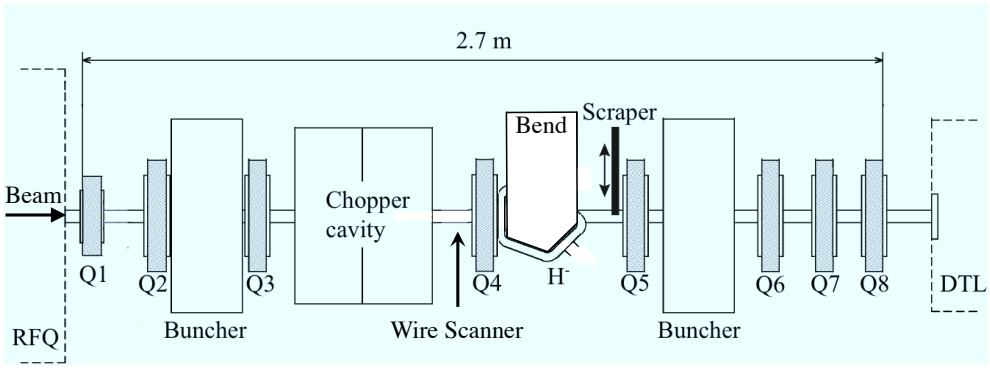

Figure 1: Layout of MEBT1. We use the chopper cavity, the upstream buncher cavity and the wire scanner between the chopper cavity and Q4 for the measurement.

centroid of a beam bunch. The earlier and later particles than the centroid are deflected in same amount if the phase deference is same. Consequently, it is hard to extract the beam width in phase direction from an x plane measurement.

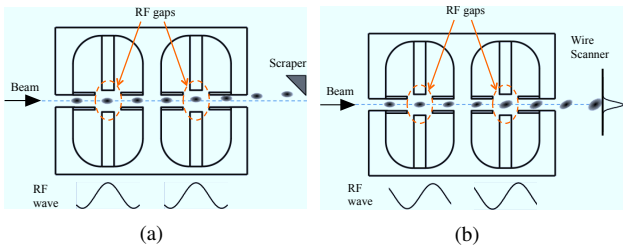

Figure 2: The RF setting and a beam bunch behavior — (a) In the nominal operation (b) In the measurement.

If we set the RF phase shifted by $\pi/2$ from the nominal operation, the centroid of a beam bunch is not deflected at an RF gap, because the centroid passes through a gap at zero-crossing. Whereas, particles away from the centroid are deflected in accordance with the relative phase difference from the centroid ($\Delta\phi$). Consequently, a beam bunch rotates on the $x' - \phi$ phase space as shown in Fig. 2(b). If the transverse emittance is negligibly small, the x position after the deflection is a function of $\Delta\phi$. We can obtain a beam distribution in phase direction by the measurement of the x distribution downstream of the chopper. Unfortunately, the beam is a finite transverse emittance. Instead we obtain a root-mean-square (rms) beam width (σ_ϕ).The deflected rms beam width on the x plane at the distance of D is

$$< (x + D\theta(\Delta\phi))^2 > = < x^2 > + D^2 < (\theta(\Delta\phi))^2 >, \quad (1)$$

where $< x^2 >$ is square of rms beam size without deflection and θ is deflection angle of each particle. This equation shows that we can obtain the σ_ϕ from the measurement of x distribution with and without the deflection.

Originally, this method is considered by Prof. Naito from KEK [5]. Although it is important to adjust the asynchronous phase of both RF gaps to a zero-crossing, the ambiguity of phase difference due to the series connection of RF gaps is an obstacle for an accurate measurement. The introduction of the additional amplifier in this summer resolves the ambiguity. Consequently, it is possible to conduct the measurement.

Emittance

The σ-matrix at the chopper (σ^C) is expressed from the σ-matrix at the upstream buncher (σ^B) and the transfer matrix between them (R) as $\sigma^C = R\sigma^B R^T$. The element σ_{55}, which is equivalent to the square of σ_ϕ, σ^C_{55}, is written as

$$\sigma^C_{55} = (\sigma^C_\phi)^2 = \varepsilon \left(\beta^B R^2_{55} - 2\alpha^B R_{55}R_{56} + \gamma^B R^2_{56}\right), \quad (2)$$

where ε is the emittance, and α^B, β^B and γ^B are Courant-Snyder parameters at the buncher, respectively. The lattice is RF gap + Quadrupole + Drift. The matrix elements without impulse from the space charge forces are $R_{55} = 1 + kL/\beta\gamma^3$ and $R_{56} = L/\gamma^2$, where k is an electric field of the buncher and L is the length of the lattice. Substituting them into Eq. 2 and deforming it with focusing on k, Eq. 2 is expressed as

$$(\sigma^C_\phi)^2 = \frac{\varepsilon\beta^B L^2}{\beta^2\gamma^6}\left(k + \frac{\beta\gamma^3}{L} - \frac{\alpha^B}{\beta^B}\beta\gamma\right)^2 + \varepsilon^2\frac{L}{\gamma^2}\frac{1}{\varepsilon\beta^B}. \quad (3)$$

Therefore, $(\sigma^C_\phi)^2$ is the second order polynominal function of k, and the minimum width is equivalent to the square of $\varepsilon^2 L/\gamma^2\varepsilon\beta^B$. Since $\varepsilon\beta^B$ can be calculated from the coefficient of k^2, it is possible to extract the ε from the correlation of the σ_ϕ and the k. The Courant-Snyder parameter also evaluate from Eq. 2. The R elements vary when we change k. Measurements at three k result three equations in three unknowns.

SIMULATION

We use a three dimensional particle-in-cell code, IMPACT, for an evaluation of the feasibility. In the simulation, the initial particles are launched at the entrance of MEBT1. Then, we track these particles to the WSM

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

which we use in the measurement. The output distribution from PARMTEQM [6] is taken as the initial distribution. The electro-magnetic field inside the chopper cavity is calculated with a finite element method (FEM) code, Micro Wave Studio (MWS) [7]. We treat the RFDs as two single cavity in MWS and obtain an electric field distribution at the frequency of 324 MHz.

We measure the deflection at the several electric fields to confirm the reproducibility of a simulation with the MWS field distribution. The horizontal beam distribution at the electric field of 0, 0.33, 0.50, 0.95 and 2.0 MV/m are measured by the WSM. Here we define the deflection as the displacement of the centroid of the distribution from the centroid without excitation. Figure 3 shows the comparison of the measured deflection with the simulation. The simulated deflection shows a linear correlation to the electric field. The measurements are well gathered around the simulation in the region less than 1 MV/m. Concerning to the 2.0 MV/m, we observe a decline of a beam current at the chopper downstream. It is supposed that a part of a beam bunch hits to an aperture inside the chopper and it becomes an obstacle for the calculation of the deflection properly.

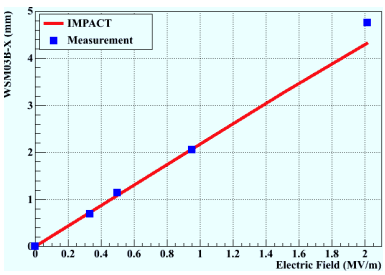

Figure 3: Correlation of the chopper electric field and the deflection at the WSM.

Figure 4(a) shows the σ_ϕ at each RF gap as a function of the buncher E_0TL. Red points are σ_ϕ at the upstream gap (#1) and blue points are that at the downstream (#2). Both distributions have a minimum σ_ϕ, and the E_0TL of minimum σ_ϕ at the gap #2 is lower than the gap #1. It is consistent that the k at minimum σ_ϕ is inversely proportional to L shown in Eq. 3. The σ_ϕ of the gap #2 is minimum at E_0TL of 0.19 MV. Since the maximum E_0TL is currently 0.17 MV, we may need to upgrade the semiconductor amplifier of the buncher to observe the minimum σ_ϕ.

Next, we calculate the boundary condition on the $\phi - E$ phase space at the buncher. From the measurement in Fig. 4(a), we extract the boundary of the ellipse at the buncher by using the R. We use a Trace3D [8] for the calculation of the R for each E_0TL. Figure 4(b) shows the boundaries and actual ellipse by IMPACT. Here we shows the boundaries at the buncher E_0TL of 0, 0.085 and 0.17 MV. Since an emittance growth is not taken into account to the Trace3D, the reproducibility of the boundaries becomes worse as the emittance growth being large. The calculated boundaries are close to the ellipse well. The effect of the emittance growth between the buncher to the chopper is supposed to be negligibly small. We consider to upgrade the semiconductor amplifier of the buncher currently. After the upgrade,It is expected to observe the minimum σ_ϕ in Fig.3 and to give more tight constraint for the ellipse in Fig. 4(a).

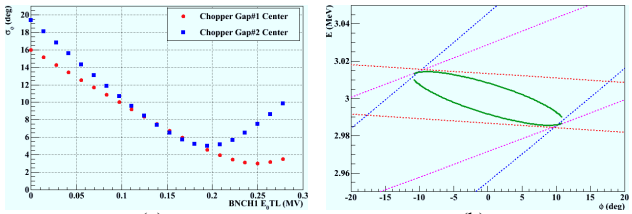

Figure 4: The simulation results — (a) σ_ϕ at both RF gaps of the chopper as a function of the buncher E_0TL (b) The ellipse and the boundaries obtained by σ_ϕ^C measurement. The dotted lines are the boundary at 0 (red), 0.085 (magenta) and 0.17 MV (blue), respectively.

SUMMARY AND FUTURE PROSPECTS

Because of the introduction of another semiconductor amplifier for the chopper, it is possible to measure the beam width in phase direction. Moreover, we also measure longitudinal beam emittance and Courant-Snyder parameters by adding the flexibility of the buncher amplitude to the beam width measurement. The data-taking is scheduled at the beginning of October. We confirm the feasibility of the measurement and evaluate the longitudinal beam profile.

Abstract

The Project X Injector Experiment (PXIE) [1], a test bed for the Project X front end, will be completed at Fermilab at FY12-16. One of the challenging goals of PXIE is demonstration of the capability to form a 1 mA H- beam with an arbitrary selected bunch pattern from the initially 5 mA 162.5 MHz CW train. The bunch selection will be made in the Medium Energy Beam Transport (MEBT) at 2.1 MeV by diverting undesired bunches to an absorber. This paper presents the MEBT scheme and describes development of its elements, including the kickers and absorber.

REQUIREMENTS

The PXIE MEBT will be a ~10 m beam line between RFQ and the first Half-Wave Resonator cryomodule (HWR). It should form the required bunch pattern, match the optical functions between RFQ and SRF, include tools to measure properties of the beam coming out of RFQ and coming to SRF, and clean transverse halo particles while transporting the bunches selected for the following acceleration with a low emittance dilution and a low beam loss. The main MEBT requirements are listed in Table 1.

Table 1. The main MEBT functional requirements

Parameter	Value	Unit
Beam kinetic energy	2.1 +/-1%	**MeV**
Input frequency of bunches	162.5	MHz
Nominal input beam current	5	mA
Beam current operating range	1-10	mA
Nominal output beam current	1	mA
Relative residual charge of removed bunches	$< 10^{-4}$	
Beam loss of pass through bunches	< 5%	
Nominal transverse emittance	< 0.27	μm
Nominal longitudinal emittance	0.8	eV-μs
Relative emittances increase	<10%	

FOCUSING SCHEME

Transverse focusing in the MEBT is provided mainly by equidistantly placed quadrupole triplets (Fig.1); the only exception is two doublets at the MEBT upstream end. Below the regions between neighboring triplets or doublets are referred to as MEBT sections. These sections are represented in Fig. 2 by rectangles color-coded according to their main function. The regular period is 1140 mm, which leaves 650 mm (flange-to-flange) space for equipment (350 mm in the section #0).

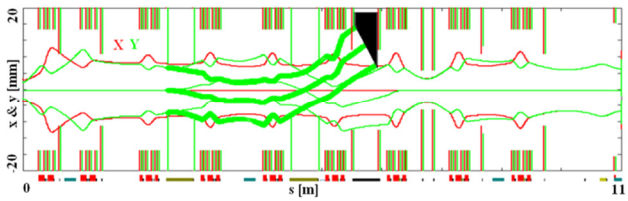

Figure 1: Scheme of MEBT optics [2] and the beam envelope. The thin lines are the central trajectory and 3σ envelope (ε_{rms_n}=0.25 mm mrad) of the passing beam, and the thick lines are the Y envelope of the chopped-out beam. Red- quadrupoles, blue- bunching cavities.

Longitudinally the beam is focused (Fig.3) by three bunching cavities (Fig.4).

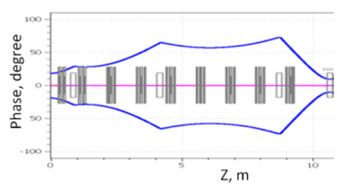

Figure 3: 3-σ bunch length through MEBT.

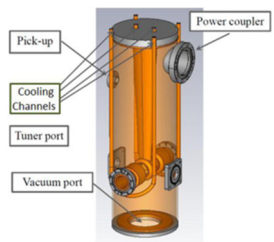

Figure 4: Conceptual design of the MEBT bunching cavity.

CHOPPING SYSTEM

The undesired beam bunches will be removed in the MEBT by a chopping system consisting of two identical kickers separated by 180° transverse phase advance and an absorber at 90° from the last kicker. In the broadband, travelling-wave kickers [3], the transverse electric field propagates through their structures with the phase velocity equal to the speed of H- ions, 20 mm/ns. Depending on polarity, bunches are either kicked toward the absorber surface or on a pass through path. In either

case, the voltage on opposites plates is +/-250V with respect to ground. The gap between the kicker plates is 16 mm. Protection electrodes with 13 mm gap are installed on both sides of each kicker. To prevent extensive irradiation resulting from beam mismatch, an elevated electrode current will trigger a beam interruption. Because of critical importance of the kicker performance, presently two versions of the kicker are been developed.

In the first version having 50 Ohm characteristic impedance of the kicker structure, the beam is deflected by voltage applied to planar electrodes connected in vacuum by coaxial cables with the length providing necessary delays (Fig. 5). Each half of the ~0.5 m kicker has 25 copper plates with dimensions of 14.6 x 50 x 1 mm. The power loss induced by the electromagnetic wave (~100 W) and beam (~40W) is removed through the Teflon-insulated cables clamped to a water-cooled structure.

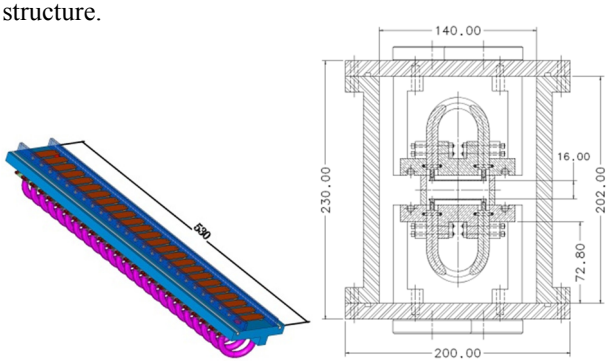

Figure 5: Mechanical schematic of the 50-Ohm kicker structure and the cross section of the kicker assembly.

The structure elements were simulated; a short mock-up was successfully measured; and presently a full-scale prototype is being designed.

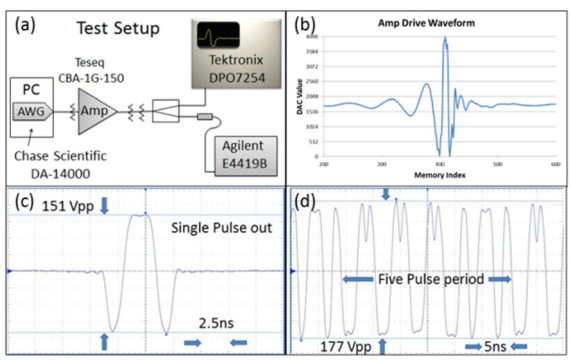

Figure 6: Test of the CBA 1G-150 amplifier with pre-distortion. (a) scheme of the test; (b) pre-distorted input signal and (c) corresponding output signal for a single pulse; (d) output for a CW pattern, corresponding to removal of four consecutive bunches followed by a one-bunch passage.

The kicker will be driven by a 1-kW linear amplifier. To decrease the lower frequency content of the output signal, the 6.15ns pulse affecting a single bunch is formed as shown in Fig.6c. Effects of a significant low frequency phase distortion in the commercially available amplifiers will be corrected by pre-distorting the driving signal generated according to an algorithm that has been successfully tested with a similar amplifier [4] of lower (150W) power (Fig.6).

The second version of the kicker has 200 Ohm impedance and consists of two helical structures (Fig. 7). Each helix is a flat wire wound with the 8.5mm helix pitch around a 28.6 mm OD copper grounded tube. The wire is suspended 4.8 mm above the tube surface by four ceramic spacers. The deflecting field is formed by flat copper 5.6x20x0.5 mm electrodes soldered to each turn of the helix.

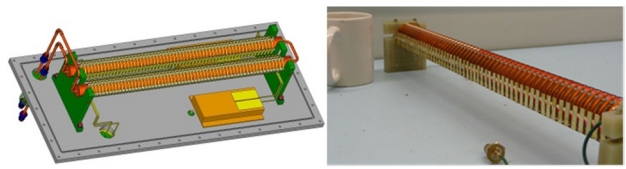

Figure 7: Mechanical drawing of 200 Ohm dual-helix kicker and photo of a single 200 Ohm helix prototype.

Simulations of the kicker structure agree well with prototype measurements (Fig. 8). Distortion during the propagation through the 200 Ohm helix is within specifications.

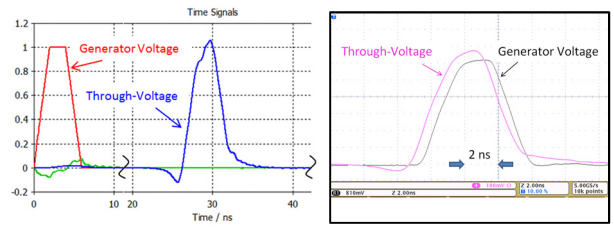

Figure 8: Simulation results of the helix kicker (left) and the prototype response (right). The traces at the right plot are time shifted.

The 200 Ohm kickers are intended to be driven by broadband, DC coupled switches in the push-pull configuration, which are under development [3].

The MEBT absorber should withstand irradiation by a 21 kW H- beam with the nominal rms beam radius of ~2mm. The design shown in Fig. 9 ([5]) addresses concerns about the heat load and resulting mechanical stresses as well as possible blistering issues.

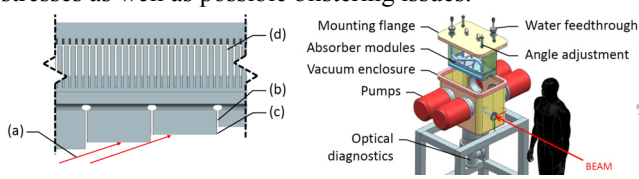

Figure 9: Conceptual design of the MEBT absorber. absorber is made of the molybdenum alloy TZM and is cooled by water flowing through transverse micro-channels. The axial stress is relieved by transverse slits. Thermal and stress analysis showed feasibility of the design. A 10-cm long prototype is being manufactured, and its thermal properties will be tested with an electron beam.

OTHER SUBSYSTEMS

Several other subsystems are at different stages of development: quadrupoles, scrapers, vacuum system, and diagnostics.

The triplet assembly, which will consist of a central (larger) and two smaller quadrupoles, a pair of dipole correctors, and a button BPM mounted between the quadrupoles, is under technical design.

The scraping system concept assumes installation of 16 scrapers grouped in 4 sets with two X and two Y scarpers per set. Each scraper is an electrically isolated, ~100W-rated plate precisely movable across half of the aperture. The scrapers will be used for several purposes:

1. For beam halo measurements and removal
2. To protect the downstream equipment from beam losses. A high-loss signal from a scraper will trigger turning the beam turn-off.
3. As an axillary beam density distribution diagnostics (in a pulse mode)
4. To form a pencil H- beam for measurements downstream (in a pulse mode)

One pair of scraper sets is to be installed at the beginning of the MEBT to protect the MEBT elements (first of all, kickers), and the second pair is located after the absorber as a protection for cryomodules. The sets in each pair are separated by ~90º of the phase advance.

The vacuum system design is at a conceptual stage. The vacuum requirements are determined by the electron detachment in the H- beam and by the necessity to have a low gas flow into the HWR cryomodule. Obviously, the electron detachment results in a loss of H- beam intensity; an additional restrictive effect is a flux of created neutral hydrogen atoms that may reach the SRF cavities. For the design of the vacuum system, we adopted the requirement of keeping the integral of the pressure over the length of the MEBT to be below $1 \cdot 10^{-6}$ Torr·m, which corresponds to loosing $\sim 10^{-4}$ in the beam intensity and adding an additional ~0.1 W heat load to SRF by the neutrals.

The gas flow from the room-temperature MEBT to the 2K HWR cryomodule causes a gas deposition on the cryogenic surfaces. While there are no exhaustive experiments or a cohesive theory on the subject, there are indications in literature that such coverage at the surface of the cryogenic cavities degrades their performance. On the other hand, the closest analogue, a HWR in the Argonne National lab, successfully operates at the pressure of $5 \cdot 10^{-8}$ Torr immediately upstream of the cryomodule, though with the residual gas composed primarily by water [6]. To be on a safe side, we aim to keep the pressure upstream of PXIE's HWR at or below of $1 \cdot 10^{-9}$ Torr (H_2).

The main source of the vacuum load in the MEBT is expected to be a flow of hydrogen created from recombination of protons at the absorber. The worst scenario of 10 mA average absorber current corresponds to ~1 mTorr·l/s of the hydrogen load. To maintain a high vacuum near the SRF, first, the absorber is placed into a large box with effective pumping speed of 2500 l/s by turbo pumps and, second, the absorber is followed by a differential pumping section (#6 in Fig.2), where the vacuum chambers are separated by a 10mm ID, 200 mm long pipe. The calculated pressure profile is shown in Fig.10. Low particulate vacuum practices will be applied to the portion of the MEBT downstream of the section #6 to prevent degradation of the SRF cavities performance.

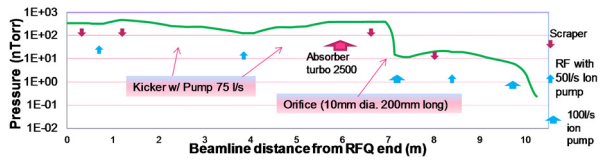

Figure 10: The pressure profile in the MEBT calculated for 10mA beam at the absorber.

The main purpose of two yellow-colored sections in Fig.2, #1 and #8, is to house beam diagnostics. A fully equipped MEBT diagnostics should allow characterizing the beam coming in and out of MEBT as well as its optics. The diagnostics are listed in Fig.2, and their detail description can be found in Ref. [7].

CONCLUSION AND PLANS

The proposed scheme of the MEBT contains all elements required for shaping and characterizing the beam coming to the Project X SRF linac. The extensive test of the MEBT operation is planned to be carried out in PXIE. The FY2013 schedule includes manufacturing and testing prototypes for the absorber, kicker, quadrupoles, and BPM.

ACKNOWLEDGMENT

The authors acknowledge multiple useful discussions of an alternative MEBT scheme with J. Staples.

BEAM LOSS MITIGATION IN J-PARC LINAC AFTER THE TOHOKU EARTHQUAKE

M. Ikegami, K. Futatsukawa, Z. Fang, T. Miyao, Y. Liu, KEK/J-PARC, Tokai, Japan
T. Maruta, A. Miura, H. Sako, J. Tamura, G. Wei, JAEA/J-PARC, Tokai, Japan

Abstract

In the course of the beam commissioning of J-PARC linac after nine-month shutdown due to an earthquake, we have experienced beam losses which were not seen before the earthquake. One of the main cause for the beam loss was the irregular RF setting for accelerating cavities to avoid multipactor at one of them, which started to pose difficulty in the nominal operation after the earthquake. In this paper, we discuss the beam loss mitigation effort putting the emphasis on the optimization of the RF setting for SDTL.

INTRODUCTION

We had a magnitude-9.0 earthquake in Tohoku region in Eastern Japan in March 2011. It caused severe damage to J-PARC facilities which forced us to shutdown for nearly nine months [1]. After significant restoration efforts, we started beam operation of J-PARC linac in December 2011 and user operation in January 2012. The linac beam power when we resumed the user operation was 7.2 kW. Then, it is increased to 13.3 kW in March 2012, which is the same as just before the earthquake. While the linac beam operation was restored in terms of the beam power, we have experienced higher beam losses than before the earthquake. Thus, we have been trying to mitigate the beam loss while supporting the user operation. The initial beam start-up in December 2011 and January 2012 was reported in another literature [2]. Therefore, we focus on the beam loss mitigation effort after restoring the user operation in this paper. It should be noted here that the history of residual radiation during the beam commissioning was summarized in the reference [3].

J-PARC linac consists of a 50-keV negative hydrogen ion source, 3-MeV RFQ (Radio Frequency Quadrupole linac), 50-MeV DTL (Drift Tube Linac), and 181-MeV SDTL (Separate-type DTL) [4]. For later reference, we should note here that the SDTL section consists of 30 SDTL tanks with $2\beta\lambda$ inter-tank spacing with β and λ being the particle velocity scaled by the speed of light and the RF wavelength, respectively. Then, each SDTL tank consists of five β-graded cells, and two neighboring SDTL tanks are driven by a klystron.

As reported in reference [2, 3], we experienced significant beam loss at the straight section after SDTL immediately after we resumed the beam operation. A main cause of the beam loss was identified to be insufficient alignment of some of the beam ducts. After conducting urgent realignment of the beam ducts [5], the beam loss was substantially reduced and become significantly less sensitive to the beam steering. However, multipactor of one of SDTL cavity has been gradually worsened and the irregular RF setting we adopted to avoid the multipactor started to cause beam losses.

In this paper, we mainly discuss the method we adopted to circumvent the SDTL multipactor while suppressing the beam losses.

MULTIPACTOR AT AN SDTL CAVITY

As mentioned above, a pair of SDTL tanks are driven by a klystron. The relative RF amplitude and phase of the tank pair are supposed to be kept balanced with the low-level RF control system. However, we noticed just before the resumption of beam operation in December 2011 that the fifth tank pair, or SDTL5, shows some unstable behavior. For this tank pair, one of the tanks tends to have arcing, or presumably multipactor, which makes the balance of RF amplitude and phase easily lost. This unstable behavior arises in a certain range of RF amplitude which contains its design amplitude. Although similar behavior has been noticed for SDTL1 to SDTL6 since before the earthquake, it caused no difficulty in operating with the design tank level [6]. Therefore, we suspect that the multipactor in SDTL5 become severer at the earthquake for some reason to cause practical difficulty in the nominal operation.

As we can avoid the multipactor by adopting higher or lower RF amplitude for SDTL5, we adopt 109 % of the design amplitude in starting the user operation in January 2012. The unstable band in the RF amplitude was widened during the beam operation and forced us to increase the operating amplitude to 116 % later. As of June 2012, we are operate SDTL5 with the same amplitude. However, the unstable region for SDTL5 is still widening gradually and reducing the operational margin.

We don't delve into the details on the multipactor itself in this paper. Instead, we discuss the irregular RF setting for SDTL we adopt to avoid the multipactor, its effect on the beam losses, and the countermeasure for the beam loss we adopted in the beam commissioning. Further detail of the multipactor will be found in the reference [7].

BEAM LOSS MITIGATION WITH IRREGULAR SDTL SETTING

Operation with 109 % Amplitude for SDTL5

In setting the RF amplitude and phase for SDTL tanks after the earthquake, it was required for us to perform the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

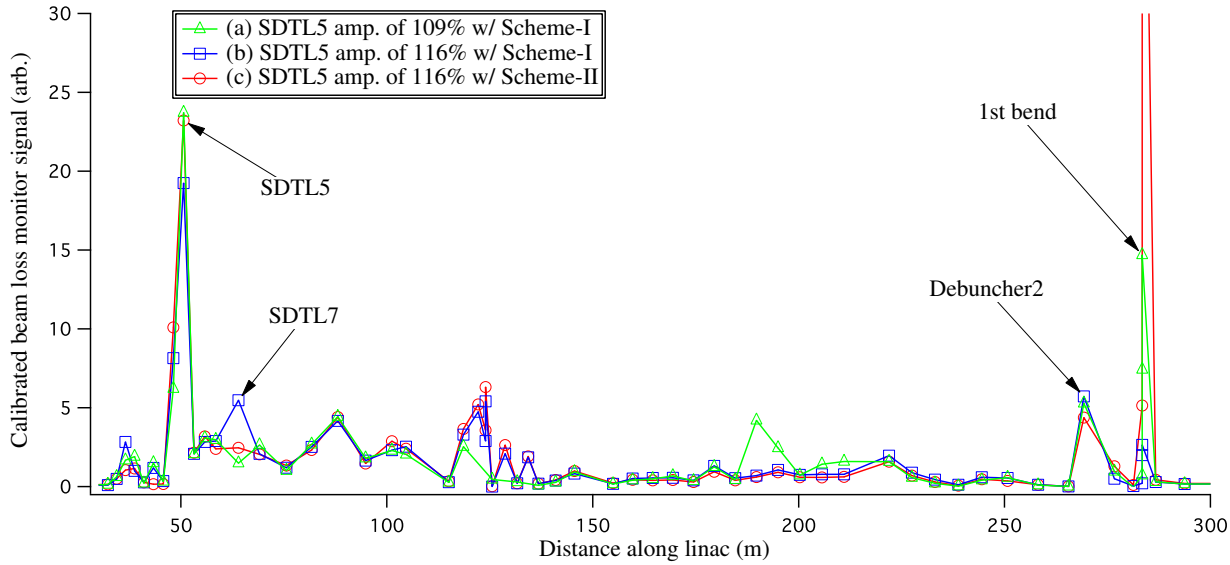

Figure 1: Calibrated beam loss monitor signal distribution along J-PARC linac and the following straight line of the beam transport line. Each marker shows the measured data with a beam loss monitor. The data are taken (a) with the SDTL amplitude of 109 % after Scheme-I tuning, (b) with the SDTL amplitude of 116 % after Scheme-I tuning, and (c) with the SDTL amplitude of 116 % after Scheme-II tuning.

phase and amplitude scan tuning [8]. At first, we adopted the RF amplitude of 109 % for SDTL5 to avoid the multipactor. In the phase and amplitude scan tuning, we needed an unusual treatment for SDTL5. Namely, we fixed the amplitude for SDTL5 and performed the phase scan only to find the phase setting to realize the design energy gain. After conducting the tuning for SDTL5, the tuning for SDTL6 and downer stream tanks were performed with the nominal procedure to set them to the design amplitude and synchronous phase.

