Both frameworks come with a set of base components but the developer may write its own components (records or GAMs). When a new record is ready to be tested in EPICS the developer has to create a new project, insert the record with all ancillary files in the project, create the configuration files, compile and run the project. In MARTe the development process is straightforward: after compiling the new component the developer has only to write a configuration file (actually by modifying a template).

Updating a Running Application The value and compound data (database links included) of a record can be tuned at runtime being each field implemented by a Process Variable (PV). To load or remove records not previously loaded in EPICS a user has to reconfigure and recompile all the application from scratch and then run it again.

In MARTe in order to change a GAM parameter it is necessary to stop the execution of every MARTe activity and reload the framework. It is however not necessary to recompile the application. A new component which allows the runtime modification of parameters and signal values called *Configuration Library* (CL) [4] was recently introduced.

Internal Data Structures

In EPICS IOCs every record field is a PV, and in order to manage thousand of PVs, EPICS makes use of hash tables for PV lookup.

MARTe is mostly based on linked lists and sophisticated data structures have not been introduced. Data querying at runtime is still lacking.

Both frameworks create during initialization all data structures that are required at runtime. It is the responsability of the developer to implement efficient (time-bounded) code in the `process` routine (EPICS IOC) or in the `execute` method (MARTe) of a computational block. In a hard real-time application unbounded delays due to badly written algorithms or network accesses could deteriorate the control.

CONCURRENT MODELS OF COMPUTATION

Concurrent models of computation (CMoC) are of great interest when dealing with embedded systems, especially feedback controllers. A model of concurrence specifies how interaction, communication and control flow will be handled between components in a software application. In the following the models of computation of EPICS and MARTe are described.

EPICS IOC Record Processing

A single record in an EPICS IOC can be accessed concurrently for reading, writing or processing. Reading and writing can trigger processing, before fetching a value (demand-driven) and after updating a value (data-driven).

The processing of a chain of records takes place within a *scan* (an operating system's thread). A scan can be locally triggered periodically (*periodic scan*) or by software and hardware events (*event scan*, *IO event scan*); remotely by `caGet` or `caPut` operations. After the processing has been triggered on the first record of a chain those records that have to be executed next are determined by the associated *links* in the database. A link can carry data and processing (INLINK, OUTLINK) or simply processing (FWDLINK). A chain of records is executed until there exist processing links or records which can be passively processed by other scans (*passive scan* in EPICS terminology). Very complex processing chains can be designed in EPICS mixing demand (INLINK, FWDLINK) and data (OUTLINK) -driven processing.

Because a single record can be concurrently accessed by different scans, per-record locks exist. Synchronization delays due to concurrency can deteriorate the real-time response of a control algorithm. Typically such a situation arises when a record is concurrently updated locally, belonging to a processing scan chain, and remotely by a CA operation (Fig. 1). The local operation issued by the EPICS IOC has lower priority then the remote operation.

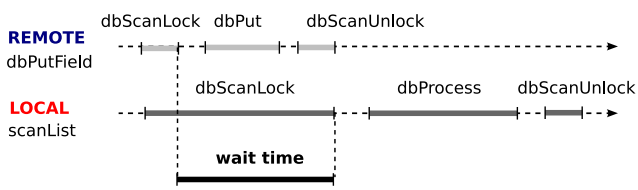

Figure 1: In EPICS a locally triggered scan may need to wait for the end of the processing of a remotely invocated record.

MARTe GAM Processing

MARTe has been designed as a software framework for hard real-time, low-latency applications. It eliminates concurrency because it is a source of delays and uncertainties in code execution. MARTe is a lock-free execution environment where each GAM executes serially in a thread (`RealTimeThread`) to which it is uniquely tied. MARTe has been designed to support a multiprocessor environment and the developer is encouraged to map a RealTimeThread per CPU.

GAMs communicate only within thread bounds where communication is made safe by the inherently serial execution of the thread. Inter-thread communication exists, but is managed by special GACQMs. GAMs communicate by means of a thread-level data buffer called *Dynamic Data Buffer* (DDB); every GAM knows how to access their private data area. This model implies a strictly data-driven processing.

As mentioned in the previous section, parameter and signal values can be modified via CL. Remotely changing a value in a running MARTe application is possible and is completely asynchronous with the execution of the RealTimeThread (highest priority task).

Processing Details

Stack Frame MARTe is less memory resource-starved than EPICS. A long EPICS' chain of passive records with many links can produce an out-of-stack exception, while MARTe will never exhibits this problem because the number of execution frames on the stack is $O(1)$ while in EPICS it is $O(n)$ where n is the number of passive chained records.

Processing Links Links in MARTe define only the flow of data and therefore they establish the data dependency between computational blocks. In an EPICS IOC links define the flow of data and processing.

Data Conversion at Interfaces Data diversity between blocks can be handled by the framework to let blocks with different data interfaces communicate. Data conversion can be managed at the node level via polymorphic get/put routines (Fig. 2) or by means of an external (global) adapter (Fig. 3). EPICS supports data diversity by means of a rich set of protocol adapters; MARTe does not support data diversity: two communicating GAMs must adhere to the same data interface.

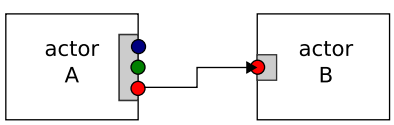

Figure 2: Actor A shown a polymorphic interface: the same **get** method will be overloaded to return different data types in function of the data type required by actor B.

Fanout In electronic circuits the output from one Integrated Circuit (IC) can be connected to several ICs. The fanout indicates how many ICs can be connected to a single output. The same concept also applies to records and GAMs. In MARTe one output signal from a GAM can be connected to as many GAMs as needed.In EPICS it is possible to have many INLINKs to the same record's field but it is not possible to have an OUTLINK or a FWDLINK connected to more than one record's field; to fulfill this need a `fanoutRecord` is supplied with EPICS.

Data Tokens In both software the processing is due to a new data token and there is no buffering between nodes and the number of tokens to be consumed in any processing of a node is always one.

CONCURRENT MODELS OF TIME

The natural way to code a control algorithm is via discretization of a continuous time model. The discretized algorithm is not aware of time, moreover it is usual practice to maintain a discrete function $f(n)$ instead of $f(Tn)$ where T, the sampling period, is explicit in the formula. The algorithm runs after the samples are transferred from the data acquisition subsystem, once per sampling period. The period T is usually fixed a priori during the design phase.

Coding the Algorithm in MARTe

In MARTe each GAM is triggered once per period and the time elapsed between calls to GAMs is equivalent to period T. Periodic timing is provided by a GACQM interfaced with a `TimeInput` GAM. Algorithmic GAMs are aware of the absolute time and of the execution period T.

Coding the Algorithm in EPICS

EPICS' records can be processed concurrently and lock mechanisms have been developed to synchronize their processing. In EPICS no time model is assumed, a record can be processed at any time. Careful design of an EPICS IOC database is required to achieve periodic processing of a record. To develop a record, a user have to take into account the possibility that a discrete algorithm will be executed in a non-uniform sampling environment.

The smart way chosen in EPICS to develop a PID controller (`pid`, `cpid` and `epid` records) is to accept that the

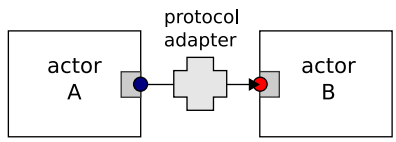

Figure 3: Both actors have a rigid interface: a protocol adaptor is necessary. A's **get** method returns a unique data type and B's **put** method fetches a precise data type.

PID will be called at non-uniform time intervals, and to define a minimum amount of time between record processings. This is defined in the Minimum Delta Time (MDT) field of the PID record. If the amount of time between the last time the record was processed and the current time is less than MDT, then the record is not processed.

REAL-TIME SUPPORT

Both EPICS IOC and MARTe have been used on VxWorks installations but this is not enough to state that they are hard real-time software frameworks. In [3] we have compared the same test control loop implemented as an EPICS IOC and as a MARTe application on a Linux PREEMPT_RT system. EPICS IOC exhibits a wider jitter compared to the MARTe counterpart. In this section we figure out from where those sources of jitter come.

Event Triggering

In MARTe the way in which a device driver (GACQM) waits for a hardware event is selectable (polling or interrupt) and defined in the configuration file. In EPICS the developer can not choose how to wait for an event, it depends on the device driver. Polling may be advantageous because it can eliminate the OS's process switching (which could introduce further delays due to scheduling other tasks).

Event Dispatching

In EPICS every event is queued for execution and never lost. There are different queues of execution and the execution policy is FIFO. One queue handles CA requests; three queues (low, medium and high priority) are shared between events and IO events and there is one queue per periodic scan (Fig. 4). This mechanism decouples an event from the associated servicing code but can generate unbounded latencies. Different scans that originate from different interrupt sources but with the same priority are enqueued on the same queue. Such an approach can introduce considerable jitter in the generated waveforms and task deadline misses. MARTe does not queue any event: events can be lost but there is no jitter due to events enqueuing.

Exploiting Multiprocessors

MARTe allows the developer to assign threads and IRQs to specific processors. This facility protects the execution and promotes a deterministic response of the thread. The affinity mask of threads and IRQs on the processors is a parameter in the MARTe configuration file.

The EPICS Operating System Interface (OSI) layer does not support multiprocessor environments, i.e. `epicsThreadCreate` does not accept any CPU affinity argument. A static set of queues is defined for each instance of EPICS IOC. This approach does not scale to multiprocessors.

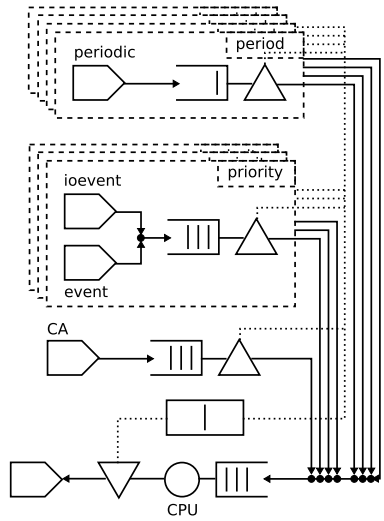

Figure 4: **EQN model** of the EPICS events queuing system running on a single processor/core machine.

FINAL CONSIDERATIONS

Since EPICS has been on the scene since 1989, the number of tools available to design and configure a system has grown. The same does not hold for the real-time support and especially for the exploitation of emerging processor technologies (multiprocessor architectures). Coding a discretized control algorithm can be tricky.

MARTe, on the other hand, has so far only a limited set of design and configuration tools. Some work is ongoing to exploit the Ptolemy [5] project as a tool for configuring and simulating MARTe applications. MARTe appears to be crafted for real-time, low latency applications. To cope with such demanding requirements it exploits emerging multi-core architectures.

DEBROS: DESIGN AND USE OF A LINUX-LIKE RTOS ON AN INEXPENSIVE 8-BIT SINGLE BOARD COMPUTER

Mark A. Davis, NSCL, East Lansing, MI 48824, U.S.A.

Abstract

As the power, complexity, and capabilities of embedded processors continue to grow, it is easy to forget just how much can be done with inexpensive Single Board Computers (SBCs) based on 8-bit processors. When the proprietary, non-standard tools from the vendor for one such embedded computer became a major roadblock, I embarked on a project to expand my own knowledge and provide a more flexible, standards based alternative. Inspired by the early work done on operating systems such as UNIX™, Linux, and Minix, I wrote DEBROS (the Davis Embedded Baby Real-time Operating System), which is a fully pre-emptive, priority-based OS with soft real-time capabilities that provides a subset of standard Linux/UNIX compatible system calls such as stdio, BSD sockets, pipes, semaphores, etc. The end result was a much more flexible, standards-based development environment which allowed me to simplify my programming model, expand diagnostic capabilities, and reduce the time spent monitoring and applying updates to the hundreds of devices in the lab currently using such inexpensive hardware.

INTRODUCTION

Since I first joined the Control Systems group at the NSCL, my primary focus has been on designing and developing software for embedded controllers. My first project was to upgrade several existing controllers from an in-house SBC design based on the Motorola 68701 micro-controller. These controllers used a low-speed RS-485 multi-drop network that resulted in frequent communication outages whenever someone disconnected one of the controllers or one of the connections failed. The goal of the upgrade project was to replace the RS-485 networks with a point-to-point Ethernet network.

To that end, an inexpensive SBC was chosen that incorporated the 8-bit Rabbit 2000 micro-controller and a 10base-T Ethernet interface. The SBC was the BL2105 from Z-World, Inc. (later purchased by Rabbit Semiconductor, and now part of Digi International Inc). This SBC includes 512K of RAM and 512K of flash memory and runs the Rabbit processor at 22.1MHz. At the time, this was a huge step up from the 68701 design which had only the built-in 128 byte RAM, 2K UVEPROM, and a top speed of 2MHz.

Another major improvement in this move was the change from programming entirely in assembly language to writing almost all the code in C.

With an Ethernet interface included on the SBC and a library of functions to support IP networking, the change in the communications interface was not a difficult task. Once that was accomplished, it was time to consider the many other enhancements made possible by the much more capable hardware.

EARLY ENHANCEMENTS

Compared to the Rabbit-based SBC, the earlier 68701 design had some major limitations:

- The tiny memory severelly limited code size
- Modifying UVEPROM requires physical access
- All code was written in assembly language

Given these limitations, there was no way to do regular firmware upgrades, much less add functionality beyond the bare requirements.

But the new hardware did not have these limitations. With vastly more RAM, software rewritable persistent storage (flash), and a high-speed communication interface, increased functionality and frequent updates were now possible. As the number of controllers and the complexity of their software grew, it quickly went from being possible to being necessary.

And so it began: More processing power at the controller level meant the controllers could do more of the work and could respond much faster to changes than the control system could. The size and complexity of the code on the controllers grew exponentially, which required additional diagnostic capabilities (adding yet more code) and an efficient way to update the firmware on the rapidly growing number of controllers.

It wasn't long before the inevitable happened: The new controller's larger memory space was used up, and there was no more room for enhancements.

A SQUARE PEG IN A ROUND HOLE

Several factors contributed to our problem of not being able to continue expanding the capabilities of the new controllers, including imitations in the vendor's development tools. But it also became apparent to me that a more basic issue needed dealing with: The programming model I was using was resulting in large, complex code that was difficult to maintain and was eating up memory much too quickly. Something needed to be done.

At the time I was using a cooperative multitasking model to keep my code organized in to separate "tasks". Scheduling consisted of the simple round-robin method of a series of function calls inside an endless loop, with each function representing one task.

In the simplest cases, each function will run from beginning to end each time it is called. This "run-to-

completion" model can be very efficient. It can also greatly simplify concurrency issues because no "task" is every pre-empted.

The problem with the run-to-completion model is that the average response time of the system for any single function grows larger and larger as the number of functions and/or the time spent in each function grows. When the average (or maximum) time for one pass through the main loop becomes too long, you are forced to break functions into smaller and smaller pieces to maintain acceptable response times.

At that point, the simplicity of the run-to-completion model falls apart. Breaking each function in to smaller and smaller parts and executing just one part each time the function is called stops the average time between calls from growing too large. But it also means it takes longer for each function to do the work it previously did during a single call.

In addition, breaking each function into pieces only works if each piece can pick up where the last one left off. It means every piece must be responsible for maintaining the internal state of the function between calls.

So every function becomes larger, slower, and more complex, even if you aren't adding any functionality to it. And each additional function or enhancement to an existing one potentially requires you to adjust the number, size, and/or content of the pieces in other functions.

And this doesn't even address the issue of different priorities for each task, and how to minimize the time between when an event occurs and when the function that needs to process it is called.

Eventually I realized that this was not a sustainable model. To run smoothly, the expanded capabilities of the controller required the behaviour of a pre-emptive, priority-based multitasking kernel, and I was trying to achieve that using a cooperative multitasking model. The result was that every task had to take on the responsibilities that are normally handled for them by a pre-emptive kernel. Once I realized this, it was painfully obvious why my code had become so large and complex. The question now was what could I do about it?

A PARADIGM SHIFT

At this point I knew a fundamental change was needed. The obvious alternative to the cooperative multitasking model was the pre-emptive one. If I had a pre-emptive kernel, there would be no need for every task to do the kernel's job. The mass of complex code I had to add to each task could be removed, which would free up a lot of memory and make them run faster. But of course, recognition of a problem doesn't automatically mean there is a practical solution.

When considering my options, my first thoughts were of MINIX and Linux. Even early versions of these operating systems where "complete" in the sense that, in additions to having pre-emptive, multitasking kernels, they also supported login shells and user commands. And I knew from personal experience that the original version of MINIX could run reasonably well on a 4.77 MHz IBM PC with only 256K memory. So I was confident that what I needed was possible.

Unfortunately, even the smallest Linux distributions I could find were far too large for my use. I briefly entertained the idea of trying to locate an electronic copy of the original source code for MINIX, but the design of MINIX varied in some very significant ways from what I needed (e.g. it used run-time loaded re-locatable binaries and a message-passing microkernel, both of which pose problems for real-time scheduling). [1]

Having failed to find a "complete" solution (a kernel, user interface, support for sockets), I decided the next best thing would be to use a pre-made kernel and write or port the rest of what I needed.

DEBROS IS BORN

I knew that, even if I found a suitable ready-made kernel that supplying the rest was going to require a lot of work. But in addition to the very real need for a more practical runtime platform, I was motivated from the start by the desire to learn about how pre-emptive multitasking actually works. When I was getting my degree in Computer Science the primary focus was on formal languages and writing compilers. There is no end to how useful the insights I gained from that knowledge have been over the years. But I am finding that the things I learned while doing this project have been just as fundamental to how I think about programming. In retrospect I am surprised that this topic was all but ignored in my college courses.

So I eagerly began my new programming and self-learning project by purchasing a pre-made kernel named TurboTask from Softools, Inc. along with a copy of their compiler.

TurboTask is a very small and efficient kernel that supported all the basic features I needed. The Softools compiler and linker produced smaller and faster code than the hardware vendor's tools, and included a copy of the hardware vendor's network stack (whose API I was already familiar with). All my early development was done using the TurboTask kernel, and the first version of DEBROS used on controllers put into production was one that incorporated it.

Unfortunately, as things progressed, it became apparent that the TurboTask kernel was not as good a fit as I had hoped it would be. It was indeed small, fast, and highly optimized. But it really was designed for someone programming at a much more hardware-oriented level. It just didn't mesh well with the needs of the UNIX-style OS I was developing. One limitation in particular - the requirement that the stacks for all tasks had to reside in the first 64K of memory – became a deal-breaker.

Eventually I had to replace the TurboTask kernel with my own task switcher, which was itself derived from an example provided by SHDesigns, the firm that sells the Download Manager/boot-loader we now use. The Softools compiler and tools, however, have continued to be critical to the success of DEBROS.

Regardless of the implementation details, by this time I had achieved my primary goal: The individual tasks no longer had to do the work of a kernel. I was able to strip out all the extra code that had nothing to do with each task's primary purpose. The resulting reduction in size and complexity was so significant it was if a thick fog had lifted and revealed a sunny sky.

But as important and fundamental as that change was, there was another one that has, in many ways, been just as important: My adoption of the UNIX standard.

THE ADVANTAGE OF STANDARDS

Like anyone that enjoys their work, I try to keep tabs on what is going on in the industry. For me this includes looking at the endless stream of new computer devices both big and small and seeing what kind of hardware and software they use.

One of the things that has become very apparent is that whatever the computing platform, be it a tiny computer no bigger than an Ethernet connector that serves up web pages, the latest smart-phone or e-book reader, or a building-size server cluster, there is one thing they nearly all have in common: Some level of compatibility with UNIX.

Linux and its offshoots (e.g. Android) are probably the best known examples. Various flavours of the Berkley Standard Distribution (BSD) are also quite common, especially when you include derivations like the open-source Darwin OS and its ancestors that form the core of Apple's OS-X operating systems. Even Microsoft provides UNIX compatible subsystems for its Windows operating systems.

The bottom line is that 40 years after it was born, the Application Programming Interface (API) spawned by UNIX has become an almost universal standard. Any programmer who has ever written a command-line application has at least some familiarity with the stdio and stdlib libraries. And if they have written a network server they know what sockets are and have almost certainly used the standard BSD socket API. So when I started writing my own OS, it only made sense that it too should be based on such a widely supported and familiar model.

Adopting a proven, widely supported standard can have many advantages over creating a proprietary interface. One that was critical to my own success was the availability of some very well written textbooks on subjects that were at the core of what I was trying to achieve. For my work on DEBROS, there were two in particular that I referred to constantly. The first is "UNIX Network Programming", by W. Richard Stevens [2]. It has since been expanded to multiple volumes and continues to be highly regarded. The second is "Understanding the Linux Kernel", by Daniel P. Bovet and Marco Cesati [3]. While the latter is a detailed look at the Linux kernel in particular, the topics and issues covered apply to any multitasking kernel. Both books are well written and I highly recommend them for anyone wanting to learn more about network programming or multitasking in general.

For programmers, the use of the UNIX standard means that writing code for DEBROS is no more difficult than writing code for any UNIX compatible OS. While DEBROS will never be fully UNIX compliant, the functions I have implemented use the same parameters and provide the same behaviour whenever practical. So learning to program for DEBROS does not require learning a new API. As proven by another person in our lab, it is possible to compile and test code written for DEBROS on other operating systems like Linux with few if any changes. Probably the most significant difference is simply learning to think on a smaller scale.

KEY LESSONS LEARNED

The primary purpose of an operating system kernel is to manage a set of shared resources. And probably the most important resource that it manages is CPU time.

In the process of writing DEBROS I learned a lot about the concepts and methods that make it possible for a kernel to manage resources effectively. Even the briefest discussion of them all would not fit in this paper. But there is one that, probably more than any of the others, serves to demonstrate both the complexity of the issues an efficient kernel must address and the ingenuity that has gone in to addressing them.

This concept is blocking vs non-blocking function calls. Anyone who has used the UNIX poll() or select() functions has been exposed to this concept to some degree. But what I found most surprising is that it applies to so many other functions, including ones I have used for decades, and yet I was barely aware of it or its importance.

Blocking and the Scheduler

The scheduler is the part of the kernel that is responsible for deciding which task should get the CPU next. While scheduling methods vary widely, they share a common goal: Don't waste CPU cycles.

The most basic piece of information a scheduler uses when choosing a task is what "state" the task is in. There are many different states a task can be in, but the key ones relevant to this discussion can be summarized as "Ready", and "Blocked".

A task is "Ready" if it currently has the CPU or has been pre-empted. The only thing a "Ready" task is waiting for is the CPU.

A task may become "Blocked" when it calls a function to perform an operation and the operation cannot be completed immediately (e.g. writing to a socket). The blocking function initiates the requested operation and then loops, waiting until the operation completes. The simplest possible wait loop looks something like this:

```
while (! eventOccured) { }
```

The problem with this very simple approach is that "blocked" tasks continue to use as much CPU time as the scheduler will give them. Blocking is very common, so this approach wastes large amounts of CPU time.

We can reduce the waste quite a bit with one small change:

```
while (! eventOccured())  { schedule(); }
```

Calling the scheduler directly allows a task to voluntarily give up the CPU. The affect here is to limit the loop to one execution each time the task is resumed.

A significant improvement, but there is still a lot of CPU time spent checking on events that haven't occurred yet. Having the scheduler choose blocked tasks less often, will minimize the waste, but at the cost of increasing the average response time to events.

The ideal situation would be for blocked tasks to use no CPU time at all. Once blocked, a process should not be given the CPU until the event that will allow it to unblock occurs. While not perfect, there is a method that does approach this ideal.

Wait Queues

A wait queue is a doubly-linked list of entities that all have something in common. The most typical use is to keep track of which tasks are waiting for an event related to a shared resource. The wait queue is created by the driver that is responsible for the resource. Tasks are added to the queue by blocking functions when they need to use the resource, and are removed by the driver when the resource becomes available.

The following shows how wait queues can be used in wait loops to make blocking much more efficient:

```
for (;;)  {
  set state to blocked and add to wait queue;
  if (eventOccured)  break;
  schedule();
}
set state to Ready and remove from wait queue;
```

While it may seem a bit odd, the order shown for these steps is critical. Any other order can result in waste we are trying to avoid or, worse yet, a hung task.

The first step is to set the state of the task to Blocked and add the task to the event's wait queue. Note that pre-empted tasks are treated as being in the Ready state, regardless of what their state is set to, so even if the task gets pre-empted after changing its state, it will not hang.

The next step is to check to see if the event has occurred. If it has, we exit the loop.

If the event has not occurred, we call the scheduler for the reasons explained previously. When we call the scheduler, one of two things will be true.

The first is that the task was not pre-empted between when it checked on the event and when it called the scheduler, or it was but the event didn't occur before it was resumed. In that case the task is still in the event's wait queue and its state is still set to Blocked. Because the scheduler was reached by the task calling it directly, it will not be resumed until the event occurs, at which point the driver will remove it from its wait queue and set the task's state back to Ready.

The other possibility is that the task was pre-empted after the check and the event occurred before it was resumed. In that case, the driver will have removed the task from its wait queue and changed its state back to Ready.

One of the subtle aspects of this logic (which was actually missed in an early version of Linux) was that you have to check on the state of the event after adding the task to the wait queue. Checking before you do so doesn't cause a problem, but checking after is critical. Consider what could happen if the only check is before:

- The check returns false and the task is pre-empted before it can add itself to the wait queue.
- The event occurs while the task is pre-empted.
- The task resumes and adds itself to the wait queue.
- The task is now dormant waiting for an event that has already occurred.

Even if the task does get resumed by a later event, at the very least it will have been delayed. Worse, it will have missed the previous event which, depending on the circumstances, could have fatal side effects.

When properly implemented and used by application code, blocking can be a very powerful tool in the quest to create an efficient system. As shown here, not only can a task block indefinitely with little or no overhead, but it will be resumed with minimal delay when the event it was waiting for occurs.

Until I wrote my own OS, the concept of blocking vs non-blocking calls barely penetrated my consciousness. Even when using calls like poll() and select() it never occurred to me how key they are to the efficient operation of the OS, as well as to writing efficient applications.

SUMMARY

The lack of a standard software platform for 8-bit microcontrollers is an impediment to their use in projects they are otherwise well suited for. Proprietary tools and programming interfaces require longer learning curves and result in non-portable software which increases the cost of using them.

DEBROS provides a way to get the benefits of a familiar standards-based programming API and runtime environment on inexpensive hardware, making them a practical alternative in many cases.

Abstract

An upgrade to the ATLAS silicon tracker cooling control system may require a change from C_3F_8 (octafluoro-propane) to a blend containing 10-30% of C_2F_6 (hexafluoro-ethane) to reduce the evaporation temperature and better protect the silicon from cumulative radiation damage with increasing LHC luminosity.

Central to this upgrade is a new acoustic instrument for the real-time measurement of the C_3F_8/C_2F_6 mixture ratio and flow. The instrument and its Supervisory, Control and Data Acquisition (SCADA) software are described in this paper.

The instrument has demonstrated a resolution of 3.10^{-3} for C_3F_8/C_2F_6 mixtures with ~20%C_2F_6, and flow resolution of 2% of full scale for mass flows up to $30gs^{-1}$. In mixtures of widely-differing molecular weight (mw), higher mixture precision is possible: a sensitivity of < 5.10^{-4} to leaks of C_3F_8 into the ATLAS pixel detector nitrogen envelope (mw difference 160) has been seen.

The instrument has many potential applications, including the analysis of mixtures of hydrocarbons, vapours for semi-conductor manufacture and anaesthesia.

INTRODUCTION

An upgrade to the ATLAS silicon tracker cooling control system may require a change from the present C_3F_8 evaporant (molecular weight = 188) coolant [1] to a blend with 10-30% of the more volatile C_2F_6 (mw = 138). Central to this upgrade a new acoustic instrument for real-time measurement of C_3F_8/C_2F_6 mixture ratio and flow has been developed, exploiting the phenomenon that the sound velocity in a binary gas mixture at known temperature and pressure depends solely on the molar concentrations of its components. This instrument builds upon the technology of ultrasonic gas analysis used in Cherenkov radiation detectors since the 1980s [2] and measures the molar concentrations of the two fluorocarbon components in the recirculating exhaust vapour following the evaporative cooling of the silicon tracker.

In the custom electronics sound bursts are sent via ultrasonic transceivers◊ parallel and anti-parallel to the gas flow. A fast transit clock is started synchronously with burst transmission and stopped by over-threshold received sound pulses. Rolling average transit times in both directions, together with temperature and pressure, enter a FIFO memory and are passed to a supervisory computer via RS232 or CANbus.

Gas mixture is continuously analyzed using SCADA software implemented in PVSS-II [3], by comparing the average sound velocity in both directions with stored *velocity vs. concentration* look-up tables. These tables may be created from prior measurements in calibration mixtures or from theoretical thermodynamic calculations. Flow rates are calculated from the difference in transit time in the two directions. In future versions these calculations may be made in an on-board microcontroller.

Within the ATLAS experiment the instrument has been used for flowmetry and mixture analysis of C_3F_8/C_2F_6 blends and also as a sensitive detector of leaks of the present C_3F_8 evaporative coolant into the ATLAS pixel detector nitrogen envelope.

MECHANICS

The mechanical envelope and ultrasonic transducer mounting are illustrated in Fig. 1. The transducers are mounted around 660 mm apart in a flanged stainless steel tube of overall length 835mm. The temperature in the tube is monitored by six NTC thermistors – (100kΩ at 25ºC) - giving an average temperature measurement uncertainty of better than ±0.3C. Pressure is monitored with a transducer having a precision better than ±15mbar.

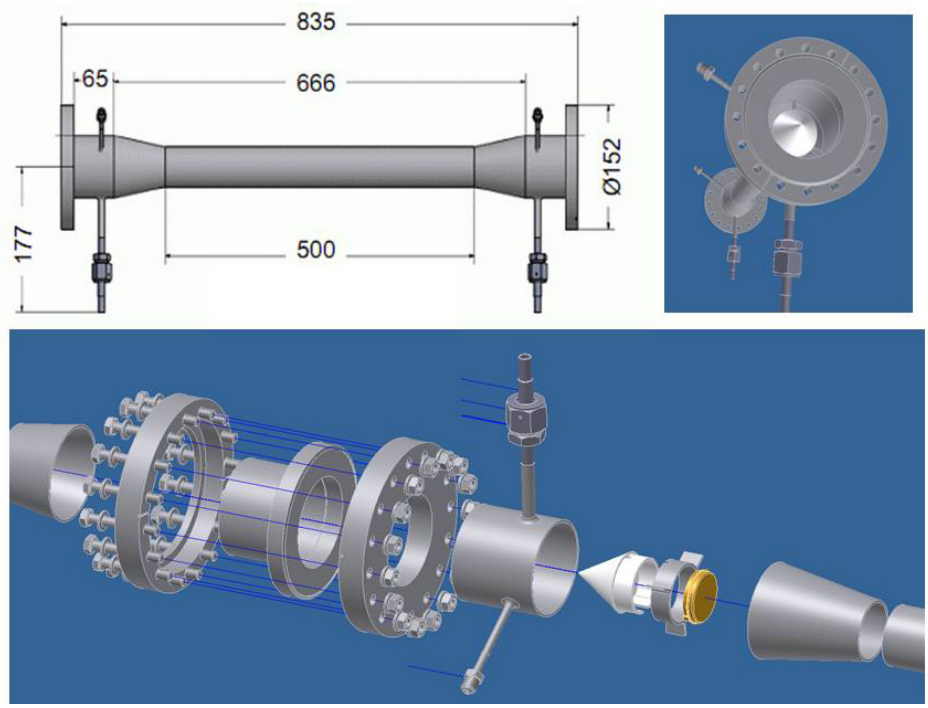

Figure 1: Views of the instrument mechanical envelope, showing an ultrasonic transducer, its mounting and axial flow-deflecting cone, together with tubes for pressure sensing and the evacuation and the injection of calibration gas.

ELECTRONICS

The custom electronics is based on a Microchip ® dsPIC 16 bit microcontroller. This generates the 50kHz sound burst signals emitted by the transducers and includes a 40 MHz transit clock that is stopped when an amplified sound signal from a receiving transducer crosses a user-definable comparator threshold.

The HV bias for the vibrating foils of the capacitative transducers, settable in the HV range 180-360V, is generated by a DC-DC converter. When transmitting, a transducer is excited with a train of (1-8) HV square wave pulses, built using the 50kHz LV pulses from the microcontroller and the DC-DC converter output. When receiving, a transducer is biased with a flat HVDC bias and its signal passed to an AD620N amplifier followed by a comparator.

Sound transit times are computed from the number of 40MHz pulses counted between the rising edge of the first transmitted 50KHz sound pulse, and the time the first received, amplified sound pulse crosses the comparator threshold. Transit times, computed alternately in the two transmission directions are continuously entered into an internal FIFO memory. When a measuring cycle is requested by the supervisory computer a time-stamped running average from the 300 most recent transit times in each direction in the FIFO memory is output, together with the average temperature and pressure, at a rate of up to 20 averaged samples per second.

In addition to the I/O connectivity for communications, the ultrasonic transducers, pressure and temperature sensors, two (4-20 mA) analog outputs provide feedback for adjustment of the C_3F_8/C_2F_6 mixing ratio by the external gas mixture control system.

CALIBRATION AND MEASUREMENTS IN PURE C_2F_6 AND C_3F_8

For high precision mixture and flow analysis the uncertainty in the sound flight distance should be minimized. It is necessary to perform a one-time transducer foil inter-distance calibration. The most convenient method is to calculate this distance from an average of measured sound transit times with the tube filled with a pure gas (or gases) having well-known sound velocity dependence on temperature and pressure. We initially made calibrations using xenon, whose sound velocity and mw (175.5 ms^{-1} at 20ºC, 137 units) are closest [4], [5] to those of the fluorocarbon mixtures in the ATLAS application [1], and whose thermo-physical behaviour is that of an ideal gas. Later calibrations demonstrated sufficient precision with nitrogen and argon, which are considerably cheaper and more widely available. The average uncertainty in transducer inter-distance measured in this way is ± 0.1mm.

Multiple measurements were made in pure C_3F_8 and C_2F_6 at around 19.5°C, with pressure in the range 0.4 - 2.7bar_{abs}[6]; conditions expected in an acoustic vapour analyzer installed in the (superheated) vapour return path some tens of metres from the evaporative zone within the ATLAS silicon tracker. The average difference between measured sound velocities and the predictions from a PC-

SAFT[□] equation of state (EOS) [6], [7], [8]) was less than 0.04% in both fluids.

SCADA & ANALYSIS SOFTWARE

The specialized software for the gas analyzer operation is coded as a standalone component in the PVSS II, v3.8 SCADA environment [3], [6]; a standard at CERN. Its main tasks include:

- vapour flow rate determination;
- sound velocity and molar vapour mixture concentration determination;
- RS232 or CANOpen communication, to start and stop the measuring cycle, and to request time-stamped bidirectional sound transit times, temperature and pressure data from the instrument FIFO memory;
- calculation and transmission of the set-points for the analog (4-20mA) output signals for C_3F_8/C_2F_6 ratio adjustment in the external cooling plant;
- visualization via a Graphical User Interface (GUI);
- archiving of sound transit times, velocities, flow, mixture composition, temperature and pressure into a local and/or remote data base.

The vapour flow rate is calculated from the sound transit times measured parallel, t_{down}, and anti-parallel, t_{up}, to the flow direction, according to the following algorithm:

$$t_{down} = L / (c + v), \quad t_{up} = L / (c - v) \qquad (1)$$

where v is the linear flow velocity (ms^{-1}), c the speed of sound in the gas and L the distance between transducers.

The gas volume flow V (m^3s^{-1}) can therefore be inferred from the two transit times by:

$$V = L/2 * A * ((t_{up} - t_{down})/ t_{up} * t_{down}) \qquad (2)$$

where A is the internal cross sectional area of the axial flow tube between the two ultrasonic transducers (m^2).

The sound velocity c can also be inferred from the two transit times via:

$$c = L/2 * ((t_{up} + t_{down})/ t_{up} * t_{down}) \qquad (3)$$

It can be seen from Eqs. (1) – (3) that knowledge of the temperature of the gas is not necessary for flowmetry.

Figure 2 shows the linearity of the ultrasonic flowmeter element of the instrument in C_3F_8 vapour at 20°C through comparison with a Schlumberger Delta G16 gas meter, at flows up to 230 $lmin^{-1}$ (~30 gms^{-1}); the maximum mass flow in the presently-available C_3F_8/C_2F_6 blend circulation system. The average precision is 2% of full scale.

The calculation of gas mixture molar ratio requires the use of ("*c, t, p*") look-up tables of gas mixture composition in the binary mixture to be analyzed, corresponding to sound velocities, *c*, at known temperatures, *t,* and pressures, *p*).

Look-up table data may be gathered from prior measurements in calibration mixtures or from theoretical data. Fig. 3 compares measured sound velocities in calibrated mixtures of C_3F_8 and C_2F_6 with sound velocity predictions at 19.2°C from a PC-SAFT EOS [7], [8] and the refrigerant-oriented extended Benedict-Webb-Rubin

[□]Purturbed-Chain Statistical Associating Fluid Theory

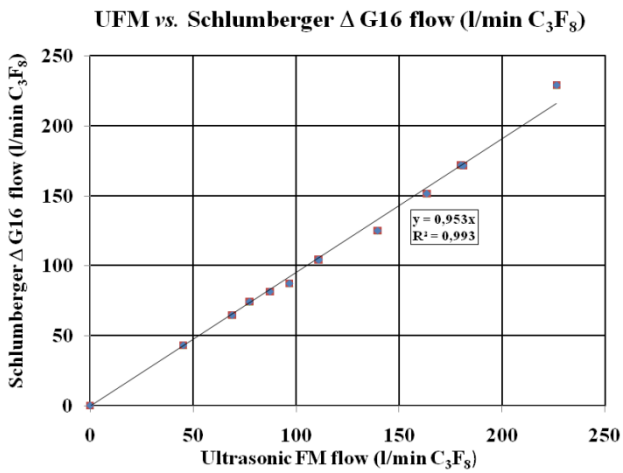

Figure 2: Ultrasonic flowmeter linearity comparison with a Schlumberger Delta G16 gas meter: C_3F_8 vapour.

(BWR) EOS used in the NIST REFPROP thermodynamic software package [9]. The (0→35%) C_2F_6 concentration range spans the region of thermodynamic interest to the ATLAS silicon tracker cooling application.

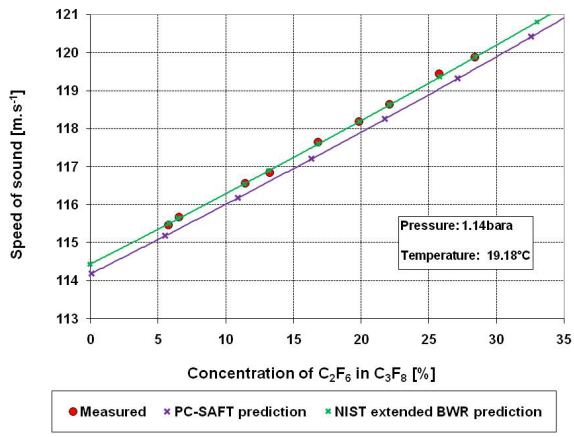

Figure 3: Comparison between measured sound velocity data and theoretical predictions in C_3F_8 / C_2F_6 mixtures.

The mixtures of C_3F_8 and C_2F_6 shown in Fig. 3 were set up by partial pressure ratio in the previously-evacuated tube, creating a molar ratio binary gas mixture. The transducer foil inter-distance had been previously established using the above-described gas calibration procedure, to a precision of ± 0.1mm.

The average difference between measured and the PC-SAFT and NIST-REFPROP predicted sound velocities in mixtures with (0→35%) C_2F_6 in C_3F_8 were respectively 0.5% and 0.05% at pressures around 1 bar_{abs} and temperatures in the range 15-25°C. It is recognised that the present version of the NIST-REFPROP [5] database is the more precise in predicting the thermophysical properties of mixtures of saturated fluorocarbons (having molecular structures of the form $C_nF_{(2n+2)}$).

The precision of mixture determination, $\delta(mix)$, at any concentration of the two components is given by;

$$\delta(mix) = \delta c/m \qquad (4)$$

where m is the local slope of the sound velocity/ concentration curve and δc is the uncertainty in the sound velocity measurement - dependent on transit time resolution, transducer spacing and uncertainties in the measured temperature and pressure (±0.2°C, ±5mbar in this instrument) or variations between these parameters and the (t, p) values of the nearest (c, t, p) curve in the calibration database. For example, at a sound velocity of ~118 ms^{-1}- corresponding to a blend of 20% C_2F_6 in C_3F_8 (Fig. 3) - the combined measurement uncertainties result in a sound velocity uncertainty of 0.06 ms^{-1}, yielding a concentration uncertainty ~0.3% at 20%C_2F_6, where the slope of the velocity/ concentration curve is ~0.18ms^{-1}%$^{-1}$.

The present software [6] uses a pre-loaded look-up table of NIST-REFPROP BWR-generated sound velocity with 0.25% granularity in C_3F_8/C_2F_6 molar mixture and covering the expected range temperature and pressures (16.2→26.1°C, 800→1600$mbar_{abs}$ with 0.3°C & 50mbar granularity). The algorithm calculates mixture composition by minimizing a quadratic norm, n_i, for each (c_i, T_i, P_i) table entry:

$$n_i = k_1(p_{i,\,table} - p_{running\,average})^2 + k_2(t_{i,\,table} - t_{running\,average})^2 + k_3(c_{i,\,table} - c_{running\,average}) \quad (5)$$

where $k_{1,2,3}$ are sensitivity parameters [6] and p, t & $c_{running\ average}$ are real-time outputs of the instrument FIFO memory.

A new software version [6] will implement a database covering a much larger c, T, P range and will allow "zooming" to smaller sub-tables (O~10,000 c, T, P data points), corresponding to a narrower process range - as in the present application.

In a second application related to the ATLAS evaporative cooling system, we use ultrasonic binary gas analysis to detect low level C_3F_8 vapour leaks into the N_2 environmental gas surrounding the ATLAS silicon tracker. Figure 4 compares measured sound velocities in mixtures containing up to 10% C_3F_8 in N_2 with sound velocity predictions from the PC-SAFT EOS[9]. A reduction in sound velocity of 0.6 m/s from the base velocity of ~351 ms^{-1} was seen during a long term (> 1 year study). From the ~-12.27ms^{-1}%$^{-1}$ average gradient of the sound velocity-concentration curve at trace C_3F_8 concentrations in the range 0→0.5% (Fig. 4) this sound velocity indicated, using Eq.(4), a C_3F_8 leak ingress of 0.049%, later traced to one of 204 evaporative cooling circuits into the ATLAS silicon tracker nitrogen envelope.

CONCLUSION

We have developed a combined, real-time ultrasonic flowmeter and binary gas analyzer, whose accuracy was determined following calibration in pure reference gases - by a set of measurements in C_3F_8/C_2F_6 blends. Sound velocity measurements were within 0.05% of the predictions of the NIST-REFPROP package, allowing mixture resolution of 0.3% in the (0-35% C_2F_6) concentration range of interest for the ATLAS silicon tracker.

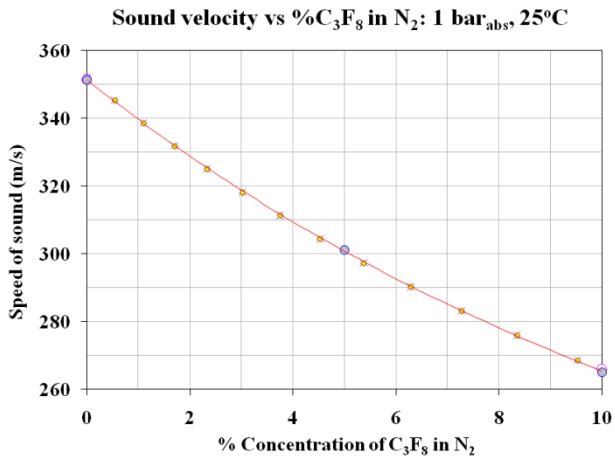

Figure 4: Comparison of sound velocity measurements (°) and PC-SAFT predictions (◊) in C_3F_8/N_2 mixtures.

The instrument presently analyzes vapour mixtures of C_2F_6/C_3F_8 and N_2/C_3F_8, respectively having a molecular weight difference of 50 and 160 units, the mixture resolution being seen to increase with the mw difference of the components. The instrument has applications in the analysis of hydrocarbon-air mixtures, refrigerant-air mixtures (leak detection), vapour mixtures for MOCVD semiconductor manufacture and anaesthetic gas mixtures.

INTERCONNECTION TEST FRAMEWORK FOR THE CMS LEVEL-1 TRIGGER SYSTEM

J. Hammer, CERN, Geneva, Switzerland
M. Magrans de Abril, Wisconsin University, Madison, Wisconsin, U.S.A.
C-E. Wulz, Austrian Academy of Sciences, Vienna, Austria

Abstract

The Level-1 Trigger Control and Monitoring System is a software package designed to configure, monitor and test the Level-1 Trigger System of the Compact Muon Solenoid (CMS) experiment at CERN's Large Hadron Collider. It is a large and distributed system that runs over 50 PCs and controls about 200 hardware units.

The objective of this paper is to describe and evaluate the architecture of a distributed testing framework – the Interconnection Test Framework (ITF). This generic and highly flexible framework for creating and executing hardware tests within the Level-1 Trigger environment is meant to automate testing of the 13 major subsystems interconnected with more than 1000 links. Features include a web interface to create and execute tests, modeling using finite state machines, dependency management, automatic configuration, and loops. Furthermore, the ITF will replace the existing heterogeneous testing procedures and help reducing both maintenance and complexity of operation tasks.

INTRODUCTION

The Compact Muon Solenoid (CMS) experiment at the Large Hadron Collider (LHC) of CERN, the European Organization for Nuclear Research, is a detector designed to find answers to some of the fundamental open questions in physics today [1].

Since millions of collisions of protons occur every second and only a small fraction of these can provide insight into new physics, events have to be selected on-line according to their properties. This is done by the trigger system, a vital part of the experiment.

The trigger system is organized in two levels: (1) The Level-1 Trigger (L1T) [2] is a custom-designed, largely programmable electronic system which preselects the most interesting collisions for further evaluation. These collisions are then examined and – if selected – stored permanently by (2) the High-Level Trigger (HLT) [3], which consists of a farm of industrial processors.

The Trigger Supervisor Framework

The L1T is configured, tested and monitored using the Level-1 Trigger Control and Monitoring System – a large and distributed system that runs over 50 PCs and controls about 200 hardware units (~ 6000 boards). Each of the components of this system is based on the Trigger Supervisor (TS) Framework [4], written in C++, providing a web interface utilizing AJAX.

The TS architecture is composed of a hierarchical tree of nodes, where the central (i.e. the top) node is in charge of coordinating the access to the subsystems [5]. Each node is accessible by a well-defined interface based on the Simple Object Access Protocol (SOAP) [6], and can run one or more commands and operations simultaneously. Operations are stateful objects that use transitions to move between different states of their internal finite state machine (FSM) – which can be defined freely.

The communication hierarchy is strictly top-down – following the request-response model – with subsystems not even knowing their supervisor nodes. Fig. 1 shows an example system setup.

Need for an Interconnection Test Framework

With more than 1000 links connecting the about 200 hardware units, thorough testing is crucial. So far, the various subsystems have used custom scripts for testing – controlling the TS nodes via SOAP commands. Needless to say, this leads to a lot of duplicated effort with a high level of maintenance required. Even more important, this approach does not allow the centrally controlled execution of tests (in particular by non-experts!), nor to execute them automatically at specific events.

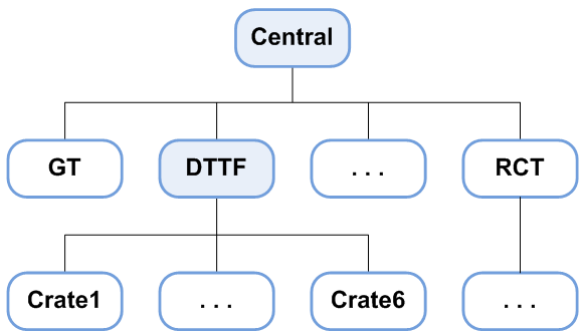

Figure 1: An example Level-1 Trigger system setup.

Instead, local test methodologies heavily rely on the respective subsystem experts and time-consuming coordination between them and the global run control operators. All these factors lead to unnecessary system downtime and a waste of precious manpower, both undesirable consequences for such a huge experiment involving large resources of manpower and investment.

A much better solution would be to provide an interconnection test framework on top of the existing TS framework. This could make use of the already available infrastructure and facilities, and provide additional common functionality for distributed testing. However, although the basic idea was already stated in [6], a sophisticated implementation was yet to be developed.

Requirements and Constraints

Among the requirements:

- Main focus on simplicity: The users should need as little effort as necessary to use the ITF (simple API, little setup/configuration, …).
- Tests can be run both locally and centrally controlled.
- Tests can be run in different network environments (with or without database; with various and even fake top nodes, …).
- Unlimited subsystem hierarchy depth.
- Shall be very flexible to allow a large range of diverse tests (including self-tests).

Imposed constraints were:

- Shall be embedded into the existing Trigger Supervisor environment, i.e. the tests shall be implemented using TS operations.
- Shall allow both interactive and scripted execution.

ARCHITECTURE

Overview

The Interconnection Test Framework is built on top of the Trigger Supervisor Framework, and therefore fully embedded into the existing environment. As a result, the ITF is highly TS specific, using the available API to communicate with subsystems and drive operations. Figure 2 shows the basic architecture:

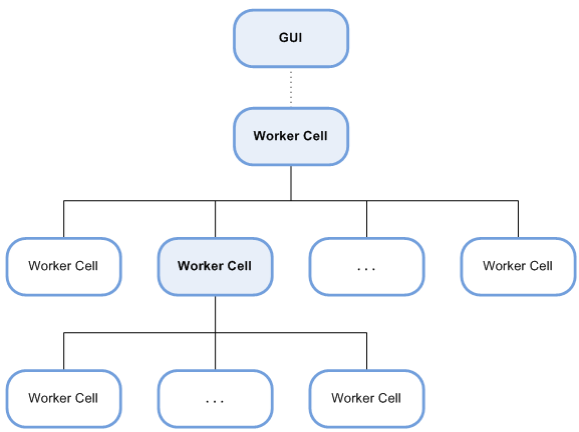

Figure 2: The architecture of the Interconnection Test Framework.

Each node runs one Interconnection Test operation – a sub class of the framework's base class, with the concrete functionality implemented by the user. Any node will automatically act as a supervisor once there are sub nodes defined for it.

Which and how many nodes (i.e. systems) are involved depends on the test case – essentially an XML document – that defines all the necessary details for a specific test (e.g. user-defined parameters).

Service Discovery (ITF-SD)

Much effort was spent on simplicity. Wherever possible, the "convention over configuration" paradigm was applied to reduce both the required initial effort to create a test case as well as the necessary maintenance.

One core feature that facilitates this strategy is the Service Discovery (ITF-SD). It allows to automatically detect all available test operations in the network which are reachable from the start node. Based on this information is automatically creates test cases without having to define the sub nodes – exploiting the already defined system hierarchy.

This eliminates the need to maintain the test cases when the topology of the network (or just the name of a subsystem) changes. Both partly pre-defined (auto-detecting a specific sub tree only) and on-the-fly test cases (auto-detecting the entire test tree) are possible.

The Finite State Machine (FSM)

The finite state machine is the main building block of a test operation. It defines the available system states and the legal transitions to move between them, and serves as the common specification for all test operations. Consequently, the FSM should be quite flexible to allow a diverse set of test types – starting from self-tests that would need only one single transition, to complex distributed tests that require loops with plenty of synchronization between the nodes.

Figure 3 shows the finite state machine that is used for the Interconnection Test Framework. It features six transitions: setup, prepare, execute, analyze, next and summarize. Each test has at least one loop, the number being either defined statically in the test case definition or set dynamically at runtime (by any node).

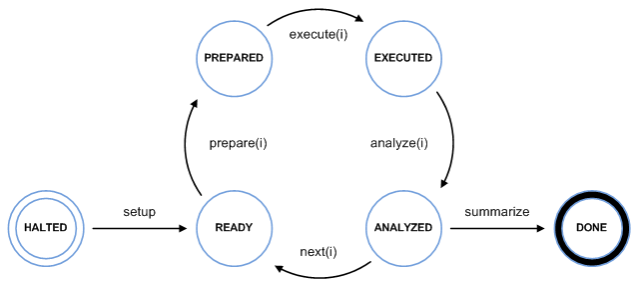

Figure 3: The finite state machine for all test operations.

FSM Pruning

As shown in the previous section, the FSM features a loop. Each loop provides four different transitions – prepare, execute, analyze and next. Each of these transitions has to be called in every subsystem in every loop. However, most test operations will not need that many steps, e.g. execute and analyze only might be sufficient. Nevertheless, the empty transitions have to be called as well – leading to a significant performance penalty when many loops are required (not to mention that every connection to be made has a risk to fail).

To get rid of these disadvantages while still providing a flexible and unique FSM, FSM pruning (or transition-skipping) is applied. During the first loop the framework automatically detects which transitions are empty (i.e. not in use) and uses this information to skip those transitions

in the following loops. This works on a per sub-tree basis. The only thing the developer has to do is not to implement the corresponding transition.

Figure 4 shows the actual FSM that will be utilized in case the prepare transition is empty.

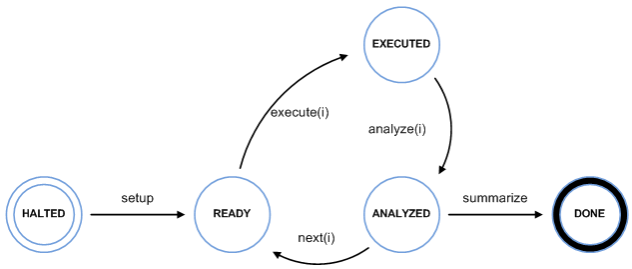

Figure 4: FSM Pruning: Skipping the prepare transition.

Sequences

Sequences are used to define the order in which a transition should be executed in different subsystems of the same level of the hierarchy. Their main purpose is to define dependencies. If nothing is specified explicitly, the default rule is to execute everything in parallel.

Shared Memory

The communication in the Trigger Supervisor system is strictly top-down. However, for some tests it is convenient or even necessary to communicate with other (e.g. the neighbor) nodes.

Therefore, the ITF provides a simple shared memory, based on name/value pairs. A name may also refer to a file on the local hard disk – the framework will automatically take care of syncing it to any node that needs the file.

The Test Result

The basic building block of a test result is the ResultItem. A ResultItem – either of type success or failure – may contain a message and additional attributes (which allows structured information). Neutral items (so-called properties) are possible too to include general information, e.g. the current state of the hardware.

It is also possible to store detailed result data in separate files. A test may generate as many ResultItems as required. To issue a failure with an empty message and two attributes all that is required is something like

```
failure("").attributes()
      .add("source", boardID)
      .add("expected", pattern));
```

(Custom) Views / Analyzers

In order to visualize the test result in a user-friendly way, result views are provided. With the default view (Fig. 5) the ResultItems of all systems and loops can easily be examined. By using AJAX even huge test results with thousands of items can be browsed through without putting a heavy load on the browser.

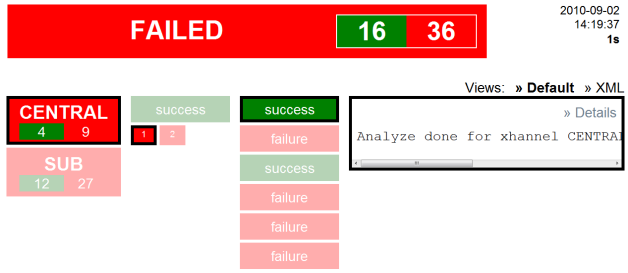

Figure 5: The framework's default result view.

In order to provide higher flexibility and facilitate a wide variety of test types, custom result views / analyzers are possible as well (like the one in Fig. 6). This allows interpreting the result in a specific way and, in particular, visualizing it according to the needs of that type of test.

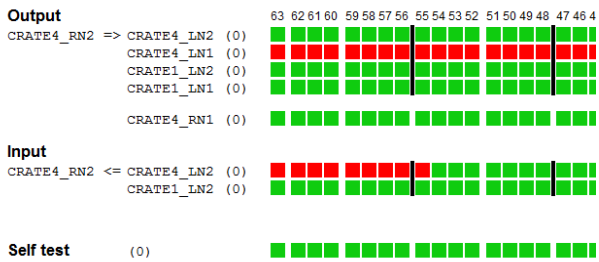

Figure 6: A custom result view.

Central History

All test results are automatically stored into the database to provide a central history. Therefore, the results can be evaluated and compared to previous results at any later time. As one of the goals of the ITF is to be database independent, this will fail silently in case no database is available.

As an additional feature automatic logging of all actions and (sub) results is provided to help debugging issues.

RELATED WORK

The CMS experiment with its many custom-made hardware units is, well, unique. Therefore, the Trigger Supervisor - a system which is responsible for centrally controlling all those units – already had to be developed in-house as there was no other solution available. Thus, the main constraint was that the Interconnection Test Framework must run within the Trigger Supervisor environment.

As a result, there was no other solution than to develop the ITF from scratch for the specific needs of the CMS Level-1 Trigger, after gathering the requirements from different subsystem groups. The basic idea has already been stated in [7], including an original, loop-free version of the finite state machine.

In the wider sense, all the XUnit frameworks can be considered related work. However, although some concepts are similar and ideas were derived in particular

from JUnit [8], those are frameworks for unit testing and not for distributed testing.

CONCLUSION

This paper introduced the Interconnection Test Framework for the CMS Level-1 Trigger System, a solution for testing connections between several nodes of a distributed system. The framework is built on top of the Trigger Supervisor framework, and allows executing transitions with arbitrary actions synchronously on several systems.

The excellent flexibility and extensibility of the Interconnection Test Framework was shown – both a wide variety of test types as well as custom result analyzers are possible. Even more important is that the framework tries to reuse many concepts of the underlying Trigger Supervisor framework, enabling the test developers to start right away by using already familiar knowledge.

However, this also means that the concrete implementation of the ITF is applicable for our environment only. Nevertheless, the concepts and the conclusions are hopefully useful for others as well.

Another limitation is due to the fact that XML is quite verbose, which limits the amount of data that can be stored without affecting performance. With the current implementation, about 10000 result items is a reasonable limit (could be improved if necessary).

Still, XML is an ideal choice for both the configuration and the result as it is highly flexible and easy to maintain (in contrast to e.g. JSON). It makes development so much faster if you are able to add attributes or entire trees on-the-fly without having to change anything in your code.

Simplicity is the main prerequisite for user acceptance, and thus the key ingredient for making the framework successful. This was achieved by reusing the concepts of the TS framework and by keeping the required test configuration to a bare minimum with features like the Service Discovery.

The second critical factor is performance. After some analysis we figured out the minimal Finite State Machine that would be needed to implement our tests. As four steps per loop would slow down many tests, we decided to automatically prune the FSM instead of providing several versions. This makes life easier for the developers but still allows high performance.

Although the framework is constantly being developed further, it already provides a stable environment for various kinds of tests in the CMS Level-1 Trigger system where it proved to be immediately applicable for real-world use cases.

ACKNOWLEDGMENT

We would like to thank Christian Hartl and Thomas Themel for providing ideas and valuable feedback. Franz Mittermayr developed the original versions of the test configuration and execution user interfaces.

A TESTBED FOR VALIDATING THE LHC CONTROLS SYSTEM CORE BEFORE DEPLOYMENT

J. Nguyen Xuan, V. Baggiolini, CERN, Geneva, Switzerland

Abstract

Since the start-up of the LHC, it is crucial to carefully test core controls components before deploying them operationally. The Testbed of the CERN accelerator controls group was developed for this purpose. It contains different hardware (PPC, i386) running various operating systems (Linux and LynxOS) and core software components running on front-ends, communication middleware and client libraries. The Testbed first executes integration tests to verify that the components delivered by individual teams interoperate, and then system tests, which verify high-level, end-user functionality. It also verifies that different versions of components are compatible, which is vital, because not all parts of the operational LHC control system can be upgraded simultaneously. In addition, the Testbed can be used for performance and stress tests. Internally, the Testbed is driven by Atlassian Bamboo, a Continuous Integration server, which builds and deploys automatically new software versions into the Testbed environment and executes the tests continuously to prevent from software regression. Whenever a test fails, an e-mail is sent to the appropriate persons. The Testbed is part of the official Controls System development process wherein new releases of the controls system have to be validated before being deployed operationally. Integration and system tests are an important complement to the unit tests previously executed in the teams. The Testbed has already caught serious bugs that were not discovered by the unit tests of the individual components.

MOTIVATION

As described in the previous publication [1], the accelerator controls system can roughly be described as 3 tier architecture, mainly written in Java and C/C++. It is composed of many layers developed by separate teams. Along with software, hardware has also been evolving and nowadays the operational environment consists of different hardware architecture running different OS at the same time.

Upgrades are very challenging since many components and teams are involved. There is no place for failure, since a beam downtime of the LHC itself only costs about 50'000CHF/h.

The different components are well tested individually with unit tests, but without any systematic function and integration tests. This is the reason why we started the Testbed project.

THE TESTBED

Overview

The main goal of the Testbed is to test components together before they are deployed into operations and validate a working set of versions. This practice is part of an overall development process to which also the SIP initiative belongs [2].

The scope of the Testbed is to test general purpose controls components. It does not include GUIs, or devices with a specific function, such as a power converter or a beam loss monitor. The tests focus on functional aspects, mainly integration and system testing, but also include verification of backward compatibility and regression testing. Some tests validate the reaction to failures. Failure can be provoked artificially by shutting down services in the Testbed, and that without disturbing the operational environment. The Testbed is composed of several different machines, representing the variety of hardware and operating systems used in the CERN accelerator complex. The core software components of the controls system are deployed on these machines and clients are emulated, a detailed description follows in the next section.

Diving into Details

The Testbed tries to mimic the operational environment of the core components (Fig. 1).

Starting from the bottom, FECs (Front-End Computer) are needed to send simulated data and are synchronized by the timing system. Both hardware types from operations are integrated: PPC with LynxOS and i386 with Linux. On these FECs, two implementations from different generation are used: the PS's GM (General Module) and the LHC's FESA (Front End System Access).

The middle-tier is composed of common middleware services which are:

- the CCDB (Controls Configuration Database) containing data essential for most of the components
- a JMS (Java Messaging System) broker to pass messages
- RBAC (Role Based Access Control) security to restrict some actions to certain users
- CMW (Controls Middleware) services as the directory server which provides the different server addresses and the proxy which protects FECs from too many connections

Finally at the top, communication libraries with APIs like JAPC (Java API for Parameter Control) or RDA (Remote Device Access) commonly used by clients are tested.

This setup allows calls from client APIs with various paths and properties, as fetching a value from a device directly or through the proxy, enabling RBAC authentication, and so on.

THE TESTS

Type of Tests

As already mentioned, the scope of the Testbed is functional and system testing. Tests validate (1) the typical primary functions and interactions the controls system provides, (2) the correct reaction of the controls system to typical errors (e.g. device failures) and (3) the backward compatibility of new components.

An example of primary functionality is device access. All controls devices implement a device/property model. The most basic interactions with such a device are *set*, *get* and *subscription* on the properties. They can be triggered at various API levels, at the lower level RDA API and at the higher level JAPC API. To validate this functionality a test first reads the property value, then sets the property to a new value, and finally checks that the new value is published through the subscription mechanism.

Correct reaction to failures can be tested with a special device class that simulates typical device errors, e.g. sending wrong data or not responding at all. Tests check amongst other things that correct exceptions with the right error messages are thrown.

Backward compatibility is checked by deploying the new and the old version (e.g. of the communication middleware) into the Testbed, and checking that they interoperate correctly. In general, different version combinations that may occur are tested, e.g. different versions of FESA with different versions of the middleware components.

Test Organization

The order in which tests are executed is important to make sure we get accurate test results.

Before running the actual function tests, the Testbed runs a series of self-tests, called preconditions tests. They verify that all Testbed components are active and configured as expected. For example, they check if a device is online, if the timing works, if the directory service and the database are accessible. If any of the preconditions fails, the Testbed stops, waiting for the defective components to be fixed. Otherwise the process continues and the actual function tests are executed. Preconditions tests are important to keep the test results clean and correct; they make sure that functional tests only fail on real malfunctions in the controls system, not because of misconfigured Testbed components.

The set of tests is also run in a well-defined, bottom-up sequence. Because a higher-level test will involve all those previous components, we first make sure that the lowest components are fully operational before running tests on higher components. First the tests targeting low level components are run, such as tests on the timing system, the directory service or the proxy. If a test on the proxy fails, then tests from JAPC are likely to also fail. By testing the proxy before JAPC, we ensure that a fault in the proxy is recognized as such, and not as a JAPC fault.

Writing and Maintaining Tests

Tests should be written by the teams who provide the library or the component or by a team dedicated to testing in order to be able to keep up with the project changes or to simply maintain the tests. But in practice the teams focus more on development of new features, so the tests are often written by third persons following the specifications.

The Testbed administrator is in charge of verifying and integrating new tests into the test suite. It happens that bad written tests give wrong errors result, but they are fairly easy to spot and quickly fixable. Those errors are

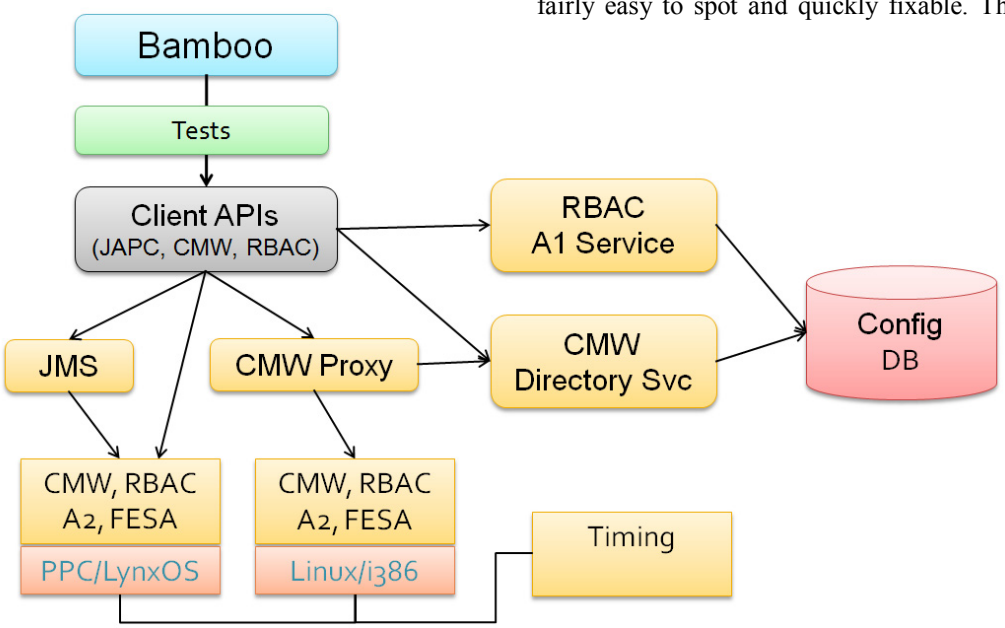

Figure 1: The Testbed structure.

habitually detected at development time.

Tests are updated when a new component with non backward compatible changes are deployed. Usually the new deployed components make the tests fail, so unless the tests are changed, they will keep failing.

Running Tests

Tests are run by our continuous integration server Atlassian Bamboo [3]. Normally, Bamboo is used as follows. A so-called Bamboo test plan monitors a source repository and triggers a build process when source code changes are committed by some developer. A build process checks out the source code, compiles the sources and runs the unit tests. If all this succeeds, a cascade of other dependent test plans can be triggered. If it fails, Bamboo sends typically an e-mail to the owner of the test plan and to the committer. Bamboo displays the results of unit tests very nicely with graphs, relevant statistics and metrics, and the detailed logs of the whole execution are available. A history of all test plan executions is kept as well. Within a test plan, several stages can be defined to divide a build into several steps. These steps are run sequentially and we use them to run the tests in a defined bottom-up sequence (Fig. 2).

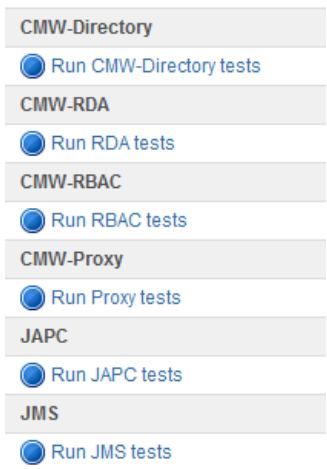

Figure 2: Bamboo's stages.

We use Bamboo to run the test suite of the Testbed every two hours. Since we use the JUnit framework to write our tests, full reports are also shown on Bamboo. Keeping the logs from each build is very handy because it happens that an error appears only once in a while, not at each run.

Using Bamboo to drive the Testbed has its limitations, the automatic deployment mechanism has to be scripted by hand (more about it in the next section), and setting up the environment such as JDK versions before running the tests is not obvious.

Automatic Deployment

As the Testbed is used for beta-testing, it is important that bugfixes can be deployed easily and quickly. We therefore invested in automatic deployment directly from the sources. Whenever a new component is ready, it is automatically built and deployed into the Testbed.

We use SVN branches to identify the source code that should be deployed into the Testbed. If Bamboo detects a commit to a specific branch, it automatically builds that branch and all the dependent projects as well. The resulting build artifacts are stored in a special binary repository, which eventually contains a set of components that have been built together. We added a post build mechanism to Bamboo, based on shell scripts, which deploys the executable artifacts into the Testbed. We use Apache Maven [4] for building, which works out-of-the box for Java. For C/C++ products, we have developed a Maven-compatible build system based on the Maven NAR plugin [5] that provides similar functionality as available in Java.

THE CASE OF CMW PROXY

This section explains in more details one particular component and the corresponding tests executed by the Testbed. The CMW proxy is a separate process used to shield devices on a front-end computer (FEC) from too many client requests. When several clients subscribe to a device through the proxy, it will manage all the subscriptions, but only do one subscription to the device. At first thought, the proxy seems to be a pretty simple piece of software, but in reality its functionality is rather tricky to implement, because it needs to be transparent to the clients and has many constraints due to RBAC security or FECs' implementation.

The middleware team, which is responsible for the proxy, updated a few of their C++ products in the release candidate repository, including the RDA communication library. They needed to deploy a new version of the proxy, which depends on RDA. Using the automatic deployment mechanism, the new proxy was updated and the tests worked fine during the first runs. But the next day, the tests were failing, because some proxied devices did not properly respond to requests. It turned out that the devices all worked fine, but the proxy was in a faulty state. We finally saw that this problem was caused by a newly introduced bug in RDA which did not properly close the connections. The Testbed had to run for 5 hours in order to reproduce this bug.

BENEFITS

The Testbed has been running for one year now and has already shown the following benefits.

More Confidence

Developers using the Testbed feel more confident in their product. The Testbed is an important complement to the unit tests, not a replacement. By running a series of tests after new software version, the Testbed ensures that a change does not break the core functionality of the controls system. The Testbed already caught several bugs and revealed few inconsistencies. The above example of

the CMW proxy product took several days to fix this bug and therefore saved some hours of beam downtime.

The Testbed is vital in our environment where many developers belonging to several teams contribute to the controls system. If one team provides a new version of their component, everyone can see immediately and well before operational deployment whether the controls system still works.

Better Understanding

The accelerator controls system is complex and hard to understand as a whole entity, hence the Testbed helps in that direction by simulating requests done operationally from the CCC. One can think of the RBAC implementation in combination with the proxy, in specific cases the proxy is overriding the client's permission. First we thought that it was a bug, but in fact it was done on purpose to force users to use the proxy.

Saving Money

The Testbed allows to validate the controls system core before it is deployed in the real accelerator complex. The overall cost of the Testbed (hardware and man power) is small compared to the cost of LHC downtime. Without having done a scientific analysis, we estimate that cost of the downtime avoided by the Testbed outgrows the cost of the Testbed itself.

Small Laboratory

The Testbed is a down-scaled replication of the accelerator controls system, which can serve as an experimental laboratory for many purposes. It was already used for early validation of new systems in an early stage of development. For example the new logging system which involves front-ends, middleware, the proxy and the JMS broker.

Another example is the new build and release tool we are working on, based on Apache Maven. It was first used in the Testbed, before even giving it to any of our Java and C/C++ developers.

FORESEEN IMPROVEMENTS

The most important improvement is to write more and better tests. Our developers should write functional tests in the same natural manner as they already write unit tests. We also have to extend test coverage to validate not only main functionality but also more advanced and less frequently used tests. It still happens (and we cannot avoid) that some bugs are discovered during operations. In these cases we need to enforce that a test is written to expose this bug.

As a second priority, we intend to extend the scope of the Testbed in several ways.

We will add new systems to be validated. At the moment, only the lower layers of the controls system are deployed into the Testbed. We plan to add higher-level core components, such as the Software Interlock System (SIS) [6], the LSA/InCA [7] system and the high-level settings management and controls system for our accelerators.

We will provide several different Testbed configurations with different versions of hardware, operating systems, Java virtual machines, and controls components. Functionality is needed to automatically re-configure the Testbed and re-deploy the controls system on it.

Finally, we might open up the Testbed to other types of tests than mere functional tests, and include performance and scalability tests.

AUTOMATED COVERAGE TESTER FOR THE ORACLE ARCHIVER OF WINCC OA

A.Voitier, P. Golonka, M. Gonzalez-Berges, CERN, Geneva, Switzerland

Abstract

A large number of control systems at CERN are built with the commercial SCADA tool WinCC OA (formerly PVSS) [1]. They cover projects in the experiments, accelerators and infrastructure. An important component is the Oracle archiver used for long term storage of process data (events) and alarms. The archived data provide feedback to the operators and experts about how the system was behaving at particular moment in the past. In addition a subset of these data is used for offline physics analysis (conditions data). Large volumes of data are produced by the different facilities at CERN (several Terabytes per year). The consistency of the archived data has to be ensured from writing to reading as well as throughout updates of the control systems. The complexity of the archiving subsystem comes from the multiplicity of data types, required performance and other factors such as operating system, environment variables or versions of the different software components. Therefore an automatic tester has been implemented to systematically execute test scenarios under different conditions. The tests are based on scripts which are automatically generated from templates, therefore they can cover a wide range of software contexts. The tester has been fully written in the same software environment as the targeted SCADA system. The current implementation is able to handle over 300 test cases, both for events and alarms. It has enabled to report issues to the provider of WinCC OA. The template mechanism allows sufficient flexibility to adapt the suite of tests to future needs. The developed tools are generic enough to be used to test other parts of the control systems.

INTRODUCTION

In a control system, archiving is responsible for recording the process data and alarms, and then making it available to understand the state a system was in at a certain point in time. The accuracy of the stored data in both value and time is a key aspect for the quality of service offered by an archiver. Operator tools such as trends or reports showing historical values rely on an efficient and accurate archiving system. Misbehaviours of these tools during a data taking period are not acceptable as they could lead to lowered operation capabilities, data loss or even a stop of the concerned system. In addition, upgrades of software components may only be applied at certain periods of time.

