Abstract.- Certain characteristics, design aspects and calculations for the magnet, dees, extraction system and central region of the injector cyclotron are reported.

1. Introduction.- $\mathrm{A} k=8 \mathrm{MeV}$ solid pole cyclotron (SPC1) is being designed and built by the NAC as an injector for a $k=200 \mathrm{MeV}$ separated-sector cyclotron (SSC) which has an energy gain factor ranging from 25 for protons to 20 for the heavier ions. ${ }^{19}$ The beam requirements for the various fields of application are fairly diverse ${ }^{21}$. Good quality proton, deuteron, ${ }^{3} \mathrm{He}^{2+}$ and $\alpha$ - beams up to maximum energy and $10 \mu \mathrm{~A}$ beam intensity as well as heavy ion beams up to $Q / A \approx 0.25$ are required for nuclear physics and related experiments while $100 \mu \mathrm{~A}$ beams must be supplied at intermediate energies for neutron therapy and isotope production.
2. Magnet.- In designing the SPC1 magnet, we aimed at a good efficiency by following the guidelines given by Howard et $\mathrm{al}^{3}{ }^{3}$. Some of the parameters and considerations which had to be taken into account, are the following. The extraction radius of 47.6 cm and the maximum average magnetic field of 0.86 T at extraction are fixed by the matching conditions to the SSC. At least 140 mm clearance between the rf-liner plates is required for the radial insertion of an ion source for heavy ions. It must be possible to raise the upper yoke and pole assembly for easy access to components inside the vacuum chamber. Due to the relatively small pole diameter, the average pole gap should not be too large, otherwise excessive trim-coil power is required to obtain an isochronous field. There should be sufficient axial focussing to keep the beam height less than $\sim 25 \mathrm{~mm}$ for the $100 \mu \mathrm{~A}$ proton and deuteron beams. The injector will be used for medical applications, and down-time should be kept to a minimum. All components should therefore be easily accessible for maintenance.

Figure 1 shows the final dimensions of the 54.5 ton magnet which we believe to be a fair compromise between all the requirements that were laid down. The two 112turn vacuum impregnated coils for the magnet were con-

structed from $16.5 \mathrm{~mm} \times 16.5 \mathrm{~mm}$ OFHC copper conductor with a 9.2 mm diameter duct for cooling water, the total copper weight being $\sim 1.85$ tons. Eight layers of windings were used for each coil, and two adjacent layers form one cooling circuit. The excitation current is supplied by a 140 V 1000 A power supply with a stability of 2 in $10^{5}$.

To make the inside of the vacuum chamber relatively accessible, the upper yoke, pole and feedthrough ring can be lifted by means of two 100 mm diameter screw shafts positioned on either side of the magnet. Each screw is driven by a high-torque low-speed hydraulic motor and the screws are synchronised by means of a roller chain. The sealing between the vacuum chamber and the lid is shown in figure 2.

Although the originally specified maximum average field at extraction was 0.86 T , a value of 0.95 T was assumed for the design of the magnet. Due to a recent request for $320 \mathrm{MeV}{ }^{3} \mathrm{He}^{2+}$ and and $220 \mathrm{MeV} \alpha$ - beams from the SSC, it will now be necessary to push the magnetic field up to $\sim 1 \mathrm{~T}$. This requires an excitation current of $\sim 960 \mathrm{~A}$ and a total power of $\sim 90 \mathrm{~kW}$ which is close to the limits of both the power supply and the cooling system. We are, however, fairly confident that this field can be generated.

The field calculations were performed with a 3-dimensional relaxation program which does not take saturation effects into account. An estimate of the saturation effects could however be made with a 2-dimensional relaxation program and it showed that, as coula be expected at these relatively low fields, saturation does not play an important role.

An interesting feature of our design is that the sectors are shifted radially outwards by $\sim 60 \mathrm{~mm}$ so as to obtain an azimuthally averaged field which is almost flat
in the radial direction. By doing this and by adding shims 5 mm thick and 50 mm wide on each sector at the extraction radius, the amount of trim-coil power required to produce an 8 MeV isochronous proton field was reduced from several kilowatts to merely 40 W . For

Fig. 3: $\nu_{z}$-values as a function of radius for three reference particles.
the 4 MeV isochronous proton field, almost no excitation current was required through the trim-coils. The degree of isochronism obtained, is illustrated by the fact that the phase of a proton, accelerated in the trim-coil field, never deviated by more than $2^{\circ} \mathrm{rf}$ from the phase curve obtained in an ideal isochronous field ${ }^{4}$ ) The $\nu_{z}$ - values for three reference particles are shown in fig. 3. It must be stressed, however, that the trimcoil fields are based on fields calculated for the given pole geometry. The real field measurements are due to start this month and we hope to be able to confirm these results soon.