After finishing the phase and amplitude scan tuning, we tried to operate with the determined RF setting. However, we experienced significant beam loss particularly at the straight section after the SDTL exit. We then tried to mitigate the beam loss by adjusting only the SDTL phases, because neighboring tanks also has unstable bands in their amplitude. In this tuning, we adopt the phase shift for SDTL5 and that for SDTL6 to SDTL15 as two tuning knobs. It should be noted that we assume the same phase shift for SDTL6 to SDTL15. This tuning was performed with the trial-and-error method to minimize the beam loss downstream with the phase-and-amplitude scan tuning result as the starting point. As a result, the phase for SDTL5 was shifted by +5 degree and those for SDTL6 to SDTL15 by -8 degree. Here, the positive phase shift is defined to increase the energy gain in the vicinity of the design phase. We call this tuning "Scheme-I" in this paper.

In the tuning, the beam loss is measured with BLM's (Beam Loss Monitors) of gas proportional counter type [9] distributed along the linac. As the output from BLM tends to saturate, we perform a calibration to linearize it [10]. The calibrated BLM signal after the Scheme-I tuning is shown in Fig. 1 as case (a). In the SDTL section with the horizontal axis of 30 to 115 m, the BLM is affected by X rays from SDTL cavity. A large peak is noticed at around 50 m, which is supposedly caused by X rays from SDTL5 operating with higher RF amplitude than usual. Another peak at around 280 m is the beam loss at the first bending magnet in the beam transport line. A large BLM signal there is often attributable to proton component generated in double stripping of negative hydrogen ions [10]. A peak at around 270 m is the beam loss at the second debuncher. As the aperture of the debuncher cavity is narrower than the neighboring beam transport lines, the beam loss naturally tends to concentrate on this location [11]. Aside from these peaks, a peak is also noticeable at around 190 m which is connected with significant residual radiation in the beam transport. This peak shows the beam loss caused by insufficient alignment of beam ducts which was avoided by realignment later. While a clear peak is not observed, we also had significant residual radiation at around 120 m. As the corresponding beam loss was not detected by the BLM's which then existed, we added BLM's in this area for later measurements (case (b) and (c) in Fig. 1).

Operation with 116 % Amplitude for SDTL5

While the beam loss was reasonably suppressed with a Scheme-I tuning for 109 % SDTL5 amplitude, gradual widening of the multipactor band of SDTL5 forced us to further increase its amplitude to 116 %.

With 116 % amplitude for SDTL5, we first tried Scheme-I tuning as in the previous subsection. However, we could not find a setting to fully suppress the beam loss this time. When we suppress the beam loss after the SDTL

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

exit, the beam loss in the middle of the SDTL section arises. Assuming the beam loss with lower energy would be preferable as the resultant residual radiation could be lower, we decided to adopt the setting to localize the beam loss at the upstream portion of the SDTL section. The resultant phase shift for SDTL5 was -6 degree and that for SDTL6 to SDTL15 was +8 degree. With this setting, the beam loss after the SDTL exit is comparable to before the earthquake, but we have visible beam loss at around SDTL7. It should be noted that the resultant phase shift is opposite to that in the previous subsection.

The beam loss distribution after the tuning is shown in Fig. 1 as case (b). In this figure, the peak at around 190 m was disappeared thanks to realignment. While the corresponding measurement with the same BLM configuration is not available for case (a), the peak at around 120 m was supposedly reduced judging from the reduction in the residual radiation [3]. Instead, a new peak arose at SDTL7 around 65 m as discussed above.

Operation with Design Longitudinal Focusing

After a certain period of user operation, we found that the beam loss at around SDTL7 caused significant residual radiation [3]. It motivated us to try an alternate scheme, namely, adoption of an optics with the design longitudinal focusing strength.

Keeping the design longitudinal focusing with increased RF amplitude, we naturally have higher energy gain. Consequently, we need to reduce the energy gain for neighboring cavities to compensate it. As mentioned above, we have multipactor for SDTL1 to SDTL6, which poses a constraint in choosing their RF amplitude. We conducted RF measurements to confirm that we can decrease the SDTL4 amplitude while avoiding the multipactor. Then, we tried an RF setting where we keep the longitudinal focusing for SDTL5 to the design strength with 116 % amplitude. Its excess energy gain is compensated by lowering SDTL4 amplitude. In this setting, the longitudinal focusing for SDTL4 is also kept to the design strength. We here call this tuning "Scheme-II". In calculating the longitudinal focusing force, we adopt the single gap approximation for SDTL4 and SDTL5 neglecting the phase slip. In the setting, the energy gain of SDTL5 is increased from the design value of 8.35 MeV to 10.00 MeV. Meanwhile, the energy gain of SDTL4 is decrease from its design 7.55 MeV to 5.90 MeV with the reduced amplitude of 83 %.

After adopting this setting, the beam loss was significantly reduced and become comparable to that before the earthquake. The beam loss at around SDTL7 disappeared by adopting this setting as shown as case (c) in Fig. 1. As seen in this figure, the beam loss at the first bending magnet around 280 m suddenly increased. While the reason for the sudden increase has not been fully understood, the beam loss was identified to be caused by protons and successfully mitigated by adjusting the chicane orbit we set up between RFQ and DTL [10].

SUMMARY

We had a large earthquake in March 2011 followed by a nine-month beam shutdown for restoration efforts. We resumed the beam operation of J-PARC linac in December 2011 and user operation in January 2012. Then, we recovered the beam power just before the earthquake in March 2012.

In the course of the beam commissioning, we have experienced beam losses which were not observed before the earthquake. Particularly, the multipactor in SDTL5 forced us to adopt irregular RF setting and it caused excess beam loss. In an effort to mitigate the beam loss, we have experimentally confirmed that we can suppress the beam loss by adopting an optics with the design longitudinal focusing. Although it may be an expected result, it would be a rare experimental demonstration because a high intensity β-graded linac is rarely operated with irregular RF setting for a long term. We have observed certain increase of the residual radiation at the second debuncher (not detected with BLM)[3] which might be attributable to the SDTL setting. Even with this reservation, this result provides valuable information in designing a counter-failure scenario for present and future high intensity linacs.

Thanks to the RF tuning and other efforts, we succeeded in reducing the beam loss in J-PARC linac to a comparable level to before the earthquake.

PLANNING FOR EXPERIMENTAL DEMONSTRATION OF TRANSVERSE EMITTANCE TRANSFER AT THE GSI UNILAC THROUGH EIGEN-EMITTANCE SHAPING

C. Xiao, O.K. Kester, Institute of Applied Physics, Goethe-University of Frankfurt a.M, Germany
L. Groening, GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany

Abstract

The minimum transverse emittances achieved in a beam line are determined by the two transverse eigen-emittances of the beam. Without coupling, they are equal to the transverse rms-emittances. Eigen-emittances are constants of motion for all symplectic beam line elements. To allow for rms-emittance transfer, the eigen-emittances are changed by a non-symplectic action to the beam, preferably preserving the four-dimensional rms-emittance.

Unlike emittance swapping, the presented concept will allow the transformation of a beam of equal rms-emittances into a beam of different rms-emittances while preserving the four-dimensional rms-emittance. This contribution will introduce the concept for eigen-emittance shaping and rms-emittance transfer at an ion beam line. The actual work status towards the experimental demonstration of the concept at the GSI UNILAC is presented.

INTRODUCTION

For injection of beams into circular machines with different horizontal and vertical emittance acceptances, the injection efficiency can be increased if these beams are flat. However, beams provided from the linear accelerator are generally round, and the horizontal and vertical emittances are quite equal.

Round-to-flat transformation requires a change of the beam eigen-emittances by a non-symplectic transformation [1]. Such a transformation can be performed by placing a charge state stripper foil inside a longitudinal field region as proposed in [2]. Inside such a solenoidal stripper, the transverse inter-plane correlations are created non-symplectically. Afterwards they are removed symplectically with a coupling correction section. The new set-up providing round-to-flat transformation is shown in Fig. 1. Such a emittance transfer section is proposed to be integrated into the existing beam line between the UNILAC [3] and the SIS synchrotron.

EMITTANCE

The four-dimensional symmetric beam matrix C contains ten unique elements, four of which describe the coupling. The rms-emittances, ε_x and ε_y, are defined as the square roots of the determinants of the on-diagonal submatrices. If one or more of the elements of the off-diagonal

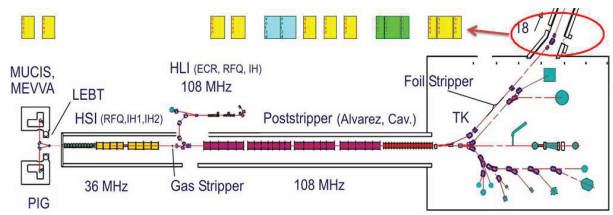

Figure 1: Conceptual layout of the transverse emittance transfer section in the GSI UNILAC.

submatrix is non-zero, the beam is x-y coupled. Diagonalization of the beam matrix yields the beam eigen-emittances, ε_1 and ε_2, and the values are calculated as:

$$\varepsilon_1 = \frac{1}{2}\sqrt{-tr(CJ)^2 - \sqrt{tr^2(CJ)^2 - 16|C|}} \quad (1)$$

$$\varepsilon_2 = \frac{1}{2}\sqrt{-tr(CJ)^2 + \sqrt{tr^2(CJ)^2 - 16|C|}} \quad (2)$$

The four-dimensional matrix J is the skew-symmetric matrix with non-zero entries on the block diagonal of form. Eigen-emittances are invariant under symplectic transformations, and the eigen-emittances are equal to rms-emittances when the inter-plane correlations are zero.

BEAM TO BE STRIPPED

Multi-particle beam dynamics simulations have been done using the TRACK code [4]. The uncoupled particle distribution at the entrance of this beam line is concluded from beam experiments and plotted in Fig. 2.

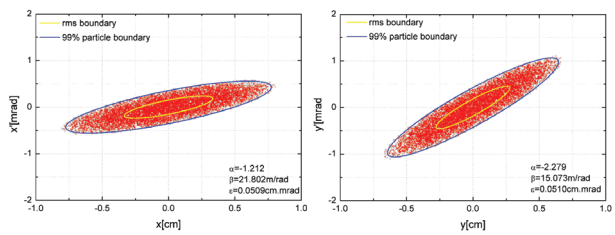

Figure 2: The particle distributions at the entrance of beam line.

The subroutines of the stripper in the TRACK code are based on the SRIM code [5]. The three-dimensional field

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

of the solenoid is calculated by the OPERA-3D code [6, 7], and the stripper foil is placed at the center. The oscillations of the rms-emittances and eigen-emittances along the longitudinal field with and without stripper are shown in Fig. 3.

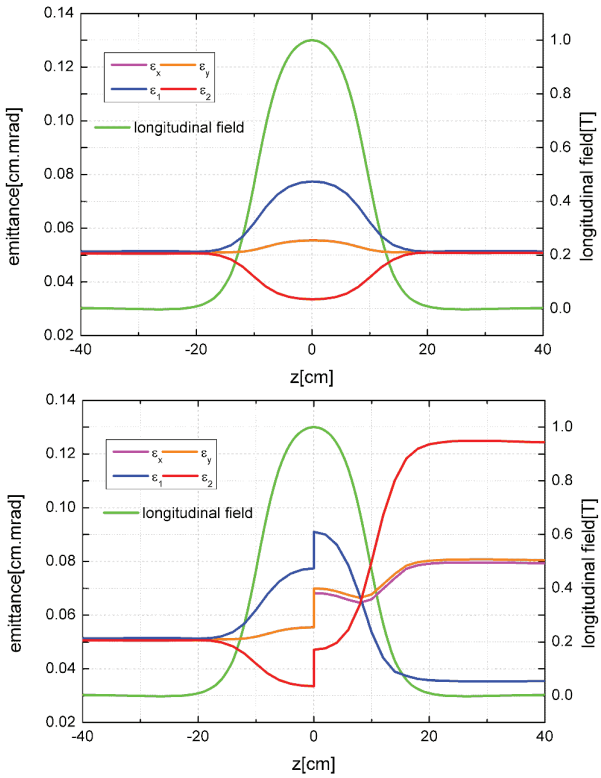

Figure 3: The rms-emittances and eigen-emittances along the longitudinal field without and with stripper foil.

Without the stripper, the eigen-emittance variation which is created by the entrance fringe field would be canceled by the exit fringe field and the beam experiences a symplectic transformation. The input and output rms-emittances are same. If the stripper is considered, the exit fringe is passed by the beam with reduced rigidity, thus overcompensating the eigen-emittances variation, and at the exit of longitudinal field region, a coupled output beam is achieved.

The foil stripper itself is modeled by increasing the spread of the angular distribution through scattering. Because of scattering the rms-emittances increase during the stripping process, and the output rms-emittances are larger than the input values. The particle distributions before and after the stripper are illustrated in Fig. 4.

COUPLING CORRECTION SECTION

The coupling correction section starts at the exit of the longitudinal field, which is then followed by a normal triplet and a skew triplet separated by appropriate drift space. A simple realization of such a system is sufficient to remove inter-plane correlations exhaustively. Along the subsequent elements after the solenoid, the gradients of

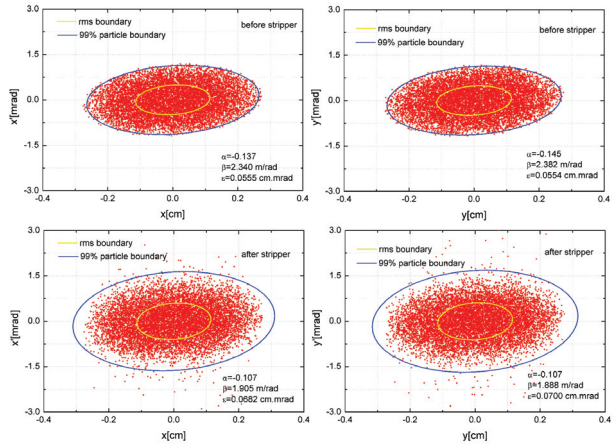

Figure 4: The particle distributions before and after foil.

normal and skew triplet are determined numerically to correct four ($\langle xy\rangle$, $\langle x'y'\rangle$, $\langle x'y\rangle$, and $\langle xy'\rangle$) beam correlations, respectively. This scheme allows total correction of any arbitrary linearly coupled beam with correction range limited only by the available quadrupole strength.

Our design process is to produce inter-plane correlations non-symplectically, thus changing the eigen-emittances in the longitudinal field, then remove them symplectically by the following quadrupole correction section. Fig. 5 shows the simulation of this process, the optics of the quadrupole correction section has been designed to bring the horizontal rms-emittance down to the lower eigen-emittance.

After the quadrupole correction section the output uncoupled beam is divergent, and since there is still a long drift space between the quadrupole correction section and the emittance measurement, another normal triplet is required. The particle distributions at the position of emittance measurement are shown in Fig. 6. The inter-plane correlations between the horizontal and vertical phase spaces are removed ($\varepsilon_x = \varepsilon_1$).

MACHINE-RELATED ERRORS

There are many sources of magnet imperfection, which are mainly generated by gradient fluctuations, rotational angle errors, and misalignment errors. The misalignment errors of the quadrupole cause the beam trajectory to deviate from and oscillate around the designed path in the beam line, but the values of rms-emitances and eigen-emittances are not affected. The gradient fluctuation errors and the rotational angle errors are the potential sources of inter-plane correlations not be removed exhaustively. We use a statistical method in which the error values of each magnet are randomly generated under given maximum values. The influences of these errors on the rms-emittances and eigen-emittances are shown in Fig. 7.

In the presence of the gradient errors, the fluctuations of the rms-emittances and eigen-emittances are not obvious, and the values of rms-emittances and eigen-emittances are almost the same and the cross-plane coupling beam after

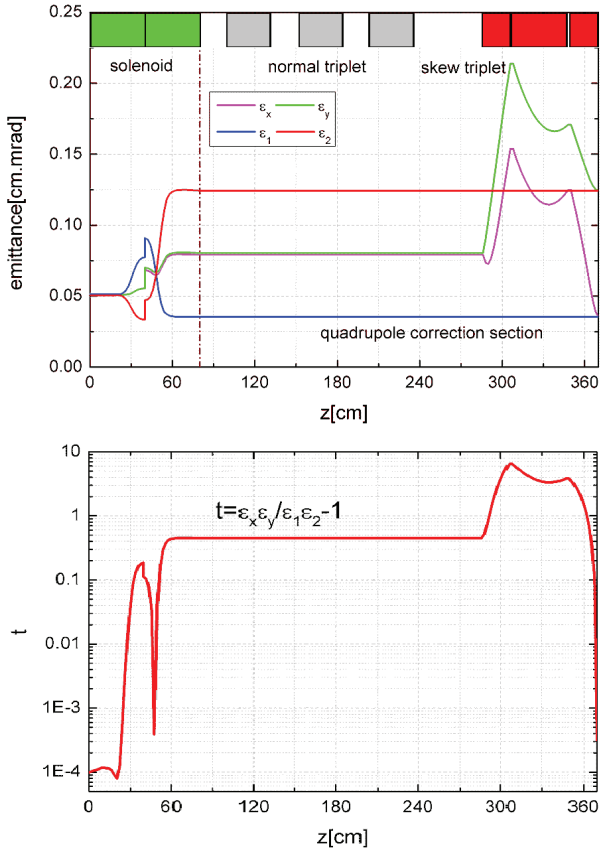

Figure 5: The emittances and the beam rms sizes along the longitudinal field and quadrupole correction section.

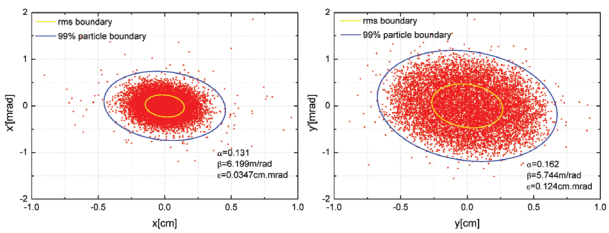

Figure 6: The particle distributions at the end of beam line.

stripper can be corrected to a large degree.

In the presence of the rotational angle errors, the values of lower eigen-emittances are almost constant but the values of horizontal rms-emittances are varied. This bias may lead to attempting to correct the implied coupling, which will actually introduce coupling rather than correct it.

Based on the manufacturing experiences of the UNILAC, the maximum values of gradient fluctuation, rotational angle and misalignment errors are 0.1% and 0.3 degree.

CONCLUSION AND OUTLOOK

The longitudinal field strength and beam sizes at the stripper foil are free parameters, the amount of emittance transfer scales with the field strength and beam rms sizes.

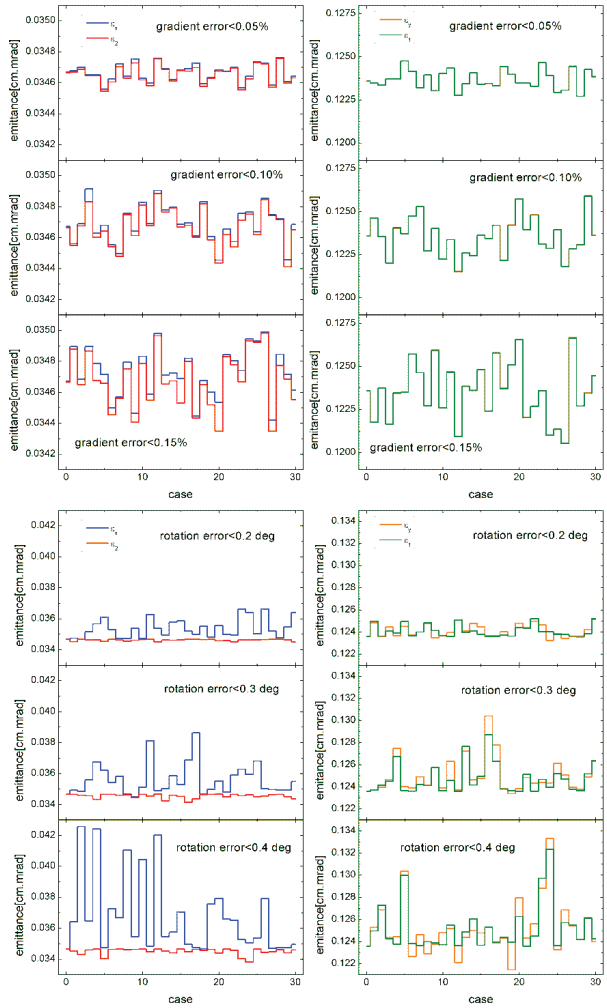

Figure 7: The influences of the gradient fluctuation and rotational angle errors.

This freedom makes the difference to a emittance swapping scheme. The simulations illustrate that the combination of a normal triplet and a skew triplet has ability to correct a coupled beam, and the beam line errors degrade the accuracy of correction.

GSI aims at experimental verification of emittance transfer by assembling the beam line presented in this paper, and the corresponding hardwire devices are under manufacturing. The beam experiment is planned for early 2014.

STATUS OF THE IFMIF-EVEDA 9 MeV 125 MA DEUTERON LINAC

A. Mosnier, Fusion for Energy, BFD Department, Garching, Germany

Abstract

The scope of IFMIF/EVEDA has been recently revised to set priority on the validation activities, especially on the Accelerator Prototype (LIPAc) extending the duration up to mid 2017 in order to better fit the development of the challenging components and the commissioning of the whole accelerator. The present status of LIPAc, currently under construction at Rokkasho in Japan, outlines of the engineering design and of the developments of the major components will be reported. In conclusion, the expected outcomes of the engineering work, associated with the experimental program will be presented.

INTRODUCTION

The International Fusion Materials Irradiation Facility (IFMIF) aiming at generating materials irradiation test data for DEMO and future fusion power plants is based on an accelerator-driven, D-Li neutron source to produce high energy neutrons at sufficient intensity and irradiation volume. IFMIF Engineering Validation and Engineering Design Activities (EVEDA) have been conducted since mid 2007 in the framework of the Broader Approach Agreement.

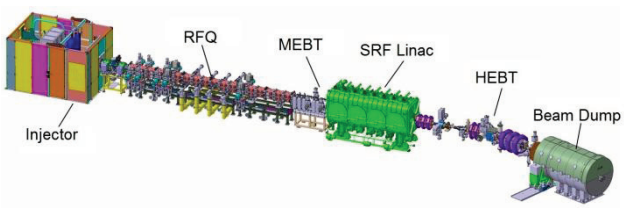

Figure 1: LIPAc layout

In order to demonstrate the feasibility and to develop the technology, a representative portion of one of the two IFMIF accelerators, up to the first section of the SRF Linac, is being designed and built. This high intensity linear accelerator prototype, called LIPAc (Fig. 1), will be assembled and commissioned at Rokkasho in Japan, with the objective to reach a stable 125 mA, 9 MeV continuous deuteron beam. These engineering validation activities are conducted since mid-2007 under the framework of the Broader Approach Agreement and are shared as follows:

- The accelerator components are designed, manufactured and tested by European institutions (CEA, CIEMAT, INFN, SCK-CEN): Injector, Radio Frequency Quadrupole (RFQ), Medium and High Energy Beam Transport lines, Superconducting RF Linac, Beam Dump, 175 MHz RF Systems, Local Control Systems, Beam Instrumentation;
- The conventional facilities (building and auxiliaries), the Central Control System, as well as the RFQ couplers, are provided by JAEA;
- The design integration and the interface management are coordinated by Fusion for Energy (F4E);
- The coordination and the integration on site are provided by the Project Team hosted in Rokkasho.

In 2010, the priority was set on the validation of the Accelerator Prototype [1] extending the duration up to mid 2017 in order to better fit the time required for the development of the challenging components and for the installation and sequential commissioning of the accelerator at Rokkasho.

ACCELERATOR COMPONENTS

Accelerator components [2] are designed, manufactured and individually tested in Europe, and then transported to Rokkasho for installation in the accelerator building.

Injector

The injector has to deliver a continuous low emittance deuteron beam (140 mA, 100 keV) with high reliability. The ion source is based on an electron cyclotron resonance cavity, excited by a 2.45 GHz magnetron [3]. The extracted beam is matched to the RFQ entrance by means of a dual solenoid focusing scheme in the LEBT. In order to meet emittance and matching requirements, the space charge must be highly compensated by injection of krypton gas and up to the RFQ entrance thanks to an electron repeller electrode. In addition, an electrostatic chopper will be implemented between the two solenoids to enable the operation of LIPAc with short pulses of very sharp rise/fall times.

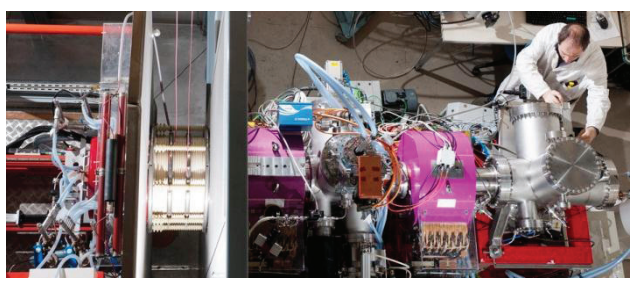

Figure 2: Top view of the Injector (P. Stroppa/cea credit).

The injector was assembled at CEA-Saclay in order to test the components in Europe before the shipment to Japan scheduled at the beginning of 2013 (Fig. 2). After the first H+ beam produced in May 2011, a test campaign was carried out in pulsed and continuous operation. Pulsed beams of 150 mA at 100 kV and continuous beams of 100 mA at 75 kV were routinely produced. The first D+ beam was extracted in April 2012, first in pulsed mode and then in continuous mode for a short period in order to limit the activation of the elements. However, as the continuous operation at 100 kV was limited by HV discharges in the extraction system, a new 5 electrode

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

system (instead of the former 4 electrode system) is being installed and injector tests will start gain at the end of September 2012 to complete the optimization (ion source plasma, krypton pressure, solenoid setting) and characterize the beam emittance which should be lower than 0.25 π mm mrad.

Radiofrequency Quadrupole

The 4-vane RFQ, under development by INFN, has to bunch the DC beam from the injector and to accelerate the beam from 0.1 to 5 MeV. The 10 m long cavity is composed of 18 x 0.54 m long modules flanged together (Fig. 3). The peak surface electric field is limited to a maximum value of 1.8 x Kilpatrick's criterion.

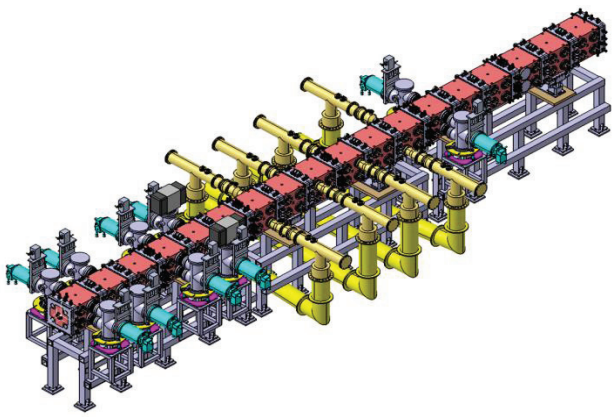

Figure 3: 3D mock-up of the RFQ equipped with RF couplers, cryo-pumps, slug tuners and cooling channels.

The RF power (about 1300 kW) is injected by 8 loop couplers, using 6 1/8" RF windows. High power tests have been performed with a high-Q load circuit at JAEA-Tokai. Final acceptance tests and RF conditioning in TW mode of two complete couplers (waveguide, window and tip modules) will be performed at INFN-Legnaro at the beginning of 2013 on a specific test bench [4] including a coupling cavity. The manufacturing of the other couplers will start just after approval of the acceptance tests.

The RF tuning of the RFQ is ensured by 22 slug tuners per quadrant. An aluminium full scale RFQ model has been built to validate the tuning procedures and the mode stabilization by means of bead-pull measurements. The tuning algorithm allowed reaching voltage errors of ±1% in 4 iterations only.

The cooling system is able to remove the dissipated power in the structure (more than 700 kW assuming 10% extra field) but also to regulate the resonance frequency and to keep the correct field profile, thanks to four independent circuits, enabling the temperature difference between the vane and the outer walls to be independently adjusted in the 3 super-modules.

A vacuum system, composed of dry primary and 10 cryogenic pumps, provides a high pumping speed to balance the gas load (dominated by beam losses), resulting in a pressure profile below 5 10^{-7} mbar all along the RFQ.

In order to test the production procedure, a full scale technological prototype (30% shorter) has been machined in INFN and brazed at CERN in two steps (1st horizontal, 2nd vertical). Leak tests and dimensional checks have been passed successfully (average vane displacement close to the target of 50 µm).

The module production [5] has been split into 3 super-modules (SM), composed of 6 modules each:

- high energy SM with homogenous aperture
- intermediate energy SM with z-dependent aperture
- low energy SM

One module of the high energy SM has been machined and brazed (Fig. 4). A maximum deformation of 100 µm has been measured, still acceptable but at the limit of the specification, and might be corrected for the next modules by using the appropriate annealing cycle and improved fixation tooling. Three modules (plus the RF plug) will be completed in November 2012 for high power tests, planned at the beginning of 2013 at INFN-Legnaro.

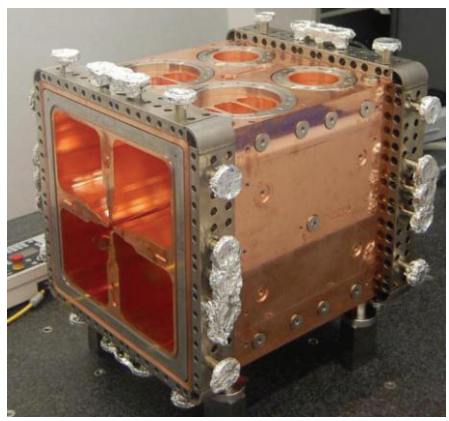

Figure 4: First RFQ module completed

SRF Linac

The high-energy section of LIPAc accelerates the beam to 9 MeV and consists of the first cryomodule (Fig. 5) of the IFMIF SRF Linac, housing eight superconducting half-wave resonators (HWR) and eight solenoid packages. The main cavity and magnet parameters are listed in Table 1.