A particular requirement of the control systems for the experiments at CERN is to make use of subsets of data stored by the archiver as so called conditions data. The availability and consistency of such data, being for instance the monitored voltages of a high voltage power supply, are then essential and necessary for the off-line physics data reconstruction and analysis. In this example, archived data will act as an input parameter to calculate the actual gain factor of a photomultiplier, which may be linked directly to the efficiency or calibration factors of the detector.

To minimize the possibility of the down-time caused by a control system built with WinCC OA, the different components need to be validated by tests performed in laboratory conditions. This validation is handled by the CERN Industrial Controls group. The group provides a centralized service and support for common controls tools, and performs the initial validation of every new version of the SCADA software components. This include testing their proper operation in new environments (new versions of operating systems, related software, etc.).

Being the least mature and one of the most complex components of WinCC OA, the Oracle archiver requires particular attention. Not only do its scalability and throughput need to be verified (as previously reported in [2]), but also a systematic verification of consistency of archiving data across all possible data types and/or software context is required. The tool presented in this paper is aimed at this kind of coverage testing.

In the paper we will describe the Oracle Archiver, the problems associated with its testing and the approach we have chosen for the architecture of the tool. We will follow by describing the architecture of individual tests, and finally present conclusions.

The tools described in this paper are aimed at testing the behaviour of the Oracle archiver and to check on the integrity of data of various types, in multiple software environments.

To cover the large number of combinations of setups/environments that require testing, a program was devised to automate the – often tedious and complicated – process of setting up the archiving test setup in laboratory conditions. It became possible to repeatedly trigger the tests in the various environments and observe the impact of single environment changes on the result. This part of the project became an independent tool (known as Bootstrapper) that found many other applications.

The testing framework had to be generic and adaptive to cover a wide range of tests. The number of similar test scenarios called for an abstraction: the scenarios can be grouped in families of tests that differ slightly from one another. A powerful mechanism combines templates with test specific configurations to produce the test case

scripts. By using 8 templates and some minimal configuration, the current 300 scripts were produced.

Eventually, each issue discovered by the tester would have to be investigated, isolated and reported to the producer of WinCC OA. We came up with an architecture where every test case is self-contained and could eventually be executed with no additional instrumentation, and hence easy to reproduce in a clean laboratory setup.

Software Contexts

The tester is supposed to be repeatedly executed in varying setups (software contexts). It shall be possible to verify the proper functioning of the RDB Archiver in the setups that have different versions and patch-levels of WinCC OA software, Operating System (versions of Linux and Windows supported at CERN), Oracle software, or any other software component that may affect the functioning of RDB Archiver in the future. Other factors such as environment variable settings (e.g. the formatting of time representation, related to the local language setting), security settings, Oracle-specific settings or the Archiver's own settings affect the behaviour of the RDB Archiver and hence extend the spectrum of software contexts in which the tester need to be executed.

Context and Behaviour of the Archiver

The process of storing data is initiated asynchronously by the change of a value (that was declared as having archiving activated). The archiver employs a sophisticated buffering mechanism to optimize the performance with respect to the database, and groups the data before flushing them. As a result, the archived data is available in the database only after a certain "dead time".

The queries for historical data in WinCC OA are performed from scripts, by means of three functions: *dpQuery()*, a versatile SQL-like interface retrieving data, *dpGetPeriod()*, a more restricted interface, and *alertGetPeriod()*, oriented to alarms. The data for historical trend plots come internally through the mechanism used by the *dpGetPeriod()* function. Hence, for the purpose of testing, the functions cover also the trending functionality.

The archiver allows archiving values for the following WinCC OA basic data types: *char, uint, int, float, bool, bit32* (bit field), *string* and *time*. It also allows archiving array types made of the above basic types (*dyn_int, dyn_string*, etc.).

In addition to the value and time-stamp, the archiver also stores meta-data, such as the status bit fields, defining for instance the quality of the data. Such information can be used later in trend plots to visually mark invalid data.

An outstanding feature of WinCC OA is its very complex and flexible model for alarms. The archiver allows for the storing and querying of complete information about the evolution of alarms in the system. The alarm information is independent from the values, and it changes dynamically as the alarms come, go, are acknowledged and commented. The whole life-cycle of an alarm is traced by the archiver, and this domain also needs to be tested.

The Oracle archiver of WinCC OA has other functionality such as filtering, smoothing (reducing the data), correcting or compressing of archived values. These features have a direct influence on the archiving process. The archiver also allows for database specific maintenance operations such as grouping values in different tables, or taking a range of unused data off-line. These are not covered by the tester at present.

APPROACH AND ARCHITECTURE

The tester was developed iteratively following a progressive build-up of knowledge of the archiver's behaviour. It allowed us to focus the tests on the most critical points. A typical testing scenario was identified as a sequence of actions: trigger the storage of a value (or alert), then retrieve it from the archive, and finally compare the retrieved data with the expected (original), considering values, timestamps and meta-data (status bits).

As already mentioned in the previous chapter the individual test cases are embedded into individual test scripts coded in WinCC OA's own "Control" scripting language (CTRL). Each test script executes the above mentioned sequence of actions and reports the results.

To cover all possible combinations of standard test scenarios for all the WinCC OA data types, the scripts are generated from templates, based on configuration data.

For the automated tester executing numerous test cases in an already pre-configured environment we therefore established the following standard procedure:

1. Retrieve the configuration of the test case.
2. Generate the test script.
3. Execute the script.
4. Visually report and save the result of the test.

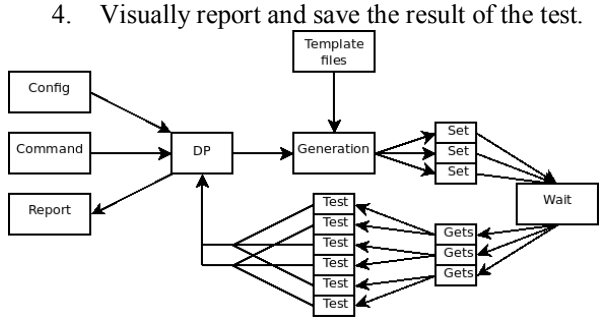

Figure 1: The tester design. (DP=Datapoint).

For all the operations of configuration, command and reporting (shown in Figure 1), the tester relies on WinCC

OA datapoints. In addition to being used to link to hardware and process variables, the WinCC OA datapoints represent variables with data-persistency and hence provide for easy inter-processes message passing.

Script Generation

The test scripts are generated whenever needed based on template scripts and adapted to each case through pre-registered configurations. Template files contain the basic structure needed to implement a test of a specific kind. Separate templates are required to address the differences between families of tests are instrumented for the particular data type (basic types, arrays, status bit or alerts) and the retrieval function they use (*dpQuery()* or *dpGetPeriod()*). The templates contain place-holders used during the generation process where they are adapted to the configuration of a test case. A configuration specifies the template file used, the name of the test, its subfamily (e.g. the retrieval function used here for display purposes), and a list of place-holder tags used within the template file. Typically, the place-holder tags allow specification of the data type of the test (*int, char, dyn_float*, etc.), the attribute of the datapoint the test targets (offline value, online value or original value), and the value used for this test.

Parallel Execution System

With a growing number of test cases the need for parallel execution became apparent. WinCC OA offers threading functionality inside the CTRL scripting engine. Due to current limitations these could not be used, therefore, a custom parallel-execution and job-queuing system free of these limitations was developed. The "script pooler" component employs a "pool" of individual CTRL language interpreter processes (managers) to schedule the execution of the subsequent test-case scripts. Each CTRL manager runs in a separate operating system process and is capable of communicating through datapoints, which allowed implementation of the parallel job queuing system. A component provides a panel to deploy and configure a list of CTRL managers for the pool. When deploying managers it is possible to configure the number of managers and pre-allocate them to individual test cases.

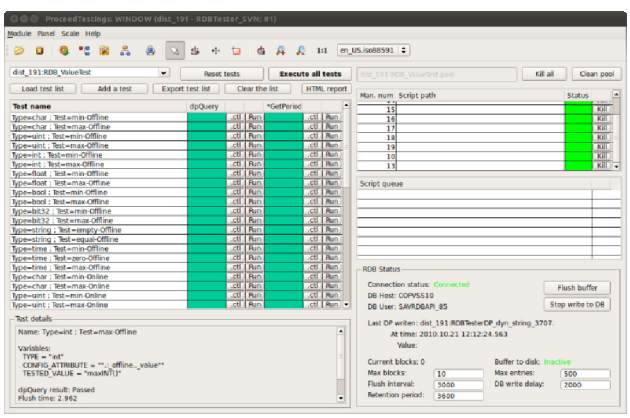

Figure 2: The overview panel of the tester.

Reporting

Once a test case has been executed, its script stores the result in a datapoint. It is then accessible later on, which allows running the tester overnight and checking the results later. The information that is stored includes: if the test passed or not, if it raised a warning, the database-flush time in case of success or the error reason otherwise. To display the results, an overview panel (see Figure 2) shows all of the relevant information for the progress of a test suite (all the tests of the same kind are executed in sequence). The panel also shows the script pooler (queue status, managers on duty, commands) as well as summary of the archiver status (latest datapoint written, buffer usage, connectivity, etc.).

TEST DESCRIPTIONS

Each test of the archiver is essentially made of a *Set* operation followed by a corresponding *Get* operation. The result of the *Get* being compared to what has been *Set* previously. Between the *Set* and the *Get* steps, however, the test has to wait for the data to go through the archiver's internal buffers and to get flushed to the database. Thus, we refer to this recurrent procedure as *Set - Wait flush - Get - Test*. Before being applied, this procedure needs to create a randomly named datapoint and configure it to be archived. The *Set* step is performed such that the timestamp on the archived data change is known.

The *Wait* step needs to be synchronized between the tests to reconcile with the buffering behaviour of the archiver. To compensate for a missing functionality within the archiver, a mechanism was implemented to confirm and notify when the archived data reached the database, or that a timeout expires. The *Get* step will then retrieve the previously archived data, using the WinCC OA data-query functions, and extracts the details necessary for the *Test* step. This last step compares the timestamps, the values, the types and the status bits.

For the eight scalar data types, each type is tested in a separate test case. Each test case performs a number of sub-tests, e.g. for successive data point elements (the offline, online and original values), and data-retrieval functions (*dpQuery()* and *dpGetPeriod()*). Finally, several value variations are introduced (e.g. maximum/minimum value for a particular type, positive/negative values). It would be excessively large and not meaningful to test every single possible value for each data type. Therefore only the *min* and *max* functions for numerical types, and an empty and a random value for the string type are tested.

For arrays the tested variations are similar to the scalar values. The special case of an empty array is handled. The size of an array, the type of its elements and the order of the elements are checked.

For the test-case of status bits the original status set is compared to the one retrieved; the actual value and the

data type variation are not the subject of the test. Different realistic status values as well as different archiving contexts such as smoothing (data reduction) are set and tested.

For alerts the tests cover the retrieval functions and datapoint attributes, and also the alert configuration itself (number of alarm ranges crossed, type of alarm (value range, discrete value, status bits)). Several scenarios were implemented for alert evolution, with permutations of the *Came, Went* and *Acknowledge* events in the alert life-cycle. Although alerts can display a hysteresis effect because of this sequence of events, the creation of a random test datapoint at the beginning of each test ensures that there is no perturbation between concurrently running alert tests.

RESULTS

An issue with flushing of the archiver's buffer was identified and isolated as soon as we began production testing. Thanks to the tester, the issue which was previously only seen sporadically in production systems could be studied, reproduced and reported to the WinCC OA vendor, and resulted in a fix being made available for CERN users.

The tester identified seven problems with data consistency for scalar data types, namely for special cases such as empty strings or ASCII-0 characters, mis-handling of timezone-setup in the operating system, or bit-field incoherence. Thanks to the requirement of the test-cases being self-contained, it was easy to demonstrate the problems to the vendor, and all of the issues were quickly resolved. Since then, the tester has been reporting the status of all tests for scalar values as "green" (passed).

The tests for array-types detected a further nine issues, which – after being studied – will also be reported to the WinCC OA vendor. Again, problems come up in the handling of non-standard cases such as empty arrays or arrays containing empty strings.

The tests for the status bits did not detect any problems. Nevertheless, the tests reassured us that the problems encountered in previous versions of WinCC OA have not re-appeared. The tests for alerts have not detected any inconsistency so far.

The tester is now routinely used to check all new releases (patches) of WinCC OA that affect the archiver subsystem. Reliable and easy-to-deploy tests significantly reduce the workload on the WinCC OA support team at CERN.

DISCUSSION

The automated coverage testing tool allowed to detect, reproduce, isolate and report a number of issues with the WinCC OA Oracle Archiver, and have them resolved in time for the 2009 run period of the LHC. Similarly, it allowed sorting out an issue with the buffer-flushing mechanism, which affected to the operation of some control systems already in production.

Test cases for array-types have been much more challenging. Firstly, they are harder to debug considering their size-related and ordered nature. Problematic behaviour sometimes appeared only with a specific order of elements. The archiving of array-typed values is nevertheless a feature rarely-used at CERN. Therefore testing and correction of its mechanism was not top priority. However, the results of failed test cases will be reported to the WinCC OA vendor to be corrected in a later version of their product.

For alerts, we decided to not make any further development of the tester until we establish a more efficient testing structure, as the alert life-cycle scenario is too complex for the current approach.

CONCLUSION

In this paper we presented the automated tester for Oracle Archiver of WinCC OA. The tester proved its usefulness in detecting and isolating problems with the archiver, by systematically testing the archiving functionality for all supported WinCC OA data types. Together with the previously discussed scalability-tests [2], the results provided by the automated coverage tester build up our clients' confidence in the Oracle Archiver.

The issues that were easily discovered by the tester confirmed that the chosen approach was the right one. Furthermore, the technical decision of implementing our own parallel-execution system brought additional advantages: a solution offering native parallelisation of CTRL scripts in WinCC OA, and a way to easily isolate the test cases into self-contained scripts, simplifies reporting the issues. Finally, the "Bootstrapper" used to prepare and start the tester evolved into an independent project and finds application beyond its original scope. We believe that the components of the tester may also be used to leverage the testing of other components of WinCC OA, such as the alert system, or the frameworks used to construct the controls applications at CERN.

AUTOMATED TESTING OF OPC SERVERS

B. Farnham, CERN, Geneva, Switzerland

Abstract

CERN relies on OPC Server implementations from 3rd party device vendors to provide a software interface to their respective hardware. Each time a vendor releases a new OPC Server version it is regression tested internally to verify that existing functionality has not been inadvertently broken during the process of adding new features. In addition bugs and problems must be communicated to the vendors in a reliable and portable way. This presentation covers the automated test approach used at CERN to cover both cases: Scripts are written in a domain specific language specifically created for describing OPC tests and executed by a custom software engine driving the OPC Server implementation.

INTRODUCTION

The architecture of many of CERN's Detector Control Systems (DCS) is, to a large degree, stable. Users of the DCSs are currently able to sufficiently control and monitor their systems to successfully create and gather physics data. Nothing is perfect however. Controllers and administrators have working systems, but there is scope for improvement: fixing bugs, adding features, improving response times to commands, reducing feedback latency etc.

The OPC Test Script Runner is a tool, developed at CERN, for writing, running and recording the results of scripted tests which engage DCS components at the level of OPC [1] (a standard providing a uniform means of controlling and monitoring devices). The tool aims to address two concerns regarding the stable DCS environment described above:

- Changes carry an inherent risk of regression: Changing X might accidentally break Y (and Z). A DCS user may request a new feature to a device, exposed via its OPC Server. The user wants assurance that, after making changes, the critical features on which the DCS relies function at least as well as they did before. Additionally the user wants assurance that the new feature functions as per specification and will continue to do so over time as subsequent modifications are made.
- It can be hard to accurately convey a bug to a vendor, and hard for a vendor to recreate a bug for diagnosis. Consider a subtle bug in an OPC Server, occurring only under some long and complicated sequence of client operations: Communicating the detail of this bug to the vendor involves the user translating this sequence into a textual description, transmitting it to the vendor who de-translates that description back into OPC client actions to replay to an OPC Server in an attempt to reconstruct the original bug. Written language can be an awkward medium for unambiguously recording a series of complex actions. Misinterpretation of one action in the sequence may result in the vendor being unable to recreate the problem for diagnosis.

OPC test scripts describe functionality and perform runtime verification. Test scripts, designed to capture behaviour of critical features, are run against new releases to check whether the modifications damaged existing functionality. Furthermore, as new features are released, their functionality is described and verified through test scripts in order to test the feature at point of release. These test scripts are added to the catalogue of regression tests to verify that functionality subsequent releases.

A similar approach applies to bug reporting - in effect a test script is written which fails, the failure highlighting the ill effects of the bug. The script is passed to the manufacturer who runs it to observe the bug first hand. The bug is fixed once the script passes.

THE TEST SCRIPT RUNNER STRUCTURE

The OPC Script Runner contains an OPC client. At their most basic level, OPC test scripts describe sequences of OPC interactions which the client carries out with the server at runtime. A test script which simply specifies a sequence of client interactions is not sufficient however, in order to ascertain whether the interactions had the desired effect, i.e. whether the test script passes or fails. There is an additional tie between the test script and script runner, namely assertions, a notion familiar to unit testing practitioners. Assertions in the script instruct the assertion handling module of the script runner to set watchpoints with specific criteria for success, failure to meet these criteria results in the assertion failing, and thus the test script failing. The test script runner records and displays assertions results. Assertions are described later in more detail.

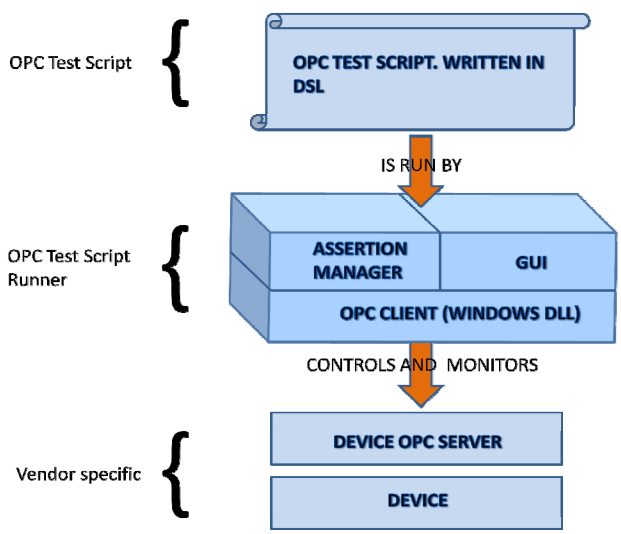

Figure 1: OPC Test Script Runner Components.

The OPC Client part of the test script runner is a MSWindows dll, written in C++, the upper part of the test script runner, handling script execution, assertion management and the graphical user interface is written in Groovy, a dynamic language for the Java Virtual machine. Interactions between the higher level processing on the JVM and the lower level OPC client are handled by open source Java Native Access (JNA).

A dynamic language such as Groovy was an important choice for the upper portion of the test script runner in order to aid defining the Domain Specific Language [2] (DSL) in which the test scripts are written. DSLs are 'small languages', designed for a particular field and consisting of nouns and verbs specific to that field. The field in this case is OPC testing, OPC nouns from the DSL include familiar OPC terms such as 'group' and 'item' and verbs pertaining to OPC nouns like an item's 'asyncWrite' or a group's 'destroy' plus unit test style verbs such as 'assertTrue' or 'assertNotEqual'. The DSL for the test scripts has been designed to promote readability, the idea is that 3rd party users such as an OPC Server vendor should be able to read a testscript and understand it in terms of the OPC interactions.

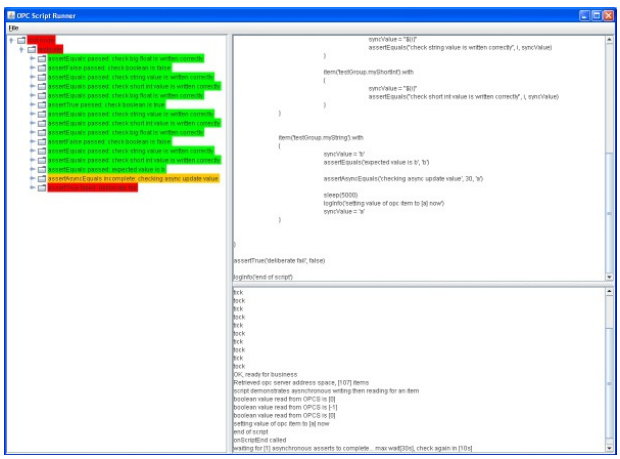

Figure 2: OPC Test Script Runner GUI layout.

The left panel displays a tree of the script's assertions colour coded on their pass/pending/fail states, the tree is dynamically built at runtime as the assertions are made and the assertion criteria met or otherwise. The top right panel displays the script text (read only) and the bottom right panel displays a log window which updates with system messages and user defined log messages written in to the script. From the menu users can open and run scripts and export script assertion results in Junit style XML format.

ASSERTIONS

Assertions are the mechanism for defining pass/fail criteria in test scripts. Two types of assertions are available:

Synchronous Assertions

These are the simplest case. A script can make assertions about an OPC item's immediate value - that it is equal to x, or not equal to y for example. Synchronous assertions pass or fail immediately. Script excerpts detailing synchronous assertions include:

- *item.assertEquals("Verifying the value of an integer item", '50')*
- *item.assertTrue("Verifying the value of a boolean item")*
- *item.assertNotEquals("Verifying the value of a string item", 'ERROR')*

Asynchronous Assertions

OPC interactions can be asynchronous in nature. For example OPC has the concept of groups: A client requests that a server builds a group and adds items to it and that the server informs the client of changes to group items at a rate not greater than some client specified frequency. From the perspective of the test script, commands can be delivered through the client but the effects only seen some time later. This use-case is handled by the asynchronous class of assertions. These assertions provide a required criteria for success (as with their sycnhronous siblings) however they also specify a time limit within which the criteria must be met. Asynchronous assertion excerpts from scripts include:

- *item.assertAsyncEquals("Waiting a maximum of 2.5 seconds for channel status to be stable:on", 2500, 1)*

Asynchronous assertions have 3 states: Pass, fail and pending (while the criteria is not met but the time limit not yet reached). This asynchronous class of assertions allow for performance test scripts. For example an asynchronous assert could be scripted immediately after multiple commands have been sent to verify whether a system remains responsive (to within the timeframe specified by the assertion) following a command flood.

A SIMPLE EXAMPLE SCRIPT AND ITS ANATOMY

The following is an OPC test script used for verifying the functionality and response time for turning channels on for a CAEN industrial power supply. Note some parenthesis and user messages have been omitted for brevity. As previously stated, the DSL in which test scripts are written is intended to be readable by 3rd parties such that they can understand what the test does and the assertions the tests make. The DSL includes a regular expression like syntax (*) to denote collections of OPC items with matching addresses.

```
init('', 'CAEN.HVOPCServer')

group('setup.software.and.hardware.chain').with
   item('**.ConnStatus').assertEquals('Ok')
   item('**.OPCServerEventMode').assertFalse()

group('set.initial.device.state').with
  items('**.Board*.Chan*.Pw').each
```

```
        it.syncValue = 'false'
items(**.Board*.Chan*.Status').each
        it.assertEquals('0')

group('main.body').with
   // set up asynchronous assertions
   items(**.Board*.Chan*.Status').each
        it.assertAsyncEquals(10000, '1')
   // turn the channels on
   items(**.Board*.Chan*.Pw').each
        it.syncValue = 'true'

// pausing for 11s to allow asynchronous criteria
sleep(11000)

group('wrap.up').with
   items(**.Board*.Chan*.Pw').each
        it.syncValue='false'
logInfo('end of script')
```

The test script runner dictates no special structure for the test scripts it executes, however experience has shown the structure followed above to be an effective skeleton:

1. Verify the software and hardware chain: Assert that the OPC Server and underlying device are present and the basic state is suitable. For example is there an OPC item which can be used to assert that a device is connected to the OPC Server and is powered on.
2. Set and verify the pre-test device state: Send commands to the underlying device to set the initial state and assert that the required initial state has been achieved.
3. The main body: Commands are issued and assertions made about the effects of those commands.
4. Wrap up: Send commands to set any post test state and assert that the post test state is achieved

USE CASES

OPC test scripts are simplest when a repeatable sequence of events and their corresponding effects can be defined. For regression test type scripts this is almost always the case: A known sequence of client/server interactions is expected to have a known set of required outcomes. So long as these outcomes are visible to the script runner via OPC then they can be verified in the form of assertions. A slightly more complicated type of test involves a known end effect (observable via OPC) but with an undefined set of events leading up to it - often this is the situation regarding subtle bugs: For example after many hours of continuous operation an OPC item suddenly ceases to update. Again, so long as the effect is observable via OPC the behaviour ought to be able to be captured using an OPC test script. Test scripts can request random numbers to introduce a stochastic element into interactions.

Some examples cases where the OPC Test Script Runner has already been employed:

1. A device vendor must switch their OPC Server implementation from an outdated OPC toolkit library supplier to another (in order to provide Windows 7 support). This change is not insignificant. A catalogue of test scripts has been written against the previous OPC Server version on XP. These scripts are being run against the new OPC Server version on windows 7 to check for bugs and deterioration in functionality.
2. The OPC test script runner has been used to successfully narrow down operations causing a memory leak in an OPC Server from an industrial power supply vendor. Memory usage is not available via OPC so this was monitored using an external tool: Windows XP Perfmon. Multiple scripts were written, each script focusing on a different type of client/server interaction (different types of reads and writes for example), and each script run for some set period whilst monitoring the memory usage. Certain scripts appear to cause the OPC Server memory usage to grow more quickly than others, providing the vendor with empirical information as to the problematic client/server interactions. The scripts (plus runner) have been passed to the vendor.

FURTHER WORK

Currently scripts are a single continuous sequence. The ability to define methods (parameterized repeat blocks of script) would allow for more concise and intuitively readable scripts.

The current implementation of the OPC Test Script Runner supports only the OPC Classic specification released in 1996 and based on deprecated Microsoft COM/DCOM technology. The OPC Foundation released a next generation OPC specification called OPC-UA [3] which looks set to gradually replace OPC Classic over time. The OPC Test Script Runner client will be updated to be OPC-UA compliant and the test script DSL extended to include OPC-UA operations.

The test scripts runs without human intervention, however, each script must be loaded and started by hand. It would be more efficient to instruct the script runner to run a catalogue of tests sequentially. For example run all scripts in a given directory.

CONCLUSION

Automated testing is an established practice in software development, providing increased assurance against the regression of existing functionality as current OPC based DCS technology evolves. Furthermore, the ability to provide vendors with runnable instances of bugs and problems can provide significant efficiency gains over writing traditional bug reports. The OPC test script runner provides a means to bring both of these benefits to bear on the field of OPC components.

BACKWARD COMPATIBILITY AS A KEY MEASURE FOR SMOOTH UPGRADES TO THE LHC CONTROL SYSTEM

V. Baggiolini, D. Csikos, P. Tarasenko, Z. Zaharieva, M. Arruat, R. Gorbosonov,
CERN, Geneva, Switzerland

Abstract

It is a big challenge to smoothly upgrade the control system of a large operational accelerator such as the LHC without causing unnecessary downtime. We have identified backward compatibility as a key measure to achieve this, because a backward compatible component can be easily upgraded. This document describes the work the CERN Accelerator Controls group does to provide methods and tools supporting backward compatibility.

BACKGROUND

Now that the LHC is operational, we from the controls group get requests from the operations team, which require a high degree of versatility. On one hand, the stability of the control system is necessary to ensure smooth operations while on the other hand, a certain amount of flexibility should be available in order to develop and deploy bug fixes and new functionality. To cope with these requirements, we are making a continuous investment in the quality assurance of our software, to improve the development process [1] and to provide new tools [2]. The work described in this document belongs into this context.

The CERN accelerator control system is highly complex, modular and distributed. The software part is structured as a three-tier system. GUIs at the top layer are written in Java and run on Linux consoles in the control room; the business layer in the middle is also written in Java but runs on powerful Linux servers in the computer center; the equipment control software at the lowest layer is written in C/C++ and runs on front-end computers with real-time-enhanced Linux and LynxOS. The Java part of the control system is composed of roughly 1000 Jar files, which are combined to around 400 different GUIs and 150 different server programs, which are deployed as over 600 processes on 400 machines. The C/C++ part on the front-end computers is represented by around 550 different device types (FESA [3] and legacy GM classes), deployed as over 70'000 device instances on 800 front-end computers. The development of all these components is done by more than 130 developers in 50 different teams. The development and collaboration is organized in a pragmatic and informal manner, with very low administrative overhead. Developers essentially collaborate along the dependencies of their software. If two components depend on each other, the respective developers will coordinate their work as needed. Even though there is no strong centralized organization to coordinate all upgrades done by the different teams, this form of collaboration is very efficient and agile. However, there are certain shortcomings as developers are not always aware of all the other components that depend on theirs, and consequently they may fail to fully coordinate their work with everyone. Therefore, an upgrade may result in down time to the LHC.

THE DEVELOPER'S VIEW

Let us examine the problem from the perspective of an experienced developer, who needs to modify a widely used library, which possibly requires changes in the signature of an API method.

Let us examine the steps this developer will follow. As a first step, he* will decide if he may modify the API method or not. He will try to understand if some other component uses that method, i.e., he will examine number and origin of *incoming dependencies*. There are three possible cases: there are no incoming dependencies, just a few of them, or many. In the first and the last cases, the situation is clear. If there are no incoming dependencies, then he can freely modify the method, because he has no backward compatibility constraints. If there are many incoming dependencies from many client components, then he cannot change the method signature; he must modify his library in some backward compatible way.

If there are just a few incoming dependencies from one or two client components, the developer can chose between two approaches: He can either accept backward compatibility constraints or he can break backward compatibility. The two solutions have opposite advantages and disadvantages. In the first case, staying backward compatible makes development more difficult but deployment easier. Backward compatibility constraints (keeping the old method signature) typically lead to sub-optimal solutions with more code to maintain. Also, the developer has to validate that the change is really backward compatible, which might be difficult. Deployment is easier because a backward compatible component can be deployed anywhere without breaking any dependent clients. Deployment can be done selectively, starting with those systems that really need the new functionality, and deferring upgrades of the other systems until the upgrade has been validated. There is no need for wide coordination or big-bang changes.

In the second case, advantages and disadvantages are inverted: breaking backward compatibility makes development easier but deployment more difficult. The developer has no backward compatibility constraints, and can choose the best solution, which generally leads to cleaner results and less maintenance. However, careful

* This article uses the masculine pronoun 'he' for brevity, but intends 'he or she'

coordination is needed with other developers responsible for dependent components. They must change their source code to adapt to the new API and re-build and re-test their components. And then, new versions of all components must be deployed at the same time. There are two issues with that: firstly, all this can be difficult to organize, and secondly, the other developers will be unhappy if they need to adapt, rebuild, re-test and re-deploy their client components too often.

The above description admits that our developer has a clearly defined API and that his clients respect this API. Reality though might be different. The developer may not have clearly specified which classes and methods belong to the API, and the clients may disregard the official API and use additional (non-API) classes contained elsewhere in the software component. As a consequence, with an insufficiently specified and enforced API, our developer has to take the precautions above for each and every public method he might want to change.

TOOLS TO SUPPORT SMOOTH UPGRADES

The description above illustrates that upgrading a widely used component is a challenging development task that must be supported by good tools. We have identified four areas for which we want to provide tools: (1) dependency analysis to identify incoming dependencies, (2) backward compatibility validation to verify that API changes are really backward compatible, (3) versioning with rules to clearly inform the dependent clients if a modification is backward compatible, and (4) API consolidation to clearly specify classes and methods belonging to the API and to enforce their appropriate usage.

The following subsections discuss each of these areas, by first presenting existing approaches and tools and then motivating and explaining own developments we did.

Tools to Analyze Incoming Dependencies

Our developer wants to know about incoming dependencies right from inside his IDE. For example, he wants to right-click on a given method and execute a command “show incoming dependencies”. As a result, he expects to get a list of client libraries that use the selected method, with the possibility to navigate to the client source code from where the selected method is invoked.

Most IDEs provide very similar functionality, namely to show the call hierarchy of a method within a given project. However, this functionally only reveals incoming dependencies from within the source code and components (Jar files) present in the IDE. It does not show incoming dependencies from external Jar files. Also, it does not take into account previous versions of components that are deployed in operations, but only shows dependencies between the latest snapshot of the source files.

There exist stand-alone tools capable of analyzing dependencies between a large set of Jars, such as Tattletale [4] and JDepend [5]. They produce a lot of useful information, but they analyze dependencies only at the class level, not at the method or field level as we need.

Therefore, we decided to develop our own tool which is based on a client-server architecture. The server creates a list of all the roughly 1000 Jar files running in production and analyses the byte code of all classes they contain using the Apache Commons Byte Code Engineering Library BCEL [6]. It collects information about method and field-level accesses from one Jar file to another. The dependency information is stored in a database, and made accessible to the client over a remote RMI call. The client is an Eclipse plug-in with the right-click-on-method functionality described above. The analysis is carried out every 20 minutes and takes roughly a minute to run.

Tools for Assessing Backward Compatibility

Our developer also needs tools which help him ensure that modifications he made are really backward compatible. Ideally, backward compatibility is verified early on, during development, warning the developer as soon as he breaks backward compatibility. We first concentrated on tools to assess *binary* backward compatibility for Java. After all, the goal is to deploy a new version of a component (a Jar file) without even recompiling the client code. The Java Language Specification [7] contains clear rules to guarantee binary backward compatibility.

The “PDE API tools” [8] contained in the Eclipse IDE provide exactly this functionality. They assess backward compatibility of a project in the IDE by comparing it with a previous version of the same project. Once this functionality is activated and properly configured, the IDE gives immediate feedback and warnings about backward compatibility violations to the developer. Although this looks like a perfect fit to our needs, there are two issues to overcome. Firstly, PDE API tools (and Eclipse as a whole) use OSGi [9] to declare the public API packages. So far, we do not use OSGi, and introducing OSGi into a software development process is a big decision, which should not be driven only by the needs of one tool. Secondly, a considerable amount of manual configuration is required to properly configure the PDE API tools. We would have to automate this because we cannot expect our developers to do it manually. Therefore, we will need to weigh the benefit of using this tool against the overhead just described.

Of course, comparing the API signatures of different versions is only the first step for checking backward compatibility. It can be considered as a sort of early-warning system for the developer while he modifies his code. To validate backward compatibility further, we rely on other means, such as function tests and our Continuous Integration server. We also validate the core elements of the control system in the Controls Testbed [2], which carries out function and integration tests. In the future, we might also explore more formal approaches to augment the API specification, such as Design by Contract [10].

Versioning Schemes and Related Tools

Once our developer has finished the modifications to his component, he has to increase the version number. All the Java components in the accelerator control system are versioned using a scheme with three numbers separated by dots (*x.y.z*), which are called *major*, *minor* and *micro* (*major.minor.micro*). Semantic versioning [11] assigns a meaning to each of these numbers: if the developer did a (backward compatible) bugfix, he increases the *micro* number, if he added functionality but the overall change is still backward compatible, he increases the *minor* number, and if he breaks backward compatibility, he increases the *major* number. If the developer uses semantic versioning, the clients can simply infer the impact of the change from the change in version number. A typical client will automatically accept new versions of a library if only the minor or micro numbers have changed.

We want to start using semantic versioning, and back it up with tools that automatically calculate the new version based on the changes made to the code. We have identified two tools providing such functionality: PDE API tools and a semantic versioning plug-in for Maven [12].

Tools to Specifying and Enforce APIs

To fully define a Java API, our developer must be able to specify the packages that contain API classes. In addition, he may add further constraints, e.g. to indicate that clients are allowed to use a given public interface (invoke its methods) but not to extend it.

Once an API is specified, it must be enforced, e.g. clients must be prevented from using non-API classes. Standard Java does not provide sufficient mechanisms for this purpose. Therefore, PDE-API tools use OSGi to specify and enforce access to API packages, and Javadoc tags to specify further API constraints. For example, the @noimplement tag indicates that an interface can be used but should not be implemented in client code.

A completely different approach is based on static crosscutting functionality provided by AspectJ [13]. The 'declare warning' construct of AspectJ makes it possible to issue warnings for illegal method access, e.g. a client accessing non-API methods. These checks are executed at compile-time, and simply require the AspectJ compiler and weaver to be executed as part of the build process.

APPLYING THE SAME CONCEPTS TO C++ CODE AND FESA DEVICES

So far, this document has only discussed Java software. The other languages we use are C and C++. We started with Java because this is the area where we need to achieve smooth upgrades first, and because Java provides many mechanisms and tools for what we want to do. Once we have a clear idea about our needs and feedback from developers, we intend to provide similar tools for C/C++.

But already now, we try to use backward compatibility concepts for the low-level software that integrates the hardware devices into the accelerator control system. As for Java, we need to provide guidelines and tools enabling the device developers to achieve smooth upgrades.

All our devices follow the device/property model, which means that a device class has properties (e.g. a Magnet has a Current property, or a Motor has a Position property). The public API of a device class is represented by the properties it exposes to its clients.

Device developers modify the public API from time to time, to make bug-fixes or to introduce new functionality. As for the Java libraries, these modifications can be backward compatible or not. For instance, adding a new property to a device class is a backward compatible modification, whereas renaming an existing property breaks backward compatibility.

Currently the versioning of FESA devices is slightly different from versioning Java software. FESA device classes do have a version, but the device developer is expected to increase it only if his modifications break backward compatibility. He can keep the version unchanged if his modifications are backward compatible. Whenever the version is increased, client code accessing the devices must be re-configured or even re-released to use the new version of the FESA class. If the version is unchanged, the modified FESA device just replaces the old one operationally as soon as it is deployed.

With the current FESA tools, the developer is only *expected* to increase the version when he breaks backward compatibility, but not *forced* to do so. This has occasionally lead to problems in the past. Developers have made non-backward compatible modifications to their FESA device/property API without increasing the version number. After the deployment of these devices, some important client applications stopped working because they relied on the old API, and LHC operations were affected.

We are now improving the development process and tools for FESA development based on the same concepts as described above for Java software development. The following paragraphs shall explain this in more detail.

A FESA developer, who needs to make a modification to his device, carries out the same steps as the Java developer discussed earlier. He first analyzes the incoming dependencies to the device property he might want to change. He then decides whether to stay backward compatible or not. In case he remains backward compatible, he needs tools to validate backward compatibility, and so on.

Regarding the tools, we are developing means to assess incoming dependencies to the device properties of FESA classes. This work is largely based on the Controls Configuration Database (CCDB) [14], which contains the configuration data for all device classes, their properties and devices. It also contains configuration of the most important client applications that use the FESA devices, such as LSA and InCA [15]. Thus, the accelerators controls system is to a large extent data-driven and the

challenge is to ensure that a coherent set of configuration data is used throughout the controls system. To achieve that, we have established a strategy with several steps. First of all we need to clearly specify the visibility of the configuration data. Previously all data – data necessary for the operation of the accelerators and data used by equipment experts for low-level device control – was exposed to everyone through public APIs. Now the approach has changed and the data for the FESA classes is divided into a public API used for operations and a private API used only by equipment experts. Another important aspect is that the CCDB needs to have feedback of who uses what from the public API, in order to ensure that only backward compatible changes are made. This feedback allows us to find out which device properties are used in operations, i.e., determine the *incoming dependencies* for a given device property.

However, not all clients of FESA devices propagate feedback to the CCDB regarding the device properties they use. We have important systems that use configuration files or other means to specify the device and properties they need, e.g. the Software Interlock System [16] or the Post Mortem Analysis system [17]. We are currently examining methods to dynamically harvest information about device property usage for all Java client applications. For this purpose, we have instrumented the JAPC communication library [18], which is used for nearly all device access from Java. JAPC dynamically tracks the device properties that were accessed and periodically uploads this information to the CCDB.

Validation of backward compatibility during development is done by the newest FESA development tools, which compare the previous version of the public device/property API of a FESA class with the one under development. If the FESA tool detects a change that is not backward compatible, it forces the developer to increase the version number according to the semantic versioning rules. This should prevent the problems described earlier in this section.

Finally - unlike Java - FESA does not need additional tools to specify and enforce the public APIs, because this is already covered very well by the existing FESA tools.

CONCLUSIONS

We need to upgrade the LHC controls system without causing any unnecessary down time. Backward compatible changes are a means of achieving this. The same concepts of backward compatibility apply to Java software and to FESA devices. In both cases, making backward compatible changes is challenging, and developers need to be supported by good tools. We have identified some promising approaches and tools, and we know how we want to apply them. We are evaluating the different alternatives and have started implementing our own tools where third party solutions are missing or insufficient. This is a non-negligible investment, but we are convinced that it will pay off, by making our work easier and the LHC operations more reliable.

SOFTWARE TOOLS FOR ELECTRICAL QUALITY ASSURANCE IN THE LHC

Mateusz Bednarek, CERN, Geneva, Switzerland,
Jaromir Ludwin, IFJ-PAN, Kraków, Poland

Abstract

There are over 1600 superconducting magnet circuits in the LHC machine. Many of them consist of a large number of components electrically connected in series. This enhances the sensitivity of the whole circuits to electrical faults of individual components. Furthermore, circuits are equipped with a large number of instrumentation wires, which are exposed to accidental damage or swapping. In order to ensure safe operation, an Electrical Quality Assurance (ELQA) campaign is needed after each thermal cycle. Due to the complexity of the circuits, as well as their distant geographical distribution (tunnel of 27km circumference divided in 8 sectors), suitable software and hardware platforms had to be developed. The software combines an Oracle database, LabView data acquisition applications and PHP-based web follow-up tools. This paper describes the software used for the ELQA of the LHC.

INTRODUCTION

A great diversity of circuits and configurations met in the LHC machine forces the use of several software technologies within one application.

This quality assurance system was developed in parallel with the machine assembly. It was expected to verify the correctness of many parameters that have never been measured before and thus be able to quickly adapt to the new circumstances. Therefore, the set of measurements and the acceptance criteria were expected to change as the installation and development works were progressing.

A flexible software platform had to flawlessly drive the dedicated hardware [1], stay in accordance with the machine layout and safely store the measured values, while allowing a central management of the full software structure.

TEST FAMILIES

The applications have been divided into three families: TP4 (Test Procedure 4) for superconducting circuits powered via the DFBs (Distribution Feed Boxes), DOC (Dipole Orbit Corrector) for locally powered superconducting orbit correctors and MIC (Magnet Instrumentation Check) for local magnet voltage pickups and quench heaters. Hardware setup for each type of tests has been described in [1].

DATABASE

A database system constitutes a core of each application. It is used in order to read application settings and store measured values. As there is no access to the network at the measurement positions each system is working on a local database (MS Access). After coming back to the surface infrastructure it synchronises its local database with the centrally hosted Oracle storage: the measured values are copied in the Oracle structure; all the settings used for the tests in the tunnel as well as the most recent layout of the machine are copied from the Oracle to the local database.

Communication between LabVIEW applications and databases is done using ODBC technology.

Some tables located in the central database have no correspondence in local MS Access files. Those tables are used by web applications. Central database includes also a number of synonyms which are pointing to views in LHC Layout database. Such synonyms are used as reference data sources for all our applications. Currently central database consists of over 80 tables.

DATA ACQUISITION

The hardware part of the measurement system as well as the user interface for the test benches are driven by a set of LabVIEW applications. Families of aforementioned applications are further divided into separate sub programs for specific types of tests like high voltage insulation tests, AC transfer function measurements, or DC ohmic parameters measurements. Typical window of measurement sub program is presented on Figure 1.

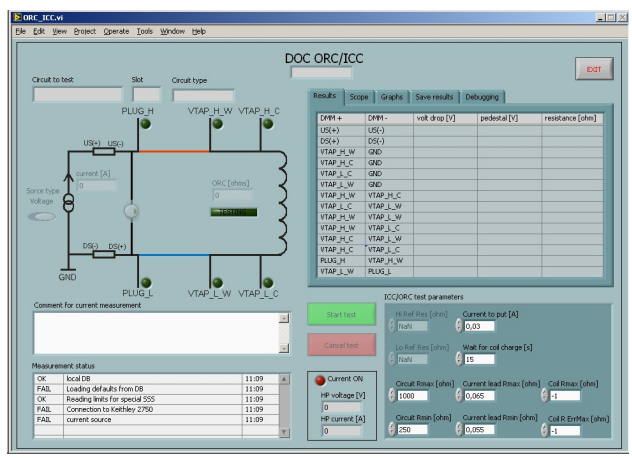

Figure 1: DOC Instrumentation Continuity Check application window.

Each data acquisition application is launched via special panels that help the user to identify the tested circuit and perform proper connections. Figure 2 presents a window of one of such panels.

Panels are designed in a way which makes skipping of the measurement by mistake impossible. Test object lists are ordered by the physical position in the LHC tunnel.

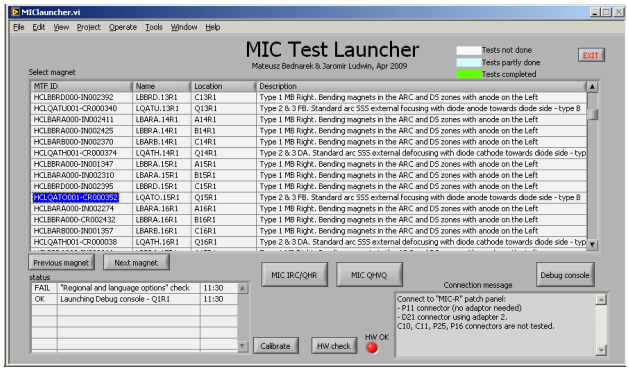

Figure 2: MIC Test Launcher, with list of available magnets to be tested and information about hardware connections that are required to perform tests on a selected magnet.

SYSTEMS' FLEXIBILITY

There were several issues that had to be kept in mind when developing the test applications for the TP4 family:

- There exist many types of circuits with different kinds of diagnostic connectors and various types and numbers of current leads.
- At the development's starting point it was not clear which signals should be measured and which precision was needed.
- A very flexible way of validating the results was needed as the acceptance criteria had to be adjusted together with the measurement campaign progress and more statistics becoming available.

Taking into account those requirements it was decided to create an application which makes use of independently prepared test scripts and validation scripts. The idea of test scripts is presented on Figure 3.

The scripts are stored in the central database. A dedicated tool can be used by a manager in order to create and store a correct script. The script is then copied to the local database of each test bench as soon as their network connection is established.

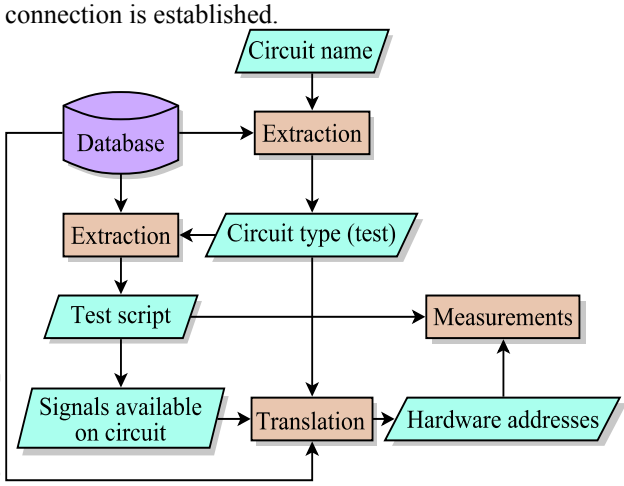

Figure 3: Signal translation in low voltage test applications.

The application determines the type of a given circuit based on the circuit's name and lookup table and extracts the proper test script. Then based on the type, it translates the signal names available on the circuit into the hardware addresses of the measurement system. This translation is used when parsing the test script. Like this no specific information is hard-coded in the source code. Adding tests, measurements and introducing new connector pin-outs is as easy as adding new records in the database.

A similar idea was applied to the verification criteria of recorded values. The great complexity of the cabling requires taking different criteria for each circuit type. As already mentioned the acceptance thresholds were often modified in order to follow the best, growing knowledge about the qualified circuits. Furthermore checking the correctness of electrical connections in the circuit often requires evaluating several mathematical formulas. Therefore the application responsible for the validation process is equipped with a mathematical formula parser.

Figure 4 shows dataflow used during the measurement results verification.

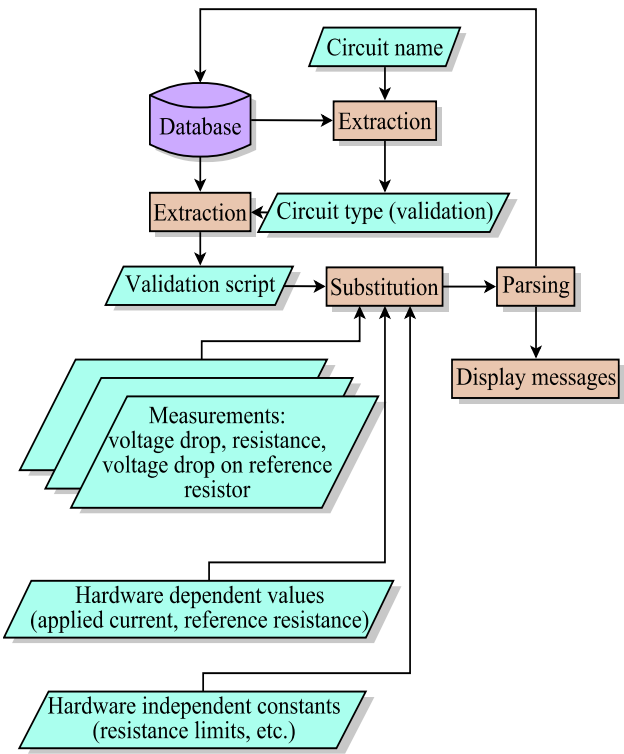

Figure 4: Measurement results validation process.

The most important data stored in the validation script are: left and right value saved in a form of mathematical expression containing test specific variables, comparison operator between left and right value, short information about the circuit property that is being checked and a message to be displayed in case the comparison of left and right values has failed.

TESTS FOLLOW UP AND REPORTING

Each application family has its own set of web pages used to check the current status of tests, analyse results and modify or add nonconformities data. Example of TP4 follow-up page is shown on Figure 5.

Tools	DFB	Circuit	IRC	ICC	TFM	TFM vs GND	HVQ	Flag	Comments
	DFBAD.7R2	RB.A23	OK	OK	OK	OK	OK (2)		**Tests after nQPS cables refurbishment in sector 2-3** 18/01/10: Old QPS HV test in C21R2: 1900V, 2min, 411 GOhm/ 4.72 nA, and C18L3: 1900V, 2min, 205 GOhm/ 9.46 nA. Test successfully repeated after repair, on the 20/01/10.

Figure 5: TP4 Follow-up page.

Access to the web pages is controlled via CERN's authentication system. After authorisation the web application is checking user permissions. A certain group of users is allowed to add or change data. All the others are only allowed to view. Any data change made via the web page is logged.

In case of tests where the result is represented as a set of multiple values, the user can export the data in a Comma Separated Values format by clicking the proper link on the test results page. For some measurements, where many identical objects are tested (e.g. quench heaters) web based statistical analysis tools were created.

In addition, a set of LabVIEW report generating programs was created, which can be used to prepare well formatted MS Word documents containing a complete history of the selected circuit within the selected LHC commissioning campaign. Such a document can be then printed and used during an intervention on site.

OTHER TASKS

Having many LabVIEW applications installed on many computers combined with the fact that most of the applications are under constant development it was necessary to create a tool that would help to deploy the new software versions.

The package manager is an application used for installation and update of the ELQA software. It is a batch script that can be started on any MS Windows machine. The script uploads test data to the central database, creates a back-up of the currently installed software, installs the most recent released version and downloads the most recent test parameters. Most of those operations are performed by calling old or freshly downloaded LabVIEW applications with proper command line parameters.

The log of the operation is available for the administrators so that all the errors can be easily tracked.

CONCLUSIONS

The very difficult and complex task of performing the electrical quality assurance of a big prototype machine such as the LHC was successfully accomplished thanks to the described software tool-chain.

The applications are based on a centrally managed database system that automatically propagates the machine layout changes, safely stores the measured data and allows a follow-up in order to avoid accidental omitting of some tests.

The three application families described in this paper are utilising over 500 LabVIEW Virtual Instruments created for the LHC electrical circuits' tests.

FURTHER WORK

Currently the hardware part of the measurement system is being upgraded in view of the upcoming long shut-down in the LHC. As new functionalities and improvements will be added, the software upgrade will follow.

In the future it is planned to add more web based statistical analysis tools. Another planned web application type are tools for easy tracking of circuit parameters change over whole time of LHC operation.

ACKNOWLEDGEMENTS

The authors would like to thank their supervisors for the great opportunity of taking part in the commissioning of the LHC. Also they would like to express their gratitude to the colleagues that supported the development of the system with clever hardware solutions without which the software would not exist. A great number of collaborators from CERN and IFJ-PAN have taken part in the measurements in the LHC tunnel and acted as testers providing the developers with precious comments and hints.

THE TIMING MASTER FOR THE FAIR ACCELERATOR FACILITY

R.C. Bär, T. Fleck, M. Kreider, S. Mauro
GSI Helmholtz Centre for Heavy Ion Research, Darmstadt, Germany

Abstract

One central design feature of the FAIR accelerator complex is a high level of parallel beam operation, imposing ambitious demands on the timing and management of accelerator cycles. Several linear accelerators, synchrotrons, storage rings and beam lines have to be controlled and reconfigured for each beam production chain on a pulse-to-pulse basis, with cycle lengths ranging from 20 ms to several hours. This implies initialization, synchronization of equipment on the time scale down to the ns level, interdependencies, multiple paths and contingency actions like emergency beam dump scenarios.

The FAIR timing system will be based on White Rabbit [1] network technology, implementing a central Timing Master (TM) unit to orchestrate all machines. The TM is subdivided into separate functional blocks: the Clock Master, which deals with time and clock sources and their distribution over WR, the Management Master, which administrates all WR timing receivers, and the Data Master, which schedules and coordinates machine instructions and broadcasts them over the WR network.

The TM triggers equipment actions based on the transmitted execution time. Since latencies in the low µs range are required, this paper investigates the possibilities of parallelisation in programmable hardware and discusses the benefits to either a distributed or monolithic timing master architecture. The proposed FPGA based TM will meet said timing requirements while providing fast reaction to interlocks and internal events and offers parallel processing of multiple signals and state machines.

FUNCTIONAL BLOCKS

Clock Master

The Clock Master is the topmost White Rabbit timing node in the system. It is the time and clock reference for all connected nodes [1] and is itself connected to a UTC source (GPS) and FAIRs RF clock system, BuTiS. It propagates absolute time and its clock down the layers of the timing network by means of a modified Precision Time Protocol (PTP) and synchronous GigaBit Ethernet.

Management Master

In the Management Master, all administrative tasks of the timing network are concentrated. There are multiple services running in this unit, allowing it to carry out the following functions:

- Dynamic Host Configuration Protocol (DHCP) Server
- Rapid Spanning Tree Protocol (RSTP) Root
- Simple Network Management Protocol (SNMP) Master

A standard DHCP server process is used to assign IP addresses to all nodes present in the timing network.

The SNMP Master is used to poll network switches for information about their current status in order to obtain a global status image of the timing network. It can also be used by administrators to configure said switches.

Since the FAIR Timing Master will broadcast command messages, the RSTP protocol is used to make the routing information for the timing network loop free. This is necessary because a loop in the routing tables would immediately lead to an infinite generation of network traffic.

Data Master

The Data Master for the FAIR accelerator deals with various different tasks. It possesses a high end CPU running an OS for easy interfacing to the control system, compatibility to FAIRs standard libraries and raw processing power as well as a Field Programmable Gate Array (FPGA) for parallelism, deterministic behavior and ultra low IO latency.

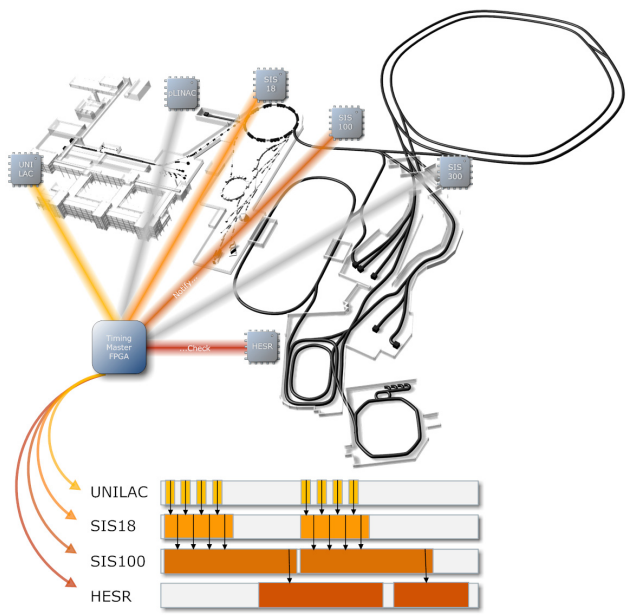

Figure 1: Sequences in a production chain [2].

The Data Master itself subdivided into three parts:

CPU/API Block Its CPU is fed by the LHC Software Architecture (LSA) with machine parameters derived from

physical requirements for beam production chains. These parameters are converted into sequence programs (Fig. 1), compiled and uploaded to the FPGA of the Data master.

FPGA/SoftCPU Cluster These programs are run in parallel on SoftCPU macros residing in the FPGA. They deal with sending out machine events paired with an execution time to WR nodes, reacting to interlocks and mutual synchronisation. At the moment, 32 of these Soft CPUs are foreseen in the Data Master, able to carry out 32 tasks full parallel with IO service times of less than 50ns.

FPGA/Event Concentrator An event concentrator macro in the data master will act as a bridge to the WR network. Its primary functions are aggregation of events into Ethernet Frames and to schedule transmission of these event messages over the timing network so they arrive on time at the respective nodes.

DESIGN CONSIDERATIONS

Why not just a High End CPU?

Modern multi-core CPUs are unsuitable because they cannot they be made deterministic enough for our purpose. This is not inherent in their design but stems from the fact that they need a full blown OS to use most of their features, not to mention RAM management. They also have comparatively slow IO handling. Even with high clock rates and vast amount of processing power at their disposal, their Interrupt Service Request (ISR) times are in the low millisecond range plus additional penalties from IO resource arbitration. While there are approaches which enforce a task based scheduling to introduce determinism, they still suffer heavily from the IO bottleneck of the carrier board.

High end multicore CPU

+ Performance clock for clock
+ Clock rates
– Determinism with (needed) OS
  – multithread scheduler
  – indirect memory management
  – garbage collection
– ISR times range in milliseconds
– IO Bottleneck

➠ Not suitable

Why no Embedded CPU with a Real Time Operating System?

While being considerably faster and more deterministic at IO and interrupt service times than high end CPUs, the ISR of embedded CPUs with real-time OSs still jitter in the microsecond range and show considerable lag under load, as shown in Figure 1.

Table 1: RTOS Latency Measurement Results [3].

	Interrupt Latency (µs)		**Context Switching** (µs)	
	max	**avg ±**	**max**	**avg ±**
Idle System				
RTL	13.5	(1.7 ± 0.2)	33.1	(8.7 ± 0.5)
RTEMS1	14.9	(1.3 ± 0.1)	16.9	(2.3 ± 0.1)
RTEMS	15.1	(1.3 ± 0.1)	16.4	(2.2 ± 0.1)
vxWorks	13.1	(2.0 ± 0.2)	19.0	(3.1 ± 0.3)
Loaded System				
RTL	196.8	(2.1 ± 3.3)	193.9	(11.2 ± 4.5)
RTEMS1	19.2	(2.4 ± 1.7)	213.0	(10.4 ± 12.7)
RTEMS	20.5	(2.9 ± 1.8)	51.3	(3.7 ± 2.0)
vxWorks	25.2	(2.9 ± 1.5)	38.8	(9.5 ± 3.2)

Embedded CPU with Real time OS

+ Fast IO
+ More deterministic
– ISR jitter
– lag peaks under load
– scalability

➠ Not suitable

A multi MCU approach to decreases IOs per MCU to be serviced and processor load would suffer from poor possibilities for process synchronisation between MCUs and lag from resource arbitration.

Why not Pure HDL on FPGAs?

Programmable hardware was the next option to investigate. While being extremely fast and the only system group capable of massive parallel processing, there are also disadvantages to consider. The main problem with HDL modules is a distinct lack of flexibility, since all sequential behavior needs to implemented as state machines. Those can only change their state in reaction to a set of external signals and their own state. This would severely increase the effort for conversion of LSA output and also mean that on the fly changes of functionality are out of the question. However, there is another option when using HDL macros.

Pure HDL circuits

+ completely deterministic
+ ultra low IO latency
– interfacing
– flexibility
– versatility
– design effort for all scenarios

➠ Not suitable

Why SoftCPUs?

SoftCPUs, little blocks of Hardware Description Language (HDL) code resembling embedded CPUs. They can offer almost all of the convenience and flexibility of a real embedded CPU, while also being closely connected to other FPGA circuits with extremely low latency. If there is no necessity for a MMU or the intention to use standard libraries, this is the best compromise between flexibility and ultra low latency design. Multiple instances with their own dedicated memory can speed up the design even more.

SoftCPU Cluster

+ completely deterministic
+ ultra low IO latency
+ interfacing
+ flexibility
+ versatility

➠ Best candidate

ARCHITECTURE

Choice of SoftCPUs

In the course of our work, many SoftCPUs have been evaluated [4]. We decided against closed source variants to keep the possibility of extending the macro with custom instructions. There is about a dozen open source SoftCPUs available today. The main criteria were speed, footprint, availability of toolchains and community/developer support. Our choice was the Lattice Micro32, a 32 Bit RISC processor macro running at about 150 MHz. While being a complete RISC processor with instruction and data caches and an interrupt handler, it has a low FPGA footprint of about 2000 logic cells. Toolchains are available, including a GNU cross compiler for Ansi C. We have also added support for the GNU debugger via JTAG interface. An average modern PFGA can offer around 250000 LUTs, four times more than enough to instantiate a SoftCPU cluster with 32 modules. Internal FPGA memory is much more likely to be the limiting factor, though. High end FPGAs contain >2 MB of internal memory. Assuming 2.5 MB, each of the SoftCPUs would get around 80kB of memory. This is more than sufficient for caches and program execution. The GNU debugger claimed about 1 kB of memory on our LM32 testbed.

Using Multiple SoftCPUs

With a One-SoftCPU-per-task policy, their IO handlers can be blocking and are not forced to use interrupts, eliminating time consuming context changes. Each SoftCPU has its own little memory controller, which completely eliminates resource arbitration lag. For fastest synchronisation of their programs, an $n * n$ sync matrix will also be implemented.

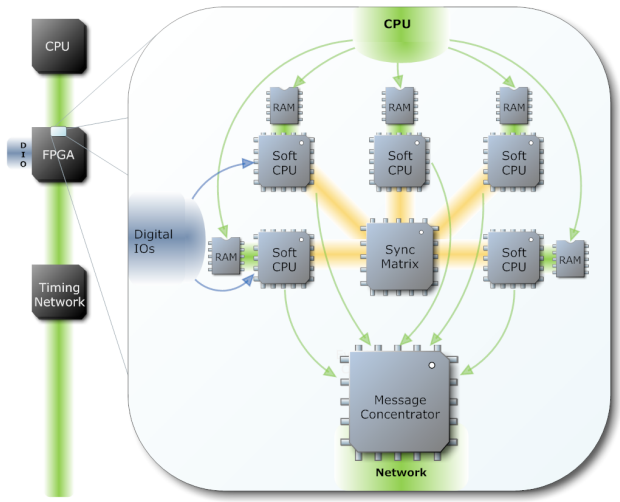

Figure 2: FPGA based SoftCPU Cluster [2].

CONCLUSION

After evaluation of timing requirements [2] and CPU, MCU and FPGA system properties, it showed that a mixed CPU/SoftCPU approach for the Data Master would be the best choice for FAIR. It is a very fast, flexible, scalable, easily extendable and future proof solution.

OUTLOOK

In the course of 2012, the design will be subjected to a real world test scenario. A first prototype of the FAIR Timing Master will be used in the testing and commissioning of the first machine module to be deployed for FAIR, the antiproton linear accelerator. Productive systems are planned to be put into service at GSI/FAIR in 2016.

TIMING SYSTEM OF THE TAIWAN PHOTON SOURCE

C.Y. Wu, Jenny Chen, Y.S. Cheng, P.C. Chiu, Demi Lee, C.Y. Liao, K.B. Liu, K.T. Hsu, K.H. Hu, C.H. Kuo,
NSRRC, Hsinchu 30076, Taiwan

Abstract

The timing system of the Taiwan Photon Source provides synchronization for electron gun, modulators of linac, pulse magnet power supplies, booster power supply ramp trigger, bucket addressing of storage ring, diagnostic equipments, beamline gating signal for top-up injection and the time-resolved experiments. The system is based on event distribution system that broadcasts the timing events over optic fiber network, and decodes and processes them at the timing event receivers. The system supports uplink functionality which will be used for the fast interlock system to distribute signals like beam dump and post-mortem trigger with less than 10 μsec response time. The hardware of event system is based on 6U CompactPCI (cPCI) form factor and available in 2011. Implementation of the software is preceding. Timing solutions for the TPS project will be summarized in the following paragraphs.

INTRODUCTION

The TPS is the latest generation synchrotron light source. Event based timing system is applied for TPS due to its high performance and flexibility which has been already verified in many advanced light sources [1]. The EVG/EVR modules for TPS project are available in December of 2010. Efforts to setup the test system were done in the first quarter of 2011. The prototype system had already applied for the TPS 150 MeV linear accelerator commissioning and acceptance during the second quarter of 2011 with highly success. Developing various software support for event system in on going. Preliminary testing of TPS timing system is on going [2]. All development will be finished before the installation of the whole event system which is scheduled in 2013.

INFRASTURCTURE

The TPS timing system is an event based system. A central event generator (EVG) generates events from an internal sequencer and external sources [3]. These events are distributed over optic fiber links to multiple event receivers (EVRs) [4]. The EVRs, which are located in the control system interface layer, decode the events referred to as hardware triggers or software interrupts. For the linac, the decoded events are further encoded by a gun transmitter and sent over a fiber link to the gun high voltage platform. The external event sources include PPS signal which is locked to GPS, AC mains 60 Hz trigger, post-mortem trigger after beam loss and machine protection system trip. The event clock is derived from the 499.654 MHz master oscillator so that it is locked to change in the RF frequency. Fig. 1 shows an overview of complete TPS timing system and interconnections between its basic components. The master oscillator can be used as an external reference from a GPS disciplined Rubidium 10 MHz clock. Fig. 2 shows TPS timing modules include EVG, EVR, EVRTG and linac gun trigger receiver. The major part of the event system is realized as a 6 U cPCI form factor to compliant control hardware standard for accelerator controls at Phase I.

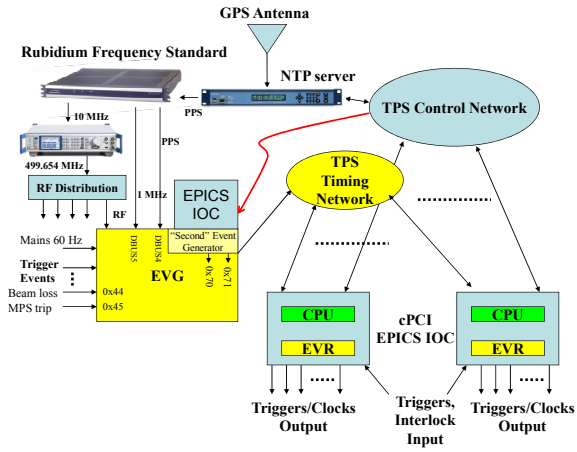

Figure 1: Block diagram of the TPS event system.

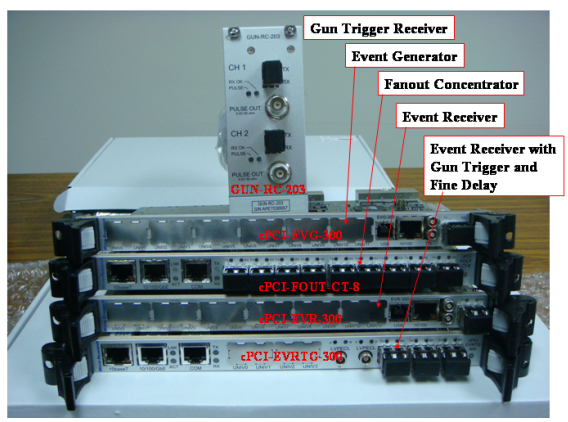

Figure 2: TPS timing modules.

Event Generator

The cPCI-EVG-300 generates event frames consisting of an 8-bit event code and an 8-bit distributed data bus, at a rate of 125 MEvents/sec. Events can originate from external trigger events, sequence RAM, software events and events received from an upstream event generator. Events from different sources have different priorities which are resolved in a priority encoder. A block of RAM is used to store a sequence of events. In cPCI-EVG-300 the input RF clock (499.654 MHz) is divided by 4 to

generate the event clock for the TPS timing system. Therefore, the resolution of timing event is 8 ns.

Event Receiver

The cPCI-EVR-300 and the cPCI-EVRTG-300 are the current available versions of 6U cPCI EVR. The cPCI-EVR-300 recovers the event stream and splits the event frame into the 8-bit event code and the 8-bit distributed data bus. The decoded events are mapped through RAM on to: trigger twelve pulse generators with programmable delay and width (32-bit prescaler from the event clock, 32-bit delay and 32-bit width) or set/reset twelve pulse generators. This EVR provides 3 programmable 16 bit prescaler from the event clock. Six UNIV I/O slots provide twelve front panel outputs can be mapped to any output such as each pulse generator output, prescaler and distributed bus bit. The cPCI-EVRTG-300 has eight channels; it includes two UNIV I/O slots support up to four various output and input, two LVPECL outputs and two SFP outputs. It is embedded jitter cleaner to deliver low jitter functionality of the EVR.

E-Gun Driver

The cPCI-EVRTG-300 has two SFP ports that can generate modulated optical signals that can be decoded by the GUN-RC-203 for linac gun driver trigger. The two SFP ports share an external inhibit signal. The GUN-RC-203 consists of two channels to provide single-bunch and multi-bunch injection respectively. It is realized as a cPCI-EVRTG-300 in the linac timing crate and a GUN-RC-203 placed on the gun HV platform. The fine programmable delay is also available and allowed to adjust the triggering position with a resolution of 10 ps over a range of 10 ns. The GUN-TX-203 mode has been designed to operate output pulse delayed by 1/4, 2/4 and 3/4 event clock period (~2, 4, 6 ns). The new module GUN-RC-300 will support arbitrary pattern generation functionality.

TIMING DISTRIBUTION

The distribution of the event stream will be a fiber optics with tree structure combined with single mode fiber (SMF) as well as multi-mode fiber (MMF) from cost points of view. The long distance link from the timing master to equipments area (Control Instruments Area, CIA, total 24 CIAs around the TPS storage ring and booster synchrotron) will be by SMF, while in CIA to EVR module will be OM3 MMF. Based upon experiences of several running light source, there will several tens of picoseconds drift in the year around due to ambient temperature change of the fiber distribution route. Several tens of picoseconds long-term drift might not cause a problem for most of applications. Drift compensation scheme by sensing fiber which lay around the facility was proposed to measure the long-term drift and make compensation globally. However, this might a correct that the timing fiber link route different path, which might have different environment, the global compensation cannot eliminate the drift for all links. Compensation for each link is standard approach for the RF reference distribution but not for event system yet. To deal with some timing station which need small time drift, the fiber link can replace the phase stabilized optical fiber (PSOF), and PSOF has a propagation delay temperature coefficient roughly 15 times better than standard optical fibers. The scheme of the fiber cabling is still in planning phase. The fiber cabling scheme will be decided in 2012.

TIMESTAMP

The Event System provides a global timebase to attach timestamps to collected data and performed actions. The time stamping system consists of a 32-bit timestamp event counter and a 32-bit second counter.

The timestamp clock and timestamp reset clock are assumed to be raising edge aligned. In the EVG the timestamp reset clock is sampled with the falling edge of the timestamp clock. In the EVR the reset is synchronized with the timestamp clock.

The two seconds counter events are used to shift in a 32-bit second value between every timestamp reset events. In the EVR the value of the seconds shift register is transferred to the seconds counter at the same time the higher running part of the timestamp counter is reset.

The distributed bus event inputs of EVG can transmit timestamp clock and timestamp reset clock independently through the distributed bus event enable register.

EVG will automatically increment and send out two seconds counter events. Using this feature requires the two externally clocks, and the events 0x70 and 0x71 get generated automatically. The timestamp generation of EVG is shown in Fig. 3.

After the rising edge of 1 PPS on DBUS4, the internal seconds counter is incremented and the 32 bit binary value is sent out LSB first as 32 events 0x70 and 0x71. Host CPU can acquire UTC second from NTP server and set second register, load to second counter and enable timestamp generator by on-demand (system boot, cold start).

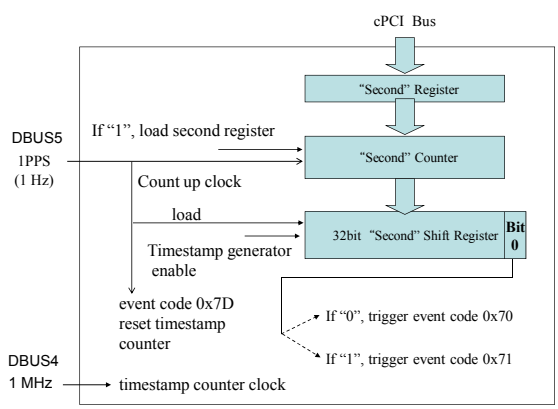

Figure 3: Timestamp generation at EVG.

The timestamp event counter either counts received timestamp counter clock events or runs freely with a clock derived from the event clock. The event counter is

also able to run on a clock provided on a distributed bus bit. The timestamp event counter is cleared at the next event counter rising clock edge after receiving a timestamp counter reset event. The seconds counter is updated serially by loading zeros and ones into a shift register MSB first. The seconds register is updated from the shift register at the same time the timestamp event counter is reset. Fig. 4 shows block diagram of timestamp logic at EVR.

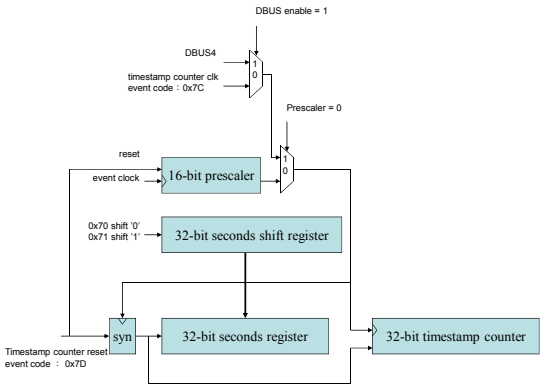

Figure 4: Timestamp logic at EVR.