By moving the sectors radially outwards instead of giving them a radial profile, we also gained the following: The $\nu_{z}$-values were increased (up to $50 \%$ ) in the central region ${ }^{\text {) }}$, machining costs were reduced and more space was made available in the valleys. The azimuthal length of the harmonic coils, especially the inner set, could therefore be increased making them more effective.
3. Dee-angle and beam behaviour in radial phase space.In SPC1 the rf-frequency ranges from 8.6 MHz to 26 MHz and the 2 nd and 6 th harmonic modes are being used for the acceleration of particles. With $90^{\circ}$-dees acceleration occurs at peak voltage. The use of $80^{\circ}$ dees, however would allow a decrease in distance between the electrostatic channel and the first magnetic channel which is better for extraction. Furthermore, the smaller dee capacity would permit the high-frequency position of the short-circuiting plate to be further away from the magnet, which is desirable from a mechanical design point of view, and the bigger dummy-dees would allow more space for the installation of diagnostic equipment.

The work of Schulte ${ }^{61}$, however, indicates that due to coupling between the longitudinal and radial phase space, a radial broadening of the beam can be expected if offpeak acceleration is used under the following conditions: acceleration on high harmonic numbers, low beam energies and acceleration near the $\nu_{r}=1$ resonance. If $80^{\circ}-$ dees are used in SPC1, all these factors exist when particles such as ${ }^{12} \mathrm{C},{ }^{20} \mathrm{Ne}$ or low energy $\alpha$-particles are accelerated. A study of the radial phase space behaviour of various beams of particles was therefore undertaken.

Calculations with a computer code were carried out for a proton beam having an energy and radial emittance of 4 MeV and $50 \pi \mathrm{~mm} . \mathrm{mrad}$ respectively at extraction (2nd harmonic) and a $6 \mathrm{MeV}{ }^{12} \mathrm{C}^{3+}$ beam having a radial emittance of (a) $12 \pi \mathrm{~mm} . \mathrm{mrad}$ and (b) $57 \pi \mathrm{~mm} . \mathrm{mrad}$ (6th harmonic). For each case eight particles, lying on an eigen-ellipse, were accelerated from near the ion source up to extraction. In the case of the 4 MeV proton beam no apparent difference between the phase-space diagrams for $80^{\circ}$ - and $90^{\circ}$-dees was observed. In the case of the phase-space diagrams for the $6 \mathrm{MeV}{ }^{12} \mathrm{C}^{3+}$ beam, however,

Fig. 4: Radial phase ellipses at $180^{\circ}$ on 2 nd, 5 th and 9 th orbits for ${ }^{12} \mathrm{C}^{3+}$ beam accelerated in $80^{\circ}$ (left) and $90^{\circ}$ (right) dee systems with CP-phase corrections and having an emittance of $12 \pi \mathrm{~mm}$. mrad at the extraction energy of 6 MeV .
a distortion of the phase-space diagram as well as a pronounced broadening of the beam could be seen when 80 -dees were used. The distortion disappeared after a correction for central particle phase was applied. Figure 4 shows the phase diagrams for $80^{\circ}$ - and $90^{\circ}$-dees at an azimuthal angle of $180^{\circ}$ for the 2 nd, 5 th and 9 th orbits. It is clear that the beam accelerated in the $80^{\circ}$-dee system spreads during acceleration to more than five times the size of the beam of the $90^{\circ}$ system in the extraction region (i.e. the 9 th orbit). Even with an emittance of $57 \pi \mathrm{~mm} . \mathrm{mrad}$, no signs of instability could be detected in the case of $90^{\circ}$-dees.