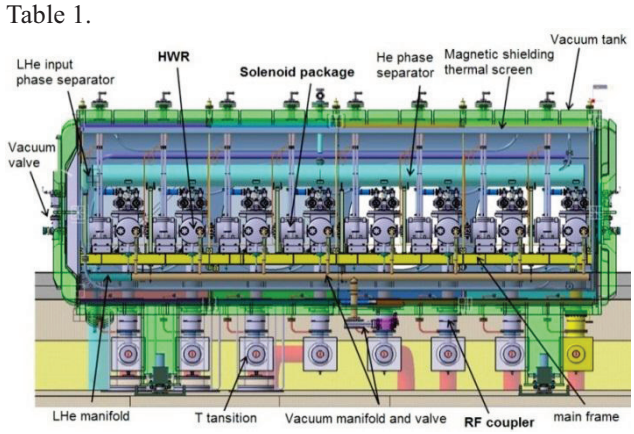

Figure 5: 3D mock-up of the LIPAc Cryomodule

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

RF optimisation of the HWR geometry lowered the electric and magnetic peak surface fields down to E_p/E_{acc}=4.4 and B_p/E_{acc}=10.1 mT/MV/m.

Table 1: Main Parameters of Cavity and Solenoid

Frequency	175	MHz
Cavity β	0.094	
Accelerating field Eacc	4.5	MV/m
Quality factor Qo	1.4 10^9	
Max. forward Power / coupler	200	kW
Max. Tuning range	± 50	kHz
Beam aperture cavity/solenoid	40 / 50	mm
Magnetic field Bz on axis	6	T
Field at cavity flange	≤ 20	mT

The original design of the tuner relied on a capacitive plunger with a large membrane to allow an elastic deformation of ±1 mm. Two prototype cavities have been fabricated (Fig. 6) and tested at cold temperature. Unfortunately, results showed a low Qo, as well as a quench at low field, pointing to a suspect plunger. In addition, potential problems occurring in the main cavity body cannot be also ruled out [6]. Following up the recommendations of a Review Panel, a new design based on a conventional compression tuner principle is under development [7]. Given the rigidity of the present resonator design, this solution implies a lengthening of the cryomodule lattice (about 10 cm) to ease the integration of the tuner between the HWR tank and the solenoid package.

Figure 6: HWR prototype.

The RF coupler [8] is composed of a water-cooled Cu antenna, a disk ceramic window, an external conductor made of helium cooled double wall tube and a tee transition between the input coaxial line and the coupler, including a duct for the cooling water. Pairs of couplers will be tested and conditioned at room temperature by means of a coupling box, especially developed to achieve large bandwidth and low losses. Two prototype couplers have been fabricated (Fig.7, left) and will be tested when the 200 kW RF source will be available, planned at the end of 2012.

The beam focussing and orbit corrections are performed by 8 sets of superconducting solenoids/steerers and beam position monitors, located before each HWR. The NbTi solenoid includes an active shielding made of a concentric outer solenoid in antiparallel configuration to lower the stray field below 20 mT at the cavity flanges. During the cold tests at 4.2K performed in a vertical cryostat (Fig. 7, right), the theoretical critical current of the magnet was reached (at about 260 A, well above the nominal current of 210 A) with a very short training [9].

The design of the cryomodule is now almost completed: cavity vacuum and cryostat insulation vacuum are separated in order to ensure a good vacuum quality. The 5-m long cryostat includes the magnetic shielding to protect the HWR from the earth magnetic field, two independent 4.5K helium circuits to cool down the cavities and the magnets, a helium phase separator and a thermal shield cooled at 60K by GHe.

Figure 7: coupler prototype (left) solenoid test (right).

MEBT, HEBT and Beam Dump

Five quadrupoles and two bunchers in the MEBT [10] fulfil the transverse and longitudinal matching conditions of the RFQ output beam to the SRF input (Fig. 8). A prototype magnet has been fabricated and validated in a magnetic test bench. A 5-gap IH buncher meets the voltage requirement (350 kV) with a minimum RF power dissipation. A prototype buncher is under fabrication and power tests are planned at mid-2013. The beam halo and out-of-energy particles coming from the RFQ are stopped in two movable scrapers, designed for a maximum 500 W

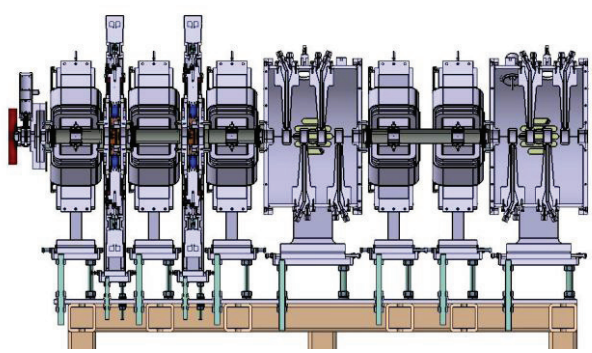

Figure 8: Medium Energy Beam Transport line.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

The HEBT (Fig. 9) which transports the beam from the Linac to the beam dump includes the following elements:

- a Diagnostics Plate for the beam characterization
- a bending magnet to reduce the neutron radiation from beam dump towards upstream components
- a magnetic beam expander to limit the power density on the beam dump (< 200 kW/cm^2)
- a lead shutter, closed during beam shutdown to act as a gamma shield from the activated beam dump
- a beam scraper to protect the last portion of the vacuum pipe in front of the beam dump.

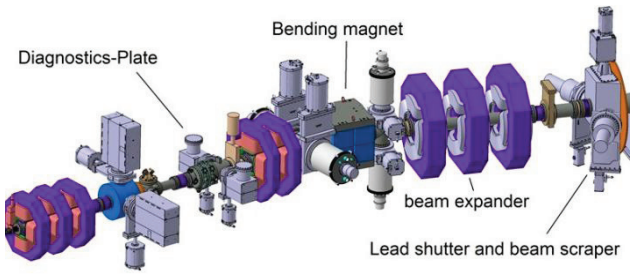

Figure 9: High Energy Beam Transport line.

A conical dump [11] made of copper has been designed to stop the 1.125 MW deuteron beam (Fig. 10). It is cooled by a high velocity water flow that circulates through an annular channel along the outer surface of the cone. Thermo-mechanical studies showed a high robustness to beam errors, CW and pulsed mode operation, buckling and high velocity coolant flow effects. A local shielding made of water tanks and polyethylene against neutrons and iron blocks against gamma rays associated with an extra frontal shielding made of a 70 cm thick concrete wall to fulfil the radiological protection requirements: low dose rates outside the accelerator vault during accelerator operation and manual maintenance inside the accelerator vault possible during beam-off phases. The HEBT and the beam dump are in the final stage of detailed design, and cartridge prototypes have been built. Hydraulic test of a full scale cartridge is on-going. Integration and test of the complete beam dump is planned at mid-2013.

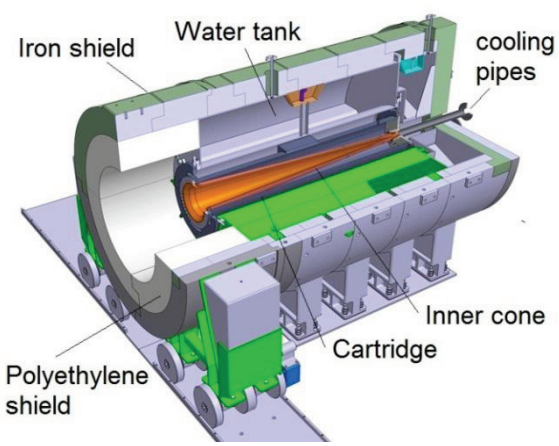

Figure 10: Beam Dump.

RF Power Systems

The RF Power System [12] is composed of 18 RF power generators to feed the 8 RFQ couplers (200 kW), the 8 superconducting half wave resonators of the SRF Linac (105 kW) and the 2 buncher cavities (16 kW). Except for the buncher cavities, which are fed by full solid-state amplifiers, the same topology has been chosen for all the power chains for standardization and scale economy reasons: they use the same main components (solid-state pre-driver and tetrodes for driver and final amplifier) which can be individually tuned to provide different RF output powers up to 200 kW (Fig. 11). The first prototype 200 kW RF source will be ready by the end of 2012 and will be used for the testing and conditioning of the HWR couplers while the first 2 x 100 kW RF module is expected at the beginning of 2013. The 16 kW solid-state amplifier should be ready for the high power tests of the buncher cavities at mid-2013.

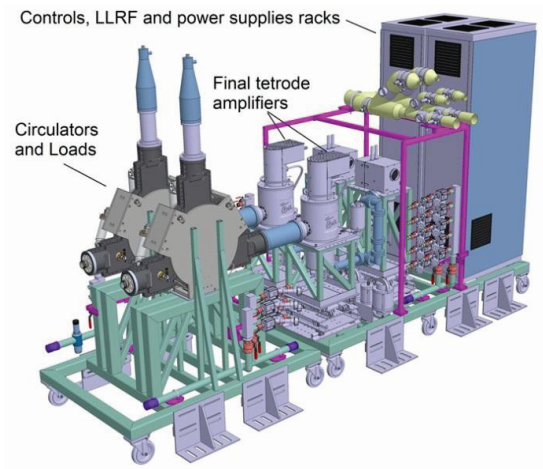

Figure 11: RF module with two 100 kW amplifiers.

Beam Diagnostics

A full set of non-interceptive diagnostics [13] to monitor and to characterize the beam all along the accelerator has been developed (Fig. 12): current monitors of various types (ACCT, DCCT, FCT), 20 beam position monitors (8 of them at cryogenic temperature), beam profile monitors (based on ionization and fluorescence of the residual gas), about 40 beam loss monitors (ion chamber LHC type), micro-loss monitors (based on CVD diamond operating at cryogenic temperature) and a bunch length monitor (residual gas). For short chopped beam pulses, SEM grids and slits will be used for emittance and energy spread measurement.

In addition, a Diagnostic plate (D-Plate) combines specific diagnostics to characterize the beam during commissioning with the beam, and will be located first at the exit of the RFQ and MEBT and second at the exit of the SRF Linac during LIPAc normal operation (Fig. 13).

The Control System (including Central Control System, Local Area Network, Personnel Protection System, Machine Protection System, Timing System, Local Control System) based on EPICS, is in progress [14].

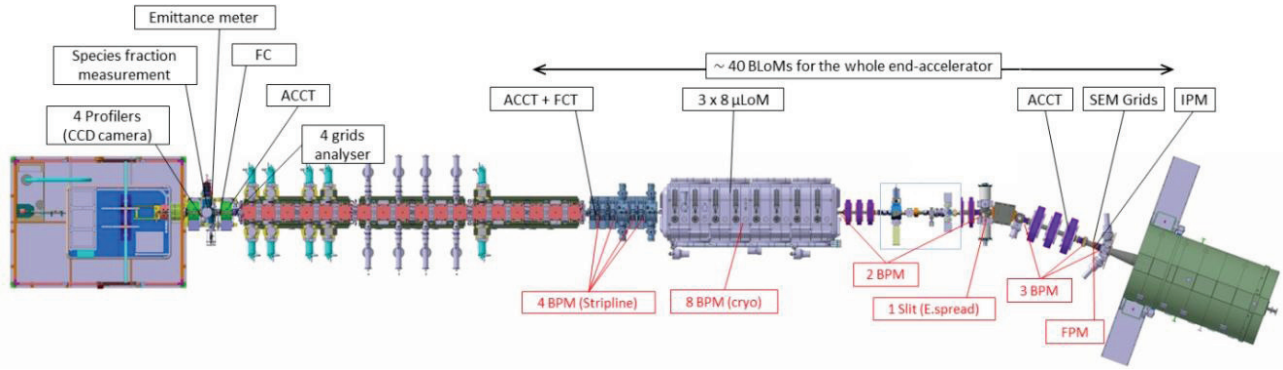

Figure 12: Beam instrumentation along the accelerator.

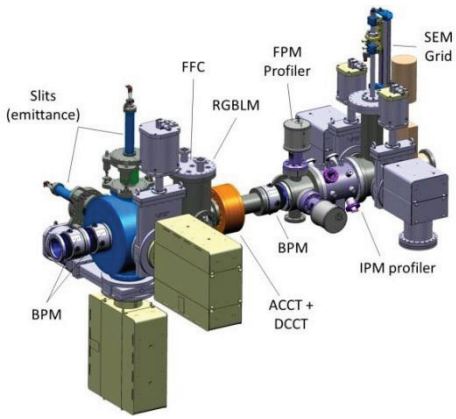

Figure 13: Diagnostics Plate.

ACCELERATOR BUILDING

The building (Fig. 14), completed in Rokkasho in March 2010, consists of an accelerator vault, a nuclear heating, ventilation and air conditioning (HVAC) area, a heat exchange and cooling water area for both radiation controlled and non-controlled areas, an access room, a control room, and a large hall for power racks, RF systems (HVPS and RF power chains) and the 4K refrigerator. The accelerator vault is surrounded by 1.5 m thick concrete walls and ceiling. The installation of the main auxiliaries has been completed and the first accelerator component, the injector, will be delivered and installed at the beginning of 2013.

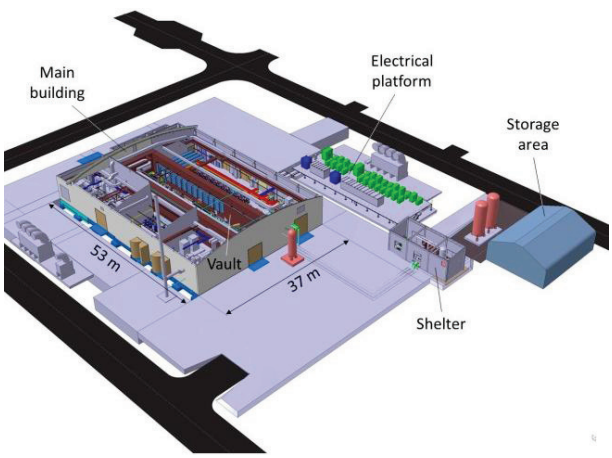

Figure 14: Building mock-up.

ACKNOWLEGMENT

This paper summarizes the collaborative work of many Institutions (F4E, CEA, CIEMAT, INFN, SCK-CEN in Europe and JAEA in Japan) for the LIPAc Project in the framework of the Broader Approach Agreement. Thus the author gratefully acknowledges the hard work and dedication of the entire staff involved in LIPAc which made possible the results presented herein.

CHINESE ADS PROJECT AND PROTON ACCELERATOR DEVELOPMENT*

W.M. Pan#, Y.L. Chi, S.N. Fu, P. Sha, IHEP, Beijing, P.R.China
Q.Z. Xing, Tsinghua University, Beijing, P.R.China

Abstract

Significance of proton accelerator on the science and application has been widely recognized in the 21st century. The high-current proton accelerator can be utilized to drive the sub-critical nuclear reactor to build the clean nuclear power system. Moreover, it can serve in the field of high-energy physics, such as the neutrino factory and muon collider. For the spallation neutron source, the high-current proton accelerator provides the important platform for the multidisciplinary development of condensed matter physics, radiation physics, material science, aerospace science and life science. So proton accelerator is developing very fast in China nowadays. There're many proton accelerators under construction over China, which includes Accelerator Driven Sub-critical System (ADS), China Spallation Neutron Source (CSNS), Compact Pulsed Hadron Source (CPHS). These three projects will be introduced in this paper.

INTRODUCTION

ADS [1], CSNS [2] and CPHS have common ground, but are applied in different fields. They're all ongoing in China at present.

ADS ACCELERATOR

ADS project is a strategic plan to solve the nuclear waste problem and the resource problem for nuclear power plants in China [3]. It's supported financially by the central government and administrated by the Chinese Academy of sciences (CAS). With its long-term planning lasting until 2032, the project will be carried out in three major phases, see Figure 1.

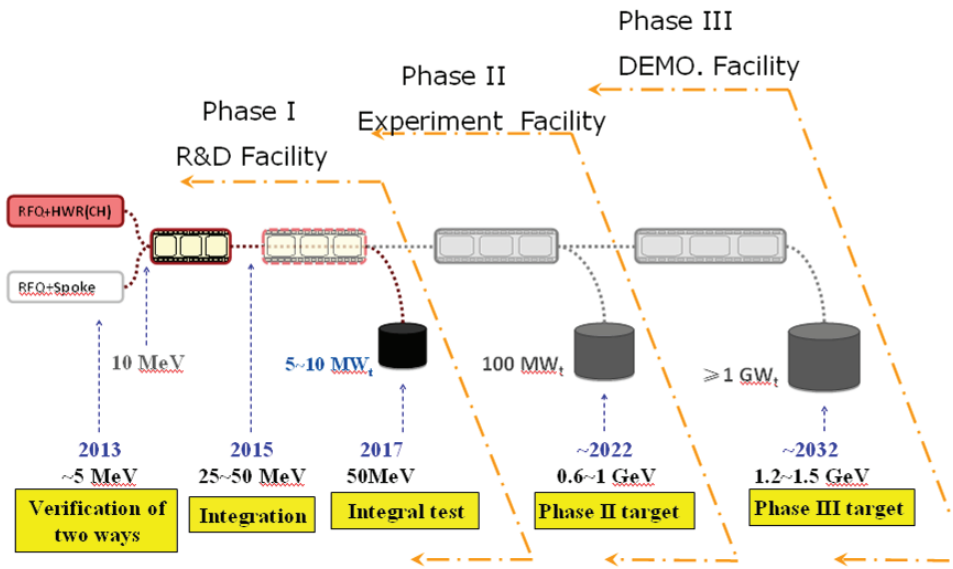

Figure 1: Road map of ADS

ADS accelerator will be built by two institutes of CAS: Institute of High Energy Physics (IHEP) and Institute of Modern Physics (IMP). It's a CW proton linac and uses superconducting acceleration structures except RFQ, the design specifications for the proton beam are shown in Table 1. For Phase I, the goal is to build a CW proton linac of 50 MeV and 10 mA by about 2015. Phase I will be executed progressively in several steps, with the 1st step to build two 5-MeV test stands of different front-end designs.

Table 1: ADS Proton Beam Specifications

Parameters	Value	Units
Energy	1.5	GeV
Current	10	mA
Beam power	15	MW
Frequency	162.5/325/650	MHz
Duty factor	100%	
Beam Loss	<1 (0.3)	W/m
Beam trips/year [4]	<25000 <2500 <25	1s<t<10s 10s<t<5m t>5m

Design Philosophy

For the ADS accelerator, it has the characteristics of very high beam power and very high reliability which are not possessed by any of the existing proton linacs. However, several proposed CW proton/deuteron linac projects are good models for the physics and technical design, such Project-X, EFIT or MYRRHA, IFMIF and EURISOL. In addition, some pulsed high power proton linacs and some CW heavy ion linacs using superconducting cavities also serve as good examples. In general, there're several key points:

- It has been common understanding that superconducting proton linac is the best choice as an ADS driving accelerator, compared with other accelerator types which are still further away from the requirements as shown in Table 1. So hundreds of superconducting cavities (HWR, spoke, Elliptical) are widely used, as Figure 2 shows.
- High reliability is the most crucial for ADS. To achieve this goal, it's necessary to have enough redundancy for the entire accelerator. For the very low energy part, it's difficult to apply the local compensation as main linac, thus two parallel injectors are adopted. When one is on operation, the other is hot-spare and can be switched to the operation quickly. Figure 2 show that.
- Another key point of design is that beam losses should be kept as low as possible along the linac, with a usual acceptance of 1 W/m for all high-power proton accelerators. This is more difficult for the ADS, the beam power of which is 10 times higher. It also means a beam loss rate of 7e-8/m at the higher energy part, and requires very delicate error and beam loss studies.
- Beam emittance in the 3-D planes is very important. As the beam loss rate should be controlled at an extremely low level, all the measures should be considered to control the emittance growth along the linac, especially the halo emittance that is directly linked to the beam loss. Anyway, the total geometry emittance may increase during the acceleration due to all the errors and mismatches, so big physical aperture is adopted at higher energy section.

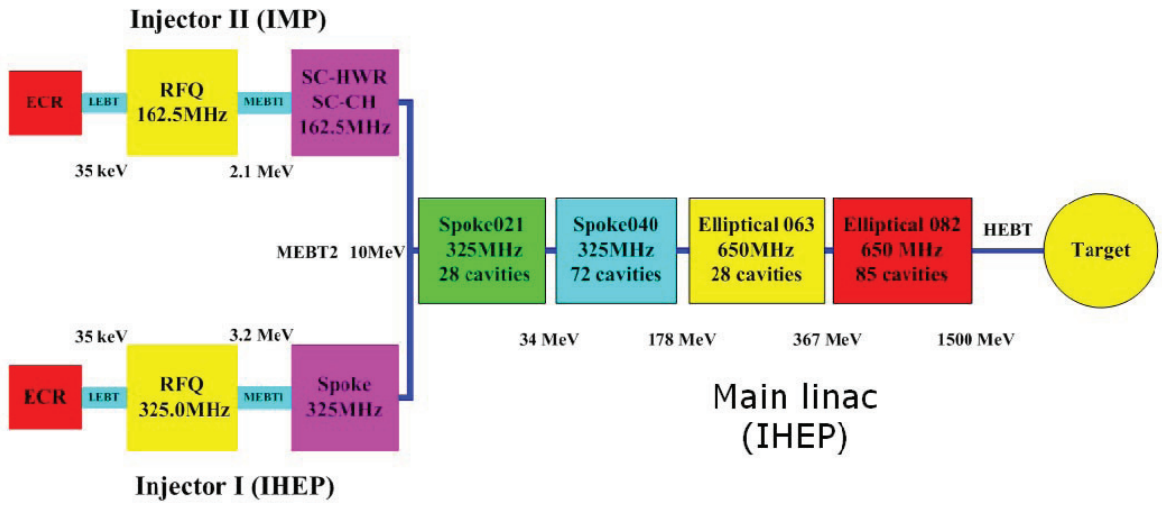

Figure 2: Layout of ADS accelerator

Injector I

Injector I will be built by IHEP, which Figure 2 demonstrates. The frequency of RFQ and Spoke cavity is 325 MHz, which is the same as Project-X. CW RFQ and low beta superconducting spoke cavity are the obstacles Injector I faces.

Currently, the design of RFQ has been determined, and the machining of prototype is ongoing now. Table 2 indicates main parameters of RFQ.

Table 2: Main RFQ Parameters

Parameters	Value	Units
Injection energy	35	keV
Output energy	3.2	MeV
Pulsed beam current	15	mA
Beam duty factor	100%	
Beam transmission	98.7%	
Total power	320.94	kW
Accelerator length	469.95	cm

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Although very low-beta single spoke cavity are considered very difficult to develop and lack of experience, it's straightforward for IHEP to adopt such a spoke cavity for the superconducting acceleration structure in the Injector I since the main linac uses the same type of cavities but with higher beta, which will reduce the time and cost in the cavity development. Main parameters are listed in Table 3.

Table 3: Main Parameters of Spoke Cavity

Parameters	Value	Units
Diameter	468	mm
length	180	mm
Beam aperture	35	mm
Beta	0.12	
R/Q	142	Ω
G	61	Ω
Epeak/Eacc	4.54	
Bpeak/Eacc	6.37	mT/(MV/m)

Now the prototype of spoke cavity is under machining now (Figure 3), which may finish in Oct, 2012. Then the vertical test may be done at the end of 2012.

Figure 3: Spoke bars after welding.

Injector II

IMP is in charge of Injector II [5], the frequency of which is 162.5 MHz, half of the frequency of main linac. It can reduce the power density of RFQ, thus the difficulty of cooling. Therefore, 162.5-MHz half wave resonator (HWR) is adopted. Furthermore, superconducting CH cavity is also a potential choice.

The physics design of RFQ, which is developed by collaboration with LBNL, has been completed. Table 4 shows main parameters. And the prototype is being fabricated now. The fabrication of HWR cavity is together with spoke cavity. It may finish in October of 2012, too.

Table 4: Main Parameters of RFQ

Parameters	Value	Units
Injection energy	35	keV
Output energy	2.1	MeV
Pulsed beam current	15	mA
Beam duty factor	100%	
Beam transmission	99.5%	
Total length	420.8	cm

Figure 4: Outer tube of HWR.

CSNS LINAC

CSNS is the first large-scale, high-power accelerator project to be built in China. It locates at Dongguan, Guangdong province. Through years of preparation, it has began the construction in Sep, 2011. The goal is that it will provide 100 kW proton beam (1.6GeV) on a target in 2018. The total budget of CSNS is $260,000,000, which includes an 80-MeV H- linac, a 1.6-GeV cycling synchrotron, the spallation neutron target and 3 neutron spectrometers, as Figure 5 shows.

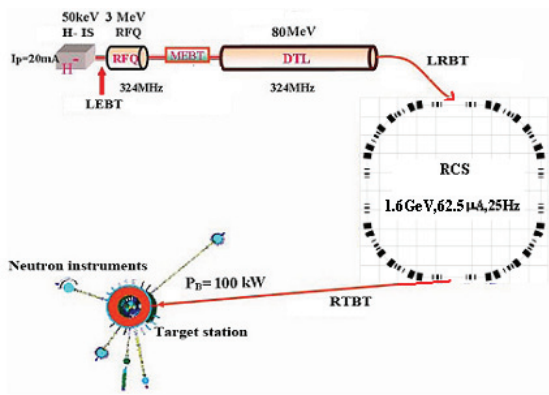

Figure 5: Schematics of CSNS.

Physics Design

CSNS accelerator [6] can produce proton beam of 1.6-GeV kinetic energy at 25 Hz repetition rate, striking a solid metal target to launch neutrons. Table 5 lists main parameters.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Table 5: CSNS Parameters

Project Phase	I	II
Beam Power on target [kW]	100	500
Proton energy t [GeV]	1.6	1.6
Average beam current [μA]	62.5	312.5
Linac energy [MeV]	80	250
Linac RF frequency [MHz]	324	324
Macropulse duty factor	1.0	1.7
RCS circumference [m]	228	228
RCS harmonic number	2	2
RCS Acceptance [πmm mrad]	540	540

The linac is made up of H- ion source, LEBT, RFQ, MEBT and DTL. But superconducting cavities (spoke or elliptical) will be applied in Phase II.

Present status

According to the plan, CSNS linac will start installation at the end of 2013 when the linac tunnel becomes available. Almost all the linac components have started fabrication or procurement at present.

CPHS PROJECT

CPHS in the Dept. Engineering Physics, Tsinghua University, is driven by one pulsed high-current proton linear accelerator. The accelerator consists of the Electron Cyclotron Resonance (ECR) ion source, Low Energy Beam Transport (LEBT) line, Radio Frequency Quadrupole (RFQ) accelerator, Drift Tube Linac (DTL) and High Energy Beam Transport (HEBT) line. The function of the whole accelerator system is to produce the proton beam, accelerate it to 13MeV, and deliver it to the target where one uniform round beam spot is obtained with the diameter of 5 cm. The whole performance of the CPHS facility relies critically on the accelerator system.

Four neutron beam lines are planned in the CPHS project at Tsinghua University, among which two lines are being constructed for the Small Angle Neutron Scattering (SANS) and neutron imaging. The neutron will be generated by the proton beam bombarding a Beryllium target.

Design

Main parameters of CPHS accelerator is listed in Table 6. Figure 6 is the layout of CPHS.

Table 6: Main Parameters

Parameters	Value	Units
Beam power	16	kW
Beam energy	13	MeV
Average current	1.25	mA
Pulse repetition rate	50	Hz
Protons per pulse	1.56×10^{14}	
Charges per pulse	2.5×10^{-5}	C
Pulse energy	0.325	kJ
Pulse length	500	μs
Peak current	50	mA
Beam duty factor	2.5	%
RF frequency	325	z MH
Output energy of the ion source	50	keV
Output energy of the RFQ	3	MeV
Output energy of the DTL	13	MeV

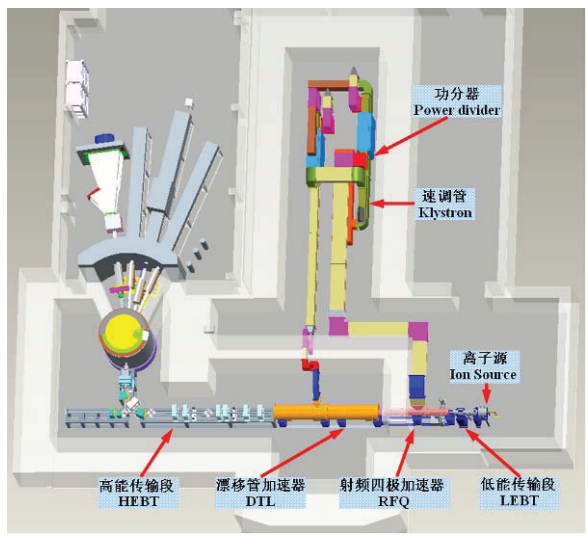

Figure 6: Layout of CPHS.

ECR Ion source and LEBT

The Electron Cyclotron Resonance (ECR) ion source is adopted to produce the proton beam. A three-electrode extraction system is to extract the 50keV proton beam from the plasma chamber. The LEBT matches the proton beam produced by the ion source to the RFQ accelerator. The 1.4m-long LEBT consists of two solenoid lens, two steering magnets, two diagnostic champers and one cone structure (the cone, ACCT and electronic trap).

The ECR proton source and LEBT are under conditioning now, and the maximum output proton beam has reached 60 mA, as Figure 7 shows.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

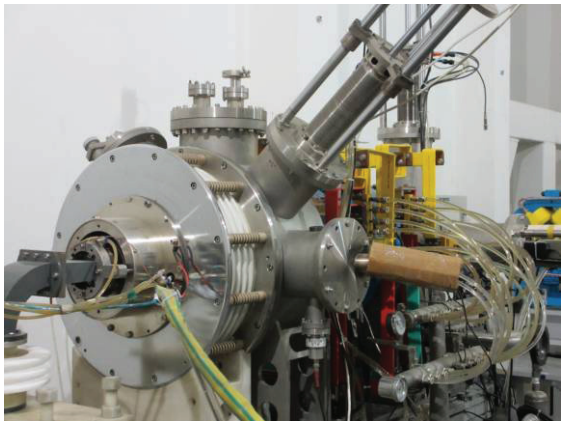

Figure 7: ECR and LEBT.