TIMING SYSTEM DIAGNOSTICS

In normal operation, the rising edges of booster clock, storage ring clock and coincide clock should be lock. Machine clocks are monitored using an oscilloscope. EPICS support for the oscilloscope is prepared. Simple pattern analysis software (Matlab scripts) will analyze the relationship of clocks. If clocks out of lock, it will alarm and stop the system. A time to digital converter (TDC) measure timing difference amount clocks is another auxiliary supports. The wiring schematic is given in Fig. 5. The TDC module will analyze the positions of the clock edges and measures the mismatch. The oscilloscope will display machine clocks waveform for operation. If the machine clock mismatch exceeds 10 ns, then a SYN-FAIL signal will be sent to the machine protection system and notify operators.

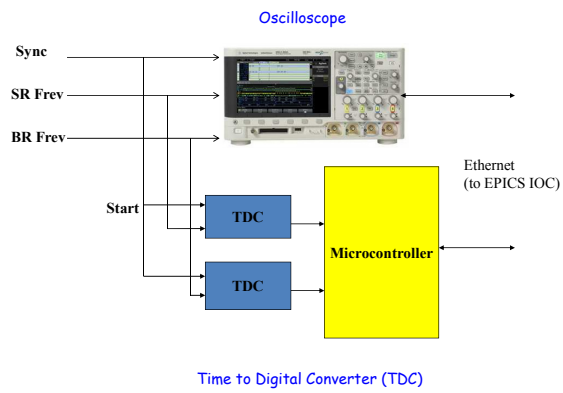

Figure 5: Timing system healthy monitoring.

Based upon the reports of several light sources, there are several tens of psec drift around the year. This is acceptable for most of the accelerators timing and users timing requirement. However, to measure the timing drift of specific links, several approaches can be used.

1. Measure the RF clock versus machine clock edge at EVR site. It needs a stable RF reference available at site.
2. Measured an environment sense fiber around the ring back to the timing master. The difficult is that each link might expose different route on the cable tray. There are some local heating sources on the tray due to the nearby power cables.

TIMING INTERFACE FOR BEAMLINE

The timing interface was developed to provide hardware signals for synchronization of beamline equipment with the electron bunch structure in the storage ring and with the process of Top-up operation. Signals at each experiment station include RF clock, machine clock, top-up injection gating. Top-up gating signals include long gate over whole top up injection cycle and short gate over top up for single injection cycle and few unassigned channels that can be configured to user requirements. For the beamline need high precision timing to synchronize their laser system or data acquisition system, sub-ps RF link will be available.

CONFIGURATION TOOLS

The timing system is integrated into the TPS EPICS control environment. The EVG configuration pages define the options of cPCI-EVG-300. These include configuration of the EVG operating mode, selection of RF and AC divider, definition of multiplexed counter, optional transmission of software events, enable of event trigger inputs and specify event code and timestamp into the sequence RAMs. The EVR configuration pages configure the options for the cPCI-EVR-300, such as pulse delay, width and polarity, front panel output assignments and distributed bus enable and event decoding mapping RAMs. Applications to control the timing system are built with the usual EPICS tools for databases and EDM for user interface.

DOWNLINK AND UPLINK FUNCTIONALITY

The event system not only distributes events to EVRs but also deliver event uplink functionality by the help of the fanout concentrator.

Measurement of the global response time for the TPS timing systems uplink and downlink is presented in Fig. 6 for two stage fanout concentrator and 310 m single mode fiber. This event code 0x45 is used for indication of MPS-TRIP event. The event is stimulated by an external trigger produced by an EVR2. According to the oscilloscope pattern the EVR2 transmitted event by MPS-TRIP trigger and EVR1 decoded event pulse are shifted with respect to each other by 2.45 μs. The global response time is 4.42 μs which consists of EVG, EVR1, EVR2, three fan-out

concentrators processing times and propagation delay time along timing system fiber network (Fig. 6).

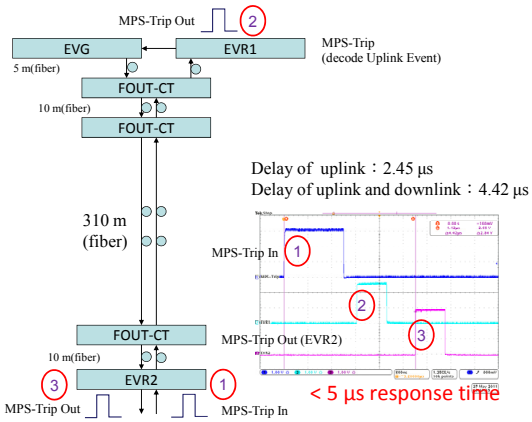

Figure 6: Timing measurement of uplink and downlink with 310 m fiber and three stages of fan-out concentrator.

INJECTION SEQUENCE CONTROL

To accommodate various operation and injection scenarios of the TPS storage ring and booster synchrotron, sequence control plays a crucial role. The sequence is stored at sequence RAM of the EVG module. Adopting Matlab scripting for the sequence control of the TPS accelerator is considered seriously due to expertise of available manpower and high productivities compare to another tools. The timing sequence control is also considered to use Matlab scripts embedded in the timing master EPICS IOC which host the event generator module. Since the TPS machine repetitive rate is 3 Hz, the booster power supply ramping waveform is 3 Hz sinusoidal wave and T-ZERO defined at 0 msec. The storage ring extraction time is T-ZERO+166.66 msec. There are sufficient time for sequence RAM management (start/stop, replace contents of sequence RAM locations …etc.). The scripts will access (read and set) the EVG related EPICS PVs by LabCA. So, the sequence control OPI can set parameters related to the sequence and execute by the sequence control scripts running in the timing master EPICS IOC.

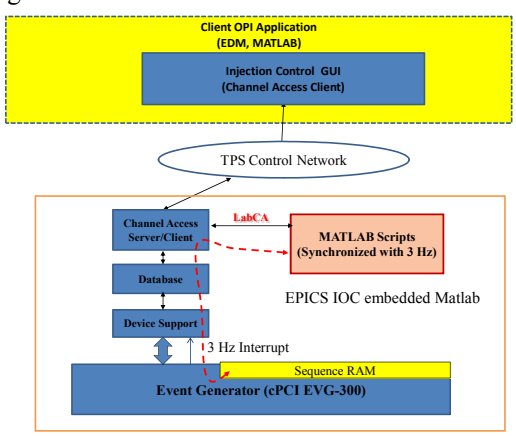

Figure 7: Block diagram of proposed timing sequence control.

The Matlab scripts for injection sequence control detect sequence RAM interrupt, check injection conditions or operation modes and replaces sequence RAM contents. The Block diagram of timing sequence control is represented in Fig. 7. All parameters for the machine operation modes and parameters will be designed as specific EPICS PV, such as bucket address, repeat cycle, top-up injection, decay mode and etc. Preliminary operation modes supported includes:

a. E-gun pulser: multi-bunch and single bunch.
b. Multi-bunch width adjust.
c. Booster magnet cycle before beam trigger.

k. Linac operation only.
l. Auto stop injection when safety interlock actuated, stored current exceeds target value.
m. …etc.

SUMMARY

The event system for the TPS project is being implementation stage. The prototype has been deployed in early 2011 for linac acceptance test. Configuration tools have been developed and revised continually. Preliminary sequence control is in proceeding. Timestamp function of event system will be tested.

ACKNOWLEDGEMENT

The authors thank help from many experts on the timing system especially Yuri Chernousko of the DLS, Kazuo Furukawa of the KEK, Timo Korhonen of the PSI/SLS, and Jukka Pietarinen of the MRF.

NSLS-II BOOSTER TIMING SYSTEM

P. Cheblakov, S. Karnaev, BINP, Novosibirsk, Russia
Joe De Long, BNL, Upton, NY 11973, USA

Abstract

NSLS-II light source includes the main storage ring with beam lines and injection part consisting of 200 MeV linac, a full-energy 3 GeV booster synchrotron and two transport lines.

The booster timing system is a part of NSLS-II timing system which uses hardware from MicroResearch Finland: Event Generator (EVG) [1] and Event Receivers (EVRs) [2,3]. The booster timing is based on the events coming from NSLS-II EVG: "Pre-Injection", "Injection", "Pre-Extraction", "Extraction". These events are referenced to the selected RF bucket of the storage ring and correspond to the first RF bucket of the booster.

EVRs provide triggers both for the injection and the extraction pulse devices. EVRs also provide the timing of booster cycle operation and generation of events for cycle-to-cycle updates of pulsed and ramping parameters, and synchronization of the booster beam instrumentation devices.

This paper describes the final design of the booster timing system. The timing system functional diagrams and block diagram are presented.

INTRODUCTION

The NSLS-II timing system is based on solutions and experience of the Diamond Light Source timing system [4,5] and uses events coming through fiber optic from the central EVG. The feature that simplifies the booster timing and beam injection from the booster to the storage ring is the fact that ratio of their perimeters is 5. It allows the use of two groups of events referenced to one selected RF bucket of the storage ring. The first group ("Pre-Injection" and "Injection") provides injection of the beam into the booster. "Pre-Injection" event sets the first RF bucket for the booster. All other events coming from the EVG are referenced to this bucket automatically. The second group of events coming in 300 ms after the first group ("Pre-Extraction", "Extraction") provides extraction of the accelerated beam from the booster and injection to the storage ring.

With a help of EVRs, each group of events initiates a set of triggers for triggering of pulsed devices, control and measuring electronics, and beam diagnostics systems. EVRs provide two scales for triggering. The first scale is for triggering the pulsed septums and the bump magnets in millisecond range and uses TTL outputs of EVRs. The second scale corresponds to triggering of the kickers in microsecond range and uses CML outputs. Also EVRs provide revolution frequency and 10 kHz clocks for control and measurement equipment.

BOOSTER TIMING SYSTEM STRUCTURE

A block diagram of the booster timing system is presented in Fig.1. The booster timing system receives events from the central EVG. These events are distributed over fiber optic links (blue lines) and fan-out modules to EVRs.

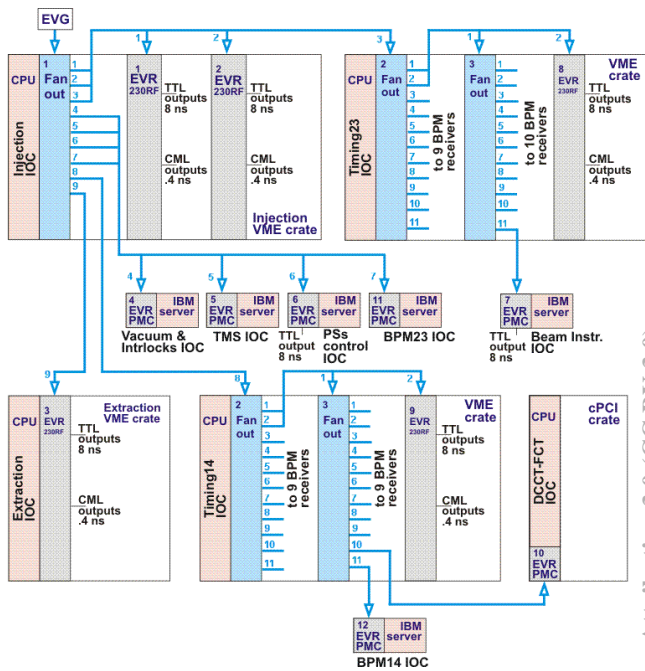

Figure 1: Block-diagram of the booster timing system.

Three EVR-230RF are located in two VME crates: two EVRs are used for injection and one - for extraction. These EVRs provide hardware triggers for injection and extraction equipment.

Also two EVR-230RF are used for synchronization of BPM receivers and other beam diagnostics equipment. These EVRs are placed in VME crates in diagnostic racks and are used for generation of the booster revolution frequency signal and 10 kHz signal for clocking of power supply controllers (PSCs). One EVR generates triggers for cameras in order to provide synchronization with the beam passing.

Six PMC EVRs are placed in six IBM servers. One PMC EVR generates triggers for three chassis with PSCs for providing a synchronous start of the ramp power supplies.

One PMC EVR is placed in cPCI controller for triggering beam diagnostics ADCs which are placed in cPCI crate.

TIMING EVENTS

The time of the booster operation cycle is 1 sec. Two beam injections with a 100-msec interval are proposed to increase the accelerated beam current. The ramp time is 300 msec. A simplified diagram of the booster operational cycle and timing events is presented in Fig. 2. The red curve shows a current value in the bending magnets.

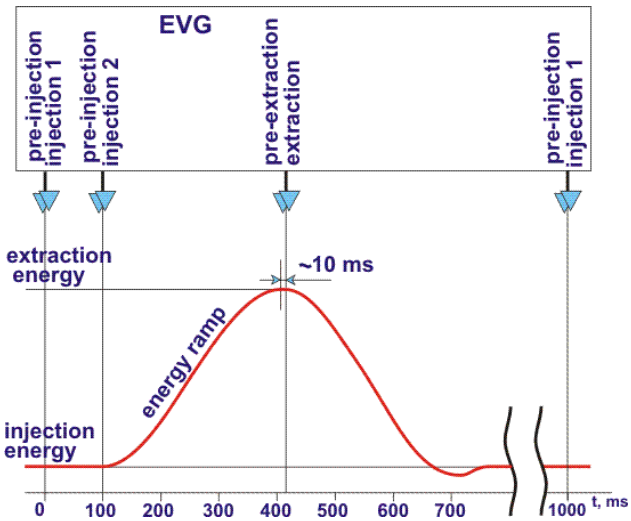

Figure 2: Simplified timing diagram of the booster cycle.

The EVG will provide six events referenced to the selected RF bucket of the storage ring for reference of the booster control timing to the NSLS-II beam:

- Two “Pre-Injection” events spaced 100 msec apart.
- Two "Injection" events coming after 50 turns in the storage ring (132 μs) after "Pre-Injection".
- "Pre-Extraction" event coming in 300 msec after “Pre-Injection” event.
- "Extraction" event coming after 350 turns in the storage ring (925 μs) after "Pre-Extraction" event.

The set of the events listed above provides synchronization between the booster and storage ring bunches.

BEAM INJECTION TIMING

Injection from the linac to the booster is repeated twice with a 100-msec interval in each cycle. A detailed diagram of injection triggering signals from EVRs is shown in Fig. 3.

The following triggering signals are required to control the injection pulsed devices:

- BIT1 (Booster Injection Trigger) - start of the table processing in all Power Supply Controllers (PSCs) [6] (EVR TTL output).
- BIT2 – start of volt-second digitizer for measurement of a pulsed magnetic field value (EVR TTL output).
- BIT3 – start of injection septum current wave form digitizer for digitizing the injection septum pulse current shape (EVR TTL output).
- BIT4 - start of the injection septum (EVR TTL output).
- BIT5-BIT8 – start of injection kickers (EVR CML outputs).
- BIT9 – start of injection kickers current wave form digitizer for digitizing the injection kicker pulse current shape (EVR TTL output).
- BIT10 - stop of the volt-second digitizer (EVR TTL output).

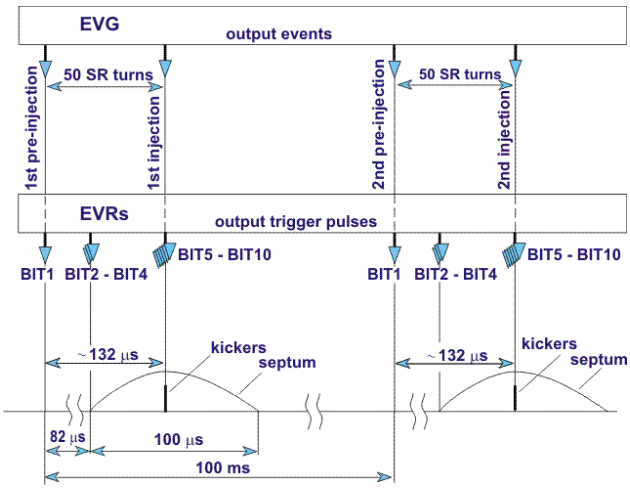

Figure 3: Injection timing diagram.

Both injections use the same triggering signals, but some signals (BIT2, BIT3, BIT9, BIT10) come from different EVR TTL outputs: one output is used for the first injection, another - for the second injection. This allows us to divide measurement channels for the first and the second injections.

Also 10 kHz frequency will be provided from EVR for clocking of PSCs. This signal will be sent from EVR to all PSCs via CML fan-out modules.

BEAM EXTRACTION TIMING

Extraction from the booster is initialized by "Pre-Extraction" event coming 300 msec after “Pre-injection” event. At this moment the beam is accelerated up to 3 GeV and is at the energy flat to provide stabilization of beam parameters during 10 msec. After coming of "Pre-Extraction" event, pulsed bump magnets deflect the beam orbit close to the extraction septum, then, at the moment of maximum deflection, the septum PSs and kicker PSs start. The diagram of extraction procedure is shown in Fig. 4.

The following triggering signals are used for extraction procedure:

- BET1 (Booster Extraction Trigger) - start of extraction Volt-Second Digitizer (VSD) for measurement of bump and septum pulsed magnetic field values at the extraction moment (EVR TTL output).
- BET2 – start of extraction current Wave Form Digitizers (WFD) for digitizing the extraction bump

and septum magnets pulse current shapes (EVR TTL output).

- BET3 – start of bump magnets (EVR TTL output).
- BET4 - start of the extraction septum (EVR TTL output).
- BET5, BET6 – start of extraction kickers (EVR CML outputs).
- BET7 – start of extraction kicker current fast Wave Form Digitizer (EVR TTL output).
- BET8 - stop of the volt-second digitizer (EVR TTL output).

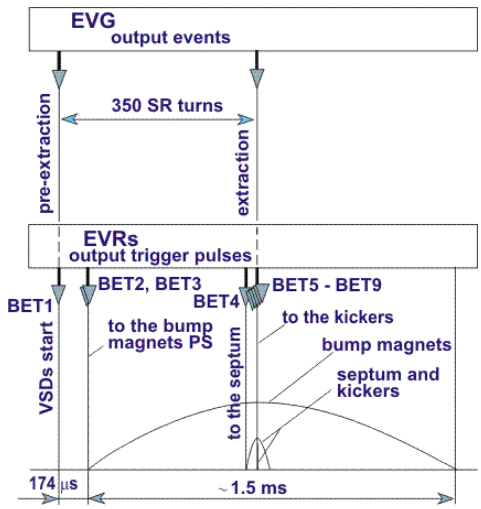

Figure 4: An extraction timing diagram.

BEAM INSTRUMENTATION TIMING

Several triggers are required for the beam instrumentation timing:

- BDT1 (Booster Diagnostics Trigger) - start of high speed digitizer DC222 for FCT (EVR TTL output).
- BDT2 – start of a high resolution digitizer for measurement of signal from DCCT (EVR TTL output).
- BDT3 – start of Tune Measurement System (TMS) controller (EVR TTL output).
- BDT4-BDT9 - start of beam flag cameras (EVR TTL outputs).
- BDT10, BDT11 – start of SR Monitor (SLM) cameras (EVR TTL outputs).

The first "Pre-Injection" event will be used for triggering of on-board EVRs in each of 37 BPM receivers. For this purpose four fan-outs are used in two VME crates (see Fig. 1).

The booster revolution frequency signal will be provided from EVR for Beam Position Monitor receivers and TMS clocking. These signals will be sent from EVR via CML fan-outs.

SOFTWARE

The timing system is integrated into the EPICS based control system through EPICS records. The EVR .db records configure next parameters of the EVR: pulse delay, pulse width, pulse polarity, output assignment, etc. An example of application proposed to be used for control of test stand timing is built with the use of CSS (see the application screen in Fig. 5).

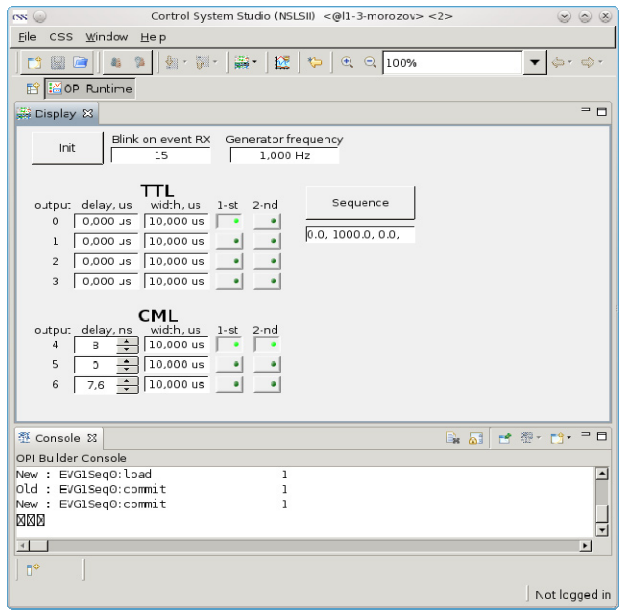

Figure 5: Screen for the EVR control.

SUMMARY

The detailed design of the NSLS-II booster timing system is finished.

The timing system based on the standard equipment provides all required triggers and signals for the booster PSs and electronics.

Some part of electronics now is being used at power supplies test stand.

Software is based on EPICS, now it is under development, its completion is planned before the start of the booster commissioning in October, 2012.

NETWORK ON CHIP MASTER CONTROL BOARD FOR NEUTRON ACQUISITION

E. Ruiz-Martinez*, T. Mary, P. Mutti, J. Ratel and F. Rey. Institut Laue-Langevin, Grenoble, France

Abstract

The acquisition master control board is designed to assemble the various acquisition modes in use at the Institut Laue-Langevin (ILL). The main goal is to make the card common for all the ILL's instruments in a simple, modular and open way, giving the possibility to add new functionalities in order to follow the evolving demand. It has been necessary to define a central element to provide synchronization to the rest of the units. The backbone of the proposed acquisition control system is the denominated master acquisition board. The master board consists on a VME64X configurable high density I/O connection carrier board based on the latest Xilinx Virtex-6T FPGA. The internal architecture of the FPGA is designed as a Network on Chip (NoC) approach. The complete system also includes a display board and *n* histogram modules for live display of the data from the detectors.

INTRODUCTION

The master board centralizes the timing information and the synchronization signals used in the hardware management of the data acquisition of the instrument. At the ILL the standard acquisition system common to most of the instruments is based on a VME bus solution, where all the boards become slaves of one master card.

The present article reports on the development of a master board using a general-purpose carrier card for use in future applications. The MPC 1200 carrier board has been developed by collaboration between IOxOS Technologies and the Instrument Control Service (SCI) at the ILL. The document will start with the description of the network on chip approach using a Virtex 6 FPGA. The MPC 1200 carrier board section describes the multiple features, the IO connections and the devices present on the board. The MPC front-end section summarizes the MPF modules used in the carrier board and the design of the front panel used within the master acquisition application. The implementation part explains the main blocks employed in the master acquisition and the development kit provided in the TOSCA II architecture. The discussion will end with the main conclusions gathered in the development of the project.

NETWORK ON CHIP

The standard shared bus architecture, widely used since years, is all based on master/slave interactions. A master reads or writes one or several slave resources, which can be IO registers and/or memory locations. Several new trends have been introduced like for instance cache memory, optimized burst transactions, split transactions with un-compelled request and completion, but without modifying fundamentally the initial principle. These standard shared buses have two main inconvenient:

- the physical media interconnecting the masters with the slaves shall be shared. In order to allocate the media to the master an arbitration mechanism is needed with a direct impact on the latency and the bandwidth performance.
- the physical media size (number of pins) is limited in construction. It is difficult to built interfaces with thousands of IO.

The TOSCA II architecture has been defined to support the shared bus architecture but with optimal latency and bandwidth performance. The implementation has been done in new high performance Xilinx Virtex-6T FPGA. The interconnection between the masters and the slaves are no more implemented with a shared media but with a full mesh switch where the master owns a direct connection to every slave. This approach presents the following advantages.

- due to point to point connection the bandwidth performance is not shared and can be specifically defined by the master and the slave implementation.
- due to individual connection between masters and slaves, the latency is fully under the control of the slave and no more related to the media sharing.

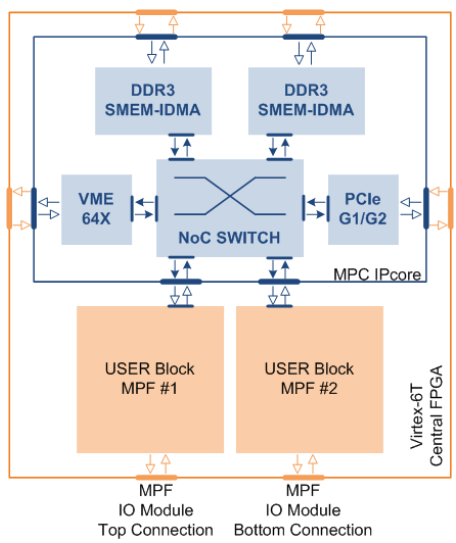

Figure 1: Network on chip architecture.

The NoC approach, see Figure 1, is possible thanks to the fact that the targeted FPGA has enough resources (DPRAM and LE) and that there is no limitation in the number of connections inside the FPGA routing. Another key feature of the TOSCA II Architecture is based on the

*ruizmartinez@ill.fr

full availability of the interface IP core, at VHDL source level for all the key functions (PCI, PCI Express, DDR2/DDR3 controllers, DMA engines, switch infrastructure) [1].

The XILINX Virtex-6T Central FPGA top is organized in a hierarchy level composed of two main blocks:

- the MPC IP core integrating the basic carrier board infrastructure as NoC switch, PCI express EP, VME64x master/slave, the DDR3 shared memories controller with IDMA and the interrupt controller
- two USER blocks, one for each MPF IO connector, fully configurable by the end user.

The MPC IP Core is released in binary format (NGC), along with generic USER block examples and the needed files for the implementation of a fully functional FPGA for the MPC 1200.

MPC 1200 CARRIER BOARD

Compared to other products based on mezzanine cards extension (i.e., FMC or XMC), the MPC 1200 edge-to-edge interconnection solution, see Figure 2, provides full PCB area utilization, direct VME64x front panel access without any restriction on front panel connectors type, and enhanced air cooling capability with standard heat-sink while keeping modularity and versatility.

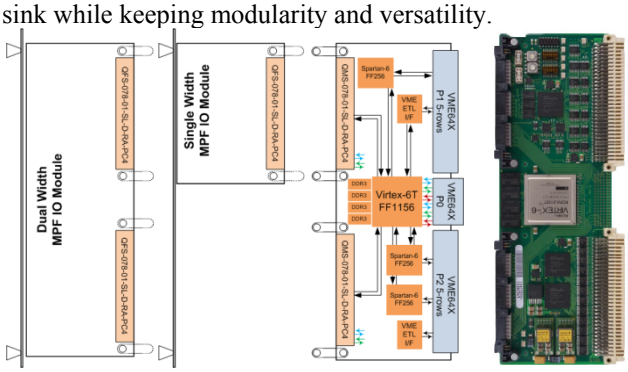

Figure 2: MPC 1200.

The central Virtex-6T FPGA embeds a proprietary IP core providing a complete master/slave VME64x interface. The master/slave VME64x IP core is part of the TOSCA II infrastructure and therefore provides transparent bridging capability such as PCI Express to VME64x [2].

The VME slave interface implements the legacy VME/VME64 addressing configuration with static switches and/or VME64x CR/CSR. The VME slave handles all addressing modes and is fully programmable through an in-going scatter-gather. The VME master interface, driven by the internal FPGA infrastructure supports also all VME addressing mode including 2eVME and 2eSST.

The MPC 1200 integrates on-board DC-DC power supplies for the on-board FPGA and for the MPF IO modules. These DC-DC power supplies are also dimensioned to support the whole Virtex-6T device family. To fully support the Virtex-6T Central FPGA capability, the MPC 1200 integrates three additional Spartan-6 XC6SLX9- FF256 companion devices. Two are dedicated to the VME P2 User IO support and the third one is used for power-up management and FPGA configuration.

The VME P2 user IO (32+32+40 signals on 5-rows connector, see Figure 3) is supported through the two Spartan-6 programmable routing infrastructure providing a 5 V tolerant electrical interface with the P2 connector. The interconnection with the central Virtex-6T FPGA is supported through high-speed (up to 1Gb/s) low level 1.8 V SE or DE signaling.

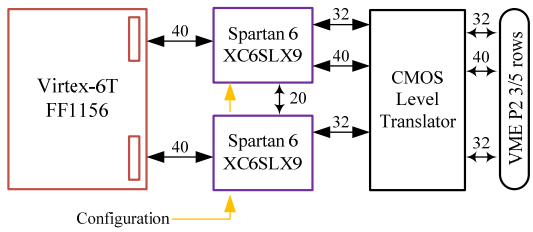

Figure 3: VME64x P2 User IO.

The master acquisition board uses the VME P2 signals to manage the synchronization among the different acquisition and histogram modules. These signals are shared with the boards present in the crate. The input/output direction of the P2 signals is configurable depending on the instrument mode of acquisition.

The FPGA configuration is assured by power on (PON) finite states machine (FSM) implemented in a Spartan-6. The FPGA configuration bit-streams for the Spartan-6 and Virtex-6T are all stored in high-speed serial flash EPROM devices. The FPGA bit-streams can be directly downloaded from the VME slave interface or PCI Express EP.

The carrier board includes as well four 128 Mbit SPI Flash EPROM devices with 4-bit read-out. Four DDR3 memory devices are connected to the Virtex-6T central FPGA. These memory devices can be interfaced as two or four independent DDR3 controller. The DDR3 memory controller IP core provides the complete control of the DDR3 devices and it has been fully integrated in TOSCA II. Other functions such as I2C and SPI interfaces, GPIO management, PON FSM controller, and power supplies monitoring, are integrated within the Virtex-6T central FPGA firmware.

MPF FRONT END

Two Multi-Purpose Front IO (MPF IO) module sizes are supported. The single-width size is derived from the 3U eurocard and the dual-width from the 6U eurocard.

The MPF IO Modules solution has several advantages compared to the FMC extension approach:

- larger PCB size available
- direct access to the front panel without limitation on the IO connectors (no micro connectors required).

- full VME component height allowing installation of heat-sink on critical devices.
- better physical and galvanic isolation for noise sensitive application (i.e. ADC with resolution better then 12-bit).

The MPF IO modules are attached to the MPC 1200 carrier through the SAMTEC QFS/QMS connectors (see Figure 4). The MPC 1200 provides to the MPF modules a full collection of power supplies with up to 4.1 A. (8.2 A on the 1.0 V). For each MPF connector the Virtex-6T IO support is limited to 100 SE (50 DE) signals distributed over 2.5V Virtex-6T IO banks. The use of Spartan-6 devices as data concentrators boosts data bandwidth up to 50 Gb/s [2].

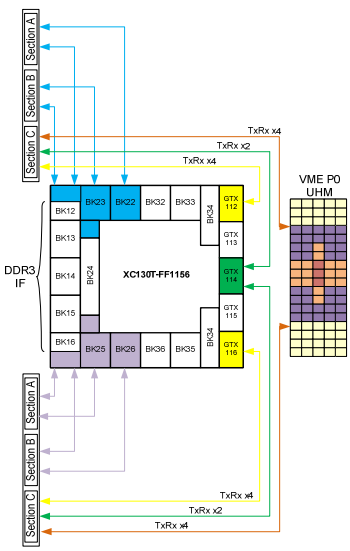

Figure 4: Front panel MPF IO connection.

The front end of the master acquisition board contains the signals coming from external modules involved in the acquisition procedure, like pulses from a rotating machine or an external clock for synchronization purposes. These signals have been grouped in a customized front panel with 12 one-point LEMO for individual inputs, and a DB26 high-density connector. In future applications the front panel could be modified including a processor, flash ADC digitizers or high speed digital connectors for high performance applications [3].

IMPLEMENTATION

The implementation of the master acquisition board has been developed in VHDL using the user area of the TOSCA II architecture. TOSCA II is delivered with full VHDL source code together with a set of test-benches and bus functional models (BFM) to set up a complete VHDL simulation environment for functional verification purposes. The TOSCA II architecture is based on a PCI Express switch centric structure implementing a memory mapped model with segregated I/O space (control plane) and memory space (data plane) [4].

In the master acquisition board each acquisition mode in use at the ILL is developed in a functional and independent block. These blocks are able to manage the synchronization signals, using the front-end and the VME P2 interface, according to the specific needs of the instrument. Depending on the measurement technique adopted, the following acquisition modes are accessible via the master board [5]:

- Simple integral count: available for both single and multi-detectors, it allows a neutron's counting time from 100 *ns* to $(2^{64}\text{-}1)\cdot 10^{8}$ *s* with a time resolution of 100 *ns*. While the gate generated by the master acquisition board remains active all the neutrons arriving at the detector will be counted and the corresponding histograms are stored in the acquisition cards.
- Time of Flight (ToF): the continuous neutron flux produced by the ILL's reactor is pulsed by means of a rotating chopper with frequencies between a few Hz up to 500 Hz. The energy of a detected neutron is calculated starting from the traveling time from the chopper to the detector once the distance of the two elements is known. The master acquisition board is able to manage four independent ToF consisting of up to 2048 variable duration time channels, from 100 *ns* up to 43 *s*. The acquisition card will provide the corresponding histograms where all the detected neutrons are arranged as a function of their arrival time.
- Kinetic: used especially for soft matter studies to trace phenomena with long duration in time, it is very similar to the previous mode. In this case the neutron flux is continuous and the start signal is delivered by an external event. The acquisition card delivers time-slice histograms where the neutrons are arranged according to their arrival time. A combination of ToF and Kinetic mode is also possible when a chopper is available on the instrument. In this case the neutrons in each kinetic time-slice are arranged according to their respective ToF.
- Doppler: two backscattering spectrometers are equipped with a Doppler motion at the monochromator. This last one is moved with a velocity parallel to the reciprocal lattice vector [6] and, as a consequence, the energy of the reflected neutron is modified via a longitudinal Doppler effect. The velocity of the monochromator is varied periodically following a sinusoidal function. The master acquisition board receives via the front-end external synchronization signals corresponding to different velocities. The acquisition card produces a histogram where the neutrons are accumulated into the corresponding equidistant velocity channels.
- Oscillating Radial Collimator (ROC): diffraction experiments on instruments equipped with Position Sensitive Detectors (PSD) suffer from background originated by the sample environment [7]. A specific diffracted beam collimator has been designed to reduce the off-sample parasitic scattering without

perturbing the resolution or the scattering from the sample. This collimator is oscillated through a specific angle with a linear angular velocity. The master acquisition board coordinates the neutron's count depending on the movement of the collimator.

CONCLUSION

As shown in the previous section, the instruments at the Institut Laue-Langevin required a large variety of acquisition modes. This, together with the need of properly synchronize several acquisition cards, has pushed the development of a new master acquisition board. An inappropriate management of all the different external signals connected to the acquisition could cause loses of information during the experiment and/or in the subsequent data analysis. Versatility is a mandatory requisite for the new board since it should be adapted to all the instruments without major changes. The results of all those constraints is a master board design conceived as a VME carrier board with high density I/O connection, leaving the autonomy to use the front-end for custom applications. The board is based on a central Virtex-6 FPGA which embeds a full mesh switch where the master owns a direct connection to every slave, having fully connection with the resources present in the board: PCI express, VME64X master/slave, DDR3 memory controllers and the user area, where the master acquisition application has been implemented.

THE GLOBAL TRIGGER PROCESSOR: A VXS SWITCH MODULE FOR TRIGGERING LARGE SCALE DATA ACQUISITION SYSTEMS

S. Kaneta, C. Cuevas, H. Dong, W. Gu, E. Jastrzembski, N. Nganga, B. Raydo, J. Wilson,
Jefferson Lab, Newport News, VA, U.S.A.

Abstract

The 12 GeV upgrade for Jefferson Lab's Continuous Electron Beam Accelerator Facility requires the development of a new data acquisition system to accommodate the proposed 200 kHz Level 1 trigger rates expected for fixed target experiments at 12 GeV. As part of a suite of trigger electronics comprised of VXS switch and payload modules, the Global Trigger Processor (GTP) will handle up to 32,768 channels of preprocessed trigger data from multiple detector systems that surround the beam target at a system clock rate of 250 MHz. The GTP is configured with user programmable Physics trigger equations and when trigger conditions are satisfied, the GTP will activate the storage of data for subsequent analysis. The GTP features an Altera Stratix IV GX FPGA allowing interface to 16 Sub-System Processor modules via 32 5-Gbps links, DDR2 and flash memory devices, two gigabit Ethernet interfaces using Nios II embedded processors, fiber optic transceivers, and trigger output signals. The GTP's high-bandwidth interconnect with the payload modules in the VXS crate, the Ethernet interface for parameter control, status monitoring, and remote update, and the inherent nature of its FPGA give it the flexibility to be used large variety of tasks and adapt to future needs. This paper details the responsibilities of the GTP, the hardware's role in meeting those requirements, and elements of the VXS architecture that facilitated the design of the trigger system. Also presented will be the current status of development including significant milestones and challenges.

GTP RESPONSIBILITIES

Level 1 Trigger

As part of the 12 GeV trigger upgrade, the GTP is the central processor for the Level 1 trigger in Jefferson Lab's new data acquisition system. It is designed to simultaneously generate up to 32 independent, programmable triggers with a fixed latency from the event occurrence at a 4 ns resolution.

The new system will essentially eliminate trigger dead time by pipelining the detector sampling and trigger decision calculations. The data pipeline replaces long spools of delay cable previously used and instead stores the data and time samples in memory devices on the VXS ADC and TDC payload boards. When triggers are received, the associated data are read out of these buffers for long-term storage.

The trigger calculations will also be pipelined and computed in parallel to maintain continuous availability of triggers. In order to ensure there is no trigger processing dead time, the triggers must be able to fire successively at the 250MHz global clock. The trigger must also reach the front end modules before the buffers run out of space and overwrite data which satisfy trigger conditions. Hardware limitations define a maximum buffer size of 3.2 µs [1].

Synchronization of the trigger data is also critical to ensure triggers are calculated correctly. A clock synchronization signal is used to align the data of all transmitters so that the summation across channels uses samples from the same point in time. It also helps align transceiver channels themselves to remove skew caused by the deserializers. This is done by aligning the reading of the transceiver memory buffers after all channels have received valid data.

Figure 1 shows the flow and concentration of data through the trigger system data path. Each Crate Trigger Processor (CTP) accepts data from its TDC or flash ADC modules in one of two forms, either threshold crossing (hit bits) or energy sum which is determined by the detector type. Fiber optic cables link the CTP to the Sub-system processors (SSP) which align and combine these data by detector system and forward to the GTP for trigger calculation. Not shown is the Trigger Supervisor (TS) which makes the final decision among the multiple trigger signals. It is linked to the GTP via a 32-bit parallel bus operating at the trigger clock rate of 250 Mhz.

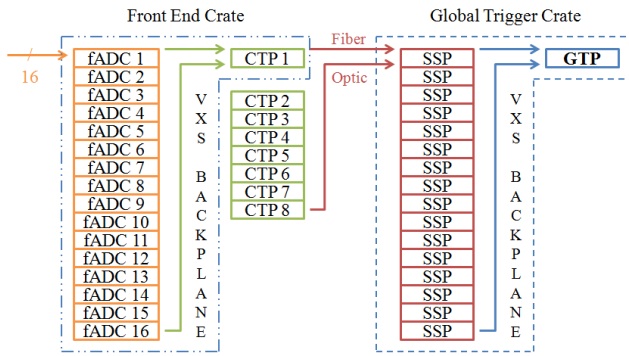

Figure 1: Level 1 Trigger System Data Flow.

User Interface

With an increase in complexity and quantity of trigger equations, the ability to intuitively configure them becomes more important. To help with the setup of trigger equations, a direct link to the GTP in the form of an Ethernet connection will be used. The interface will be a web page served from the GTP and will allow manipulation of coefficients and some adjustment to the form of the trigger equations. To provide greater levels of customization, reconfiguration of the FPGA is available using images in non-volatile memory. Users will be able to select between multiple pages already stored or upload new configurations.

VXS ELEMENTS

The VXS architecture has several advantages compared with other commercial off-the-shelf (COTS) chassis and backplane solutions. Making use of these elements has shortened the design process and reduced some of the associated risks.

VME Extension

Development on VME systems over the years has produced a set of verified hardware and software blocks which can be used in VXS platforms. Connectors P1 and P2 on VXS Payload modules remain unchanged from their VME counterparts allowing backward compatibility with existing designs. Designs consisting of VME and VXS modules can coexist in VXS chassis.

It is important to note that since the VXS Switch module was not previously defined in the VME standard, it contains no direct connections to VME boards, requiring at least one VXS Payload with P0 to enable communication between all modules.

VXS Architecture

VXS Payload modules include a high speed P0 connector in addition to the standard VME P1 and P2. This connector provides eight high speed differential signal paths and two single ended signals to each of the two VXS Switch modules specified by the VITA 41.0 VXS standard [2]. Several VXS Standards, including VITA 41.2, optionally refine these signals for specific communication standards as four transmit pairs and four receive pairs which are reversed on the backplane and two I^2C single ended lines. If full duplex communication is required, this convention is convenient to help reduce pin mapping errors [3].

VXS has a dual star architecture specifying two Switch modules, each with high speed and single ended connections to up to 18 payload ports [2]. Figure 2 shows the connections between the two Switch cards and a Payload. Where applicable, the transmitter and receiver are specified with respect to Switch A. In addition, transmit, receive, and I^2C designations are optional and specified in VITA 41.1 and 41.2 and are made to illustrate a possible configuration [4].

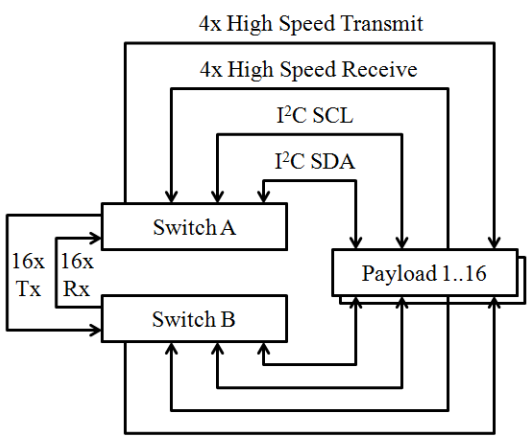

Figure 2: Example VXS Signal Mapping.

HARDWARE IMPLEMENTATION

Ethernet

The inclusion of Ethernet in an embedded system requires several hardware and software components to implement. Full TCP/IP over Ethernet is normally processed by a microprocessor running an embedded operating system and an Ethernet stack, a collection of functions related to the processing of Ethernet packets. Depending on the level of Ethernet implementation required, a simpler protocol such as UDP (user datagram protocol) can be implemented, saving costs on development tools and licenses. Non-volatile memory is required to store microprocessor boot code while fast on-chip and DDR2 memory is needed for many functions including instruction and data caching as well as dynamic memory allocation, program code space, and packet buffering. The electrical interface includes an Ethernet jack, magnetics, and a physical interface device (PHY). The Ethernet MAC (medium access controller) is available as an FPGA IP core and can be used with both TCP/IP and UDP protocols.

Given the flexibility that must be built into the design at its early stages, the GTP will use its FPGA resources, either Altera's embedded soft processor Nios II or logic elements, to provide Ethernet capabilities. A processor design helps deal with uncertainty inherent to TCP/IP networks including packet loss, retransmission and packet reordering. A pure logic element implementation of UDP benefits from very high throughput and efficiency but may prove impractical if the network quality impacts the data integrity.

VXS also allows for Gigabit Ethernet over the backplane using high speed signals. Due to the rates involved and FPGA capabilities, only simple circuitry is required. This consists of LVDS transceivers to buffer the backplane connection from the FPGA. A second processor may be instantiated in the FPGA to establish this link, minimizing the initial hardware investment.

External Memory

The GTP prototype contains both volatile and non-volatile memory in the form of DDR2 and NOR flash devices, respectively. A total of 512 Mb of flash storage and 2048 Mb of DDR2 memory are onboard.

The DDR2 memory is available in two 1024 Mb (128 MB) devices with fully independent address and data busses to accommodate two separate Ethernet interfaces, each with its own processor and memory buffers.

To hold multiple FPGA configurations, one flash device is logically segmented to contain several pages which are loaded using a CPLD (complex programmable logic device) configuration controller. The flash is programmed either via the Ethernet connection or through the front panel JTAG port. A second flash device is used to hold instructions and data for the CPU in addition to the Ethernet web server file structure.

Fiber Optic Transceivers

The CTP and GTP share many design aspects and could be used interchangeably when configured appropriately. To ensure full hardware compatibility, a four channel fiber optic transceiver was included on the GTP. These transceiver channels occupy four of the 36 lanes available on the FPGA. In cases where the additional functions of the GTP including Ethernet connectivity are required at the crate level, a GTP can be substituted. A firmware update would be required to provide CTP functionality in the FPGA.

Configuration

The CPLD's primary function is to provide safe configuration and reconfiguration control for the FPGA. It has access to a 256 Mb flash memory dedicated for storage of multiple FPGA images. The FPGA, which can also access the flash, can program images downloaded via the Ethernet interface and then command the CPLD to initiate reconfiguration. A safe FPGA image is stored without access by the user, allowing restoration of the GTP if the update over Ethernet fails.

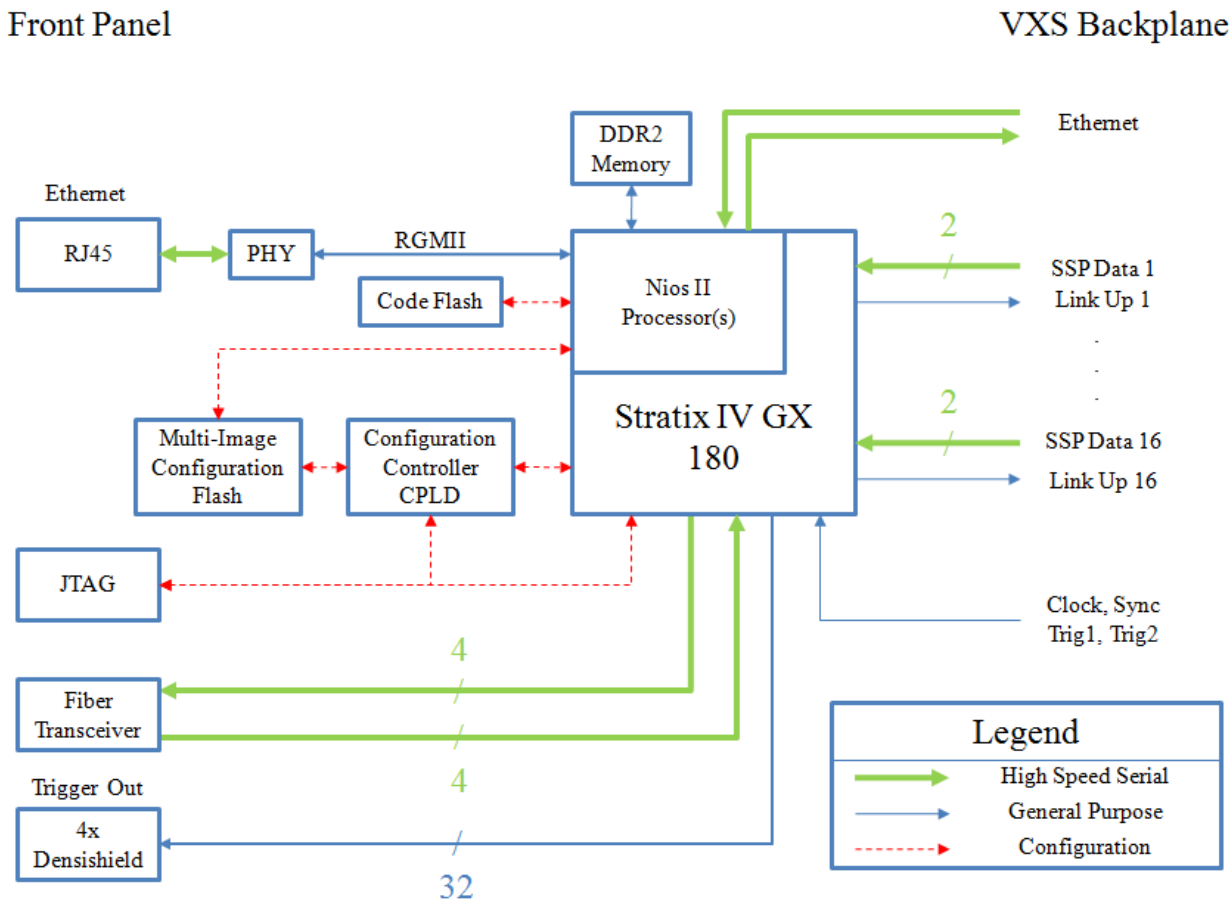

Figure 3: Simplified Global Trigger Processor Hardware Block Diagram.

Transceivers

In order to support the bandwidth and quantity of high speed signals arriving from the 16 SSP modules, an FPGA with integrated transceivers is the perfect solution. Using discrete devices with large parallel busses would not be practical given the number of pins and traces that would be required.

The selection of the Altera Stratix IV GX was made based on several criteria. While rated for speeds greater than 6 Gbps on all speed grades, the clocking structure places some limitations on a subset of the transceiver channels when all are utilized. With 32 transceivers allocated for receiving data from SSPs, four channels remain for use with the fiber transceivers, using all 36 lanes available on the FPGA.

A modified version of the Xilinx Aurora protocol has been selected for communication between the SSP and GTP. It is an open standard designed to encapsulate high speed links [5]. Because of the synchronization of the trigger data rate with the transceiver link rate, some of the Aurora protocol overhead has been removed including flow control and error handling. Lane initialization, channel bonding, and 8B/10B encoding are maintained. Low bit error rates are being targeted to account for the lack of error handling.

PCB Construction

While only a single GTP is required for each of the four experimental halls, efforts were made to keep the PCB costs to a minimum. The design was primarily driven by the interconnect required to tie all the components together and signal integrity, largely for the high speed signals and fast interfaces such as DDR2.

The FPGA requires almost a dozen different power rails between unique voltages and isolated supplies, driving the layer count for power planes. No power nets were run on signal layers and all are routed as split planes, minimizing impedance by providing wide plane connections. Power and ground on adjacent layers also adds high frequency decoupling for the FPGA and other sensitive components.

To maximize signal integrity, all signal and power layers are referenced to ground to provide close proximity, low impedance return paths. The result is a 16 layer board with six signal layers, four power layers and six ground layers. While conservative, all layers have critical signals which could be affected by inadequate or unbalanced routing. For example, matched DDR2 signals routed on two different layers could have increased skew and reduced margins without also matching return path.

With a transceiver link rate requirement of 5 Gbps, additional steps were taken to reduce stubs and minimize reflections. Since the concentration of trigger data requires data flow in only one direction, receive channels were given routing precedence. On incoming lanes from the SSP, all via stubs were eliminated by routing them on external layers rather than adding the cost of backdrilling. Only two full height vias were used, one for the VXS connector pin to the bottom layer and another from the bottom layer to the FPGA pad on top.

The VXS switch connector mapping distributes signals evenly by Payload Port across its four differential connectors. Since only two channels from each payload were used, this allowed all receive signals to be broken out on a single layer and all transmit lines on another.

Current Status

The GTP prototype is complete, shown in Figure 4, and hardware evaluation has begun. FPGA vendors provide many tools to help test hardware, in some cases with minimal development effort. In particular, Altera's Quartus II software comes equipped with a Transceiver Toolkit which allows rapid testing of transceiver channels. This allows manipulation of settings and data patterns in addition to bit-error rate (BER) monitoring and eye opening measurement to optimize the link signal integrity. Using a pseudo-random bit sequence (PRBS), the SSP to GTP links are performing well at 5 Gbps with PRBS31, a rigorous test pattern containing long strings of consecutive ones and zeros.

Altera's DDR2 memory controller core and External Memory Interface Toolkit help verify external memory data, address and command signals. Using a JTAG link between the PC and FPGA, calibration and margining can performed and the results reported. At a memory speed of 666 MHz, both memory devices pass by wide margins on all data and strobe lines.

Ethernet hardware development and TCP/IP software development are complex compared with most other interfaces. In order to provide the most flexibility, the GTP was designed to integrate all protocol layers above the physical interface within the FPGA. Altera's Qsys system builder allows the creation of customized systems by placing components in FPGA logic using a graphical user interface (GUI) and defining the interconnect. The architecture which is normally contained in a special purpose IC must now be developed and debugged in order to begin the Ethernet hardware evaluation.

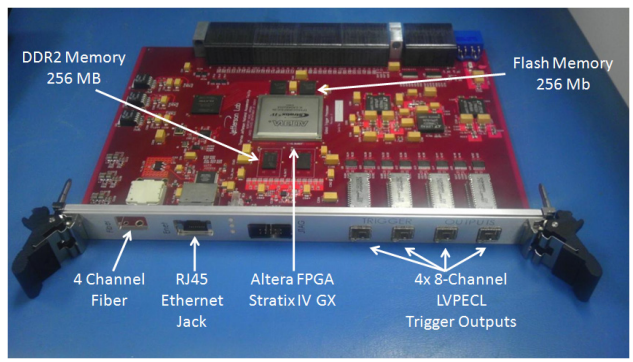

Figure 4: GTP Prototype.

CONCLUSION

Jefferson Lab's new Global Trigger Processor is a powerful, flexible platform well suited to handle the processing and communication requirements of the upgraded trigger system. It leverages the VXS architecture to build on both the experience and hardware of legacy VME systems. However, the GTP is also capable of a myriad of other tasks given its interconnect with the payload boards within the VXS crate, Ethernet and fiber optic connections to external devices, and plentiful onboard storage. While still in development, the GTP promises to adapt to evolving demands throughout the duration of the 12 GeV experimental program.

MEASURING ANGLE WITH PICO METER RESOLUTION

P. Mutti*, M. Jentschel. T. Mary, F. Rey, Institut Laue-Langevin, Grenoble, France,
G. Mana, E. Massa, INRIM, Turin, Italy

Abstract

The kilogram is the only remaining fundamental unit within the SI system that is defined in terms of a material artefact, more specifically a PtIr cylinder kept in Paris. Therefore, one of the major tasks of modern metrology is the redefinition of the kilogram on the basis of a natural quantity or of a fundamental constant. The Institut Laue-Langevin (ILL) and its high-resolution γ-ray spectrometer GAMS with its new optical interferometer can play a crucial role in this attempt.

INTRODUCTION

In the effort of redefining the kilogram one must approach a 10^{-8} relative accuracy in its practical realization. A joint research project amongst the major metrology institutes in Europe has proposed the redefinition of the kilogram based on the mass of the ^{12}C atom. The goal can be achieved by counting in a first step the number of atoms in a macroscopic weighable object and, in a second step, by weighing the atom by means of measuring its Compton frequency ν_C. It is in the second step of the procedure, where the ILL is playing a fundamental role with GAMS, the high-resolution γ-ray spectrometer.

Energies of the γ-rays emitted in the decay of the capture state to the ground state of a daughter nucleus after a neutron capture reaction can be measured with extremely high precision via Laue-diffraction. In order to match the high demand in angle measurement accuracy, a new optical interferometer with 10 pico radian resolution, linearity over a total measurement range of 15° and high stability of about 0.1 nrad/hour has been developed. To drive the interferometer a PLL circuit has been implemented for the heterodyne frequency generation. As the same time a new FPGA based electronics for real time phase measurement and axis-positioning control has been realized.

In the present paper, the basic concepts of the FPGA implementation will be revised and a complete analysis of the performances of the new electronics will be presented.

PHYSICAL MOTIVATION

Two approaches are currently proposed in order to be able to link a new definition of the kilogram to a fundamental constant.

The first project, the so-called "Watt-balance" [1], suggests linking the kilogram to Planck constant h. The second approach, the so-called "crystal density" [2], proposes to measure Avogadro constant N_A and define the kilogram via the mass of a free carbon atom: $1000/12 \cdot N_A \cdot A_r$ (^{12}C). Additionally one could also determine the energy equivalent to the mass of a ^{12}C atom, leading to the fundamental constant $N_A \cdot h$.

A direct measurement of the energy equivalent is difficult since small masses correspond to enormous energies. However, measuring the mass and energy balance in a thermal neutron capture reaction offers an attractive possibility to realize this concept. The key difficulty in the experiment is the precise absolute determinations of γ-ray energies emitted after the thermal neutron capture reaction.

This is done by diffraction of γ-rays at perfect Si crystals and measuring the very small diffraction angles in absolute terms. The aimed uncertainty for the determination of $N_A \cdot h$ is 10^{-8}, which requires an adequate accuracy for the diffraction angles' measurement and the calibration of the apparatus.

A key step towards a new $N_A \cdot h$ measurement is a new optical interferometer with 10 prad precision and linearity over a total measurement range of 15° and high stability of about 0.1 nrad/hour. Figure 1 shows the layout of the interferometer with all the optical elements in place and the various beams' paths.

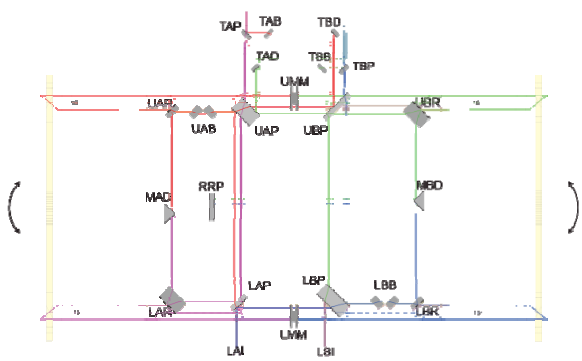

Figure 1: The optical layout of the new GAMS interferometer.

The interferometer follows a Mach-Zehnder layout, which allows a strict separation in space between all beams. This avoids unwanted mixing, which would lead to non-linearity in the angle measurement. A more detailed description of the interferometer can be found in Ref. [3].

The interferometer is designed such that we have the possibility to measure the rotation of both spectrometer axes using a single set of optical elements. This highly symmetric layout increases the stability and the accuracy of the angle measurement by self-compensating eventual drift of the apparatus. All the optical elements are high quality fused silica pieces with custom-made surface treatment. All the key optical elements of the

interferometer are chemically bonded [4] to the CLEARCERAM base of the spectrometer to avoid the use of glue. The roof-prisms and retro-reflectors used in the realization of the optical path are hollow since in solid elements the path length is not constant with respect to rotation [5].

THE NEW LASER SOURCE

Classical interferometers allow typical displacement measurements around 10^{-2} of the optical wavelength. This resolution can be improved by a factor of 100 by using in each interferometer arm a different wavelength.

This concept is realized in our new interferometer. Starting from a highly stabilized monodyne laser source, the single laser wavelength is split into two beams and each of them is frequency shifted. The two frequencies are obtained by mixing to a beat signal of 100 kHz with a carrier frequency of 40 MHz.

We have developed a Phase-Locked Loop (PLL) circuit that allows mixing the reference signal of a commercial lock-in amplifier with a signal of a precision signal generator. The two frequencies are transferred to the laser beam via Acousto-Optic Modulators (AOM). After frequency shifting the laser beams are injected into the interferometer via glass fibres. The interference signal will be detected as a beat node modulation. The phase of this beat signal is proportional to the length variation of the interferometer paths originated by the rotation of the axis.

The phase gets measured relative to a reference signal generated within the interferometer thanks to a newly developed phase measurement electronics described in more details in the following chapter.

PHASE READ-OUT AND NANO POSITIONG ELECTRONICS

The interferometer delivers for each of the two axes a measurement signal and a reference signal. If one axis is rotated, the phase of the beating of the according signal changes with respect to its reference. In order to determine the absolute displacement of the axis in angular term one has to measure the phase change and count integer periods (where one period is equivalent to one optical fringe or to an angle of about 0.5 μrad). To perform those tasks we have developed a dedicated electronic module based on a VIRTEX-4 FPGA. For compatibility reasons with the existing ILL's electronics and for a maximum of flexibility, the implementation adopts the M-Module (ANSI/VITA 12-1996) [6] mezzanine standard (see Fig. 2). While the back of the mezzanine card contains the FPGA chip and the carrier I/F connector the front part implement all the analogue circuits necessary to treat all signals from the interferometer as well as all the front-panel connectivity.

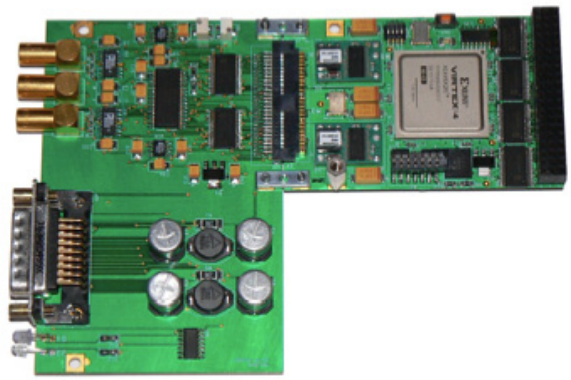

Figure 2: The M-Module responsible for the phase read-out and the fine positioning of the spectrometer's axis.

The beating signals from the photodiodes are first filtered to eliminate the DC offset and the narrow band AC noise due to the detection of ambient light. The signals are then transformed into square waves by high stability differential operational amplifiers. The phase difference between the reference and the interferometer signal is then measured by time interval counting. The module is driven by a master clock running at 100 MHz, which allows the 100 kHz periods to be sampled with an accuracy of ± 10 nsec. This uncertainty is equivalent to 0.0005 interferometer fringes (50 prad). The counting of integer fringes (equivalent to full periods) provides the necessary information for the macroscopic positioning of the spectrometer axes using DC motors coupled to high precision rotation stages. The accuracy of the phase measurement can be pushed up to 0.00005 fringes by means of a sliding average over 100 values, at the price of reducing the sampling frequency down to 1 kHz.

The axis fine positioning is achieved using a piezo actuator controlled by a 0-10 *V* signal provided by a 14-bit Digital-to-Analogue Converter (DAC). Alternatively, the card offers the possibility of a digital output to directly control the piezo positioning. At present a positioning resolution of 0.01 fringes has been obtained, being limited only by the amplitude of the residual external vibrations transmitted to the axis. To remove any axis drift and to minimize those residual vibrations, the phase information is used as feedback for a close loop real-time regulation mechanism. This regulation is based on hardware Proportional-Integral-Derivative (PID) controller that corrects for any deviation of the measured phase from the desired one.

The phase information is also recorded in coincidence with the γ-events from the HPGe detector in the acquisition card. This supplementary information is fundamental to correctly interpret the measured data since it allows removing the impact of mechanical vibrations that affects the accuracy of the angle measurements due to the incorrect determination of the axis position during the data acquisition.

CARD PERFORMANCES

A series of tests have been carried out to evaluate the overall performances of the ILL's phase read-out electronics in comparison with those provided by the commercial dual phase, wide bandwidth, DSP lock-in amplifier SIGNAL RECOVERY model 7280. The lock-in amplifier uses a different approach to derive the phase information. It uses frequency mixing in combination with a low-pass filter to convert the signal's phase and amplitude to a DC voltage signal. Its main advantage is the capability to handle signals with a high signal-to-noise level.

All tests for which we report the results in the following were performed using a high precision signal generator feeding both the reference and the interferometer signal therefore, the expected phase difference should be equal to zero. Figure 3 shows the evolution of the phase measurement when the beating frequency is increased from 1 kHz up to 120 kHz.

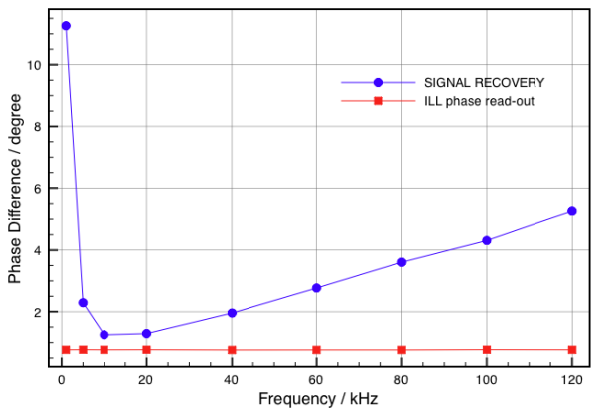

Figure 3: Comparison of the phase offset versus beating frequency.

Having in mind that both inputs are fed with the same beating frequency the expected phase offset should remain constant. With the exception of the first 2 points, the results show clearly a linear correlation between the frequency variation and the phase offset values in the case of the SIGNAL RECOVERY lock-in amplifier. Our explanation is that the observed behaviour is due to the filters and amplifiers that are present at the input stage. For very low frequency, it is evident in the data how the two input channels of the SIGNAL RECOVERY seem to diverge. We do not have a clear explanation for such behaviour. The same measurement repeated using our read-out electronics does not show any appreciable variation of the measured phase as a function of the beating frequency.

A second series of tests has been performed to verify the stability of the phase values with respect to amplitude variations of the input signals. The obtained results are summarized in Fig. 4 where the phase difference has been plotted versus input signal amplitude. As for the previous measurement, the same input signal has been used for both inputs resulting in an expected zero phase difference. While in the case of our read-out electronics this result is confirmed a part from an initial offset, the SIGNAL RECOVERY lock-in shows a strong dependency between phase value and input signal amplitude.

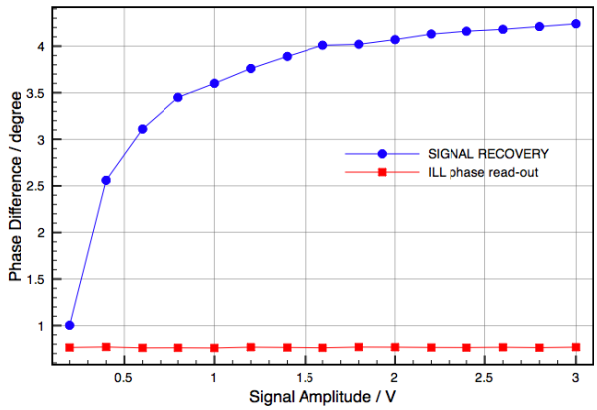

Figure 4: Comparison of the phase offset versus input signal amplitude.

In Fig. 5 and Fig. 6 we compare the power density spectra of the phase difference measured by both the SIGNAL RECOVERY lock-in amplifier and our electronics. The frequency resolution of the SIGNAL RECOVERY spectrum is 0.2143 Hz. The standard deviation of the SIGNAL RECOVERY phase noise (the *rms* value of the signal) - calculated by the square root of the integral spectrum in the 0.1 Hz to 500 Hz frequency interval - is 0.016 degree. The cut-off at about 100 Hz is due to the 1 ms minimum time-constant of the output low-pass filter (6 dB/octave).

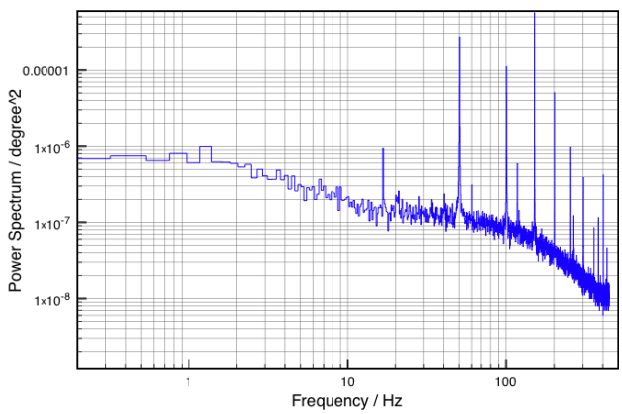

Figure 5: Noise power spectrum obtained with the SIGNAL RECOVERY lock-in amplifier.

The *rms* values are comparable for both the SIGNAL RECOVERY lock-in amplifier and our phase read-out electronics but since for this last one there is no cut-off at 100 Hz, the resulting bandwidth is larger and consequently the total noise lower. At lower frequencies it is evident, especially in the case of the SIGNAL RECOVERY, a slight noise level increase. The fact that the same effect is much less pronounced in our electronics

seems to confirm the previous results showing a much higher sensitivity to frequency and amplitude noise in the case of the SIGNAL RECOVERY.

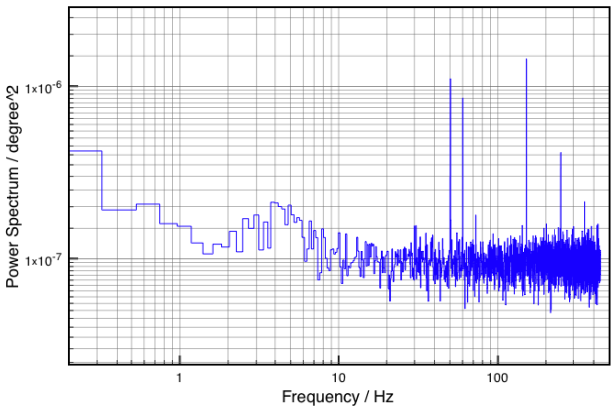

Figure 6: Noise power spectrum obtained with our phase read-out electronics.

From the SIGNAL RECOVERY data we can calculate an the *rms* noise level in the 0.1 Hz to 10 Hz interval of 0.041 degree. This value corresponds to 1.4 mV amplitude noise (*rms* values) of the signal generator in the same frequency band. The remaining noise present in our electronics is probably due the jitter of the quartz (50 ppm accuracy) used to cadence the FPGA and, therefore, to determine the time intervals for the phase measurement. To verify this hypothesis, a new version of the same card implementing a high precision quartz (30 ppb accuracy) is currently under development. Having established the good performance of our electronics, we continued the tests replacing the signal generator inputs with those obtained by a simplified version of our interferometer. The goal was to determine all possible sources of phase noise due to the laser injection and/or the optical fibre as well as to monitor the time stability of those elements.

CONCLUSION

In order to satisfy the specific requirement in terms of high precision phase measurement and positioning accuracy related to the operation of the new ultra high-resolution γ-ray interferometer under development at the ILL, we have specifically developed a new phase read-out electronics. The card adopts the M-Module mezzanine standard for a maximum of flexibility. It is based on a Virtex 4 FPGA that controls both the phase measurement and the fine axis positioning.

An exhaustive series of tests has been performed to evaluate the overall performance of the new electronics. The obtained results are very encouraging, showing a very small, when not absent, sensitivity to frequency and signal amplitude noise. A further step in noise reduction will be achieved with the implementation of the new high-precision quartz.

NSLS-II BOOSTER POWER SUPPLIES CONTROL

P. Cheblakov, S. Karnaev, S. Serednyakov, BINP, Novosibirsk, Russia
W. Louie, Y. Tian, BNL, Upton, NY 11973, USA

Abstract

A special set of devices was developed at BNL for the NSLS-II magnetic system Power Supplies (PSs) control [1]: Power Supply Controller (PSC) and Power Supply Interface (PSI). PSI is placed close to current regulators and is connected to the PSC via fiber-optic 50 Mbps data link. PSC communicates with EPICS IOC (Input/Output Controller) through a 100 Mbps Ethernet port. The main function of IOC includes ramp curve upload, ADC waveforms data download, and various process variables control. The 256 Mb DDR2 memory on PSC provides storage for up to 16 ramping tables for both DAC channels, and a 20-second waveform record for all ADC channels. The 100 Mbps Ethernet port enables real time display for 4 ADC waveforms.

The NSLS-II booster PSs are divided into two groups: ramping PSs, which provide passage of the beam during the beam ramp in the booster from 200 MeV up to 3 GeV in 300 ms time interval, and pulsed PSs, which provide beam injection from the linac and extraction to the Storage Ring.

This paper describes a project of the NSLS-II booster PSs control. Characteristic features for the ramping magnets control and pulsed magnets control in a double-injection mode of operation are considered in the paper.

INTRODUCTION

NSLS-II 3rd generation light source [2] is currently being constructed at Brookhaven National Laboratory, USA. It will be a storage ring operating at 3 GeV. To provide an effective continuous operation of the storage ring a full-energy booster [3] is proposed. The booster will accelerate electron beam from 200 MeV to the nominal energy with average beam current of 20 mA. The booster will be capable of multi-bunch and single bunch operation. Maximal number of bunches in one accelerated train is 150.

Two modes of the booster operation are planned: 1 Hz cycle with two beam injections with a 100-ms interval and 2 Hz cycle with one beam injection. The energy ramp period is 300 ms in both modes.

The required relative accuracy of the main PSs (dipoles, quadrupoles) control is 10^{-4} for the current plateaus (at beam injection and extraction) and 10^{-3} for the ramp.

Power supply control system will provide beam passing in the booster during acceleration. It will synchronously control all magnetic elements for this purpose. Also it will provide operations on orbit correction at any moment of injection, acceleration and extraction, tune and chromaticity adjustment at any moment of beam existence in the booster, response matrixes measurements, and power supplies and magnet parameters monitoring.

Power supply control should be synchronous with other accelerator subsystems to perform its functions. The synchronization is done through timing system [4]. The PS control equipment receives a trigger pulse from the timing system and uses 10 kHz signal from Event Receivers, which is synchronous to the main RF oscillator. This synchro signal allows providing the required relative accuracy of PSs at the ramp.

BOOSTER POWER SUPPLIES OPERATION

Two modes of operation are supposed for the booster: a one-second cycle with double injection with a 100-ms interval, and a 0.5-second cycle with single injection. Beam ramp time is the same for both cases: 300 milliseconds. Typical current diagrams for different PSs are provided in Fig.1.

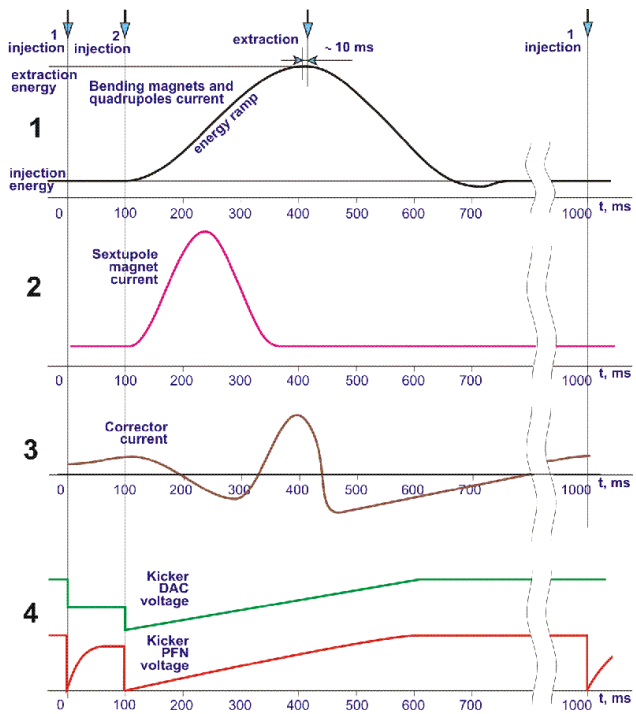

Figure 1: Booster elements current and voltage diagrams.

Diagram #1 shows change of bending magnet current in accordance with change of the beam energy. Depth on the plot in the region of 700 msec represents closure of magnetic loop for the dipole magnets.

Diagram #2 represents sextupole current compensating chromaticity deviation due to eddy current and magnet saturation effects.

Diagram #3 shows bipolar change of corrector current. The corrector ramp function should be changed in real

time at each booster cycle to provide an effective beam orbit correction.

Diagram #4 represents control and measuring signals for the injection kicker. Use of PSC allows change of DAC voltage during 100-ms interval synchronously with beam injections in hardware.