These results clearly show that an $80^{\circ}$-dee geometry is not acceptable for acceleration in the $h=6$ mode and as a result, SPC1 is now being designed with $90^{\circ}$-dees.
4. Extraction.- The extraction system for SPC1 consists of one electrostatic channel (EC) extending from $177^{\circ}$ to $219^{\circ}$ and two focussing magnetic channels MC1 and MC2 (figure 2 of reference 1). A maximum field strength of $90 \mathrm{kV} / \mathrm{cm}$ on the EC is required to extract the 8 MeV proton beam. If the outer set of harmonic coils is used for extraction, the fieldstrength can be decreased by $\sim 1.3 \mathrm{kV} / \mathrm{cm}$ per gauss of first harmonic component. Thus, in principle, the fieldstrength could be reduced to $60 \mathrm{kV} / \mathrm{cm}$ for 8 MeV protons. For the least favourable case (i.e. $4 \mathrm{MeV}, 100 \mu \mathrm{~A}$ proton and deuteron beams), the calculated extraction efficiency is more than $90 \%$.

Extraction starts before $\nu_{r}=1$. During subsequent transit through the fringe field, the particles experience a very strong axial focussing force and the beam crosses over sharply inside the dee (fig. 5.) The dee is cut away at this point to allow the use of an active magnetic focussing channel $\sim 10 \mathrm{~cm}$. long. The required gradient in this channel is $24 \mathrm{~T} / \mathrm{m}$ for the 8 MeV proton beam and $16 \mathrm{~T} / \mathrm{m}$ for the 4 MeV beam. When

Fig. 5: Axial (A) and radial (R) envelopes for an $8 \mathrm{MeV}, 12 \pi \mathrm{~mm} . \mathrm{mrad}$ deflected proton beam.

Fig.6: The geometry of the magnetic channel MC1 as a passive channel (a) and an active channel (b). The resulting flux densities for 4 and 8 MeV passive channels ( $c$ and $d$ ) are contrasted with the active channel results (e and f).
used as a passive element with a cross section as shown in figure 6, the desired gradient for the 4 MeV beam is obtained, but the corresponding gradient for the 8 MeV case is only $18 \mathrm{~T} / \mathrm{m} .{ }^{44}$ Activating coils will therefore be used to increase the gradient. Figure 6 shows the calculated maximum and minimum gradients obtained in the two fields under consideration when 14600 ampére-turns are used. The first harmonic component caused by the field perturbation due to this channel is small. At 40 cm we calculated $10^{-4} \mathrm{~T}$ and at 45 cm $7 \times 10^{-4} \mathrm{~T}$.

In the second focussing channel, extending from $350^{\circ}$ to $365^{\circ}$, an average gradient of $\sim 4 \mathrm{~T} / \mathrm{m}$ is needed to produce the required beam properties at the first dipole in the beamline. As we want this channel to provide horizontal steering as well, we are presently designing a C-magnet for this purpose.
5. Axial acceptance calculations.- Preliminary calculations have been initiated to determine the possible influence of the acceleration gap height ( $H$ ) and the inclusion of a magnetic cone field on the axial acceptance of SPCl central region. The electric field in the acceleration gaps was approximated by a Gaussian distribution and the vertical acceptance was determined by calculating the transmission matrix by means of an orbit code and projecting the acceleration gaps on axial phase space at $90^{\circ}$ behind the puller slit. In figure 7

Fig. 7: Axial co-ordinate of gap lips as projected onto phase space at $\theta=90^{\circ}$ (behind the puller) for 8 MeV protons.
the $z$ intercepts in phase space of the projected gaps are plotted as a function of radial distance with the gap numbers indicated on each curve. Also plotted as horizontal straight $l i n e s$ are the maxima along $z$ of the projected eigen-ellipses.

The three sets of curves were obtained for a gap height of 40 mm with and without a cone field of 80 G , and a gap height of 20 mm . Similar curves were obtained for $\dot{z}^{4}$.

We found this representation very useful to evaluate the effect of different parameters on the axial acceptance. Noting that the curves show singularities at those positions where the ions cross the median plane one may deduce an average $v_{z}$-value from these graphs. The results yield $v_{z}$-values of $0.1,0.12$ and 0.13 respectively. Increased focussing, i.e. greater $v_{z}$ is indicated by a shift of the whole pattern towards smaller radi (lower gap numbers) while increased acceptance is indicated by a raising of the minima.

Another parameter to be studied by this method is the starting phase. We also intend using these curves to determine the optimum position for the axial slits.