RFQ

Maintaining the good quality of the beam, Radio Frequency Quadrupole (RFQ) accelerator can bunch, focus and accelerate the low-energy CW proton beam from the ion source. The CPHS RFQ has a structure of four-vane and accelerates protons from 50keV to 3MeV. The inter-vane voltage increases with the beam energy. The total length of the RFQ is greatly shortened with a high transmission rate. The coupling plates are not necessary for the 3 m-long RFQ. The RFQ are designed to be matched to the DTL directly without MEBT.

Machining, brazing and assembly of the RFQ (3MeV/50mA) have been finished, and the result of the cold test at THU is satisfactory, which Figure 8 shows.

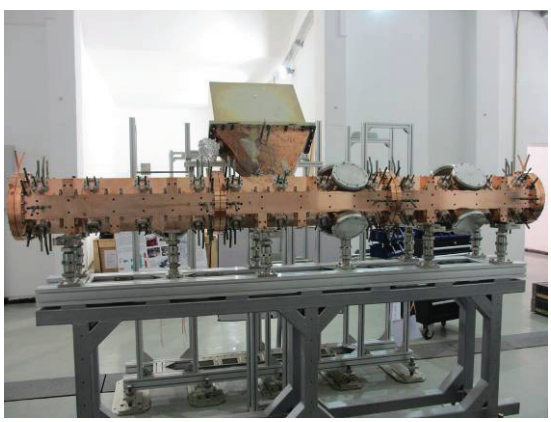

Figure 8: RFQ.

DTL

Samarium-cobalt permanent magnets are adopted as the transverse focusing quadrupoles for the CPHS DTL . The field gradient is designed to be almost constant (84.6 T/m). The lattice structure is FDFD, which ensures small envelop of the beam. The DTL is matched directly with the RFQ accelerator. The average accelerating field increases almost linearly from 2.2MV/m to 3.8MV/m.

The construction of the DTL will be completed in 2013.

HEBT and Target

The CPHS HEBT (Figure 9) is to deliver the 13MeV proton beam accelerated by the DTL to the target station, with minimum beam loss, and obtain one uniform round beam spot with the diameter of 5 cm on the target. To decrease the influence of the recoil neutrons on the DTL, the proton beam is deflected before it bombards the target.

To carry out the proton irradiation experiment with the 13MeV proton beam directly bombarding the target, one straight beam line is designed simultaneously. Two sweeping magnets are designed to obtain the uniform beam spot of 10cm×10cm on the target.

Figure 9: HEBT and target station.

While the HEBT beam line is ready, the 3 MeV proton beam will be used to produce the neutron at the end of 2012.

ACKNOWLEDGMENT

Colleagues of IHEP, IMP, Tsinghua University contribute to this paper. Thanks for them!

Abstract

The Facility for Rare Isotope Beams (FRIB) at MSU includes a driver linac that can accelerate all stable isotopes to energies beyond 200 MeV/u at beam powers up to 400 kW. The linac consists of 330 superconducting quarter- and half-wave resonators operating at 2 K temperature. Physical challenges include acceleration of multiple charge states of beams to meet beam-on-target requirements, efficient production and acceleration of intense heavy-ion beams from low to intermediate energies, accommodation of multiple charge stripping scenarios (liquid lithium, helium gas, and carbon foil) and ion species, designs for both baseline in-flight fragmentation and ISOL upgrade options, and design considerations of machine availability, tunability, reliability, maintainability, and upgradability. We report on the FRIB accelerator design and developments with emphasis on technical challenges and progress.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB), baselined as a 7-year, US$680 million construction project, is to be built at the Michigan State University under a corporate agreement with the US DOE [1]. FRIB driver accelerator is designed to accelerate all stable ions to energies above 200 MeV/u with beam power on the target up to 400 kW (Table 1). As shown in Figure 1, the driver accelerator consists of Electron Cyclotron Resonance (ECR) ion sources, a low energy beam transport containing a pre-buncher and electrostatic deflectors for machine protection, a Radiofrequency Quadrupole (RFQ) linac, linac segment 1 (with Quarter-wave Resonators (QWR) of β=0.041 and 0.085) accelerating the beam up to 20 MeV/u where the beam is stripped to higher charge states, linac segments 2 and 3 (with Half-wave Resonators (HWR) of β=0.29 and 0.53) accelerating the beam above 200 MeV/u, folding segments to confine the footprint and facilitate beam collimation, and a beam delivery system to transport to the target a tightly focused beam. The reaccelerator (ReA) consists of similar β=0.041 and 0.085 accelerating structures [2].

Table 1: FRIB Driver Accelerator Primary Parameters

Parameter	Value	Unit
Primary beam ion species	H to ^{238}U	
Beam kinetic energy on target	> 200	MeV/u
Maximum beam power on target	400	kW
Macropulse duty factor	100	%
Beam current on target (^{238}U)	0.7	emA
Beam radius on target (90%)	0.5	mm
Driver linac beam-path length	517	m
Average uncontrolled beam loss	< 1	W/m

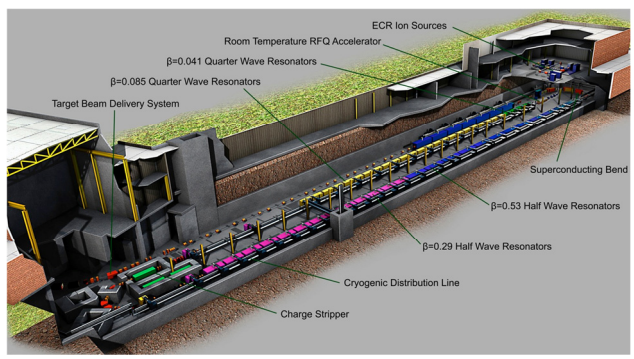

Figure 1: Layout of the FRIB driver accelerator.

DESIGN PHILOSOPHY

Full-energy linac technology is chosen to deliver primary beam that can meet the FRIB requirements of rare-isotope productivity and separation accuracy. Up to 400 kW of beams are focused to a diameter of 1 mm (90%), energy spread of 1% (95% peak-to-peak), and bunch length of < 3 ns (95%) on the target.

Superconducting (SC) technology is the energy-efficient choice for the CW linac. SC acceleration of heavy-ion beams is feasible from very low energy (500 keV/u) with practically sized cavity bores by housing both the cavities and solenoids in a cryomodule. A two-cell scheme is chosen throughout the entire linac providing both efficient acceleration and focusing. Developments of digital low-level RF control and solid-

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

state RF amplifier technologies have made individual cavity powering and control reliable and cost efficient.

Furthermore, high availability, maintainability, reliability, tunability, and upgradability are especially required for the FRIB accelerator to operate as a national scientific user facility.

- Availability: The accelerator is designed with high beam-on-target availability accommodating normal, alternative, and fault scenarios. In the normal scenario, a liquid lithium stripper is used to raise the average charge state of ^{238}U beam to 78+ for efficient acceleration. Alternatively, helium gas confined by plasma windows with differential pumping can be used to strip the ^{238}U beam to a lower average charge state of 71+. Fault scenarios include the situation when superconducting (SC) cavities underperform by up to 20% of the design gradients. Furthermore, key components and subsystems are implemented with spares and design redundancies.
- Maintainability: The average uncontrolled beam loss is limited to below 1 W/m level for all ion species from proton to uranium, to facilitate hands-on maintenance. For a proton beam at high energy, this level corresponds to an average activation of about 1 mSv/h measured at a distance of 30 cm from the beam chamber surface, 4 hours after operations shutdown. For heavy ions like uranium at low energies, activation and radiation shielding is of less concern; the 1 W/m limit addresses concerns in damage on superconducting cavity surfaces and in cryogenic heat load. To facilitate maintenance of individual cryomodules, warm interconnect sections are used between cryomodules, and U-tubes with bayonet connections are used for cryogenic distribution.
- Reliability: A Machine Protection System (MPS) minimizes component damage and operational interruption (e.g. magnet quench and cryogenic load increase) caused by both acute (fast) and chronic (slow) beam losses. Upon acute beam loss, the MPS response time is 35μs (including diagnostics, signal processing, and residual beam dumping). MPS responding to slow beam loss is complicated by low sensitivity of conventional ion chamber loss detection to low-energy heavy ions and beam-loss signal background from adjacent linac segments with which beam energies are significantly different. Beam-halo- scraping rings in the warm interconnect sections and possible thermal sensors at cold regions are planned for more sensitive loss detection [3].
- Tunability: The accelerator is designed to be easily tunable during both beam commissioning and operations. In linac segment 1, where beam transverse-phase advance is large, cold beam-position monitors (BPM) are implemented in the cryomodules. Efforts are made in establishing beam-tuning strategies based on virtual accelerators and on-line models under normal and fault conditions.
- Upgradeability: Space is reserved in linac segment 3 to house another 12 cryomodules to readily increase the energy of ^{238}U beam above 300 MeV/u. If cavities with 35% higher accelerating gradient are used in linac segments 2 and 3, the beam-on-target energy can be raised above 400 MeV/u for ^{238}U. The linac tunnel allows future expansion so that a dedicated light-ion injector can be added supporting rare isotope production using the isotope separation on-line (ISOL) method [1]. Using an RF deflector cavity and a Lambertson septum magnet, $^{3}He^{+}$ beam supplying protons to the ISOL target can share cycle with the ^{238}U beam feeding the fragmentation target; thus simultaneous users are supported. Furthermore, space is reserved to house instrumentations including non-destructive diagnostics and sub-harmonic buncher that are compatible with future user demands of experiments.

ACCELERATOR PHYSICS CHALLENGES

The FRIB accelerator design combines the complexity of heavy ion accelerators with the engineering challenges of high-power accelerators. Due to the low charge-to-mass ratio, heavy ion acceleration is often not efficient. Uncontrolled beam loss, which usually is not an issue for low-power heavy ion machines, is of primary concern for the FRIB accelerator. Comparing with high-power proton machines like the Spallation Neutron Source (SNS) linac where apertures of the elliptical SC cavities are large and beam amplitude reaches maxima in the warm locations of the focusing quadrupole magnets, the apertures of the FRIB QWR and HWR accelerating structures are small and beam amplitude reaches maxima in the cold solenoid locations inside cryomodules. Requirements on beam halo prevention, detection and mitigation are stringent.

To maximize beam intensity on the target, beams of multiple charge states are accelerated simultaneously (2 charge states of 33+ and 34+ before stripping, and 5 charge states of 76+ to 80+ after stripping for ^{238}U). Bends of second-order achromatic optics are used to fold the beams, and cavity phases are adjusted so that beams are longitudinally overlapping at the charge stripper.

Conventional charge strippers like solid carbon foils are not sustainable at the power of a ^{238}U beam at 17 MeV/u during normal operations [4]. FRIB accelerator lattice needs to accommodate beam acceleration of different charge states resulting from various stripping methods including liquid lithium and helium gas (average charge state from 63+ to 78+ for ^{238}U). Buncher cavities of fundamental (80.5 MHz and 322 MHz) and double (161 MHz) linac RF frequencies are strategically placed in the folding segments to preserve beam quality.

Due to the short stopping distance in surrounding materials, uncontrolled beam loss of the low-energy heavy ions can cause damage to the surface of accelerating structures much more easily than a proton beam. On the other hand, due to the low level of radio-activation, losses of low-energy heavy-ion beams are difficult to detect [3]. Beam-loss detection and machine

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

protection often rely on beam scraping. On the other hand, scraping of partially stripped ions may lead to higher ionization further complicating beam collimation and machine protection.

Due to requirements of frequent longitudinal and transverse focusing in the superconducting acceleration structure, focusing solenoids are placed inside cryomodules adjacent to cavities. Alignment tolerance of these solenoids is ±1 mm under cryogenic conditions. Horizontal and vertical steerers are needed to thread the beam and correct the beam orbit.

Stringent beam-on-target requirements demand tight optical control, error control, and advanced beam diagnostics. The primary beam of 400 kW needs to be focused into a diameter of 1 mm with below ±5 mrad transverse angular spread. The desired range of beam power variation on target is 8 orders of magnitude. Orbit stability needs to be controlled at 0.1 mm level.

TECHNOLOGY CHALLENGES

Charge Stripper

The FRIB baseline design of charge stripping [4] was based on the ANL work on a liquid-lithium high-power thick target where it was demonstrated power deposition of 20 kW (from an electron beam) with the liquid lithium operating well in an accelerator environment [5]. During the last couple of years the stability of a thin liquid film with the correct thickness for the FRIB stripper (~600 μg/cm^2) was achieved (Figure 2). The next step is to show that the power deposited by the primary beam on the moving film (~ 1 kW) will not destroy or perturb it.

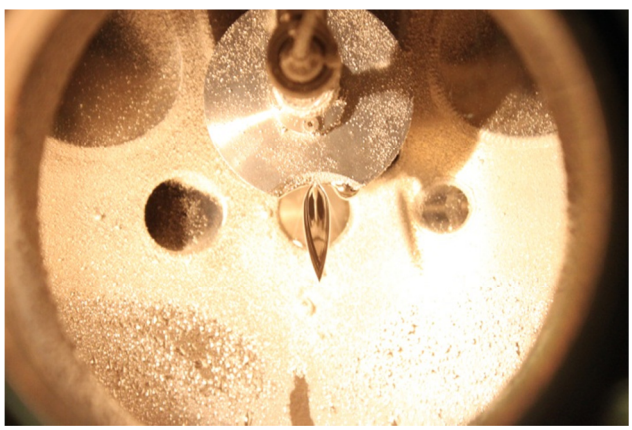

Figure 2: Liquid lithium film established at ANL.

A second option for the stripper consisting of a helium gas cell enclosed by plasma windows was considered. The RIKEN group has shown [6] that helium gas produces a higher average charge state than a nitrogen gas stripper. The purpose of the plasma windows is to limit the helium gas leaking out of the gas cell [4].

Superconducting RF

FRIB driver linac is the first full-size SC linac using a large quantity (340) of low-β cavities. Cavity design is optimized not only for optimum performance but also for low production cost. This requirement guided the choice of the cavity geometries, materials and mechanical solutions, avoiding complicated shapes, minimizing the amount of electron beam welds, eliminating bellows, optimizing construction and surface treatment procedures. FRIB cavities work with superfluid helium at 2 K. The increase in cavity Q more than compensates the energy required for the 2 K cryogenic system operation. This innovative choice in a low-β linac allows operation of cavities in stable pressure conditions with high safety margin on the maximum surface fields [7].

After a 10-year development, the 2nd generation QWR prototypes are used in the ReA3 linac (7 with β_0=0.041 in operation and 8 with β_0=0.085 under installation). This cavity type underwent modifications including the displacement of the RF coupler from the bottom plate to the resonator side and an increased distance between the tuning plate and the inner conductor tip, in order to remove a critical thermal problem in the design. The new tuning plate includes slots and undulations to increase its maximum elastic displacement and thus its tuning range, and a "puck" whose length can be adjusted for cavity tuning before final welding. Concerning the β_0=0.53 HWR prototype, which is similar in design to the β_0=0.29 cavity, 4 units of the 2nd generation have been built by 2 different vendors in addition to the one built in house. After positive test results, the β_0=0.085 QWR and the HWRs designs are further refined in a 3rd generation design with increased diameter that takes maximum advantage of the space available in FRIB cryomodules.

Test results and production cost considerations led to the choice of buffered chemical polishing (BCP) for FRIB cavity's surface treatment. The effort was concentrated in the development of a reliable procedure able to produce field-emission free, high gradient cavities. The treatment includes the following BCP steps: 1) bulk etch (~150μm removal), 2) differential etching in QWRs for final cavity tuning if required, 3) light etch (~30 μm removal). Thermal treatment in high vacuum at 600 °C is applied before step 3) for Hydrogen removal to prevent Q disease. High pressure water rinsing (HPR) is applied before cavity final installation. To assure surface cleanliness, dust particle count is performed on resonator surfaces during cavity assembly in the clean room and the water purity is continuously monitored during HPR. During BCP both the cavity and acid temperatures are stabilized to control the removal rate and to avoid excess of hydrogen absorption in Nb. The acid flow path in the β_0=0.53 HWR was studied by means of simulations and experiments to obtain homogeneous removal over the entire inner resonator surface. The implementation of the 120°C final thermal treatment showed negligible improvement of the Q-slope at 2 K but significant reduction at 4.2 K [8].

The 2nd generation prototypes of β_0=0.085 QWR and 0.53 HWR have been tested in vertical dewars at 2 K exceeding FRIB design specifications. The residual resistance measured in the prototype families was below 5 nΩ up to about 100 mT in QWRs, and about 80 mT in

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

HWRs. Considering that the FRIB specified limits are 11 nΩ and 70 mT, a large safety margin exists for upgrades.

The 3rd-generation cavity design optimization resulted in significant improvement of peak fields E_p/E_{acc}, B_p/E_{acc} and shunt impedance R_{sh}, with consequent reduction of the overall linac cost and operational risk. E_p and B_p in operation could be moved below the safe values of 35 MV/m and 70 mT in all cavities. The design gradients of the β_0=0.085 QWR and β_0=0.29 HWR are raised by 10% without increasing the total cryogenic load, allowing a reduction of two cryomodules. The apertures of all QWRs were enlarged from 30 to 34 mm, and their bottom rings were modified for efficient tuning-plate cooling using a low-cost design. The HWR designs were optimized to facilitate the mechanical construction and tuning procedure. In all cavities, the helium vessel is made of titanium to avoid brazed Nb-to-stainless-steel interface.

The Technology Demonstration Cryomodule (TDCM) consists of two β_0=0.53 HWRs operating at 2 K and a 9 T solenoid operating at 4.5 K arranged in a "top-down" configuration. The cryomodule was tested [9] at the design cryogenic temperatures demonstrating excellent cryogenic and LLRF control stabilities. Multipacting was found to impede the performance of the cavities and the coupler [9]. Future tests are planned on magnetic field and shielding studies, mechanical-type and pneumatic-type tuner evaluations, multipacting mitigation, and integrated tests with both β_0=0.29 and β_0=0.53 HWRs.

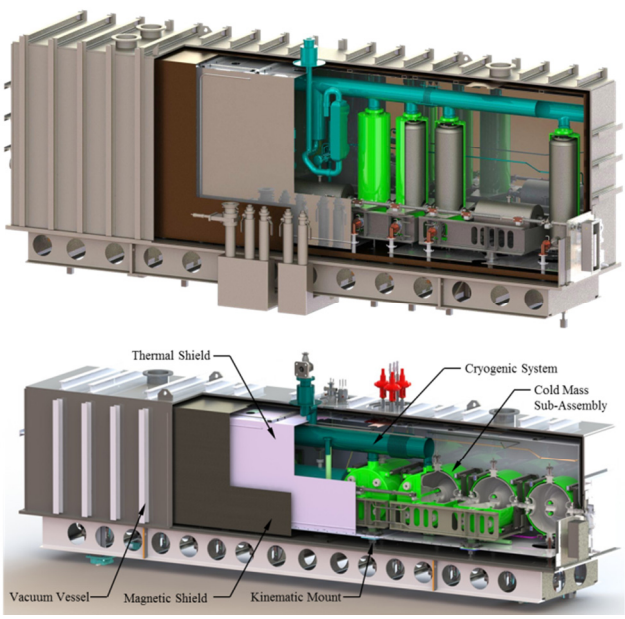

Figure 3: FRIB "bottom-up" cryomodule designs. The top cryomodule incorporates 8 β=0.085 QWRs, 3 solenoids, and 3 cold beam position monitors; the bottom cryomodule incorporates 8 β=0.53 HWRs and a solenoid.

The FRIB cryomodule design has evolved significantly from the "top-down" ReA3 style to a "bottom-up" design [10]. Key features including rail system, support system, heat and magnetic shields are simplified along with improvements in assembly and alignment. Figure 3 shows the current design incorporating a torque-resistant structural frame made of stainless steel. We incorporate machined fiberglass compression posts supporting the coldmass in the cryomodule vacuum vessel. Three posts on linear roller bearings oriented towards the center of thermal contraction serve as 6-degree-of-freedom kinematic supports. This design controls the alignment of the coldmass while allowing thermal contraction. Cavity and solenoid attachment points to the rails are all machined after welding to ensure assembly consistency.

DESIGN & ACQUISITION

A summary of the accelerator design status was given in Ref. [1] including the front end, linac segments, folding segments, beam-delivery system, and reaccelerator. Also discussed was subsystem status including the cryogenics, cryomodule, RF, ion source, RFQ, magnet and power supply, diagnostics, vacuum and alignment, controls, and utilities [1]. After the project baseline in April 2012, the FRIB project entered into its final design phase when detail-engineering designs are performed at MSU. While critical processing and assembly are to be performed in house, fabrication of a large quantity of repetitive components is planned through mass production and out-sourcing by industrial providers [11].

The FRIB project plans to place approximately 450 procurements valued at more than $50k each. The sum of all technical equipment procurements amounts to $217M excluding conventional facility construction. We have implemented a procurement strategy that strives to reduce vendor risks for the best value to the FRIB project:

- We work directly with the vendors understanding their individual risk concerns and proposing mitigations:
  - Perform certain tasks in-house if the vendor lacks capability;
  - Adjust engineering designs to allow vendor to implement familiar fabrication approaches;
  - Identify key-personnel bottlenecks at the vendor, and provide technical support where necessary;
  - Work closely with the vendor in mass-production planning and subsequent quality monitoring;
  - Accept components on mechanical (dimensional) properties instead of functional (e.g. electromagnetic, RF) performance;
  - FRIB to purchase high-cost materials that expose to market fluctuations (e.g., Nb).
- We evaluate how the project fits into the supplier's total capabilities and long-term business plans to gauge supplier management's commitment to solve production challenges and risks.
- We develop long-term supplier relationships for mass production. Phasing of procurements from prototypes to production sensitizes vendors to be able to successfully produce the unique components.

So far we have implemented this strategy to negotiated favorable prices for all the SRF material purchases and the production of 174 β=0.53 HRWs [9].

COLLABORATION & PARTNERSHIP

FRIB accelerator systems design has been assisted under work-for-others agreements by many national laboratories including ANL, BNL, FNAL, JLAB, LANL, LBNL, ORNL, and SLAC, and in collaboration with many institutes including BINP, KEK, IMP, INFN, INR, RIKEN, TRIUMF, and Tsinghua University.

The cryogenics system is designed in collaboration with the JLAB cryogenics team. The refrigeration process incorporates the cumulative experience from both JLab and SNS cryogenic systems. The recent experience gained from the JLab 12 GeV cryogenic system design is utilized for both the refrigerator cold box and the compression system designs. The Floating Pressure Process – Ganni Cycle [12] is to be implemented to provide efficient adaptation to the actual loads.

The charge stripping system is under development in collaboration with the ANL Physics Division. We borrowed the LEDA ion source and LEBT from LANL to modify the optics to obtain a 1 to 3 mm diameter beam spot on the liquid-lithium film at MSU. Once the new optics is checked on a new platform that is matched to the ANL lithium loop, the device will be moved to ANL for the integrated test.

The SRF development benefit greatly from the expertise of the low-β SRF community. Weekly teleconferences are held with participations from INFN, TRIUMF, JLAB, and ANL. FRIB is collaborating with ANL on the coupler and tuner developments, and assisted by JLAB on cavity processing.

FUTURE PERSPECTIVES

The FRIB accelerator design is advanced towards beginning construction in 2014. Early procurements before 2014 is strategically planned to establish the front end test stand to demonstrate critical components of the ECR ion source and the fully powered RFQ, to contract on long lead-time cryogenic refrigeration subcomponents, to acquire cryogenic distribution equipment that needs to be installed before accelerator tunnel completion, and to acquire SRF components to be assembled in the pre-production cryomodules. Upon fabrication, installation, and integrated tests, early beam commissioning is expected to be staged from 2017 to 2019. The facility is scheduled to meet key performance parameters supporting user operations before 2021. Full design capability is expected to be reached in 4 years after the beginning of operations. Science driven upgrade options may be pursued at any stage of the project.

ACKNOWLEDGMENTS

We thank the Accelerator Systems Advisory Committee chaired by S. Ozaki for their valuable advice and guidance, B. Laxdal, P. Kneisel, and A.C. Crawford for their participation in the FRIB weekly teleconference, colleagues who participated in FRIB accelerator peer reviews including A. Aleksandrov, G. Ambrosio, W. Barletta, G. Bauer, G. Biallas, J. Bisognano, S. Bousson, M. Champion, M. Crofford, R. Cutler, B. Dalesio, G. Decker, J. Delayen, H. Edwards, J. Error, J. Fuerst, K. Kurukawa, J. Galambos, J. Galayda, J. Gilpatrick, S. STATUS AND COMMISSIONING PLAN OF PEFP 100-MEV LINEAR ACCELERATOR*

Hyeok-Jung Kwon#, Yong-Sub Cho, Ji-Ho Jang, Han-Sung Kim, Kyung-Tae Seol, Young-Gi Song, Dae-Il Kim, Bum-Sik Park, Sang-Pil Yun, Jin-Yeong Ryu,
PEFP/KAERI, Daejeon, Korea

Abstract

One of the goals of the Proton Engineering Frontier Project (PEFP) is to develop a 100-MeV proton linear accelerator, which consists of 50-keV proton injector, 3-MeV radio frequency quadrupole (RFQ), 20-MeV / 100-MeV drift tube linac (DTL) and 20-MeV / 100-MeV beam lines. The 100-MeV linear accelerator and beam line components have been installed in the tunnel and experimental hall. After the completion of the utility commissioning, the commissioning of the accelerator starts with a goal of the beam delivery to the 100-MeV target room located at the end of the beam line. The proton beams will be supplied to users from March 2013. In this paper, the status and commissioning plan of the PEFP 100-MeV linear accelerator are presented.

INTRODUCTION

The PEFP was launched by the Korean Government at 2002 as a 21st century Frontier R&D program. It has three main objectives; to develop a high power proton linac, to develop proton beam utilization and accelerator application technology, to industrialize developed technologies.

The specifications and schematics of the 100-MeV, 20mA proton accelerator developed by PEFP are shown in Table 1 and Figure 1 respectively. The PEFP proton accelerator has its own characteristics; to supply high duty & high average current beam to users, to supply proton beam with wide range in beam energy and current, to supply proton beam into 3 beam lines simultaneously, and to supply beam with large area up to 300mm in diameter. The main application fields of the accelerator are such that; industrial field with ion cut, semiconductor switch application, radio isotope production, medical field with proton therapy research, biological field with mutation of plants & micro-organism, space technology field with research on radiation effect on materials, and basic science field with neutron application.

The project host city is Gyeongju who supplies land and supporting buildings such as main office building, regional cooperation centre and dormitory and so on. The main buildings for accelerator and experimental hall, utility and substation are provided by the central government. The construction of the main buildings will be completed in October, 2012.

The development of 100-MeV DTL was completed in 2010. The main accelerator components such as RFQ and DTL were designed by PEFP, fabricated by the 17 Korean domestic industries, assembled and tested by PEFP. As a front end, a 20-MeV linac was developed, installed and operated since 2007 at KAERI Daejeon site waiting for the PEFP site preparation at Gyeongju. [1][2] The operation of 20-MeV linac at Daejeon was finished at November 2011. Since then, the machine was disassembled and delivered to Gyeongju site at February 2012 when the accelerator tunnel was prepared. The 100-MeV accelerator and two beam lines were installed inside the accelerator tunnel and the experimental hall, respectively. The commissioning of the accelerator will start at the end of 2012 after the klystron gallery, modulator room and utility are prepared.

Table 1: Specifications of the PEFP Proton Accelerator

Parameter	DTL-I	DTL-II
Output Energy (MeV)	20	100
Max. Peak Beam Current (mA)	20	20
Max. Beam Duty (%)	24	8
Average Beam Current (mA)	4.8	1.6
Max. Pulse Length (ms)	2	1.33
Max. Repetition Rate (Hz)	120	60
Max. Avg. Beam Power (kW)	96	160

ACCELERATOR DEVELOPMENT

20-MeV Linac Operation

The 20-MeV linac was installed at Daejeon site temporarily in 2005 waiting for site preparation at Gyeongju. The 20-MeV linac got an operation license in 2007, since then the machine was used to study the machine itself and to test 100-MeV accelerator components in addition to supply proton beams to users. The key technologies developed during 20-MeV linac operation are as follows.

The digital LLRF system was developed from the analogue system in 2007 and upgraded in 2010. The digital LLRF system utilized a commercially available control board with FPGA. The control algorithm with PI was developed by PEFP. The board can produce synchronized NCO output signal equipped in the board, therefore it does not need an analogue IQ modulator. By installing mixers at input and output section symmetrically, the LLRF system became more stable against the external reference signal perturbation. The delay of the system was measured to be less than 1us. The OPI interface of the LLRF system is GUI mode with EPICS. Various waveforms, such as RF forward power, RF reflected power and cavity field level can be monitored as well as the resonant frequency error measurement function. [3][4] The high power test results showed that the amplitude and phase were maintained within 1% and 1degree respectively. By using the digital LLRF system, the beam current could be stabilized during operation. [5]

The klystron power supply was changed from DC high voltage power supply to the high voltage converter modulator (HVCM) in 2009. The design duty of the 20-MeV machine is 24%. A CW klystron and DC high voltage power supply were used in the initial operation period. At that time, the electron beam of the klystron was operated in DC mode and only the RF operation was in pulse mode. Therefore the operation efficiency was very low because the machine could not be operated at high duty due to the insufficient radiation shielding, whereas the power consumption was 4MW to drive two CW klystrons. To increase the efficiency, the high voltage converter modulator was developed as a klystron power supply for 100-MeV linac. When the modulator was delivered, it was installed in 20-MeV linac RF system with the purpose of testing the modulator itself and driving the 20-MeV linac. The system efficiency of the 20-MeV linac could be increased by driving the klystron electron beam in pulse mode. In addition, several problems of the first modulator were identified and fixed. The debugging of the first delivered modulator was reflected on the successive procurements of the modulator. [6]

The ion source was changed from duoplasmatron type to microwave type in 2011. The main purpose of this change was to meet the ion source requirement of more than 100 hours continuous operation without maintenance. The former duoplasmatron type ion source satisfied all the requirements such as beam current, beam emittance and so on except the life time. Due to the filament, its life time was limited to 40 hours. But the life time of the ion source should be more than 100 hours based on the operation scenario of the 100-MeV linac. Therefore microwave ion source was developed because one of its advantages was long life time. The developed microwave ion source was tested for 100 hours at the test bench and it showed no degradation of the performance. After the test at the test bench, it was installed at 20-MeV linac and used as a proton injector. The microwave ion source had been operated for 243 hours without maintenance until the November, 2011. [7][8]

For beam diagnostic devices, the beam position monitors (BPM) for 100-MeV linac and the beam transfer line were developed and tested at the 20-MeV beam line in 2011. The beam test results showed that the BPM produced the expected signal and was good enough for the beam phase measurement. [9]

In addition to the technology development of each accelerator components, the integrated test of the accelerator was carried out.