BOOSTER POWER SUPPLIES CONTROL STRUCTURE

There are 58 ramping PSs: 3 PSs for 3 groups of dipole magnets, 3 PSs for 3 groups of quadrupole magnets, 16 sextupole PSs, and 36 PSs for corrector magnets. Beam injection and extraction are provided by 9 pulsed PSs (injection and extraction septums, extraction bump magnets, 4 injection and 2 extraction kickers) and one DC extraction septum PS.

44 sets of PSC-PSI are proposed to be used for PSs control: 6 dual-channel sets for bending magnets and quadrupoles, 28 dual-channel sets for sextupoles and correctors, 10 single-channel sets for injection/extraction magnets. All devices will be placed in racks in the injection service area near the booster tunnel. A block-diagram of the booster power supply control is presented in Fig.2.

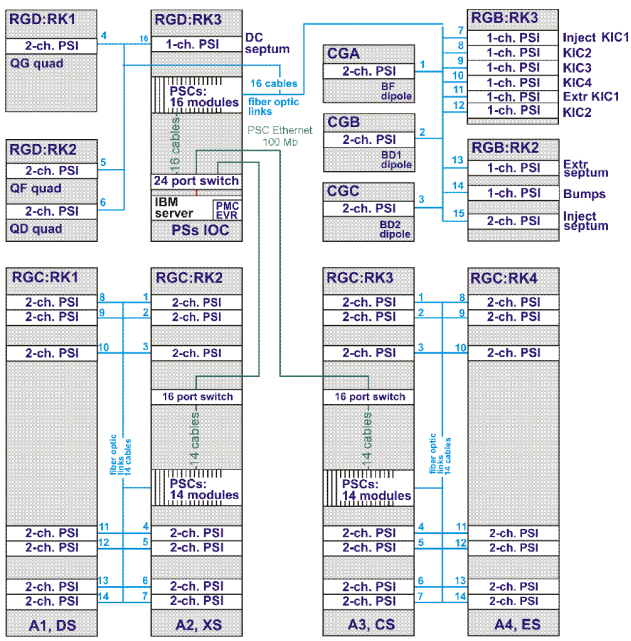

Figure 2: Block-diagram of the booster power supplies control. Distribution of the equipment among the racks.

It is supposed to use one IBM server (PSs IOC) to control all booster PSs. All PSCs will be distributed in three chassis and will be connected via switches in 1 Gbps network. .To maximize the communication speed, each PSC is directly connected to IOC via the Ethernet port. This will be the same for NSLS-II storage ring power supply control [1].

Ethernet interface of PSC is 100 Mbps, but it can only receive less than 13-14 kbyte ramping data per second due to the limit of FPGA softcore CPU, softcore MAC and a free light weight TCP/IP stack.

PSC-PSI DESCRIPTION

Main Parameters

PSI has one or two precision 20-bit DACs, three channels of precision 16-bit ADC for each DAC, six channels of 16-bit ADC for each DAC, sixteen digital inputs, 8 digital outputs. PSI is connected to PSC via fiber-optic 50 Mbps data link.

PSC is equipped with 256 Mb DDR2 memory, which provides sixteen 40 kb ramp tables for each ADC channel and a 20-second waveform record for all ADC channels. PSC has a 100 Mbps Ethernet port for connection with control system.

Operation Description

PSC version described in this paper is designed for the booster control. It has a short set of commands for interaction with high level applications:

- "Rst" resets all PCS registers to the initial state.
- "Enbl" is used for PSC disabling/enabling.
- "RampEnbl" is used for disabling/enabling of ramping mode.
- "BrkCmd#" breaks current ramp table processing and brings DAC# at "BrkRate#" (see below) rate to "BrkEnd#" state.

To provide a flexible operation PSC has the following set of setting parameters:

- "Mode" switches mode of PSC operation: Stop/Ramping Mode/Static Mode. Static mode is used for control of DC PS in the case when a transient process in PS due to a new DAC set is unimportant.
- "DoutMode" switches digital output mode: Static (level)/Pulse. Digital output pulse mode allows setting digital output to "High" level for specified time, then the level will be returned back to "Low" value.
- "DoutPlsWdt" - pulse width (ms) in digital pulse mode.
- "ClkSrc" - updates clock source: external (from backplane)/internal 10 kHz.
- "ClkDivd" - clock divider factor (0 - /1; 1 - /2; …. 254 - /255) for changing of the ramp time.
- "ActvTbl#" selects DAC# active ramping table (0-15 for DAC1, 16-31 for DAC2).
- "InActvTbl#" selects inactive ramping table for download.
- "BrkRate#" sets DAC# break rate.
- "BrkEnd#" sets DAC# break end setpoint.
- "AdcID#" selects ADC channel for #-waveform reading.

Also a set of indication parameters can be read from PSC:

- "PscLoadingRamp" - PSC ramping table download indication (Loading or Done).

- "PscFrountT" - PSC main board temperature.
- "PscRearT" - PSC rear board temperature.
- "PscIP" - last byte of PSC IP address (192.168.1.x).
- "PscDDR2Check" - DDR2 memory check during bootloading (Good/Failed).
- "PscFiberSd" - status of fiber link between PSC/PSI (Good/Failed).

PSC firmware provides reading/writing of the following values:

- Writing eight values of digital outputs and two DAC setpoints (DAC setpoints are used for static mode of operation).
- Uploading from IOC selected (determined by "InActvTbl#") ramping table of 40 kbyte data for ramping mode of operation.
- Reading sixteen digital inputs and eighteen ADC values.
- Downloading to IOC of two 10 kHz ADC waveforms selected from ADC1-ADC16 in real time.
- Downloading to IOC of two 1 kHz ADC waveforms for both DACs in real time. The order of ADC channels in the waveforms: ADC1,2,3,4,5,6,7,8,17 for DAC1 and ADC9,10,11,12,13,14,15,16,18 for DAC2. Each ADC has 1280 points in the waveform.

PSI is capable of detecting the status change sequence of digital inputs with a 10 ns resolution.

The ramping mode of operation will be used for all booster PSs: both for ramping PSs, and for pulsed/DC PSs. In the case of DC PS (for example, DC septum) the ramp table will be filled by one setting value.

In each cycle each PSC starts processing of ramping function downloaded from IOC by common trigger from the timing system. Also each PSC receives 10 kHz clocks from EVR in order to provide mutual synchronization.

SOFTWARE

Software interface for interaction with PSC (see Fig. 3) is based on EPICS.

Figure 3: EDM screen for testing of PSC/PSI.

At the moment an EPICS driver for PSC is developed and all process variables are implemented, EDM screen is prepared for testing of all PSC/PSI signals and commands.

It is supposed to use this screen for the first tests of the booster PSs at the test stand in BINP. Additional scripts for uploading of ramp tables from text or MATLAB files will be used.

A Ramp Manager (RM) application for operation with PSs during commissioning of the booster is being developed now. RM will provide edition of ramp function tables, synchronization of different PSs tables, generation of ramp function tables and uploading it to IOC, storing/restoring tables, visualization of ramp functions and measured waveforms. An example of RM python screen is presented in Fig.4.

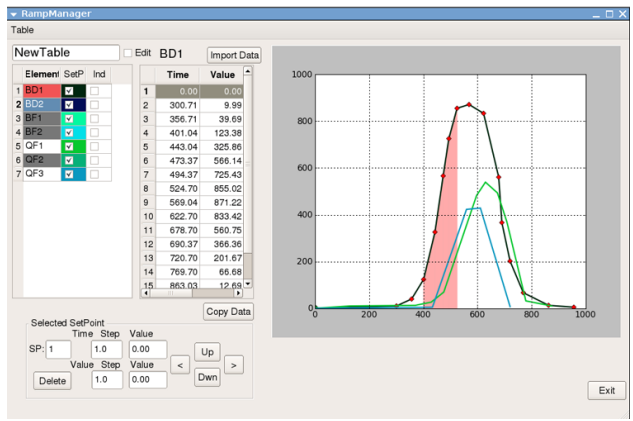

Figure 4: Ramp Manager screen.

SUMMARY

The detailed design of the NSLS-II booster PSs control is finished and all requirements are satisfied. Specifications for operation logic and parameters of Power Supply Controller and Power Supply Interfaces are worked out and are implemented in the firmware. Software is under development, its completion is planned before the start of the booster commissioning in October, 2012.

THE CONTROLLER DESIGN FOR KICKER MAGNET ADJUSTMENT MECHANISM IN SSRF

R. P.Wang, M. Gu, Z. H. Chen, R. Chen
Shanghai Institute of Applied Physics, Chinese Academy of Sciences, Shanghai 201800, China

Abstract

The kicker magnet adjustment mechanism controller in SSRF is to improve the efficiency of injection by changing the magnet real-time, especially in the top-up mode. The controller mainly consists of Programmable logic controller (PLC), stepper motor, reducer, worm and mechanism. PLC controls the stepper motors for adjusting the azimuth of the magnet, monitors and regulates the magnet with inclinometer sensor. It also monitors the interlock. In addition, the controller is provided with local and remote working mode. This paper mainly introduces related hardware and software designs for this device.

INTRODUCTION

Shanghai Synchrotron Radiation Facility, currently in routine operation stage for nearly two years, as a 3rd generation light source in China. SSRF storage ring will run in top-up operation mode[1]. Therefore, the SSRF injector will be in top-up injection .while in the Injecting, the electron beam which comes from the high energy beam transport line will be bumped to the closed orbit. To ensuring photon beam position stability, the beam in the storage must be remaining its orbit while travelling the injector. However, because of the manufacturing and installation differences, the magnetic field is not completely the same. This may make the beam deviate from the designed orbit, and reduce the injection efficiency. In order to reduce the impact of injection, we developed this device. It can be able to precisely measure the magnetic azimuth angle, and adjust it in real time.

ARCHITECTURE

Figure 1 shows the kicker magnet adjustment mechanism's architecture. In this system, the controller based on PLC, with the auxiliary hardware circuit, it selects the control object, adjusts the platform motion, detects the position and provides the protection. As the four kickers is not adjusted in the same time, we design one controller to adjust four platforms in instalments .By the switching, the controller can scan the current location of four the platform as well as focus on one. While in the scanning mode, the four position feedback information is received by the PLC cycle, and displayed on the control interface, and the power of motor is cut off. Otherwise, when in the adjusting mode, one of four kickers is focused, and the power supply of other kicker motor is cut off, so as to ensure the accuracy of selected objects, but also improve the safety performance. In addition, the stepper motors are equipped with brake system used as motion safety protection. Then there is an emergency, the motor is braking, and the platform is secured. Besides local interface, the controller also provides remote interface via Ethernet.

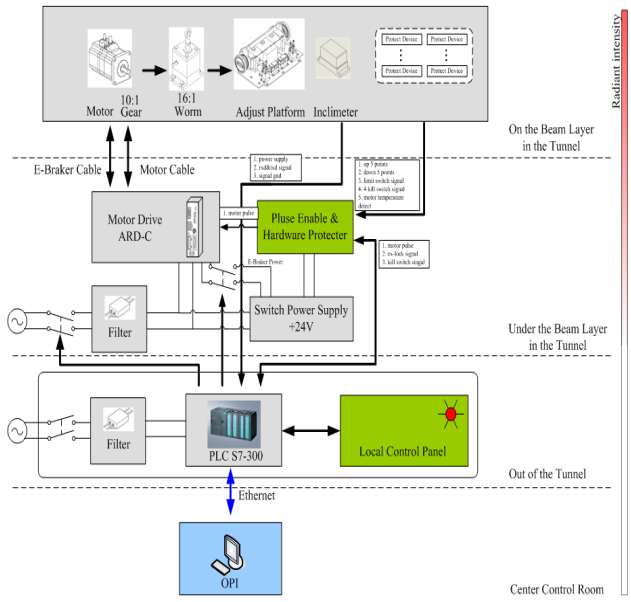

Figure 1: Adjust Platform Control System.

MECHANICAL STRUCTURE AND POSITIONING ACCURACY

Figure 2 is the motion scheme of the adjustment mechanism. The Platform is fixed on the point O. and the other underlay is the worm. When the stepper motor rotates, the worm controls points A movement up and down, then the magnet platform rotates slightly as the centre O, the relative position between magnet and beam then to be adjusted. In this Design, the motor step angle is 0.36°, and 1000 steps per revolution. With the mechanical design, the step motor can control the adjustment platform in less than 6 μrad。The speed of the motor is determined by the pulse frequency come from fm353. Considering the actual situation, the real adjusting range is very small, and the speed of the adjustment can be very slow.

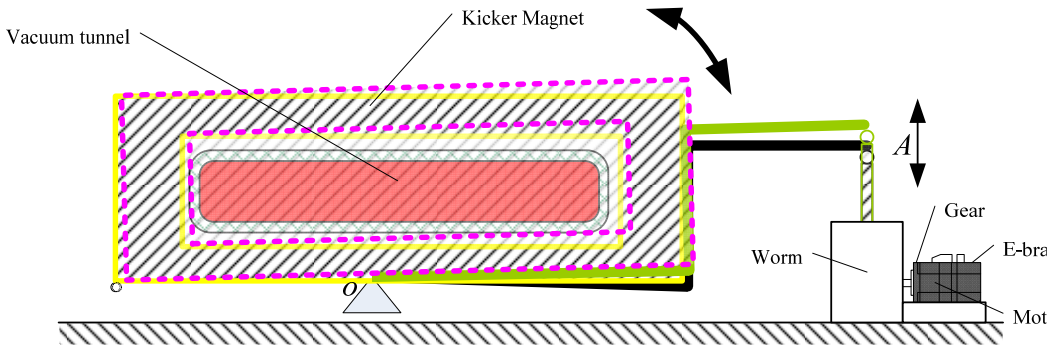

Figure 2: Motion scheme.

FEEDBACK CONTROL AND SOFTWARE DESIGN

Feedback Control

Position feedback is derived from inclinometer through optical fiber, through which PLC's SM340 module can acquire the real-time and high-precision position information. The benefit of inclinometers is the measurement is more direct with 2d angle and not subject to mechanical platform installation space conditions [2]. The inclinometer has many output forms such as RS232/RS484,CAN2.0,0.5-4.5V and 4-20mA. Furthermore, Inclinometer can measure the temperature and send it with the angle. With a view to actual position feedback form, special attention should be paid to check and confirm the increment direction of inclinometer during control system debug and assemble stage. If we set a wrong increment direction of inclinometer, we would get a decreasing angle but actually we need a increasing angle, and vice versa. Thus, such condition must be avoided.

The controller based on SIEMENS S7-300 PLC has so fast scanning speed and the adjusting range is so small that it can use close-loop control technology while the inclinometer is not very fast. During motors keep moving, PLC judges continuously whether motors have got to the destination position set by user through comparison between destination angle and current angle from inclinometer.

Safety Protection

With the exception of accurate motion control, the controller must ensure the safety protection. In this controller, software limit, kill switch and mechanical hard stop are used to implement up and down position protection. Software limits on the one hand prohibit setting value beyond the normal range; on the other hand, through comparison between software limits and feedback values from inclinometer, PLC must stop motor immediately and give warning indication. Kill switch can cut off pulses by hardware as well as give signal to PLC. Mechanical hard stops are used to stall the motor if the kill switch fails.

Software Design

Software designs are composed of two parts, one is program design based on PLC, and the other is program design based on EPICS.

PLC program design environments are SIEMENS Step 7 and WinCC Flexible 2008. Step 7 is used to develop motor control program and WinCC Flexible 2008 is used to develop application based on local panel. According to actual application, PLC's task modules mainly consist of motion control, inclinometer reading, safety protection, communication with EPICS and etc. Of all PLC's function modules, motion control is one key part. Because we utilize close-loop technology to realize accurate angle of magnet platform, we must adjust the motor speed into appropriate range in accordance with characteristic speed curve of stepper motor. Local panel program communicated with PLC via Ethernet mainly utilize WinCC Flexible 2008 to implement right status configuration and display.

Present EPICS environment is based on EPICS base-3.14.9 and Linux environment is Fedora Core 11. The communication between soft IOC and PLC is via Ethernet TCP/IP. To make EPICS save the last running statuses and parameters after IOC restarting, the autosave module is applied in the S7plc driver packages. Figure 3 is the interface in remote mode.

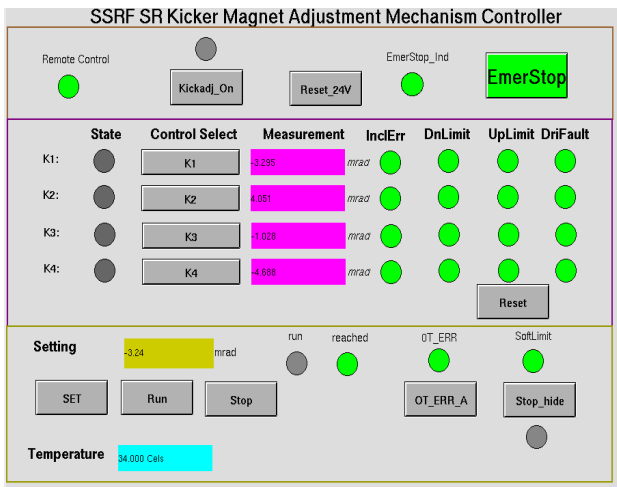

Figure 3: Interface in remote mode.

CONCLUSIONS

The adjustment mechanism has been installed on the storage ring injection kicker, and works well. The adjusting range can be achieved from -10mrad to -10mrad, the running accuracy is ±20urad. With the Software limit、kill switch and mechanical hard stop, the controller works in stable and reliable operation. By using this device to tilt the magnet, the rms value of the first 200 laps Track is less than ±4μm, which one can reached ±100μm before tilt optimized.

ALBA TIMING SYSTEM - A KNOWN ARCHITECTURE WITH FAST INTERLOCK SYSTEM UPGRADE

Oscar Matilla, David Beltran [on leave], David Fernandez-Carreiras, Jerzy Jan Jamroz, Jorg Klora, Jairo Moldes, Ramón Suñé [on leave] ,CELLS-ALBA Synchrotron, Cerdanyola del Vallès, Spain

Abstract

Like most of the newest synchrotron facilities the ALBA Timing System works on event based architecture. Its main particularity is that integrated with the Timing system a Fast Interlock System has been implemented which allows for an automated and synchronous reaction time from any-to-any point of the machine faster than 5µs. The list of benefits of combining both systems is large: very high flexibility, reuse of the timing actuators, direct synchronous output in different points of the machine reacting to an interlock, implementation of the Fast Interlock with very low cost increase as the timing optic fiber network is reused or the possibility of combined diagnostic tools implementation for triggers and interlocks. To enhance this last point a global timestamp of 8ns accuracy that could be used both for triggers and interlocks has been implemented. The system has been designed, installed and extensively used during the Storage Ring commissioning with very good results.

INTRODUCTION

Alba [1] is a synchrotron light source under installation located nearby Barcelona. This 3 GeV third generation light source is planned to deliver the first X-rays beam to the users in 2012. The Linac has been commissioned in 2008, the booster in 2010 and the Storage Ring in 2011. The seven Beamlines included in the “Phase One” are being commissioned at the end of 2011.

The timing system is one of the critical systems in a synchrotron. Its main function is to synchronize the operation of the different parts of the accelerator. Including the injection procedure (Linac, Booster and Storage Ring) and the diagnostic devices.

When the Alba project started the initial triggering specifications were fixed by Accelerators Division. The main request was being able to generate triggers synchronously with the RF master frequency (499.654MHz in Alba case) in different points of the machine with a very low jitter (bellow 100ps), and to adjust the delay of some triggers in steps lower than 16ns.

Reviewing the state of the art of the timing systems developed in similar facilities it was found that two main approaches had been adopted historically: signal based model and event based model.

In the signal based architecture one reference frequency is downsampled to generate some trigger pulses that finally are distributed and delayed at each one of the destination points where it is needed to produce a trigger.

In the event based model the transmission is not of different pulses (or train of pulses) but of a code which is generated synchronously to a master frequency and transmitted following a typical start topology to all the points where the trigger output has to be produced. At each one of these points the continuous stream of these codes is decoded and a trigger pulse with an adjustable delay is generated if needed. One of the main difference between both approaches is that in the event based case all triggering information reach all the points of the facility. That involves full flexibility to change trigger parameters (as the decodification is remotely controlled) and a much easier maintenance. This is the main reason why all the newest synchrotrons have followed this architecture lately.

At some point other requirements were needed by Accelerators division about some trigger and fast interlock systems needs. The request could be divided to have two independent main characteristics: being able to produce synchronous outputs in different points of the machine and being able to react very fast to an interlock.

The idea of combining all those systems in a unique one which could give the maximum possible flexibility and performance came up. This paper explains how this system was defined as an upgrade of the Event based architecture and the process that was followed to implement and commission it.

STANDARD ARCHITECTURE

To establish a common framework a brief description of the different elements in the event based timing architecture will be done (please refer to Figure 1).

The first element is a device that generates the codified event stream (from now called EVG) synchronous to the RF frequency. In the case of Alba, it was also requested being able to generate events synchronous to a external 50Hz signal. The aim was being able to produce triggers synchronous to the AC 220V 50Hz power to minimize any possible effect in the ripple voltage of the power supplies for some specific triggers.

The event stream generated with the EVG is distributed following typical tree architecture to all the points where the trigger needs to be generated. To spread the signals there are some units called Fan Outs that produces multiple identical stream outputs from one event stream input.

Finally in the different destination points there are elements called Event Receivers (EVR from now) that decodes the stream. If some predefined event codes are received the trigger output with some preprogrammed characteristics (delay, pulse width, etc…) will be executed. The outputs will be synchronous to the event stream input and therefore to the master RF frequency in all the facility.

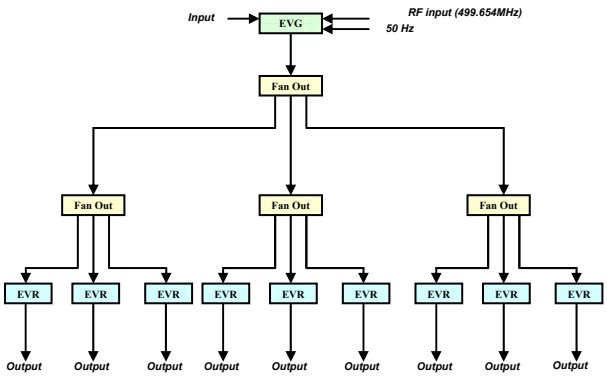

Figure 1:Event based timing architecture.

At Alba two different tenders were published: the first one included the electronics boards based in cPCI standard that were needed for each module (EVG, Fan Outs and EVRs). Among the bidders offers the contract was awarded to Micro-Research Finland Oy [2].

And in the second tender the optic fibers used for the timing network were included. More than 10Km of OM3 cable with 4 fibers were requested with a very low dispersion in the optic fibers length to avoid thermal effects in the delay change and also to minimize the delay adjustment procedure in the facility. The contract was awarded to Reichle & De-Massari (R&M)[3].

For very specific cases a delay adjustment within the bunch time was needed to be generated (in Alba case 2ns): Linac gun trigger, an streak camera used for diagnostic purposes and in the booster kickers magnets. For these cases a special product was requested to MRF which provided a special 6U cPCI card allowing delay adjustment of 10ps steps (EVRTG-300).

FAST INTERLOCK ARCHITECTURE

General Layout

When other triggering specification needs arose which could not be fulfilled with the Alba Equipment Protection System [4], as the capability to react synchronously to an interlock in different points in the machine or to react to an interlock in the sub miliseconds range, different approaches about how to fulfill such needs were considered.

The timing system already offered a platform to produce synchronous outputs and also the transmission of the triggers was fast enough. Moreover the timing network already covered more than 80 different points all over the accelerator. Therefore the idea of upgrading the timing system implementing a bidirectional communication link was considered as the best possible option.

Also there were different factors that reinforced following such direction: the first one was the high flexibility that this architecture would involve, the second was that the diagnostic tools of events timestamp that already were going to be implemented in the timing system could also be used for interlocks diagnostics. Doing in this way the timing diagnostic tools could become a very powerful tool to be used as it will be described later.

Finally from the cost point of view it appeared as a very good solution as the timing network was composed by four fiber cables (following a market "de facto" standard) which only one was used at that time.

Therefore the objective was being able to generate an independent event stream from the EVRs towards the EVG using the same timing protocol. That stream of events would be needed to be multiplexed in a new unit called “Fan Out Concentrator” which would become one of the main parts of this new architecture as it was needed to manage collision or saturation scenarios. Finally the interlock event stream would arrive to the EVG that would introduce the event in the normal timing event flow so the interlock could arrive to all the points of the machine following the same path as the rest of triggers generated by the EVG. Please refer to Figure 2 for a simplified architecture diagram.

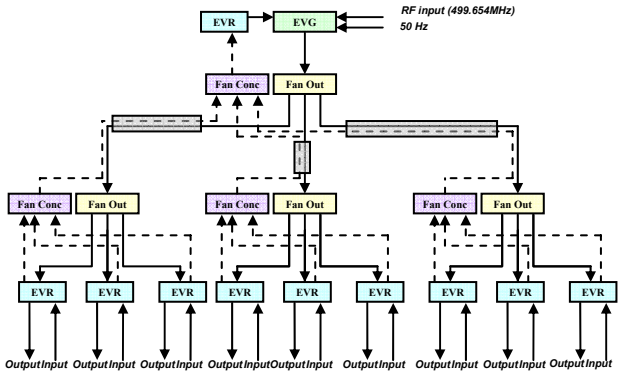

Figure 2: Fast Interlock System architecture.

To generate this system, MRF was contacted and a collaboration agreement was achieved that lead us to a new EVR firmware with all the capabilities implemented and with the development of a new unit by MRF: the Fan-Out Concentrator (cPCI-FCT-8).

Response Time

In a typical timing system the delay between the trigger generation at the EVG and its distribution to the EVR is not an important issue as far as all the triggers outputs are delivered synchronously. But if the timing system is required to react to interlocks it is needed to characterize the response time of the system.

In the hardware implementation we are using the codification/decodification process of the events uses 30 event clock cycles. In the case of Alba is 125MHz that is lead us a total is 240ns. So taking into account the number of stages present in Alba.

$$\text{time} \approx 240\ \text{ns} \times 7\ \text{stages} + 5\ {}^{\text{ns}}\!/_{\text{m}} \times 500\ \text{m} \sim 4.2\ \mu\text{s}$$

To understand the real magnitude of this number it has to be considered that the interlock propagation from any-to-any part to the machine and production of a reaction is a value closer to 4µs where 60% of the time is used just for signal propagation over the optic fiber. So no big margin for speed propagation improvement seems to exist for the future.

Timestamp

Each EVR has an internal time reference. In the case that a predefined event is received a timestamp log is possible to be acquired. This feature that is useful for triggering information it is still more interesting when interlock information can be acquired with common time reference being possible to match triggering effects and interlocks.

The same timing network is used to distribute the global clock reference to all EVRs. The system is based in a in a GPS receiver with a built in OCXO oscillator that provides PPS with an accuracy higher than ±100ns. Once this pulse is generated a reset for the seconds counter is sent via an event by the EVG. Everytime the reset is produced in a EVR an internal counter of 125MHz clock with accuracy higher than 40ppm is restarted.

For managing the PPS distribution and transmitting the UTC 32 bit seconds value an in-house electronic module was developed at Alba: the NTP Timestamp Server.

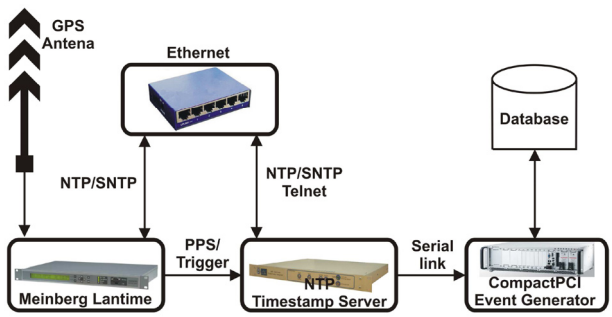

Figure 3: Global time reference distribution.

In the end at each EVR is available a timestamp of UTC time in seconds plus 8ns accuracy. So any event or interlock can be timestamped with 8ns accuracy.

APPLICATIONS

In this section a brief description of the practical applications where the Fast Interlock system has been used is presented.

RF Plants Fast Interlock

In total there are seven RF plants at Alba; six in the Storage Ring and one in the Booster. It has been developed in-house an electronic module that centralizes the safety conditions under which each one of the plants can operate (Figure 4). If those conditions are not fulfilled the plant is stopped locally and a different Fast Interlock event for each plant is generated. That event will execute in less than 5 µs all preprogrammed diagnostic and safety actions.

The unit can detect interlocks from three different RF detectors, 8 independent Arc detectors, one timing input (link to the Fast Interlock System) and a dry contact (normally used for slow signals as vacuum loss scenario detection). The reaction time is of 175ns with 5ns jitter and everything is fully programmable from its 10/100 Base-T Ethernet Port.

Internally an Alarm Log Engine has been implemented acquiring a maximum of 512 alarms sequences with 20ns timestamp that can be correlated with the global timestamp of the machine.

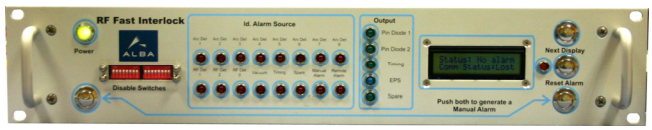

Figure 4: RF Fast Interlock Module.

BPM Fast Interlock

Alba has in total 176 BPM distributed around the 16 sectors of the Booster and the Storage Ring. Each one of the BPM is acquiring the X and Y orbit continuously. In case of an eventual distortion of the orbit outside certain predefined limits an interlock is generated.

In case that an BPM interlock is detected a Fast Interlock event is generated and will produce an immediate stop of the RF Plants and a distribution of a Post Mortem trigger to the rest of BPMs for acquiring a synchronous snapshot of the orbit. It has been defined 32 different fast interlock events: one for each one of the sectors of the SR and the booster. Doing in this way it can be easily identified the first sector where the orbit was disturbed which is a useful information for the Diagnostic group.

In the next figure a complete sequence of one BPM interlock timestamped with the Fast Interlock System is shown. A orbit interlock is detected in one BPM in SR in sector 13 and timestamped. The Fast Interlock system induces a shutdown of the six RF Plants 4µs later and that leads to a loss of the orbit in the rest of BPM sectors after 290µs.

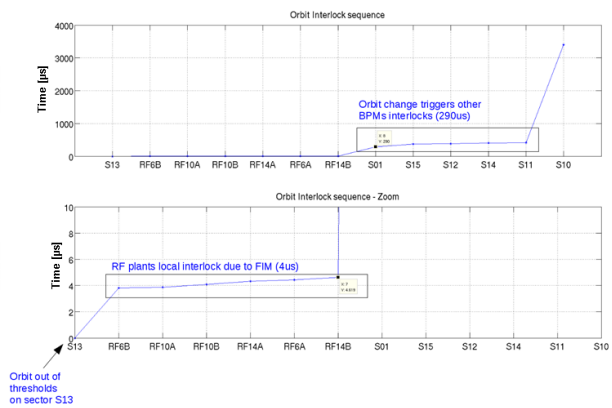

Figure 5: Orbit interlock sequence.

Front Ends

An independent Fast Interlock event has been defined for each Front End. In case of a vacuum loss scenario the RF plants will be automatically stopped to minimize the quantity of beam time that the vacuum gauges that closes had to absorb and to timestamp the beam loss.

CONCLUSION

In this paper a new architecture for the timing system has been proposed as an upgrade of the typical event based architecture that allows for fast interlock system implementation.

Several years have been needed since the initial idea came up until all the system has been developed, implemented, tested and commissioned. Currently the system has been working without problems for more than one year giving excellent service to Accelerator Division for the machine operation and completely integrated in the Control System (please refer to [5] for detailed information as it has been decided to detail the software implementation in an independent document).

Among the list of benefits one would highlight its very fast reaction time achieved that currently seems difficult to improve as 60% is spent in the transmission of the signal over optic fibers, the extremely high flexibility and reconfigurability, easy maintenance, its relatively low cost and the global combined timestamp tool that can be used both for triggers and interlocks using a common time reference.

CONTRIBUTION

Many people have contributed to this project over the time. We would like to thank to the whole Accelerator Division specially to F.Pérez, A. Olmos, U. Iriso and A. Salom[on leave]. Also to S. Astorga, X. Fariña, J. Pagés, A. Ruz and B.Saló for their dedication to the timing network check. To Y.Chernousko (Diamond Light Source) for his inestimable help in the first steps of this trip. And to J. Pietarinen from MRF [2] for getting involved in this project with the technical excellence we are already used from him.

ALBA HIGH VOLTAGE SPLITTER - POWER DISTRIBUTION TO ION PUMPS

J. Jamroz, E. Al-dmour, D. Beltran, J. Klora,
R. Martin, O. Matilla, S. Rubio-Manrique

CELLS-ALBA Synchrotron, Cerdanyola del Valles, Spain

Abstract

High Voltage Splitter (HVS) is an equipment designed in Alba that allows a high voltage (HV) distribution (up to +7kV) from one ion pump controller up to eight ion pumps. Using it, the total number of high voltage power supplies needed in Alba's vacuum installation has decreased significantly. The current drawn by each splitter channel is measured independently inside a range from 10nA up to 10mA with 5% accuracy, those measurements are a base for vacuum pressure calculations. A relation, current-pressure depends mostly on the ion pump type, so different tools providing the full calibration flexibility have been implemented. Splitter settings, status and recorded data are accessible over a 10/100 Base-T Ethernet network, none the less a local (manual) control was implemented mostly for service purposes. The device supports also additional functions as a HV cable interlock, pressure interlock output cooperating with the facility's Equipment Protection System (EPS, ref: [1]), programmable pressure warnings/alarms and automatic calibration process based on an external current source. This paper describes the project, functionality, implementation, installation and operation as a part of the vacuum system at Alba.

INTRODUCTION

Alba's vacuum system contains 458 7kV ion pumps, 392 of them were selected to be supplied by HVS-s, it means that 392 HV outputs had to be distributed in the different positions of the machine, in the most efficient way and reducing costs for the HV cables. The best installation topology was designed and finally 83 HVS units were produced and installed, "20x8channel" supplying the booster and "63x5channels" supplying the storage ring, front ends and linac.

High Voltage Splitter was a collaborative project between Q-Lambda company [4] which developed a current measuring solution (sensor) under the high voltage, Vacuum Section in Engineering Division which provided necessary theoretical assumptions and calculations, R&D Section in Engineering Division which managed mechanical design, Electronics Section in Computing Division [2] which developed the project, managed a HV current sensor evaluation, upgrades and troubleshooting, and Control Section in Computing Division which developed a TANGO control system.

IMPLEMENTATION

HVS contains two systems: low voltage electronics which manages data processing, control, communication, and high voltage electronics which supplies ion pumps, splits the high voltage and measures the current consumption of ion pumps.

A typical HVS application is presented in Figure 1. The standard arrows show an Ethernet data flow, while a user records pressure measurements each second. The big arrows depict the high voltage distribution from one high voltage power supply to eight ion pumps. The checked arrows provide a basic implementation storing time related data into a database.

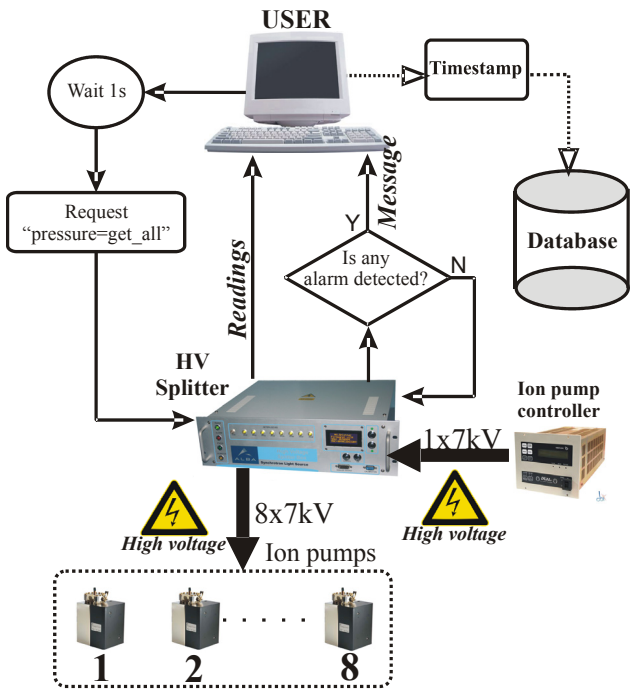

Figure 1: Typical application.

During this process, the current drawn by each HV channel is measured independently.

PRESSURE MEASUREMENT

Extensive performance evaluations under high voltage conditions have been done to proof the functionality. The pressure measurement involves a current consumption conversion into a pressure reading under constant conditions which are configured and predefined by a user,

and determined by a high voltage value and ion pump model.

Theory

A real correlation example current-pressure describing 25[lps] noble diode ion pump supplied with constant high voltage U=7kV is presented in Figure 2.

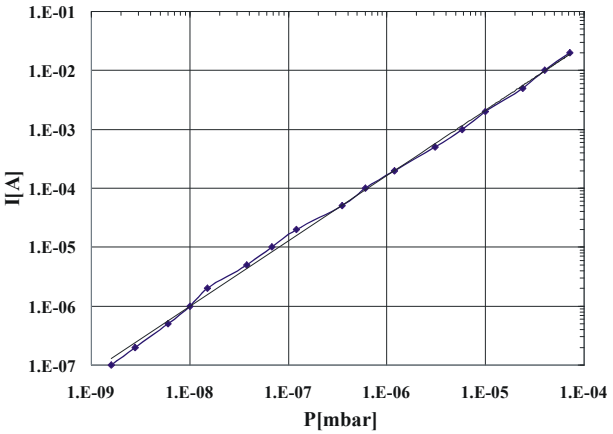

Figure 2: 25lps noble diode ion pump, Uconst=7kV.

The characteristics is almost linear and can be described by Equation 1. The chart, equation and related theoretical support were provided by Gamma Vacuum [3]- manufacturer of ion pumps. Generally all other pump models (25, 75, 150, 300, 500[lps]) strongly correlate with the theoretical formula.

$$P[\text{mbar}] = \frac{0.08778 * \frac{5600}{Voltage[\text{V}]} * Cal_{Factor} * I[\text{A}]}{IonPump_{Speed}[\text{l/s}]}$$

Equation 1: Default pressure implementation.

The HVS current measurements are based on Q-Lambda sensors [4]. The sensors are current-to-voltage converters which provide a linear voltage output (0-8V) related to a logarithmic current input (10nA-10mA). A real conversion is presented in Figure 3, the characteristic "V=f(I)" shows a difference in current readings acquired under low voltage using a current source reference and high voltage (7kV) supplying ion pumps.

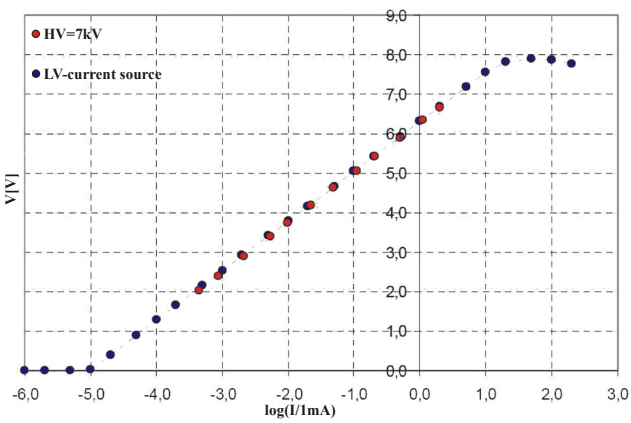

Figure 3: Current measurements "V=f(I)" under high and low voltage conditions with a Q-Lambda current sensor.

The output voltage dispersions are almost negligible, lower than 5%, so tests and calibration issues can be performed under low voltage without any quality risk.

Current Calibration Process

HVS integrates an automatic calibration process based on a Keithley 2611A source/meter working as a current generator/reference. The implementation is presented in Figure 4.

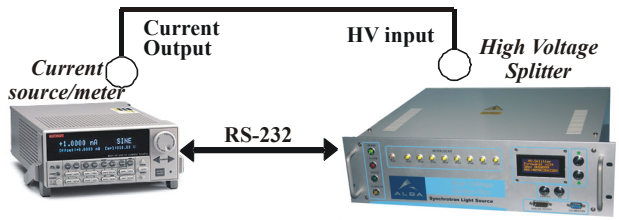

Figure 4: High Voltage Splitter calibration.

The Keithley current source is able to set a fixed current with an error lower than 0,001%. Two connections are necessary between those two instruments to execute the calibration: the serial RS-232 link and current link connected to a splitter channel under the calibration. Once the process is executed, HVS takes a control over the Keithley source sweeping all the current ranges and completing the process. For some specific ranges, HVS needs some time in order to compensate internal thermal drifts. This process is completely transparent for a user and assures 5% accuracy inside the range 10nA up to 10mA. The calibration data are fully available remotely for backup purposes.

Pressure Reading Implementation

A user can bind a pressure value to a current one making a set current-pressure, once the set is prepared, can be applied to any channel determining calculations of the final pressure readings (e.g. like in Figure 2, blue line). It means, a user can adjust HVS pressure readings with a full flexibility (even nonlinear characteristics), in total 13 sets can be programmed: one per each ion pump model (25, 75, 150, 300, 500[l/s]) and 8 independent ones. One set has to be tied to one channel, by doing it this way, a user can adjust the pressure readings of a channel for his particular real installation determined by real measurements, experience, or other gauge instruments, and not being fixed purely to the theory. If those sets has not been inserted, the default configuration is applied based on Equation 1 which gives very accurate readings as well.

ALARMS & PROTECTIONS

Pressure Alarms

Two different pressure alarms can be configured with two independent thresholds for each channel. If the

pressure reading of any channel exceeds the first threshold level, a warning message is visible in the splitter front panel and also the control system is informed with a proper warning event over Ethernet. The second pressure alarm activation provides the same warning/alarm messages, plus opens a dry contact output informing Alba's Equipment Protection System [1].

Equipment Protection System

An exceptional vacuum loss scenario is indicated with the dry contact EPS output. As this trigger shuts down the accelerator, a redundant activation mechanism has been implemented. It is possible to set up to 8 different EPS alarm configurations which contain alarm conditions for different ion pumps (channels). One particular configuration example is presented in Table 1, it shows that the machine will stop if the second pressure threshold is exceeded in the channels: Ch2,Ch3 and Ch8.

Table 1: EPS Alarm Configuration Example

	Ch1	Ch2	Ch3	Ch4	Ch5	Ch6	Ch7	Ch8
EPS Config		X	X					X

HVS has also an external interlock input. Its purpose is to combine the EPS alarm with any other external interlock e.g. provided by any ion pump controller etc.

Cable Interlock

In order to increase security during the instrument operation, a cable interlock system has been implemented. An ion pump controller provides a cable interlock security mechanism which generates a 5V high impedance signal to interlock circuitry inside a high voltage cable. A functional diagram is depicted in Figure 5.

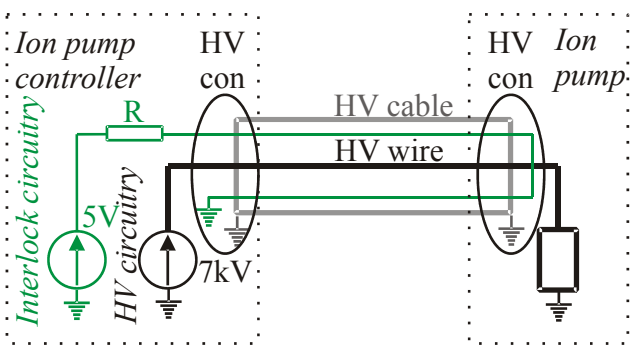

Figure 5: HV cable diagram for one ion pump controller and one ion pump.

When a high voltage cable is connected to an ion pump, a shortcut is applied to the interlock circuitry. In this way, the controller senses the high voltage cable status. If a low level is detected, it means that the high voltage cable has been correctly connected and the high voltage output can be enabled.

In case of HVS, a cable interlock distribution system has been designed to preserve this security protection. Internally all interlock signals are connected in series. It means that all high voltage cables connected to their splitter have to be correctly connected to ion pumps, otherwise the high voltage will not be enabled by a supply controller as the cable interlock protection will prevent that. HVS also detects which is a cable that is unconnected (failing) and reports it on its display and remotely. The HVS interlock distribution is depicted in Figure 6.

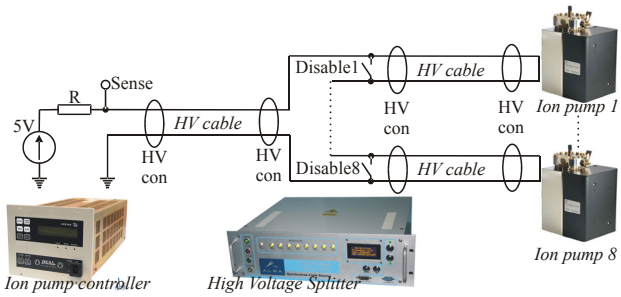

Figure 6: Cable Interlock diagram for one ion pump controller, HVS and 8 ion pumps.

CONTROL & OPERATION

Local Control

The local control is based on a keypad which allows to navigate between two submenus:

- "Measurement menu" - shows actual measurements.
- "Settings menu" - allows to change configurations.

Remote Control

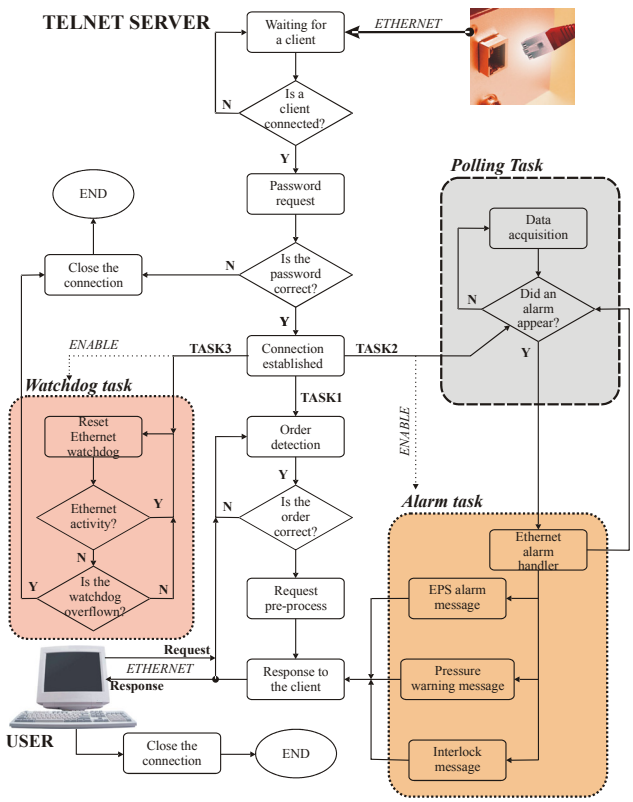

Figure 7: Telnet server – block diagram.

HVS provides its settings, status, measurements and records over Ethernet network. A DHCP protocol applies an automatic IP configuration and Telnet provides a bidirectional interactive text-oriented communication. Over 80 different string commands are available giving a full flexibility for any kind of implementations, plus an event based system informs a control room about any exceptional situations. The remote workflow is presented in Figure 7.

Operation Modes

HVS has two operation modes: commissioning and secure. In the commissioning mode, a user has unrestricted access to configuration settings using the local control menu. In the secure mode, the access to the configuration settings are limited only to Ethernet commands. A change from one mode to another can be done only remotely, so via the control room.

HVS is aimed to work in the secure mode. It assures that there is no accidental action done with the local control which could generate some alarms in the machine.

CONCLUSIONS

High Voltage Splitter has been a collaborative in-house project between many different sections: Vacuum, Mechanics, Electronics and Controls at Cells. The project development and tests took around one year, and first units were applied in first vacuum installation of the booster. From that point on, HVS-s have been fully working for more than 2 years also supplying the storage ring, front ends and linac. In total, 83 units were installed which made HVS a key instrument in Alba vacuum system.

Full implementation flexibility, complete integration to Alba's TANGO based control system, diagnostic purposes and cost efficiency make this project a great solution and improvement of synchrotron technologies.

Abstract

High accuracy low current readout is an extensively demanded technique in 3rd generation synchrotrons. Whether reading from scintillation excited large-area photodiodes for beam position measurement or out of gold meshes or isolated metallic coated surfaces in drain-current based intensity monitors, low current measurement devices comprise an ubiquitous need both for diagnostics and data acquisition in today's photon labs. In order to tackle the problem of measuring from various sources of different nature and magnitude synchronously, while remaining flexible at the same time, ALBA has started a project to develop a 4 independent channel electrometer. It is based on transimpedance amplifiers and integrates high resolution ADC converters and an Ethernet communication port. Each channel has independently configurable range, offset and low pass filter cut-off frequency settings and the main unit has external I/O to synchronize the data acquisition with the rest of the control system.

INTRODUCTION

With around 110 channels distributed in 7 beamlines, current measurement based diagnostics are the most common in Alba photon labs.

The most extended method for low current readout relays on range-configurable transimpedance amplifiers that convert the currents generated in the different sources into voltages. Those voltages are later read out either by ADCs or converted to pulses by Voltage to Frequency Converters (VTFs) and counted in counter cards. Lately, also some solutions based on charge integrators are appearing in the market, but transimpedance amplifiers are still the most common battle horse when it comes to low current measurement.

The dynamic range of the aforementioned currents spans from 1mA to few pA with bandwidths below a few kHz.

Apart from the characteristics of the current signal, it's important to mention that a usual problem coming up while measuring such low currents is the appearance of noise coupled, most often, from the power network, either through the cables or any other element of the setup. While noise coupling reduction techniques like proper shielding are the most effective solution, preventing the noise appearance, one desirable feature of the subsystem in charge of the measurement, especially for slow varying signals, is the possibility of selecting low band pass filters that attenuate out-of-band noises.

The beamline control system reads these currents with acquisition times typically in the range of 1ms to 1s and quite often the acquisition window must be precisely synchronized with other elements in the lab environment.

The different diagnostic equipment come with channels arranged in different configurations, from typical single channel intensity monitors to dual or quad-channel in 1D or 2D X-ray beam position monitors.

Beyond pure current measurements, beamline scientists often face the need of automate the compensation of low-frequency drifts due to thermal load changes or mechanical instability in optical components as mirrors or monochromators. To do that, an output signal to steer piezoelectric actuators or stepper motors can be generated after processing the signal acquired from photodiodes or drained out of isolated metallic surfaces exposed to the X-rays.

In order to provide us with a general platform to confront all those applications having as common link the measurement of low currents the Electronics section in Alba Computing Division launched the AlbaEm project.

The main target of this project is to produce a modular, transimpedance amplifier based, 4 independent channel electrometer with Ethernet communication with the possibility of accepting I/O expansion boards.

In the next paragraphs we detail the characteristics of the designed solution and the current status of the project.

SYSTEM ARCHITECTURE

The system architecture was chosen to maximize modularity to simplify at the same time future upgrades of the different subsystems, troubleshooting and maintenance.

The platform can be divided in the following main parts: Microprocessor board, current amplifiers (up to 4 units), main, I/O board and front panel board (see Fig. 1).

Current Amplifiers

With a first typical bipolar transimpedance amplifier layout stage and a second voltage gain stage, the amplifier provides gains from 1E+4 to 1 E+10 V/A for ±10V output in 8 full ranges from 1mA to 100pA. In the first stage, specific circuitry provides input offset voltage adjustment down to 1μV.

This first part feeds a second order low pass filter with 3dB cut-off frequency configurable to 100Hz, 10Hz and 1Hz. The filter can also be bypassed.

Finally, an output buffer stage allows polarity inversion and feeds both the upstream internal ADCs and a rear panel connector.

The analog ground is isolated from the equipment chassis to prevent ground loops and all the configuration is SPI based and stored in an onboard FLASH memory.

Microprocessor Board

The Electronics section in Alba Computing division has made extensive use of Rabbit microprocessor MiniCores

[1] in the past. These modules consist of small form factor PCBs with an embedded Rabbit microprocessor, flash and RAM memories and ethernet PHY. The microprocessor has a CISC arquitecture and supports different peripherals.

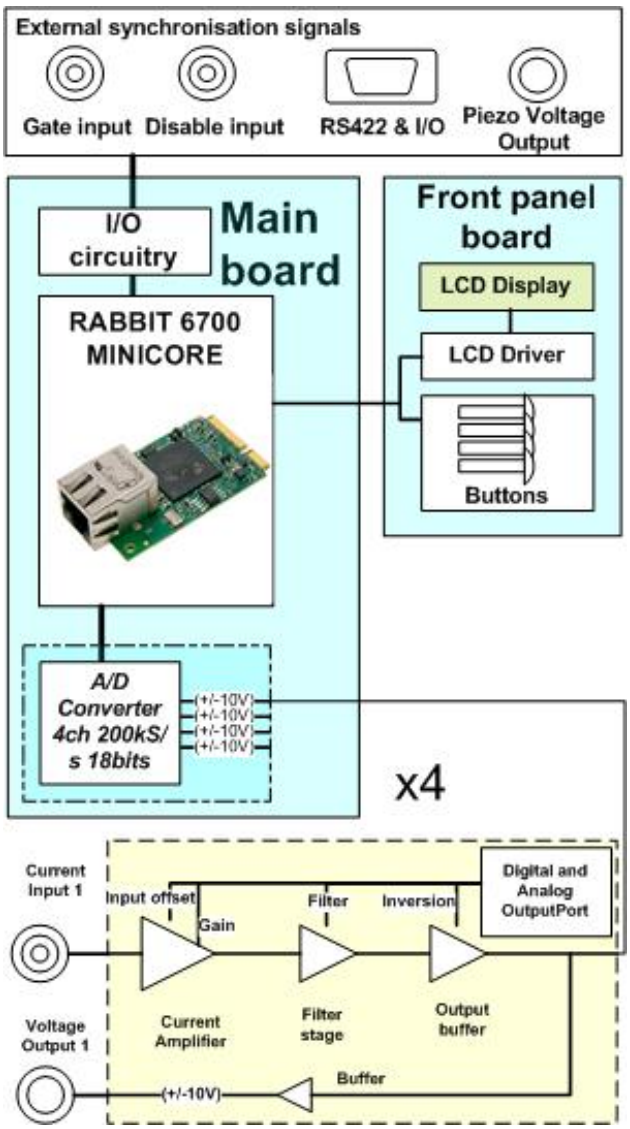

Figure 1: General system architecture.

The accumulated know-how and all the libraries developed for previous projects made the choice of one of these minicores the best option to minimize development time.

In the chosen MiniCore a 200MHz microprocessor is the central module. It has 1MB of RAM that can be used for data storage purposes. The microprocessor cares about the control and configuration of the rest of the subsystems either through SPI or its 8-bit external parallel bus. Communication is achieved via the onboard 10/100Mb Ethernet port.

Main Board

The main board hosts the rest of the boards and the ADCs and all the necessary gluing circuitry. Steered from the microprocessor board, a fast quad-channel 18bit bipolar ADC that can be run at sampling rates up to 200kHz carries out the data acquisition. With 1MOhm impedance inputs, an onchip 2nd order antialiasing filter and a configurable sinc digital output filter that helps to improve SNR and reduce data throughput unnecessary for low bandwidth, it fits perfectly the needs of an application like this.

I/O Circuitry

This subsystem contains the circuitry to adapt digital signal levels between the microprocessor and the exterior both for the synchronisation input signals and the output signals generated in applications where regulation of external actuators from current input signals is necessary.

Front Panel

Despite the electrometer is meant to be fully controlled remotely, a basic user interface will be available at the front panel so that it can be used as bench-top unit if necessary. The panel has an attached board carrying the minimum electronics to steer an LCD display and interface buttons to the microprocessor.

PROJECT STATUS

The first amplifier prototype was designed in November 2010 and first tested in January 2011. Thanks to the good results of the first amplifier prototype, the facility gave thumbs up to the project one month later. It was decided that it would be produced a number of electrometers for the beamline commissioning in October this year. Due to the strong schedule constraints, it was decided to mount in those electrometers a microprocessor and a 12bit ADC already used in another project. This board would be replaced later by the final one in the elements were the extra resolution would be required.

In the next paragraphs are described the performance of the designed amplifier and the acquisition board used for this first version of the device (see Fig. 2).

Figure 2: Low resolution electrometer rear panel.

Amplifier

The amplifier design has successfully reached the final stage. With up to 5 decades of noise free dynamic range, 3.2kHz bandwidth (1.5kHz for the last three ranges), filters providing extra out-of-band noise rejection, input offset voltage reduction down to 1uV (optimum for reading pA currents from large PIN diodes without saturating the amplifier output) and low drifts, it provides a very good foundation to add all the planned electrometer functionality (see Table 1).

In Table 1 are displayed the noises measured at the output of the amplifier and the correspondent SNR for each range and three different filter configurations. They were measured at constant input current of 10% of each range and a 20bit ADC. The output RMS voltage noise measured has been converted to current units to simplify the table interpretation.

Control and Signal Acquisition Boards

The work on the first prototype of the fast ADC main board is ongoing. In parallel, and based on a development for a previous inhouse project, the microprocessor and a 12bit ADC have been used to produce a lower resolution electrometer. This version, has been designed keeping it compatible with an upgrade to the future high-end ADC. That upgrade will just need the replacement of the main board with the one containing the new ADC, keeping chassis, amplifiers, microprocessor and firmware (with the evident exception of exchanging the low level library accessing the ADC by the new one).

Table 1: RMS Output Noise in Current Units and SNR for the Different Range and Filter Configurations

	No filter		10Hz		1Hz	
Range	**RMS**	**SNR(dB)**	**RMS**	**SNR(dB)**	**RMS**	**SNR(dB)**
1mA	7nA	103	7nA	103	7nA	103
100µA	700pA	103	700pA	103	700pA	103
10µA	300pA	90	70pA	103	70pA	103
1µA	50pA	86	7pA	103	7pA	103
100nA	4pA	88	800fA	102	700fA	103
10nA	700fA	83	150fA	96	80fA	102
1nA	500fA	66	100fA	80	20fA	94
100pA	500fA	46	100fA	60	20fA	74

Performance

This model has a limited sampling rate of 1kHz and a maximum bandwidth of 500Hz (due to the presence of the antialiasing filter). While the 12bits resolution of this electrometer version's ADC and its internal noise are an evident performance penalty, its use as diagnostics according to commissioning plan will be most often for acquisitions in the 0.1s range where averaging improves the total system noise.

The total ADC subsystem noise was found to be 7mVrms (for a ±10V span) that averaged by 10 or 100 samples (acquisition times of 10ms or 0.1s for the fixed 1kHz sample rate) leaves good 4 decades of noise-free current measurement in each range (provided that the ADC is the noise limiting element for that range).

Functionality

In order to ease the integration of the electrometer in the beamline control system, the following features have been implemented:

- Digital filter averaging: A size configurable moving average filter can be enabled to low-pass filter the digitized currents.
- Buffered measurements: The electrometer saves in its memory a sequence of a software predefined number of acquisitions. This acquisition "points" are available to the beamline control system as soon as they are acquired. It is not necessary to wait till sequence acquisition end to get the values.
- Software triggered acquisitions: The electrometer averages current readouts at the maximum sampling rate during a preconfigured time window after a command arrival.
- Hardware triggered acquisitions: A TTL trigger signal accessible from the rear panel starts an acquisition for a preconfigured time window
- Hardware gated acquisitions: The TTL signal defines the beginning and the end of the acquisition time window.
- Events: A list of clients can be provided by software. When the electrometer finishes an acquisition it sends to those clients the acquired values via UDP. This feature reduces the need of polling and the amount of network traffic.
- Remote firmware update. New features can be added remotely via TFTP. This reduces the maintenance and firmware update times and simplifies the addition of new features.

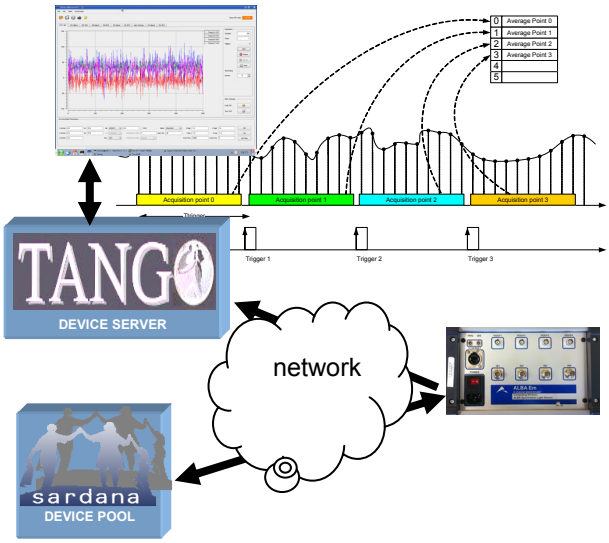

Figure 3: Integration in the beamline control system.

Integration in the Beamline Control System

The electrometer has been successfully integrated in SARDANA[2], the TANGO[3] based control system for instrumentation and data acquisition used at ALBA beamlines. In the current architecture, a python low level library to access the electrometer via UDP and a Sardana Pool Controller permit synchronization of measurements with other data acquisition in the beamline, while a TANGO Device Server acts as interface for GUIs (see Fig. 3).

SCHEDULE

The first amplifier prototype was designed in November 2010 and first tested in January 2011. In Fabruary of this year the project was finally approved and the first units with the 12 bit ADC were assembled and tested by May 2011. 25 electrometers were produced during summer for the beamline commissioning in October this year. During all this time the firmware has been steadily improved. The first fast ADC prototype is expected for February 2012. The implementation of functionality for optical equipment position regulation will come later.

CONCLUSIONS

AlbaEm is a living project. With very good results in the analog part of the design and an already mature functionality, it can fullfill the scientist requirements for the October 2011 commissioning at the Alba beamlines.

The amplifier is considered to be the final one for general purposes, though other versions could be built in case more specific applications arise.

An acquisition system based in a 12bit ADC used in a previous inhouse project has been designed, implemented and tested. The units are prepared to be updated with just one part replacement wherever extra resolution is necessary. A fast 18bit ADC is expected to be ready the first quarter next year.

In less than one year, the team has been able to put together 25 units of a robust system that fulfills the basic needs for current based diagnostics. Currently, these 25 units are already installed in the 7 beamlines and ready for the first photon beams.

Moreover the high potential of the new updates should convert AlbaEm in a platform that will allow us to tackle all the future needs of the scientists at Alba beamlines.

ACKNOWLEDGEMENTS

We want to thank P. Fajardo, H. González and R. Hino from the Detector and Electronics Group at the European Synchrotron Radiation Facility for sharing with us their knowledge on current measurements and transimpedance amplifiers. Without their help this project wouldn't have come to results so fast.

We also want to profit to these lines to thank A. Milán and G. Cuní in the Controls Section of ALBA Computing Division for their contribution in the integration of the electrometer in the contol system.

And last but not least, we want to thank to A. Camps and the ALBA Electronic Section technicians S. Astorga, X. Fariña, J. Pagés, A. Ruz and B. Saló that worked hard this year in order to meet all the deadlines.

THE TIMBEL SYNCHRONIZATION BOARD FOR TIME RESOLVED EXPERIMENTS AT SYNCHROTRON SOLEIL

J-P. Ricaud*, P. Betinelli-Deck, J. Bisou, X. Elattaoui, C. Laulhé, P. Monteiro, L. S. Nadolski, G. Renaud, S. Ravy, M. Silly, F. Sirotti, Synchrotron SOLEIL#, Saint Aubin, France

Abstract

Time resolved experiments are one of the major services that synchrotrons can provide to scientists. The short, high frequency and regular flashes of synchrotron light are a fantastic tool to study the evolution of phenomena over time. To carry out time resolved experiments, beamlines need to synchronize their devices with these flashes of light with a jitter shorter than the pulse duration. For that purpose, Synchrotron SOLEIL has developed the TimBeL board fully interfaced to TANGO framework. This paper presents the main features required by time resolved experiments and how we achieved our goals with the TimBeL board.

INTRODUCTION

In synchrotron facilities, bunches of electrons turn inside a storage ring. Each time a bunch passes in front of a beamline, the beamline receives a flash of intense light. These light pulses are used by scientists to study phenomena evolving over time.

The short duration of the flashes allows the experiment scientist to freeze the current state of the sample. By analogy with photography, when the exposure time or the flash duration is too long, a moving subject will appear fuzzy on the picture (Figure 1). If the exposure time or the flash time is reduced, the subject appears clearly.

Figure 1: Fuzzy picture due to long exposure.

Thanks to the circular storage ring of a synchrotron facility, the light flashes occur continuously and at the revolution frequency. Using this stroboscopic effect, it is possible to study the evolution of a sample over a long period of time.

At Synchrotron SOLEIL, three main bunch filling patterns are dedicated to temporal studies: single bunch, eight bunch and hybrid modes (Figure 2). The associated flash frequencies are 847kHz for the single bunch and the hybrid modes, and 6.77MHz for the eight bunch mode. The flash duration is between 20ps to 40ps RMS. A low alpha mode to reduce this time down to 4ps will be proposed to users by the end of the year.

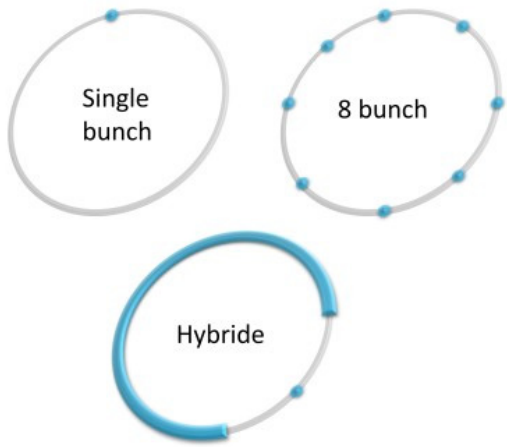

Figure 2: Hybrid, single and 8 bunch filling mode.

REQUIREMENTS

Synchrotron light flashes are not sufficient for scientists to perform time resolved experiments. They also need to synchronize their devices with bunches of electrons flying inside the storage ring, and delays must be added to compensate for cable and device time offsets (Figure 3).

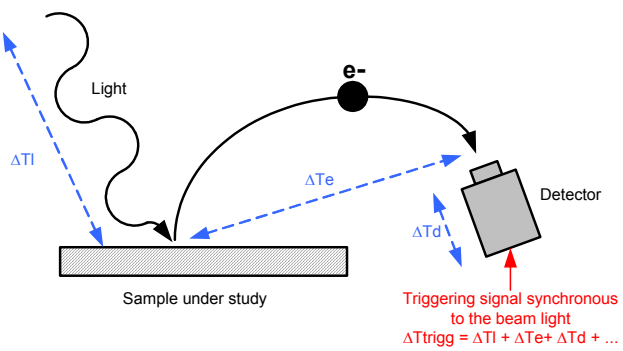

Figure 3: Delay offsets.

Because there are no dedicated pickup electrodes at Synchrotron SOLEIL, the synchronization triggers are generated from the radio frequency clock (352.196MHz). To guarantee synchronization with each bunch of electrons, the jitter of the system must be less than the bunch length (20ps RMS for the normal operating mode).

* jean-paul.ricaud@synchrotron-soleil.fr
# http://www.synchrotron-soleil.fr

As a first step a survey was performed to determine the needs of ten beamlines. A requirement matrix was made based on these inputs. It led us to design a system with: two independent outputs. Each output should provide a frequency between 88MHz and 0.76Hz. Each output should be delayed by step of #10ps between 0 and 1.44µs. This is enough to cover the full revolution period of the storage ring (1.18µs). The high / low level ratio of the pulse should be adjustable by the user. Clock outputs should be automatically synchronized to the storage ring clock. This allows us to always have the same time offset with respect to the electron bunch each time the machine is filled with a temporal bunch filling pattern. All these features must be user configurable through the control system.

To fulfill the above requirements, we have developed the TimBeL (TIMing BEamLines) board.

THE TIMBEL BOARD

The TimBeL system is a compact PCI board. It is made of a mother with one daughter board (Figure 4). All functions are performed inside a FPGA (Field Programmable Gate Array) implemented on the mother board. A PLX Technology [1] chip is used to communicate with the compact PCI crate. To enable experiments to remain always synchronous with the same bunch of electrons, the storage ring clock (CLK_SR) and the radio frequency clock (CLK_RF) are provided by the machine to beamlines. These clocks are used inside the FPGA as main clocks for state machines.

Because the jitter is too large on the FPGA outputs, a daughter board with a jitter cleaner has been added to the system. This board also provides delay lines for compensating time offsets by 10ps steps.

This architecture is versatile. Both the mother board and the daughter board may be upgraded independently to improve performance or to meet new requirements. Considerable work has been done on the PCB (Printed Circuit Board) to ensure good signal quality and integrity on both boards.

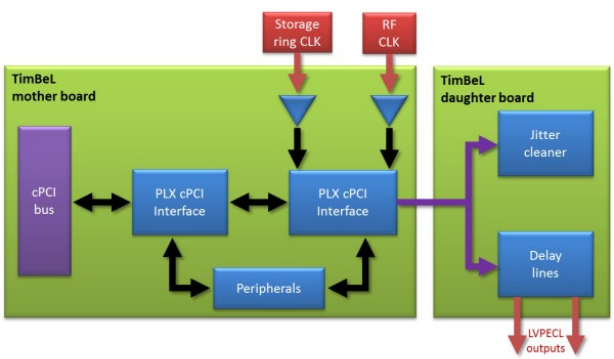

Figure 4: TimBeL architecture.

The mother board may also be used with other types of daughter boards for applications other than beamline synchronization.

A Tango device is used to configure the board outputs frequencies and time delays. This device accesses the FPGA's registers through a low level driver developed at Synchrotron SOLEIL (Figure 5).

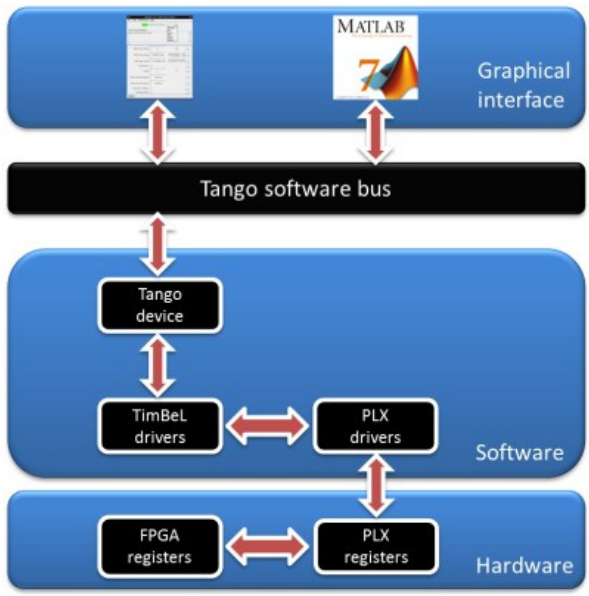

Figure 5: Software architecture.

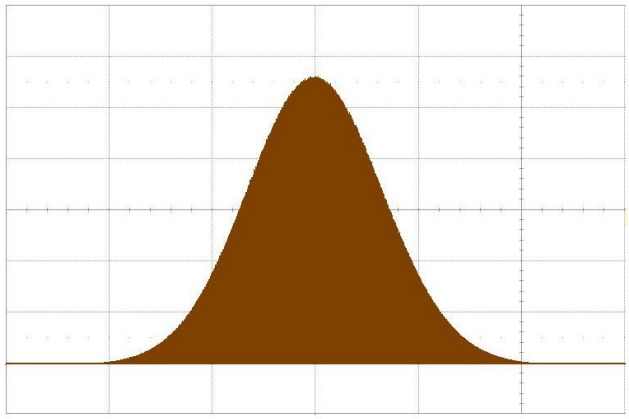
Mechanical parts of the system have also been designed by Synchrotron SOLEIL. Manufacturing of the boards is however entrusted to an external subcontractor.

JITTER PERFORMANCE

The major concern with the performance of the board was jitter. To remain synchronous to the electrons bunches, the jitter must be lesser than 20ps RMS and we have totally achieved this goal.

The differential LVPECL outputs have a jitter of 3.3ps RMS @ 6.77MHz which is the 8 bunch frequency (Figure 6). In single ended mode, a LVPECL output has a jitter of 3.8ps RMS @ 6.77MHz. The source jitter (R&S signal generator [2]) is about 7ps RMS. All measurements have been made with a LECROY SDA 820Zi-A oscilloscope [3].



Jitter Kit	Period@level	Freq@level	Cycle to Cycle
mean	147.64257 ns		-2 fs
sdev	3.31 ps		5.73 ps
pkpk	29 ps		50 ps
max dev+	14 ps		23 ps
max dev-	-15 ps		-27 ps
max dev	15 ps		27 ps
num	101.493e+3		67.644e+3
status	✔		✔

Figure 6: TimBeL jitter.

Although it was not designed for this purpose, an Input / Output port on the board is also frequently used by beamlines as it directly provides a single ended LVTTL clock. On this I/O, the jitter is about 24ps RMS, measured with a TEKTRONIX TDS6640B oscilloscope [4].

SOME RESULTS

Each year, a few weeks are dedicated to time resolved experiments. In 2011, Synchrotron SOLEIL has provided its users with 2 single bunch and 2 eight bunch runs. Already 4 weeks of hybrid operation have been allocated and for the commissioning of the pump-probe lasers on TEMPO and CRISTAL beamlines this mode will be delivered until the end of the year.

Since 2009, a total of 6 beamlines have been using the TimBeL board either with their own devices or with the devices of their users. To date, all users have been satisfied by this board and its functionalities. No major complaints or problems have been reported.

Among other experiments, during last month, CRISTAL beamline has used this board to study photoinduced spin transition in molecular crystal [5]. The TimBeL was used to trigger a laser, a shutter, and an XPAD3.2 [6] synchronously with electron bunches inside the storage ring.

At the TEMPO beamline pump probe experiments were performed to directly observe the effect of Oersted fields in nanostripes during spin injection [7]. The TimBeL board is currently used for time resolved photoelectron spectroscopy experiments [8] and will be an essential element for planned experiments which will couple fs-laser pulses with the soft X-rays coming from the beamline.

The TimBeL board was also used successfully to test the pseudo single bunch mode under study at Synchrotron SOLEIL [9]. In this special hybrid mode, an isolated bunch of electrons is placed on a different closed orbit with respect to other bunches, using a fast pulsed corrector, active only for the isolated bunch. A TimBeL board was used on the machine to trigger the fast kicker magnet at a frequency of 1kHz. Another board was used on the TEMPO beamline to trigger the Scienta SES 2002 synchronously to this bunch. The first results obtained at the end of 2010 were very promising. This is an innovative and on-going in-house development.

CONCLUSION

A few years after the commissioning of the machine synchronization system [10], Synchrotron SOLEIL provided to beamlines the TimBeL board for time resolved experiments.

Unlike the machine timing system, the TimBeL board has been entirely designed by Synchrotron SOLEIL. This has helped us to modify and adapt it to experiments requests several times. Five firmware upgrades have been made since the board was installed on beamlines. Because we are perfectly familiar with this board, it was possible to adapt it very quickly, in just a few days, to new experimental needs and new data acquisition procedures.

The TimBeL board is a low cost and versatile system that has given satisfaction to beamlines for time resolved experiments.

