SPECTRAL RESPONSE OF A MARTIN-PUPLETT INTERFEROMETER FOR ELECTRON BUNCH LENGTH MEASUREMENTS

C. Kaya*, U. Lehnert, Forschungszentrum Rossendorf, Dresden, Germany

Abstract

At the ELBE Free Electron Laser (FEL) at Forschungszentrum Dresden Rossendorf (FZD) electron bunches having lengths between 1 to 4 ps are generated. It is required to compress these electron bunches to lengths below 1 ps which necessitates diagnosis of the electron bunch parameters. We use a Martin-Puplett interferometer (MPI) which is a modification of the Michelson interferometer, where the beams are linearly polarized at specific orientations. It measures the autocorrelation function of the coherent transition radiation (CTR) from a view screen which is an optical replication of the electron bunch.

The interferometer setup consists of various optical components like polarizers, beam splitter, mirrors and Golay cell detectors. In our measurement a wire grid was used as a polarizer and also as a beam splitter. A thorough understanding of the response of the optical components, as a function of the CTR wavelength range of our interest, is required for correct analysis of the measured signal. We have therefore simulated the response of the entire interferometer setup including the diffraction losses and the window transmission and compared the results to experimental measurements.

INTRODUCTION

ELBE is based on a superconducting electron linac. The ELBE linac is designed to operate with an accelerating field gradient of 10 MV/m so that the maximum design electron beam energy at the exit of the second module is 40 MeV. ELBE delivers an electron beam with an average current of up to 1 mA. The electron source is a DC thermionic triode delivering beam with energy of 250 keV. The gun beam quality predefines the accelerated beam quality. In the ELBE the electron bunch is compressed to 10 ps after the electron beam injector. In the accelerator the electron bunch length is in the range of 1 to 10 ps. We use a Martin-Puplett interferometer (MPI) which is a modification of the Michelson interferometer, where the beams are linearly polarized at specific orientations. It measures the autocorrelation function of the coherent transition radiation (CTR) from a view screen which is an optical replication of the electron bunch.

In our work we want to determine the workable wavelength range for our Martin-Puplett interferometer setup. We have therefore simulated the response of the entire experimental setup. We also describe in this study our measurements of the electron bunch length, which is in the picosecond range. The bunch length is estimated from a frequency domain fit of a specially constructed analytical function to the measured power spectrum of the bunch. The power spectrum is obtained as a Fourier transform of the measured autocorrelation function of the CTR. The CTR autocorrelation function is measured with the help of a Martin-Puplett interferometer.

EXPERIMENTAL SETUP

A polarizing Martin-Puplett interferometer (shown in Fig. 1) is used to analyze the spectrum of the far-infrared radiation. CTR passes through a quartz window and is reflected by a parabolic mirror. Then the CTR is polarized vertically by a wire-grid linear polarizer and made incident on a beam splitter. For our measurements the wire grids are wound from 20 µm gold plated tungsten wire with 100 µm spacing (from center to center), which are used as polarizers and beamsplitters. The reflected beam from the beamsplitter then goes to a roof mirror which is fixed, while the transmitted beam goes to a movable roof mirror. These two reflected beams then interfere and then split by a second beam splitter (analyser) the polarization directions are detected using two Golay cell infrared (IR) detectors.

GENERAL DESCRIPTION OF TRANSITION RADIATION

In our experiment the transition radiation is generated when the electron beam is impinged on an aluminum target rotated by 45° with respect to the incoming beam (shown in Fig. 2). The spectral energy flux of backward transition radiation is given for electrons by the Ginzburg-Frank formula [1]:

254
where $I$ is the spectral energy flux in a solid angle $d\Omega$, $\beta$ is the ratio of electron velocity to velocity of light ($V/c$) and $\theta$ is the polar angle with respect to the backward transition radiation.

Figure 2: Emission of transition radiation.

The polar angles (opening angle) of the transition radiation for different beam energies are calculated using the above formula (1). The plots (shown in Fig. 3) show that the opening angle of the beam decreases with the radiation energy. Polar angle will be large for low electron energy. This information is useful in determining the optimum distance of the parabolic mirror from the beamline window. The maxima in emission occurs at $\theta = \pm 1/\gamma$, where $\gamma$ is the Lorentz factor of the electron.

Figure 3: Transverse emission characteristics of transition radiation according to equation (1) for different electron energies of 5-10-15-20-25-30 MeV as behind the ELBE LINAC. Red curve is for 5 MeV electrons, light blue curve is for 30 MeV electrons.

**SIMULATION OF OPTICAL COMPONENTS OF INTERFEROMETER**

For Martin-Puplett type interferometers the response of the wire grids are found to be strongly bandwidth-limited. In order to determine the workable wavelength range for the interferometer, we compute the interference depth dependence on wavelength. After the first polarizer, the electric field direction of coherent transition radiation is polarized almost vertical. For our simulations we have used vertical electric field direction of CTR before the beamsplitter. In the experiment the beamsplitter wire grid is oriented at $45^\circ$ with respect to the vertical electric field component. Therefore, the electric field divides into two components: (i) parallel to the wire grids and (ii) perpendicular to the wire grids (shown in Fig. 4). If the thickness $d$ (20 $\mu$m) of the wires and the spacing $s$ (100 $\mu$m) are small compared to the wavelength of the incident light, the module of the reflection coefficients for the vertical electric field components parallel and perpendicular to the wires can be calculated as follows [2]:

\[
|R_{\parallel}| = \left[1 + \left(\frac{2s}{\lambda}\right)^2 \ln\left(\frac{s}{\pi d}\right)\right]^{-\frac{1}{2}} \\
|R_{\perp}| = \left[1 + \left(\frac{2s}{\lambda^4 d^4}\right)^{-\frac{1}{2}}\right]^{-\frac{1}{2}}
\]

Figure 4: On the beamsplitter vertical electric field (black line) component.

A part of the radiation will also get transmitted through the beamsplitter. When the wire grids is ideal (no absorption or scattering), sum of the reflection and transmission coefficients should be one. We have simulated the vertical and horizontal electric field components after each optical component and obtained the intensities of the radiations reaching the two detectors. We have calculated the relative intensities at both the detectors as a function of frequency (0-3 THz). We have restricted the frequency range to 3 THz because it is the workable limit for the polarizers and beamsplitters. Figure 5 shows the interference depth given by the difference between the signals of the vertical and horizontal detectors.

The lower cut-off frequency at the detector input windows is about 0.5 THz. Using the Martin-Puplett interferometer we can thus measure CTR in the frequency range of 0.5-2.7 THz. This indicates that we can measure bunch lengths between 0.5 and 2 ps with our setup.

**03 Time Resolved Diagnostics and Synchronization**
CONCLUSIONS

We have calculated the response of the experimental setup as a function of the CTR wavelength which is essential for correct analysis of the measured signal. We have simulated the autocorrelation function where diffraction losses at the detector windows are taken into account. From there we derive an operation range of 0.5-2 ps for the bunch length determination with our MPI. Using MPI measurements and by comparison of the experimental results with our simulations we have estimated the electron bunch lengths. If the electron bunch length is compressed below 0.5 ps we will not be able to measure it with our MPI setup.

ACKNOWLEDGEMENTS

I would like to thank Dr. P. Michel and the operators at the ELBE Germany, for supporting my experiments. Also I want to thank Dr. P. Evtushenko at the JLabFEL, USA who had built the setup and for the information we obtained from his thesis.