The long-time operation was tried to check the pulse loss statistics. The total number of pulses was 14,400 and the total pulse loss rate was 0.56%. Among them, 0.01% was due to the spark at the ion source and 0.55% was due to the spark at the RFQ. The spark at the RFQ was the main cause of the beam pulse loss. [10] For the long-pulse operation test, it was not difficult to increase the beam pulse width up to 500us. The 500us beam pulse is shown in Figure 2. The high repetition rate test was also carried out. The RF system was operated at 20Hz and the repetition rate of the beam from the ion source was increased from 1Hz to 15Hz. The beam pulse at 15Hz is shown in Figure 3. All the system including low level RF and data acquisition system was operated without any problems. The radiation dose was measured at the target room fence which is 1m apart from the radiation shielding block. The neutron dose rate was 500uSv/hr at 15Hz and gamma ray dose rate was 150uSv/hr. We did not increase the duty because of the insufficient radiation shielding at Daejeon site. [11]

The beam parameters such as beam energy, beam profile, beam emittance and beam phase were measured in parallel with the machine study. The beam energy was measured with the time-of-flight method by using two BPMs installed at the 20-MeV beam line. The result was 20.2MeV and this was compared with other two methods; dose measurement and range measurement with the aluminium foil, Gafchromic film and ion chamber. Both results showed a good agreement within 1% with each other. To measure the beam profile, we used the wire scanner. The beam profiles depending on various operating conditions of the quadrupole triplet installed at the 20-MeV beam line were measured and the beam radius was compared with the PARMILA results.

The beam emittance at the upstream of the RFQ was measured by using the electric sweep scanner. The measured emittance was 0.35 π mm mrad in normalized rms value which showed higher than the design value of 0.2 π mm mrad. It is necessary to optimize the operation parameters of the ion source and LEBT. The beam emittance at the downstream of the 20-MeV DTL was also measured by using quad scan method. The last magnet in the triplet was used to change the transfer matrix. The measured emittance was 0.22 π mm mrad, which was well agreed with the design value. [8]

The BPM signals were utilized for the beam phase measurement, which is important at the commissioning stage of the 100-MeV linac because a phase scan method

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

is considered as a tuning method of the RF amplitude and phase. The beam phase was measured at various amplitude and phase of the RFQ and DTL and the results were compared with the PARMILA results. Finally, we could establish the phase scan algorithm based on the measurement data. [12]

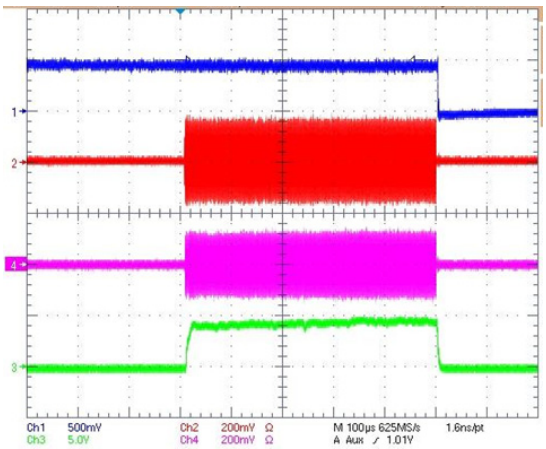

Figure 2: 500us beam operation (Time : 100us/div.)

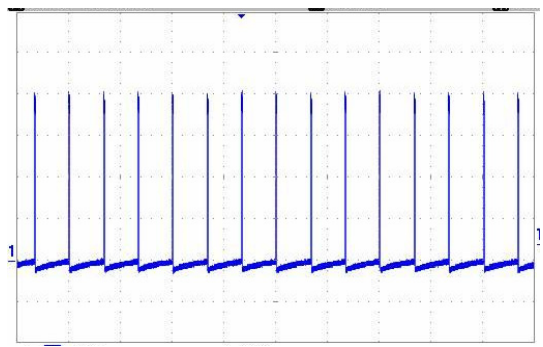

Figure 3: Beam pulse at 15Hz (Time span: 1s)

A 20-MeV beam was supplied to the users during the 20-MeV machine operation in Daejeon site. The users who want a beam service submit an application form through the Internet and the beam line operator contacts the users and discusses the irradiation conditions. After that, the beam line operator does the beam service by using the sample prepared by the users. During beam irradiation to the specimen, the beam line operator communicates with the linac operator through the control system which includes personal protection logics. The beam conditions were adjusted to the specific user demands however the typical operation conditions were 5mA peak current with 50us pulse width, 1Hz repetition rate during beam service. There were total 1603 samples irradiated by using 20-MeV linac for five years. The number of sample treatment increased from about 100 samples in 2007 to more than 680 in 2011 as shown in Figure 4. For five year beam service, most of the users (66%) come from the Research Institute, and the others come from the University (22%) and Industry (12%). The most frequent application field was Bio-Technology (60%) including the cancer cell irradiation and mutation study. The research and application field related to the Nano-Technology (17%) which included a nano-particle synthesis was next to Bio-Technology.

As mentioned above, the operation of 20-MeV linac at Daejeon site was finished at November 2011. Since then, the machine was disassembled and delivered to Gyeongju site at February 2012. The DTL tanks and klystrons were moved with the vibration free truck as shown in Figure 5. After the movement, the field profile of the DTL was measured and the difference was within 3% before and after the movement.

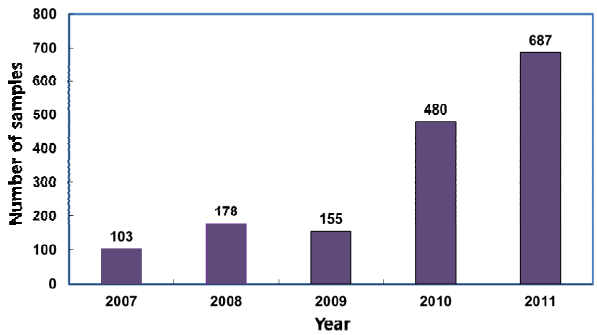

Figure 4: Number of samples depending on fiscal year

Figure 5: 20-MeV DTL tanks on the vibration free truck for the movement to Gyeongju site

100-MeV Linac Development

The fabrication of the 20-MeV ~ 100-MeV DTL tanks was completed at December 2010. It consists of seven tanks and total 163 ea. drift tubes. It has hollow type electromagnet for beam focusing whereas the 20-MeV DTL has a pool-type electromagnet. The length of each tank is 6.8m. The 100-MeV DTL tank has one klystron per one DTL tank and one Resonant Frequency Control Cooling System (RCCS) for each tank.

The fabrication of two Medium Beam Energy Transport (MEBT) tanks was also completed. MEBT tanks will be used as a longitudinal matching section between 20-MeV DTL and 100-MeV DTL because there is a long drift space between them for 20-MeV beam extraction. The MEBT tank is a kind of DTL tank with three gaps.

The 350MHz klystron is used as a RF amplifier for the PEFP linac. The specification of the klystron is 1.6MW peak power with 1.5ms pulse width, 60Hz repetition rate. It was modified from the TH2089F CW klystron to produce a higher peak power and reduced duty. There are

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

total 7 klystrons for 20-MeV ~ 100-MeV DTL, and all the klystrons were delivered to Gyeongju site and waiting for installation.

The high voltage converter modulator is used to drive the klystron. The specification of the modulator is 5.8MW peak power with 1.5ms pulse width, 60Hz repetition rate. There are two distinct features in the PEFP modulator. One is to keep the pulse voltage droop less than 1% by the adjustment of the switching frequency. The other is to limit the load arc energy less than 20J spontaneously by the internal resonant characteristics, which means that the crowbar is not necessary in the modulator. One modulator drives two or three sets of the klystrons simultaneously. Total 4 sets of modulator are necessary for whole accelerator including 3-MeV RFQ, 20-MeV DTL and 100-MeV DTL and all of them were delivered. One of the modulators was used to drive the 20-MeV linac at Daejeon site for 3 years. The normal operation conditions was 2.8MW peak power with 1ms pulse width, 4Hz repetition rate. It was tested up to 30kW in average power.

A RCCS is used to control the resonance frequency of each DTL tank by supplying the temperature–controlled water to drift tubes. The maximum heat load is 94kW. It should cover large range of heat load from lowest heat load from the magnet only to the highest heat load from the full duty RF power in addition to the magnet heat load. The operating temperature range of the RCCS was designed from 21°C to 33°C to reduce the DTL tuning requirement. Within the above temperature range, the RCCS can maintain the temperature accuracy within ±0.1°C by using two sets of three-way valves. Also the RCCSs were ready to installation.

One of the most important interfaces between machine and building was the waveguide connecting accelerator located in first floor with the klystron located second floor. The waveguide was specially designed, fabricated and tested with care and embedded inside the ceiling of the tunnel during the building construction.

Beam Line Development

The important components of the beam line are AC magnet which distribute the proton beams into three beam lines pulse by pulse successively and 300mm aperture beam window to extract large area beam into the air for irradiation, in addition to the main dipole and quadrupole magnets. All the dipole and quadrupole magnets were fabricated. The magnetic properties of the magnet were measured and the geometrical fiducialization was also finished. Two AC magnets, one for 20-MeV beam, the other for 100-MeV beam were also fabricated. The sweep frequencies of the AC magnets are 15Hz for 20-MeV beam line and 7.5Hz for 100-MeV beam line. The maximum bending angle of the AC magnet is 20 degree. The AC magnet will be driven by the power supply with fast switch technology. The material of beam window is a 0.5mm thickness AlBeMat with concave geometry. The energy loss through the beam window is 0.6MeV for 100-MeV beam. The window will be forced air-cooled by using the blower.

COMMISSIONING PLAN

Each of the high power devices such as modulator and klystron will be commissioned after the commissioning of the all utilities is completed. The first devices to be on-site commissioned are 4 sets of modulator. The modulator will be tested at low power level of 2kW in average power with non-inductive resistor. The beam and RF test of the klystron will be done after the modulator tests are completed. Initial test of the klystron will be done without connection to the DTL tank and reflecting all the RF power to the dummy load by using a shorting plate installed one arm of the circulator. The on-line RF conditioning of the DTL tank will be done after the high power test of the klystron-modulator system finishes.

The beam commissioning goal of the accelerator is to deliver a 100-MeV, 1kW beam to the beam dump located at the end of the accelerator. The commissioning goal of the beam line is to deliver a 100-MeV, 1kW beam to the beam dump located in the TR103 target room.

An important step of the beam commissioning process is to determine the RF amplitude and phase of each DTL tank. We adopt a phase scan method [12][13]. For this purpose, a strip line BPMs will be used at the downstream of each DTL tank to pick up the beam phase signal. Then the signal is delivered to the commercially available control board. The control board treats both the LLRF control signals as mentioned above and beam phase signal because both signal needs RF reference. In addition to the hardware, software to treat the phase scan data was implemented in Matlab. An experimental data of the beam phase as a function of RF phase with the fixed relative amplitude A/A_0 is compared with the implemented PARMILA simulation results to generate a χ-value for each case of A/A_0. The quadratic fitting of the χ-values can determine the RF amplitude and phase.

INSTALLATION AND SCHEDULE

The 100-MeV linac was installed inside the tunnel as shown in Figure 6 after the survey of the tunnel was performed and the supporting structures were prepared at March 2012. The total length from the ion source to the beam dump is 93m. The magnets of the 20-MeV / 100-MeV beam line were also installed at May 2012 as shown in Figure 7. [14]

Based on the construction schedule, the klystron gallery and modulator room will be prepared in September 2012, and the utility commissioning will be finished in October 2012. Form September, the modulator will be delivered to the modulator room in 3rd floor and installation starts. Also all the RF components including klystron, RCCS and waveguides will be installed in the klystron gallery of 2nd floor. The accelerator commissioning starts from the modulator commissioning step by step after the utility commissioning is completed. The DTL conditioning will start in January 2013 and the beam acceleration into the beam dump is planned in February 2013. The construction status of the accelerator building is shown in Figure 8.

CONCLUSION

The PEFP launched by the Korean government in July 2002, is developing a 100-MeV proton linac and installing the facilities at Gyeongju project site. The 20-MeV part of the linac has been successfully developed, tested and operated for 5 years at Daejeon. After finishing operation at November 2011, it was moved to the project site at Gyeongju. The installation of the 100-MeV linac and beam line magnets were finished in March 2012. The modulators and klystrons will be installed from September 2012. The construction of the accelerator building including the commissioning of the conventional facility will be completed in October 2012. The commissioning of the accelerator starts from the modulator commissioning. The important milestones are to start the DTL tank conditioning in the tunnel in January 2013 and to deliver the 100-MeV proton beam into the beam dump in February 2013.

Abstract

SACLA, part of an X-ray free-electron laser, has been constructed, and was successfully lased at 0.06 nm in 2011. SACLA mainly comprises a low-emittance thermionic electron gun, an 8-GeV linear accelerator using C-band (5712 MHz) cavities and 18 in-vacuum undulators. A concept used to develop this machine involves compactness compared with the other machine, such as LCLS with a length of more than 1 km. Stable X-ray lasing of up to 0.06 nm to also be a concept demands extremely stable accelerator components, such as a 50 fs temporal stability of an rf phase at a cavity in an injector. We have now realized a 700 m compact machine by using low-emittance at an electron gun, an accelerating gradient of more than 35 MV/m by a C-band accelerator, and short-period undulators. Continuous lasing for more than several days is strongly supported by these stable components and small operator's trimming, and has also been established by reducing perturbation sources to laser instability. SACLA is regularly operated for user experiments, such as material imaging with an extreme amount of data.

INTRODUCTION

SACLA has been constructed in order to generate an X-ray laser of up to a wavelength of around 0.06 nm, and is now under operation for user experiments [1]. We can explore new science, such as revealing protein membrane structures, by this machine.

SACLA was designed in accordance with the following two concepts, called SCSS concepts [2]. One is a short machine length, like compactness, which is associated with low construction costs. Next, is an ultra stable machine, which guarantees stable laser intensity, contributing to reliable experiments. In order to realize this concept, we employ a method using a high-brightness, low-emittance thermionic electron gun operated at a 500 kV high-voltage pulse [3], a C-band accelerator with a high-gradient acceleration of more than 35 MeV/m [4] and an in-vacuum undulator with a short period and a narrow gap [5]. Their high-brightness electron beam and narrow gap as well as short period, λ_u, associated with a large undulator parameter, K, and a short radiation wavelength, λ, allow us to reduce the gain length of self-amplified spontaneous emission (SASE) along the undulator beam line. High-gradient acceleration is also effective to make a short accelerator. Hence, the machine length becomes shorter than other X-ray free electron laser (XFEL) machines of over 1 km, such as the linac coherent light source (LCLS) at SLAC [6] and Euro-XFEL at DESY [7]. This SCSS concept is the most prominent characteristic of our SACLA.

Ultimate stability of an X-ray laser, which is guided by ultra-stable accelerator components, is also a crucial part of SACLA. As examples to realize stable X-ray lasing conditions, it is necessary that the electron beams and related undulator radiation should spatially overlap within 4 μm in STD along the undulator line [8], if we allow for reduction of the SASE intensity up to half of the peak intensity (design value). The demanded rf phase (temporal) stability at cavities in an injector is around 100 fs in STD, if we also accept a peak electron-intensity fluctuation of 10% in STD, corresponding to a peak X-ray laser intensity fluctuation of 10% in STD [9], which is almost the intrinsic intensity jitter of statistical SASE generation. The amplitude of the Pierce gain parameter, ρ, for FEL amplification along an undulator section directly reflects the overlap factor, OF, between the electron beam and its radiation [10], and also the charge density of the electron beam [2]. For example, these component stabilities mean a stable low-emittance value and electron beam energy stability established by the emission stability of the electron beams form the thermionic electron gun, the rf phase and amplitude stabilities of acceleration cavities, the magnetic field stabilities of beam-transport magnets, undulator magnetic field stability, and components alignment in order to secure the interaction between the electron beams and the beam radiated field along the undulator line.

We must realize these required values to secure stable X-ray laser radiation, as well as the concept. This paper introduces accelerator components and their performances, X-ray lasing performance, and the present issues to deteriorate the lasing performance of SACLA.

SACLA'S MACHINE LAYOUT, ITS FUNCTION AND COMPONETS

Layout and Function

Figure 1 shows the machine configuration of SACLA, which mainly comprises a 500 kV thermionic electron gun, a 238, 476, 1428 MHz multi-sub harmonic bunching and accelerating system as an injector, 8 S-band detuned-accelerating structures, 128 C-band choke-mode accelerating structures, 18 in-vacuum undulators and an X-ray beam line. The individual components of SACL work as follows. At first, the electron gun emits electron beams with a low emittance of 0.6 πmm-mrad in rms, a pulse width of 3 μs in FWHM and a 1A peak current.

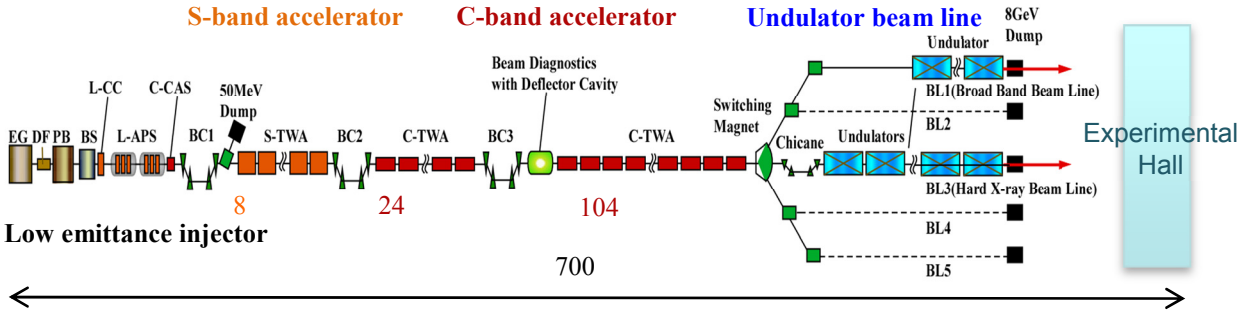

Figure 1: Machine layout of SACLA. SACLA comprises a low-emittance injector including a CeB6 500 kV thermionic electron gun (EG), a beam chopper (DF), a 238 MHz sub-harmonic buncher (SHB or PB), a 476 MHz booster cavity (BS), an L-band correction cavity (L-CC), L-band alternating periodic structures (L-APS) and a C-band correction accelerating structure (C-CAS)), a bunch compressor 1 (BC1), 8 S-band accelerating structures, a bunch compressor 2 (BC2), 24 C-band accelerating structures, a bunch compressor 3 (BC3), 104 C-band accelerating structures and undulator beam lines (BL1 and BL3) with 18 undulators.

Table 1: Present parameters of the X-ray and electron beam of SACLA

X-ray	
Wavelength (Å)	~ 0.6
Peak Power (GW)	10
Pulse Length (fs)	200 ~ 30
Photons per pulse	2 x 10^{11}
Pulse Energy (mJ)	0.1 ~ 0.5
Bandwidth	10^{-3}
Peak brilliance (ph/s/mm^2/mrad^2/0.1% BW)	1x 10^{33}
Coherence (transverse) (longitudinal)	2D coherent Multimode
Electron Beam	
Energy (GeV)	~ 8.5
Charge (nC)	0.2 ~ 0.3
Peak current (kA)	~ 3
Pulse width (fs)	10 ~ 70
Normalized Emittance (π mm mrad)	0.1 ~ 0.5
Repetition rate (Hz)	~ 60 (Max.)

Then, a high-voltage chopper forms a 1 ns beam width in FWHM from the 3 μs width to fit the rf phase space of a 238 MHz sub-harmonic buncher (SHB) in order to make velocity bunching. After this, the electron beam is accelerated up to 1 MeV by a 476 MHz booster cavity (booster), and the booster makes velocity bunching. Following the booster, L-band (1428 MHz) alternating-periodic structures (APS) develop further velocity bunching up to about a beam pulse width of 10 ps, produces energy chirp along an electron bunch for the following magnetic bunching process and accelerates up to a beam energy of around 30 MeV. Next, magnetic bunching using 4 bending magnets chicane as a bunch compressor 1 (BC1) compresses a bunch length up to about 3 ps. 8 S-band accelerating structures also cause energy chirp along the bunch for the bunch compression of BC2, and accelerate the electron beam up to 450 MeV. Following this, 24 C-band accelerating structures accelerate the beam up to 1.4 GeV, and provide energy chirp for bunch compression at BC3, which is the final bunch compression stage. These bunch compression processes correspond to an off-crest rf wave acceleration part, which is very sensitive to any outside perturbation, such as an environmental temperature change. A successive part of the bunch compressors, as mentioned above, is 104 C-band accelerating structures, which only accelerate the electron beam at the rf crest part up to an energy of ~ 8.5 GeV. The rf crest acceleration is relatively ten-times more insensitive to perturbations from the environment compared with off-crest acceleration. After obtaining full energy, such as 8.5 GeV, the electron beam passes through an undulator line with an effective length of 90 m in order to amplify an X-ray laser up to a wavelength of 0.063 nm by the SASE process, and to emit the laser to an experimental hall. Table 1 summarizes the characteristics of both the electron beam and the X-ray laser beam. In addition to the present configuration of SACLA, as mentioned above, we have a spare room for 4 other beam lines of BL1, 2 ,4, 5 to meet the requirements of multi-users. BL1 already and partly works for electron-beam tuning and emitting wide-band spontaneous light.

Low-emittance Thermionic Electron Gun

One of the key instruments of the SCSS concept is a thermionic electron gun [3], which is crucial to obtain a low-emittance electron beam. This electron gun uses cathode material of a CeB_6 single crystal heated up to about 1550 ºC; a high voltage pulse of around 500 kV with a pulse width of 3 μs in FWHM is added to the cathode. This single-crystal material is usually used for an electron microscope. This cathode with 3 mm in diameter and 5 mm long radiates an intense electron beam with

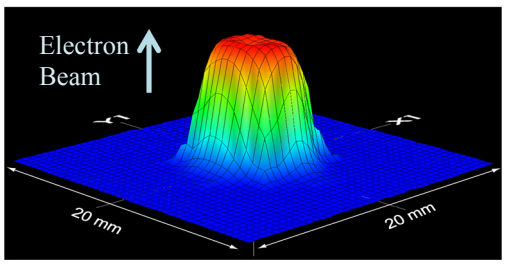

Figure 3: Spatial transverse profile of the beam emitted from the electron gun with a 0.6 πmm-mrad emittance.

a low emittance of 0.6 πmm-mrad from a very smooth surface within a flatness of several μm, when applying a high-voltage pulse. Figure 2 shows the outlook of the electron gun installed in to a SACLA accelerator tunnel. Figure 3 also shows the transverse profile of the radiated electron beam having 0.6 πmm-mrad emittance. The 500 kV high-voltage pulse is generated by almost the same high-voltage pulse modulator as in the klystron case, mentioned below. This modulator generates a 37.5 kV pulse. Then, this pulse is stepped up to 500 kV with a transformer. For impedance matching and interchangeability to a C-band high-power rf system, as also mentioned below, a 500 kV klystron like dummy tube without cavities is employed, because of the high-impedance of our cathode.

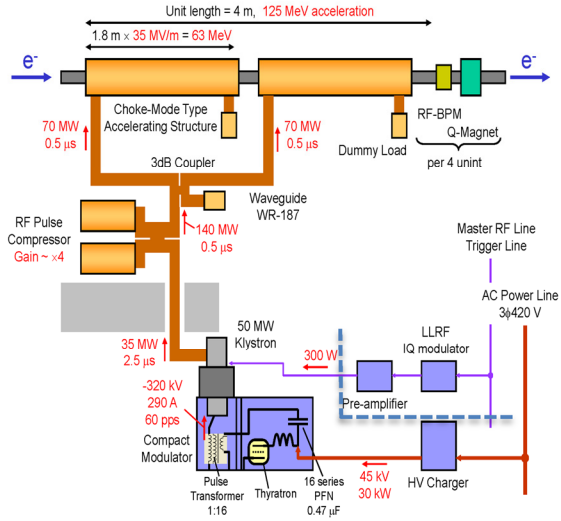

Figure 4: Schematic diagram of the C-band accelerator system. The system comprises 2 C-band accelerating structures, high-power waveguide components, a 50 MW klystron with a 2.5 μs rf output pulse width, a pulse modulator and a high-voltage inverter power supply.

C-band High-gradient Acceleration System

A C-band acceleration unit is depicted in Fig. 4 [4]. There are 64 units in a SACLA accelerator building. Each unit has two 1.8 m choke mode accelerating structures, a vacuum waveguide system including an rf pulse compressor, SLED, with an rf multiplication factor of 4, a 50 MW klystron generating a 2.5 μs width rf pulse, a 350 kV pulse modulator to drive the klystron, a 45 kV inverter power supply, and a low-level rf (LLRF) and timing system. When the klystron generates a 35 MW rf pulse, the SLED generates a 200 MW peak rf pulse fed into the 2 accelerating structures. Then, these structures provide a 35 MV/m acceleration gradient. Figure 5 shows the preset acceleration gradient produced by the C-band system. The 350 kV high-voltage pulse is formed with a pulse transformer placed under the klystron from a 45 kV pulse, which is generated by a pulse forming network (PFN). This PFN is charged with the 45 kV inverter power supply, and the 45 kV pulse is made by switching charge in capacitors constituting the PFN with a thyratron.

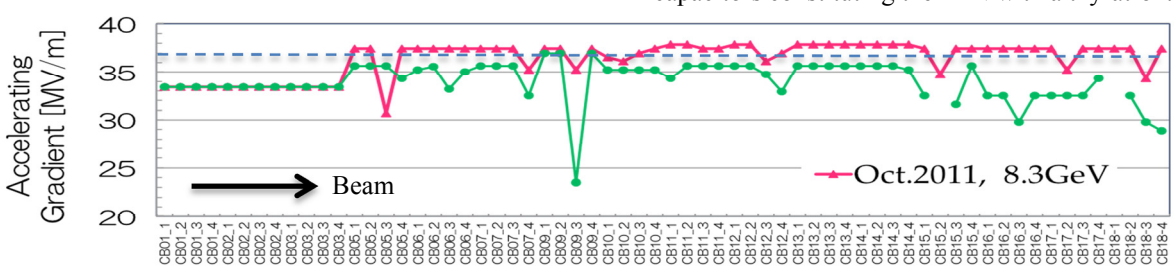

Figure 5: Acceleration electric-field gradients of all the C-band units along the SACLA accelerator. The electric-field gradients of almost all the C-band units after BC3 reach values of more than 37 MV/m. The red line with the solid triangle dots shows the case at a beam energy of 8.3 GeV; the green line with the solid round dots shows the case of 7 GeV. The blue dotted line is a reference value of 37 MV/m.

In-vacuum and Short Period Undulator

One of the effective methods to reduce a gain length of FEL amplification is an in-vacuum undulator [5], in which short period permanent magnets assemblies are installed into a vacuum chamber. Therefore, the gap distance between the magnets, which the electron beam passes through, is as narrower as possible compared with an out-vacuum undulator having a vacuum beam duct in the gap. This means we can obtain a large K value by a strong magnetic field conducting a large ρ value and a short gain length. Furthermore, since the gap is movable, the wavelength of the X-ray laser generated with the undulator is changeable. The present minimum gap is 3.5 mm. Figure 6 shows a view of SACLA's 18 undulators installed into a radiation shield room, and Table 2 summarizes the fundamental parameters of our in-vacuum undulator.

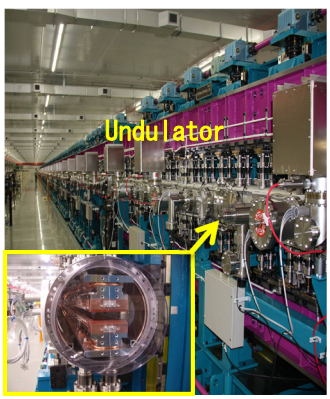

Figure 6: 18 undulators along the BL3 of SACLA.

Table 2: Fundamental parameters of the undulator of SACLA.

Magnet Structure	Hybrid Type
Permanent Magnet Material	NdFeB
Length (m)	5
Period Legth (mm)	18
Number of Periods	277
Number of Undularors for BL3	18
Minmum Gap of Magnet (mm)	3.5
Maximum K value	2.2
K at 0.12 nm, E = 7 GeV	1.8

Key Components to Support Stability

There are many crucial devices to secure SACLA's lasing stability. However, we do not have much space in this paper. Hence, the 2 key components of SACLA, as most important devises, are explained as follows. One is the inverter power supply for the klystron modulator, which decides the rf phase and amplitude stability of a klystron output. Because a change in the output voltage of the inverter power supply is associated with a klystron high-voltage change, it varies the electron beam velocity (energy) in the drift tube of the klystron. The demanded voltage stability of the power supply is less than 100 ppm (rms), which comes from a required rf temporal (phase) stability of 100 fs in the accelerating structures of the off-crest part, as mentioned in the introduction. Our developed inverter power supply employs hybrid coarse and fine voltage-control power supplies working in parallel. Figure 7 shows the voltage-control performance of the inverter power supply, which is sufficient for our demand.

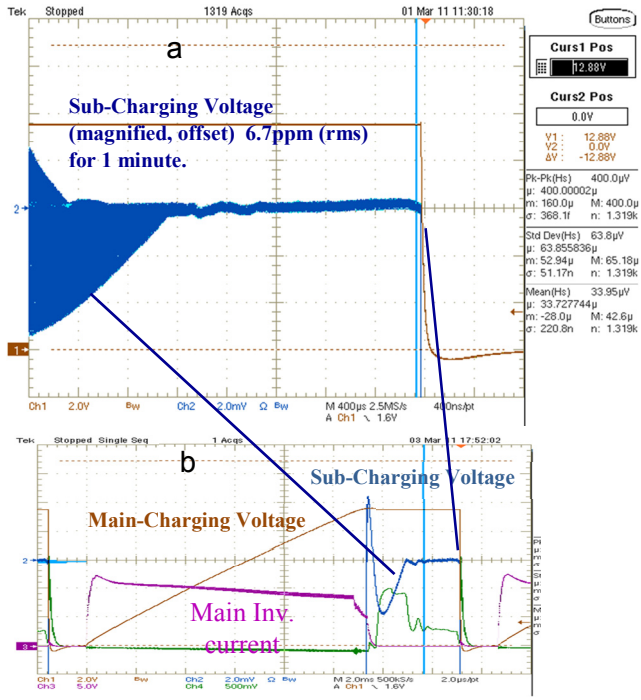

Figure 7: Voltage stability of the inverter power supply. The stability is 6.7 ppm in rms for 1 minute. The upper "a" drawing shows the magnified amplitude and time scales case. The lower "b" shows the reduced amplitude and time scales case.