THE RF CONTROL SYSTEM OF THE SSRF 150 MEV LINAC

S.M. Hu, J.G. Ding, G..Y. Jiang, L.R. Shen, M.H. Zhao, S.P. Zhong
SSRF, SINAP, Shanghai 800-204, P. R.China

Abstract

Shanghai Synchrotron Radiation Facility (SSRF) use a 150 MeV linear electron accelerator as injector, its RF system consists of many discrete devices. The control system is mainly composed of a VME controller and a device interface. The device interface is a home-made signal conditioner with DC power supplies. The DC power supplies are used for driving the mechanical phase shifters. This uniform signal conditioner serves as a hardware interface between the controller and the RF components. The control software is based on EPICS toolkit. Device drivers and related runtime database for the VME modules were developed. The operator interface was implemented by EDM.

INTRODUCTION

The injector of the Shanghai Synchrotron Radiation Facility (SSRF) is a 150 MeV linear electron accelerator [1], and it is shown in Figure 1. The RF system of the 150MeV Linac is composed of many individual components with different interfaces. The layout of RF system is shown in Fig. 2. A universal RF device interface was designed and manufactured to accomplish the RF system control mission. Connections between the local controller and RF devices are fully isolated by either the controller interface or the devices itself.

The RF controller consists of a VME system and a device interface. It controls many of the discrete RF components directly, that include 3 solid RF amplifiers, 12 klystron focus coil Power supplies, 3 phase shifters, and it also monitors vacuum of the klystrons and operates the reverse power protect resetting keys. Besides, there are several sub control systems:

- A sub-harmonic cavity is tuned by a stepping motor, which is controlled through a serial communication server.
- A Phase control sub-system [2] consist of a compact PCI cabinet and several modules.
- The controls for the 2 sets modulators [3] of RF power system by PLCs.

The Linac RF control system has been put into operation since July of 2007 and worked stably by now.

Figure 1: 150MeV Linac of SSRF.

SYSTEM CONFIGURATION

The Linac RF control system employs Ethernet-based distributed architecture. In the RF control system, we adopt the Experimental Physics and Industrial Control System (EPICS). The RF control system consists of

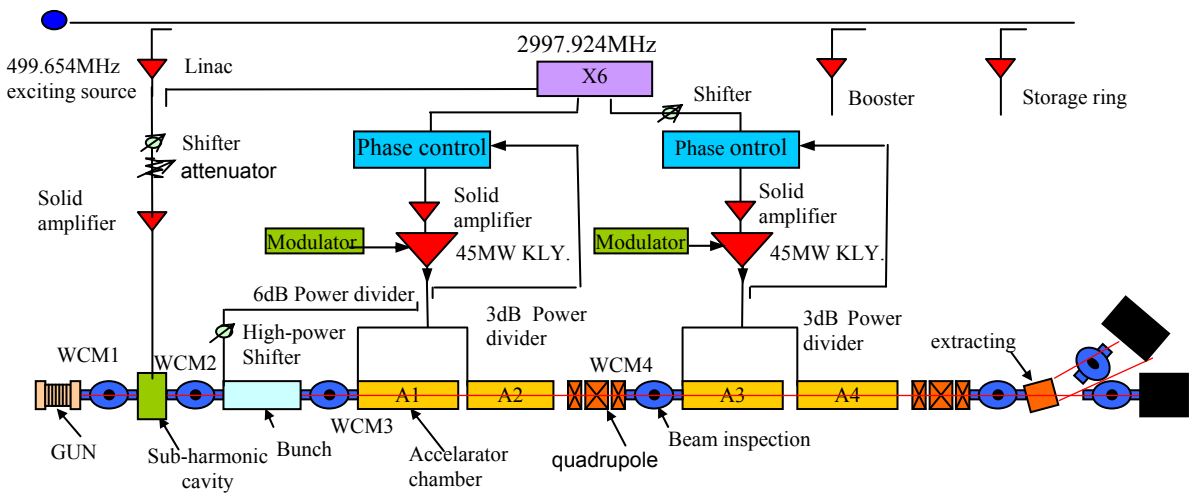

Figure 2: 150MeV Linac RF system layout.

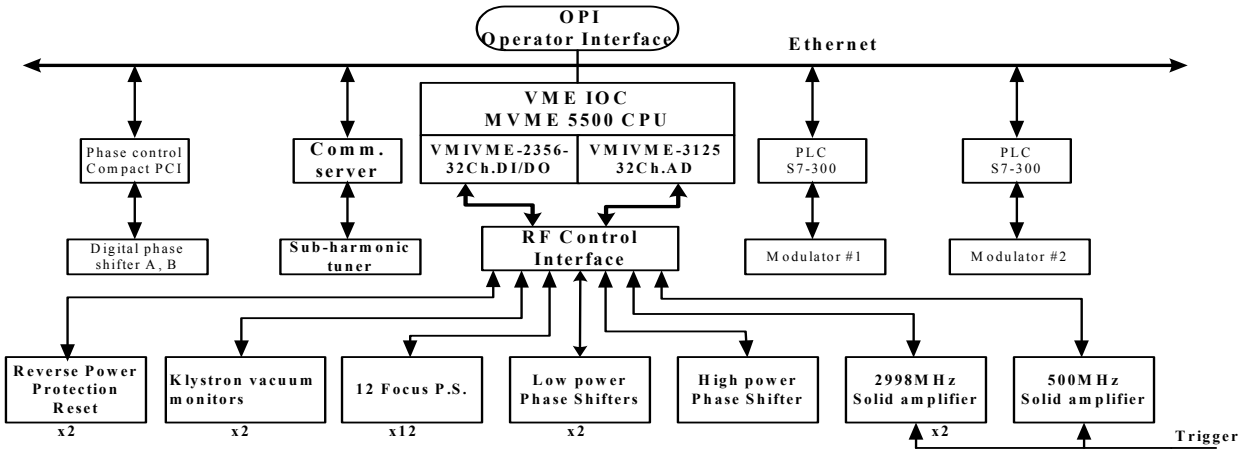

Figure 3: RF control system structure.

Operating Interfaces (OPI), Input/Output Controller (IOC). The Gigabit Ethernet switches link the OPI and IOCs to the SSRF control net. The SSRF timing system provides triggers to the amplifiers and modulators. The structure of RF control system is shown in Figure 3

Controller and Interface

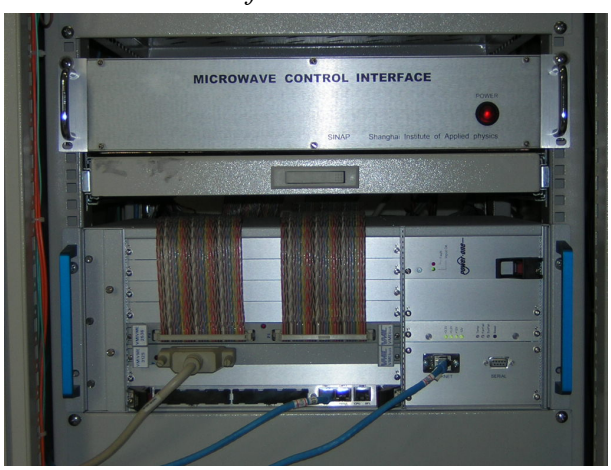

Figure 4: IOC controller and Interface.

The RF Controller and interface are shown in Figure 4. It consist of a 9-slot VME crate, a MVME 5500 CPU board, a VMIVME 2536 digital I/O isolated interface board and a VMIVME3125 A/D isolated interface board.

The dedicated interface of RF devices is designed and manufactured by SSRF for the linac RF control system. It is used not only for interface conditioning, but for power supply as well. The interface is designed for universal purpose, its most configurations are jumper selectable. The input/output interface between the controller and devices are optoelectronic isolated.

Software

EPICS toolkit was used for development of the RF control system. For different equipment interface and communication protocol, specific device support and driver is necessary to make the device to be controlled by EPICS [4]. The VME device support and drivers adopted in the RF control system were developed. The epics driver for VMIVME 2536 was written in 2002, for a 100MeV Linac control system; and epics driver for VMIVME 3125 was written in 2006. There are some drivers provided by the EPICS community, for example, S7-PLC [5] and NetDev [6] are used for Ethernet device control.

The operator interfaces of the RF control system were implemented by EDM.

CONCLUSION

The RF control system of SSRF 150MeV Linac has been operating for a period of more than 4 years, it has been testified that this control system is a low cost and more cost-effective solution to SSRF linac RF system. The control interface is a universal and convenient adapter to the controller and RF devices, and it works stably.

ONLINE EVALUATION OF NEW DBPM PROCESSORS AT SINAP *

Y. B. Leng #, X. Yi, L. W. Lai, G. Q. Huang, Y. B. Yan, SINAP, Shanghai, China.

Abstract

In this paper, we report our online evaluation results for new digital BPM signal processors, which are developed for the SSRF and the new Shanghai SXFEL facility. Two major prototypes have been evaluated. The first algorithm evaluation prototype is built using commercial development toolkits modules in order to test various digital processing blocks. The second prototype is designed and fabricated from chips level in order to evaluate the hardware performances of different functional modules and assembled processor.

INTRODUCTION

Digital beam position monitor (DBPM) processor is world wide used in light sources and FEL accelerators [1-3]. Few microns resolution at turn-by-turn (TBT) rate and sub-micron resolution at slow application (SA) rate are achieved for circular accelerators with commercial product [4].

In order to accumulate technologies and enhance capability of instrument development two prototypes of DBPM processors have been initiated since 2008 at SINAP. One prototype is based on commercial ADC evaluation board (ICS1554) to test various signal processing blocks and EPICS IOC interfaces [5]. The other prototype is custom designed and built from chips level to be a hardware frame of processor [6]. The primary target of this processor is SSRF storage ring. But equipped with proper RF front-end this processor could be used for the new Shanghai SXFEL facility. Both prototypes have been completed and passed lab test recently. After that these two prototypes merged together to form a final version ready for online evaluation.

The practical beam signal is totally different with sine wave produced by RF signal generator in lab. Online evaluation has to be performed to verify the functionality and performance of the new DBPM processors. A spare button-type BPM sensor (C15BPM8) in the SSRF ring, which delivering the same signal as other BPMs, is used for this purpose. All function blocks including turn-by-turn, fast application (FA) and slow application are loaded into the new processor to acquire real beam data.

SPATIAL RESOLUTION EVALUATION

500k samples of TBT data, 500k samples of FA data and 3k samples of SA data are acquired to evaluate the spatial resolution of BPM processor. Figure 1 shows the histogram of these data in the vertical plane at 200 mA. Since the distribution of position readings is the combination of processor electronics noise and real beam orbit noise, the actual resolution should be better than σ. That means the TBT resolution of the new DBPM processor is better than 1.4 μm, FA resolution is better than 0.38 μm, and SA resolution is better than 0.21 μm.

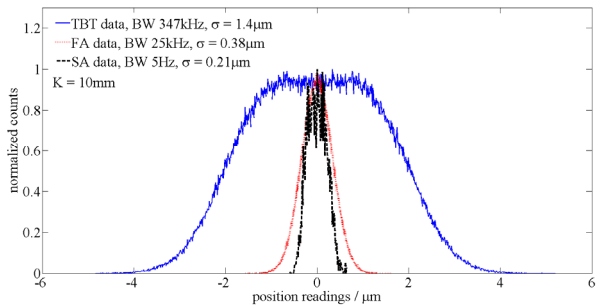

Figure 1: Spatial resolution evaluation online.

Non-Gaussian distribution of TBT data comes from a narrow band noise, which frequency is few tens kHz, produced in the DDC stage. The next optimization will focus on this.

Figure 2 shows the result of TBT resolution evaluation with different beam current. Resolution of 2 μm can be achieved when beam current is larger than 100 mA.

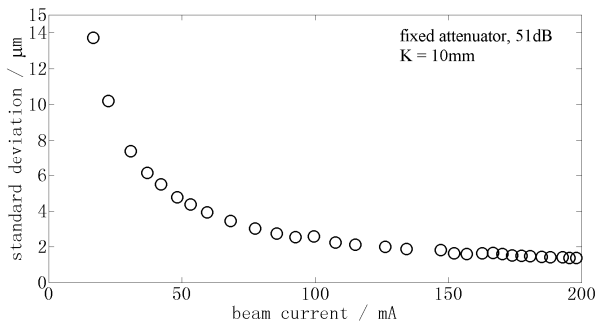

Figure 2: TBT resolution evaluation with different beam current.

TBT APPLICATION

The frequency domain analyze of TBT data is very powerful tools for machine study. All kinds of orbit noise which bandwidth lower than half of revolution frequency will show in the spectrum of TBT data and be identified easily. Combined with exciting kickers, fabric tune value, beta function and betatron oscillation phase advance can be derived from TBT data of multiple BPMs as well. Traditional DDC algorithm based TBT block has been implemented in the new BPM processor to demonstrate the above capabilities. Figure 3 shows the spectra of TBT data at vertical plane captured during injection.

*Work supported by 100 Talents Program of the Chinese Academy of Sciences and National Natural Science Fund (No. 11075198)
#leng@sinap.ac.cn

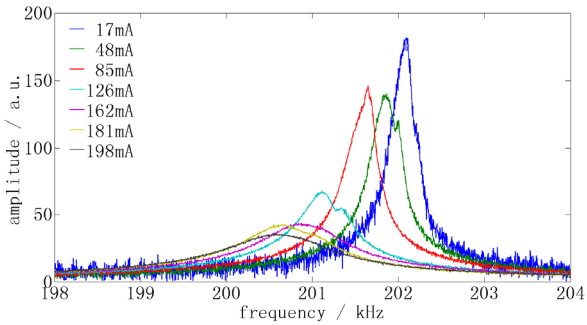

Figure 3: Beam spectra at different currents.

The buffer size as large as 500k samples provides Hz level frequency resolution. The tune shifts and betatron oscillation peak splitting during injection are easily observed. The information of beam impedance can be retrieved by fitting tune shifts with beam currents, shown in the Figure 4.

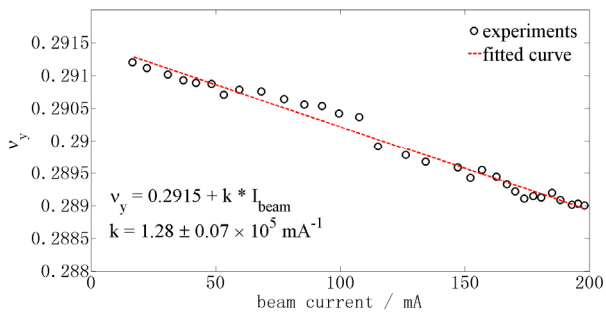

Figure 4: Betatron tune shifts during injection.

FA APPLICATION

Precise analyze of low frequency noise at TBT rate requires million samples of data. It will add too much CPU loading to processor to damage its reliability. Another choice is using fast application data (typical tens kHz) to do this job. In our case the data rate of FA block is configured to be 50 kHz and the buffer size is set to be 500k samples.

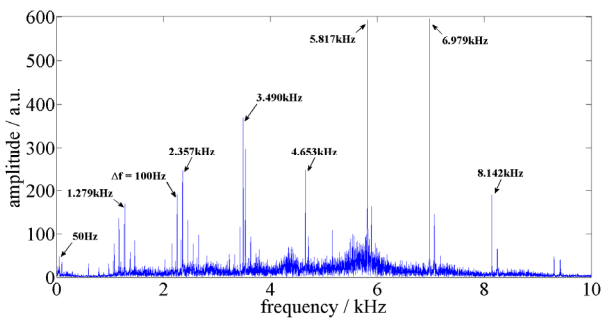

Figure 5: Orbit noise below 10 kHz.

Figure 5 shows the major horizontal orbit noise below 10 kHz. Low Q energy oscillation peak (5.8 kHz) and high Q electronics noise (1.279 kHz, 2.357 kHz, 3.490 kHz, and so on) coming from LLRF are easily observed. More optimization work of RF system can be done based on this analyze.

When we focus on the orbit noise below 100 Hz, the more details can be found shown in Figure 6. The central frequency of major part of vertical orbit noise is about 5 Hz. The horizontal orbit noise consists three parts: 1~2 Hz, 20 ~ 30 Hz and 40 ~ 60 Hz. The horizontal and vertical ratio of power line noise and its second harmonic indicate that the noise is probably coupled from magnet power supplies but not BPM processor. The more orbit optimization work can be done based on this analyze.

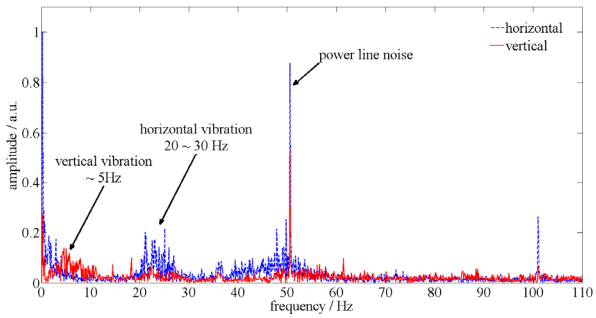

Figure 6: Orbit noise below 100 Hz.

SA APPLICATION

The basic functionality of SA block is providing close orbit information. With good calibration method and good linearity of ADC module the sum signal of four channels also can be used for beam current and lifetime measurement.

Figure 7 shows the orbit variation before, during and after injection captured by new DBPM processor. The horizontal orbit disturbances due to injection kicking during injection and the orbit changes due to close orbit correction after injection are clearly recorded.

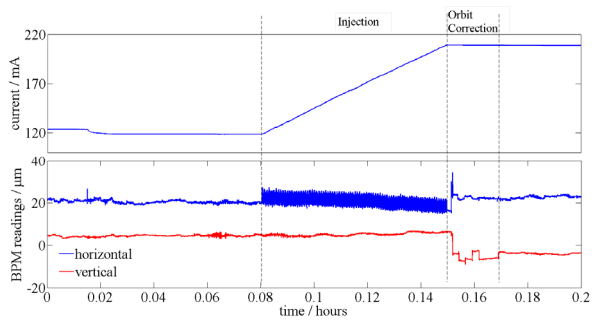

Figure 7: Measured orbit variation during injection stage.

The new processor shows very good linearity which makes measurement of beam current using sum signal possible.

Figure 8 shows the comparison of measured beam currents by DCCT and DBPM. The measurement error of DBPM due to nonlinearity is smaller than 1 mA in the range of 100 ~ 200 mA. This performance could be improved when high order calibration method applied.

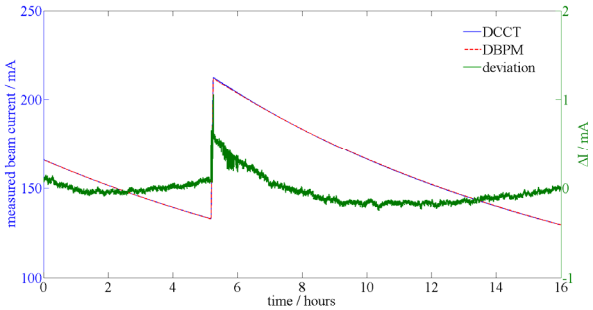

Figure 8: Comparison of measured beam currents by DCCT and DBPM.

Figure 9 shows the lifetime measurement result using DCCT and DBPM. It is obvious that the lifetime resolution of DCCT is much better than DBPM. But the traces of two measurements match together perfectly. The lifetime resolution of DBPM can be improved by involving more BPMs.

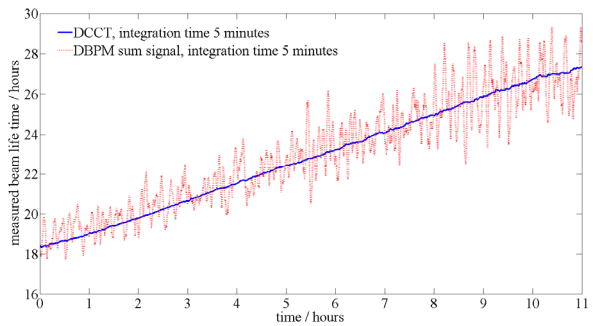

Figure 9: Beam lifetime measurement using DBPM sum signal.

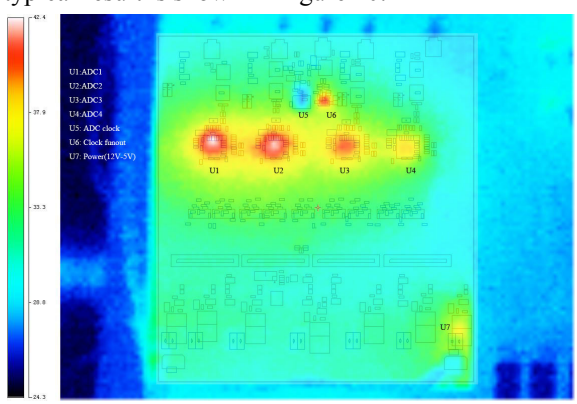
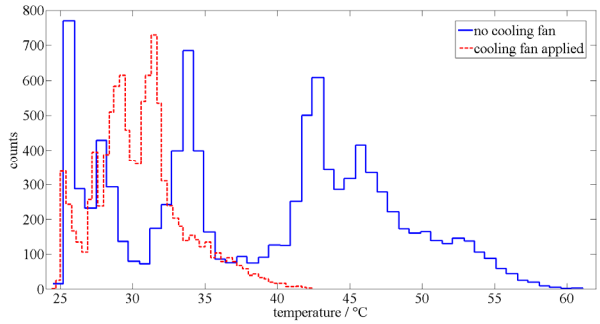
THERMAL LOADING INVESTIGATION

Thermal loading is a critical issue for high performance instruments. High thermal loading, large thermal gradient or large thermal drift of circuit could crash the precision, reliability and long-term stability of DBPM processor. In order to collect enough information for the next technical prototype a thermal imager is used to investigate the thermal distribution of RF and ADC modules in the field. A typical result is shown in Figure 10.



(a) Spatial distribution of thermal loading.



(b) Histogram of thermal loading.

Figure 10: Thermal loading investigation of ADC module.

It is obvious that ADC chips are major thermal producers and cooling fan is definitely needed. After cooling fan applied the temperature of ADC chips decrease from 60 degree down to 42 degree and the average temperature of PCB board decreases from 43 degree down to 32 degree. More precise cooling design will be made and the new lower power ADC chips will be used in the next technical prototype based on this investigation.

CONCLUSTION

A prototype of new digital BPM processor has been evaluated online at SSRF storage ring. Major signal processing blocks including TBT, FA and SA have been tested. Thermal loadings of RF and ADC module were investigated. Evaluation results show that the functionality and performance are comparable with commercial products and satisfied the requirements of operation and machine study. Evaluation results confirmed the current design. The next technical prototype will be built soon.

BINP SB RAS, Novosibirsk, Russia

Abstract

This paper describes the temperature-monitoring system of Novosibirsk FEL. The main task of this system is to prevent the FEL from overheating and its individual components from damage. The system accumulates information from a large number of temperature sensors installed on different parts of the FEL facility, which allows measuring the temperature of the vacuum chamber, cooling water, and windings of the magnetic elements. Since the architecture of this system allows processing information not only from temperature sensors, it is also used to measure, for instance, vacuum parameters and some parameters of the cooling water. The software part of this system is integrated into the FEL control system, so measurements from all sensors are recorded to the database every 30 seconds.

INTRODUCTION

A high-power free electron laser (FEL), based on the microtron-recuperator[1], is under construction now at Budker Institute of Nuclear Physics. The first and second phases of the project were commissioned recently. The system for monitoring of the temperature of FEL components during its operation takes a very important place among other diagnostic systems of the FEL. The system consists of a large amount of temperature sensors installed on different parts of the FEL facility, including the vacuum chamber of the microtron-recuperator, the windings of the magnetic elements, and the elements of the water cooling system. The sensors are installed mainly at places with a hazard of overheating. They are also installed at places where temperature measured can give some useful information about the FEL operation, e.g. places of possible beam losses.

MEASUREMENT HARDWARE

The measuring part of this system consists of a few types of sensors (or some measuring devices) installed on different parts of the microtron-recuperator. Let us enumerate all these types and briefly describe the principles of their operation:

1. Temperature sensors. This is a small winding of copper wire enclosed in a metal case and toughly connected to the place the temperature of which is to be measured. The leads of this winding are connected to a special electric circuit. The output voltage of this circuit depends on the resistance of the winding. As the resistance of copper wire depends on its temperature and this temperature is actually equal to the temperature of the surface this sensor is connected to, the temperature could be calculated from the output voltage value. The calculation formula is as follows:

$$T = A * U + B \quad (1)$$

where A and B are constant coefficients and U is the output voltage.

2. Water sensors. These sensors are very similar to the temperature sensors, two large metal plates with a very small spacing used instead of a copper-wire winding . These sensors are installed on the floor of the accelerator hall. If water gets between these plates, the resistance of this circuit decreases noticeably, and the output voltage of the circuit also changes much. So, if the output voltage exceeds a certain value, one can suppose that there is water on the floor of the accelerator hall.

3. Vacuum “sensors”. These sensors are actually control devices for vacuum pumps. These devices measure the current of a vacuum pump; convert it to the output voltage, which could be measured by an ADC. These pumps are installed on different parts of the vacuum chamber of the microtron-recuperator, so collecting values of their currents could give information about the vacuum state of the accelerator chamber. The calculation formula for the pump current is as follows:

$$I = A * e^{B*U+C} \quad (2)$$

where A, B and C are constant coefficients, and U is the output voltage.

The output voltages from sensors of all the three types are measured by a few identical multi-channel ADCs connected to one CAN line and working in the same measurement mode. Thus, all the sensors of these three types are united into one subsystem of the common control system. The quantities of sensors for different stages of the FEL are shown in table 1.

Table 1: Quantity of Sensors for the 1st, 2nd and 3rd Stages of the FEL

Sensor type	FEL Stage		
	1st	2nd	3rd
Temperature	98	112	165
Water	3	3	3
Vacuum	14	19	25

The total scheme of this system is presented in Figure 1.

CONTROL HARDWARE

The choice of measurement devices is influenced by the following factors:

1. The accuracy of value to measure. Temperature sensors impose the highest requirements on the measurement accuracy. The measurement error of these sensors must not exceed 0.3 degree of Celsius. Since the coefficient *A* in formula 1 equals 300.0, the output voltage must be measured with an accuracy of 1.0 millivolt. So, the measuring device must have a less resolution.
2. The large quantity of identical sensors with readings to process. This factor makes one use devices with as many input channels as possible. It is also desirable that the device should support the multi-channel measurement regime. Application of devices with such characteristics would reduce the required number of devices and consequently the cost of the system.
3. The very low frequency of measurement. All above values – temperature, vacuum pump current, water presence – are parameters that change very slowly. For example, temperature changes noticeably only in tens of seconds. Therefore, a period for processing of readings of all sensors of five to ten seconds would be enough.

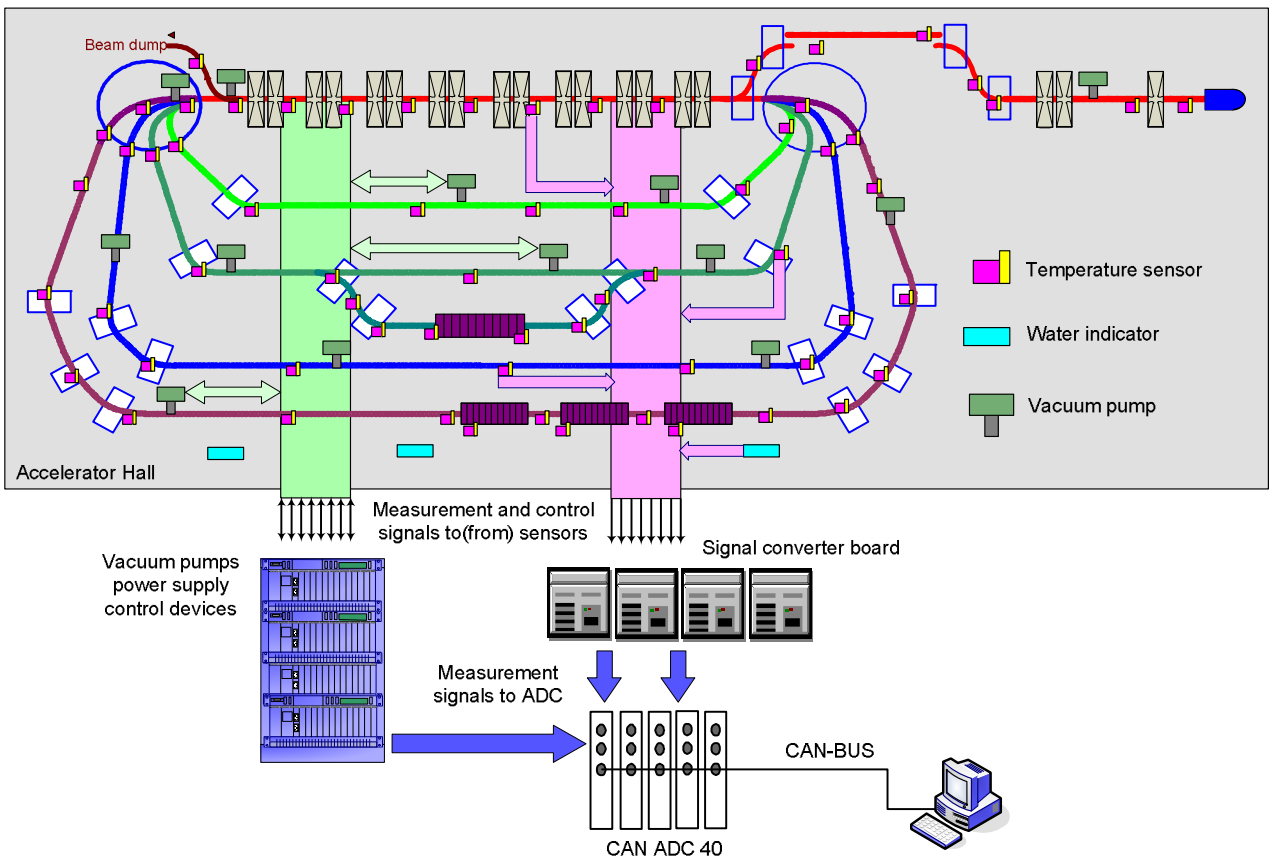

Figure 1: Main scheme of the system.

CANADC40 devices have been chosen for this system. These devices are 40-channel ADCs with the CAN-BUS[2] interface. They were designed and manufactured at BINP [3]. They meet all the above requirements.

Since different quantities of sensors are used for different FEL stages, the number of CANADC40 devices also varies (see Table 2).

Table 2: Quantity of CANADC40s and Channels Used for all FEL Stages

FEL Stage	CANADC40 Qty	Total channels	Used channels
1	4	160	115
2	8	320	144
3	8	320	193

CONTROL SOFTWARE

The control software for this system is a single application running on the IBM-PC computer. Communication with the CAN-BUS is realized with a CAN-to-Ethernet gateway developed at Budker INP. The main features of this application are as follows:

1. Representation of all sensors on a mnemonic scheme of the microtron-recuperator, which is displayed in the main window of the application. The position of the sensor in the scheme approximately corresponds to its position in the accelerator chamber. Every sensor is a small picture, which varies for different types of sensors. The color of the picture reflects the actual state of a sensor – *Normal, Not Connected, Warning,* and *Alarm*. The mnemonic scheme with sensors is shown in Figure 2.

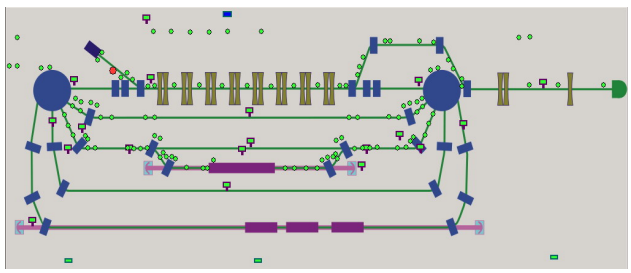

Figure 2: The mnemonic scheme of the microtron-recuperator.

2. Representation of values from all sensors as a row of vertical columns. In addition to the row of values, the second row contains the columns of time derivatives of the values of the sensors. The column height depends on the value of sensor or its derivative, correspondingly. Besides, the color of column reflects the state of sensor, as in the case of the sensor picture in the mnemonic scheme. A fragment of these rows is presented in Figure 3.

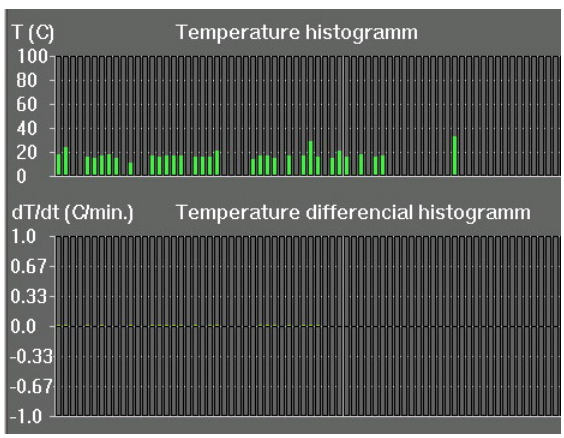

Figure 3: Temperature and derivative columns.

3. Flexible tuning of the configuration of the application. Using external configuration files, the user can specify a few different regimes of operation, which include different sets of sensors, different numbers of CANADC40 devices to be used, different pictures of mnemonic schemes and so on. This allows using one control application for all three stages of FEL operation. Depending on content of the configuration file and command-line parameter, the application operates in a corresponding FEL stage.

4. The Epics Channel Access Server. The server is built-in inside the application and runs in a separated thread. In the server, the Process Variables (PVs) represent the values and status of all sensors, processed in the actual operation mode. The PV name is connected with the name and type of a sensor in the application. The content of the Process Variables is used in a few high-level client applications. Besides, the Channel Archiver application writes down all values of Process Variables on the hard drive every 30 seconds. The stored history of the values of all sensors can be extracted for further analysis (see Figure 4).

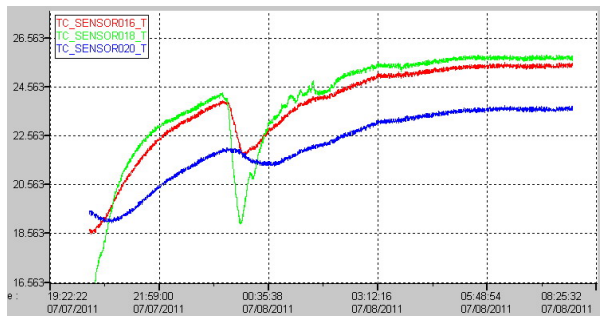

Figure 4: History of the values of a few temperature sensors.

CONCLUSION

The above-described system has been under operation for the first and second stages of the FEL for about 8 years. During the operation, the temperature measurement system demonstrated high reliability and ease of usage. The large quantity of sensors of different types and intelligent visualization of the collected information – values and their derivatives – give much information on the actual state of the FEL facility. The Epics Channel Access server in the program allows transferring data measured to any client application in the FEL control LAN.

TESTING DIGITAL ELECTRONIC PROTECTION SYSTEMS

S. Gabourin, A. Garcia Muñoz, CERN, Geneva, Switzerland

Abstract

This paper outlines the core concepts and realisation of the Safe Machine Parameters Controller (SMPC) test-bench, based on a VME crate and LabVIEW program. Its main goal is to ensure the correct function of the SMPC for the protection of the CERN accelerator complex. To achieve this, the tester has been built to replicate the machine environment and operation, in order to ensure that the chassis under test is completely exercised. The complexity of the task increases with the number of input combinations. This paper also outlines the benefits and weaknesses of developing a test suite independently of the hardware being tested, using the "V" approach.

INTRODUCTION

The SMPC ensures the correct configuration of the LHC machine protection system, and that safe injection conditions are maintained throughout the filling of the LHC machine. The SMPC receives information in real-time from measurement electronics installed throughout the LHC and SPS accelerators, determines the state of the machine, and informs the SPS and LHC machine protection systems of these conditions.

The SMPC is built to ensure reliability and availability of the transmitted information. The reception of the information and the generation of the state of the machine are done in complete redundant VME boards. An arbitration module then determines the correct information to send from the redundant information provided. This redundancy ensures high system dependability.

At the same time, redundancy makes calculations and the overall system more complex and subject to numerous errors or unexpected behaviours that would not be an issue for a non-redundant system. For this reason, a dedicated tester, the Safe Machine Parameter Tester (SMPT), has been developed to identify possible weaknesses of the system, and to validate the correct function of the SMPC.

SAFE MACHINE PARAMETERS

Components

The SMPC (see Figure 1) is composed of three types of electrical boards, Receivers (CISR), Generators (CISG) and an Arbiter (CISA) all based on the same basic PCB design, but having different functionality thanks to different VHDL code in FPGAs.

For the LHC, there are two redundant CISR (CISRA and CISRB), each one decoding a pair of energies and a pair of intensities. These CISR pass information to 2 redundant CISG (CISGLA and CISGLB).

The CISG use energies and intensities from the CISR, in conjunction with flags directly received from LHC beam instrumentation, and other information provided by Ethernet, to derive energy, intensity, and a set of flags and values representing the LHC machine state. Some of these flags are transmitted directly to the extraction Beam Interlock System (BIS) ensuring the safe transfer of beam between the SPS and LHC machines [1].

Data from both CISG is sent to the arbiter board (CISA) which assembles the redundant information and determines the overall state of the system, before transmitting the information to client systems through the LHC General Machine Timing (GMT) .

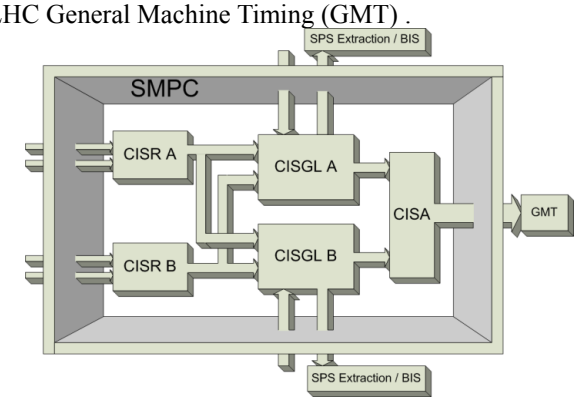

Figure 1: LHC SMPC and clients.

Each board has a pair of Field Programmable Gate Arrays (FPGAs). A "control FPGA" tasked with the execution of critical operations, in which the SMP mission-critical functions are implemented. And a "monitor FPGA" which does not interfere with the critical part, but receives information from it, formats and makes it available for observation and interpretation through the Java software supervision.

Functions

The main goal of the SMPC is to transmit energy and intensity values and to translate input information into states/flags. Principle flags are:

- The Beam Presence Flag (BPF), which evaluates to TRUE when a beam is circulating in the LHC. This is directly received by each CISGL and sent to SPS extraction and CISA.
- The Setup-Beam Flag (SBF), which evaluates to FALSE when the circulating beam is considered as dangerous for the tunnel equipment (magnets, etc) if any problem inducing the loss of the beam occurs.
- The Moveable Devices Allowed In / Stable Beams flags (MDI/STB) are used by the four main experiments (ATLAS, CMS, ALICE and LHC-b). The MDI flag is set to true when a specific energy is reached, when the beam is squeezed at each of the four interaction points, and when the appropriate beam mode is set. Similarly the STB becomes true when the beam mode is stable in addition to the MDI being true.

SAFE MACHINE PARAMETER TESTER

As the SMPC has a heavy dependency on external equipment, it is not possible to test it completely in the real machine environment, it receives information from and transmits information to a diverse set electronics in both the LHC and SPS machines. The SMPT reproduces the machine environment by sending all the different information to the SMPC, replicating the characteristics of each system connected to the SMPC. The SMPT is implemented in a separate VME crate, and a LabVIEW program supervises and controls the SMPT, as well as reading back the states of each element of the SMPC, checking if its behaviour is as expected.

The VME Crate SMPT

The task of the SMPT is to simulate all the inputs (energy, intensity, flags, etc), retrieve the output signals and cross-check the state of the SMPC versus the prescribed function in the specification. The SMPT uses the same hardware boards as the SMPC with different VHDL programs (see Figure 2):

- five CISTR are used to simulate energy and intensity frames (in yellow) sent to the CISRs, and the BPF sent to the back panel of the SMPC (in blue),
- a CISTA is used to read back and verify the output of the CISA which normally goes to the GMT (in blue),
- two CISTCL read the current loop flags directly sent by the back panel from the CISGL to the SPS extraction lines (BPF, SBF) and to the BIS.

On Figure 2, the SMPT VME crate is represented on top with the front panel outputs and inputs which connect to all SMPC connectors on the front panels (on bottom left) and back panel (on bottom right).

Fibres optical connections are represented in yellow, electrical ones in blue, and current loops in green.

LabVIEW Software

The SMPT is monitored and controlled through a LabVIEW program realising the actions required for each test. The front panel of the program, shown on Figure 3, represents the hardware state of each SMPC board, including their connections, and their internal states. A colour-coding is used to display the state of each element:

- dark gray for elements which are not tested (The majority of elements on picture 3),
- dark blue for elements which are currently or are going to be under test (The four SBF equations of CISGLB),
- green for elements successfully tested (the CISA energy and all its dependant tests) and
- red for elements whose test has failed (The intensity priority test in the CISGLA).

Three users' actions are possible:

- "Ctrl click" on an object (rectangle, label or frame) to launch this specific test. On picture 3, the SBF label of CISGLB was clicked to obtain the blue objects,
- "Ctrl shift click" to launch this specific test and all dependant ones. On picture 3, this has been done on the Energy object of the CISA which has induced the test of all green objects
- "Shift click" to show the diagnostic of a test which has been executed, this opens a window showing a breakdown of the test steps.

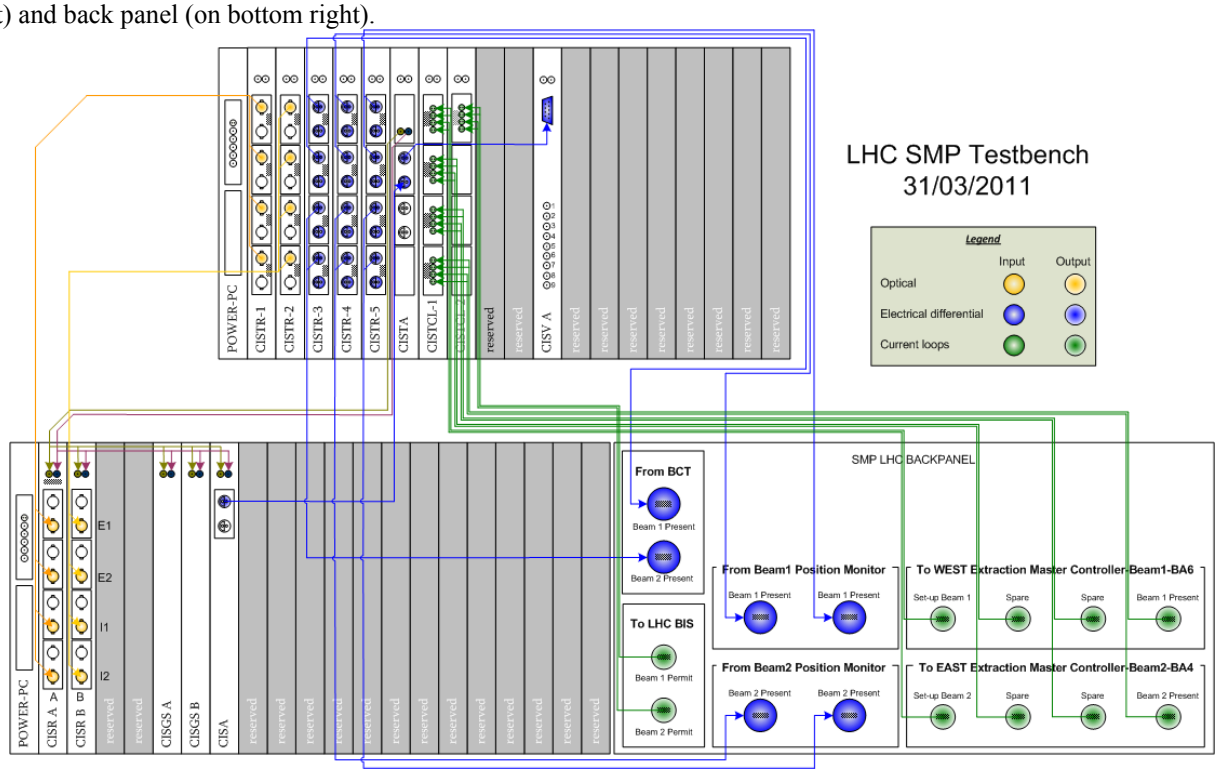

Figure 2: LHC Connexion between SMPT and SMPC.

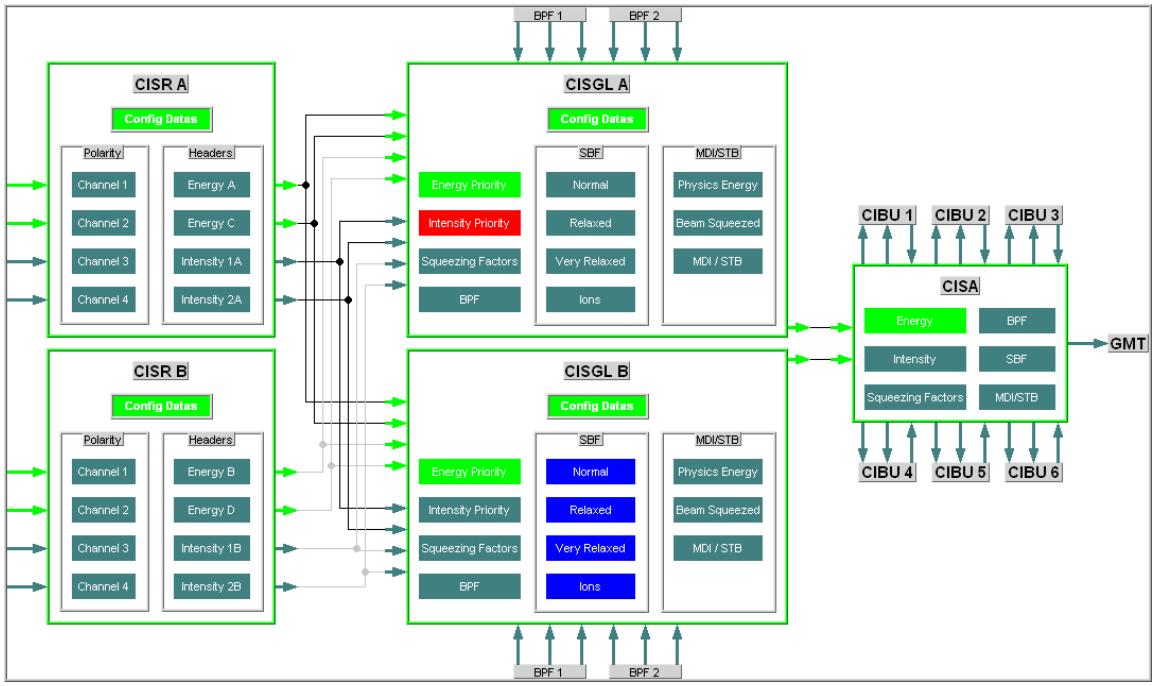

Figure 3: Front panel of the LHC LabVIEW tester.

FESA Layer

The communication between the program and the VME crates SMPC and SMPT is done through a CERN standard architecture called FESA. FESA is a C-based set of drivers developed at CERN to communicate with several devices, and it provides information which can be interpreted by several programming languages such as LabVIEW or Java.

In this application, FESA is used to access all registers and history buffers (HB) implemented in each monitor FPGA. Each HB is a 1024 record rolling buffer which contains specific events with their time of occurance and status, and which are written only when necessary by the mean of triggers inside the SMPC hardware. The registers and the HB allow information about the status, intermediate calculus and timing parameters of the different functionalities to be determined. This information is shown on the front panel of the LabVIEW tester in the picture 2.

The reading is done through simple requests or subscriptions with a refresh rate of one Hertz.

TEST METHODOLOGY

"V" Approach and Predicate Logic

The "V" approach is based on the desire to have the SMPC entirely reproduce to specification requirements. The SMPC was developed from the specification and, in parallel, a set of tests were implemented to validate the behaviour described in the specification, without taking into account how the SMPC was built. As a normal test system, the SMPT allows the validation of the behaviour of the SMPC with respect to the specification. This parallel development has the added advantage of highlighting any kind of ambiguity in the specification itself.

This "V" approach is a good way to consolidate the specification, at the same time, the initial specification was not written with this in mind. To avoid misunderstanding, misinterpretation or un-defined conditions, further effort was carried out to generate a documentation free of ambiguity, using Formal Methods (FM). FM are used to describe the behaviour of a system, independently of its realisation (hardware, software, abstraction...), even if there are several ways to realise a system, depending on the target where the logic is foreseen to be established. FMs in this case took the form of Predicate Logic, similar to a programming language, giving an exhaustive description of how the system has to work, with only a single interpretation.

For example, the SBF is calculated for each particle beam from several input conditions. There are four equations (Normal, relaxed, very relaxed, ions) which give an intensity threshold *THD* (i.e. a number of particles) for a specific LHC proton beam energy. If the LHC beam intensity is below this threshold, the SBF is true (the beam is a set-up beam), otherwise it's false.

For each beam, the SMPC receives two intensity values *IA* and *IB*, each one associated with a "valid intensity" flag, respectively *IA_valid* and *IB_valid*. The intensity value used for the calculation is the highest if both are valid. If not, the maximum intensity value (all bits to '1') is chosen as it automatically sets the SBF to false, which is the fail-safe value (as it is the more dangerous case). The SBF can be expressed as the expression:

$$SBF = (IA\_valid)\&(IB\_valid)\&(IA \leq THD)\&(IB \leq THD)$$

This expression is the basis used to build the SMPC and to define for the SMPT which tests can validate the SMPC behaviour.

Test Structure & Organisation

Full tests coverage is impossible to reach, as 428 bits are derived by hardware and software connections. Moreover, for the LHC SMPC, 82 32-bits registers can be written to change the system configuration and behaviour. This represents a total of 2^{3052} input combinations, without taking timing requirements into consideration.

The main approach to reduce the number of tests is to modify only the inputs which have effect on parameter under test. Moreover, complex functionalities can be tested in steps, by validating intermediate results first.

Tests involving thresholds are a particular case. The threshold and the threshold value plus one are fixed numbers which are always tested. But to be more complete, it's important to add tests of the intervals below and above the threshold. As all values cannot be considered, the solution kept is to choose a random value inside each different interval.

The test bench software has been built to facilitate the addition, modification or suppression of tests. The tests are not defined in the program itself but in an Excel file named "Tests to do" on Figure 4.

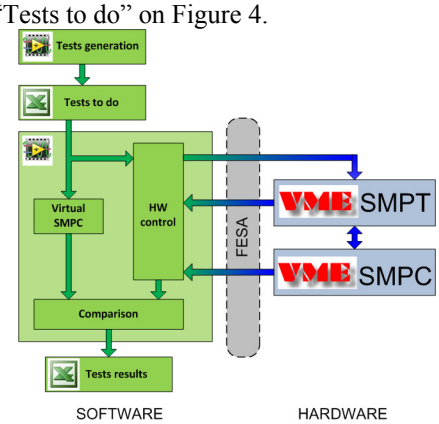

Figure 4: Tests organisation structure.

This file contains each possible elementary test divided in steps. A step is defined as a set of actions which are realised at the same time. Eight actions (all optional) are defined, each one in a separate worksheet:

- three write: for the hardware it can be frames or flags, for the software it is registers,
- four read: for the hardware it can be frames or flags, and for the software registers or HB records,
- one sets the delay before starting the next step.

The writing of this file requires a meticulous approach, so another LabVIEW program (Tests generation on igure 4) has been realised to facilitate the definition of tests.

Tests Sequence

As tests are defined by the program on-the-fly, it's impossible to know in advance what the expected results are. This is also due to some stimuli which have to be chosen randomly at the very start of tests. For this reason, it is mandatory to introduce a subprogram able to calculate at the end of each step the expected internal state (registers and HB) of every board. This "virtual" SMPC is built directly from the specification (as the real SMPC) and gives the possibility to validate the information gathered from the hardware.

The virtual SMPC reads the test steps and transforms them into an array which each cell is a combination of all states of all SMPC inputs for a specific time. The time granularity is 1ms, thus a 5 second test sequence generates an array of 5000 cells. The outputs signals and the FPGA memory are also simulated and calculated for each step, and then sent to the Comparison module.

In parallel, the test steps are read by another subprogram, the hardware control (HW control), which formats them into commands to be executed by the SMPT, waits for the real delays, and reads signals and memories of the SMPC and of the SMPT. All the gathered information is compiled to have a similar structure than the virtual SMPC results, and is also sent to the Comparison module.

The Comparison code compares the real and the virtual data and gives the results following the colour code of Figure 3 (green if all is the same and red otherwise). In case of failed test, it's possible to open the diagnostic window of the program; the results are also saved in an Excel file (Tests Results on Figure 4).

FUTURE PLANS AND CONCLUSION

The main improvement concerns the reduction of time consumption for tests, as well for the SMPC than for the virtual SMPC. In total the SMPC needs more than 5 hours to be tested; the virtual SMPC needs 20 minutes. Presently, the SMPC communicates with the hardware using FESA, and needs to wait for the data to be refreshed before readings. This refresh occurs every second, asynchronously with the test process. Then the time to wait before having new data is between a few milliseconds and a second. Instead of using FESA, LabVIEW could connect on the VME crate through a SSH connection and read the memories thanks to low-level programs which already exist for manual operation. This would allow an improvement in the time for testing the SMPC. Concerning the virtual SMPC, the actual method is to simulate iteratively the memories and outputs at every millisecond, which becomes huge for tests of more than 1 minute. This can be replaced by an equation independent of time, capable of evaluating the system state in a single calculation, given all inputs. In this case any test would complete within a few millisecond. Such an equation has already been defined for the CISR.

To conclude, FM and "V" approach ensure having specification out of ambiguity and a system which behaves as specified. These techniques are particularly efficient as the system is more complex, as for the SMPC version 3.1, currently in use in the CERN control room.

THE DIAMOND MACHINE PROTECTION SYSTEM

M. T. Heron, S. Lay, Y. Chernousko, P. Hamadyk, N. Rotolo,
Diamond Light Source, Oxfordshire. UK

Abstract

The Diamond Light Source Machine Protection System manages the hazards from high power photon beams and other hazards to ensure equipment protection on the booster synchrotron and storage ring. The system has a shutdown requirement, on a beam mis-steer of under 1msec and has to manage in excess of a thousand interlocks. This is realised using a combination of bespoke hardware and programmable logic controllers.

The structure of the Machine Protection System will be described, together with operational experience and developments to provide post-mortem functionality.

INTRODUCTION

Diamond, a third generation 3GeV synchrotron light source[1], commenced operation in January 2007. The storage ring (SR) is based on a 24-cell double bend achromatic lattice of 561m circumference. It uses a full-energy booster synchrotron and a Linac for injection. The spectral output is optimised for high brightness up to 20keV from Undulators and high flux up to 100keV from Multipole wigglers. The current operational state includes twenty photon beamlines, with a further twelve beamlines now under design or construction.

The design of the Diamond control system [2] is based on the EPICS control system toolkit. It primarily uses VME IOCs as the plant interface. The EPICS control system undertakes plant supervision and operation within defined limits, but does not protect equipment from damage. Independent from the control systems there are hardware and PLC-based subsystems to ensure correct operation of process-based equipment, e.g. cryogenic systems, and protection of equipment. These systems constitute the Machine Protection System.

MACHINE PROTECTION SYSTEM REQUIREMENTS

The Diamond machine protection system is required to protect equipment from damage, both at the local and the global level, by managing the hazard. This is achieved in most cases by controlling the source of the energy. At the global level this involves protecting the vacuum vessel from damage by the photon beam, and series-connected magnets from thermal damage. At the local level this again involves protecting magnets from thermal damage, and photon front ends and vacuum equipment from damage. The MPS further ensures that photon front ends are only operated when insertion devices are within approved ranges of beam current and gap, and that vacuum conditions are such that Gas Bremsstrahlung production is within acceptable levels.

When the required response times for the protection of this equipment are considered, it is evident that most occurrences can be addressed using commodity PLCs. However, the protection of the vacuum vessel against the thermal load of a mis-steered beam requires the dumping of the stored electron beam in under 1 msec (including detection, logic, transmission and beam dump). This therefore requires a dedicated hardware-based solution.

In view of the size of the Diamond facility, a fibre optic infrastructure was installed from each of the accelerator instrumentation areas to a common area. This has been utilised by the MPS, thereby minimising cable runs and potential earth loops.

The MPS is required to ensure protection of equipment, but to operate independently from the supervisory layer of the control system, the EPICS IOCs. The latter ensures correct operation of the equipment within prescribed limits, and only when this fails should the MPS act. Similarly, the Personnel Safety System [3] at Diamond is independent of the Control System and the MPS, and ensures the protection of personnel from various hazards. At the point where the MPS and PSS systems interface, the MPS issues requests to the PSS, with the PSS having the final control of any radiation source.

Whilst the PSS at Diamond is designed against a process based on the standard IEC61508, the MPS design process is not so rigorous, but adopts good practice in managing hazards. It uses simple logic to enable functional testing, solutions designed to fail safe and undergoes periodic validation re-testing to ensure ongoing system integrity.

PRINCIPLE AND ORGANISATION

The MPS monitors a large number of interlock signals from diagnostics instrumentation, vacuum instrumentation, photon front ends and plant monitoring subsystems. Based on logic it can then remove the source of the energy to ensure protection of equipment. Depending on requirements, interlocks are managed on a Local or a Global basis. The Global system is structured as two layers, and supports fast- and slow-response-time interlock requirements.

A Global MPS (GMPS) module takes the interlock permits for a given interlock circuit from each of the cells of the accelerator, and, subject to all interlocks being good, produces a permit to operate the source of energy: the RF amplifier for vessel protection and the PSU for magnet protection (see Figure 1). The Local MPS module takes fast Interlock inputs from one cell of the Storage Ring or one quadrant of the Booster. Fast interlocks are those that must drop the beam in under 400μsec (the maximum speed of the interlock) in the event of failure.

Examples of this type of measurement are signals from electron beam position monitors, beam blow up, beam obstruction (vacuum isolation valves) and reduction in the quality of the vacuum in the storage ring. The module also takes the permits from PLCs that manage the slow interlocks for that local cell.

Slow interlocks are processed by PLCs which manage interlocks where a response time greater than 100msec is acceptable. These include water cooling, vessel and magnet temperature, and component interlocks from photon front ends and photon beamline control subsystems. The PLCs also produce local permits for the correct operation of equipment controlled from within the same cell, an example being the Quadrupole magnet PSUs.

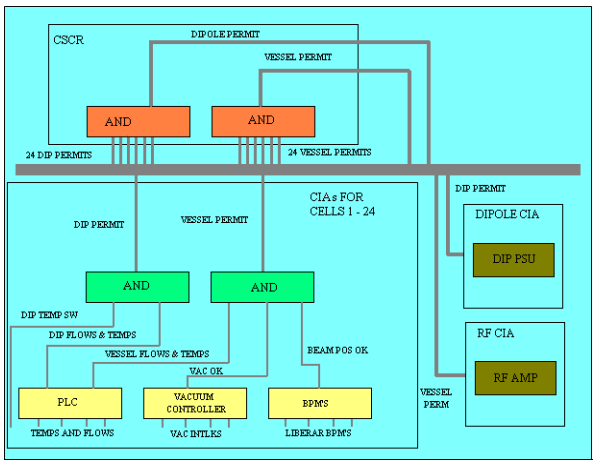

Figure 1: Architecture.

System Realisation

The interlock system is based around DLS-designed machine protection cards. The interlocks feed to the LMPS card from the monitoring equipment, and if all interlocks are good, the enable signal is generated. The enable signals for each cell are fed via fibre links to a GMPS card which produces the permit required by the RF or Dipole Power supply to operate.

The Local MPS Card

Each Local MPS (LMPS) card can receive up to 32 interlocks as input signals and can be configured as one or two independent channels. The LMPS modules are located in a VME-based IOC that provides power, time reference and an interface to the control systems for monitoring. The output permits are produced as a 5MHz pulse train and are distributed over optical fibre links to the GMPS module. For a good permit the 5MHz clock is the active state, so that is possible to differentiate between a failed interlock, which gives zero output from the optical receiver, and a broken fibre, which gives a high output from the optical receiver.

The 32 inputs to the LMPS card are optical-isolated to support 24 volt signal levels. Each input is ORed with a signal from a jumper so that it can be overridden (or disabled) by inserting the jumper. The outputs from all the OR gates, which represents the status of the used inputs, are then ANDed to give an overall logic state. This is then latched on by a Reset signal from the controls systems. Each LMPS module is monitored by a Hytec 8001 digital I/O board to read the state of the jumpers and inputs, to provide reset signals and to monitor the transition to fault condition. The loss of an individual interlock removes the output and sends a signal to the Hytec 8001 board to latch the transition. The output can only make the transition to the enabled state when all the interlocks are good and a reset signal from the 8001 is asserted.

The Global MPS Card

The Global MPS (GMPS) cards form a “star” point for the Local MPS cards. The GMPS provides the same functionality as the LMPS card, but takes 5MHz optical inputs as the interlocks. Each card produces 4 permit outputs as optical signals.

The RF/Dipole Interface Card

The interface from the GMPS to RF amplifiers and dipole power supply is provided by the MPS decode module. The 5 MHz event stream is detected to provide a logic level, which is made available as a relay clean contact, opto coupled and TTL output.

A variant of this decode module provides logic functionality to cascade the Vessel Protection interlock from the RF amplifier to the Dipole power supply. This is to address the possibility that an attempted switch-off of the RF amplifier fails to dump the beam. In this case, the failure to dump the beam is detected, causing the MPS signal to the SR dipole to be removed. To date this variant has not been implemented.

The PLC Subsystem

The PLC subsystem uses OMRON CJ1 & CJ2 PLC hardware [4] integrated into a customised chassis. The decision to encapsulate the PLC into crates was taken to provide an element of future-proofing, as the PLC inside the chassis can be upgraded to keep up with advances in technology, whilst maintaining the same plant interface. It also helps maintain consistency of layout and simplicity of construction of control system cabinets. Using a standard 3U 19” crate for the PLC encapsulation with defined I/O interfaces has further enabled consistent I/O assignment and rapid on-site commissioning. An example of this is shown in Figure 2.

Vessel thermal protection is realised using a PLC crate for monitoring slow interlocks associated with water flow and temperature of the vessel and other components. This can monitor 432 digital inputs and 288 Thermal inputs, and provides 96 local permits, which connect in to the LMPS or direct to local PSUs.

Variations of the PLC subsystem have been realised for thermal protection, for control of vacuum valves, and for ID gap and Gas Bremsstrahlung protection. In all cases they build on the same hardware components, the same

software components and the same interface to the control system, thereby ensuring good standardisation.

Figure 2: PLC sub system for control vacuum valves.

Communication

Communication between EPICS and the Omron PLC's associated with the MPS is realised using the Omron FINS protocol over a standard serial connection. This allows reading from and writing to single registers or block registers, where registers can be data memory or I/O locations (writing to direct I/O was disabled).

Summary of Implementation of MPS on the SR & Booster MPS

The storage ring (SR) MPS is structured as two circuits: vessel protection and dipole magnet protection. For each circuit the GMP module receives 24 permits from LMPS modules, one per cell of the SR. The LMPS modules each receive permits from the local PLC module for that cell. For the vessel permit, there are also interlocks from the photon front-end PLC systems and from the photon beamlines. This is shown in Figure 3.

The booster MPS is structured as four circuits: vessel protection, dipole magnet protection, F-quad protection, and D-quad protection. For each circuit the GMP module receives 4 permits from LMPS modules, one per quadrant of the Booster SR. The Local MPS modules each receive permits from the local PLC module for that cell.

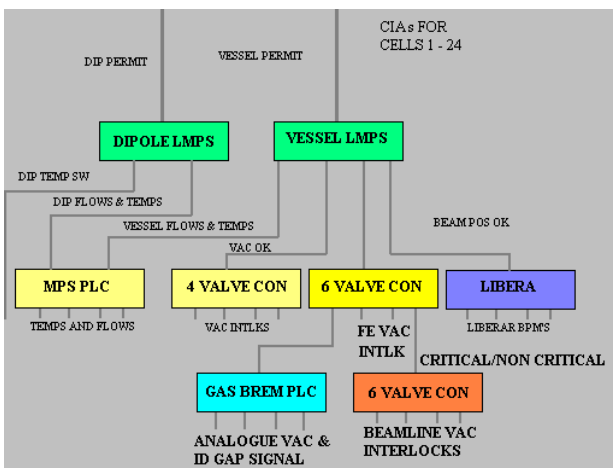

Figure 3: Beamline/Front end connection.

PLC Software

Diamond has structured the PLC ladder logic in such a way as to provide a standard set of drivers for all applications that were deemed likely. The code is structured to ensure that the software engineer, when integrating the unit into a system, has to follow the same pattern regardless of where the system is being used, and what it is being used for. This is to permit easy interpretation and fault finding, and to allow additions to be made to that system by other engineers.

The standard programme structure is broken down into a number of sections for housekeeping (where revision control, hours run and watchdog operation are managed), input conditioning, interlock chains, device drivers, power -supply unit enables and interlock forwarding.

Generally only the interlock logic section and the interlock forwarding need any adjustments to suit the location.

CONTROL SYSTEM INTERFACE.

EPICS provides the user interface to the MPS system. An EPICS driver communicates with the MPS card via a Hytec 8001 64-bit digital I/O board with modified firmware. This allows the reading of the state of the 32 inputs and 32 jumpers directly and previously unused bits in the 8001's control and status register indicate the interlock state and provide the means to generate a reset signal to enable the interlock. The system also allows each permit to be dropped as part of the start-up testing after a shutdown. An overview of the whole system is presented to the operator which shows the status of the global permits. It is then possible to drill into the LMPS via the IOC crate in which it is based. It is further possible to see the status of each individual input on a PLC via the serial link between the PLC and the IOC.

PERFORMANCE

In terms of performance, the most critical requirement is the dumping of the electron beam to protect the vacuum vessel. This has been measured as ~600 µsec and is the sum of:-

- BPM detection delay ~200 µsec,
- Delay between BPM output from Global vessel permit ~250 µsec,
- Delay of GMPS OP through RF amplifier and cavity to beam dump. ~ 150 µsec.

OPERATIONAL EXPERIENCE

The system has proven to be very easy to commission and allows good scope for expansion as upgrades to the storage ring are carried out. By using the modular approach, commissioning could be carried out in isolation on each section as it was completed. This was particularly useful to DLS as the SR was not completed in consecutive sections.

Many of the interlocks for the MPS originate within the CIA, and because all of the field wiring is brought back into the MPS rack, a lot of the initial fault finding could be carried out without the need for vault entry. This saved

time and reduced disruption during the machine commissioning phase.

Occasional problems with spurious tripping that did not give an event record were an issue that has prompted a re-design of the LMPS for the reasons described below.

FUTURE DEVELOPMENTS

Post Mortem Buffer

The arrangement of latching the failed interlock is supposed to capture the first interlock to be lost, thereby diagnosing the original cause of the beam loss. On a beam loss, the beam position interlocks activated within the clock window are also latched along with the true first interlock. If the first interlock is a non-position interlock, it will come up along with all the beam position interlocks and so can be identified. Also, if the first interlock is a position interlock, the post mortem in the Libera BPMs provides clear information as to the cause. However, this falls down in the event of a spurious interlock from a BPM, or from a LMPS to the GMPS module. The latter caused a series of false beam dumps due to inadequate transmission power between the LMPS and the GMPS module and reduction of optical output with aging of transmitters, so that spurious failures of interlocks were registered by the GMPS. The originating LMPS module was only identified by monitoring the decoded inputs to the GMPS with a logic analyser. This has resulted in a redesign of the GMPS to add post-mortem capability, and improved transmitter power on LMPS modules to ensure an adequate optical budget.

Remote IO PLC

For the next phase of photon beamlines a new generation of Omron PLCs has been selected. These have enabled the adoption of Remote IO and an Ethernet interface between the control system and the PLC.

Remote I/O provides a way of reducing cabling complexity and improving flexibility on deploying I/O into the field. RIO uses standard Ethernet cabling and Profinet, and RIO modules are built up into standard junction boxes, one for thermal monitoring and another for general purpose I/O. The Remote I/O does not perform any logic on any of the signals; it simply acts as a receiver and passes everything back to the PLC crate. This necessitates configuration of RIO output modules such that in the event of failure of RIO communication I/O fails to the safe state. The PLC logic is protected by a watchdog timer to protect against failures in communication with RIO.

The new PLC CPU (CJ2M) has a built-in Ethernet connection which allows both EPICS and the programming software to share the connection. EPICS communication is handled over UDP using FINS protocol whilst programming is realised over TCP/IP.

CONCLUSION

In summary the DLS Machine Protection system is modular in structure which has facilitated deployment and maintainability. It has met its design specification for shutdown time and has proven its worth on a number of occasions when there have been vacuum incidents or localised increases in heat due to cooling problems.

PERSONNEL PROTECTION, EQUIPMENT PROTECTION AND FAST INTERLOCK SYSTEMS: THREE DIFFERENT TECHNOLOGIES TO PROVIDE PROTECTION AT THREE DIFFERENT LEVELS

D. Fernández-Carreiras, D. Beltran*, J. Klora, J. Moldes, O. Matilla, R. Montaño, M. Niegowski, R. Ranz*, A. Rubio, S. Rubio-Manrique, CELLS, Cerdanyola del Vallès, Barcelona, Spain

Abstract

Alba [1] is a synchrotron light source under installation located nearby Barcelona. This 3 GeV third generation light source is planned to deliver the first X-rays beam to the users in 2012. The Linac has been commissioned in 2008, the booster in 2010 and the Storage Ring in 2011. The seven Beamlines included in the "Phase One" are being commissioned at the end of 2011.

The Fast Interlock System, Equipment Protection System (EPS) and the Personnel Safety System (PSS) ensure that the operations are done safely for the machine components and people.

All three use independent hardware and communication channels, and they guarantee different response times and safety levels. The Fast Interlock System, works in the microsecond range, the EPS in the millisecond, and the PSS has a cycle time of 150 milliseconds. However, the PSS has some extra requirements, since it is related to human lives safety, and therefore it requires the highest possible reliability. It ensures a Safety Integrity Level 3 (SIL3) according to the international norm IEC 61508.

FAST INTERLOCK

The Fast Interlock is implemented upgrading the single channel links channels employed by the Timing system, to a bidirectional system. It is based on events, relying on a tree architecture where the root (event generator) gathers and redistributes the interlock events from/to all the leaves (event receivers). Each event receiver is configured to perform an action (i.e. activate pulse on an output) for a particular event code. The cards (event generators, event receivers and fiber optics fan-outs) have been produced by MRF [2]. There is one event generator and about 88 Event Receivers distributed, which currently have configured about 480 connections to equipments [3].

When an interlock signal is produced in the Beam Position Monitors (BPM), Radio Frequency plants (RF), and Front Ends (FE), it is transmitted back to an event-receiver adjacent to the event generator which redistribute the events to the whole tree. The fiber optic links have all a fixed length, 200 meters, required for ensuring the precision in the synchronization events. The time between the generation of one interlock event in one node, and the reception is in the order of four microseconds.

The fast interlock system, provides accurate timestamps of each event (interlock), allowing a 8 nanosecond resolution in the discrimination of interlock-events for postmortem analysis.

*On leave

EPS

Besides few hundreds of interlock signals, which require an action in the microsecond range, there are other seven thousand managed by the EPS. The EPS guarantees a transmission in the millisecond range. Typically the cycle times are below the 20 ms. The EPS is responsible for all interlocks in the machine and the beamlines. All signals managed by the Fast interlock are also backed up by the EPS.

The Equipment Protection System manages permits and interlocks avoiding damaging the hardware. It is built on B&R PLCs [4] with CPUs installed in cabinets in the service area and distributed I/O modules installed in shielded boxes inside the tunnel and in the beamline hutches. CPUs and remote periphery are interconnected by the X2X fieldbus. A deterministic network, Ethernet-PowerLink, interconnects all CPUs to each other.

Architecture and Technology

The EPS is built on a network of PLCs and remote peripheries. The EPS for the Accelerators includes 56 B&R CPUs X20CP1484, all equipped with Ethernet interface 100 Base-T and Ethernet PowerLink.

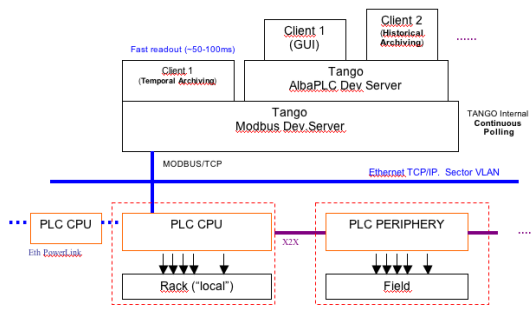

Figure 1: Architecture of the EPS PLC System.

In addition, 110 main periphery cabinets are linked to the CPUs by the X2X bus. Lead-shielded boxes are installed inside the Tunnel to make cables shorter, cheaper and easier to install. The deterministic Ethernet PowerLink network runs on a separated industrial switch. It is a deterministic OSI Level2 network. Interlocks between different subsystems are transmitted over this media. Every Beamline has an independent system, usually composed by one CPU and 2 main remote peripheries, having few hundreds of signals. Figure 1 shows the conceptual design of the EPS.

The standard Ethernet network handles communication with Human Machine Interfaces, Archiving services, etc.

The PLCs is connected to the main control system VLAN in that sector (or beamline). A Tango device server polls values from PLC CPUs using Modbus/TCP. On top of this, another Tango device Server, AlbaPLC, provides dynamic attributes named according to the field devices, in order to make easier the integration in the SCADA.

Automatic Code Generation

The controls and cabling database stores the information concerning not only cables, but equipments, channels, connectors, domain names, boot servers, etc. In particular all equipment codes with channels names and connections are stored in this database.

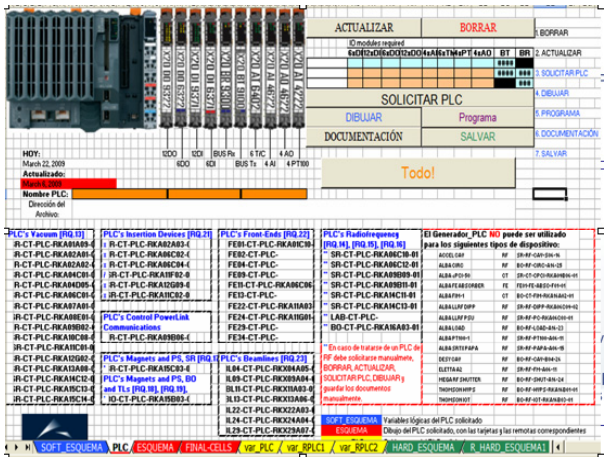

Figure 2: Excel application for EPS code generation.

Most of the code in the PLC is generated automatically from the cabling database. A Visual Basic Script running in excel generates another file containing the declaration of variables, data structures, software tasks, modbus mapping and documentation. Figure 2 shows a view of this excel file. The parts of the code still excluded from the automatic generation are the logic conditions. Additionally, Tango attribute names and the expert GUIs are also generated from the controls equipment and cabling database.