Next, an indispensable part is the LLRF system [11], which mainly determines the beam temporal stability associated with lasing instability. This system comprises a master oscillator that generates 238, 476, 1428, 2856, 5712 MHz reference signals to drive the high-power rf source, like the klystron, through an in-phase quadrature modulator for pulse modulation and rf amplitude and phase control, and a 500 W solid-state pulse amplifier. These signals are transmitted by phase-stabilized optical fibers with a thermal optical length coefficient of 2ppm/K. The temperatures around these LLRF components, as well as the optical fibers, are controlled by cooling water within 0.1 K to reduce any rf phase and amplitude drifts. One of the performances of the LLRF system is shown in Fig. 8, which is the rf amplitude and phase stabilities at 238 MHz SHB driven with a 10 kW solid-state pulse amplifier. This amplifier is directly connected to the LLRF system. The rf phase and

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

amplitude stabilities are 0.0067 deg. and 1 x 10^{-4} in rms for 24 hours, respectively. These values are almost sufficient for our demand.

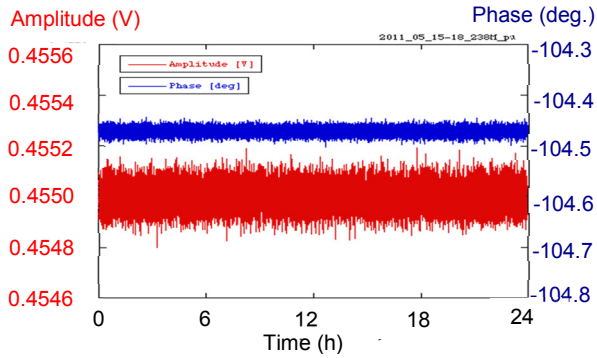

Figure 8: Phase and amplitude stabilities of the 238 MHz SHB. The phase stability is 0.0067 deg. in rms and the amplitude stability is 1 x 10^{-4} in rms for 24 hours.

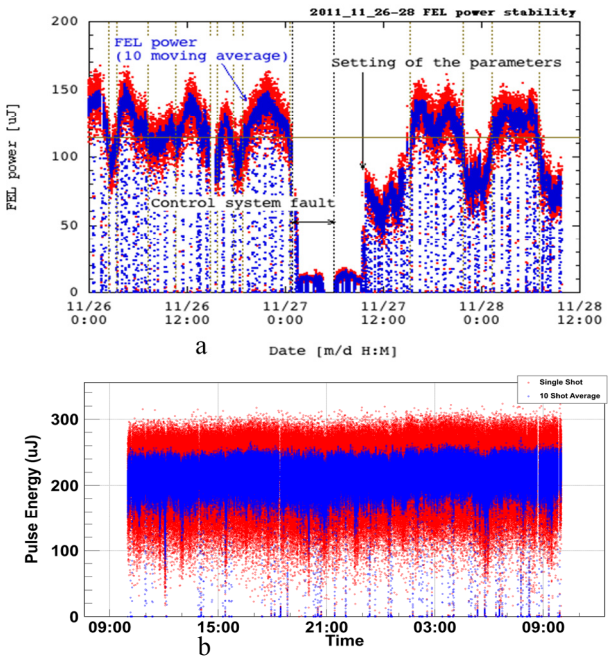

Figure 9: Lasing intensity stabilities. a, intensity variation for 3 days with the rf phase and amplitude control of all SACLA's cavities and the incident beam orbit control for BL3; b, lasing intensity stability with the operator's fine trimming for the rf phase and amplitude of the injector cavities.

LASING PERFORMANCE AND PROBLEM

SACLA lased at 0.1 nm in June, 2011, after beam commissioning by using the above-mentioned instruments. Then, the lasing intensity stability of SACLA, as shown in Fig. 9-a, was not sufficient. For 3 days, we could keep the X-ray lasing with only feedback control loops of the rf phases and amplitude of all the cavities and an incident beam orbit on the undulator of BL3. After this, improvements of the instrument stabilities, such as temperature regulation betterment in the injector cavities (e.g. SHB) from within 0.1 K to within 0.004 K, were performed [12]. Finally, we obtained further lasing intensity stability, as described in Fig. 9-b. However, this intensity stability was established by the operator's fine trimming of the rf phases and amplitude at the cavities around the injector. The frequency of the trimming is once or twice an hour.

SUMMARY

SACLA, 700 m long, which is shorter than the other XFEL machines, lased at up to 0.063 nm in 2011. This is the world shortest wavelength of a laser. The lasing intensity stability is an acceptable level for user experiments. This means the short-term instrument stabilities already reached at our demanded values, like a temporal electron beam stability of 100 fs. However there is still laser intensity drift caused by the characteristic drifts of accelerator instruments, such as insufficient temperature regulations of the rf cavities in an injector. Operator trimming of the rf phases and amplitude at the injector cavities cures the lasing intensity drift up to an acceptable level. We are now planning and executing improvements to obtain further laser-intensity stability without operator trimming.

ACKNOWLEDGMENT

The authors appreciate the members of the XFEL/SPring-8 construction group their support to our study and development.

LCLS OPERATIONAL EXPERIENCE AND LCLS-II DESIGN*

Tor O. Raubenheimer#, for the LCLS/LCLS-II Team, SLAC, Menlo Park, U.S.A.

Abstract

Five months after first lasing in April 2009, the Linac Coherent Light Source (LCLS) began its first round of x-ray experiments. The facility has rapidly attained and surpassed its design goals in terms of spectral tuning range, peak power, energy per pulse and pulse duration. There is an ongoing effort to further expand capabilities while supporting a heavily subscribed user program. The facility continues to work toward new capabilities such as fs-scale pulses, self-seeding, synchronized THz for pump-probe, and multiple-bunch operation. Future upgrades will include polarization control as well as hard and soft x-ray self-seeded operation. The facility is already starting to construct a major expansion, with two new undulator sources and space for four new experiment stations referred to as the LCLC-II.

LCLS FACILITY

The Linac Coherent Light Source Facility (LCLS) at SLAC National Accelerator Laboratory is based on the last third of the SLAC linac where a high brightness beam is generated in an off-axis injector and then accelerated to ~14 GeV [1,2]. The concept for the facility was laid out in 1992 at the Workshop on 4th Generation Light Sources at SLAC [3]. Now, the LCLS is well on its way to realizing all the scientific capabilities envisioned in *LCLS – the First Experiments* [4], which described six broad areas of opportunity for research with an x-ray laser.

The facility achieved its design goals during the first weeks of operation [5] and is developing new capabilities on an almost weekly basis. Essentially all the experiment techniques envisioned for LCLS are being tested and proven in operation and the full suite of three experimental stations in each of two experiment halls have been commissioned as indicated in Table 1.

Table 1: LCLS Experimental Stations

Experimental Station	Start of User Operations
Atomic, Molecular & Optical Science (AMO)	October, 2009
Soft X-ray Materials Science (SXR)	June, 2010
X-ray Pump-Probe (XPP)	October, 2010
Coherent X-ray Imaging (CXI)	February, 2011
X-ray Correlation Spectroscopy (XCS)	November, 2011
Matter in Extreme Conditions (MEC)	April, 2012

* Work supported in part by the DOE Contract DE-AC02-76SF00515.
# tor@slac.stanford.edu

The principal performance goals of LCLS-I were to produce:

- X-ray pulses of 230 femtoseconds duration or shorter
- Photon energies ranging from 800 eV to 8,000 eV
- 10^{12} photons per pulse at 8 keV

As noted, these goals were achieved or exceeded promptly at the outset of commissioning, in April- May 2009; a list of the present operating parameters can be found in Table 2. A rapid and productive research program commenced with a 1,300 hour operation run, October-December 2009, during which 152 experimenters participated in 11 experiments. Productivity has continued to increase; in FY2010, 359 experimenters participated in LCLS experiments. Demand for access to LCLS continues to grow as illustrated in Fig. 1 where the proposals for each the experimental stations is is plotted versus run number; each run is roughly 5 months in duration. However, as shown in Fig. 1, the LCLS productivity is already limited by capacity; only one in four proposals receive beam time.

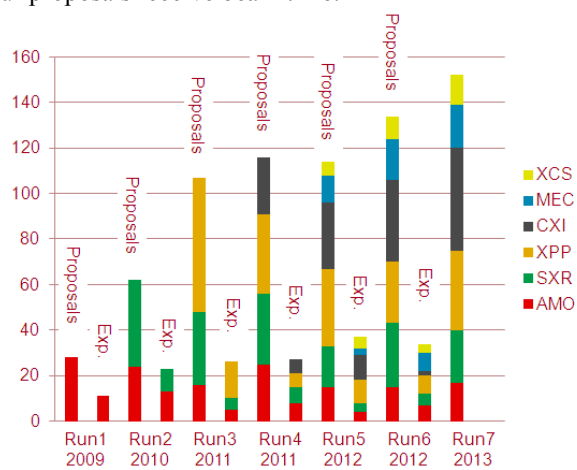

Figure 1: LCLS proposals and experiments receiving beam time by experimental station and run number.

OPERATIONAL EXPERIENCE EXTENDED LCLS CAPABILITIES

Rapid progress in accelerator research and accelerator commissioning has made it possible to expand LCLS capabilities well beyond the LCLS the goals listed in the previous section. The energy produced in a single x-ray pulse has reached 6 mJ. The operating range of photon energies, originally specified at 800-8,000 eV, has been expanded to 480-10,000 eV, limited by the electron beam energy and the fixed period and magnetic field in the undulator. The pulse duration can be varied between a few femtosecond (fs) and 500 fs with soft x-rays and a few fs to ~100 fs for hard x-rays.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Table 2: Typical LCLS X-ray Beam Characteristics

X-RayTuning Range	480 - 10,000	eV
Peak Power	up to 70	GW
Bandwidth, 8,000 eV	0.2 typical; <0.01 seeded	% FWHM
Bandwidth, 800 eV	0.5 typical	% FWHM
X-Ray pulse duration	~3-500	x 10^{-15} sec
Beam size at waist, 800 eV	20, typical	μm, RMS
Beam divergence, 800 eV	20, typical	μrad, FWHM
Beam size at waist, 8,000 eV	15, typical	μm, RMS
Beam divergence, 8,000 eV	3, typical	μrad FWHM
Energy/Pulse	> 2 typical, 6 max	mJ
Energy Jitter/Pulse	5 typical	%
Pulse Repetition Rate	120	Hz

Perhaps the most important measure by which LCLS has exceeded its design goals is in it's flexibility. The x-ray pulse length and pulse energy and the beam and photon energy can all be rapidly varied; typical x-ray parameters are listed in Table 2. For example, the LCLS routinely operates with 80 fs pulses, a duration at which it readily produces 2 mJ/pulse. But the pulse duration can be readily adjusted from a few fs to 500 fs in response to user needs. Such changes can be achieved in a matter of minutes in most cases. Generally, peak power remains constant or is increased somewhat as the pulse duration is reduced. This ability to change pulse length has proven to be extremely important and data collection at several pulse durations is now a routine part of most LCLS experiments.

Similarly, many experimenters will want to scan many x-ray photon energies during their shifts. With the fixed gap undulator in the LCLS, this requires adjusting the beam energy. The photon energy can be varied between 480 to 10,000 eV. Making small changes of a few % can be done in minutes while making larger changes can take as long as an hour.

This performance is due to an injector that significantly exceeds the design performance [6], a linac and bunch compression system that is extremely well understood [7], extensive feedback and control systems that allow varying across a broad range of parameters with minimal impact to the expected performance [8], and a long highly precise undulator and beam-based alignment system [9].

Finally, another critical performance metric is the x-ray availability for user experiments. The LCLS runs delivering x-rays over a 5-day block of time (typically two experiments) followed by two days for scheduled maintenance or machine development, The facility has been running extremely well, with better than 93% availability of x-rays for the users [10] as illustrated in Figure 2.

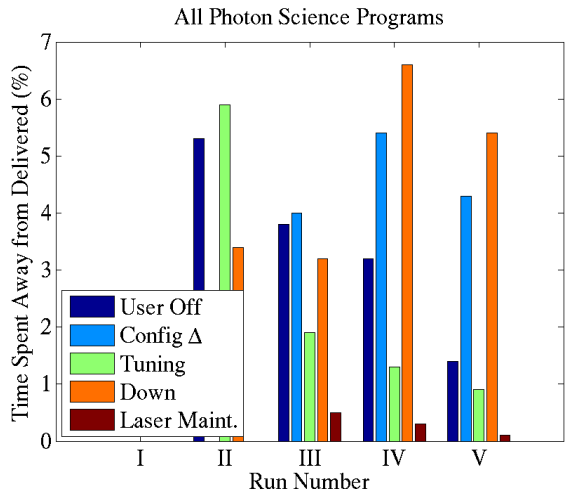

Figure 2: LCLS availability from May 2010 through May 2012; note that User Off and Configuration Δ are counted as available time to users while Tuning, Down and Maint. Are counted as unavailable time (Ref. [10]).

LCLS R&D PROGRAM [11]

The capabilities of LCLS continue to expand at a rapid pace. In the next few months and years, it will be possible to:

Produce pulses with duration approaching 1 fs: Two techniques for producing very short (~1 fs) x-ray pulses were proposed during the design of LCLS [12,13], and both have yielded very good results during accelerator studies and in x-ray experiments. Operation with low (20 picocoulomb) charge, it has been possible to produce electron bunches shorter than 10 fs with pulse energies of ~0.14 mJ. This configuration is used in routine operations at the request of x-ray experimenters. Using new techniques for measuring the electron bunch length [14,15], it may be possible to achieve 1 fs rms resolution. Direct measurement of the x-ray pulse length is perhaps even more important. A new X-band deflecting cavity is being installed after the undulator and it should provide fs-scale resolution of both the electron beam and the x-ray pulse [15]. Studies of the x-ray spectrum and development of accurate x-ray timing diagnostics will hopefully enable better understanding of the time structure of the x-ray pulse.

Produce short, hard x-ray pulses with full temporal coherence; A very attractive scheme for self-seeding short hard x-ray pulses [16,17] was proposed and has been demonstrated in the LCLS producing a bandwidth roughly 50 times smaller than SASE [18,19]. The scheme can be implemented without significant impact on other operating modes. Compatibility with normal operations has been established and seeded beams will be offered to users starting in the Fall of 2012 [20]. A soft x-ray self-seeding experiment is being design for the LCLS and will be tested in roughly two years.

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

Produce terawatt-level peak powers; When generating temporally coherent x-ray pulses, it is also possible to heavily taper the undulator to extract very high peak powers. Simulation studies appear to support the generation of terawatt-level peak powers with tapers on the order of 10% [21]. Studies are being performed on the LCLS to verify the physics of heavy tapering.

Provide polarization control: LCLS is presently developing options for polarization control. In specific, the DELTA undulator [22] is a novel compact design with a fixed gap that would fit with the LCLS undulator system. Both the polarization and the K are fully adjustable. SLAC is building a 3.2-m prototype to be installed and tested at the end of the LCLS undulator [23].

Provide a synchronized source of high-field pulsed THz radiation: Passing the electron beam through a thin conducting foil will generate Optical Transition Radiation (OTR). With a bunch length of 10-100 fs, one can expect OTR in the frequency range 10-100 THz; however it is more useful to think of the OTR as an electromagnetic pulse with time structure similar to the derivative of the beam current. SLAC researchers are presently investigating the feasibility of producing OTR pulse with electric fields in the range 0.1-1 volt per Ångstrom. If successful, these pulses might be transported to the Near Experiment Hall hutches for THz pump/x-ray probe investigations.

Provide two x-ray FEL pulses (using two electron bunches), separated by a few nanoseconds, has been demonstrated [24]. This is an enabling step toward novel techniques for pump/probe experiments with LCLS or simultaneous 120 Hz operation of multiple undulators using a single injector.

LCLS-II PROJECT [25]

The LCLS-II Project (LCLS-II) will provide a major enhancement of the LCLS. LCLS-II will enable operation and optimization of the electron beam for its two new undulator sources with complete independence from operation of the existing LCLS undulator x-ray source and experiment stations. LCLS-II will also construct the essential infrastructure necessary to enable LCLS to continue growth in both capacity (up to four x-ray sources and ten experiment stations) and capability (a range of photon energies from 250 eV to >20 keV, a 100x-1,000x increase in brightness and >10X increase in peak power). The design of LCLS-II draws heavily on experience from construction and operation of LCLS. In addition, key design features of LCLS-II have been chosen to support new capabilities presently under development at LCLS.

The LCLS-II will take advantage of existing SLAC infrastructure and accelerator facilities, most notably the second kilometer of the 3-km SLAC linac. The addition of this second electron source will greatly enhance LCLS operations flexibility. Experience has already shown a surprisingly high demand for changes in x-ray pulse duration. It is common practice to change pulse durations once or twice a day. With two completely independent sources of electrons, the new undulator sources for LCLS-II can be optimized without compromising the needs of experiments using the LCLS undulator. LCLS-II also re-uses the off-axis vault at Sector 10 to house the injector linac, and the beam transport facilities originally built to inject electrons into the PEP-II ring. This transport line passes through Sectors 20-30 of the SLAC linac, which provides electrons to LCLS. The operating range of the hard and soft x-ray undulators is illustrated in Figure 2 while Figure 3 is a schematic of the LCLS-II layout and associated electron beam diagnostics. Finally, Figure 4 shows the planned civil construction and the location of the new Undulator and Experimental Halls.

This expansion of the LCLS facility will build upon the proven performance characteristics of the LCLS, enabling groundbreaking research in a wide range of scientific disciplines. LCLS-II will create unbounded opportunity for research into atomic-level dynamics of processes that are fundamentally important to materials science, chemistry and the life sciences. The LCLS-II conceptual design provides greatly enhanced capacity and capability for the LCLS facility.

The Linac Coherent Light Source II (LCLS-II) Project conceptual design will provide the following facility enhancements:

- A hard x-ray undulator source (2-13 keV).
- A soft x-ray undulator source (250-2,000 eV).
- A dedicated, independent electron source for these new undulators, using sectors 10-20 of the SLAC linac.
- Modifications to existing SLAC facilities for the injector and a new shielded enclosure for the two new undulator sources, beam dumps and x-ray front ends.
- A new experiment hall capable of accommodating at least four experiment stations.

The undulator sources will produce spatially coherent plane-polarized x-rays by self-amplified spontaneous emission (SASE). They will be designed to be compatible with future upgrades to include full temporal coherence and polarization control.

Much of the new technical systems and facilities will be virtually identical to those constructed in the original LCLS Project (LCLS-I) and the LCLS Ultrafast Scientific Instruments equipment project (LUSI). The LCLS-II Project will build on experience and lessons learned during LCLS-I construction, commissioning and operation so as to reduce cost, schedule and technical risk.

There are, however, important differences between the LCLS-II design and LCLS:

- The LCLS-II undulators are variable-gap devices that are being produced at LBNL and are similar

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

in design to those planned for the European XFEL or in common use at many storage ring light sources

- The LCLS-II undulator hall is 302-m in length, 132-m longer than in LCLS. This will provide sufficient length to achieve SASE performance goals at 13 keV, and additional length for undulators and other hardware necessary to achieve 1 TW power levels at 13 keV.
- LCLS-II has one experiment hall, whereas LCLS-I constructed two halls
- The LCLS-II experiment hall is 80-m in length, an increase of 10-m compared to LCLS

The LCLS-II undulator hall will provide ample space for future upgrades such as self-seeding systems, polarization-control "afterburner" undulators and generation of multi-color x-ray pulses. The tunnel can also accommodate a large number of post-saturation tapering undulators to produce x-ray pulses with extreme peak powers (approaching one terawatt).

Much of the new technical systems and facilities will be virtually identical to those constructed in the original LCLS Project (LCLS-I). The LCLS-II Project will build on experience and lessons learned during LCLS-I construction, commissioning and operation so as to reduce cost, schedule and technical risk.

The LCLS-II Project will enable expansion of LCLS to keep pace with the explosive growth of research opportunities and user demand which will saturate the existing facility.

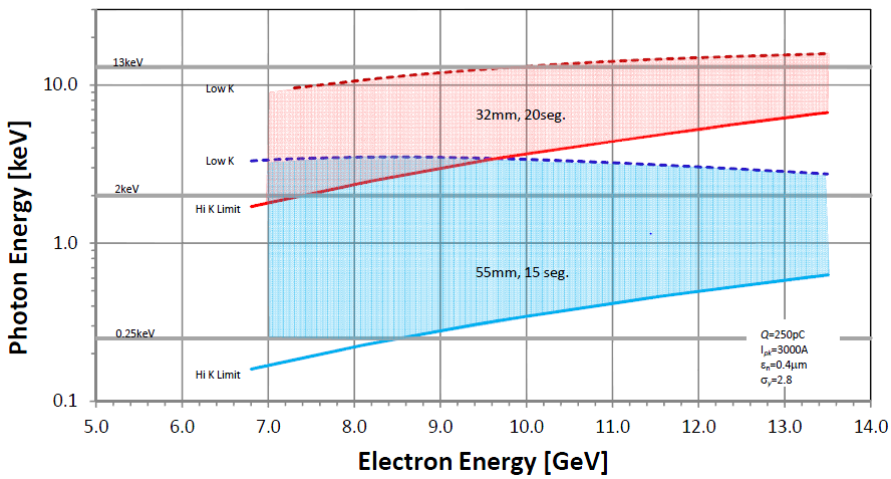

Figure 2: Photon energy versus electron beam energy at saturation for the two new undulator sources proposed in the LCLS-II Project. The blue field indicates the range of the soft x-ray (SXR) undulator source and the red field indicates the hard x-ray operating range range. The lower range on the curves is set by the largest *K* available for each undulator while the upper bounds on the curves is set by the installed length of undulator which is initially planned to be 66-meters in the SXR and 88-meters in the HXR; the upper bounds increase with the installation of additional undulator segments which can be accommodated in the long Undulator Hall which is roughly 300-meters in length.

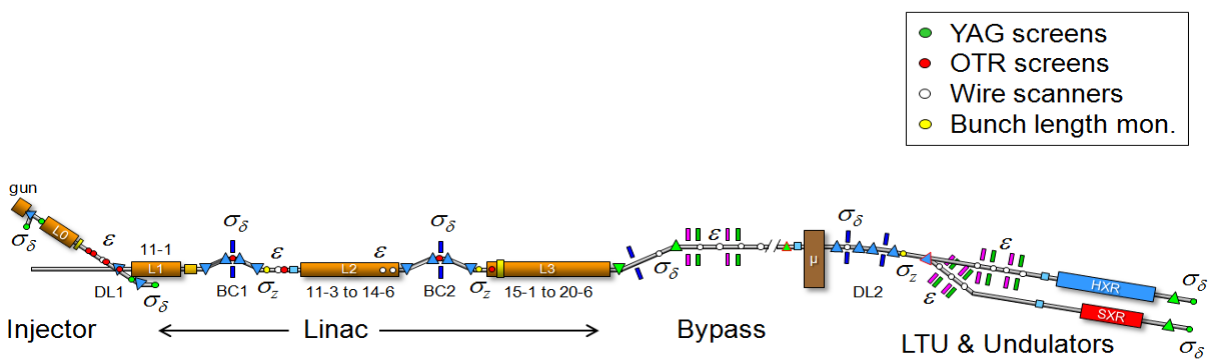

Figure 3: Schematic of the LCLS-II design illustrating the Injector, Linac and bunch compressors, the 1.2 km long bypass around LCLS-I and the Linac-to-Undulator (LTU) and undulators. The primary beam diagnostics are shown for each section.

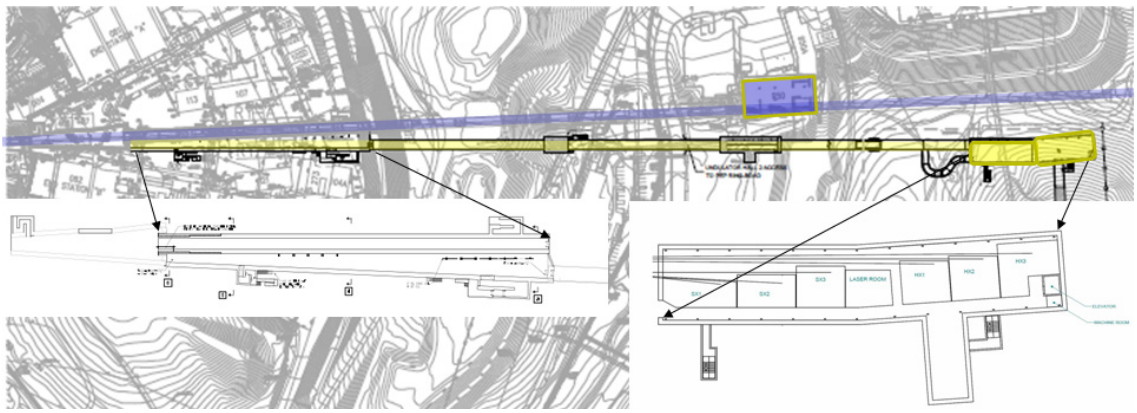

Figure 4: Layout of LCLS-I and LCLS-II. Items tinted blue are existing LCLS facilities. Items tinted yellow are new LCLS-II facilities. Blow-ups of the Beam Transport Hall extension and the new Experiment Hall are shown below the site layout. The LCLS-II Beam Transport Hall is attached to the existing facility at the "headhouse". The long Undulator Hall, roughly 300-meters in length, will be used to support a number of possible upgrades including self-seeding, multi-color generation, polarization control and the generation of terawatt-scale peak x-ray powers.

ACKNOWLEDGEMENTS

The author is grateful to John Galayda and Zhirong Huang for their careful reading of the paper and the LCLS and LCLS-II Teams for their assistance.

THE HIGH-CURRENT ERL AT BNL*

I. Ben-Zvi#, BNL, Upton NY, USA

Abstract

The electron hadron collider eRHIC will collide polarized or non-polarized electrons with a current of 50 mA and energy in the range of 5 GeV to 30 GeV with hadron beams, including heavy ions or polarized light ions of the RHIC storage ring. The electron beam will be generated in an Energy Recovery Linac (ERL) contained inside the RHIC tunnel, comprising six passes through two linac sections of about 2.5 GeV each. The electron ERL poses many challenges in term of a high-current high-polarization electron gun, HOM damping in the linac, crab cavities, harmonic cavities and beam stability. Three R&D projects are underway to provide experience with the eRHIC ERL components. A prototype high-current ERL is under commissioning to test performance at up to 300 mA of the ERL. A prototype polarized-electron gun based on funneling of 20 separate cathodes, providing 3.5 nC per bunch, is under construction and a Coherent electron Cooling (CeC) proof-of-principle experiment is under construction.

INTRODUCTION

RHIC, the Relativistic Heavy Ion Collider at Brookhaven Lab, found it first: a "perfect" liquid of strongly interacting quarks and gluons — a quark-gluon plasma (QGP) — produced by slamming heavy ions together at close to the speed of light. The fact that the QGP produced in these particle smashups was a liquid and not the expected gas, and that it flowed like a nearly frictionless fluid, took the physics world by surprise. Similarly, searches for the source of "missing" proton spin at RHIC have opened a deeper mystery: So far, it's nowhere to be found. To probe these and other puzzles, nuclear physicists would like to build a new machine: an electron-ion collider (EIC) designed to probe structures with extreme precision, at the scale of 10^{-15} meters, both protons and heavy ions to reveal their inner secrets.

The use of an Energy Recovery Linac (ERL) for the electron accelerator of eRHIC was suggested [1] as means to achieve high-luminosity, outstanding polarization and convenient upgradability features. Given a hadron machine design, a linac-ring configuration allows a 10- to 50-fold higher luminosity than an optimized ring-ring design. ERLs combine the advantages of linear accelerators, like beam quality, immunity to resonances, high degree of polarization and beam disruption with those of storage rings, such as high beam power and stability.

#benzvi@bnl.gov

A polarized electron beam with an energy up to 30 GeV would collide with a number of ion species accelerated in the existing RHIC accelerator complex, from polarized protons with a top energy of 250 GeV to fully-stripped uranium ions with energies up to 100 GeV/u covering a C.M. energy range from 45 to 175 GeV for polarized e-p, and from 32 to 110 GeV for electron heavy-ion-collisions. Using the present significant margin of the RHIC superconducting magnets the maximum beam energy could be increased by 10 or more percent.

The eRHIC design is based on using one of the two RHIC hadron rings and a multi-pass ERL. Using an ERL as the electron accelerator assures high luminosity in the range of 10^{33}~10^{34}cm^{2}s^{-1}. Locating the ERL inside the RHIC tunnel allows for significant cost savings and natural staging: the energy can be increased from the initial 5 - 10 GeV of the first stage to the final 30 GeV by incrementally adding additional accelerating cavities to the two main linacs. eRHIC will be able to provide electron-hadron collisions in up to three interaction regions. [2]

Polarized electrons will be generated in a high-current 20 photocathode funneling electron gun. The ion beams of the RHIC component will be cooled by a novel Coherent electron Cooling (CeC) system. The machine will heavily rely on SRF technology for production and acceleration of electrons, cooling of hadron beams and realizing crab crossing collision scheme.

In this paper we will describe the layout of the multi-pass eRHIC electron ERL, and describe R&D projects carried out in the Accelerator R&D Division of the BNL Collider-Accelerator Department (C-AD) towards the realization of eRHIC, including the polarized electron source, the SRF cavities (5-cell accelerating cavities, crab cavities), the R&D high-current ERL and the CeC Proof-of Principle (PoP) experiment.

LAYOUT OF THE ACCELERATOR

eRHIC General Layout

Figure 1 presents a layout of the collider with locations of various systems in the existing RHIC tunnel. The injection system consists of an electron gun, 10 MeV SRF injector linac (with no energy recovery) and 600-MeV single-pass SRF ERL. Two 2.45 GeV SRF linacs in combination with six passes make the main ERL. In addition to the main SRF linacs, eRHIC will have energy loss and energy spread compensation linacs (not shown in the figure). The CeC accelerator will consist of a low frequency SRF gun and buncher and a 136 MeV ERL. Finally, there will be SRF crab cavities for both hadrons and electrons (not shown in figure). The lattice provides separation of the electron orbits to individual arcs in the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

arcs, similar combiners to bring the orbits on the axis of the linac sections and bypasses for the interaction points.

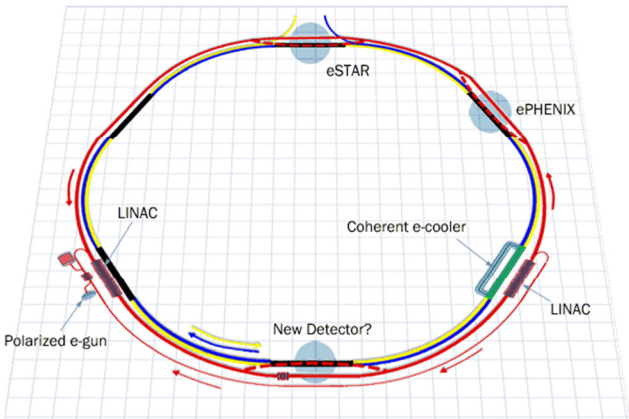

Figure 1: A schematic of the design for adding an electron ring (red), and possible future detector, to RHIC to create eRHIC, which would be the world's first electron-ion collider (EIC).

eRHIC Lattice

The lattice of recirculation passes is based on a low-emittance near-isochronous cell, which allows a flexible tuning R56 parameter and has a large dipole filling factor to minimize synchrotron radiation. The four splitters/mergers provide the transition between the beam line in the linacs and six vertically arranged recirculation passes in the arcs. The by-pass lines around the experimental detectors are provided for all recirculation passes except the top energy pass. The electron and proton bunch frequencies at different proton energies are matched by a combination of path length variation of the electrons and the electron RF harmonic. More details on the electron optics can be found in [3].

One potential weakness of the ERL is transverse beam break-up (BBU) instability that could severely limit the available beam current. Strong damping of HOMs has been the method of choice for suppressing BBU instabilities. A new method of suppressing BBU by many orders of magnitude has been recently proposed [4,5]. This method uses the chromaticity of the transverse motion, a naturally occurring effect, to dephase the transverse instability.

SRF Systems

The rather extensive SRF systems of eRHIC are described in detail by Belomestnykh [6,7]. These include ERL cavities at 704 MHz, low frequency injector cavities at 112 MHz, energy loss and energy spread compensation cavities at 1408 MHz, and crab cavities at a number of harmonics – 225 MHz, 450 MHz, 676 MHz and 1013 MHz. In this paper I will concentrate on the main linac cavities and the ERLs. The ERLs do not include any quadrupole magnets, still providing reasonably low beta-functions in the linacs. SRF linacs for the three ERLs (main ERL, 600-MeV pre-accelerator, and CeC) will utilize the same 704-MHz linac technology with minor modifications. Some parameters of these linacs are presented in Table 1. Two main ERL linacs will be located in the IP2 and IP10 straight sections, where their lengths are limited to 200 m for each linac. Parameters of the main linacs are listed in Table 1. The energy of the main ERL will be increased from 5 GeV in Phase I to 30 GeV in stages by adding cryomodules to the main linacs until they occupy all allotted space. Due to limitation on the beam loss power, the beam current will be lowered at energies above 20 GeV to keep the synchrotron radiation power loss below 10 MW.

Table 1: Parameters of the 704-MHz SRF Linacs [6,7]

Parameter	Main	Pre-acc.	CeC	injector
E gain [MeV]	2450	590	136	10
Current [mA]	50	50	70	50
Length [m]	200	60	19	5.2
No. of cavities	120	30	8	2
E_{acc} [MV/m]	19.2	18.5	15.1	4.7

eRHIC Main Accelerator Cavities at 704 MHz

A five-cell 703.8-MHz superconducting cavity for high-current applications (Figure 2) is under development at BNL and Stony Brook University [8,9,10]. This cavity has been designed as a universal high-current cavity with respect to damping yet with optimized shunt impedance and low surface electric fields, suitable for proton acceleration as well as electron ERL service.

The cavity has an optimized shape that supports strong damping of higher order modes (HOMs), which is accomplished via six antenna-type couplers attached to the large diameter beam pipes. The prototype copper cavity and niobium cavity were engineered and constructed by Advanced Energy Systems, Inc. (AES) and the niobium cavity is shown in Figure 3. Each cavity will be housed in an individual cryomodule. A series of such basic cryomodules will form one long cryomodule with 1-meter long transitions to room temperature at the ends.

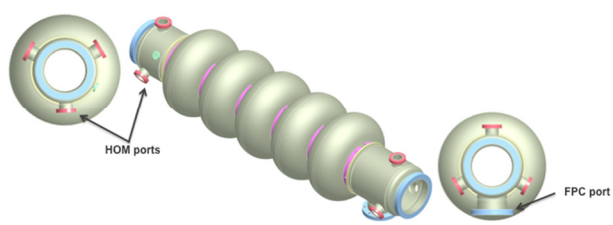

Figure 2: Schematic high-current 704 MHz SRF cavity.

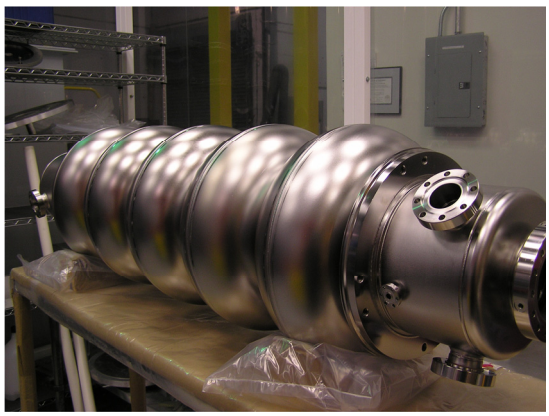

Figure 3: Niobium five-cell 704 MHz SRF cavity.

THE R&D HIGH-CURRENT ERL

The plan for the high-current eRHIC ERL calls for six acceleration passes (and six deceleration passes) of 50 mA in a SRF linac structure. This is a lot of current through each cavity – equivalent to 600 mA. Thus an important part of our R&D program is building a high-brightness 300 mA Energy Recovery Linac (ERL) [11] (see Figure 4).

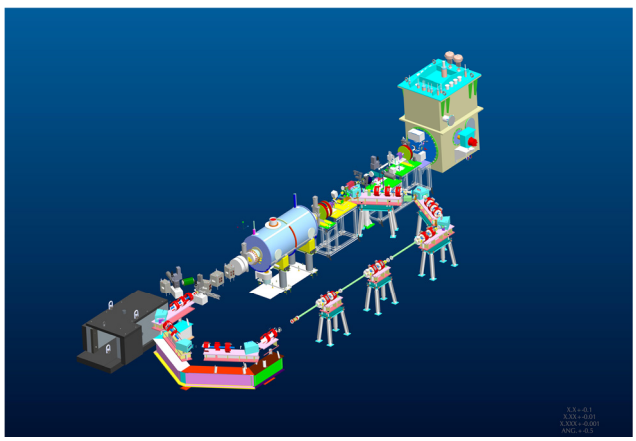

Figure 4: Schematic layout of the R&D Energy Recovery Linac at BNL. The electron gun is on the upper right side; the 5-cell accelerating cavity in the middle and the beam dump is on lower left.

The ERL is in final assembly stages, with commissioning of subsystems going on at present time. The objective of this ERL is to serve as a platform for R&D into high current ERL, in particular issues of halo generation and control, Higher-Order Mode (HOM) issues, coherent emissions for the beam and high-brightness, high-power beam generation and preservation.

BNL is developing several superconducting RF guns for different applications [12]. The first gun is based on a half-cell 1.3 GHz elliptical cavity, made by AES. This gun is used to study generation of polarized electrons from GaAs photocathodes. The second gun, made by Niowave Inc. is based on a quarter-wave resonator, operating at 112 MHz. This gun will be used for photocathode studies, including a diamond-amplified cathode, and to generate high charge, low repetition rate beam for the coherent electron cooling experiment. The third gun, shown in Figure 5, is a half-cell elliptical cavity operating at 704 MHz. It was engineered and constructed by AES and is designed to produce very high average current (up to 500 mA) electron beam at 2 MeV for the ERL prototype from a multi-alkali. This RF gun is equipped with a load-lock cathode delivery system. The accelerating unit of the ERL is a 704 MHz strongly HOM-damped 5-cell cavity built by AES. The AES built ERL ring has a highly flexible single-pass loop and a comprehensive system of beam instrumentation. At the time of writing of this manuscript, all elements of the ERL are in house and most are installed and surveyed to their exact positions. The first beam from the SRF gun is expected in December 2012, beam through the 5-cell cavity is anticipated in February 2012 and beam through the ERL loop in May 2013. We plan to study the performance of this unique machine: The high QE photocathodes and their load-lock delivery system, the SRF gun capable of 500 mA current at 2 MeV beam kinetic energy, the zig-zag beam merger, the highly damped 5-cell SRF accelerating cavity, and various advanced instrumentation elements.

Figure 5: The SRF Photocathode electron gun installed in the ERL vault, as seen from the cathode insertion side Notice the dual waveguide system of the fundamental power couplers.

Of particular interest are the high-current, low-emittance properties of the system, like coherent emissions, beam halo evolution and mitigation and emittance preservation. We plan to increase the current gradually from sub-mA to ampere-class in stages.

THE CEC POP EXPERIMENT

An effective cooling of ion and hadron beams at energy of collision is of critical importance for the productivity of present and future Nuclear Physics Colliders, such as RHIC, eRHIC and ELIC. Such cooling would allow to cool beam beyond their natural emittances and also to either overcome or to significantly mitigate limitations caused by the hour-glass effect and the intra-beam scattering. It also would provide for longer and more efficient stores, which would result in significantly higher integrated luminosity. To efficiently cool the transverse and longitudinal emittances of high-energy proton and ion beams by an order of magnitude, the novel technique of Coherent electron Cooling (CeC) is being considered [13].

The CeC principle of operation is as follows: Initially the hadron beam that is being cooled enters a drift space called "modulator", where it overlaps an electron beam of the exact same average velocity. In the modulator each hadron induces a density modulation in the electron beam. The electron beam is then sent to an undulator, which serves as a high-gain FEL. The density modulation is amplified by the FEL to a desired extent. Then both hadron beam and electron beam are brought to an overlap, following a precise temporal delay, in another drift space called the "kicker". There the hadrons interact with the self-induced electric field of the electron beam and receive energy kicks toward their central energy. The process reduces the hadron's energy spread, i.e. cools the hadron beam. The longitudinal cooling can be shared to cool transversally. Simulations show cooling times of tens of minutes can be achieved for the high-energy proton beam of RHIC, an achievement that cannot be done with traditional stochastic- or electron- cooling techniques.

The eRHIC CeC system will use a small ERL, with 136 MeV energy to produce the 70 mA electron beam for the cooler. A proof-of-principle experiment at RHIC for the CeC technique is under preparation [14]. The electron accelerator for this experiment will use a 20 MeV SRF linac at 704 MHz, based on the cavity described above, and injected by a 112 MHz SRF electron gun [12] equipped with 500 MHz copper buncher cavities.

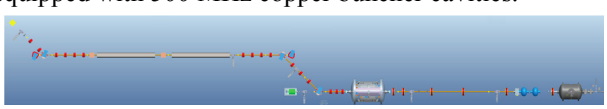

Figure 6: Layout of the Coherent electron Cooling POP experiment. See text for details.

Figure 6 shows the schematic layout of the Proof-of-Principle CeC experiment in RHIC. From right-to-left: 112 MHz SRF gun, normal conducting 500 MHz buncher cavities (blue), transport (solenoids in red), 704 MHz accelerating cavity, dog-leg, modulator section (focusing solenoid in red), FEL amplifier, kicker section (with focusing solenoids) then a bend to an electron beam dump.

THE POLARIZED GUN AND INJECTOR

Since the luminosity in a collider is proportional to the number of particles in each bunch, we want to increase the beam current, hence the bunch charge. When polarized electrons are required the gun performance is ultimately limited by the rapid aging of the cathodes caused by ion back-bombardment. The number of ions that are created in the gun and hit the cathode is proportional to the beam current and the vacuum pressure. A high beam current is therefore a direct cause of cathode aging. The approach we are taking at BNL is to multiplex a large number of cathodes in what is known technically as a funneling scheme. We call it the "Gatling gun" [15, 16], due to its similarity with a historical multiple barrels machine gun. The Gatling Gun R&D project aims to prove the concept of a DC gun with twenty separate cathodes. The beams from these cathodes are merged using a rotating magnetic field. We are carrying out R&D aimed at proving that the destruction caused by the back-scattered ions is reduced for each cathode by a factor of twenty. Each cathode will produce a pulse stream at a frequency of 700 kHz, controlled by a laser. The timing of firing the laser beams is such that each cathode is emitting with a delay relative to the previous one. The 20 cathodes combined thus produce a bunch stream at 14 MHz. As seen in Figure 7, the beams coming out of the cathodes pass through a hole in the anode, then a focusing solenoid, then a 30° fixed field bending-magnet. When the beams reach the central axis of the gun, they are bent onto the exit common path by a field, rotating at 700 kHz.

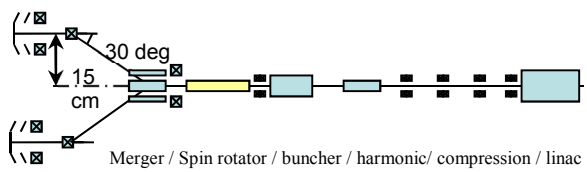

Figure 7: Schematic of the Gatling Gun injector.

The funneling device [17] generates combined dipole and quadrupole-magnetic fields; the symmetries of fields are well preserved, and they can bend and focus the 200 keV beam by 30° with little emittance growth. Our simulations demonstrate that the radius of the good field (0.1%) region is more than 6 cm; the power losses in the coils (including the eddy-current effect) are about 600 W, and the power losses (viz., eddy current, hysteresis, and residual) are about 650 W.

Low frequency SRF structures will be used at the initial stages of acceleration/bunching in the 10 MeV main ERL injector and in the CeC injector.

3.5-nC bunches of polarized electrons will be produced at each cathode for each pulse. The bunches will be relatively long to alleviate space charge effects and will

have to be shortened prior to injection into the 704 MHz SRF linac. This will be accomplished by velocity modulation in a 112 MHz quarter wave SRF buncher. A third harmonic single-cell elliptical SRF structure will be used for linearization. The buncher will operate at accelerating voltage of 1.3 MV and the third harmonica cavity – at 0.6 MV. The gun is in an advanced state of construction, as can be seen in Figure 8, showing the chamber accepting the fixed dipoles and the laser ports.

Figure 8: A component of the funneling polarized electron gun. Laser input ports are shown on top.

SUMMARY

The Accelerator R&D Division of the Collider-Accelerator Department at Brookhaven National Laboratory is carrying out R&D on eRHIC, a high-current, high-energy Energy Recovery Linac (ERL) designed for colliding 50 mA polarized electrons at an energy of 20 GeV with the beams of the Relativistic Heavy Ion Collider (RHIC). The R&D includes the design of the 6-pass ERL beam dynamics, accelerating cavities, crab cavities and other SRF devices. Three focused R&D efforts in this context include the construction, commissioning and testing of three major systems: A 20 MeV, 300 mA R&D ERL, a Proof-of-Principle (PoP) experiment in Coherent electron Cooling and a PoP experiment to demonstrate a funneling polarized electron gun, aimed at extending the current state-of-the-art 4 mA guns to as much as 20 times higher.

ACKNOWLEDGMENT

The various R&D projects described in this paper are the work of a very large number of colleagues at BNL in general, mostly in the Collider-Accelerator Department (C-AD) and in the Accelerator R&D Division of C-AD. The dedicated and expert work of these colleagues is gratefully acknowledged.

THE SWISS FEL RF GUN: RF DESIGN AND THERMAL ANALYSIS

J.-Y. Raguin, M. Bopp, A. Citterio, A. Scherer
PSI, CH-5232 Villigen, Switzerland

Abstract

We report here on the design of a dual-feed S-band 2.5-cell RF gun, developed in the framework of SwissFEL, capable of operating at 100 Hz repetition rate. As in the LCLS RF gun, z-coupling, to reduce the pulsed surface heating, and a racetrack coupling cell shape, to minimize the quadrupolar component of the fields, have been adopted. The cell lengths and the iris thicknesses are as in the PHIN gun operating at CERN. However the iris aperture has been enlarged to obtain a frequency separation between the operating π mode and the $\pi/2$ mode higher than 15 MHz. An amplitude modulation scheme of the RF power, which allows one to obtain a flat plateau of 150 ns for multibunch operation and a reduced average power is presented as well. With an RF pulse duration of 1 μs it is shown that operation at 100 MV/m and 100 Hz repetition rate is feasible with very reasonable thermal stresses.

INTRODUCTION

Paul Scherrer Institut is completing the study of the accelerating systems of SwissFEL, a Free Electron Laser which targets a maximum electron beam energy of 5.8 GeV. SwissFEL is designed for two standard electron beam operation modes, one with a 200 pC charge per bunch and a core slice emittance of 0.43 mm·mrad and the second with a 10 pC charge per bunch and a core slice emittance of 0.18 mm·mrad. SwissFEL, the main linac frequency being the C-band American frequency 5712 MHz, operates with a repetition rate of 100 Hz and two electron bunches, with a spacing of 28 ns, are accelerated at each RF pulse.

The proposed 2.5-cell RF gun operates with a nominal body temperature of 40 °C in the π mode at the S-band frequency of 2998.8 MHz, such a frequency having a common sub-harmonic with the SwissFEL C-band main linac frequency. The beam energy at the exit of the RF gun is about 7 MeV. The two full cell lengths and the iris thicknesses of the RF gun are identical to the ones of the CTF3 PHIN RF gun [1]. The upstream cell, shorter than the two full cells, has a longitudinally adjustable backplane. The middle cell is coupled to two rectangular waveguides symmetrically arranged to cancel the dipolar component of the field. The racetrack interior shape of this coupling cell is optimized to minimize the quadrupolar field component, as in the LCLS RF gun [2]. Long lifetime and reliable operation with the targeted peak on-axis electric field of 100 MV/m requires the optimization of the two RF coupling port dimensions to reduce the dynamic thermal stress due to pulsed heating. With the high 100 Hz repetition rate, mechanical stresses caused by thermal loading have to be thoroughly addressed.

SWISSFEL RF GUN DESIGN

Design with 2D RF Simulations

Ignoring at this stage the middle cell coupling ports, RF simulations performed with the 2D electromagnetic code SUPERFISH [3] are used to determine the radius and the elliptical shape of the irises between the cells compatible with reduced surface electric fields and large frequency separation between the operating π mode ($TM_{010-\pi}$ mode) and the $\pi/2$ next lower mode ($TM_{010-\pi/2}$ mode). The radius of the upstream cell and of the two full cells are adjusted to reach a balanced on-axis field at the operating frequency. The 2D RF design was then guided by the requirements that the mode separation between the operating π mode and the $\pi/2$ mode be higher than 15 MHz and that the peak surface electric field is not higher than the electric field on the cathode. The large mode separation between the operating mode and the next lower mode reduces the impact of the lower mode on the electron bunch energy spread and projected emittance. It is also expected to make the field balance less sensitive to thermal expansion under operational conditions and to manufacturing dimension deviations that may occur during production [4].

Fig. 1 shows the electric field contour lines of the π mode. The cell radii are optimized to obtain field flatness at the operating frequency. The dimensions of some geometrical parameters, used also for the final 3D design, are specified in Table 1. The elliptical profile of the irises is characterized by an aspect ratio of 1.7:1 so that the maximum surface electric field is lower than the peak field on the cathode.

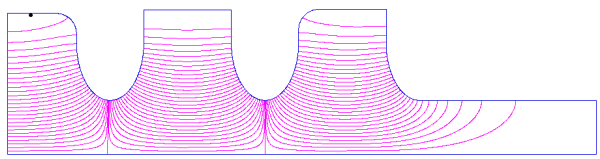

Figure 1: Electric field contour lines of the operating π mode

Table 1: Geometrical parameters of the SwissFEL RF gun

Parameter		Value	
Cell length	20.5 mm	26 mm	26 mm
Iris thickness		20 mm	
Iris radius		16 mm	
Drift radius		16 mm	

Final Design with 3D RF Simulations

The dimensions obtained with the 2D code SUPERFISH are used as input to complete the RF design of the gun with the 3D electromagnetic code HFSS [5], in particular the

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

design of the two RF coupling ports and of the racetrack shaped coupling cell [2, 6]. The coupling apertures, located in the middle cell, are optimized to minimize field distortion, to obtain a coupling coefficient β around 2 and to ensure that the temperature rise per pulse of the most exposed areas does not exceed 50^{o}C. To fulfill these three criteria, the two main features that have been adopted are coupling apertures running longitudinally all along the coupling cell, i.e. z-coupling scheme, and a large inner edge radius of the apertures. In addition, a balanced on-axis electric field is obtained with a minor change of the upstream and downstream cell radii. A cross-section of the RF gun is shown in Fig. 2.

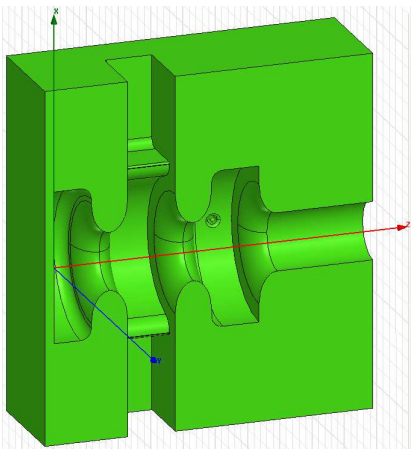

Figure 2: Cross-section of the SwissFEL RF gun.

Fig 3 shows the on-axis electric field along the RF gun in the final RF design. The ratios of the three maxima of the on-axis electric fields are higher than 98%.

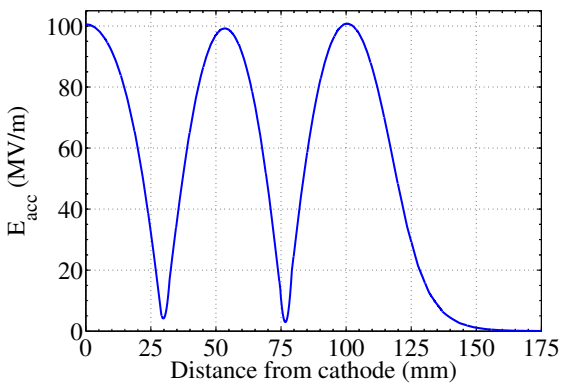

Figure 3: On-axis electric field of the SwisFEL RF gun.

The coupling apertures induce field distorsion in the vicinity of the gun axis that may deteriorate the electron bunch quality. The two symmetrically arranged apertures allow one to cancel the dipolar component of the fields. To reduce the quadrupolar fields, the coupling cell has a racetrack transverse profile. For a given inner edge radius of the apertures, there is some specific combination of aperture width and length of the racetrack straight section which minimizes the quadrupolar component. Fig 4 shows the amplitude of the longitudinal electric fields along both transverse directions of the coupling cell middle plane (see Fig 2 for the definition of the x- and y-axis). Such equal amplitudes are obtained for a width and an inner radius of the coupling apertures of 17.73 mm and 8.5 mm, respectively whereas the racetrack straight section is 7.1 mm long.

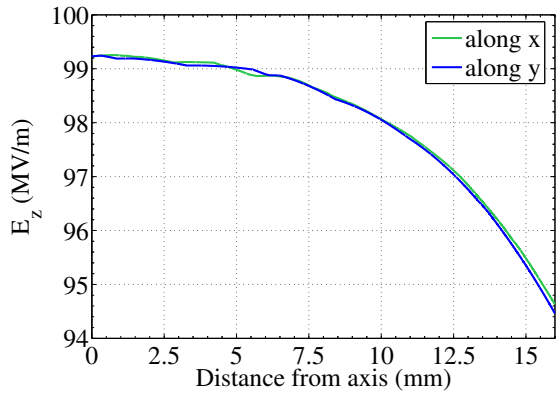

Figure 4: Amplitude of the longitudinal electric field along transverse directions of the SwisFEL RF gun.

The design coupling coefficient β has been chosen to be 2. Overcoupling the cavity at the operating frequency decreases the filling time of the RF gun. The nominal accelerating field can then be reached with a shorter RF pulse, a requirement for reducing the mechanical stresses on the gun body due to thermal loading. In the final design, the π-mode resonance frequency is within 100 kHz of the design frequency with a calculated coupling coefficient β of 1.98. The $\pi/2$ mode is about 16 MHz lower in frequency and the coupling coefficient β is 0.2.

An upper bound of the temperature rise per pulse on the inner surface of the RF gun can be analytically estimated by assuming a constant amplitude of the surface magnetic field over the whole pulse length. This limit $(\Delta T)_{max}$ is given by the formula: $(\Delta T)_{max} = (R_s/K)\sqrt{D/\pi}\sqrt{t_{pulse}}|H_s|^2$, where R_s, K and D are the surface resistance, the thermal conductivity and the specific heat of copper, respectively, at the operating frequency, whereas t_{pulse} and $|H_s|$ are the pulse length and the amplitude of the surface magnetic field, respectively. The distribution of the temperature rise for a 3 μs pulse on the surface of one of the coupling apertures is shown on Fig 5. The amplitude of the surface magnetic field corresponds to a peak on-axis electric field of 100 MV/m. The maximum temperature rise, located all along the aperture, is lower than 45 ^{o}C.

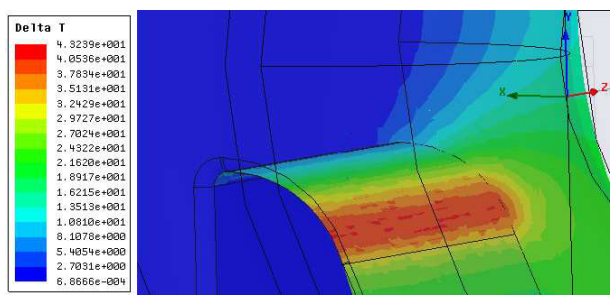

Figure 5: Coupling aperture temperature rise for a 3 μs RF pulse and a peak on-axis field of 100 MV/m.

TRANSIENTS AND THERMAL STRESSES

Since SwissFEL is planned for a two-bunch operation with a 28 ns spacing, an amplitude modulation scheme of the RF input power is proposed to maintain a constant amplitude of the peak accelerating field for a duration longer than the bunch spacing. Assuming zero rise and fall times, an RF power of about 14 MW is required to reach the 100 MV/m nominal peak accelerating field with a 3 μs rectangular RF pulse. In the amplitude modulation scheme, assuming a 1 μs total RF pulse and targeting the nominal peak accelerating field, an RF power of about 18 MW during the first 850 ns of the RF pulse feeds the cavity. The RF power is then quickly reduced to about 14 MW and is kept constant during the last 150 ns of the RF pulse. Such a scheme results in a flat-topped accelerating field of 100 MV/m (see Fig 6). The reflected power is maximum at the end of the RF pulse and is about 28 MW.

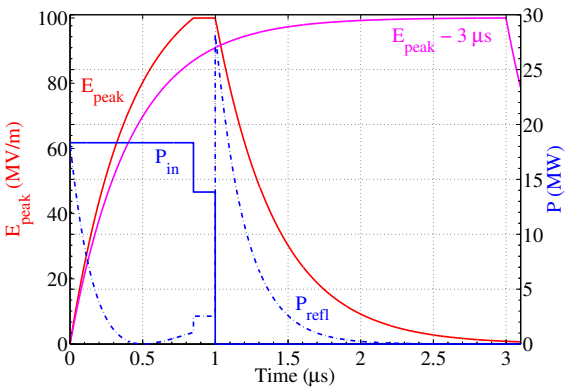

Figure 6: Transient-states of the peak accelerating field and of the RF input and reflected powers.

With this amplitude modulation scheme and with a repetition rate of 100 Hz, the average dissipated power is as low as 0.9 kW (see Fig 7). The temperature rise per pulse on the coupling apertures due to pulsed heating, estimated more rigorously by taking into account the transient behavior of the magnetic surface field during the whole pulse duration [7], is reduced to about 18 °C. With a 3 μs rectangular RF pulse, the average dissipated power is about three times higher and the temperature rise is about twice higher.

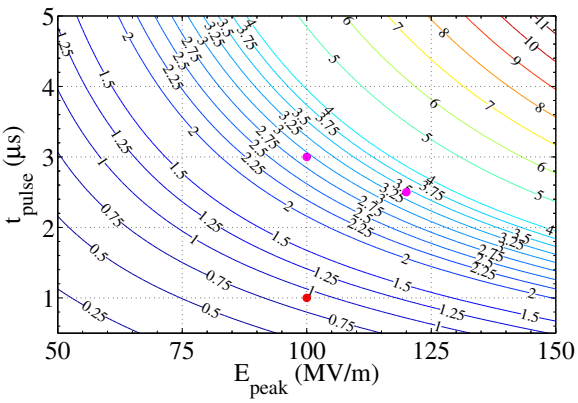

Figure 7: Average dissipated power (kW) vs. peak accelerating field and pulse length for a repetition rate of 100 Hz.

The number, size and location of the cooling channels in the RF gun body are determined with ANSYS [5] simulations for operation with an inlet water temperature of 40 °C and a maximum average dissipated power of 3.5 kW. The thermally induced stresses in the gun body are within an acceptable range with a 0.9 kW thermal load (see Fig 8).

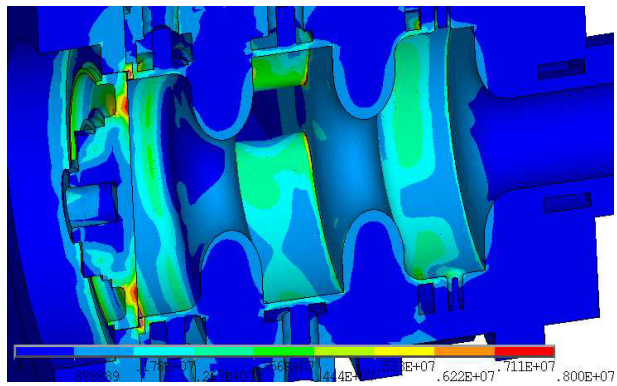

Figure 8: Thermal stress (N/m^2) for a 0.9 kW average load on the SwissFEL RF gun body.