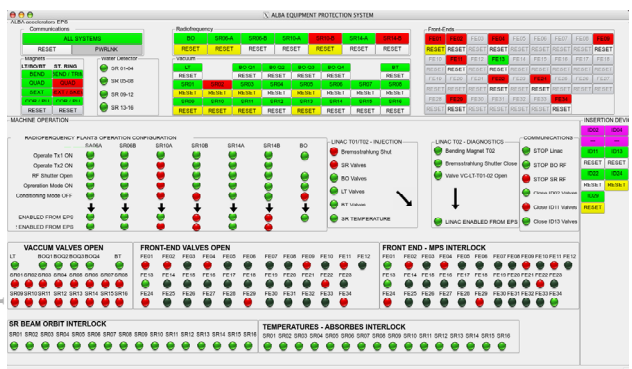

Figure 3: The main EPS GUI for the Machine.

Subsystems and Logic

The EPS covers mainly six subsystems. Those are: Vacuum, Magnets, Radio Frequency, Insertion devices, and Front-Ends. Besides, every Beamline has an independent EPS system, connected to the Accelerators with eight wired signals. The logic of each subsystem is complex and adapted to every particular case. As a general rule, when a problem arises, any other subsystem shall be informed. In particular if a vacuum valve closes as a result of an overpressure in a vacuum pipe, the RF shall be shut down and the beam killed. All these communications are transmitted over PowerLink, although there are some cases considered more critical which are also wired from one PLC to another, like interconnections of different vacuum sectors or as we have just mentioned, the links between Beamlines and Front-Ends. Figure 3 shows the main user interface for the Equipment Protection System.

PSS

The PSS is an independent system built on Pilz Safety Programmable Logic Controllers (PLCs) [5]. It manages access to restricted areas, such as Linac, Tunnel and Beamline lead hutches, and surveys radiation levels. It prevents people to get a radiation dose higher than the limits given by the law. It is subjected to Ionizing Radiation Regulations. It is independent from any other system in Alba and the Spanish Nuclear Safety Council shall approve it.

The PSS is governed by the international norm IEC 61508. It rules the use of electrical and software driven safety systems to provide risk reduction up to an acceptable level. The ALBA PSS Safety Integrity Level aims SIL3. Besides this, the PSS follows the rule of "Redundancy and Diversity". Redundancy will be achieved by having two independent lines for every signal. Diversity means that any action will be applied to two different parts of the system, for example disabling the RF comprises revoking the permit for the RF driver and for the High Voltage Power Supplies (HVPS). In other words, each action results in two redundant outputs. The installation of the system has been outsourced and is being achieved by the companies Pilz and PROCON. Although the PSS is one independent system, It has two parts: Accelerators y Beamlines, The accelerators PSS controls the Tunnel and The Linac bunker. It consists of two PLCs intercommunicated by the safety bus. The tunnel has four access doors, whereas the linac bunker has one door.

Hard X-Ray beamlines have two hutches controlled by the PSS. In the case of Soft X-Rays beamlines only the Optics hutch is lead-shielded and controlled by the PSS. A beamline has a "Independent" PSS with a dedicated PLC connected to the Acelerators PSS (Main) by the Safety Bus. It can be disconnected from the Main PSS, only in some well defined safe conditions. In case of failure it provokes the Main PSS goes to safe state.

Functionality

There are 24 radiation monitors, manufactured by Thermo [6] (FHT 6020A controller) are distributed in the service area and experimental hall. They monitor both

gamma and neutron doses integrated over four hours and providing two alarm levels. Each alarm level has a Pilz PNOZ S4 Safety Relay, activated when the radiation reaches the alarm threshold. All inputs/outputs to/from the PSS are digital. Every door has two different limit switches, one of which works also as magnetic lock (Pilz PSEN lock, and PSEN code).

Interlocking the doors once the restricted areas have been evacuated ensures access control. In order to make sure that a zone is clear of personnel, a search patrol is needed. A Search patrol is started from the control room and performed in bunker and tunnel by two authorized people. Once the Permit is given in the control room, the patrol begins. Nobody but the persons performing the patrol are allowed in the bunker and tunnel. Search buttons all around the tunnel are pressed in sequence. Every button has to be pressed in a time interval, not before a minimum time and having a timeout. The PSS has four main states, OPEN (free access), INTERLOKED (once the search patrol has been completed, RESTRICTED, and SAFE. An indicator shows also the presence of beam in the restricted areas. The restricted access function is implemented only for the Accelerators PSS in order to make short interventions in the restricted areas without needing a new patrol. This restricted access mode is allowed in the control room to one (up to six) authorized person (magnetic card). After taking one of the personal keys this person can go in the restricted area. Once all keys are in place in both the door cabinet and the control room, the system goes to "interlocked" again. When an unsafe condition arises, the system goes to safe state. Doors are unlocked only after a decay time, unless an emergency stop is pressed.

The Control Room

The SCADA and the Operation keys are in a cabinet in the control room. The SCADA, only meant for monitoring and diagnostics, reads tags from standard (not-safety) data blocks in the PLCs. It does not have write access to the PLC. The operation permits are given with physical keys. The Pulsed power supplies and the Booster and Storage Ring bending magnets can also be manually disabled from the control room.

Architecture and Technology

The system is built around the Pilz PSS SB2 3006-3 ETH-2 CPU, two of them for the accelerators, tunnel and linac, and one for each beamline. All CPUs are intercommunicated by a Pilz Safety Bus (certified SIL3). Keys, door switches, emergency stops and relays are also SIL3. Safety relays are installed in radiation monitors, Bending magnet power supplies, Radiofrequency (RF) High Voltage Power Supplies (HVPS) and Inductive Output Tubes (IOT), as well as in other electronic boxes like the RF detectors and the Electron beam current detectors. The RF waveguides and Front-End Shutters have also SIL3 PILZ PSEN 1.1p20 switches.

Logic

The logic is organized in permits and interlocks, a permit is the result of a set of conditions fulfilled. An interlock is a condition for granting or revoking permits. For example, in order to open the front-end, the hutch must be interlocked, emergency-stops armed, the operation keys in place, etc.

CONCLUSION

Nowadays, the PLC technology is used in a wider range of applications that traditionally were linked to other technology. Safety PLCs are today a common choice in the industry for high risk environments where a failure might have many people killed, like trains, etc. Also, standard PLCs are cheaper, smaller and more powerful and we found a large variety in the market today. A distributed system combining Ethernet (used as a fieldbus) and a proprietary X2X fieldbus is proven to be cost-effective solution. Periphery can be closer to the devices, making cabling easier and cheaper. Where the required response times are several microseconds, a solution with PLCs is not viable anymore. Those cases are often a reduced subset and can be accomplished with "ad-hoc" solutions. For this particular case, the upgrade of the Timing system, to support bidirectional links for implementing fast Interlocks, took place. It was proposed by Alba and Implemented and made available in the market by MRF.

CONTRIBUTIONS

Many people has worked in these projects, in particular we would like to thank X. Queralt, the Safety Officer, S. Marchal, B. Saló, J. Jamroz (electronics group). Also, special thanks to P. Berkvens, the safety officer of the ESRF, for his help and his advises with the PSS logic. The EPS is one of the most important customers of the cabling database, developed and maintained by CELLS Management Information System group, especially I. Costa and O. Sánchez.

ARCHITECTURE FOR INTERLOCK SYSTEMS: RELIABILITY ANALYSIS WITH REGARD TO SAFETY AND AVAILABILITY

S. Wagner, A. Apollonio, R. Schmidt, M. Zerlauth, CERN, Geneva, Switzerland
A.Vergara-Fernandez, ITER Organization, St.Paul-lez-Durance, France

Abstract

In the design of interlock loops for the signal exchange in machine protection systems, the choice of the hardware architecture impacts on machine safety and availability. The reliable performance of a machine stop (leaving the machine in a safe state) in case of an emergency, is an inherent requirement. The constraints in terms of machine availability on the other hand may differ from one facility to another. Spurious machine stops, lowering machine availability, may to a certain extent be tolerated in facilities where they do not cause undue equipment wearout. In order to compare various interlock loop architectures in terms of safety and availability, the occurrence frequencies of related scenarios have been calculated in a reliability analysis, using a generic analytical model. This paper presents the results and illustrates the potential of the analysis method for supporting the choice of interlock system architectures.

INTRODUCTION

For particle accelerators like the LHC and other large experimental physics facilities like ITER, the machine protection relies on complex interlock systems. They are required to trigger machine stops in case of emergency, but not spuriously. *Machine stop* implies, for example, the extraction of the energy stored in magnet powering circuits and, in case of the LHC, the extraction of the beams from the machine.

For the interlock loops protecting the LHC superconducting magnet circuits, spurious triggers of machine stops, lowering availability, can be tolerated to a certain extent since they do not affect the longevity of the equipment. In ITER's case on the other hand, high machine availability, and therefore limited spurious triggers of machine stops are required since each fast stop causes significant magnet aging due to the induced forces. The number of tolerated spurious machine stops for the LHC lies in the range of a few tens per year (around 10% of all fills), while for ITER it is expected to be limited to only a few in the whole lifetime of 20 years .

In conjunction with the development of a prototype for ITER interlock loops, a reliability analysis comparing six possible interlock loop architectures has been performed.

This paper in the first part introduces the method and the generic model used for the analysis. The second part discusses some results of the performed studies. The third part introduces the approach developed for the verification of the model and intermediate verification results.

METHOD

The following sections summarise the most relevant aspects of the interlock loop model used for the analysis. It is based on the method introduced in a study of a part of the LHC Machine Protection System [1].

Interlock Loop Model

The model reflects an interlock loop ('system') with 4 components, as illustrated in Fig. 1.

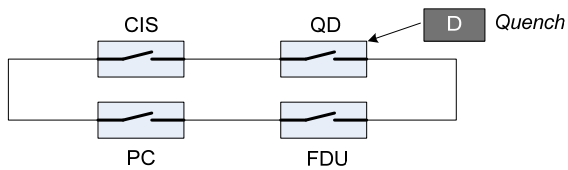

Figure 1: Basic model of interlock loop with 4 components.

The components are considered to be switches, which can fail in two modes, *blind* and *false*, according to failure rates λb and λf (Fig. 2, left). The system demand is modelled by virtual component *D,* following demand rate x (Fig. 2, right).

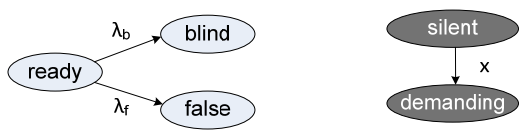

Figure 2: State diagrams reflecting component behaviour and system demand.

The different states represent the following conditions:

- *Ready*: switch closed, ready to open upon demand (initial state)
- *Blind*: failed closed, not ready to open upon demand
- *False*: Switch open, spuriously or upon detection of switch-internal failure (i.e. without demand)
- *Silent*: nominal condition of monitored machine equipment, no demand (initial state)
- *Demanding*: Emergency condition detected, demanding machine stop (loop opening)

The possible state configurations occurring within a given observation time tf, represent four scenarios. They are exemplified by means of a generic quench loop, including components QD (Quench Detection), FDU (Fast Discharge Unit), PC (Power Converter) and CIS (Central Interlock System, Fig. 1). In case a quench of a magnet is detected (i.e. system demand), the QD is triggered to open the loop, thus informing the PC to switch off the power supply and the FDU to extract the energy from the magnet powering circuit:

(1) *Mission completed*: neither quench nor spurious loop opening during an operational cycle
(2) *False trigger* (→Preventive stop): loop opening due to failure of any switch (mode *false*), without quench
(3) *Demand success* (→Emergency stop): loop opening by QD upon quench
(4) *Demand missed* (→Missed emergency stop): missed loop opening upon quench due to QD failed closed (mode *blind*)

Scenario 4 (worst case scenario) includes the potential of severe damage to the machine, hence interfering with machine safety. Together with scenarios 2 and 3, it defines the machine availability reflected by scenario 1.

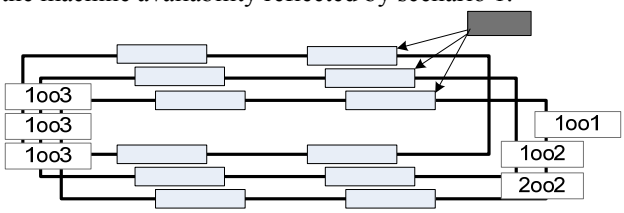

Figure 3: Models of interlock loop for different architectures (featuring up to three redundant lines).

Figure 3 gives an overview on the models for the six architectures under consideration, derived from the generic model introduced above:

- 1oo1: single-line solution, no redundancy
- 1oo2: two redundant lines with 1-out-of-2 logic
- 2oo2: two redundant lines with 2-out-of-2 logic
- 1oo3: three redundant lines with 1-out-of-3 logic
- 2oo3: three redundant lines with 2-out-of-3 voting
- 3oo3: three redundant lines with 3-out-of-3 logic

For a *False trigger* of *2oo2* for example, both lines need to be open due to switch failures.

Model Input Parameters

Table 1 summarises the model input parameters, representing seven 'degrees of freedom' for case studies.

Table 1: Model Input Parameters

Parameter	Description
Components:	
λf	Failure rate *false*
λb	Failure rate *blind*
x	Demand rate
Operation:	
tf	Observation time
Architecture:	
k	Number of lines
n	Number of components/line
-	'Voting'

Model Assumptions

The presented model includes a series of assumptions and simplifications:

- Independent failures of components
- Identical components (with regard to reliability, i.e., failure rate)
- All components in initial state at t=0 (system 'as-good-as-new')

Besides these rather common assumptions, there are a few others more specific to an interlock loops:

- Any switch opening is recognised as 'line opening', independent of the (potentially *blind*) state of components in the same line. This reflects a loop with redundant readout.
- The demand is limited to one loop component (i.e. QD). The demand signal is fault free and, in case of redundant lines, is simultaneously distributed to all lines (Fig. 3). This neglects possible redundancy of the triggering source.
- A switch opening due to failure mode *false* is permanent, i.e. an open switch stays open till the end of current operational cycle. This neglects transient failures.
- The voting (included in the 2oo3 architecture) is fault free. This assumes a technical solution for the voting that does not add significant complexity that might lower reliability.

Analytical Model Description

The model uses an analytical description [1,2] adapted and extended to the characteristics of the system under consideration.

The most relevant improvement concerns the inclusion of voting and the (related) elimination of the *False missed* scenario (being absorbed in the remaining four scenarios).

Model Implementation

The analytical model description is implemented using Maple like in the previous studies [1,2].

RESULTS

Table 2 shows the default values of the input parameters, defined as the starting point for extended case studies.

Table 2: Default Input Parameters

Parameter	Default value		Comment
Components:			
λf	1E-4	[h^{-1}]	MTTF: 12 months
λb	1E-5	[h^{-1}]	MTTF: 15 years
x	2E-4	[h^{-1}]	MTTF: 6 months
Operation:			
tf	720	[h]	30 days
Architecture:			
n	4	[-]	cp. basic model

The values for the component failure rates (λf, λb) and the demand rate (x) are derived from MTTF estimations based on experience with the LHC. The observation time (tf) of 30 days reflects the expected length of an ITER

Table 3: Scenario Probabilities for the Different Architectures (Default Input Parameters)

	1oo1	1oo2	2oo2	1oo3	2oo3	3oo3
Mission completed	6.50E-01	4.88E-01	8.12E-01	3.66E-01	7.31E-01	8.52E-01
False trigger	2.33E-01	4.10E-01	5.68E-02	5.43E-01	1.42E-01	1.40E-02
Demand success	1.17E-01	1.03E-01	1.30E-01	9.08E-02	1.27E-01	1.32E-01
Demand missed	3.99E-04	1.54E-06	7.97E-04	6.57E-09	4.60E-06	1.19E-03

operational cycle, i.e. the continuous operation between two maintenance periods.

The number of components per line (n) corresponds to the basic model (Fig. 1 and 3). The remaining architecture parameters are defined by the architectures under consideration.

Table 3 presents the results for the case study based on the default input parameters:

- With regard to *Demand missed*, the 1oo3 architecture is top (lowest probability), while with regard to *Mission completed* the 3oo3 architecture is (highest probability).
- With regard to the combined aspects, the 2oo3 architecture solely ranks in the 'top three solutions' for both *Demand missed* and *Mission completed*.
- Compared to the 1oo1 architecture (ranking second best with regard to the combined aspects), the 2oo3 architecture features a decrease of *Demand missed* and an increase of *Mission completed*.

Translating these observations in terms of safety and availability, the following statements result (for the given default parameters):

1. With regard to safety, the 1oo3 architecture is top, while with regard to availability it is the 3oo3 architecture.
2. With regard to the combined aspects, the 2oo3 architecture is a best-compromise solution, ranking top three for both safety and availability.
3. Compared to the 1oo1 architecture, the 2oo3 architecture includes an increase of both safety and availability.

In order to prove these statements, a series of sensitivity analyses have been performed. In the following, the results of the variation of failure rate *false* (λf) are presented. The further sensitivity analyses based on the variation of the remaining input parameters (*blind* rate, demand rate, observation time and the number of components per line) are beyond the scope of this paper.

Variation of λf between 1E-7 h^{-1} and 1E-2 h^{-1}

The variation reveals that while statement 1 holds for the entire considered range of λf , statements 2 and 3 are true (T) for λf ≤ 1E-4 h^{-1} only, not for higher λf (Table 4).

The reason is that for higher λf, the 2oo3 architecture exceeds the 1oo1 architecture in terms of *False trigger* (Fig. 4, crossing line), which results in a decrease of *Mission completed* compared to the 1oo1 architecture (Fig. 5). Hence, as of a certain parameter range, the 2oo3 architecture is outperformed by 1oo1 in terms of availability.

Table 4: Assessment for Statements 1 to 3 for λf Varied between 1E-7 h^{-1} And 1E-2 h^{-1}

Stat.	1E-7	1E-6	1E-5	1E-4	1E-3	1E-2
1	T	T	T	T	T	T
2	T	T	T	T		
3	T	T	T	T		

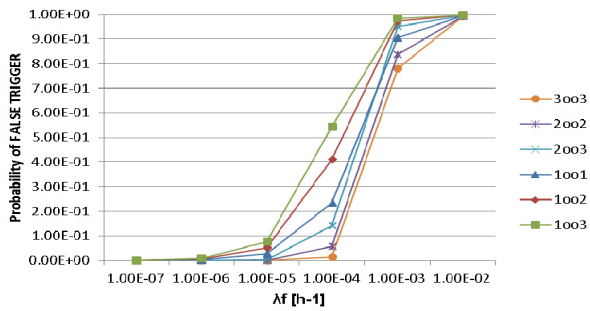

Figure 4: Probability of *False trigger* against λf between 1E-7 h^{-1} and 1E-2 h^{-1}.

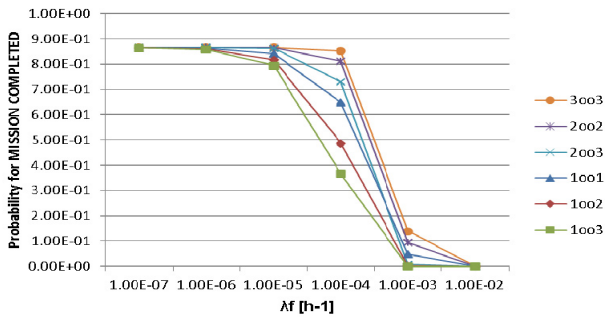

Figure 5: Probability of *Mission completed* against λf between 1E-7 h^{-1} and 1E-2 h^{-1}.

Summarising the above observations, the following extension to the three statements is to be made:

4. Statement 2 and 3 require reasonably low failure rates *false*, λf .

The confirmation of statement 1 is provided by Fig. 5 and 6, showing the advantage of the 3oo3 architecture with regard to availability (Fig. 5) and the advantage of the 1oo3 architecture with regard to safety (Fig. 6).

Discussion

The lower performance of the 2oo3 compared to the 1oo1 architecture for high λf can be explained by the total number of components included in the architectures. As of a certain λf, the voting is no longer able to compensate

for the (three times) higher amount of components. However, such high failure rates are not reflecting electronic devices in use nowadays. Their rates are expected to be in a lower range.

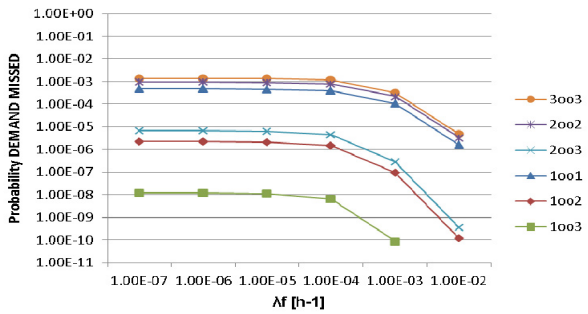

Figure 6: Probability of *Demand missed* against λf between 1E-7 h^{-1} and 1E-2 h^{-1} (logarithmic scale).

The constraint expressed by statement 4 only relates to the availability aspect. The 2oo3 architecture does appear in the top three with regard to safety for the entire considered range of λf, hence outperforming 1oo1 in terms of safety.

The introduced method allows for additional comparison from a different point of view. Instead of assessing the performance of the architectures based on given input parameters, the architectures can be compared in terms of the reliability of the components required to achieve a desired system performance. This may lead to statements like *in order to achieve an availability X, the 2oo3 architecture allows for Y orders of magnitude higher component failure rates compared to other architectures*.

The presented analysis has been taken into account in the decision-making with regard to the design of a prototype for the ITER quench loops. Considering the results of the analysis and the possibility for testing and maintenance during operation provided by redundant architectures (which can counter the related disadvantage of increased amount of components), a 2oo3 solution is being envisaged.

VERIFICATION

As mentioned above, the analytical model description used in this analysis is a further development of the approach introduced in earlier studies. For the verification of the results, and the underlying analytical description, a study based on Monte-Carlo simulation has been started.

The simulation of a single operational cycle includes two basic steps:

- Generation of random numbers representing the times of state transitions (i.e. of component failures or system demand), according to the input parameters (failure and demand rates)
- Assignment of the resulting time sequence of state transitions (within the given observation time) to one of the four scenarios

The simulation of a multitude of operational cycles then allows for statistical analysis:

- Derivation of the relative occurrence frequencies of the different scenarios

The simulations are implemented using Matlab. Two independent approaches are being developed which differ in the scenario assignment step:

- Explicit assignment based on the time sequence of random numbers
- Implicit assignment based on a graphical model representation including step functions and signal transmission (implemented using Simulink)

The intermediate results of the explicit approach show good agreement with the results presented in Table 3, indicating relative errors in the range between 1E-6 and 1E-2 for the frequent scenarios (based on 8E7 simulated cycles). For the rare scenario *Demand missed*, the error is not meaningful since the number of simulated cycles is too low for a reasonable accuracy.

The implicit approach is still under development. Currently, there are results available on the 1oo1 architecture only and with fewer simulated cycles due to a significantly increased need of simulation time compared to the explicit approach. The intermediate results show a relative error in the range between 1E-4 and 1E-1 for the frequent scenarios (based on 5E4 simulated cycles).

CONCLUSIONS

This paper presents the method and results of a reliability analysis addressing the properties of various interlock loop architectures with regard to machine safety and availability. It shows the advantages of a 2oo3 architecture for systems with high requirements in both safety and availability.

Further application and development of the method is ongoing. Subsequent studies are being performed addressing the interface between interlock loops (e.g. quench loop) and the protected machine subsystems (e.g. magnet powering circuits), including detectors.

The Monte Carlo approach for the verification of the different studies is being further developed. In addition, the validation of the models is to be addressed, in particular with regard of the fault-free voting assumption underlying the model.

Abstract

Recent incidents of breaches, in control systems in specific and information systems in general, have emphasized the importance of security and operational continuity in achieving the quality objectives of an organization, and the safety of its personnel and infrastructure. However, security and disaster recovery are either completely ignored or given a low priority during the design and development of an accelerator control system, the underlying technologies, and the overlaid applications. This leads to an operational facility that is easy to breach, and difficult to recover. Retrofitting security into a control system becomes much more difficult during operations.

In this paper we describe our experiences with implementing ISO/IEC 27001 Standard for information security at the Electronics Department of the National Superconducting Cyclotron Laboratory (NSCL) located on the campus of Michigan State University (MSU). We describe our risk assessment methodology, the identified risks, the selected controls, their implementation, and our documentation structure. We also report the current status of the project. We conclude with the challenges faced and the lessons learnt.

INTRODUCTION

NSCL's distributed control system uses Experimental Physics and Industrial Control System (EPICS), and is managed by the Electronics Department (EE). While attempting to secure the control system, it became evident that it could not be done in piecemeal fashion. Hardening one part of the system does not suffice; the weaker links in the chain are either obscured or ignored, and leave the entire system as vulnerable as before. So EE wanted to address security in a holistic manner, and decided to implement the ISO/IEC 27001 Standard for information security.

Confidentiality, Integrity, Availability

The cornerstones, basic principles, or foundations of information security are Confidentiality, Integrity, and Availability (CIA). Confidentiality ensures that only authorized personnel have access to information. Integrity ensures that the information remains valid by guarding against unauthorized modifications and destruction. Availability guarantees that the information is available whenever requested (by authorized personnel).

* This work was supported in part by the National Science Foundation under the Cooperative Agreement PHY-06-06007.

ISO/IEC 27000 STANADARDS

ISO/IEC Standard 27001 and 27002 form the crux of the 27000 series of standards. ISO Standard 27001 (based on British Standard 7799 Part 2) provides guidance to establish, implement, operate, review, and improve an Information Security Management System (ISMS). ISO 27002 (based on British Standard 7799 Part 1) describes the best practices to manage information security risks. ISO 27001 presents a management system: a framework of policies, procedures, guidelines and associated resources to achieve the security objectives of the organization. ISO 27002 presents a set of controls: means to manage security risks.

ISO 27001 advocates an iterative process-based approach built on Plan-Do-Check-Act (PDCA) model to establish and manage an ISMS [1]. It recommends four phases for ISMS: establish, implement and operate, monitor and review, and maintain and improve. It mandates management responsibilities, internal audits, reviews, and continuous improvement of the ISMS.

ISO 27002 is divided into eleven clauses [2]. Each clause is divided into categories. Each category has an objective and a set of controls to achieve that objective. The security clauses in ISO 27002 are:

- Security Policy
- Information Security Organization
- Asset Management
- HR Security
- Physical Security
- Communication and Operations Management
- Access Control
- Information Systems Acquisition, Development, and Maintenance
- Information Security Incident Management
- Business Continuity Management
- Compliance

An organization is certified against ISO 27001 and not ISO 27002. Annex A of ISO 27001 refers to the controls of ISO 27002.

ARGUS THE ISMS

In this section we describe the implementation of Argus, our ISMS. Its roadmap is shown in **Figure 1**. We first defined Argus' scope (it was limited to the EE department and related support services), and the guiding policy for the ISMS. Next we chose the OCTAVE Allegro [3] as our risk assessment methodology. Using this approach we identified our critical information assets:

information that is important to us. This included controls and PLC software, documentation of our systems, software licenses, EPICS archiver database, and IOC configurations. Then, we identified the containers of the information assets. The containers can be of three categories: technical (server, software, hardware etc), physical (paper, folders etc), and human (intellectual property, ideas etc).

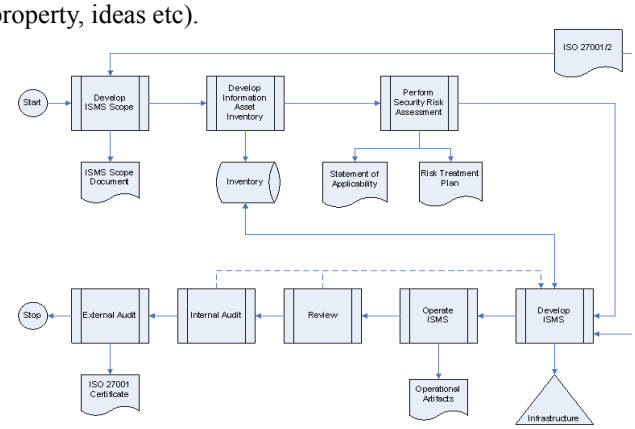

Figure 1: Argus Roadmap.

Risk Assessment

As the next step, we identified the conditions (areas of concern) that can affect the information assets or their containers. Then we qualified them with actors, means, and outcomes. This resulted in a list of threats to our assets. An example of such threat is: anyone with access to control network can modify the IOC configuration files. We then evaluated the impact (see Table 2) of every threat based on a set of measurement criteria (

Table 1). This gave us a relative risk score (RRS) for each risk. An example of this score is shown in Table 3 for the risk - "inadvertent modification of EPICS channel values".

Table 1: Risk Measurement Criteria

Impact Area (IA)	IA Priority
Safety and Health	5
Reputation	4
Financial	3
Legal	2
Productivity	1

Table 2: Impact Values

Impact	Value
No Impact	0
Low	1
Medium	2
High	3

Table 3: Relative Risk Score for a Risk

Impact Area (IA)	IA Priority	Impact Value	Score
Safety and Health	5	Low (1)	5
Reputation	4	Med (2)	8
Financial	3	High (3)	9
Legal	2	None (0)	0
Productivity	1	Low (1)	1
Relative Risk Score			23

We used the RRS to prioritize the risks. . Based on the relative risk score and probability of risk occurrence, we could categorize the risks into various levels. An example of such risk level matrix is shown in Table 4.

Table 4: Risk Levels

Probability	Relative Risk Score			
	60+	40 to 59	20 to 39	0 to 19
High	Level I	Level I	Level II	Level III
Medium	Level I	Level II	Level II	Level IV
Low	Level II	Level II	Level III	Level IV

We treated the risks based on the risk level or priority. Risk treatment involved one of the following actions:

- Avoid the risk by using the controls from ISO 27002 or controls developed in-house
- Reduce the risk by using the controls
- Accept the risk or residual risk. If the risks are of low probability and incur high cost for mitigation, they may be accepted. However, all acceptable risks must be documented and approved by EE department head.
- It is possible to transfer a risk by insuring against it but we did not have any such risks.
- It is also possible to share risks, with vendors of other labs, but we did not encounter such risks.

Documentation

Documentation forms a critical part of any management system. The policies, procedures, standards, and guidelines related to Argus are structured in a hierarchical fashion. Policies refer to related procedures which in turn point to relevant guidelines, standards etc (see Figure 2). The top level policies and procedures are linked together in the *Argus Security Handbook*. The existing document system used by the lab for ISO 9001, 18001, and 14001 management systems is also being utilized for Argus' documentation.

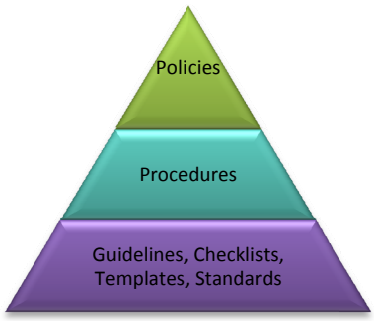

Figure 2: Argus Documentation.

		Information Class				
		Class I	Class II	Class III	Class IV	Class V
Access Medium	Control Network	Not Allowed	No Controls for PVs and Embedded Controllers. Authorization for other data.	Authorization, Encryption	Authorization, Encryption	No controls for read. Authorization, encryption for write.
	DAQ Network	Not Allowed	No controls for read. Authorization for write.	Authorization, Encryption	Authorization, Encryption	No controls for read. Authorization, encryption for write.
	Office Network					

Figure 3: Access Control Matrix.

ARGUS CONTROLS

The controls used in Argus are identified in Argus Statement of Applicability. A security policy for the department and a policy for its periodic review were defined. An organization structure is put in place to focus on information security and management of Argus. It consists of Information Security Board, IT Group, and Information Security Manager. The EE department head leads this organization. The physical and human resource security policies and procedures are based on current practices which were found to be adequate. For disaster recovery, the backup tapes are taken off-site on a weekly basis. A mechanism for live off-site backups, to a remote facility, is being implemented. Business continuity plans and procedures are defined but not tested. Many of the standard operations and communications management controls were found to be adequately covered by the current practices; the rest were implemented.

The current Trouble Reporting System used for the existing ISO based management systems (9001, 18001, and 14001) is being utilized for security incident management. Legal, statutory, and contractual compliance policies are based on NSCL's and MSU's policies.

The existing software development and project management policies and procedures were incorporated into Argus. New policies and guidelines on secure software development practices were developed.

Access Control

The information assets were classified into five categories, Class I through V, Class I being the most sensitive and Class V being least sensitive. Information assets in the department can be accessed through various means: Internet, Michigan State University Wired or Wireless Network, NSCL Controls Network, NSCL Office Network etc. Access controls were defined based on the information class and access method. An example access control matrix is shown in Figure 3. To improve security, the various networks within the lab were segregated, through a firewall, at the end of last year.

ARGUS LIFECYCLE

Argus is a living system; it continuously improves itself through reviews, audits, and feedbacks. The phases and activities of its lifecycle, defined in *Argus ISMS Policy* and *Argus ISMS Procedure*, are summarized below.

- Plan
  - Define Scope and ISMS Policy
  - Develop Approach to Identify, Evaluate, and Treat Risks
  - Identify and Analyze Risks
  - Evaluate Risk Treatment Options
  - Select Controls to Treat Risks (Statement of Applicability)
- Do
  - Develop Risk Treatment Plan (RTP)
  - Implement RTP
  - Measure Effectiveness of Controls
  - Manage Information Security Incidents
  - Implement Training and Awareness Programs
- Check
  - Monitor and Review Argus
  - Conduct Internal Audits
  - Measure Argus' Effectiveness Based on Audits, Incidents, Feedback etc
  - Review Risk Assessment
- Act
  - Identify Improvements Based on Reviews/Audits
  - Identify and Implement Corrective and Preventive Actions

RETROSPECTION

Challenges

Control Systems have been designed, by vendors and the community, with little emphasis on security. They are not designed to guard against malicious code or unauthorized access. So they have to be secured through external means such as management procedures, user training, and network isolation. It is also difficult to harden control system platforms such as PLCs. We found that it is difficult to implement secure software development processes. Programmers should understand and guard against security issues like buffer overflows,

memory leaks, SQL-injection etc which add to their programming effort. Static and dynamic source code analysis tools are useful but require programmers to learn to use them.

The educational and research oriented environment in the lab is also not favourable for implementing security procedures. Changing the culture of the organization is a challenge. Security conflicts with convenience, and finding the balance is difficult.

Lessons Learnt

ISO 27001 is an extensive standard; implementing it is an onerous task. However, it is not necessary to implement it across the entire organization in one shot. The standard allows the scope to be adjusted. Hence, it is crucial to start small, implement it, and then expand. For the initial iteration, start with the current practices, document them, establish the initial ISMS, and them improve upon it. Do not make drastic changes to the current processes; this will only infuriate the users. Remember, users are an important, if not the most important, part of the overall security system.

The most important factor for the successful implementation of any management system, especially ISO 27001, is management support. Without it, the required changes to the organization's culture are impossible.

Leverage the infrastructure of existing management system like ISO 9001. There are several similarities among these standards, which allow the infrastructure and processes to be shared.

ISO 27001 implementation requires support from every unit of the organization, so involve all the units in the process especially during risk assessment. We made a deliberate decision not to use consultants to help us with the implementation. An in-house team is required to manage the ISMS. The consultant may help with the templates and guidance, however bulk of the work still needs to be done by the in-house team. It is worthwhile to train the in-house team in ISO 27001 audit and related trainings.

ARGUS PROJECT

Risk assessment, Statement of Applicability, Risk Treatment Plan, and initial set of documentation have been completed. The registrar for external audit has been selected through a formal bidding process. The external audit of Argus comprises of pre-assessment, Stage I audit, and Stage II audit. The Argus documents are currently being vetted. Internal audit and pre-assessment are expected to be completed by end of 2011.

The project to develop Argus was started in August of 2009; it is expected to finish in the early 2012. The estimated effort was approximately 1000 person hours, of which approximately 800 have been currently spent.

CONCLUSION

. Was the implementation worth the effort and cost? We think so. Due to this exercise, we have a very good insight into our vulnerabilities, threats, and risks. This experience has helped us incorporate security as a design element in the development of our systems. The original intent was to eventually expand this to the rest of the lab. Even though this implementation was not a requirement from our current customers, we feel that it will eventually attract more security-sensitive projects to the lab.

ACCESS SAFETY SYSTEMS – NEW CONCEPTS FROM THE LHC EXPERIENCE

T. Ladzinski, Ch. Delamare, S. di Luca, T. Hakulinen, L. Hammouti, F. Havart, J-F. Juget, P. Ninin, R. Nunes, T. Riesco, E. Sanchez-Corral Mena, F. Valentini, CERN, Geneva, Switzerland

Abstract

The LHC Access Safety System has introduced a number of new concepts into the domain of personnel protection at CERN. These can be grouped into several categories: organisational, architectural and concerning the end-user experience. By anchoring the project on the solid foundations of the IEC 61508/61511 methodology, the CERN team and its contractors managed to design, develop, test and commission on time a SIL3 safety system. The system uses a successful combination of the latest Siemens redundant safety programmable logic controllers with a traditional relay logic hardwired loop. The external envelope barriers used in the LHC include personnel and material access devices, which are interlocked door-booths introducing increased automation of individual access control, thus removing the strain from the operators. These devices ensure the inviolability of the controlled zones by users not holding the required credentials. To this end they are equipped with personnel presence detectors and the access control includes a state of the art biometry check. Building on the LHC experience, new projects targeting the refurbishment of the existing access safety infrastructure in the injector chain have started. This paper summarises the new concepts introduced in the LHC access control and safety systems, discusses the return of experience and outlines the main guiding principles for the renewal stage of the personnel protection systems in the LHC injector chain in a homogeneous manner.

INTRODUCTION

The access safety system is a vital component of every accelerator facility without which beams cannot be injected and accelerated in a machine. Its principal duty is to ensure that if there is beam in the machine no human being is inside, and if there is a human inside that no beam can be injected.

The Large Hadron Collider access system was put in operation in 2008 following one year of gradual commissioning. It introduced new concepts and safety levels, which were not present in the earlier accelerators at CERN. Within the activities of the LHC injector chain upgrade, the injector complex access safety systems are also being overhauled. Our team is currently involved in the renovation of the Proton Synchrotron (PS) personnel safety system and plans are underway to start the upgrade of the access and safety system of the Super Proton Synchrotron (SPS). These activities should bring the level of safety of the corresponding access systems at least to the level of the LHC system and provide the so much sought after harmonisation of equipment and user experience over the entire accelerator complex of CERN.

SAFETY PROJECT ASPECTS

An access safety system is a complex interlock mechanism acquiring the status of, and acting on, hundreds of Elements Important for Safety (EIS) [1]. We distinguish between EIS-access and EIS-beam. The EIS-access consist of the personnel and material access devices, doors, moveable shielding walls etc. The EIS-beam are accelerator components that can stop the circulation and the injection of beams. The choice of EIS-beam allows redundancy for each interlock chain with technological diversity (e.g. a bending magnet and a moving stopper obstructing the beam aperture). The number of individual components under the responsibility of various organisational units with different approaches to safety provides additional challenges to the overall safety system design and project coordination activities.

In order to achieve the desired level of safety, the safety systems at CERN are designed using the IEC61508 [2] family of standards as a methodology framework. The IEC61508 uses a probabilistic approach to quantify the risks and to check that a system can cope with the requirements defined for each safety function. To this end it introduces the notion of Safety Integrity Level (SIL), which is a measure of safety. It allows to determine the target level of risk reduction that a safety instrumented system should provide. It is scaled from 1 to 4. The higher the occurrence rate of a hazardous event or the severity of its consequences, the higher the SIL level and the implementation constraints. In order to deal with the functional safety aspects, a project strategy has to take into consideration the following aspects [3]:

- preliminary risk analysis;
- specification of the safety instrumented functions with their corresponding SIL level, e.g. stopping the beam in case of an intrusion has been evaluated as a SIL3 function;
- preliminary safety study based on the first version of the functional analysis of the architecture;
- design and implementation of the system based on V-shaped lifecycle model;
- verification and validation of the system;
- organisation of operation and maintenance;
- definitive safety study of the "as built" system, verifying that the SIL of each safety instrumented function has been achieved.

A vital organizational aspect of a safety project is the independence of teams conducting various project steps. This is often achieved by outsourcing the development tasks to external companies. The CERN team participates in the specification and verification phases, the actual implementation is done by a specialized contractor meeting the tender process requirements. The final validation that the system fulfils its mission is done by yet another independent body – the Departmental Safety Officer of the Beams Department conducts an independent test before permitting any beam operation. In addition, throughout the project lifecycle independent consultants are hired to conduct the safety studies and evaluate the SIL level achieved.

THE LHC ACCESS SAFETY SYSTEM ARCHITECTURE PRINCIPLES

Control and Safety Separation

Following the principle of strict separation of the functional safety part from the process control part, the LHC access system is made up of the LHC Access Control System (LACS) and the LHC Access Safety System (LASS) [4].

The role of the LACS is to provide a physical barrier enclosing the LHC accelerator and dividing it into clearly delimited sectors, and to identify the person and verify his or her access authorisations. The LACS controls the access equipment and provides audio and video links between the control room and the field.

The LASS is an interlock system ensuring that no beam can circulate or be injected in case of access operation and that every intrusion detected during the beam operation leads to an immediate stop of the accelerator in a controlled manner. Its EIS-access comprise 40 personnel and 29 material access devices, 203 doors dividing the underground areas into 82 sectors, 17 mobile shielding walls etc. The EIS-beam which can, in parallel to the LHC beam dump system, stop any circulating beams and any injection of new beams are: the mobile beam dumps, horizontal dipole chains and injection septa in the two transfer lines from the SPS to the LHC, the separation magnets in the two collimator regions of the LHC and two reinforced vacuum valves.

The division into two distinct systems allows the use of different hardware, software and testing solutions, each more suited for the specific needs of the subsystem.

Two Channel System

The LASS control system has a distributed architecture and uses the Siemens 417FH Programmable Logic Controllers (PLC). At each of the LHC points a local controller monitors the state of all the EIS of that point and calculates the site resultants which are transmitted to the global controller. The global controller acquires the information obtained from each of the local units and takes the necessary safety actions, calculating a global resultant to enable or disable the global access safety veto. The controller units are linked via a dedicated redundant fibre network routed in the LHC tunnel.

This architecture has been complemented with a relay logic cable loop that provides a technologically redundant logic mechanism to stop the beams in case of an intrusion via the external envelope of the accelerator. In this way, not only the sensors and actuators are provided with sufficient redundancy, but also the central system logic. This goes beyond the commonly used architectures, where a SIL3 system is composed of redundant sensors and actuators and a SIL3 certified logic controller (which is internally redundant providing two execution channels for the safety program). However, the total response time of a system based solely on the PLCs might exceed the needs of the process, as a distributed architecture relies on numerous timeouts before driving the system into a failsafe state in case of a safe failure. Moreover, the IEC61513 standard, a nuclear sector extension of the IEC61508, recommends diversity of means to achieve the safety objectives and thus to minimise a common cause of failure. This is where the simple relay logic steps in.

In the case of the LHC, the relay logic was added to protect the risk of intrusion. For the PS complex this concept has further been expanded to provide redundant logic mechanism that acts also in case of a momentarily lost safe state of an EIS-beam. Contrary to the LHC, which in fact is one accelerator, the PS is divided into several machines with transfer lines providing beam from one to another. In case of a problem with an EIS-beam in one machine, the interlock system immediately acts on the EIS-beams of the upstream accelerator.

External Envelope Inviolability

In a long shutdown period anyone authorised can enter the accelerator. Once this period is finished, all the machine interlocked areas are patrolled to make sure that nobody was left behind. As this process is long, the machines are subdivided into access sectors, each having a binary memory called “search”. The search is armed at the end of a patrol and disarmed only in case of intrusion or an entry in the shutdown period. During beam operation period, short technical stops are often necessary to allow accesses for corrective maintenance interventions. The technicians entering the interlocked zones are not protected by the collective search/patrol mechanism, but instead are given personal protection tokens. As long as all the tokens are not restored, the interlock system will not allow beam operation. This safety concept functions correctly provided there is no possibility of entering the interlocked areas without a token. Hence, the EIS-access of the accelerator external envelope must form an inviolable barrier. In the pre-LHC machines this was achieved by means of video surveillance by the control room operators. The sheer size of the LHC and the number of concerned personnel entering the interlocked areas has put the efficiency of such a solution in question. The external envelope has therefore been equipped with access devices or door-booths, which operate on the same principle as an air-lock

chamber. They are small volumes closed at each end with doors, of which only one can open at a time.

In addition to its volume, which is only large enough to accommodate one person, the Personnel Access Device (PAD) is equipped with a complex automatic system based on ground pressure sensors, infrared radar and photo-electric cells surveying the interior at each passage to eliminate piggybacking and tailgating. Furthermore, the usage of a PAD enhances security making it impossible to trespass the interlocked area. Iris biometric recognition system inside each PAD verifies a match between the access badge used and the identity of the access requester. The access control system, in turn, verifies the person's access authorisations and their validity, and checks the status of the periodic obligatory safety trainings and tests.

The Material Access Device (MAD) is also a door-booth, but of much bigger volume, and allows the introduction of bulky material into the interlocked zones. Each MAD is equipped with a human presence detection system. It comprises infrared barriers close to the doors, two volumetric consumer-off-the-shelf detectors and a motion detection system with a millimetre resolution developed at CERN. The later uses a high resolution digital camera (3M pixels) capable of covering the whole MAD volume (approx. 20m3) and a custom algorithm. By analyzing the digital video frames in real time it estimates precisely the quantity of motion inside the MAD on the basis of small luminosity variations in the frame's pixels. A special analysis of any mutated pixels allows discriminating the real movement from the background noise inherent to all digital images.

LHC EXPERIENCE & NEW CONCEPTS

Usability

The LHC access system was built to a higher degree of safety than its predecessors, but the overall ergonomics has not seen major changes with the exception of the introduction of the door-booths. With the explanations on the use of the devices becoming part of the mandatory safety training, the usability problems have decreased and only sporadically users are rejected e.g. because their backpack obstructs the photo-electric cells in the PAD.

Work Acceptance Tool

Passing through a door-booth requires more time than using a door and this fact combined with the extremely high usage rates during the technical stops (see Table 1) may lead to occasional congestion at the access points.

Table 1: LHC Access Statistics from a 5 Day Long Technical Stop (29.08.2011 – 2.09.2011)

Area	Entry & Exit Passages	Refused Passages	**Total**
Service Area	5'831	243	6'074
Tunnel Area	1'766	13	1'779
Experimental Area	3'209	55	3'264
Total	10'806	311	**11'117**

Analysis has shown that the major congestion factor was the relatively long time it took for the operator to verify if an entry request was in relation to a planned maintenance activity. This was largely resolved with the introduction of the Work Acceptance Tool (WAT), linking an intervention planning tool and the access control system. During technical stops, the WAT automatically limits access to planned maintenance interventions only.

Separation of Token Distribution from PAD Cycle

The LHC access system seldom uses the shutdown access mode ("general" in the LHC terminology), as the day-time maintenance is often interweaved with night-time testing activities requiring the interlocked areas to be patrolled and free of personnel. Hence, in most cases the person entering is in possession of a safety token to preserve the sector search. The delivery of a safety token is integrated with the PAD entry cycle and thus a new token cannot be delivered until the previous person has successfully entered. In the PS, the two actions will be decoupled, with the user first taking the token under the supervision of the operator and then entering the PAD, while the operator can already treat another request.

Maintainability

Maintenance has always been an issue for the access systems as they are required 24 hours a day, 7 days a week; when the accelerator is operating with beam and even more so, when it is in access mode.

Maintenance Doors

Traditionally, the accelerators at CERN had been operated in annual cycles of 7 to 8 months of beam followed by 4 to 5 months of maintenance shutdown. In LHC the long superconductive magnet warming and cooling time has led to a change in the operation calendar strategy with the introduction of short annual shutdown periods and a long shutdown once every few years when the magnets are being repaired. The annual maintenance periods have thus become much shorter making it very difficult to perform the necessary maintenance and verifications activities, especially of the complex access devices of the external envelope. This has resulted in ongoing studies with the goal of moving the external envelope to a second line of protection (e.g. the ventilation doors behind the access devices) during beam operation, thus providing the maintenance teams the time to do preventive interventions on all surface access points while the accelerator is in beam operation.

Removing the EIS-beam from an Interlock Chain

The EIS-beam are surveyed by the LASS permanently. Should they quit their safe state in access mode, the LASS blocks access and, in case of multiple failures, orders evacuation of the interlocked areas. EIS-beam can only undergo maintenance during a complete shutdown of the accelerator complex. This is regulated by a strict procedure. In order to facilitate their disconnection from the system using special "out-of-chain" keys, additional safety functions have been recently introduced. As long as all the EIS-beam are not connected, the upstream chain interlock will not allow beam operation.

Extensibility

An extension of an existing safety system requires the same rigorous approach as the original development project. This strictness filters non-justified *ad hoc* demands and preserves the safety integrity of the system. Until now one major extension has been identified for the LHC access system. It concerns extending the scope of the system not only to cover the radiation hazards, but also risks related to a major helium release in the tunnel and an upgrade is planned for the first long shutdown.

New SIMBA/SIMIT Test Platform

Any change, whether an addition of one EIS or a big extension requires a big testing effort. The LASS test platform [5] provides a test-bed for 2 out of 9 LHC sites at a time. The drawbacks of this test platform are the need for hardware reconfiguration of the I/O modules when changing the simulated LHC sites and a very basic simulator user interface. In the PS, composed of 19 different machines, each with specific configuration, a more versatile test platform is needed to be able to cope with testing of possible extensions. It will be based on Siemens SIMBA module which allows emulation of any I/O configuration without costly hardware reconfiguration and SIMIT software tool facilitating simulation scenarios.

Reliability and Availability

During the past three years of LHC operation, the access interlock has only once caused a spurious beam dump and has been available all the time. The LASS has reacted correctly on all occasions and the safety of the personnel has never been compromised. However, the availability of the LHC for physics has been slightly affected by several spurious sector search drops in access mode, resulting in lengthy patrols. There is no single explanation to the origin of the lost patrols, but they can be attributed to one of the following origins:

- electromagnetic compatibility (EMC) issues;
- lack of synchronisation between control and safety;
- data exchanges between the access point controllers.

EMC Improvements

In the LHC, most of the originally installed magnetic door sensors have been recently replaced by more robust electromechanical contacts. These are not affected by the magnetic fields, but need delicate adjustments. For the PS, a thorough campaign of EMC measurements has been done prior to choosing the access equipment locations.

PAD Control and Safety Synchronisation

In the rest position the LHC PAD inner doors are open. Hence, a safety action applied in the middle of a PAD entrance cycle may in some cases result in the LASS briefly registering both the inner and outer doors opened, which results in a patrol drop. The separation of process control and safety does not preclude synchronisation of the control tasks with the safety actions and the currently designed PS access devices should have one PLC running the two tasks in two processes, with safety having a higher priority, but the control being well synchronised.

Simplified Access Point Control Architecture

An LHC access point composed of one PAD and a MAD is equipped with a total of 5 industrial controllers and a PC which adds to the above mentioned synchronisation issues all the problems of communication between the tasks running in the different controllers. The PS personnel safety system architecture will use only 2 controllers and one PC, as the architecture chosen supports process level integration and not integration of many consumer-off-the-shelf solutions.

Anti-Fraud Detection as a Safety Function

The critical detection of a fraudulent passage in access devices - human presence in a MAD and multiple persons in a PAD - is currently performed by several local controllers. This may lead to the unavailability of the devices in case of failure of one of the controllers. To improve the dependability of these processes it was decided to implement them as new safety instrumented functions of the PS safety system. Moreover, the PS PAD model chosen provides less internal volume making it virtually impossible to fraud.

CONCLUSIONS

The LHC Access System has been in production since early January 2008. The past four years have shown that it has met the desired safety integrity level, thus confirming both the project organisation and the design choices.

In this paper the IEC61508 based methodology used in the project lifecycle phase was presented as well as the important technical principles of the LHC access system. The experience gathered during the operation and maintenance phase was further discussed focusing mostly on improving the system in order to reduce accelerator downtime resulting from access related issues. New concepts have been identified and discussed. They currently start being introduced in the access safety systems of the LHC and its injector chain.

THE LASER MEGAJOULE FACILITY PERSONNEL SECURITY AND SAFETY INTERLOCKS

Jean-Claude Chapuis, Jean-Paul Arnoul, Alain Hurst,
Mathieu Manson, CEA/CESTA, Le Barp 33114 France

Abstract

The French CEA (Commissariat à l'Énergie Atomique) is currently building the LMJ (Laser Mégajoule), at the CEA Laboratory CESTA near Bordeaux. The LMJ is designed to deliver about 1.4 MJ of 0.35 µm light to targets for high energy density physics experiments. Such an installation entails specific hazards related to the presence of intense laser beams, and high voltage power laser amplifiers. Furthermore, the thermonuclear fusion reactions induced by the experiment also produce different radiations and neutrons burst, and also activate various materials in the chamber environment. All these hazards could be lethal. The SSP (Personnel Safety System) was designed to prevent accidents and protect personnel working in the LMJ.

DESIGN METHODOLOGY

Saftey Studies

For each type of hazard generated by the LMJ process (laser, high voltage, radiations), scenarios of accidents are identified and qualified in terms of gravity and frequency.

Table 1: Gravity v.s. Frequency

Gravity →	Lethal	Impor-tant	Impor-tant	Major	Major
	Major injury	Signi-ficant	Signi-ficant	Impor-tant	Major
	Minor injury	Minor	Signi-ficant	Signi-ficant	Impor-tant
	Incon-fort	Minor	Minor	Minor	Signi-ficant
		Rarely (< 2 times / year)	Some-times (< 20 times / year)	Often (< 200 times / year)	Perma-nent (> 200 times / year)
		Frequency of exposure →			

The table 1 is then used to determine the risk level (i.e. the importance of the potential accident) that is used in the table 2 that indicates the number ant the type of the associated protection barriers necessary to mitigate the risk at an acceptable level.

The CEA security methodological guide defines 2 types of barriers:

- The technical barriers (TB), that are any technical device used to protect the workers, such as access control or safety interlocks,
- The procedural barriers (PB) that involve a human action, that are used in complement of the TB to increase the protection level when necessary.

It also specifies the number of required barriers versus the identified risk level, with 2 options: desirable or acceptable. The choice between those options is generally technical, but it is often also cost driven.

Table 2: Risk Level v.s. Number of Barriers

Risk Level	**Number of barriers**	
	Desirable	Acceptable
Major	3 TB's	2 TB's + 1 PB
Important	2 TB's	1 TB + 1 PB
Significant	1 TB	2 PB's
Minor	2 PB's	1 PB

Functional Analysis

The objective of the Personnel Safety System is to prevent transitions from a safe state to a forbidden state**.**
The safe states are:

- Presence of hazard requiring the absence of personnel,
- Presence of hazard AND all the persons are qualified to work in presence of the hazard,
- Absence of hazard.

The forbidden states are:

- Presence of hazard requiring the absence of personnel AND presence of personnel,
- Presence of hazard AND a person is not qualified to work in presence of this hazard.

So the transitions that must be prevented with adapted barriers are the following:

- Entrance of a person when a hazard requires the absence of personnel,
- Entrance of a person not qualified for a present hazard,
- Occurrence of a hazard requiring the absence of personnel in presence of personnel,
- Occurrence of a new hazard in presence of unqualified personnel.

Two different kinds of safety systems are required to prevent these transitions:

- Access control to the building and to its different areas, that involves doors switches, safety locks and associated hardware.
- Risk management that involves safety interlocks, in relation with the potentially hazardous equipments. These equipments have to wait for permissive before generating any hazard, and have to acknowledge when the hazard is present.

FUNCTIONNAL ARCHITECTURE DESIGN

Design Principles

To satisfy at the lowest cost the requirements of safety regulations and those of the operation management, the choice was made to implement a functional architecture built around two independent technological barriers when required by the risk level.

The combination of these two independent technological barriers allows managing the dynamic evolution of the compromise between hazard presence and worker presence in the rooms, throughout the various scenarios identified in the safety studies.

Each technical barrier is composed of two subsets, one dedicated to hazard sources management, and the other one dedicated to worker presence management.

The two completely independent barriers, even at the sensor or actuator level, are designed with different technologies adapted to the required Safety Integrity Level (SIL 2 or SIL 3). The combination of these 2 barriers is equivalent to a unique barrier with a rate of dangerous failure of ~10^{-6} per year.

IEC 61508 Standard

The **IEC** (International Electrotechnical Commission) 61508 standard specifies a set of requirements for functional safety of electrical / electronic / programmable electronic safety-related systems.

It defines 4 levels of requirements or « SIL » that must be respected according to the acceptable failure objective of a safety function, either in continuous operation mode, or in low demand operation.

These levels are used to specify the safety requirement of each device or software involve in the SSP.

Table 3: SIL v.s. Average Failure Probability

Safety Integrity Level	Average probability of Failure on Demand per year
SIL 4	$\geq 10^{-5}$ à $< 10^{-4}$
SIL 3	$\geq 10^{-4}$ à $< 10^{-3}$
SIL 2	$\geq 10^{-3}$ à $< 10^{-2}$
SIL 1	$\geq 10^{-2}$ à $< 10^{-1}$

FUNCTIONAL DESCRIPTION OF SUBSETS

The SSP is composed of 3 main subsystems:

- The first technical barrier (TB #1),
- The second technical barrier (TB #2) totally independent from the first one,
- The SSP supervisory system that present different GUIs to the operator.

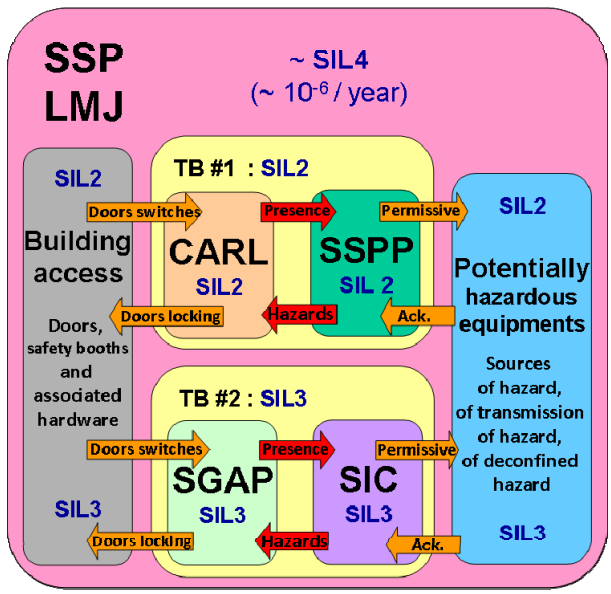

Figure 1: General SSP architecture.

First Technical Barrier

The first barrier designed in SIL 2 is based on a programmable technology (safety PLC). It is itself composed of two functional subsets:

- The "CALR" (Contrôle d'Accès des Locaux à Risques) ensuring access control to the areas that present hazards, by using contactless personal badges (RFID technology) and safety locks.
- The "SSPP" (Système pour la Sécurité du Personnel Programmé) controlling both the presence of hazards and their authorizations (permissive) at the equipment level.

The probability of a dangerous failure of the first barrier is between 10^{-2} and 10^{-3} per year.

Second Technical Barrier

The second barrier designed in SIL 3 is based on a non programmable technology (safety relays or equivalent). It is itself also composed of two functional subsets:

- The "SGAP" (Système de Garantie d'Absence de Personnel) whose objective is to ensure the absence of workers in the target bay during a powerful laser shot, thus preventing the risk of death due to a neutron flash. Access management to the rooms is done using access keys provided by a guard.

- The "SIC" (Système d'Interverrouillage Centralisé) that ensures, with key based safety interlocks, that the laser beams and the power conditioning system cannot be activated unexpectedly during a maintenance period.

The probability of a dangerous failure of this barrier is between 10^{-3} and 10^{-4} per year.

SSP Supervisory Software

Dedicated GUIs are provided to the operators in charge of the LMJ safety.

The main GUI presents the status of all the LMJ SSP. It has an alarm zone and an event log to allow alarm managing, and different control zones with push buttons to deliver risks authorization. Other GUIs present to the operator a general view of risks, a general view of the process state and a general view of the building security. Detail views are dedicated to hazardous equipments such as laser bundles, power conditioning devices, and Laser sources.

This software layer is designed with Panorama E^2 (the CODRA Company SCADA product) under Windows 7. It is independent from the safety loops which are controlled at the lowest level by PLC.

AUTOMATIC ANALYSIS AT THE COMMISSIONING OF THE LHC SUPERCONDUCTING ELECTRICAL CIRCUITS

H. Reymond, O. O. Andreassen, C. Charrondiere, A. Rijllart, M. Zerlauth,
CERN, Geneva, Switzerland

Abstract

Since the beginning of 2010 the LHC has been operating in a routinely manner, starting with a commissioning phase and then an operation for physics phase. The commissioning of the superconducting electrical circuits requires rigorous test procedures before entering into operation. To maximize the beam operation time of the LHC, these tests should be done as fast as procedures allow. A full commissioning need 12000 tests and is required after circuits have been warmed above liquid nitrogen temperature. Below this temperature, after an end of year break of two months, commissioning needs about 6000 tests. As the manual analysis of the tests takes a major part of the commissioning time, we automated existing analysis tools. We present here how these LabVIEW™ applications were automated, the evaluation of the gain in commissioning time and reduction of experts on night shift observed during the LHC hardware commissioning campaign of 2011 compared to 2010. We end with an outlook at what can be further optimized.

INTRODUCTION

The first LHC Hardware Commissioning Campaign (HCC) was started early 2008. The aim of this crucial phase, mandatory before to put the accelerator into operation, was to test in real conditions all the equipment and systems of the machine. It included protection systems and all the superconducting electrical circuits.

For this purpose, two types of tools were developed [1], one to manage the execution of the tests and a second to provide data analysis, to deal with the big amount data from the tests. The initial approach used when designing these analysis tools, was to help the users to perform manual analysis of the data with a tool that permitted to select a test result set, automatically load interesting signals and display them in a GUI that could easily be used by experts from several domains.

During the HCC, human and time resources have been optimized. Less people were available for the LHC start-up tests therefore to speed up the tests, the framework and the applications have been improved to permit execution of tests in parallel on several circuits. Furthermore, with the increased electrical circuit's knowledge, it has been possible to set limits to measured and calculated parameters, which led to automate part of the analysis.

SYSTEM OVERVIEW

The Electrical Circuit Commissioning (ECC) consisted of a series of tests to provoke a reaction of all interlock and protection systems. Different current cycles (see Fig.1) were applied on these circuits to validate them, up to nominal current.

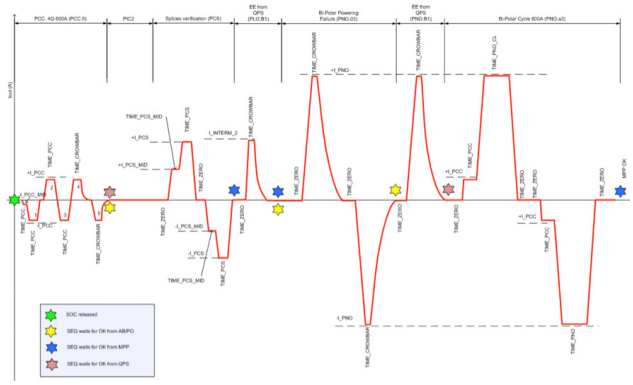

Figure 1: Current cycles for 600A circuit validation.

Each reaction of a protection system generated a so-called "Post Mortem" file, in which the most important parameters were stored in a circular buffer with time stamped data. These files were then collected and archived to be later analysed using the Post Mortem Analysis tools.

The Post Mortem Analysis System

The Post Mortem framework is made of three main systems [2]. The *Sequencer* application edits test cycles and sends commands to the power converters. The *Post Mortem Request Handler* (PMRH) collects the data files from the involved equipment and associates them to the test parameters sent by the *Sequencer*. The *Post Mortem Event Analyser* (PMEA) provides a GUI for experts to easily retrieve and analyse a test.

Several GUIs have been built to present data of specific tests. They display the executed current cycle, the values returned by the involved equipment and the calculated values (ramp, min-max, delays, resistances...).

Principle of Validation of an Electrical Circuit

The validation of an electrical circuit is performed as follows: From the sequencer, an operator selects the circuit to be tested and attributes a series of test steps to be performed, depending on the circuit type (nominal current and specific limits). Automated checks are made to verify that the circuit is available and not blocked by interlocks. When all conditions are met, the sequencer generates and sends commands to the power converter of the related circuit.

During the current cycle execution, the protection equipment reacts and generates post mortem files. These files are collected by the PMRH, from all systems in the

interlock and protection chain of the circuit. Their data are merged into one event. Then all available events are presented in the PMEA GUI. It gives an overview of the executed tests that are waiting for analysis, but also those already verified.

To validate a test step of a circuit, the event generated must be analysed and signed by experts of all involved domains (interlock system, powering, quench protection, cryo). When all the experts have signed and accepted the analysis results, this information is returned to the *Sequencer*. This allows the system to launch the next test step. In case of rejection of one analysis, the circuit powering is blocked.

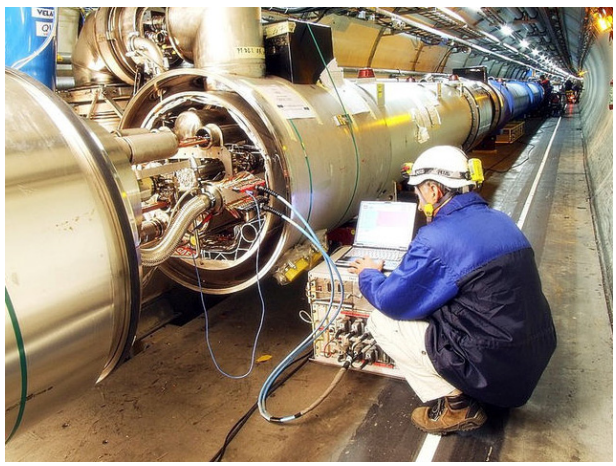

Figure 2: High Voltage qualification in the LHC tunnel.

Then the problem must be investigated and solved before a new test sequence is launched. This could means an intervention in the LHC tunnel (see Fig. 2) to make on site measurements to understand the facts, replacement of some parts in case of device failure or sometimes loading a new firmware release into an electronic system.

Each tunnel intervention must be scheduled and well organized to optimize the time and the work of the involved teams.

LHC Circuits Layout

The LHC circuits are divided into eight independent sectors. Each circuit can supply one or many magnets, depending of the circuit type. For example, one 13kA power converter drives 154 dipole magnets. There is a large range of different circuits, with currents of 60A, 80A, 120A, 600A, 6kA, 8kA and 13kA. These circuits power all the main dipoles and quadrupoles and their respectives correctors, such as sextupoles, octupoles, decapoles and dodecapoles.

ELECTRICAL CIRCUIT COMMISSIONING EVOLUTION

Almost all of the test management and analysis tools used today have been developed for the first complete Hardware Commissioning of the machine in 2008. Many improvements were made during the next campaigns, thanks to the experience gained. But also an effort to enhance the efficiency was conducted in order to minimize the testing phases, with the objective to increase the time dedicated to physics.

In the early age of the ECC, the sequencer could only manage one test at a time. It was then modified [3] so that it can run tests on various circuits in parallel. Introducing this feature in the test sequences was possible due to the sectorisation, but also by the large range of circuit types.

To meet this challenge we instantiated some parts of the PMRH code, used for collecting the PM files. As the PMRH, the PMEA and all analysis tools were developed with LabVIEW™; it was easy to introduce VI templates, and then call them as a clone when needed. From the analysis framework point of view, introducing parallelism in the tests was transparent.

Taking into account the Human Factor

At that stage the experts, started to be drowned in hundreds of events per day; to analyse and sign. In effect, without counting the selection tools for viewing the tests and those dedicated to the display of data as curves with pre-loaded signals, it took about 3 minutes to analyze a test. With an average of 300 tests per day to achieve the objectives, 15h in front of the screen were necessary, to check similar plot and table results. As the slightest variation could have an enormous importance in terms of reliability and safety of the machine.

As for any major achievements, taking or not into consideration the human factors that may be crucial for the success of the project. In the case of ECC, for many technical fields, the same experts who participated in the design and installation of the system then participated in validation tests, and sometimes also applying hardware corrections and compliance. It is not difficult to understand that whatever the motivation and professional commitment of the person who analyzes, his acuity and assessment will not be the same between the first and the 200th analysis. So, even by applying the same criterias, the first bad events will be surely rejected, but later could be accepted as near to the limits.

Introducing Automated Analysis

To overcome the problem of the number of tests to be signed by the experts, it was decided to automate some analysis. This was made possible from the ECC 2009, using the knowledge acquired from the previous campaign. Hence some acceptance ranges and even more restrictive criterias could be defined to specify automatic analysis algorithms for some particular circuits.

The first tool fitted with automated analysis was the Powering Interlock Controller (PIC) [4]. Originally it was dedicated to verify delays and status of digital signals, coming from the interlock system. The role of the expert beiing to check some patterns and signals synchronisation, according to various parameters, such as circuit type, test type and protection equipment present in the interlock loop.

After one complete ECC, expected delays and synchronisation scenarios were well known. They have then been coded in LabVIEW™ and introduced in a new PIC analysis (see Fig. 3). The left part shows interesting digitals and analog signals; the right side is dedicated to a summary table, with measured and expected values. Overranged values are highlighted in red. The bottom area is reserved for the final analysis result represented by a big passed / failled indicator and a user comments field. A button allow experts to sign the test (accept or reject) after authentication.

The PIC analysis tool was a good candidate to start automatisation. Once digital signals patterns and delays are measured and valided by the interlock equipment experts, they remain almost fixed for the system lifetime. Second, the PIC systems commissioning needs repetitions of the same test on large number of circuits. So automatising is a real benefit.

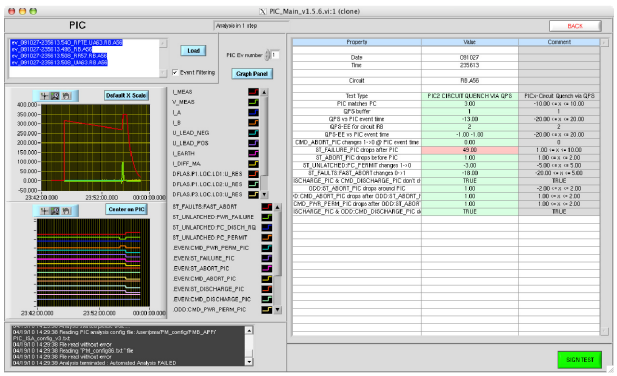

Figure 3: Analysis panel for PIC2 test type.

Following this example, two other analysis have been automated. The Powering to Nominal used to measure and check a set of values during some current cycles execution (resistance, ramp rate, overshoot). The Discharge analysis aims to study power converter reactions that receive a slow or fast power abort signal. For these two applications, useful signals were presented as XY graphs and compared to expected criterias, displayed in a concise results table.

Full Automated Analysis and Test Signing

A last step in improving the efficiency of ECC has been developed and used at the beginning of the LHC HWC 2011, with the automated execution and signing of the analysis.

The analysis tools, with automated verification procedures, allows on one hand to verify the proper functioning of these tools (application of criteria adapted to the test conditions) and on the other hand to use the confidence in the system acquired during the validation campaigns of electrical circuits in 2009 and 2010.

From a technical point of view, the PMA applications have been modified to incorporate the automation. A selection tool has been added to the PMEA, to select which test types will be automatically analyzed and signed, in the three applications involved (PIC, PNO and Discharge).

On the PMRH side, the buffer collection was configured thanks to a look-up table, that associates each test type with the expected number of buffers for each equipment covered by the test. Hence, once all the data are received, the required analysis for an event can start immediatly. The PMRH being a server, it is possible to run in parallel dozens of analysis.

For the three analysis functions involved, we added them to a new execution mode. So when a call for an "automated-signing" is defined by the PMRH, the analysis runs, the results are generated and the signature (passed or failed) applied by the program. The final result of the test and the parameters of the event are then put at disposal to the experts, via the GUI of the PMEA.

They are also forwarded to the *Sequencer*, which then could block the electrical circuit in case of rejection, or launch the next stage of the test, if accepted. All these steps are executed transparently for the users, only failed analysis are highlighted in the PMEA, waiting for a deeper investigation by an expert.

Validating the Validation Tools

One of the crucial aspects of an automatic analysis is its integrity and reproducibility. Once the expert is confident with the tool, it is clear that he/she will not spend time looking at the passed analysis. Operation and safety of the machine depends then on the software quality.

To check these criterias, reference tests were selected by different experts for each type of analysis. Thus it is possible to restart as many times as necessary the tests (with known results) to verify the compliance of the results. A special module has been developed in the PMRH, it allowed us to quickly validate our tools at the beginning of an ECC, after modification, or in the case of a change of the LabVIEW™ version.

PRESENTATION OF THE RESULTS

The first two Hardware Commissioning Campaigns were a complete machine commissioning. In 2008, before the first exploitation of the machine, 15532 tests have been executed during 164 days, among them 12666 were successful. In 2009, after the incident that occured on September 19th 2008, 13611 tests have been performed in 89 days, with 11175 successfull. This moved the efficiency up to 82.10%.

For the following campaigns, the allowed timescale was drastically reduced to increase the time dedicated to physics operation. Moreover, most of the electrical circuits were not warmed above 80K during the last technical stops, it was then possible to reduce the number of tests, according to the circuits history.

In 2011 the ECC has been done in 21 days, with 6092 tests executed. From these, 3204 were automatically signed, 2065 by PIC analysis and 1139 by PNO. But still 1101 test for PNO.d1 and 496 for PNO.d3 had to be manualy signed with the Discharge analysis tool.

Several Sources of Improvement

Since the 2010 ECC, new valuable features have been integrated in the PMA framework: automated analysis, accepted tests results directly sent to the MTF (Manufacturing and Test Folder repository of the related circuit). This gives a full traceability of circuit behaviour, without possible error due to human input. On the other side, for failed tests, a non-conformity report is generated and forwarded to the dedicated management tool. This gives to the expert in charge an overview of the encountered defects, but also a trace of what has to be fixed, reducing the risk of missing one issue.

The time saved thanks to the signature test automation, freed the experts for critical tasks such as monitoring the repair of problems. This also allowed reducing the number of persons involved in the test execution.

The change in the organization of the tests [5] has been an important contribution too. The availability of night shifts launching a large amount of sequences of tests during the night, on all sectors in parallel gives the field workers the opportunity to organize and fix problems on non-compliant systems the following day.

CONCLUSION AND PERSPECTIVES

The Electrical Circuit Commissioning of the LHC is now a well-defined and documented exercise fitted with powerful procedures and software.

The automated analysis and results signing have proven their utility and efficiency. Reducing the time devoted to this task, helped to reorganize the experts' responsibilities and to decrease the number of people implicated.

A big effort has been done to take into account the human factor, when developing the analysis framework. Some improvements have still to be done, for user training, as specification of the tools are not directly written by future users, lots of practical features and useful tips included in the tools are unknown to them.

Most of the electrical circuits have been qualified to 3.5 TeV operation. During the next 2013 long shutdown, their qualification to 7 TeV (i.e. nominal magnet current) will require extended sequences of tests. Here again, fully automated analysis tools will be a key point for an efficient ECC execution. The future LHC operation needs more powerful applications to study complex conditions and machine interaction. They will help operators to overcome difficult behaviour and to get a forecast about equipment and systems status.

AUTOMATIC INJECTION QUALITY CHECKS FOR THE LHC

L. N. Drosdal, B. Goddard, D. Jacquet, R. Gorbonosov, S. Jackson, V. Kain, D. Khasbulatov, M. Misiowiec, J. Wenninger, C. Zamantzas, CERN, Switzerland.

Abstract

Twelve injections per beam are required to fill the LHC with the nominal filling scheme. The injected beam needs to fulfill a number of requirements to provide useful physics for the experiments when they take data at collisions later on in the LHC cycle. These requirements are checked by a dedicated software system, called the LHC injection quality check. At each injection, this system receives data about beam characteristics from key equipment in the LHC and analyzes it online to determine the quality of the injected beam after each injection. If the quality is insufficient, the automatic injection process is stopped, and the operator has to take corrective measures. This paper will describe the software architecture of the LHC injection quality check and the interplay with other systems. Results obtained during the LHC run 2011 will finally be presented.

INTRODUCTION

The LHC is filled through two transfer lines (TI2 and TI8) from the last pre-injector, the SPS. Currently the LHC runs with 1380 bunches per beam, which require 12 injections (plus one low intensity bunch) per ring. The maximum number of bunches per injection is 144 corresponding to 1 MJ stored energy.

Injection is a complicated process. The correct number of PS batches has to be injected in the correct RF bucket in the LHC. The injector timing system [1] and the LHC RF system ensure LHC dynamic injection requests and synchronisation. The extraction event from the SPS is forwarded to the LHC timing system as LHC injection event to trigger beam instrumentation.

The series of required injections is pre-programmed as an injection sequence driven by the injection sequencer. According to the filling scheme requests are sent to the injector timing system. At each injection the injection quality check (IQC) analyses data from key equipment in the LHC and the transfer lines and provides a result instructing the injection sequencer how to proceed: continue, stop or repeat the same request.

The IQC also provides software interlocks which are picked up by the software interlock system (SIS) and inhibit injections. A GUI for visual display of the detailed result is provided for monitoring and operator interaction, see Fig 1. The interplay of the IQC with other systems is shown in Fig. 2. There is also a playback tool for reviewing events. This paper presents the IQC architecture and results from the LHC run 2011.

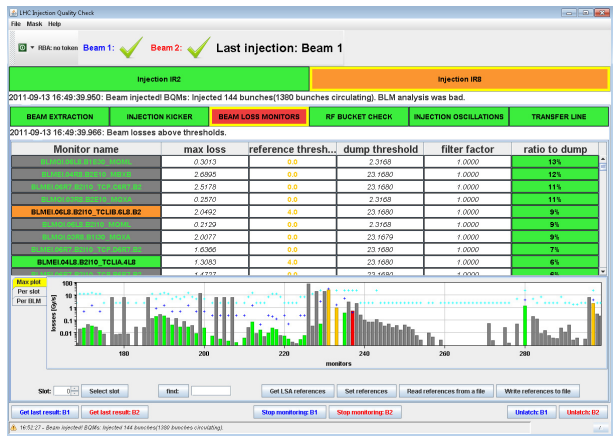

Figure 1: IQC GUI for monitoring and operator interaction. BLM panel showing loss distribution over the injection region.

LHC INJECTION QUALITY CHECKS

The injection quality check analysis is triggered automatically at each LHC injection event. Only data which has a time stamp within a certain time window around the injection time stamp are accepted. This window is set individually for each system and ranges from 1 s before the injection to 6 s after.

The analysis is composed of separate analysis modules which are launched as soon as the required data is ready. The different modules are combined to an overall result at the final stage.

Data collection takes on average 4.5 s and analysis about 0.5 s. In case of missing data the analysis automatically times out after 10 s. The injection sequencer and IQC analysis are independent for beam 1 and beam 2. In this way the next injection can already be requested while the analysis on the other beam is still ongoing.

IQC Architecture

The IQC uses the LHC post mortem framework for data storage and analysis [2]. Data collection as well as analysis are written in JAVA and are running on JAVA servers. The results are published through Java Messaging System (JMS) and are picked up by the by the injection sequencer, the SIS and the IQC GUI.

For threshold management the IQC analysis uses the LSA Management of critical settings [3]. The thresholds can be modified by experts in the IQC GUI.

Event data stored on the post mortem server can be replayed offline on a separate, but identical application. This feature can be used for diagnostics of previous events, for testing and to make statistics.

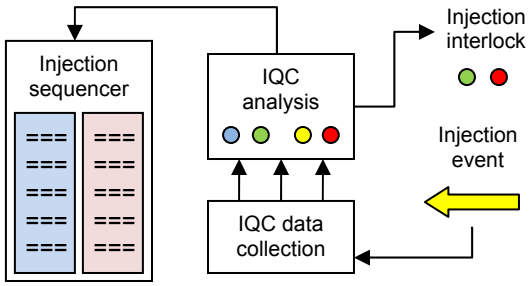

Figure 2: Figure showing the interplay of the IQC with injection sequencer, the SIS (Injection Interlock) and timing system. The analysis is triggered by the injection event. The overall result is published to the injection sequencer, and flags are produced for the SIS.

ANALYSIS MODULES

Correctly Filled Bunch Pattern

Not every injection request is successful. Due to bad beam quality beam might not even be extracted from the SPS. To determine whether the beam was injected into the LHC, the results of the upstream and downstream BCTs in the transfer lines are combined with the BQM result. Three devices are used for the analysis due to reliability issues of the BCTs in the transfer lines. If the devices disagree the overall outcome of the IQC is UNKNOWN.

The LHC BQM uses the wall current monitors to find the longitudinal positions of the injected bunches [4]. In the module RF bucket check, the IQC compares this information with the requested filling pattern. In case of inconsistency the IQC stops the injection sequencer.

Injection Kicker Checks

The LHC injection kicker system (MKI), consisting of four vertical kicker magnets per beam, needs to have a short kicker rise time of less than 1 μs, little ripple on about 8 μs long flattop and fall times not longer than 3 μs, [5]. The characteristics of the injection kicker waveforms generated by oscilloscopes in the tunnel are analysed by the IQC after each injection. With the tight IQC thresholds deterioration of the kicker characteristics are noticed immediately.

Beam Losses

The module which is used mostly and provides very useful information for injection tuning is the beam loss module. At each injection the beam loss monitor crates of interest are triggered to produce a special buffer for the IQC, consisting of 512 beam loss samples per monitor around the injection event with 40 μs integration times.

The transfer line collimators (TCDIs) are at the end of the lines and losses on these are seen on the BLMs of the LHC superconducting magnets. The BLMs have low dump thresholds and small losses on the transfer line collimators can already lead to a beam dump while filling the LHC. The loss profile from the transfer line collimators is a valuable diagnostic for beam quality problems in the transverse plane.

Also the losses around the protection devices (TDI, TCLIa, TCLIb) protecting against injection kicker failures are shown. Losses from uncaptured circulating beam, satellites or uncaptured beam from the injectors as well as nominal beam in case of kicker problems ends up on these. The loss signature for the different cases is typical and is used for problem identification. Fig. 3 shows the loss distribution plot from the IQC BLM panel.

In addition to the LHC ring data the beam loss monitors in the transfer lines are also recorded.

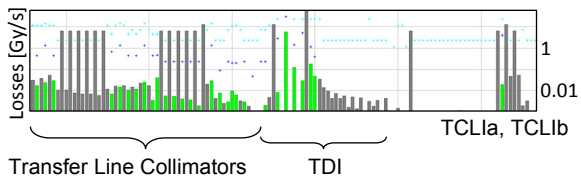

Figure 3: Distribution of beam losses as seen in the IQC GUI. The beam loss pattern is used to indicate the source of losses.

Injection Oscillations and Transfer Line Trajectory

The setting of all the protection devices in the LHC is valid for a given aperture in the machine. The settings have to include tolerances for orbit distortions, energy errors, beta beat and injection oscillations. If the injection oscillations are larger than the tolerance, protection against beam impacting the aperture during e.g. injection kicker errors cannot be guaranteed.

Orbit information as well as turn-by-turn data from BPMs triggered at injection is acquired by the IQC in the LHC injection regions. The injection oscillation amplitudes have to be below the IQC limit of 1.5 mm (1.75 mm for TI 2 H).

If the limit is exceeded, the SIS inhibits injection of high intensity for that particular beam. A special flag is provided by the IQC for the SIS for that purpose. Low intensity (about 10^{12} protons) can be injected to correct. The flag is automatically reset as soon as the injection oscillations are within limit again.

The reading of the BPMs in the transfer lines are also recorded in the IQC. The trajectory offsets in the transfer line collimators have to be minimised to reduce losses.

2011 EXPERIENCE

Since the first running period in 2010 the IQC analysis has become an integral tool of understanding injection problems and optimising injection efficiency. The beam loss monitor results are used routinely.

Statistics From Mid July to Mid August 2011

60 LHC fills from mid July to mid August 2011 were analysed. Within this period 1483 IQC analyses were triggered. The IQC latched 7.9% of the time indicating quality issues. For 11.7% of the events the expert warning result was given due to beam losses. The full distribution

of results is given in Fig. 4. For a detailed distribution of failures see Fig. 5.

During the period of these 60 fills the injections were very clean. The beam scraping in the SPS was used at maximum to cut beam tails. No other injection issues occurred. The less than 1 % of IQC result "UNKOWN", associated with missing data, indicate the good performance of the overall system.

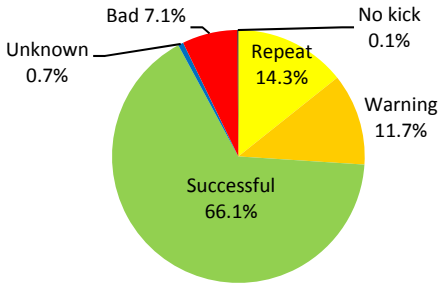

Figure 4: Distribution of IQC results over a period of 60 fills. In total there were 1483 injection events, where 7.9% latched.

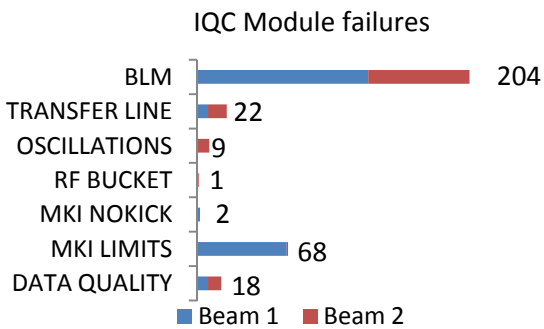

Figure 5: Distribution of module failures over 1483 injections; beam losses, transfer line (BLMs and BPsM), injection oscillations, RF bucket check, MKI not pulsed, MKI waveform out of thresholds, bad data quality. The total number is given right of the plot, the bars indicate the distribution between beam 1 and beam 2.

Data Collection Issues

The IQC is depending on a large number of data sets from many sources. In case of missing data the IQC automatically stops injection. During the commissioning run of 2010 events with missing data were frequent. All data collection problems could be solved during the winter shutdown and the beginning of the LHC run in 2011. The remaining issue is the data quality from the transfer line BCTs we still frequently have issues with the data quality. During the analysed period of above for 47.9% only one of the BCTs produces data or the two BCTs give inconsistent data. For the total of 60 fills analysed for only 18 events (1.2%) a data set was missing and caused an injection interlock.

Beam Quality Issues Discovered

In this section examples are presented where beam quality issues could be discovered due to the IQC results.

At the beginning of injecting full SPS batches into the LHC, consisting of 144 bunches, spaced by 50 ns, the IQC indicated large injection oscillations in the vertical plane for beam 1, see Fig. 6. It turned out that the injection kick length had not been long enough and some of the beam was kicked on the falling edge of the waveform. It was subsequently prolonged.

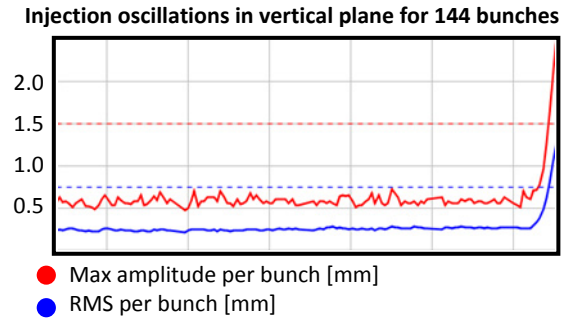

Figure 6: Injection oscillations in the vertical plane for 144 bunches. The last bunches had larger oscillation amplitudes due to too short kicker waveform. [23:21:38 20/6-2011]

The transfer lines suffer from trajectory stability problems in the horizontal plane [6]. Slow drifts, shot-by-shot and also large bunch-by-bunch variations have been recorded. The IQC injection oscillation analysis was very useful to detect the large bunch-by-bunch differences for beam 2 H, see Fig. 7. The source for these is probably the horizontal extraction kicker in the SPS. The issue is still under investigation.

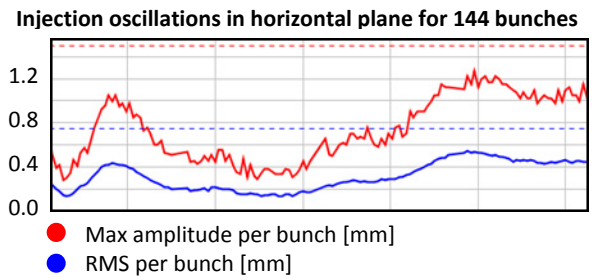

Figure 7: Injection oscillations amplitudes in the horizontal plane for 144 bunches for beam 2. A bunch-by-bunch variation of more than 1 mm was discovered. [01:28:57 25/9-2011]

On 18th of April 2011, 11 magnets were quenched during a high intensity injection attempt when an injection kicker flashover of one of the four beam 2 magnets occurred. The problem could be diagnosed immediately with the IQC MKI analysis indicating the shortened waveform for one of the four kicker magnets, see Fig. 8.

The IQC BLM buffer is now also used for studying very fast beam loss phenomena occurring shortly after injection, called UFOs [7].

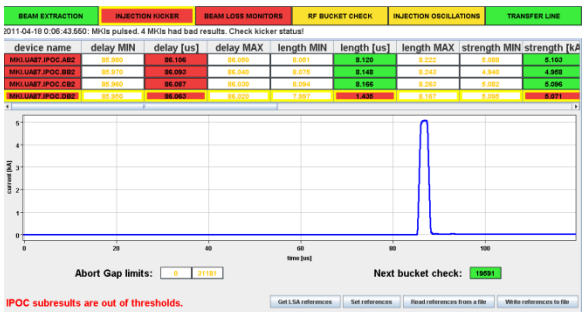

Figure 8: IQC MKI panel showing the MKI waveform of magnet D which had a flashover and had a length of about 2μs only instead of the required 8 μs.

CONCLUSION

The LHC injection quality check has become an important part of the LHC software suite ensuring good quality beams and injection protection. The chosen modular architecture based on the post-mortem framework has proved valuable and allowed stepwise commissioning and easy diversification of the analysis.

The IQC analysis is used offline and online on a routine basis to tune and improve injection. It has played a major role to achieve routine LHC filling with 1 MJ beams.

FIRST EXPERIENCES OF BEAM PRESENCE DETECTION BASED ON DEDICATED BEAM POSITION MONITORS

A. Jalal, S. Gabourin, M. Gasior, B. Todd, CERN, Geneva, Switzerland

Abstract

High intensity particle beam injection into the LHC is only permitted when a low intensity pilot beam is already circulating in the LHC. This requirement addresses some of the risks associated with high intensity injection, and is enforced by a so-called Beam Presence Flag (BPF) system which is part of the interlock chain between the LHC and its injector complex. For the 2010 LHC run, the detection of the presence of this pilot beam was implemented using the LHC Fast Beam Current Transformer (FBCT) system. However, the primary function of the FBCTs, that is reliable measurement of beam currents, did not allow the BPF system to satisfy all quality requirements of the LHC Machine Protection System (MPS).

Safety requirements associated with high intensity injections triggered the development of a dedicated system, based on Beam Position Monitors (BPM). This system was meant to work first in parallel with the FBCT BPF system and eventually replace it. At the end of 2010 and in 2011, this new BPF implementation based on BPMs was designed, built, tested and deployed.

This paper reviews both the FBCT and BPM implementation of the BPF system, outlining the changes during the transition period. The paper briefly describes the testing methods, focuses on the results obtained from the tests performed during the end of 2010 LHC run and shows the changes made for the BPM BPF system deployment in LHC in 2011.

INTRODUCTION

A high intensity particle beam injection into the LHC must not be permitted if no low intensity beam is already circulating, confirming the set-up of the primary machine parameters, like beam orbit, operational point, chromaticity, etc. For this reason, the extraction and injection process of beam from the SPS to the LHC is tightly interlocked. Two BPF flags, one for each beam, are generated and transmitted to the extraction interlock systems indicating the presence, or absence, of a circulating beam in the LHC.

In the 2008, 2009 and 2010 runs each flag was derived from the system measuring the beam currents passing through the FBCTs installed on the LHC beam pipes. The FBCT system was designed for beam instrumentation purposes and could not fulfil all rigorous requirements of the LHC MPS. To increase the reliability of this important protection feature a dedicated BPM system has been developed in addition to the FBCT solution. Finally, in the spring of 2011 the FBCT BPF system was phased out in favour of the dedicated BPM implementation.

SYSTEM ELEMENTS

The BPF system uses signals from the FBCT and BPM systems. The BPM BPF system [1] is based on four signals per LHC beam derived from electrodes of a dedicated BPM. Each electrode drives an input of a dedicated BPF analogue front-end [1], which in turn derives Boolean beam presence flags. For beam-1 these flags are BPF_1A, 1B, 1C and 1D, for beam-2: BPF_2A, 2B, 2C and 2D. The BPF front-end sets a flag to TRUE if the corresponding signal exceeds a threshold and the beam has been already circulating for certain time.

A pair of FBCTs also evaluates beam presence based on the circulating beam characteristics, deriving BPF_1E and 1F for beam-1, 2E and 2F for beam-2. This gives a total of six flags per beam as illustrated in Fig. 1.

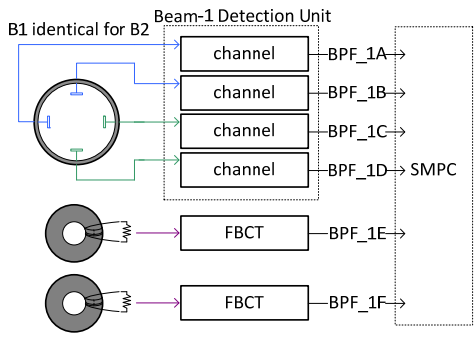

Figure 1: System Elements.

These flags are then transmitted to the Safe Machine Parameters Controller (SMPC). The SMPC logic carries out a voting on the six input flags using a pair of two-out-of-three (2 oo 3) majority voter blocks and also filters the signals to remove spurious transitions. This results in a pair of Beam Presence Flags per beam which are transmitted to the extraction Beam Interlock System (BIS). This pair is also combined to give a single BPF which is broadcast for general consumption via the LHC General Machine Timing (GMT), as sketched in Fig. 2.

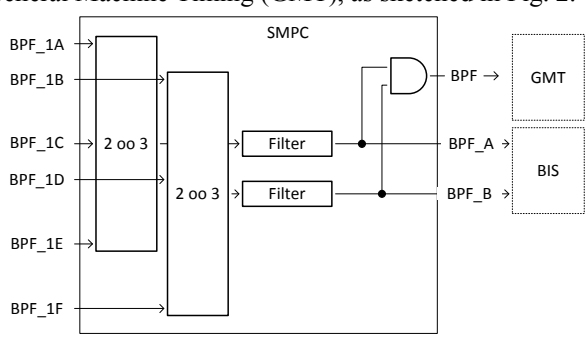

Figure 2: Combination and Voting Logic.

TESTING AND CHARACTERISATION

The BPM implementation was tested in parallel with LHC operations in late 2010. This allowed the system to be characterised with respect to the FBCT.

The test consisted of comparing two of the BPF from the BPM (BPF_1A and BPF_1B) with intensity values during ordinary LHC operations with beam. The intensity values were given by the LHC FBCT, the BPF values were logged by the BIS. The test period covered five weeks of 2010 operation with beam (25/10 – 19/11).

As the LHC was operating normally with beam, there were a large amount of transitions. For the analysis, the key area of interest was the intensity value at the moment of a BPF transition from TRUE to FALSE, or from FALSE to TRUE. Figure 3 shows typical characteristics of intensity, threshold and BPF transitions.

Threshold During Normal Operation

The beam intensity was recorded at the time of every flag transition; this resulted in a consistent value of intensity with an average around 3 x 109, as shown in Table 1. There are, however, two important limitations in this test method: The Pick-up selection, and the FBCT accuracy.

The pick-ups being used for the characterisation were those on the upper and left side of the beam pipe as shown in blue in Figure 1. The signal amplitude on each BPM electrode depends on the distance of the beam to the electrode, so the signals are only equal for a centred beam. The minimum intensity threshold values observed are related to a beam that was circulating closer to the BPM electrode, resulting in a larger signal. On the other hand, the maximum threshold intensity values are due to a beam circulating further from the BPM electrode, thus giving a smaller signal. These results are summarised in Table 1.

Table 1: Thresholds for the BPM BPF system

	Beam 1	Beam 2
Min value	2.11×10^9	1.75×10^9
Max value	6.05×10^9	6.33×10^9
Average	3.3×10^9	3.5×10^9

On average, the beam intensity at the transition point, with significant position dependence, is around 3×10^9 charges. The observed intensity threshold dependency on beam position was removed for the 2011 implementation [1].

The second limitation with this method is that it followed normal LHC operation, where the beam is injected or dumped in a single turn, with the threshold value given from the FBCT reading at that instant. The threshold value determined in this manner is dependent on the measurement algorithm and time delays of the FBCT system. Therefore a dedicated run was organised, to determine the threshold of the BPM system with a higher precision.

Threshold During Dedicated Run

Slowly decreasing the beam intensity proved the best method for determining the threshold, as the threshold is passed, oscillations of the BPFs occur. Oscillations like this are the best indicators that the beam is very close to the threshold value of the dedicated BPMs. As shown in Table 2, the threshold was determined to be around 6×10^8 charges giving rise to a noise around 2 kHz.

Table 2: Low Intensity Noise

Flag	Time	Intensity	Frequency
Beam 1	04:15:43.956	5.9×10^8	2.1 kHz
Beam 2	20:19:12.617	5.9×10^8	2.4 kHz

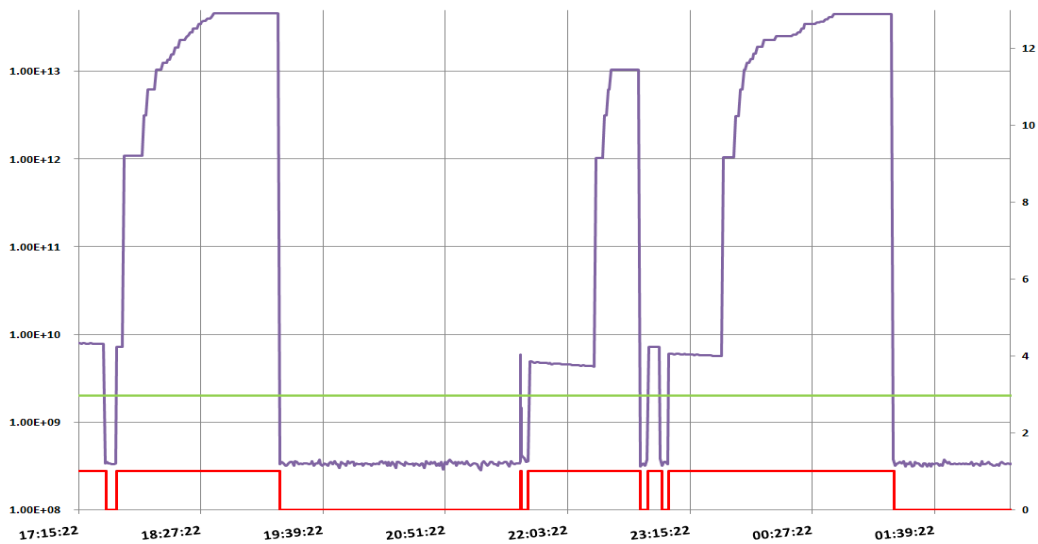

Figure 3: Intensity (Purple), Threshold (Green) and Beam Presence Flag (Red) Normal Operation.

This noisy behaviour was only observed in the case of *decreasing* intensity, and not in other situations. This is due to the noise being only observable when the intensity variation is relatively slow. An injection of beam into LHC represents an instantaneous (turn-by-turn) increase of the intensity, well above threshold, which doesn't give any noise on the BPF signals.

The noisy transitions for beam intensity close to the threshold were removed for the 2011 implementation [1].

Time Delay

As the individual BPF system channels are independent, a time delay could be observed between the BPF_1A and 1B signals. Table 3 shows an example of this situation. The first two rows have no time difference between flags: they both switch to true at the same time, corresponding to an injection of beam into the LHC. On the other hand, the second and third rows show that the two flags change the state to FALSE at well different times: BPF_1A is delayed by some three minutes compared to BPF_1B:

Table 3: Pick-Up Time Delay

Time	Transition	Flag
09:50:59.410	F→T	BPF_1A
09:50:59.410	F→T	BPF_1B
10:59:21.900	T→F	BPF_1B
11:02:42.541	T→F	BPF_1A
11:30:53.410	F→T	BPF_1A
11:30:53.410	F→T	BPF_1B

Of the 600 transitions analyzed, 93% of them have a delay between flags of less than 3µs. The remaining 7%, with the exception of the single example above, have a delay between 30ms and 90ms. In all cases this corresponded with a very slow gradual decrease in beam intensity, and on a flag transition from TRUE to FALSE. The discrepancy in switching times was attributed to off-centred beam.

2011 IMPLEMENTATION

The characterisation of the BPM implementation in 2010 was very successful, and a revised implementation of the BPF electronics was put into operation in summer 2011. This included four important changes to address observations from 2010 [1]:

Position Dependence

As shown in Fig, 4, signals from the opposite BPM electrodes are summed before being split and passed to the channels of the BPF front-end. This removes most of the dependency on beam position for the evaluation of the flags.

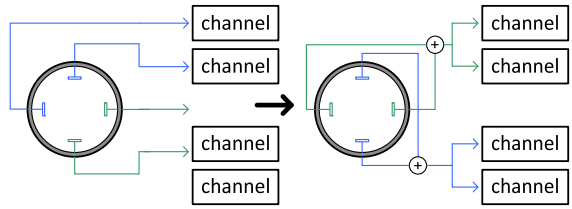

Figure 4: Suppression of Position Dependence.

Hysteresis

Hysteresis was added to remove noisy transitions as the beam intensity passes through the threshold.

Threshold

The threshold of 6×10^8 was considered to be a good demonstration of the system sensitivity, at the same time, was lower that the threshold intensity of the LHC beam orbit measurement system. This system is essential for reliable LHC operation, so beam intensity must guarantee its operation. For that reason the BPF system threshold was raised to about 2×10^9 charges, by attenuating the BPM signals before the BPF analogue front-end (see Fig. 5).

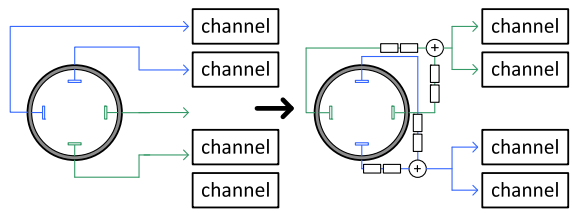

Figure 5: Increase of Threshold.

Fast Beam Current Transformer

Finally, the flags from the FBCT system were disabled from the voting logic of the SMPC. Instead of operating with six BPF and two 2 out of 3 voters, there are four BPF, which must all be TRUE for the corresponding global BPF to be TRUE.

CONCLUSIONS

The prototype beam presence flag system based on BPM signals was tested in principle in 2010 and with minor modifications was put into regular operation for the 2011 LHC run. Whilst the system has been proved to work with a threshold of 6×10^8, it has been implemented with a threshold of 2×10^9 to protect the LHC.

ACKNOWLEDGEMENTS

This work has been the result of a close and productive collaboration between the LHC machine protection and LHC beam instrumentation groups.

DEVELOPMENT OF A MACHINE PROTECTION SYSTEM FOR THE SUPERCONDUCTING BEAM TEST FACILITY AT FERMILAB*

A. Warner#, L. Carmichael, M. Church, R. Neswold, FNAL, Batavia, IL 60510, U.S.A

Abstract

Fermilab's Superconducting RF Beam Test Facility currently under construction will produce electron beams capable of damaging the acceleration structures and the beam line vacuum chambers in the event of an aberrant accelerator pulse. The accelerator is being designed with the capability to operate with up to 3000 bunches per macro-pulse, 5Hz repetition rate and 1.5 GeV beam energy. It will be able to sustain an average beam power of 72 KW at the bunch charge of 3.2 nC. Operation at full intensity will deposit enough energy in niobium material to approach the melting point of 2500 °C. In the early phase with only 3 cryomodules installed the facility will be capable of generating electron beam energies of 810 MeV and an average beam power that approaches 40 KW. In either case a robust Machine Protection System (MPS) is required to mitigate effects due to such large damage potentials. This paper will describe the MPS system being developed, the system requirements and the controls issues under consideration.

INTRODUCTION

The beam at Fermilab's New Superconducting RF Beam Test Facility [1], when operational, will need systems to protect critical components from beam induced damages such as beam pipe collision and excessive beam losses. The MPS must therefore identify hazardous conditions and then take the appropriate action before damage is caused. Since the loss of a full bunch train can result in significant damage, the MPS must be able to interrupt the beam within a macro-pulse and keep the number of bunches below the damage potential once the protection system reacts; the goal is to keep the number of bunches on the order of 3-6 bunches. With the high possible bunch frequency of 3 MHz this necessitates a reaction time in the range of 1-2 µs with cable delay included for the 134 metre long machine. The MPS will use the status of critical sub-systems and losses measured by a fast Beam Loss Monitor (BLM) system, using scintillators and photomultiplier tubes (PMT) to identify potential faults. Once a fault is observed, the MPS can then stop or reduce beam intensity by removing the permit from different beam actuators, including the laser pulse controller.

MACHINE LAYOUT

The machine layout is shown in Fig. 1. The accelerator consist of an electron gun, a 40 MeV injector, a beam acceleration section consisting of 3 TTF-type or ILC-type cryomodules initially, and multiple downstream beam lines for testing diagnostics and performing beam experiments. The facility will accommodate up to 6 cryomodules in the final stage. From a machine protection point of view, the dump locations shown describe the final destination of the beam that traverses a path along the beam-line. These paths are termed operation modes and are validated by the MPS before the beam permit is released. The MPS validates these paths by monitoring all critical devices and diagnostics along the path and ensuring that they are all in good status and ready to receive beam at the requested intensity.

The machine will be capable of operating over a wide range of beam parameters as long as the total beam power remains below the limit of the beam dump capability and satisfies radiation shielding requirements. For machine protection purposes several beam modes have been defined; the beam mode sets limits on the number of bunches and therefore the intensity. Initially the following two modes will be active in the system:

- Low intensity mode – which allows the minimal beam intensity needed for OTR/YAG diagnostics. This is below the threshold potential for beam induced damage. In this mode there is no fast reaction to beam loss within a bunch train.
- High intensity mode – which does not impose a limit on the number of bunches, but enables fast intra-train protection by the MPS.

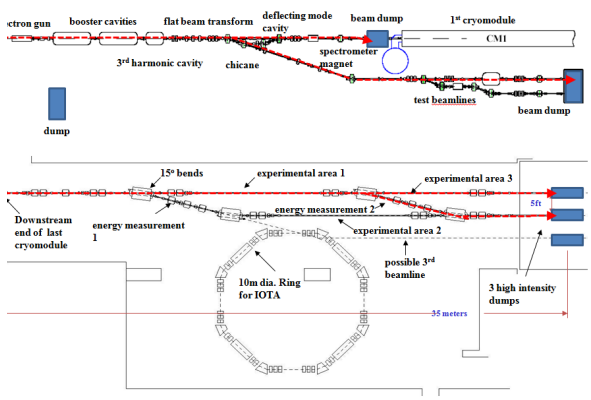

Figure 1: Machine layout.

MPS OVERVIEW

The simplified overview block diagram of the proposed MPS is shown in Figure 2. The MPS has connections to several external devices and sub-systems. The top layer comprises signal providers such as fast beam loss monitors, RF signals, quench protection, toroid transmission, vacuum, magnet power supplies and more. All devices in this category send status information to the MPS logic layer (permit system). Only simple digital

*Operated by Fermi Research Alliance, LLC, under Contract No. DE-AC0207CH11359 with the United States Department of Energy
#warner@fnal.gov

signals (e.g. on-off, OK-not OK) are transmitted. All devices or subsystems that are determined to be pertinent to protecting the machine or necessary for machine configuration are included here. The state of the machine is determined from this comprehensive overview of the inputs and allowable operation modes are determined based on this information by the middle logic layer. The main goals for the MPS system as a whole are:

- Provide precise protection of all critical components by first determining the fault severity (high, intermediate, etc) and then taking the appropriate action to avoid damage.
- Allow for high availability by ensuring that the maximum requested beam intensity is allowed for the detected fault severity.
- Monitor MPS components and perform periodic self-checks in order to ensure robustness and a high level of reliability.
- Provide well-integrated, user-friendly tools for fault visualization, control and post-mortem analysis.

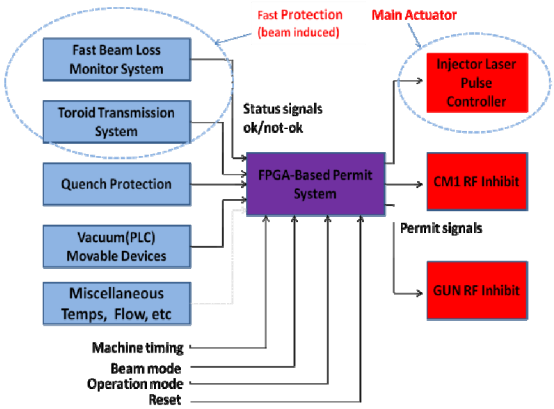

Figure 2: MPS Overview.

The permit system part of the MPS is capable of handling events on all time scales relevant to the machine. This layer is FPGA based and is thus fully programmable and handles complex logic tasks. The logic here will be designed to ensure safe operating conditions by monitoring the status of critical devices and by imposing limits on the beam power. It prohibits beam production or reduces the beam intensity by disabling the gun RF and the injector laser unless the requirements for the specific predefined modes are fulfilled when that mode is requested. The final layer of the system shows the main actuators. This comprises all of the points where the MPS logic may act on the operation of the machine and prevent beam from being produced or transported; the main actuator being the injector laser. When any of the non-masked inputs signal an alarm status the MPS permit system (logic layer) can do one of several things based on the severity of the fault: i.e. switch off the injector laser to suppress the production of new bunches, reduce the intensity by dialing back the number of bunches, or inhibit the rf power from the first cryomodule (CM1) as a precaution against transport of dark current from the RF gun.

BEAM LOSS MONITOR SYSTEM

Several types of beam loss monitors (BLMs) will be used for the detection of electromagnetic showers. The fast protection system is being designed to interrupt the beam within a macro-pulse and will rely heavily on the ability to detect and react to losses within a few nanoseconds; for this reason the primary loss monitors for fast protection are made of plastic scintillator with photomultipliers attached and have already been designed, built and tested. Figure 3 shows some measurement results.

Figure 3: FBLM showing pulse beam losses.

The BLMs will serve the dual purpose as an accelerator diagnostic and as the primary detectors for fast machine protection. The monitors must therefore deliver a measurement of beam and dark current losses to the control system as well as generate a fast alarm signal when the beam losses exceed user-defined thresholds. The time resolution of the loss measurement must provide the ability to distinguish single bunches within each macro pulse. This requires a sampling frequency of at least 3 MHz with a repetition rate of 5 Hz. The BLMs must be integrated into a robust beam loss monitoring system capable of generating an alarm condition that is derived by comparing the outputs of the PMT signals with various programmable thresholds. This alarm output is a critical component for machine protection. The desire is to provide a machine protection trip well before the beam can damage accelerator components. If one of the programmed thresholds is exceeded or if an error condition such as a high voltage failure or failed monitor is detected the system should report this to the MPS logic which in turn reduces the intensity or inhibits the beam.

The main requirements for the BLM system are:

- Provide both machine protection and diagnostic functions.
- Instantaneous read-back of beam loss
- Digital output for integrating and logarithmic signal (16 bit)
- Built in self test and onboard signal injection for testing of monitors between pulses.
- FPGA controlled
- Local data buffer
- VME interface to ACNET control system
- Continuous and pulsed monitoring
- Wide dynamic range

Cryogenic Loss Monitors

Although loss monitors are typically one of the main diagnostics for protecting the accelerator from beam induces damage. Most accelerator facilities do not cover the cold sections of the machine with loss monitors. To address these issues a Cryogenic Loss Monitor (CLM) ionization chamber capable of operation in the cold sections of a cryomodule has been developed and will be installed and tested [2]. The monitor electronics have been optimized to be sensitive to DC losses and the signals from these devices will be used to study and quantify dark current losses in particular, see Figure 4. In order to increase the resolution bandwidth and the response time of the devices a new scheme which uses a Field Programmable Gate Array (FPGA) based Time-to-Digital converter (TDC) method is implemented [3] instead of a standard pulse counting method. This potentially renders these monitors as useful devices for both dark current monitoring and machine protection. These monitors under consideration are custom built detectors. They are an all metal designed which makes them intrinsically radiation hard and suitable for operation at 5 Kelvin to 350 Kelvin.

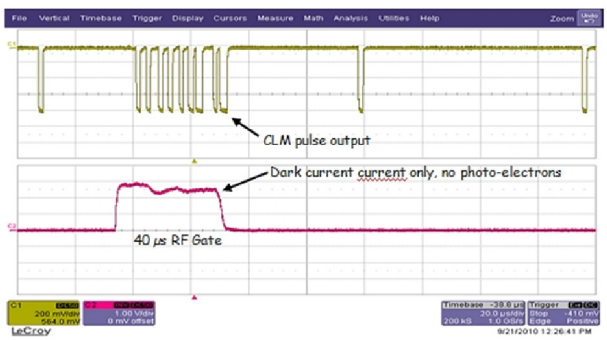

Figure 4: reaction of CLM to dark current losses in a test beam.

LASER PULSE CONTROLLER

One of the main actuators for the MPS is the injector laser pulse control. This will be the device that controls the number and the spacing of bunches in a macro-pulse by picking single laser pulses out of a train. This is achieved by manipulating the Pockels cell (voltage-controlled wave plates). This system is also the main actuator for beam inhibits issued by the MPS. It is envisioned that this would be a VME board with a fully programmable FPGA. It would have inputs for the requested beam modes defined by the logic layer of the MPS, the MPS permit signal, the 3 MHz machine timing, and for a macro-pulse trigger. Based on the laser/gun design, it would have control outputs for the Pockels cell driver, a mechanical shutter and a first bunch timing signal. From the protection system point of view the pulse controller is used to:

- Block the Pockels cell based pulse kickers as long as **any** MPS input is in an alarm state.
- Enforce the limit on the number of bunches as given by the currently selected beam mode.
- Close the laser shutter on request of the MPS. This may happen when there is no valid operation mode or when some combination of loss monitors exceed thresholds which trigger a dump condition.

CONTROLS INTEGRATION

The MPS will need server support for the various hardware systems to View, Configure and Diagnose the system. Already there are currently several servers under development for the beam loss monitor system and the laser pulse controller. These servers were implemented using the PowerPC 5500 series boards running VxWorks 6.4 and implementing the ACNET protocol. Some of the main requirements for these servers include:

- Time-stamping at a sub-microsecond resolution in order to allow for data correlation.
- Circular buffers that are logged using ACNET data loggers and thus provide a repository used for post-mortem analysis.

A control system that is well integrated with all MPS components, from the various front-ends to the high level applications, is critical to leveraging the full functionality of that control system.

CONCLUSION

Significant effort is underway towards developing a reliable MPS for this new facility. System integration and commission challenges lay ahead.

THE MACHINE PROTECTION SYSTEM FOR THE R&D ENERGY RECOVERY LINAC*

Zeynep Altinbas#, James Jamilkowski, Dmitry Kayran, Roger C. Lee, Brian Oerter,
Brookhaven National Laboratory, Upton, NY 11973, U.S.A.

Abstract

The Machine Protection System (MPS) is a device-safety system that is designed to prevent damage to hardware by generating interlocks, based upon the state of input signals generated by selected sub-systems. It protects all the key machinery in the R&D Project called the Energy Recovery LINAC (ERL) against the high beam current. The MPS is capable of responding to a fault with an interlock signal within several microseconds. The ERL MPS is based on a National Instruments CompactRIO platform, and is programmed by utilizing National Instruments' development environment for a visual programming language. The system also transfers data (interlock status, time of fault, etc.) to the main server. Transferred data is integrated into the pre-existing software architecture which is accessible by the operators. This paper will provide an overview of the hardware used, its configuration and operation, as well as the software written both on the device and the server side.

INTRODUCTION

An ampere class 20 MeV superconducting Energy Recovery Linac (ERL) has been built to test concepts for high-energy electron cooling and electron-ion colliders. One of the goals is to demonstrate an electron beam with high charge per bunch (~5 nC) and extremely low normalized emittance (~5 mm-mrad) at an energy of 20 MeV. The ERL R&D program was started by the Collider Accelerator Department (C-AD) at BNL as an important stepping-stone toward a 10-fold increase of the luminosity of the Relativistic Heavy Ion Collider (RHIC). This program aims to demonstrate CW operation of an ERL with an average beam current in the range of 0.1-1 ampere, combined with very high efficiency of energy recovery [1].

The R&D ERL requires a protection system to prevent damage to hardware due to high beam current. The Machine Protection System (MPS) for the R&D ERL is designed as a device-safety system that generates interlocks based upon the state of input signals generated by select sub-systems. It exists to protect key machinery such as the 50 kW and 1 MW RF Systems. When a fault state occurs, the MPS is capable of responding with an interlock signal within several microseconds. The Machine Protection System inputs are designed to be fail-safe. In addition, all fault conditions are latched and time-stamped.

The ERL MPS is based on a National Instruments hardware platform, and is programmed by utilizing National Instruments' development environment for a visual programming language.

HARDWARE

The MPS runs on a programmable automation controller called CompactRIO (Compact Reconfigurable Input Output). The National Instruments CompactRIO platform is an advanced embedded control and data acquisition system designed for applications that require high performance and reliability. This small sized, rugged system has an open, embedded architecture which allows developers to build custom embedded systems in a short time frame.

The National Instruments CompactRIO device that is used for the MPS is an NI cRIO 9074 (see Fig. 1). The cRIO 9074 is an 8-slot chassis with an integrated real-time processor and an FPGA. The embedded processor is a 400 MHz Freescale MPC5200 that runs the WindRiver VxWorks real-time operating system. The FPGA is a Xilinx Spartan 3 with 2 million gates (46,080 logic cells) and 720 KB embedded RAM. The cRIO 9074 also features a 256 MB nonvolatile memory. CompactRIO combines an embedded real-time processor, a high-performance FPGA and hot-swappable I/O modules to form a complete control system. Each module is connected directly to the FPGA and the FPGA is connected to the real-time processor via a high-speed PCI bus (see Fig. 2).

Figure 1: The National Instruments cRIO 9074 [2].

ERL critical sub-systems such as the RF system require the MPS to respond on a microsecond scale. High-speed I/O modules were chosen to meet the necessary timing requirements. The 24V capable module has sinking digital inputs with 7 µs response time, and the TTL module has digital inputs and outputs with 100 ns response time.

SOFTWARE

The MPS interface is written in LabVIEW (Laboratory Virtual Instrumentation Engineering Workbench).

*Work supported by Brookhaven Science Associates, LLC under Contract Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.
#altinbas@bnl.gov

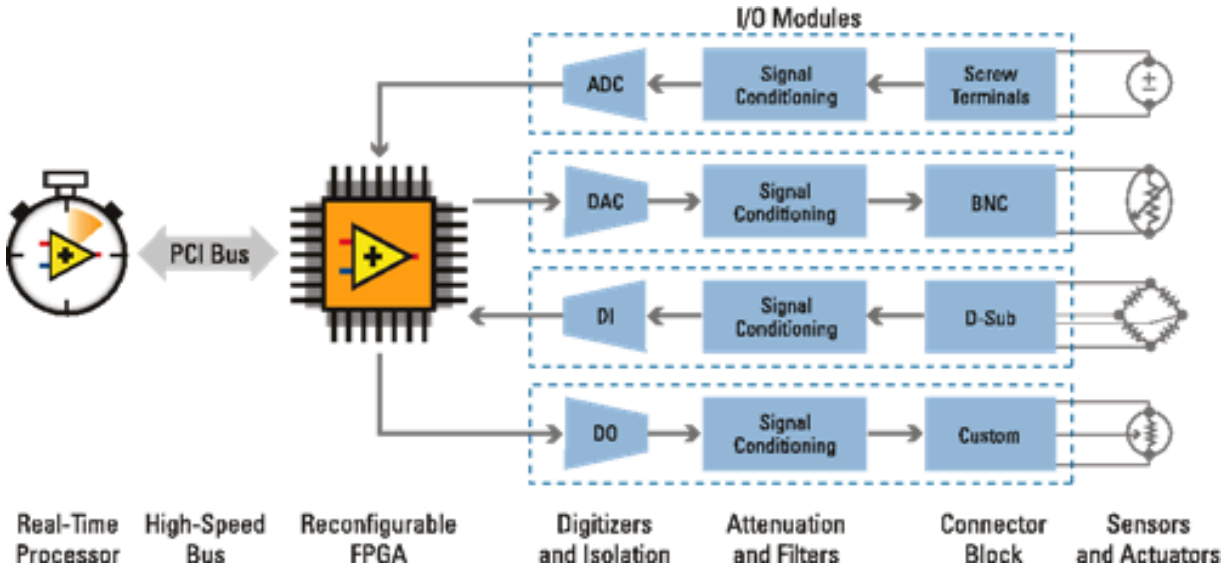

Figure 2: Block diagram showing a generic CompactRIO architecture [2].

LabVIEW is a graphical programming environment used to develop measurement, test, and control systems utilizing graphical icons and wires that resemble a flowchart. The National Instruments CompactRIO platform requires two different LabVIEW software modules corresponding to the System's interface, one for the Real-Time processor and one for the FPGA. These modules contain custom functions specific to the Real-Time processor or the FPGA in addition to all the functionalities of the standard LabVIEW module.

The code for both the Real-Time processor and the FPGA is developed on a host computer. The program for the FPGA is developed by using a standard LabVIEW software module. The LabVIEW FPGA code is then translated to VHDL code and compiled using the Xilinx tool chain. The program for the Real-Time processor is also developed by using a standard LabVIEW software module. When ready, the code for the Real-Time processor and the FPGA is downloaded to the CompactRIO device via Ethernet. Once the code is downloaded, the CompactRIO can run in a stand-alone mode, or communicate directly with a host via Ethernet.

Running directly on the CompactRIO platform, the MPS interface accepts the various input signals and generates any necessary interlocks. An interlock is generated when a logic high (fault) is seen at the input. If a cable is disconnected or broken, an internal pull-up ensures the system will generate an interlock. Exception is given to the RF sub-system which provides normally-high inputs due to equipment constraints. These inputs are inverted within the LabVIEW FPGA. If one of the continuously polled input levels change to high (indicating a fault), the fault is latched, and the time of the event is recorded using a 32-bit LabVIEW tick counter function. This provides a microsecond time stamp. The MPS interface also provides the capability to enable and disable inputs. Enabled and latched inputs are then combined and passed to other critical systems as interlocks. The input latches are cleared only after a software reset has been issued.

Operators communicate to the MPS interface using the main ERL server. Interaction with this Linux server is handled by a separate TCP server using the locally-constructed Simple Network Access Protocol (SNAP). SNAP provides remote access to the statuses of all MPS inputs and enable/disable controls for each. Additional handshake information between the server and the CompactRIO hardware across the network chain is used to monitor the overall status of the system. Commands can be sent and statuses read from the main ERL server process through a standard Collider Accelerator Department (C-AD) text-based parameter editing page that can be accessed from networked workstations or thin-clients. A web server capability is also provided by National Instruments to allow the developer to monitor and control the system remotely, avoiding interaction with the main ERL server.

EXISTING SYSTEM

The original ERL MPS was implemented and tested during the Cold Emission Test in 2009. In this configuration, the MPS had nine sub-system inputs and four outputs. As per the requirements, each sub-system provides either a TTL level or normally-open dry contact. All the inputs are latched when a fault occurs, and the fault time is recorded. This information is displayed by the MPS interface until the reset button is activated in an attempt to clear latched inputs. If the fault condition is still present, the appropriate latch maintains the interlock status. When the MPS turns on initially, the same reset button is used to establish a connection and inform the hardware that the sub-systems are ready to be monitored. This practice is utilized in order to prevent the MPS from starting prematurely in the case of a power-loss. The interface also has an indicator derived from the inputs, to

display the status of the critical sub-systems. The system response time is ~3-4 µs.

The MPS communicates with the ERL main server by sending data every 10 minutes, or every time a value changes.

PERFORMANCE

The MPS for the R&D ERL was recently used during the conditioning of the fundamental power couplers (FPC) [3]. The existing CompactRIO chassis is populated with 4 I/O modules: a 32-channel 24V capable input module, two 8-channel TTL input-output modules, and a 4-channel SPST relay output module. The layout is illustrated in Fig. 3. The inputs were expanded from nine to twenty-eight for this test. This did not require any additional I/O modules. The response time has increased to ~8 µs with the addition of the necessary logic and the defined I/O channels. This increase occurs because once more than 8 channels per module are utilized CompactRIO transitions to a byte-wide polling scheme. In other words, for up to 8 channels, the I/O is routed directly to the FPGA; when more than 8 channels are used, the I/O is transferred using a National Instruments proprietary Serial Peripheral Interface (SPI). The MPS hardware can be expanded by installing more I/O modules into the 4 remaining available slots in the CompactRIO chassis. The overall system size can also be expanded by daisy-chaining to another chassis via EtherCAT [4].

The Commercial of the Shelf (COTS) hardware-based MPS is extremely time and cost effective compared to a custom design. The initial configuration of the system took about three months and modifications for the FPC conditioning took about a week. This short development time compliments the system flexibility and expandibility, resulting in a very effective solution with minimal resource requirement. The whole system, including the software modules, cost about US ~$5,000.

PRE-OPERATION, DURING OPERATION AND POST-OPERATIONAL VERIFICATION OF PROTECTION SYSTEMS

Iván Romera¸ Maxime Audrain, CERN, Geneva, Switzerland

Abstract

This paper will provide an overview of the software checks performed on the Beam Interlock System ensuring that the system is functioning to specification. Critical protection functions are implemented in hardware, at the same time software tools play an important role in guaranteeing the correct configuration and operation of the system during all phases of operation. This paper will describe tests carried out pre-, during- and post-operation, if protection system integrity is not sure, subsequent injections of beam into the LHC will be inhibited.

INTRODUCTION

In order to prevent damage in the Large Hadron Collider (LHC) due to uncontrolled beam losses or failures, a Machine Protection System has been implemented which detects potential dangerous situations and eventually extracts the circulating proton beam of the machine into a graphite absorber. The heart of this system is the Beam Interlock System (BIS) [1] which allows a fast and reliable transmission of beam dump requests to the LHC Beam Dumping System (LBDS).

The BIS has been designed as a highly dependable system, meaning that a failure of the BIS could lead to a sequence of events that result in a significant damage of the LHC. To prevent this and in order to verify the integrity of the BIS, a set of operational checks have been implemented.

MOTIVATION

To protect the LHC ring from beam damage the BIS relies on 17 Beam Interlock Controllers (BIC) installed in the underground areas spanning over more than 27 km. The BICs are linked using redundant optical fibres which define the Beam Permit Loops (BPL). These loops propagate beam dump requests, from more than 190 user systems connected to the BIS, to the LHC Beam Dumping System (LBDS). With such a complex distributed system, the need of having software operational tools for diagnostics is a must.

The aim of the operational tools is to verify the system´s operation from end-to-end and to inhibit next beam injection into the LHC in case of a problem detected.

The scope of the project covers all software modules implemented to provide to the operators and equipment experts the necessary tools to guarantee the safe operation and to ensure that the system is in an “as good as new” state.

The verification of the BIS is carried out in three stages: (1) pre-; (2) during- and (3) post- operational checks which are executed on demand by the LHC Sequencer [2] depending on the operational mode of the machine. The outcome of the checks leads to the actions represented in Table 1.

Table 1: Result of Operational Checks

Test	Passed	Failed
Pre-	Injection allowed	Injection inhibited
During-	Continue operation	Warning experts
Post-	Injection allowed	Injection inhibited

The operational tools described hereafter are implemented with the standard tools and infrastructure used in the CERN accelerator control system (i.e.: Java, Swing, Spring Framework, Controls Middleware CMW and the Controls Configuration Database CCDB).

PRE-OPERATIONAL CHECKS

Before injecting beam in the machine, it is required to ensure that all safety critical components of the BIS are correctly configured and ready for operation. The configuration of such relevant components is defined in an Oracle reference database (CCDB) and maintained by the system experts with a strict versioning and access control. A wrong configuration of a critical part of the BIS could have serious implications on safety (e.g.: in case of a user system input that should never be masked is connected to a maskable input); it could lead to miss a beam dump request from a user system and in the worst case could lead to important damage to the machine.

Pre-Operational Checks Implementation

The pre-operational checks have been implemented as a sequence in the middle tier of the LHC Sequencer, which is a high level software application in charge of orchestrating the execution of tasks in a controlled way, helping the operators to drive the LHC. The pre-operational tests are launched programmatically before the beam injection phase, guaranteeing the consistency in the configuration of the physical system against the reference database.

In case of encountering any inconsistency, a failure will be propagated to the BIS by disabling the software permit through the Software Interlock System (SIS) which will inhibit next beam injection (see Fig. 1). In addition, a new entry on the LHC logbook will be created for log tracking.

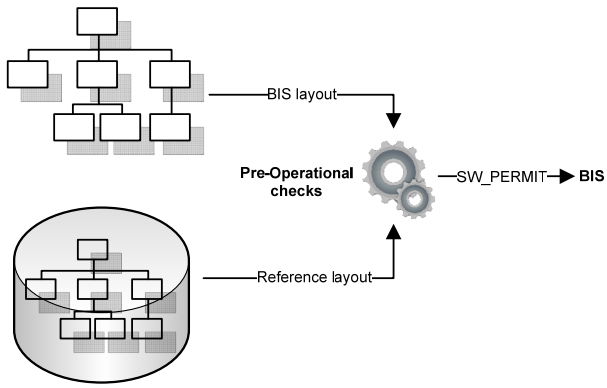

Figure 1: Pre-Operational checks workflow.

The sequence of checks implemented includes:

- Jumper configuration: it guarantees that no masked hardware inputs exist. It verifies that both redundant input channels from the user systems are enabled if required for operation.
- User system presence: it verifies the existence of the user system interfaces on those inputs defined as enabled in the database.
- User system ID: it prevents crossings between user system connections. It verifies that the unique identifier of the user system interface matches with the one defined in the database.

Besides, it is possible to perform on demand tests with each individual user system of the BIS. These tests consist in requesting the user system to force independently both redundant channels to the BIS to a false state to guarantee that the system is able to perform a beam dump request. Due to timing constraints this action cannot be performed on every user system before injection, however it is strongly recommended to be executed on a regular basis (e.g.: technical stops) to prevent possible blind failures of the user system interfaces.

DURING-OPERATION CHECKS

During beam operation, it is required to verify the integrity of the infrastructure and that several critical elements behave correctly and within tolerances. The online monitoring can have some impact on the dependability of the system, as despite critical protection functions are built into the hardware, the online verification can contribute to improve the availability of the system (e.g.: detection of a faulty redundant power supply that can be repaired during a technical stop in the shadow of beam operation).

In case of errors detected, the equipment experts will be informed but no other actions will be taken.

Implementation in DIAMON

The during- operation checks have been implemented as monitoring agents in the DIAMON [3] framework, which is a monitoring tool in charge of diagnosing problems in the controls infrastructure. This solution was chosen as it is a standard and flexible tool used in the controls group that provides embedded services such as access to the logging system or role-based access control to restrict the access to the agents. The checks are structured into two parts: (1) related to the infrastructure and (2) related to the critical hardware itself. With regard to the infrastructure the agents check:

- Frontend VME hardware (redundant power supply status, fan speed, fan temperature, …).
- VME Operating system parameters (memory and CPU load, disk space, system resources, user processes running …).

With respect to the critical hardware, the agent monitors:

- pulse per second reception and timing alignment problems from the LHC Machine General Timing (GMT).
- spurious glitches in the reception of critical fail-safe signals (i.e.: high radiation levels can cause glitches on the link. See Fig. 2).
- matrix clock frequency within predefined tolerances.
- redundancy of power supplies for user interfaces with the user systems.
- consistency of non-critical serial channels used for monitoring.

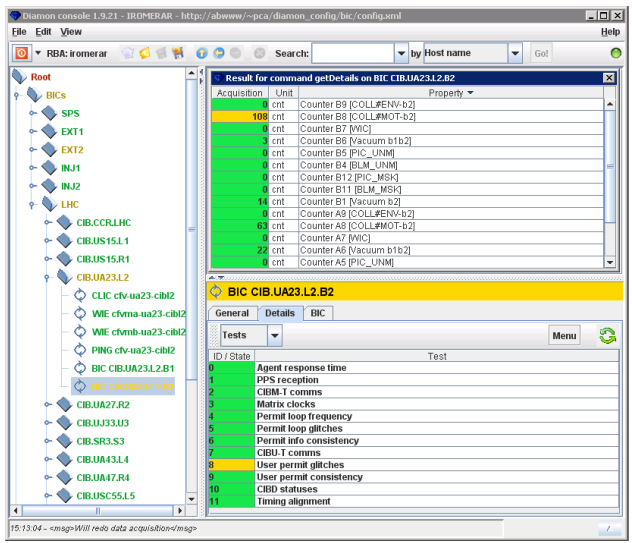

Figure 2: BIC agent in DIAMON console.

POST-OPERATIONAL CHECKS

After a beam dump, it is required to identify that the BIS was not the source of the beam abort and that all safety critical components of the system worked as expected. If the protection system integrity is compromised, beam operation must be inhibited until the problem is solved.

The post- operational checks were designed to fulfil the following requirements:

- be triggered after the reception of a PM event

- collect buffers from every BIC in the LHC and Injection Lines (INJ) as well as from LBDS system to reconstruct the sequence of events
- receive configuration data from reference database
- perform system checks and compare measured data against references
- inhibit beam operation via a software channel to the BIS if any relevant problem is found during the analysis
- display a summary of the checks performed, providing clear information of problems identified
- provide analysis of archived dumps

Furthermore, the post- operational checks of the BIS have to provide clear information about who was the first protection system provoking the beam dump.

Implementation in the Post-Mortem Framework

The Internal Post Operational Checks (IPOC) have been implemented as an analysis package in the PM framework [4], which is the system in charge of identifying the cause of the beam abort by performing individual system checks on the different equipment systems. These checks are immediately launched after an emergency dump. In such cases a PM event will be distributed all around the machine via the GMT and the PM buffers of the BICs are frozen, covering a time window around the event. The data PM buffers are pushed to the LHC PM server through a dedicated client library for analysis.

The IPOC module covers the following aspects of the BIS (e.g.: Fig. 3 shows the IPOC module being part of the PM framework):

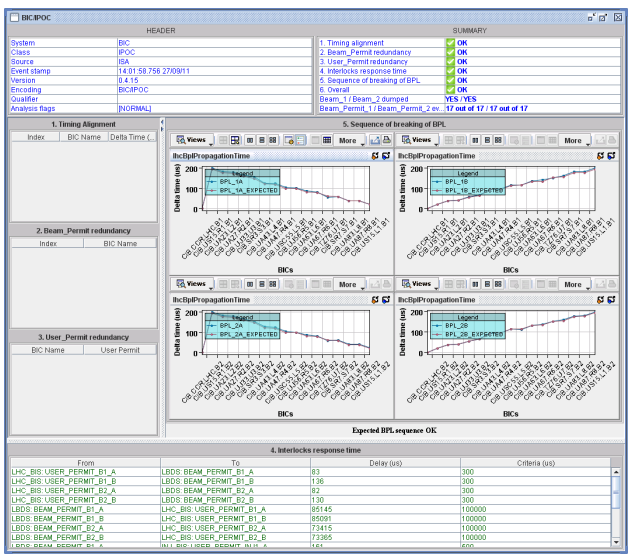

Figure 3: BIS-IPOC console.

- all records in the PM buffers of all BICs are time-stamped with the same timing references. This is vital for correlation of data.
- redundancy in the communication channels from the user systems up to reception of dump requests to LBDS is working.
- optical propagation delays in the Beam Permit Loops are as expected when comparing to the references.
- propagation of interlock signals between BIS and LBDS are correct and within tolerance.

CONCLUSIONS AND FUTURE PLANS

Operational verification tools must guarantee the correct configuration and integrity of the critical components of the BIS during all phases of beam operation. They have been intensively used during more than two years of LHC operation and partially deployed on the injector complex. It is demonstrated that the use of such tools plays an important role on prevention and diagnosis of problems and allowed gaining confidence in the reliability of the BIS.

In the near future it is foreseen to consolidate and improve the existing tools and to extend the scope of these checks to the BIS of the Super Proton Synchrotron (SPS) and related extraction areas.

SAFETY CONTROL SYSTEM AND ITS INTERFACE TO EPICS FOR THE OFF-LINE FRONT END OF THE SPES PROJECT

J. Vasquez*, A. Andrighetto, G. Bassato, L. Costa, M. Giacchini, INFN, Legnaro, Italy
M. Bertocco, UNIPD, Padova, Italy

Abstract

The SPES off-line front-end apparatus involves a number of subsystems and procedures that are potentially dangerous both for human operators and for the equipments. The high voltage power supply, the ion source complex power supplies, the target chamber handling systems and the laser source are some example of these subsystems. For that reason, a safety control system has been developed. It is based on Schneider Electrics Preventa family safety modules that control the power supply of critical subsystems in combination with safety detectors that monitor critical variables. A Programmable Logic Controller (PLC), model BMXP342020 from the Schneider Electrics Modicon M340 family, is used for monitoring the status of the system as well as controlling the sequence of some operations in automatic way. A touch screen, model XBTGT5330 from the Schneider Electrics Magelis family, is used as Human Machine Interface (HMI) and communicates with the PLC using MODBUS-TCP. Additionally, an interface to the EPICS control network was developed using a home-made MODBUS-TCP EPICS driver in order to integrate it to the control system of the Front End as well as present the status of the system to the users on the main control panel.

INTRODUCTION

Selective Production of Exotic Species (SPES) is an Istituto Nazionale di Fisica Nucleare (INFN) Project for the development of the Nuclear Physics as an intermediate step toward EURISOL and to cover interdisciplinary applied physics in the fields of material science and medical applications. The project is based on a facility (Fig. 1) for the production of neutron-reach Radioactive Ion Beams (RIB) using the Isotope Separation On-Line (ISOL) technique [1, 2].

The radioactive ion beams are produced by proton induced fission on a Uranium Carbide (UCx) direct target at a rate of $10^{13} fission/s$. The radioactive ions are re-accelerated at energies higher than 10 $AMeV$ for mass region $A = 130$. Re-acceleration will be performed by the superconducting linear accelerator complex (PIAVE-ALPI) of the LNL. The expected beam-on-target is on the order of 10^8 pps for ^{132}Sn, ^{90}Kr, and about $10^5 - 10^6$ pps for ^{134}Sn, ^{95}Kr considering a total efficiency of 2% from the $+1$ source to the experimental target [2, 3, 4, 5].

* jesus.vasquez@lnl.infn.it

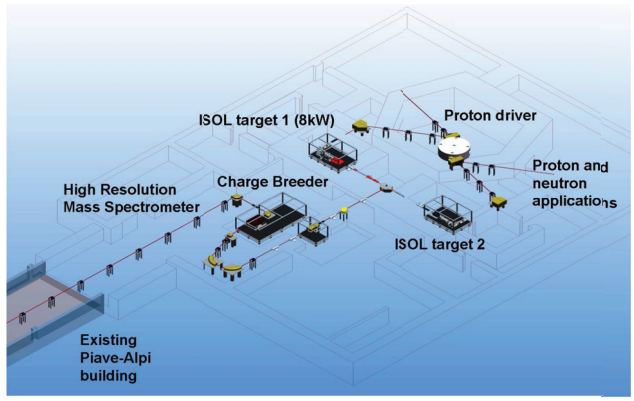

Figure 1: The SPES facility.

At the present, a test bench, called the Front End (Fig. 2), has been constructed at the LNL. It is an apparatus for the acceleration of stable +1 ions up to energies of 30 keV. It permits testing and improving the key systems used on the RIB production like the target complex, the ionization devices and the beam focalization and transport subsystems.

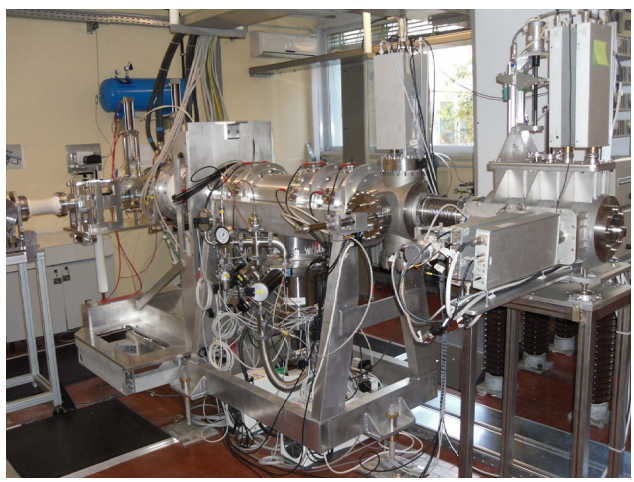

Figure 2: The off-line Front End of the SPES project.

The control system of the Front End has been developed using heterogeneous hardware and software solutions but they are integrated under an unique communication model based on the "Channel Access" of the set of open source tools EPICS (Experimental Physics and Industrial Control System) [6]. Moreover, thanks to this unification, the entire apparatus can be controlled from a main control panel developed using Control System Studio (CSS) collection of user interface tools.

The SPES off-line Front End apparatus involves a number of subsystems and procedures that are potentially dangerous for both human operators and equipments. Among the most potentially dangerous systems are: the high voltage power supply, the ion source complex power supplies, the target chamber handling mechanisms and the laser source.

In order to prevent possible injuries to the operators and damages to the equipments, a safety interlock system has been developed. Furthermore, this system has been interconnected to the EPICS Channel Access in order to have and unify control system.

THE SAFETY CONTROL SYSTEM

The Safety control system have been designed using self-controlled devices and applying redundancy for achieving a PL e/Cat. 4 (EN/ISO 13849-1) and a SIL3 (EN/IEC 62061) safety level. It was developed as a decentralized, distributed structure using Schneider Preventa safety devices. This safety modules are in charge of enabling or disabling the systems that are potentially dangerous, according to the conditions of the system.

The enabling or disabling of a system is done by the safety device controlling two contactors, serially connected, that transmit the power supply to the system. Controlling two contactors increase the reliability of the protection.

The conditions are determined by the status of critical variables (from the safety point of view) that are continuously being monitoring by the same safety devices. To maintain a required level of reliability, the monitoring of the variables is carried out using safety devices.

The critical variables monitored by the safety devices are: the status of the isolation cage gates (using safety magnetic limit switch), the presence of a person around the target chamber (using safety mats), the activation of the command to move the target chamber (using a safety two-hand controller), the activation of an emergency stop (using safety emergency push buttons), the temperature of the target chamber surface (using thermocouples and PT100 devices), the air system pressure (using a pressure switch), the water system flux (using flux meters) and the vacuum level inside the Front End (using vacuum heads and a pressure switch).

A system can be controlled by as much safety devices as critical variables are associated to its operation. Each pair of contactors (for each safety device) is serially connected to the others. In this way, only when every one of the safety devices enables the system, the power supply is transmitted and the system is power on.

For each system, an additional contactor has been added. It is controlled directly by a PLC in order to be able to power on the system when the user requires it, once the right conditions are satisfied. As an additional function, the PLC monitors the status of all the safety modules. A touch screen is used to allow the user to power on and off each system (when possible) and to show him the status of the system.

The PLC used is a BMXP342020 from the Schneider Electrics Modicon M340 family, while the touch screen is a XBTGT5330 from the Schneider Electrics Magelis family. They communication is carry out through the MODBUS-TCP protocol.

The system controlled by the safety controls are: the high voltage power supply, the ion source complex power supplies, the target chamber handling systems and the laser source. Figure 3 shows the safety system for the laser source as an example.

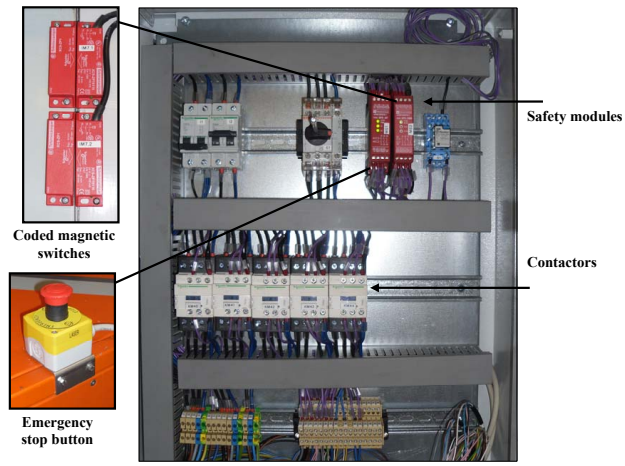

Figure 3: The LASER safety control system.

THE INTERFACE TO EPICS

An EPICS IOC (Input Output Controller) implementing a home-made MODBUS-TCP driver was developed in order to interconnect the EPICS and the safety control systems. This driver requests the PLC the status of the variable associated to the safety control systems and write them on EPICS records, available thus to the entire system through the EPICS Channel Access (CA).

The IOC is implemented on a Linux PC using two Ethernet interfaces: one is use for the PLC communication (MODBUS-TCP) and the other one is use for the EPICS communication (Channel Access). (Fig. 4). On the other hand, the MODBUS-TCP driver was developed using the "StreamDevice" device support for EPICS.

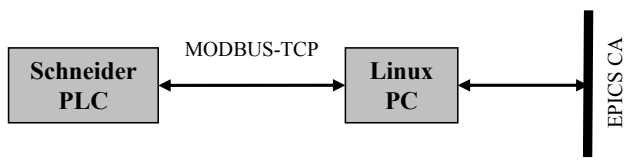

Figure 4: EPICS and safety control systems interconnection.

The MODBUS request is assembled on the IOC record data base and then it is encapsulated on the TCP/IP datagram by the StreamDevice device. The resulting packet is send to the PLC through the corresponding Ethernet interface.

The PLC receives the request, processes it, and them sends the respond through the same Ethernet interface to the IOC. This packet is first received by the StreamDevice who extracts the MODBUS response from the TCP/IP datagram. Next, this MODBUS response is delivered to the IOC record data base where the requested information (the variable status) is read, process and placed on suitable records that are accessible on the Channel Access.

Once the variable statuses are accessible on the Channel Access, they can be monitored by any Channel Access client inside the EPICS network. In our particular case, the statuses of the variables are presented to the user on the Front End main control panel (Fig. 5).

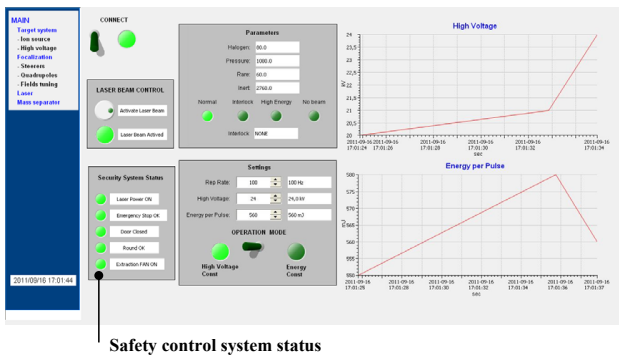

Figure 5: Safety control systems status presented on the LASER control GUI.

CONCLUSIONS

The SPES off-line Front End apparatus involves the use of potentially dangerous equipments. Additionally, the project is getting close to its operative time. Consequently, it was necessary to develop and implement a safety control system to protect both, the equipments and, more importantly, human operators that will be involve soon with the system.

The fact that the project involves dangerous conditions to human being, it demands that the safety control system must be as reliable as possible. Because of that, a distributed hardware-oriented safety control structure was implemented, using special safety devices and techniques achieving PL e/Cat. 4 (EN/ISO 13849-1) and a SIL3 (EN/IEC 62061) safety levels.

Furthermore, although the safety control system is decentralized and not controlled by any other system, a surveillance PLC collects the status information and presents it to the user locally on a touch screen and remotely on the Front End main control panel through an interface to the EPICS Channel Access.

Abstract

During the last JET tokamak shutdown a new ITER-Like Wall [1] has been installed using Tungsten and Beryllium materials. To ensure plasma facing component (PFC) integrity, the real-time protection of the wall has been upgraded through the project "Protection for the ITER-like Wall" (PIW). 13 CCD robust analogue cameras view the main areas of plasma wall interaction and regions of interest (ROI) are used for monitoring in real time the surface temperature of the PFCs. For each camera, ROIs will be set up pre-pulse and, during plasma operation, surface temperatures from these ROIs will be sent to the real time processing system for monitoring and preventing damages on PFCs by modifying the plasma parameters. Since 2005 a real time safety system for the monitoring of the PFCs is routinely used on the tokamak Tore Supra [2]. Based on this successful experience, a similar video and associated control system has been implemented at JET for the PIW. The overall system and the first results are presented in this paper.

THE PIW PROTECTION CAMERAS

The main criteria for selecting the PIW protection camera were guided by the JET hostile environment and especially:

- the robustness under high magnetic field
- the resistance to neutrons and radiations.

The chosen HITACHI black and white CCD analogue camera was used successfully in the past on JET. The simplicity of its technology makes this camera very robust under magnetic field.

The main characteristics and used settings of this camera are:

- Sensor: 752x576 pixels
- Output: 752x288 analogue Video non-interlaced
- 50 fields per second
- External synchronisation
- Exposure time: 20ms
- Standard IR cut filter removed and replaced with a near IR narrow band pass filter centered on 1µm with 50 nm width.

The expected dynamic range is shown is shown on Figure 1 with various optical apertures.