CONCLUSIONS

A dual-feed S-band 2.5-cell RF gun operating in the π mode has been designed for SwissFEL which allows a two-bunch operation with an amplitude modulation scheme of the RF input power. A peak on-axis accelerating field of 100 MV/m can be maintained constant for 150 ns within a 1 μs total RF pulse length. For a pulse repetition frequency of 100 Hz, the total average power loss is then less than 1 kW and the temperature rise per pulse is well below the critical limit. Thermo-mechanical studies led to a design such that the RF gun can safely operate with a thermal load lower than 3.5 kW. The RF gun can then also operate safely at 120 MV/m in the single- and two-bunch regimes. However, the RF pulse length shall not exceed 2.5 μs when operating without amplitude modulation of the input power.

DEFLECTING STRUCTURES WITH MINIMIZED LEVEL OF ABERRATIONS*

V. Paramonov †, INR of the RAS, Moscow, 117312, Russia

Abstract

Deflecting structures are now widely used for bunch phase space manipulations either in special bunch diagnostic or in emittance exchange experiments. As a tool for manipulation, the structure itself should provide the minimal phase space perturbations due to non linear additives in the field distribution. Criterion of the field quality estimation is developed and deflecting structures are considered for minimization of non linear additives.

INTRODUCTION

The Deflecting Structures (DS) - periodical structures with transverse components of the electromagnetic field - initially were introduced for charged particle deflection and separation. The bunch cross DS synchronously with the deflecting field Ed, corresponding the phase $\phi = 0$ in the structure and particles get the increment in the transverse momentum p_t. There are a lot of papers, see for example [1], describing DS design and application for such purpose. At present for short and bright electron bunches DS found another applications, either for bunch special diagnostic, [2], or emittance exchange experiments. Both directions are related to the transformation of particle distributions in the six dimensional phase space and DS operates in another mode - the bunch center cross DS at zero E_d value, $\phi = 90^o$. There are also a lot of papers, describing it in more details. Application for Particles Distributions Transformation (PDT) provide additional requirements - a tool for transformation should provide the minimal, as possible, own distortions to the original distributions.

FIELD DISTRIBUTION QUALITY

For deflecting field E_d description the widely used basis of $TM - TE$ waves can not be used due to degeneration into TEM at $\beta = 1$. A basis of hybrid waves $HE - HM$ was introduced, [3], [4] to avoid this methodical problem. The common representation for the field distribution in the DS aperture is

$$\vec{E} = C\vec{E}_{HE} + D\vec{E}_{HM}, \quad \vec{H} = C\vec{H}_{HE} + D\vec{H}_{HM}, \quad (1)$$

with the weighting coefficient C, D depending both on supporting structure and on operating mode. It is the method of description and results treatment. The physical object - the deflecting force - is the transverse component of the Lorenz force

$$\vec{F}^L = e(\vec{E} + [\vec{v}, \vec{B}]), F_x = eE_d = e(E_x - \beta Z_0 H_y), \quad (2)$$

where $Z_0 = \sqrt{\frac{\mu_0}{\epsilon_0}}$, expressed in (2) through the transverse E_x and H_y components in Cartesian coordinates.

In any periodical structure for Traveling Wave (TW) operating mode each field component $E_j(r, z)$ in the beam aperture can be represented in the complex form as the set over spatial harmonics:

$$E_j(r, z) = \widehat{E_j(r, z)} e^{i\psi_j(z)} = \quad (3)$$
$$= \sum_{n \to -\infty}^{n \to +\infty} a_{jn}(r) e^{\frac{-i(\Theta_0 + 2n\pi)z}{d}},$$

where $\widehat{E_j(r, z)}$ and $\psi_j(z)$ are the amplitude and the phase distributions, d is the structure period and $a_{jn}(r)$ is the transverse distribution for the n-th spatial harmonics. The period length is defined from synchronism with the main a_{j0} harmonic, $d = \frac{\Theta_0 \beta \lambda}{2\pi}$.

The bunch emittance deterioration during PDT take place due to non linear additions both in transverse and longitudinal distributions of the field. There is inevitable nonlinearity at $\beta < 1$ even in main harmonic distribution, vanishing for $\beta \to 1$, [3], [5]. But the main source of additions are higher spatial harmonics. For each harmonic the transverse and longitudinal distributions are rigidly coupled and are proportional to harmonic amplitude. To estimate field quality, we have to estimate the level of spatial harmonics, [5]. Spatial harmonics are essential at the aperture radius $r = a$ and higher harmonics attenuate to the axis as

$$a_{jn}(0) \sim a_{jn}(a) \cdot exp(-\frac{4\pi^2 n}{\beta\Theta_0} \cdot \frac{a}{\lambda}), \quad |n| \gg 1, \quad (4)$$

where λ is the operating wave length. At the axis $r = 0$ just lower harmonics $n = \pm 1, \pm 2, \pm 3$ are really presented. For harmonics estimations in details and 'in total', let us introduce parameters $\delta\psi_j(z)$ and Ψ_j at the axis $0 \le z \le d, r = 0$

$$\delta\psi_j(z) = \psi_j(z) + \frac{\Theta_0 z}{d}, \quad \Psi_j = max(|\delta\psi_j(z)|), \quad (5)$$

with the physical sense as the deviation and the maximal phase deviation of the real wave component from the synchronous harmonic. The qualitative estimation and correct value for $a_{jn}(0)$ one can get as

$$|a_{jn}(0)| < \frac{(\widehat{E_j(0, z)}_{max} + \widehat{E_j(0, z)}_{min})\Psi_j}{2n}, \quad (6)$$
$$a_{jn}(0) = \frac{\int_0^d \widehat{E_j(0, z)} sin(\delta\psi_j(z)) sin(\frac{2\pi n z}{d}) dz}{d}.$$

From linearity, we can apply $\delta\psi_j(z)$ and Ψ_j for quality

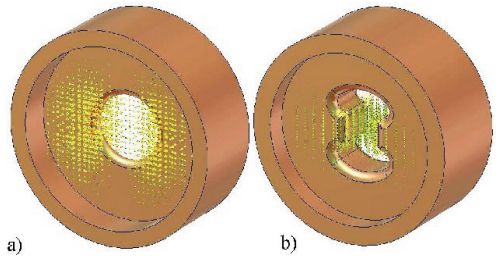

Figure 1: DLW (a) and TE - type (b) deflectors.

estimation both in longitudinal $E_z, \delta\psi_z(z), \Psi_z$ and transverse $E_d, \delta\psi_d(z), \Psi_d$ field components, also estimating PDT quality in these directions. To emphasize the differences in field distribution, the developed method is applied for analysis of DLW [6] and TE - type deflectors, Fig. 1.

OPERATING MODE

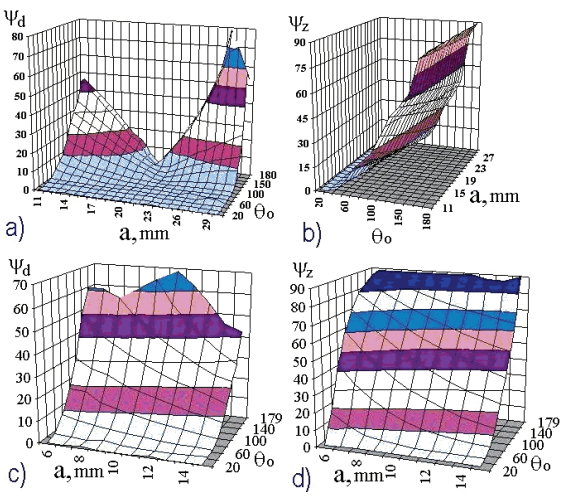

Figure 2: The surfaces $\Psi_d(a, \Theta_0)$ (a,c) and $\Psi_z(a, \Theta_0)$ (b,d) for the DLW (a,b) and TE - type (c,d) deflectors.

Assuming operating frequency $f_0 = 3GHz$, in Fig. 2 are shown the surfaces $\Psi_d(a, \Theta_0)$ and $\Psi_z(a, \Theta_0)$ for the DLW and TE - type deflectors both for TW $0 < \Theta_0 < 180^0$ and Standing Wave (SW, $\Theta_0 = 180^0$) operating mode,[5].

TW Operation

As can be seen from Fig. 2, small Ψ_d, Ψ_z values all time are at lower $\Theta_0 \leq 60^o$ values. For spatial harmonics the decrement of attenuation in (4) is inverse proportional to Θ_0 and $a_{zn}(0), a_{dn}(0)$ all time are small for low Θ_0. It is the common property of slow wave systems. Any periodical structure has reduced aberration level in TW operation with low Θ_0, both in E_z and in E_d distributions. For DLW harmonics attenuation is essentially stronger due to larger aperture radius.

Another effect is very important for E_d distribution and is in mutual phasing of transverse E and H components. For the opposite E_x and H_y phasing (DLW) electric and magnetic components work for deflection together (1), but E_x spatial harmonics compensate or even cancel $Z_0 H_y$ harmonics. It extends low Ψ_d region to higher Θ_0 values, Fig. 2a, and $\Psi_d < \Psi_z$. For the same E_x and H_y phasing (TE deflector) deflection form electric and magnetic components is partially compensated (1), but E_x and $Z_0 H_y$ harmonics add, $\Psi_d > \Psi_z$. The significant harmonics cancellation takes place at $|E_x^0| \sim |Z_0 H_y^0|$ - for comparable amplitudes of synchronous harmonics in E_x and H_y distributions. One can see clear canyon in $\Psi_d(a, \Theta_0)$ surface in Fig. 2a and for the bottom of this canyon $|E_x^0| \approx |Z_0 H_y^0|$. The structures with opposite phasing can provide very small aberrations level in E_d distribution.

In the Table 1 are listed the relative harmonics amplitudes for DLW TW operation. In comparison with DLW LOLA deflector, [6], or similar structures with $\Theta_0 = 120^o$, operation with $\Theta_0 = 60^o$ leads to aberrations reduction in times, especially for longitudinal force. Conditions for RF efficiency in TW case also are more flexible, as compared to SW case. The end cells with RF couplers are the points of special consideration, [5].

Table 1: The relative $a_{zn}(0) \cdot 10$ and $a_{dn}(0) \cdot 10$ values for DLW.

Operation $a =, mm$	Θ_0	E_z, $n=1$	E_z, $n=2$	E_d, $n=1$	E_d, $n=2$
TW,23.80	60	-0.048	-0.007	0.006	-0.009
TW,23.58	90	-0.581	-0.004	0.009	-0.001
TW,22.33	120	-1.950	-0.048	0.020	-0.015
SW,12.0	180	-6.103	-1.385	-3.818	-0.623
SW,19.4	180	-5.619	-0.691	-0.271	-0.148

SW Operation

In the case of short deflectors SW operation is more efficient in RF sense. But individual E, H components, including E_z at $\Theta_0 = 180^o$ have a single, either real or imaginary part in representation (1), resulting in $\Psi_j = 90^0$ for each component separately. For longitudinal force aberration reduction is possible just by aperture radius increasing -it is not so effective as for low Θ_0 TW case.

The deflecting field E_d is composed from two components, E_x, H_y and has in representation (1) both real and imaginary parts, similar to TW case. Relations (5),(6) work for E_d study even for Θ_0 SW case.

Because harmonics attenuation at $\Theta_0 = 180^o$ (assuming $\beta = 1$) is not effective, the single way for aberration reduction in E_d is harmonics cancellation for E_x and H_y distributions under opposite phasing. It can be realized in DLW by aperture radius choice for the preliminary specified disk thickness t_d, [8]. In the Table 1 are given results for optimized SW case ($a = 19.4mm, t_d = 5.4mm, \Psi_d \sim 1.5^o$, $\frac{Z_0 H_y^0}{E_x^0} = 0.98$). In SW DLW E_d aberration reduction is possible, but at the expense of moderate RF efficiency.

SUPPORTING STRUCTURE

The hybrid HE_n, HM_n waves exist in a supporting RF structure. But the classification of a supporting structure with a complicated field distribution is always rather conditional. In Fig. 3 the plots of $\frac{Z_0 H_y^0}{E_x^0}$ balance are shown,

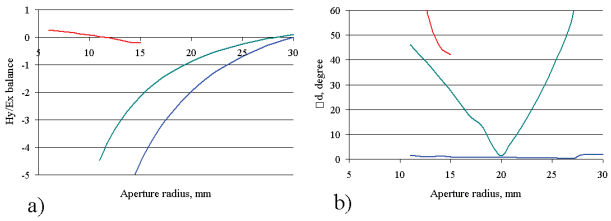

Figure 3: The field balance $\frac{Z_0 H_y^0}{E_x^0}$ (a) and $\Psi_d(a)$ plots (b) for DLW deflector $\Theta_0) = 60^o$ (blue), $\Theta_0) = 180^o$ (green) and TE - type deflector, $\Theta_0 = 180^o$ (red).

having even for well studied DLW in the first passband a large variety $-10 \le \frac{Z_0 H_y^0}{E_x^0} \le 0.5, 10mm \le a \le 30mm$ with different $\vec{E}, \vec{H}$ distributions, [5]. Similar field transformation we can provide in TE deflector, [7], Fig. 4.

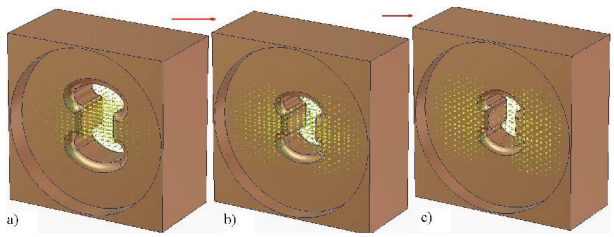

Figure 4: Field transformation for deflecting mode in the TE - type deflector.

At the structure axis we can define C, D in (1) from the already calculated E_d distribution and connect it with $\frac{Z_0 H_y^0}{E_x^0}$ balance. For E_d aberration minimization, especially for SW case, we need the opposite phasing of transverse $\vec{E}, \vec{H}$ components. Now it is the single sustainable sign for structure selection. Such phasing means the negative power flow near, but doesn't mean, in general, total negative flow, which define a negative dispersion in operating point. Even in simple DLW the inversion aperture radius a_i, corresponding to $\beta_g = 0$, essentially depends on Θ_0, [5].

For effective aberration reduction in E_d we need in the balance $|\frac{Z_0 H_y^0}{E_x^0}| \approx 1$. But the case of $|Z_0 H_y^0| = |E_x^0|$ is very close, probably coincides, to inversion point. It results in non monotonous (for TW case, [5]) or narrow (for SW case, [8]) dispersion curve. The method for DLW dispersion curve correction is described in [8]. Also the practice of Ψ_d minimization shows, that $(\Psi_d)_{min}$ is close, but not identical to $|Z_0 H_y^0| = |E_x^0|$ condition.

The DLW has just one parameter, effective for $\frac{Z_0 H_y^0}{E_x^0}$ balance control, aperture radius a, see Fig. 3a, which defines RF efficiency also. By splitting control over transverse $\vec{E}, \vec{H}$ components in TE - deflector, which is defined by r_a, r_w combination, see [7], we also can get opposite H_y and E_x phasing, Fig. 3a. Continuing the structure transformation, shown in Fig. 4, we come in the region $|Z_0 H_y^0| \approx |E_x^0|$ from the top in Fig. 3a. The field distribution becomes as in right picture in Fig. 3 and there are no evident reasons denote transformed option as TE-type. We lose in RF efficiency (Z_e value), as compared to original case, Fig. 1b, [7], but still remain essentially higher, as compared to simple DLW. The level of aberration is practically the same as for optimized in $(\Psi_d)_{min}$, see Table 1, case $a = 19.4mm$, classical DLW structure. The parameters of such SW deflectors in details, including end cells and RF coupler cell, are considered in [8].

SUMMARY

In any periodical DS aberrations, both in E_z and in E_d, are lowered in TW operation with $\Theta_0 \le 60^o$, especially for large aperture radius. Essential improvement in E_d distribution also takes place for opposite phasing of transverse $\vec{E}, \vec{H}$ components at the axis. Such TW DS provide the best results in PDT linearity. For TW operation with $\Theta_0 \ge 120^o$ and SW, $\Theta_0 = 180^o$, aberration reduction is possible in E_d only, by aberrations cancellation in oppositely phased and balanced transverse $\vec{E}, \vec{H}$ components. In a simple SW DLW it is realized for moderate RF efficiency. By splitting control over transverse $\vec{E}, \vec{H}$ components we get efficient SW DS with low E_d aberration level.

ACKNOWLEDGMENT

The author warmly thanks Dr. K. Floettmann, DESY, for support and collaboration with all beam dynamics conclusions.

RESULTS OF TESTING OF MULTI-BEAM KLYSTRONS FOR THE EUROPEAN XFEL

V. Vogel, L. Butkowski, A. Cherepenko, S. Choroba, I Harders and J. Hartung,
DESY, 22607 Hamburg, Germany

Abstract

For the European XFEL multi-beam klystrons, which can produce RF power of 10 MW at an RF frequency of 1.3 GHz, at 1.5ms pulse length and 10 Hz repetition rate, were chosen as RF power sources. Twenty-seven of horizontal multi-beam klystrons (MBK) together with connection modules (CM) will be installed in the XFEL underground tunnel. The CM will be installed on the MBK and connects the MBK to the pulse transformer with only one HV cable, because the CM has a filament transformer inside as well as all diagnostics for HV and cathode current measurements. MBK prototypes together with CM prototypes have been tested for long time at a test stand at DESY, about 4600 hours of operation for each of horizontal MBK with full RF output power, full pulse length and repetition rate of 10 Hz. Testing of first MBKs from series production has been started. In this paper we will give an overview of the test procedure, summarize the current test results and we will give a comparison of the most important parameters.

INTRODUCTION

For the XFEL project [1] as a source of RF power for 27 RF station were chosen the horizontal MBK made by two companies: MBK TH1802 from "Thales" [3] and MBK E3736H from "Toshiba" [4]. The main parameters of MBK are given in Table 1.

Table 1: Main parameters of L-band MBK for XFEL

Parameters	Design value	Test value
Output power (MW)	10	10.3
RF pulse length (ms)	1.5	1.5
Efficiency (%)	> 63	64
Repetition rate (Hz)	up to 30	10
Max average RF power (kW)	150	155
Max average power in collector (kW)	300	270
Max drive power (W)	<200	<150
Bandwidth (MHz)	3	>3

Both prototypes of MBK were tested on DESY MBK test stands [2], a total time of testing exceed of 4600 hours for both of tubes. The test was done with full RF power of 10 MW, full RF pulse length of 1.5 ms and with repetition rate of 10 Hz. Fig. 1 shows the top view of the test stands. Because the all of RF station will be located in the underground tunnel it is very important do not have the open oil during installation of MBK. It was proposed and tested the connection between MBK and HV pulse transformer through connection module (CM) [5, 6 and 7] and HV cable. Several types of HV cables and connectors as well as CM prototypes were tested. Big advances of using CM are that CM has inside a high voltage high frequency filament transformer and monitors for measurement of klystron voltage and cathode current. Fig. 2 shows the one of klystrons with CM and HV cable.

RESULTS OF MBK PROTOTYPES TEST

Since February 2008 we started the test of the first of horizontal MBK prototype on DESY site. For the test of MBK it was specially developed two radiation protected

test chambers. Each of both klystron waveguides outputs was connected through WR650 directional coupler and RF power divider to the two of RF loads. Using four of RF loads for the one klystron allow us made the test of average output RF power up to level of 155 kW. The waveguide system was pressured by dry air up to 1.35 bars absolute. The pressured waveguide and air flow up to 10 litters per minute allow us work without breakdown on the level of pulse power of 5 MW in one of klystrons output arm with pulse length of 1.5 ms and repetition rate of 10 Hz. Fig. 3 shows the view of one of klystron output arms. During prototypes test all klystrons parameters were proofed and we have measured a bandwidth, the gain, the phase response and efficiency of the tubes [8, 9, 10 and 11]. Fig. 4 shows the tubes efficiency in depends of output power level and Fig. 5 shows the gain curve for the different value of klystron beam voltage. Fig. 6 shows the wave shape of beam voltage and cathode current.

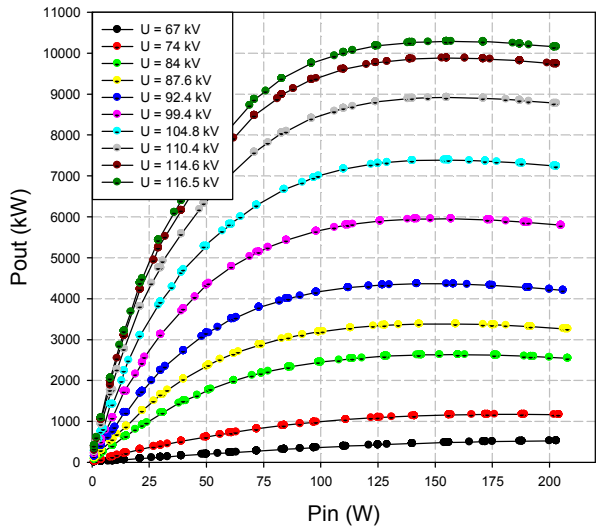

Figure 5: Gain curve for the different value of high voltage.

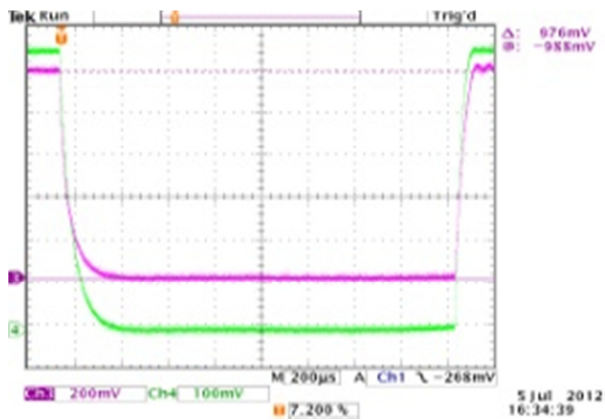

Figure 6: Wave shape of beam voltage and cathode current, the measurement from voltage and current monitors located inside CM.

PROTECTION SYSTEM

The horizontal MBK for XFEL will use the M type of dispenser cathode, for this type of cathode we can expect average tube lifetime of 145000 hours, but in the real operation the lifetime of tube can be thoroughly reducing by service conditions, several events can happen as: the gun arcing, RF breakdown, beam losses inside tube, operation of the tube in the bad vacuum and number of cathode switch cycles. To minimize the influence of service conditions to the klystrons lifetime the special fast protection system (KLM) [12] was developed and tested, the main task of KLM are: to detect as quickly as possible all events which can destroy the tube, then stop input power to the tube and send signal to stop HV pulse. The tube recovery procedure should depend on the kind of events has happened. To make decision which type of recovery procedure should be used, KLM accumulate the

signals from different type of sensors. At first, both outputs of klystron and klystron input should have a directional coupler (DC). DC is one of most important devices, the signal from that used for detection of reflected power from waveguide distribution system (WDS) and for analysing difference of expected output impulse shape and real impulse shape. At second, to detect a breakdown on the air side of output window of the klystron or breakdown in the waveguide section between window and DC it was used fast light sensors. To detect the gun arc in the klystron it was used HV breakdown sensor. The measurement of the level of vacuum inside tube, level of partial discharge in the HV system and information from sounds detectors help us to understand the reason of event and help use the right recovery procedure and make true estimation of time to recovery the RF station back to the normal operation.

Figure 7: The first serial MBK for XFEL on DESY site.

CONCLUSION

In February 2008 the first prototype of MBK for XFEL had been installed on the MBK test stand DESY. In March 2010 we have started the test of second MBK. Up to September 2012 the testing time for both of MBK prototypes reach about 4600 hours of operation at the level of 10 MW output power, RF pulse duration of 1.5 ms and repetition rate of 10 Hz. The value of pulse high voltage was about 117 kV, high voltage pulse duration 1.7 ms. The average time between two gun arcs for E3736H is about 230 hours and for TH1802 is about 460 hours. The klystrons were tested together with connection modules (CM) and different types of HV cables. During testing time we didn't observe any sign of degradation of klystrons parameters as well as CM parameters. The all of using testing equipment's work without any problem and DESY are ready to start the test of serial MBK and since August 2012 we have in DESY site the first serial MBK for XFEL. Fig. 7 shows our team and the first of serial MBK.

COMPUTATIONAL MODEL ANALYSIS FOR EXPERIMENTAL OBSERVATION OF OPTICAL CURRENT NOISE SUPPRESSION BELOW THE SHOT-NOISE LIMIT

A. Nause, E. Gover, Tel Aviv University, Israel

Abstract

In this paper we present simulation analysis of experimental results which demonstrate noise suppression in the optical regime, for a relativistic e-beam, below the classical shot-noise limit. Shot-noise is a noise resulting from the granular nature of the space-charge in an e-beam. It is linear to the beam current due to its Poissonic distribution in the emission process. Plasma oscillations driven by collective Coulomb interaction during beam drift between the electrons of a cold intense beam are the source of the effect of current noise suppression. The effect was experimentally demonstrated [1] by measuring Optical Transition Radiation (OTR) power per unit e-beam pulse charge. The interpretation of these results is that the beam charge homogenizes due to the collective interaction (sub-Poissonian distribution) and therefore the spontaneous radiation emission from such a beam would also be suppressed (Dicke's subradiance [2]). Analysis of the experimental results using GPT simulations will demonstrate the suppression effect. For the simulation results we used a full 3D GPT model of the ATF section in which the experiment took place at.

INTRODUCTION

Shot-noise is a noise resulting from the granular nature of the space-charge in an e-beam. The discreteness of the particles and the randomness of electrons emission from the cathode causes time dependent fluctuations of the charge and current density at any cross section along the beam transport line. This noise was first reported in 1918 by Schottky who made experiments in vacuum tubes.

Noise is best characterized in terms of the Fourier transform of the time-varying fluctuations in electric current, namely, by its spectral density. Gover and Dyunin showed in a 1D model [3] that it is possible to observe and control optical frequency energy and current (shot noise) fluctuations in a dense relativistic charged particles beam. GPT simulations were used to demonstrate this effect for a real-like beam starting from Shot-noise [4]. Moreover, at certain conditions, when the dominant noise in the beam is current shot noise (density fluctuations), it is possible to reduce significantly the beam noise by virtue of a collective interaction process along an interaction length corresponding to a quarter period longitudinal plasma oscillation in the beam. This means that the charge distribution in the beam can be homogenized in this process.

First experimental observation of this phenomenon using OTR from a metallic foil was presented last year [1]. Noise suppression using a dispersive section (dog-leg bend) was demonstrated in SLAC [5]. TR is proportional to the current-noise amplitude [6], and therefore can be used in order to estimate the suppression in the current noise. In this paper we press analysis of the experimental results and demonstrate this effect using full 3D GPT simulations that were carried out for this purpose.

1D Model of Noise Dynamics in Charged Electron Beams

In electron-beam transport under appreciable space-charge conditions, the microdynamic noise evolution process may be viewed as the stochastic oscillations of Langmuir plasma waves [3]. In the linear regime, the evolution of longitudinal current and velocity modulations of a beam of average current I_b, velocity βc and energy $E = (\gamma - 1)mc^2$, can be described in the laboratory frame by [7]:

$$\frac{d}{d\phi_p}\breve{i}(z,\omega) = -\frac{i}{W(z)\breve{v}(z,\omega)} \quad (1)$$

$$\frac{d}{d\phi_p}\breve{v}(z,\omega) = -iW(z)\breve{i}(z,\omega) \quad (2)$$

where $\breve{i}(\omega) = \breve{I}(\omega)e^{i\omega z/\beta c}$, $\breve{v}(\omega) = \breve{V}(\omega)e^{i\omega z/\beta c}$. $\breve{I}(\omega)$, $\breve{V}(\omega)$ are the respective Fourier components of the beam current and kinetic-voltage modulations. The kinetic-voltage modulation is related to energy and longitudinal velocity modulations: $\breve{V}(\omega) = -(mc^2/e)\breve{\gamma} = -(mc^2/e)\gamma^3\beta\breve{\beta}$, $\phi_p(z) = \int_0^z \theta_{pr}(z')dz'$ is the accumulated plasma phase, $W(z) = r_p^2/(\omega A_e \theta_{pr}\epsilon_0)$ is the beam wave-impedance. A_e is the effective beam cross-section area, $\theta_{pr} = r_p\omega_{pl}/\beta c$ is the plasma wavenumber of the Langmuir mode, $r_p < 1$ is the plasma reduction factor, $\omega_{pl} = \omega_{po}/\gamma^{3/2}$ is the longitudinal plasma frequency in the laboratory frame. The single-frequency Langmuir plasma wave model expressions [3] can be solved straightforwardly in the case of uniform drift transport. After employing an averaging process, this results in a simple expression for the spectral parameters of stochastic current and velocity fluctuations (noise) in the beam assuming that they are initially uncorrelated[]:

$$\breve{i}(L,\omega) = \cos\phi_p(L)\breve{i}(0,\omega) + (\sin\phi_p(L)/W_d)\breve{v}(0,\omega) \quad (3)$$

where $\phi_p = \theta_{pr}z$, $\theta_{pr} = r_p\frac{\omega_p'}{v_0}$, $\omega_p' = (\frac{e^2 n_0}{m\epsilon_0\gamma^3})$, $W_d = \sqrt{\mu_0/\epsilon_0}/k\theta_{pr}A_e$.

The beam current noise evolution is affected by the initial axial velocity noise through the parameter

$$N^2 = \overline{|\breve{v}(0,\omega)|^2}/W^2\overline{|\breve{i}(0,\omega)|^2} = (\omega/c\beta k_D)^2 \quad (4)$$

Copyright © 2012 by the respective authors — cc Creative Commons Attribution 3.0 (CC BY 3.0)

where $k_D = \omega_{pl}/c\sigma_\beta$ is the Debye wavenumber and $c\sigma_\beta$ is the axial velocity spread. Equation (4) suggests that current noise suppression is possible if the beam is initially cold $N^2 < 1$, and if plasma phase accumulation of $\phi_p(L) \sim \pi/2$ is feasible.

NOISE SUPPRESSION EXPERIMENT