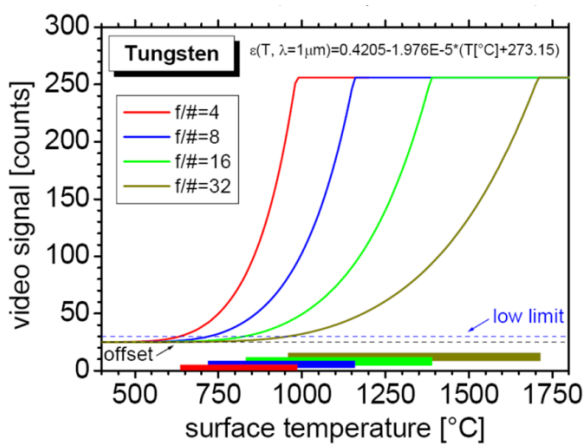

Figure 1: Hitachi camera dynamic range NIR filter : 1µm, Δλ : 50 nm.

VIDEO DIGITIZATION AND DISTRIBUTION

The video is captured using a PLEORA iPort PT1000 frame grabber and it is sent on GigE network through an optical fiber link.

The main characteristics of the iPort are:

- Analogue video input
- GigE Ethernet output
- Sample rate: 15 MHz
- Multicast capability

The iPort multicast capability allows the video distribution through a network switch to 3 different systems as shown in Figure 2.

- Real Time Processing System for PIW protection
- Video capture and replay system for data storage
- Live display system for visualization in JET control room

*See the Appendix of F. Romanelli et al., Proceedings of the 23rd IAEA Fusion Energy Conference 2010, Daejeon, Korea

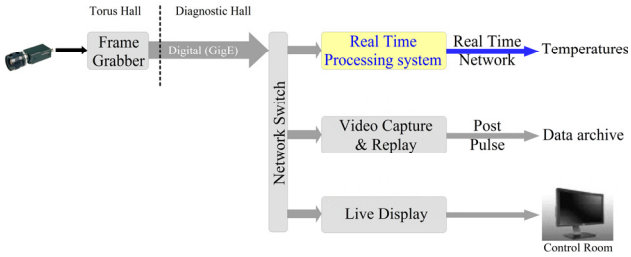

Figure 2: Video digitization and distribution synoptic.

THE REAL TIME PROCESSING SYSTEM

The Real Time Processing System (RTPS) has been divided into a 'Real Time Processing Unit' (RTPU), for surface temperature calculation, and a 'RTPU Host', for connection between RTPU and other systems.

The RTPU host is based on a standard industrial PC with Windows Embedded operating system.

As shown in Figure 3, the choice have been made to manage 2 RTPU with one JET standard industrial PC so one standard PC will manage 2 cameras.

This choice will reduce the risks by distributing the processing units in different host computers. Then for the 13 cameras that will be installed, 7 PCs are necessary.

The main functions of the RTPS are:

- Capture the camera data from Pleora iPORT modules with Intel Pro 1000 network boards and send them to RTPUs through the PCIe bus
- Get all the configuration files and values from JET Database and "Level One" then send them to the RTPUs through the PCIe bus. The configuration data are the ROI map, the dead pixel map, the Non Uniformity Correction matrix (NUC: offset and gain correction) and the calibration files that are Lookup Table (LUT) with 6 possible LUTs so 6 different materials and/or optical transmission can be managed (Beryllium, Tungsten, Tungsten coating…)
- Collect results (maximum temperature values for each ROI…) from RTPUs and send them through the JET Real Time Data Network to the Vessel Thermal Map (VTM) [3]
- Handle the central timing for synchronisation with JET pulses
- Allow ROI display for proper positioning check

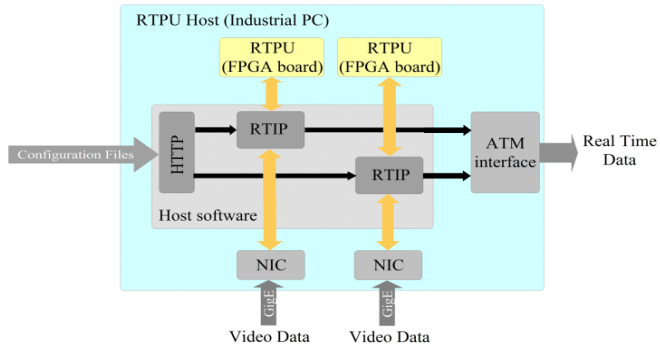

Figure 3: RTPS synoptic.

THE REAL TIME UNIT

The RTPU design, shown on Figure 4, is based on commercial Xilinx Virtex5 FPGA boards (Field Programmable Gate Array).

The on board FPGA ensures the PCIe bus and the DDR2 RAM management and of course the PIW protection functionalities.

All the parameters issued from configuration files are loaded in the on board DDR2 RAM before JET pulses. Using Video Frame Buffer Controller (VFBC) and FIFO, the video and parameters are sent synchronously to the PIW protection engine.

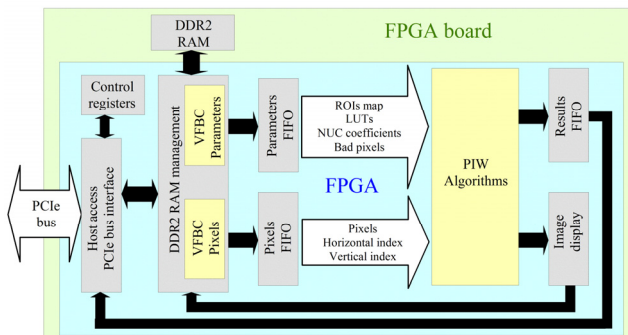

Figure 4: RTPU synoptic.

Programmed under Simulink using Xilinx System Generator block set, the FPGA can manage simultaneously up to 96 ROI per camera which can have any shape.

Each ROI is defined pixel by pixel and can be split in several different areas and can overlap with others. Each pixel can belong to up to 6 ROIs.

The main functionalities included in the RTPU FPGA algorithms (schematically shown on Figure 5), are:

- The PCI express bus and the on board DDR2 RAM management
- Two input FIFO interfaces for synchronisation between algorithms and RAM that are the "Image input" FIFO which handles the pixels value, vertical and horizontal synchronisation and the "Parameters" FIFO which handles the ROI and the Dead pixels maps, the NUC matrix and the used LUT for each pixel

- One "Results" output FIFO which handles all the results for each ROI
- One "Image processed" output FIFO which is mandatory for ROI map control
- The specific PIW algorithms are:
  - Dead pixels and NUC corrections
  - Neutrons impacts removal using configurable filter (Salt and Pepper 3x3 or Median 3x3)
  - Apparent surface temperature calculation using LUT (Lock Up Table) with 1 LUT per ROI chosen among the 6 stored in FPGA memory
  - For each ROI the following values are calculated : Hottest pixel surface temperature (T), hottest pixel position (x,y coordinates), uncertainty estimation using a dynamic sub ROI algorithm centered on hottest pixel (ie: Count number of pixel N in the sub ROI with value greater than X % of T, Hottest pixel is valid if N > threshold, N and X are configurable)
- And control registers which handles the filter selection, the dynamic sub ROI setup, the ROI highlighting…

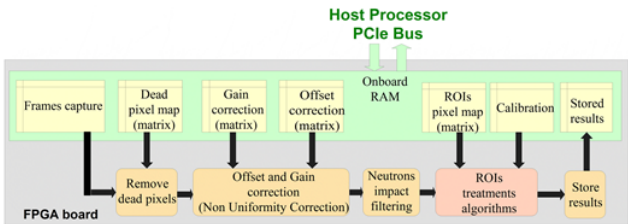

Figure 5: FPGA embedded algorithms.

THE USED COMMERCIAL FPGA BOARD

The chosen commercial board is a "Sundance Multiprocessor" PCI express SMT122T FX70T board, schematically described on Figure 6, for which the main features are:

- 4 lane PCI express interface
- 1 FPGA Xilinx Virtex5 FX70T FGG665
- 2 DDR2 memory banks (256Mbytes per bank)
- 1 Serial PROM 64Mbit
- 2 Marvell 10/100/1000 Ethernet PHYs

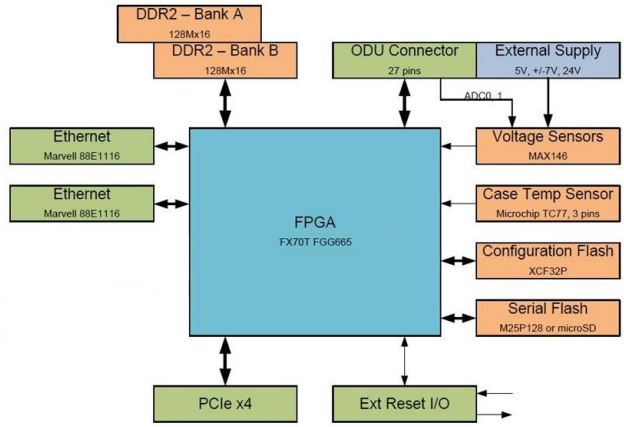

Figure 6: SMT122T FX70T synoptic.

TOOL FOR ROI DEFINITION

A graphical tool, running under Matlab, has been designed for creating the ROI definition file.

This tool allows the ROI drawing using JET background images. The main functionalities are:

- ROI drawing and naming with multiple sub-ROI capability
- ROI or sub-ROI deleting
- Area exclusion inside ROI
- Material (LUT) to ROI assignment
- RTPS readable file creating

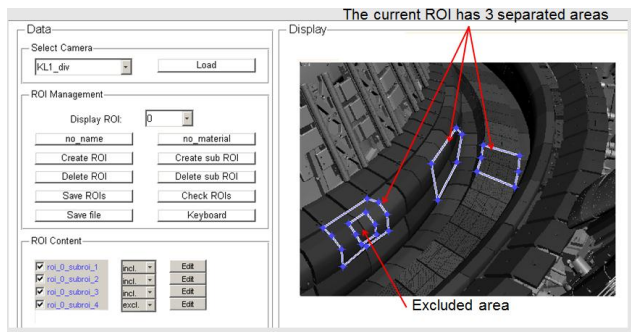

Figure 7: Software interface view.

EXAMPLE OF OBTAINED RESULTS

A preliminary result obtained using image processed displayed and recorded movies playing capabilities has been obtained and is shown on Figure 8.

In this example, 6 ROIs have been used, the results are displayed in the bottom of the image:

- Maximum ROI value
- Maximum coordinate (y,x)
- ROI number of pixel (used for ROI integrity verification)
- Number of pixel in the sub ROI with value
  - greater than X % of hottest pixel value (used for uncertainty evaluation)

The ROI number 0 is highlighted for control.

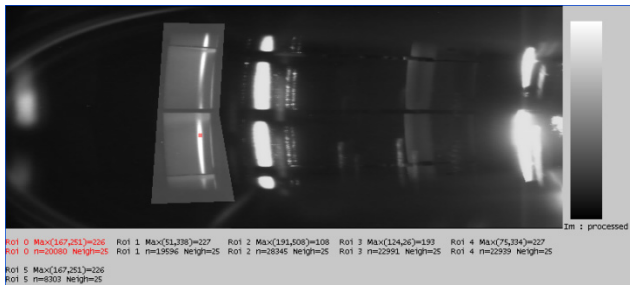

Figure 8: Obtained results example.

CONCLUSION

In the frame of the JET's ITER Like Wall project (first wall in Beryllium and divertor in Tungsten), a real time protection system for these plasma facing components (PIW) has been installed during last shutdown. Composed with a set of 13 CCD cameras, the protection system is based on one commercial FPGA board per camera. In the proposed approach, each FPGA board can manage up to 96 ROIs whilst for each ROI the value and position of the hottest pixel are delivered and sent to JET's VTM. The system has been successfully commissioned and validated during JET's experiments and plasma operations have been stopped by PIW system following a detection of pixels above the threshold limit. The system is now ready for routine operation and it will be particularly used for further development of high performance plasma scenario.

FIRST OPERATIONAL EXPERIENCE WITH THE LHC BEAM DUMP TRIGGER SYNCHRONISATION UNIT

A. Antoine, C. Boucly, N. Magnin, P. Juteau, N. Voumard, CERN, Geneva, Switzerland

Abstract

Two LHC Beam Dumping Systems (LBDS) remove the counter-rotating beams safely from the collider during setting up of the accelerator, at the end of a physics run and in case of emergencies. Dump requests can come from 3 different sources: the machine protection system in emergency cases, the machine timing system for scheduled dumps or the LBDS itself in case of internal failures. These dump requests are synchronized with the 3 µs beam abort gap in a fail-safe redundant Trigger Synchronization Unit (TSU) based on a Digital Phase Locked Loop (DPLL), locked onto the LHC beam revolution frequency with a maximum phase error of 40 ns. The synchronized trigger pulses coming out of the TSU are then distributed to the high voltage generators of the beam dump kickers through a redundant fault-tolerant trigger distribution system. This paper describes the operational experience gained with the TSU since its commissioning with beam in 2009, and highlights the improvements, which have been implemented for a safer operation. This includes an increase of the diagnosis and monitoring functionalities and a more automated validation of the hardware and embedded firmware before deploying or executing a post-operational analysis of the TSU performance, after each dump action. In the light of this first experience the outcome of the external review performed in 2010 is presented. The lessons learnt on the project life cycle for the design of mission critical electronic modules are discussed.

INTRODUCTION

The TSU re-phases the dump requests with the circulating beam such that the 100 % rising edge of the magnetic field in the extraction kicker coincides with the end of the beam abort gap in the circulating beam [1].

Locked to the LHC beam revolution frequency, two redundant TSUs produce continuously dump trigger pulse trains synchronised with the beam abort gap. The distribution of these pulse trains is inhibited until a beam dump is requested. The first pulse which pass the inhibit stage are then sent via two redundant trigger fan-outs (TFO) to all the power trigger modules. In this way the first pulse after the reception of a dump request will synchronously trigger the system.

In case the beam revolution frequency is lost during more than one turn, an internally synchronised direct digital synthesiser based on a Numerically Controlled Oscillator (NCO) and on a Digital Phase Lock Loop (DPLL), precisely locked on the beam revolution frequency, will issue an internal dump request and will generate a dump trigger which is synchronous with the beam abort gap.

In addition, the two redundant TSUs continuously cross-check their DPLL synchronisation. A phase discrepancy greater than 40 ns between the two TSUs automatically issues a synchronous dump. If the synchronisation of only one of the TSU fails, a synchronous dump trigger is forced by the redundant system.

During the LHC cold check-out period all the functionalities of the TSU modules have been extensively tested and commissioned. No major technical issues have been identified at that stage. First operational experiences with beam have demonstrated the correct operational performance of the TSU module [2].

Nevertheless, some unforeseen events like asynchronous synchronous dumps* induced by the TSU modules have been recorded during the LHC commissioning. Despite a high level of embedded diagnosis and monitoring functionalities, tools to capture spurious synchronisation failures like synchronous asynchronous dump appear to be missing.

In addition, due to its key function within the critical LBDS system, it has also been decided to perform an external review of the TSU module and its embedded software in order to check and validate its functionality.

REVIEW

Early 2008, an internal review of the LBDS in general and of the trigger synchronisation and distribution system (TSDS) in particular has been conducted with the goal to validate all the implemented technical solutions before the start of the commissioning of the LBDS with beam. The final recommendation of this review has suggested to perform a more detailed review of the TSU module and its embedded software, and, to build a test bench for validation of its different functionalities.

Subsequently an external review of the TSU module has been performed in 2009/2010 by a company specialized in electronics engineering R&D, with the aim to obtain a detailed evaluation of the TSU module functional suitability and an identification of conception and/or implementation errors. The review objectives were:

- The validation of the correct implementation of the functional requirements,

* The TSU trigger outputs is asynchronous compared to the LHC revolution frequency but the 15 extraction magnets of the beam dump kicker are triggered in a synchronous way.

- The identification of possible hardware and software anomalies,
- The verification of the pre-series performance,
- The recommendation of possible improvements,
- The proposal of guidelines of possible maintenance procedures for the embedded software.

The review has been divided into three phases, requirement review, design review and hardware & software review, with an executive summary fully documented at the end of each phase.

The Requirement Review

The objective of the requirement review phase was to ascertain the adequacy of the requirements in defining the characteristics and the functionalities of the TSU module and to check that all requirements are covered by at least one module or sub-module of the TSU design, which could be in hardware, software or a mix of both.

A high level hierarchy that identifies all hardware and software modules with their corresponding functionalities has been created and cross-checked through a validation matrix with the list of all functional requirements.

The requirements review demonstrated that all requirements are indeed properly covered by at least one module and that all links between modules are coherent. However, it has been noted that the architecture of some required functions, like the PLL design, are sometimes too complex even although the hardware and software architectures are correct.

The Design Review

The second part of the review consisted in an in-depth analysis of the TSU module design in order to ensure that its conceptual design meets the baseline requirements and that its performance levels, typically reliability and availability, are within specification. A low level hierarchy has been created for this purpose and a requirement coverage matrix issued to synthesize the results with a basic OK/NOK status result for every requirement associated with a criticality level. A failure severity classification based on three levels of criticality has been used (Table 1)

Table 1: Criticality Levels

Critical	Failure that can induce a dysfunction considered as serious.
Major	Failure that can affect functionality considered as non-critical or with low probability.
Minor	Failure with no risk for the global functionality.

Over more than 200 functional requirements which were analysed the design review phase has identified 11 requirements as not properly implemented, from which only one has been classified as “critical”. Indeed it has been demonstrated that in case of an internal failure in one of the two redundant TSU modules, the faulty TSU indicates correctly its faulty state to the redundant module but doesn't generate any trigger, (in any case, an asynchronous dump should have been issued). Four other failure cases have been classified as major due to their possible impact on the module availability and the six remaining cases have been evaluated as minor

The Hardware and Software Review

An in-depth analysis of the TSU electronic circuit and its embedded software has concluded the review. The hardware has been completely checked with respect to modern state-of-the-art hardware design techniques as well as the embedded VHDL software. In addition, the major embedded software modules have been fully simulated and their reactions to incorrect operational conditions analysed in detail.

The analysis of the electronic circuit has highlighted the possibility of the propagation of an internal hardware failure to the redundant module, lack of protection against external environment perturbations, missing Electro-Static Discharge (ESD) and Electro-Magnetic Interference (EMI) protections and under-sized components in case of unforeseen DC mode operation. These design errors have been considered by CERN as minor taking into account the specific environment and operational conditions under which the TSU module is operated. Nevertheless, it has been decided to take these remarks into account for the development of the next hardware version of the TSU module.

The software analysis has highlighted missing debouncers to prevent meta-stable behaviour on some input signals and a wrong behaviour in case of a large phase jump of the beam revolution frequency signal that will imply an asynchronous synchronous dump output trigger. Both remarks have been confirmed by CERN as valid and implemented in a new release of the embedded software.

NEW TOOLS

On the basis of the first years of operation, two different tools have been developed in order to improve the maintenance, the monitoring and the post-operation diagnosis of the TSU.

An automated test bench has been developed to validate the hardware and software modifications before their operational deployment, and a trigger synchronisation unit internal post operational check (TSU IPOC) has been implemented with two functions: a monitoring function to acquire the sequence of synchronisation and triggering signals after each dump and a logic analyser of the dump events sequence for validation of its correct execution.

Automated Test Bench

When an update of the TSU module is required, the major difficulty during its re-commissioning comes from the need to have all the external conditions available in order to re-validate its correct functionality. As these conditions are only met when the machine is closed, a full

re-validation of the TSU, which is located in an underground gallery directly adjacent to the machine tunnel, is impossible.

Thus, An automated test bench based on a PXI crate has been developed to emulate all TSU external signals (dump request clients, beam revolution frequency, arming command…), to check the correct functionalities of the TSU through the application of different stimuli and error signals on the emulated signal and to validate the TSU response through the acquisition of the different TSU output signals, internal diagnosis registers and IPOC analysis result.

The test bench has been developed around a NI-PXI 8184 embedded controller running LabVIEW Real-Time. A NI-PXI 5412 arbitrary waveform generator has been used for emulation of the beam revolution frequency while the other signals are emulated through either an NI-PXI 5402 arbitrary function for frequency based signal or a NI-PXI 6115 multifunction I/O module for digital input.

All input functions and their actions are controlled through a LabVIEW based user interface (Figure 1). Through this interface, each individual signal can be independently tested or an automated test sequence can be launched.

When operated in automated test mode, the response to different failure cases on each input signal is tested. The test bench analyses all results and sets a flag on each test when passed. In the case of a failure, the test bench automatically records which rule has been violated.

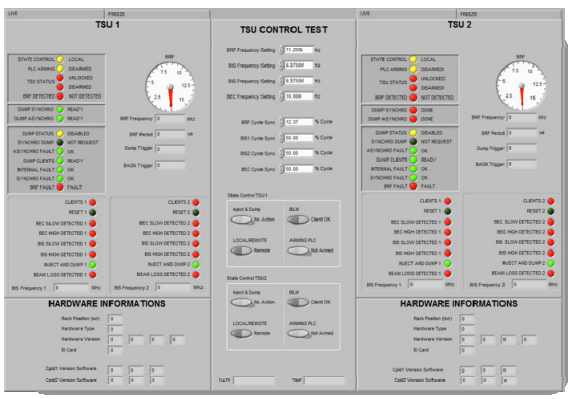

Figure 1: Test bench user interface.

TSU IPOC

The first release of the TSU embedded software includes detailed internal diagnosis functions. It appears rapidly that a tool to correlate in the time domain the response of the two redundant TSUs as well as the trigger signal distribution to the generators was missing.

A TSU IPOC with monitoring function has been developed to get a better understanding of the entire LBDS triggering process, from the capture of the dump requests up the monitoring of the synchronisation process and the generation and distribution of trigger and re-trigger signals.

The system is based on a PCI 32 bit 125 MS/s digital I/O module from SPECTRUM. The acquisition software is running on the LINUX front-end and has been implemented within the FESA framework.

Signals acquired after each dump include the dump requests, the beam revolution frequency, the re-phased beam revolution frequency, the synchronous trigger outputs from the TSU and the fan-out circuits as wel as the asynchronous trigger outputs and the re-trigger pulse chain signals.

A JAVA GUI permits an on-line analysis of the events sequence of the last dump and a replay previous dump for off-line analysis. An overview of a typical dump event sequence is shown in Figure 2.

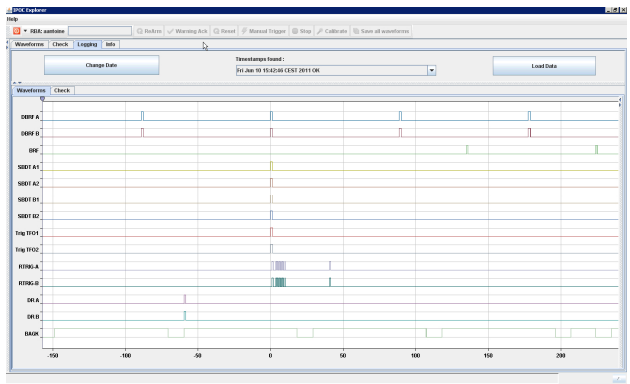

Figure 2: TSU IPOC Monitoring.

A second functionality of the TSU IPOC, based on signals acquired by the monitoring function, is the logic analyser function.. This automated analysis, performed after each dump, checks the correct sequence of triggering and re-triggering pulses, the correct delays between the different signals, the sanity of the signals, the correct frequency and phase offset between distributed and internally generated re-phased beam revolution frequency. For each analysis, a global and a detailed report is generated and archived. Figure 3 shows a typical dump event analysis summary.

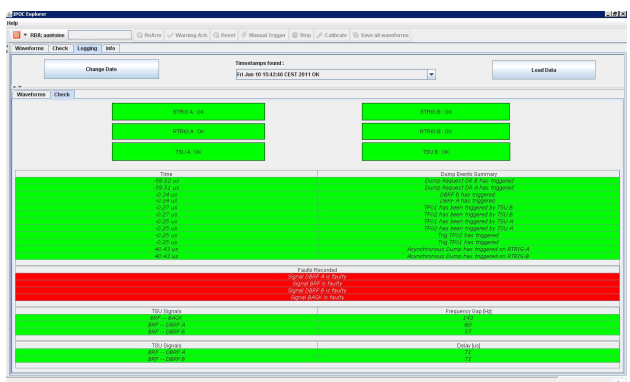

Figure 3: TSU IPOC logic analyser.

Up to now the IPOC has no link with the LBDS interlock system and its results don't affect the operational condition of the LBDS. In the future, this system will be included within the LBDS External Post Operational Check (XPOC) system [3] and thus force an expert to analyse and acknowledge failures before continuing with machine operation.

IMPROVEMENTS

Since its commissioning several minor updates on the TSU units have been applied successfully. Most of these updates have been induced by changes of specification, mainly to implement additional diagnosis. One has been made to remove a critical bug identified during the commissioning with beam. Here is a short summary of the different updates:

- Correction of a critical bug to avoid asynchronous synchronous trigger due to a hardware error in the design on the trigger output management output logic. This part, initially designed with combinational discrete components was responsible for a random phase shift of the synchronisation trigger pulse when the dump request was received;
- Implementation of the acquisition of UTC time stamp of the dump request;
- Implementation of a fast inhibit mechanism to LHC injection interlocking system in order to avoid the possibility to inject beam in the machine one turn after a beam dump;
- Consolidation of the TSU output signals for integration within the TSU logic analyser.

An important embedded software release has also been started for implementation of the external review recommendations. All critical and major identified failure cases were cured in this update, but the automated test failed. It was demonstrated that the change in the VHDL code induces a new routing of the FPGA circuitry, which revealed an insufficient filtering of the +1.2V power supply of the TSU board. A stronger inductance supported by a new decoupling capacitor was implemented and the following automated test bench passed with more than 35000 arming/dump sequences without any failure. That new release will be deployed at the end of 2011.

Finally, the review has taught us a new way of working for future projects. The project life cycle for a design, V cycle, consists on dividing the designers in two independent teams. The first team creates all the steps to design a final product (requirements, high level and low level architecture, etc.), while the second team is developing verification tools for all steps of the project to the final product, including the design of the final test bench. In that way, most of common modes in the conception are rejected which improves the reliability and the robustness of the final product.

CONCLUSION

The first operational experience and the external review led to the creation of three new functions. An automated test bench that allows the validation of any hardware or software modifications before deployment in operation, a TSU IPOC monitoring function with an on-line graphical interface to show a dump trigger signature and a TSU IPOC logic analyser looking at defined rules to validate the correct operation of the TSU units once in operation. Additionally, the external review has given us a new methodology in project design improving the reliability of final products, the V cycle.

The last release of the TSU units, taking into account all critical and major design errors highlighted by the external review, is now ready for deployment after a successful completion of the automated test process.

A new hardware design release will be started in 2012 to improve the robustness of the interfaces.

LHC COLLIMATOR CONTROLS FOR A SAFE LHC OPERATION

S. Redaelli, R. Assmann, R. Losito, M. Donzé, A. Masi, CERN, Geneva, Switzerland

Abstract

The Large Hadron Collider (LHC) collimation system is designed to protect the machine against beam losses and consists of 108 collimators, 100 of which are movable, located along the 27 km long ring and in the transfer lines. The cleaning performance and machine protection role of the system depend critically on accurate jaw positioning. A fully redundant control system has been developed to ensure that the collimators dynamically follow optimum settings in all phases of the LHC operational cycle. Jaw positions and collimator gaps are interlocked against dump limits defined redundantly as functions of time, beam energy and the β^* functions, which describe the focusing property of the beams. In this paper, the architectural choices that guarantee a safe LHC operation are presented. Hardware and software implementations that ensure the required performance are described.

INTRODUCTION

The nominal beam stored energy at the Large Hadron Collider (LHC) will exceed 350 MJ, to be compared with the quench limit of super-conducting magnets of a few mJ per cm^3 and the damage limit of metal of a few hundred kJ per cm^3. The collimation system, based on 108 collimators located around the ring, protects the machine against beam losses and cleans the beam halos [1].

Each collimator has two jaws controlled by four stepping motors to precisely adjust jaw position and angle with respect to the beam. Stepping motors have been used to ensure high reproducibility of settings. Linear Variable Differential Transformer (LVDT) sensors and resolvers have been installed to monitor the position of the axes of the collimators in real-time (RT) at 100 Hz. The collimator jaws follow motion profiles expressed as functions of time, which is a unique feature for collimation systems in particle accelerators. Different sets of functions are optimized for the different LHC operational phases. Resolvers are used to detect losses of motor steps whereas LVDT readings are compared redundantly with safety limits. Limits a defined as functions of time, of beam energy and of β^* functions that express the focusing property of the beams. If the measured axis position violates any of these limits, which are always active in parallel, the low level control system requests an immediate abort of the circulating beams.

The control system of the collimators is responsible for the motion control, synchronization and survey of about 400 axes (see Tab. 1). It is characterized by challenging requirements [2] such as timing synchronization in the motion axes at the microsecond level; motion repeatability of a few micrometers and accuracy in the monitoring of the profile in execution. High reliability is ensured through architectural choices and redundancy implemented to ensure machine safety. In the next section the architecture of the LHC collimator control system is described. The redundant strategy implemented on the collimator axes monitoring and survey through interlock limit functions is then presented. An analysis of the additional interlock conditions is presented in the last section.

Table 1: Main System Parameters. The number of settings in the second part of the table is calculated for the 2011 operational cycle, with squeeze to $\beta^* = 1$m in IP1 and IP5. Energy– and β^*–limits are common to all machine cycles (same values resident in the hardware). The two dump protection collimator are not included in this list.

Parameters	Number
Movable collimators in the ring	85
Transfer line collimators	13
Stepping motors	392
Resolvers	392
Position/gap measurements	584
Interlocked position sensors	584
Motor settings versus time	1760
Threshold settings versus time	3054
Threshold settings versus energy	196
Threshold settings versus β^*	384

COLLIMATOR CONTROLS

The Control Architecture

In Fig. 1 the general layout of the LHC collimator control system (LCCS) is presented [3]. Starting from the bottom we can identify the following layers: i) Low level front-ends based on two National Instruments PXI systems for the motion control and survey ii) the collimator middle ware based on a gateway that concentrates all the data accesses from the top level application via a standard CERN middle ware server [4] and establishes peer to peer connections with the collimators' low level control systems through the Data Interchange Management protocol (DIM) [5]; iii) the Central Control Application (CCA) [6] is responsible for generating and orchestrating the settings for the whole system and for sending them to the middle ware referring to the collimators' FESA class [7]. The CCA is fully integrated into the LHC Software Architecture (LSA) environment [8].

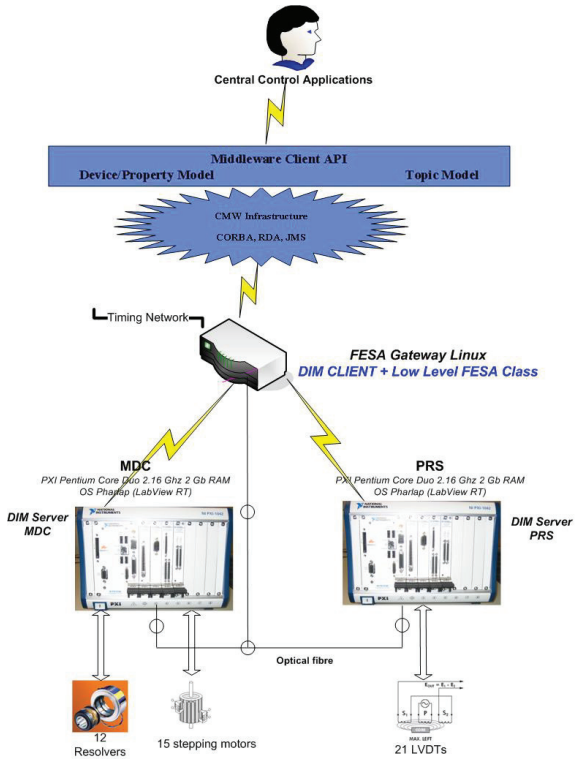

Figure 1: Architecture of the LHC collimator control system.

Low-level Control

Controls choice PXI platforms from National Instruments running LabView RT have been chosen as low level RT control system. Significant improvements of the PXI systems were applied to enhance their reliability and robustness [9]. The main changes are: i) Diskless controller equipped with the PXE network boot protocol; ii) Double core CPU to split the computational load; iii) Implementation of watch dog timers on the CPU and FPGA to detect stuck conditions on the host and bad working of the FPGA; iv) Monitoring of the system parameters (i.e. memory usage, CPU and chassis temperature, CPU load) to prevent operational anomalies (i.e. memory leakages). The control system's reliability was increased by splitting the functions of motion control and survey on two independent PXI systems: the Motor Drive Control (MDC), responsible for the generation of stepping pulses and for the resolver monitoring for up to three collimators, and the Position Readout and Survey (PRS), responsible for the synchronous monitoring of up to three collimators via the LVDTs.

Motor driver controller (MDC) The MDC receives motion commands (i.e. simple displacements or long motion profiles) from the top level through the FESA middle ware. It verifies the consistency of the requested settings against present status of the collimator, then checks for steps lost during execution in RT using one FPGA card per collimator. A specific software was developed for the step generation: in the host controller, the motion profiles are interpolated with a 5 μm step resolution to generate the set points; these are sent via a FIFO to the FPGA, where a step generation loop, operating at 1 MHz, produces the pulses for each collimator motor. Each motor's resolver is read synchronously with the generated steps at up to 400 Hz thanks to a custom reading solution based on CORDIC transformations [3]. The nominal speed for discrete movements is 400 steps/s, which corresponds to 2 mm/s.

Position readout system (PRS) The PRS is responsible to verify that the collimator jaw positions and gaps are within the safety thresholds and to trigger a beam abort otherwise. On each collimator, 6 LVDT sensors are installed to read the 4 axis position and the 2 upstream and downstream gaps. The LVDT position sensors for up to 3 collimators are read at a frequency of 100 Hz and with an accuracy of a few μm [2]. Two parallel 16 bit ADC cards sample the secondary voltages of the 7 LVDTs of each collimator. A sine fit algorithm, which is properly optimized for RT implementation, runs on the Host and estimates the amplitudes. A ratiometric technique is then used to obtain the position. The survey process also runs on the Host but the synchronization is ensured by timing signals generated on an FPGA card and passed via the PXI bus [3].

Collimator Middle-ware

A gateway is installed in each LHC point with collimators to supervise and synchronize all the systems of that point. The RT actions (e.g. MDC motion or PRS monitoring start) are triggered through pulses sent via optical fibers directly to the PXI FPGA cards. All the gateways are equipped with a CERN timing receiver and synchronized via the CERN timing network [10]. This provides not only the LHC timestamps, but also machine status information (i.e. beam energy, β^*) [11]. The information of energy and β^* are used to determine via special tables the gap limits to be sent to the PRS over the network at 1 Hz refresh rate. On the PRS specific watch dog timers have been implemented to detect network communication problems and use, in this case, the tightest limits. On each gateway a FESA server exposes each collimator's data to the operator applications via a device model with information organized in properties and data fields. On the other side, a DIM client running on the same gateway fetches data and sends commands to the DIM servers on the corresponding PXI (MDC and PRS).

POSITION LIMITS AND INTERLOCKS

Operation Cycle for Collimators

The sequence of the relevant phases through which the LHC is driven to establish collisions for physics data taking is referred to as the operational cycle. This includes the injection of high intensity beams, the energy ramp, the betatron squeeze – when the focusing properties of the lattice are changed to reduce the β functions at the collision

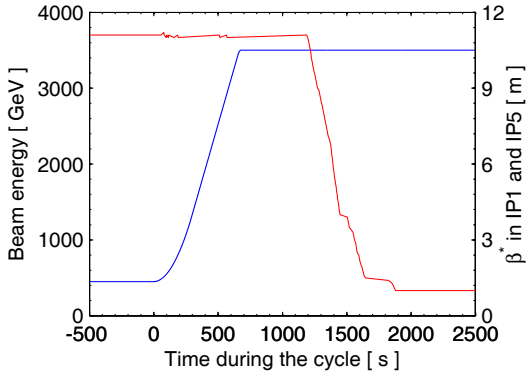

Figure 2: Beam energy (blue, left axis) and β^* in IP1 and IP5 (red, right axis) as a function of time during the LHC cycle. Time zero represent the start of the energy ramp.

points – the establishment of collisions, the physics data taking and the pre-cycle. Due to the large LHC stored energy (more than 20 MJ already at injection), beam collimation is needed in all phases. Appropriate redundancy of interlocks has been built into the system in order to ensure that the critical phases like the energy ramp and squeeze are performed with collimators at the correct positions. For this purpose, the concepts of energy– and β^*–limit functions have been built into the system in addition to standard limits as a function of time.

The beam energy and the β^* functions in a high-luminosity experiment are shown as a function of time during an LHC cycle in Fig. 2. Not shown in Fig. 2 is the pre-cycle without beam when the injection conditions are restored after a beam dump at high energy. Correspondingly, the collimators are moved as shown in Fig. 3. As representative examples, one primary collimator (TCP) of the betatron cleaning insertion and a tertiary collimator (TCT) that protects ATLAS, are shown. The measured collimator gaps and the different types of interlock limits are given as a function of time. Only dump limits, and not the warning limits, are shown.

Limit Functions Versus Time

Most accelerator systems are driven with functions of a pre-defined time duration only during energy ramp, betatron squeeze and collision preparation. The function duration is determined by the property of the power converters. A specific feature of the LHC collimators is that their jaws can be moved with pre-defined functions of time. This feature is necessary to allow the optimum settings to be maintained throughout the operational cycle, when the beam energy or the machine's optics change [12]. Correspondingly, limit functions versus time are also defined for each motor axis and for a gap. Inner and outer limits, with additional operational warning levels are defined for each degree of freedom, for a total of 24 limits functions for collimator, with a clear redundancy, since the degrees of freedom are only 4, one for each motor of the collimator.

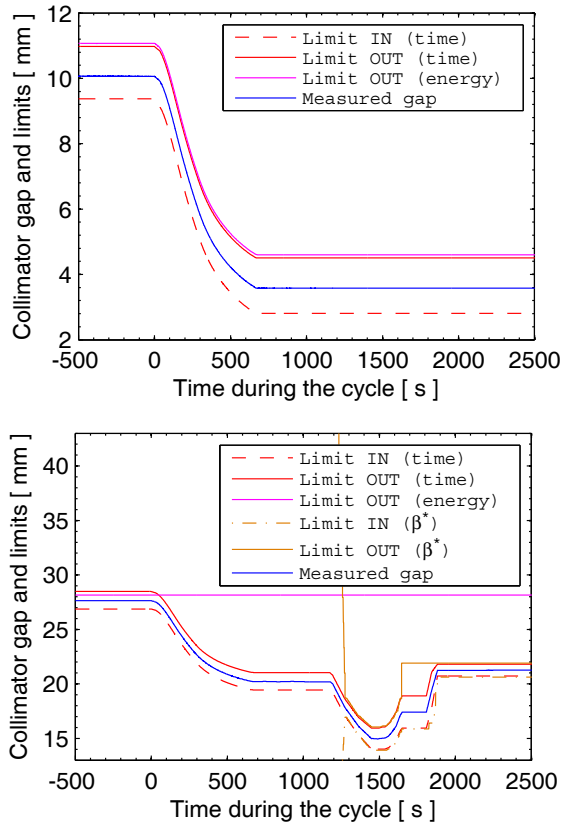

Figure 3: Gap and interlock limits versus time for a primary collimator of the betatron cleaning insertion (top) and for a tertiary collimator in IP1 (bottom) during a complete operational cycle (see Fig. 2).

Discrete Limits

Outside cycle phases driven by functions, the collimators remain idle at constant settings and discrete changes ("trims") are possible. In these cases, discrete collimator limits are used. These limits are computed from the functions: for example, the injection settings correspond to the ramp function's first point, and the limits during physics are given by the collision function's last points. Discrete limits apply for the motor axes and gaps, for a total of 12 dump limits and 12 warning limits per collimator.

Energy Limits

The limits as a function of energy were conceived to ensure that the collimator gaps follow the reduction of beam size during the energy ramp. Maximum allowed gap values versus energy are defined for each gap LVDT. The same concept is used for injection protection collimators – even if the are not "ramped" – to ensure that injection is not possible is collimator gaps are larger than safe limits [13].

β^* Limits

Additional inner and outer limits as a function of β^* are checked for upstream and downstream gap measurements (4 limits per collimator) in order to make sure that the ter-

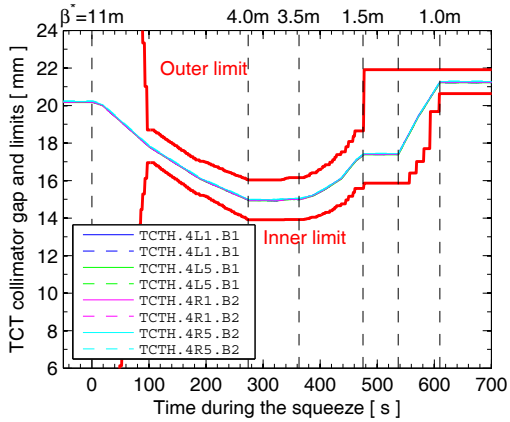

Figure 4: Measured gap position and β^*–limits of 2 tertiary collimators in IP1 and IP5 versus time during a betatron squeeze down to 1 m.

tiary collimators in the experimental region move as required while the optics is changed. The β^* information is distributed for each interaction point (IP) separately. Each collimator can be configured to use as input the β^* in any IP or the minimum of the 4 IPs. An example for 2 TCTs in IP1 and IP5 is given in Fig. 4.

Strategy for Motor Blockage

The controllers of each motor axis are blocked upon reaching the discrete or functional limits versus time in order to avoid that a collimator jaw runs into the circulating beam in the extremely unlikely case that the beam abort was not triggered by the violation of the inner position limits. This blockage mechanism also reduces the risks of mechanical damage in case of erroneous manipulations, like setting of tilt angles above the mechanical limit of 2 mrad or requested position beyond the mechanical end stops that could be reached in case of end switch failures.

Unlike the time-dependent limits, the limits as a function of energy and β^* do not block the motors. This allows the jaws to reach the open parking positions during the recycle without beam. In this phase, the energy limits generate an interlock that prevents injection of unsafe beams until the collimators are moved to safe injection settings. At every operational cycle, it is also verified that all the connections between the collimators and the beam interlock system are operational.

COLLIMATOR STATUS INTERLOCKS

In addition to the position interlocks, the PRS unit can also dump the beams in a number of cases when the machine protection role of the system cannot be ensured:

- Reboots of the low-level systems;
- Power cuts that affect the PRS PXI;
- Set of "Local" mode that allows expert checks and sensor calibrations;
- Stuck conditions detected on the PRS CPU through watch dog timer verified on the PRS FPGA.

CONCLUSIONS

In this paper the LHC Collimator control system has been presented focussing on design, architectural choices and control strategies that guarantee a safe LHC operation. In all operational cases, a highly redundant survey of collimator position ensures that the system is at the required safe settings. This strategy has been successfully validated by 2 years of LHC operation with high intensity beams.

ACKNOWLEDGEMENTS

The authors would like to thank M. Jonker, M. Sobczak for the discussions on the collimation control architecture. They are also indebted to a number of people in National Instruments, in particular B. Runnels, C. Loew, D. Shepard, G. Cirigioni, S. Concezzi, C. Moser, C. Farmer. The LHC operation (in particular M. Lamont and J. Wenninger), the machine protection, the controls (G. Kruk) and the timing teams are also kindly acknowledged.

QUALITY-SAFETY MANAGEMENT AND PROTECTIVE SYSTEMS FOR SPES

D. Benini, S. Canella, INFN-LNL, Legnaro, Italy

Abstract

The realization of a nuclear facility for the production of radioactive ion beams requires a deep study of the safety aspect: an high degree of reliability in the Protective System must be achieved to prevent hazardous situations for operators, population and the surrounding environment.

For the INFN SPES project, a *Quality and Safety Management System* is going to be realized. In this work we will present its general structure, functions and goals. We will then focus our attention on the Access Control and Dose monitoring systems which are the key features of the SPES *Protective System* in the framework of the QSMS.

INTRODUCTION

SPES (*Selective Production of Exotic Species*) is a INFN project for the realization of a Radioactive Ion Beam facility at Legnaro National Laboratory (LNL).

The radioactive beams production method is based on the ISOL technique (*Isotope Separation On Line*). The exotic isotopes are extracted from proton induced fission products in a UCx direct target, typical expected fission rates are of 10^{13} fission/s. The SPES proton driver is a two exit port cyclotron with a variable energy from 15 MeV up to 70 MeV, the foreseen maximum current value is 0,750 mA. A general layout of the SPES facility is illustrated in Fig. 1.

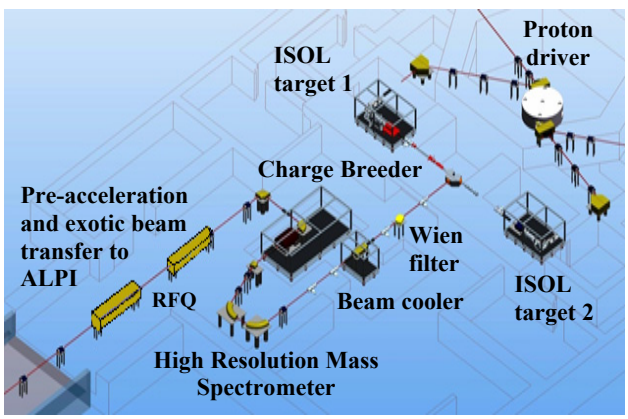

Figure 1: SPES layout.

An overall tool for managing the safety issues of SPES is the Quality and Safety Management System (QSMS), its development is one of our goals in the next future. The implementation of this System starts from the definition of the safety and quality policies to be achieved and involves the drafting of a hierarchical framework of procedures. The Access Control and the Dose Monitoring Systems will be also analyzed for the production of specific documentation.

The Protective System of SPES will be designed with the necessary intent of achieving a high level of safety and reliability, in this way dangerous situations for people and the environment will be avoided. In this paper we present the QSMS concept and its software implementation, the specific features of the SPES Protective System will also be described.

THE QSMS OF SPES

The QSMS is a managing tool that LNL has chosen to realize for handling all the phases of SPES starting from the initial stage of the facility design.

It is implemented according to Italian laws, technical standards and all mandatory prescriptions that the project must comply. Moreover the international standard ISO 9001:2008 for Quality and OHSAS 18001:2007 for Safety will be the main reference for the development of the QSMS.

An Environmental Management System (ISO 14001:2004 compliant) is already operative at LNL: the QSMS of SPES will be developed considering its structure and also the possible future integration between the two systems.

The first step for the implementation of the System is the definition of a policy of Quality and Safety for SPES, it will be pursued through the definition and the realization of specific objectives. The approach of the QSMS is to divide the SPES project in the following 5 phases of its lifecycle:

- Design;
- Realization;
- Operation;
- Maintenance;
- Disposal.

Every stage will be analysed to identify the activities that should be controlled to guarantee safety and quality for the SPES facility: starting from general guidelines the specific operating instructions for each area will be identified. Some of the aspects that will be analysed for the phases of design and construction concern, for example, the collection of all technical drawings, the identification of legal and technical requirements and the description of the techniques for hazards and risks analysis. Afterwards all the ordinary and emergency procedures for the last three phases (operation, maintenance and disposal) will be drawn.

The complete documentation concerning the QSMS is collected and catalogued according to specific storage rules that allow a fast identification of each document and an easy retrieval in the electronic archive. Documents are hierarchically organized according to a pyramidal scheme: at the top we find the general paper describing the QSMS in its whole, moving downward there are more

precise documents explaining with more details each specific activity.

Figure 2 shows the documents organization scheme of QSMS.

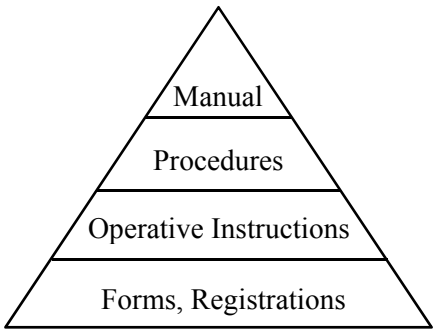

Figure 2: Scheme of the QSMS documentation.

Documents are divided in the following categories:

- Manual: is the text describing the QSMS general features explaining its purposes and organization modalities;
- Procedures: these documents describe how every single activity foreseen by the System has to be performed. They are divided in Managerial and Technical considering their connection to the organization of the management system rather than specific SPES activities;
- Operative instructions: they refer to specific procedures and contain a detailed description of how a specific activity has to be performed;
- Forms and registrations: these are report documents to be filled at the end of each activity. They are intended for operations logging.

Procedures for the Risk Analysis and the SPES Protective System

In this work we want to focus the attention on the procedures of the QSMS related to the Risk Analysis of the plant and the Protective System of SPES.

Concerning the Risk Analysis a detailed identification of the hazards and a consequent evaluation of all the risks is needed to optimize both plant design and safety systems. From the point of view of the necessary documents we are preparing a procedure describing the standard techniques that must be applied, the plant and the specific components that must be analysed, the data reports standards. The investigation method requires the use of the following techniques:

- Failure Mode and Effect Analysis (FMEA): with this method one looks for any possible failure of the plant of interest, finding out its gravity and frequency of occurrence. This is done to underline possible design errors of the plant or the presence of single components loosely reliable.
- HAZard and OPerability analysis (HAZOP): process variables are examined looking at the deviations from standard operative conditions. This is done to evidence possible failing situations of the system which can lead to an accident (called Top Event, TE).
- Fault Tree analysis (FT): it evaluates the frequency of occurrence of the TEs evidenced with the HAZOP method.

The results obtained from the combined use of this three methods give an important input for the design and the realization of the SPES Protective System. The guidelines indicated by the LNL's radiation protection officer will be another reference point to take into account, this kind of requirements will have to be completely fulfilled.

From the point of view of the QSMS the documents for the SPES Protective System will contain a detailed description of the safety disposals organization and the single procedures (ordinary and of emergency) to be followed during the facility operation.

THE SOFTWARE OF THE QSMS

The management of the data flow foreseen by the SPES QSMS will be realized through a custom software. This tool is designed to facilitate the application of the procedures of the QSMS during the different phases of the facility lifecycle. It will have to act as data collector during the project realization as well as an automation tool for the working and maintenance procedures.

We intend to realize a user-friendly interface enabling every-day use, easy procedures retrieval and fast actions logging. Flexibility is also one of the most important features, for this reason a modular structure will be implemented so that each unit can be developed, created or cancelled as needed.

Technical Description

From the technical point of view, the software is composed of two parts:

- a Relational Database Management System (RDBMS) for data collection;
- an interface that allows users interaction with the data stored in the database. To allow easy distribution of the software and multi-platform support, a web-based application has to be preferred.

To realize this project a dedicated website will be realized on proper LNL servers using the standard Apache/PHP/MySQL open source platforms.

The database is going to be divided in the following main units:

- SPES elements* of these four main areas: experimental plant, laboratories, safety systems, infrastructures (buildings, plant);
- Personnel;
- Documents;
- Stocks;
- Suppliers and other contacts;
- Laws and technical standards;

* Elements are all the equipment, plant and infrastructures in which the project SPES can be subdivided.

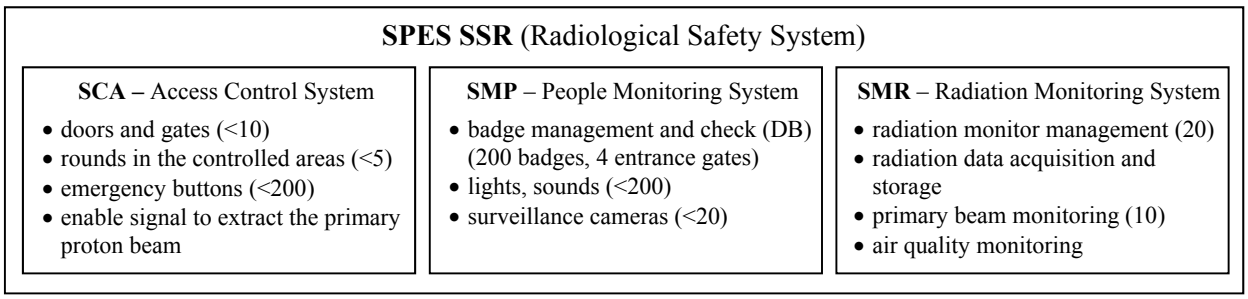

Figure 3: The three elements of SSR with the foreseen number of objects to be managed.

- Procedures (operation of equipment, maintenance, emergencies, accidents, etc.);
- Audit.

In the framework of the QSMS we will develop the SPES Protective System illustrated in the following paragraph.

THE SPES PROTECTIVE SYSTEM

The SPES Protective System will be an instrumented system with the function to detect potentially dangerous conditions for people and the environment, when such a state is detected it will have to execute a sequence of actions to restore a safe state.

For this goal, the SPES protective system will be characterized by the following attributes:

- independence from the process managing the plant, that is from the SPES control system;
- its integrity and functionality has to be maintainable and always be verifiable;
- high reliability (redundancy, at least in the most critical parts for safety);
- any access to it (for checks or maintenance) is to be performed under surveillance and monitored;
- changes are always to be logged, approved and promptly documented.

These attributes have to be maintained by good administration practices (i.e. by QSMS).

The Structure of the Protective System

The structure of SPES Protective System will rely on two interconnected sub-systems: one for conventional, the other for radiological risks. During the operating periods, a Conventional Safety System (**SSC** - Sistema di Sicurezza Convenzionale) will avoid/reduce the risks related to standard engineering (high voltage, water cooling, venting systems). The Radiological Safety System (**SSR** – Sistema di Sicurezza Radiologica) will avoid/reduce the following risks:

- irradiation and contamination of people both when SPES is running and when it is off (activated materials may still be present in the plant site);
- any case of uncontrolled sprinkling of radioactive material outside the SPES complex.

Both the SSC and SSR must avoid/reduce the safety risks also when SPES control systems and the protective systems themselves are off or in fault: they must be fail-safe.

With more details, SSR will be made up by three elements:

- an Access Control System (Sistema Controllo Accessi – **SCA**) for gates and doors, for rounds in the controlled areas, for emergency buttons and for the final enabling control signal to the primary proton driver;
- a People Monitoring System (Sistema di Monitoraggio delle Persone – **SMP**), to enable/disable people access to different building areas (by badges/tokens), to manage warning lights and tables, sounds, surveillance cameras;
- a Radiation Monitoring System (Sistema di Monitoraggio delle Radiazioni – **SMR**), to control radiation monitors, to acquire and store related data, to manage thresholds and produce alarms and interlocks, to monitor the primary proton beam quality, to check the activation level of pumped air to be eventually released outside the SPES complex.

Figure 3 shows a scheme of the SSR with its elements.

The whole SCA system will be redundant at least at level 2: two parallel systems will acquire the same signals and produce the final enable/disable output for the primary beam accelerator. In particular, a first system will be based on safety-oriented PLC architecture, while a second one, minimal but highly reliable, will be made of embedded ("custom") not-programmable logic cards (for example with FPGA based logic modules).

The SCA system will have to produce the enabling signal for the proton beam extraction from the cyclotron. Its high reliability will be based on redundancy and high quality of the hardware system for the IN/OUT signals from the field (gate and door status, round and emergency buttons) and to the actuators which will be produced by redundant detectors and command chains (at least 2 for each gate and door and for the main beam shutters), separately cabled.

For the SMP section and SMR (radiation monitors), a highly reliable PLC based architecture should be sufficient.

Any fault or anomalous behavior in any of these sub-systems will have as direct consequence the switching off of the primary beam.

EXTERNAL POST-OPERATIONAL CHECKS FOR THE LHC BEAM DUMPING SYSTEM

N. Magnin, V. Baggiolini, E. Carlier, B. Goddard, R. Gorbonosov,
D. Khasbulatov, J. Uythoven, M. Zerlauth, CERN, Geneva, Switzerland

Abstract

The LHC Beam Dumping System (LBDS) is a critical part of the LHC machine protection system. After every LHC beam dump action the various signals and transient data recordings of the beam dumping control systems and beam instrumentation measurements are automatically analysed by the eXternal Post-Operational Checks (XPOC) system to verify the correct execution of the dump action and the integrity of the related equipment. This software system complements the LHC machine protection hardware, and has to ascertain that the beam dumping system is 'as good as new' before the start of the next operational cycle. This is the only way by which the stringent reliability requirements can be met.

The XPOC system has been developed within the framework of the LHC "Post-Mortem" system, allowing highly dependable data acquisition, data archiving, live analysis of acquired data and replay of previously recorded events. It is composed of various analysis modules, each one dedicated to the analysis of measurements coming from specific equipment.

This paper describes the global architecture of the XPOC system and gives examples of the analyses performed by some of the most important analysis modules. It explains the integration of the XPOC into the LHC control infrastructure along with its integration into the decision chain to allow proceeding with beam operation. Finally, it discusses the operational experience with the XPOC system acquired during the first years of LHC operation, and illustrates examples of internal system faults or abnormal beam dump executions which it has detected.

INTRODUCTION

The LHC Beam Dumping System (LBDS) must insure the loss-free extraction of the two circulating beams over one LHC revolution, at a programmed dump at the end of a physics run, or in case of emergency.

LBDS Kicker System

The LBDS kicker system consists of 15 horizontal extraction kickers (MKD), 15 vertically deflecting septum magnets (MSD) to deflect the beam into the extraction channel, and 4 horizontal and 6 vertical dilution kickers (MKB) to dilute the beam before it reaches the absorber block (TDE) situated around 1 km away from the extraction point in the LHC ring [1].

LBDS Kicker Control System

During LHC operation, the kicker generator voltages must follow the beam energy, which can vary from 450 GeV at injection up to 7 TeV at collision energy. Moreover, the LBDS triggers must always be issued synchronously with the 3 μs beam-free abort gap that allows the magnetic field of MKDs to reach their nominal strength. To guarantee faultless operation, various fail-safe or fault-tolerant (redundant) control sub-systems have been put in place (SCSS, BETS, TSDS, FAAS) [2]. Each of these sub-systems has an Internal Post-Operation Check (IPOC) system which verifies the correct operation during the latest beam dump action. We can mention the following IPOC systems:

- The IPOC FAAS [3] systems acquire the MKD and MKB current waveforms, analyse them, and save them into the Post Mortem Data Collection storage [4].
- The Trigger Synchronisation Unit (TSU) IPOC systems [5] acquire the waveforms of the main LBDS synchronisation signals as well as all redundant trigger signals. These waveforms are analysed to check the correct synchronisation of all signals, and to ascertain that all redundant signal paths were operational. The TSU IPOC systems will save their analysis results into the Post Mortem Data Collection storage.

Beam Instrumentation

Various beam instruments are deployed at LBDS for diagnosis purpose [1]:

- Beam Loss Monitors (BLM) in the dump line and the extraction area;
- Beam Current Transformers (BCT) on the LHC ring and in the injection and extraction channels;
- Beam screen (BTV) in front of the TDE;
- Beam Position Monitors (BPM) in the extraction channels;
- Beam Synchrotron Radiation monitor for beam abort gap population (BSRA).

All beam instrumentation equipment provide their post operation data, consisting of history buffers of states and measurements at the moment of the beam dump action.

XPOC System

After each dump action, the sanity of the LBDS is verified by the XPOC system through an in-depth analysis of the LBDS performance. The XPOC analysis server will process all the post operation data stored by the various LBDS control sub-systems or beam instrumentation equipment, to make sure that all LBDS equipment performed correctly, and that the beam was extracted as expected, in a manner to ascertain that the

beam dumping system is 'as good as new' for the next operational cycle.

XPOC SYSTEM IMPLEMENTATION

The XPOC system has been programmed with Java 6, using the standard technologies selected for the CERN control application development like Swing, the Spring framework and the Controls Middleware (CMW) [6]. It mainly relies on the LHC Post Mortem Analysis Framework (PMA) [4] which provides:

- A powerful and reliable data collection system to store PM data buffers coming from all equipment;
- An event builder system to group collected PM data buffers into PM events;
- An analysis system which launches the various analysis modules for each PM event;
- Connections to other LHC control systems such as the Logging Database, the Software Interlock System and the LHC Sequencer;
- A Graphical User Interface application to display analysis results of the latest PM events, or to replay any past PM event.

The XPOC system has been deployed in the form of three parts: XPOC data collection server, XPOC analysis server, and XPOC-Viewer user interface application used for the monitoring and control of XPOC analysis server.

The two XPOC server processes run on the same computer HP ProLiant BL460c G7 equipped with two Intel Xeon(R) CPU X560@2.8GHz (with a total 24 of cores), 24 GB RAM, and running Scientific Linux CERN 5 (SLC5) operating system.

XPOC Data Collection Server

Several of the beam instrumentation devices do not use the standard PM data collection mechanism which would allow them to directly send their PM data buffers to the PM data collection server. Therefore, a special XPOC data collection server had to be developed, which uses the normal CMW subscription/notification mechanism to obtain the necessary data.

After each 'beam dumped' event received from the timing system, the XPOC data collection server starts to collect PM data buffers from a predefined list of equipment and sends them to the PM data collection server.

When all PM data buffers for a 'beam dumped' event have been collected, the XPOC data collection server builds an XPOC PM event with the predefined list of collected PM data buffers attached. Two types of PM events are generated: 'XPOC-Beam1' and 'XPOC-Beam2'; dumps of LHC beam1 and beam2 will be handled separately.

XPOC Analysis Server

Once an XPOC PM event has been built, the XPOC analysis server starts a new analysis session and launches the execution of the equipment dedicated analysis modules in parallel threads, following their configured dependencies.

After execution of all analysis modules, the XPOC analysis server publishes all module result data to the LHC Logging Database.

The overall status of the XPOC analysis session is sent to the LHC Sequencer and Software Interlock System.

User Interface

The XPOC-Viewer application shows the latest 'XPOC-Beam1' and 'XPOC-Beam2' PM event analysis results, and allows the reset of SIS latches by authorized people.

A screenshot of XPOC-Viewer is shown in Figure 1

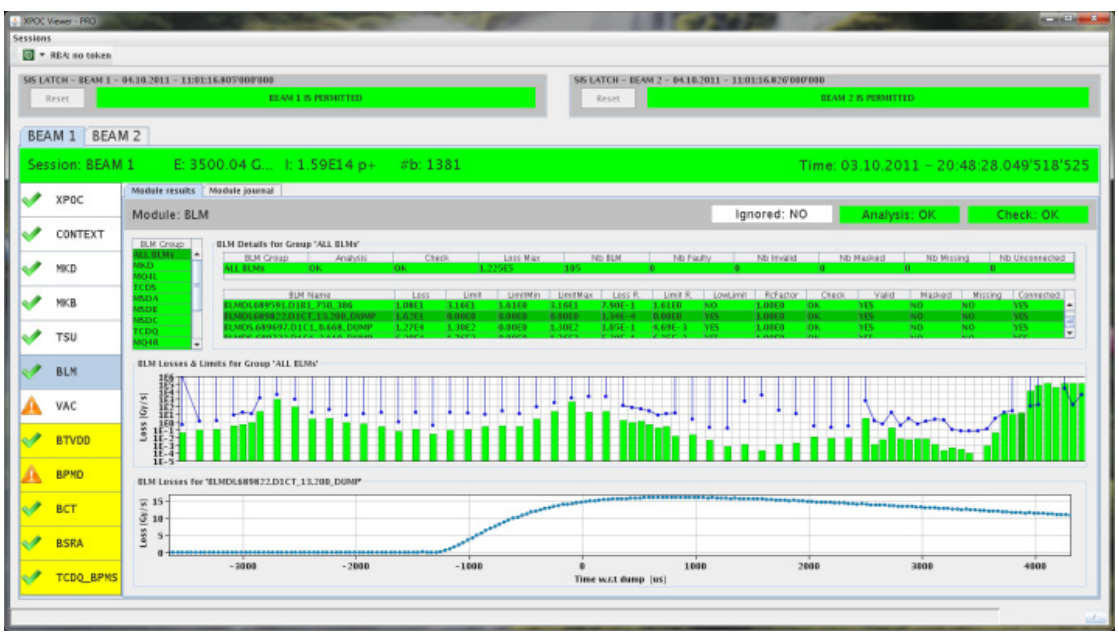

Figure 1: XPOC-Viewer application displaying status of XPOC SIS latches and BLM analysis module results.

XPOC ANALYSIS MODULES

Modules Dependencies

The list of all XPOC analysis modules is visible in the left column of Figure 1. The "CONTEXT" analysis module, which is a dependency for all other analysis modules, is executed first. Then the execution of all other analysis modules is launched in parallel, and finally the "XPOC" analysis module is executed to perform the overall analysis and give the final XPOC analysis session result.

CONTEXT Module

The aim of this module is to compute the "dumped beam intensity" and the "dumped beam filling pattern" present in the machine at the time of dump, as well as to determine the precise "dump timestamp". This information will be used by the other XPOC analysis modules to validate their input PM data buffers based on their timestamp, and to determine limits and thresholds to check data analysis results against.

The timestamp is taken from the LBDS trigger timestamp with a precision of about 100 ns (1 ns resolution). If no TSU data are available, the timestamp is taken from the PM event, which is less accurate (1 ms resolution).

The beam intensity calculation is based on three pieces of information:

- The history buffer of 30 s of the circulating beam intensity, with a sampling rate of 20 ms;
- The timestamp of the latest injection in the LHC;
- The beam intensity of the latest injection in LHC.

The circulating beam intensity is determined by performing an average over a few samples from the history buffer just before the dump action. Then the timestamp of the latest injection in LHC is compared to the dump timestamp to check if the dump took place just after injection. If a difference less than 20 ms is detected, the beam intensity of the latest injection in LHC is added to the circulating beam intensity, and the injected bunch pattern is added to the circulating beam pattern.

TSU Module

This module makes sure that the TSU cards and the trigger distribution systems functioned as expected, by checking that:

- Both TSU cards have properly detected the dump request and issued a synchronous dump trigger in less than one LHC revolution;
- The TSU IPOC has successfully checked the presence and the correct synchronisation of all LBDS synchronisation and redundant trigger signals.

MKD and MKB Modules

These two modules analyse the current waveforms in the dump kicker magnets (MKDs) and dilution kicker magnets (MKBs), recorded by the six IPOC FAAS [3]. The analysis consists of finding the critical points on the waveform to determine its characteristic values, like delay, rise time, strength, and check that these values are within predefined limits determined during the LBDS kicker calibration measurements [3].

BLM Module

This module performs the analysis of losses recorded by some BLM installed near LBDS equipment and near collimators all around the LHC. It uses the loss history buffer (+/- 3ms around the dump event) provided by every BLM device to determine their maximum loss at the moment of the dump action. It then computes loss limits based on beam energy and beam intensity provided by the "Context" analysis module. As there are quite a lot of BLM devices, they are grouped by family to easily manage their limits and write out to logging the maximum loss value per family. Each family has a reference BLM with defined ratios of loss versus energy and loss versus intensity, which allows the calculation of loss limit for a given dump action. All other BLMs in the same family have a constant loss limit ratio with respect to their family reference BLM. These limit ratios are determined by analysing the logged BLM XPOC analysis results for many 'normal' dumps at various energies and intensities. The measured losses are compared to the limits for each BLM to make sure that they all are within the computed limits.

Other Modules

Some modules are still under evaluation, so they are ignored by the final XPOC check module (their names are displayed in yellow in Figure 1). They are normally executed, and their results are displayed and logged as they provide very useful information for the understanding of the dump actions, and for long term measurement correlations.

As example, the "BTVDD**"** module analyses the Beam TV (BTV) images, taken on a screen placed a few meters in front of the TDE, to make sure that the beam reached the target at the expected position, and that the dilution was performed properly. The image is processed digitally to generate the skeleton of the beam sweep on the target. The skeleton position is then checked against the reference beam position computed based on the circulating beam filling pattern and average MKD and MKB kicker waveform.

The **"**BSRA" module checks that the beam population in the abort gap at the moment of the dump is below predefined limits.

INTEGRATION INTO THE LHC CONTROL SYSTEM

LHC Sequencer

Before injecting any beam into the LHC, the LHC Sequencer application executes a predefined list of tasks which will check the status of various devices and perform their initialisation. Checks include:

- The timestamp of the latest XPOC analysis session is compared to the timestamp of the latest LBDS trigger, to make sure that the latest dump action was properly analysed;
- The result of the latest XPOC session to make sure that no errors were detected during execution of the previous beam dump action.

If any of these sequencer tasks detects a problem regarding the XPOC analysis, the Engineer-In-Charge (EIC) is responsible for contacting an expert. The task that failed can be 'skipped' by the EIC, so it is not completely fail-safe; it is more informative.

LHC Software Interlock System

If an error is detected by the XPOC analysis server, the injection of beam in the LHC is inhibited using the Software Interlock System (SIS) by means of a so called "SIS latch". The SIS latch must be reset to proceed with beam operation. This is done using the XPOC-Viewer application, which provides two SIS-Latch reset buttons (visible on top of Figure 1), and is protected using the Role-Based Access Control (RBAC) mechanism [6]. The roles required to reset the XPOC SIS latch depend on the XPOC modules that failed. This is to make sure that the concerned expert has been contacted to check the problem before proceeding with injection in the LHC.

OPERATIONAL EXPERIENCES

The majority of XPOC analysis errors encountered so far were not related to LBDS problems, but to missing PM data buffers, mostly due to beam instrumentation equipment problems or CMW communication problems. Work is ongoing to have the very reliable data collection mechanism of the PMA framework implemented in all equipment used by the XPOC system. Nevertheless many interesting problems were detected by the XPOC system and some of them are briefly described below.

Problem with MKD Generators

MKD XPOC analysis errors occurred during operation with beam in 2008. After analysis of the long term trends of XPOC MKD logged analysis results, it appeared that some MKD characteristics were degrading. The problem was identified as a bad connection of a trigger cable [3].

Inject & Dump Synchronisation Error

During tests in Inject & Dump mode after a technical stop, the BTVDD XPOC analysis module failed at each dump action because the position of the pilot beam on BTVDD was much too high. The problem was traced back to a wrong LBDS control system parameter value for the Inject & Dump mode which was introduced during the technical stop. This resulted in the LBDS pulsing one LHC revolution too early (before beam injection), so the pilot beam (bunch #1) was not extracted at the beginning of the LBDS kicker pulses but at the end, and the extracted beam trajectory was not as expected. This problem was not seen by any other XPOC module, because all kickers pulsed properly, triggers were correctly synchronised with the beam revolution frequency, and no losses were detected by the BLM devices.

Losses Detected During Dump Action

When performing a beam dump, the BLM XPOC module often detects losses around protection equipment (absorbers and collimators). Recent analysis of the logged BLM and BSRA XPOC data showed a good correlation between the number of particles present in the beam abort gap at the time of dump and the losses measured on protection equipment. This correlation was the same for both beams. This is expected as all particles present in the abort gap during dump execution will be swept over all the LBDS protection equipment and the systems are identical for both beams. By combining these two measurements the XPOC system provided an easy way to confirm the rather complicated abort gap population measurement.

CONCLUSION

The XPOC system has proven its efficiency in detecting unexpected behaviour during execution of beam dump actions. It allowed the anticipation of some LBDS hardware problems before any system failure occurred, using the trends of logged XPOC analysis results. The LBDS stringent reliability specifications can only be met by the XPOC system guaranteeing that the latest dump was correctly executed, including all redundant parts. For this reason the reset of the XPOC SIS latch, which can only be done by experts having the required RBAC roles, is taken very seriously in daily operation of the LHC.

THE RADIATION MONITORING SYSTEM FOR THE LHCb INNER TRACKER

O. Okhrimenko, V. Iakovenko, V. Pugatch, INR NASU, Kyiv, Ukraine
F. Alessio, G. Corti, CERN, Geneva, Switzerland

Abstract

The performance of the LHCb Radiation Monitoring System (RMS) designed to monitor radiation load on the Inner Trackersilicon micro-strip detectors is presented. The RMS comprises Metal Foil Detectors read-out by sensitive Charge Integrators. MFD is a radiation hard detector operating at high charged particle fluxes. RMS is used to monitor radiation load as well as relative luminosity of the LHCb experiment. The results obtained by the RMS during LHC operation in 2010–2011 are compared to the Monte-Carlo simulation.

THE LHCB DETECTOR AND THE SILICON TRACKER

The LHCb experiment is the forward spectrometer and one of the four experiments located at the LHC. The main aim of the LHCb is precise measurement of the CP-violation and research of the B-meson rare decays [1].

The LHCb, as high energy physics detector, consists of following parts: Vertex Locator (VELO), Inner and Trigger Trackers (IT, TT) and Outer Tracker to reconstruct tracks of charge particles and they decay vertexes and to separate Primary (proton-proton collisions) and Secondary (B-mesons decay) Vertexes (PV, SV); Magnet to measure charge particle momentum; Cherenkov Detectors (RICH1, RICH2) to separate kaons and pions; Hadronic and Electromagnet Calorimeters (HCAL, ECAL) to measure the particles energy; Muon detector to detect the muons.

The LHCb Silicon Tracker (ST) is a large-surface silicon microstrip detector that constitutes an important part of the LHCb tracking system. It uses single-sided silicon strip detectors with a strip pitch of approximately 200 µm, produced from 6" wafers and arranged into up to 38 cm long readout strips. he Silicon Tracker consists of two parts: the "Tracker Turicensis" is located in between RICH1 and the LHCb dipole magnet and the "Inner Tracker" [2] covers a cross-shaped area around the LHC beam pipe in tracking stations T1–T3, in between the LHCb dipole magnet and RICH2.

The level of charged hadron fluxes at the location of the silicon sensors of the IT-2 station varies from about 10^4 to $10^5\,\mathrm{cm^{-2}s^{-1}}$ at nominal LHCb luminosity ($2\times10^{32}\,\mathrm{cm^{-2}s^{-1}}$) [3]. These fluxes are high enough to make a significant damaging impact onto the performance of the IT sensors and their frond-end electronics (Beetle). So, IT requires the system to monitor radiation loads on Si-sensors. This is task for the Radiation Monitoring System.

THE RADIATION MONITORING SYSTEM FOR THE LHCB INNER TRACKER

The main goal of the Radiation Monitoring System (RMS) is a measurement of the radiation dose load onto silicon micro-strip sensors of the IT LHCb as well as front-end electronics in order to exclude their damage as a result of an unexpected radiation incident, i.e. change of the beam trajectory, partial beam loss in the region of the detector etc [4, 5].

The RMS is based on the Metal Foil Detector (MFD) technology. The principle of the MFD operation explores Secondary Electron Emission (SEE) phenomena from the metal foil surface (emission layer ∼ 10-50 nm) caused by impinging charge particles. SEE causes extra positive charge on an isolated metal foil read out by sensitive Charge Integrator (ChI).

Several MFD advantages have determined our choice for the IT RMS:

- The possibility to provide extremely low mass of the detecting material (from practical point of viewfew tens µm);
- Simple readout electronics (charge integrators and scalers);
- Low operating voltage (∼ 20 V);
- High radiation tolerance;
- Long term performance with minimal maintenance;
- Low cost.

From the technical point of view MFD is a 5-layer structure manufactured out of 50 µm thick Al foils supported by insulating epoxy frames. The central sensitive layer is connected to the readout electronics, while two neighboring (from both sides) accelerating layers are biased by positive voltage (HV, 24 V) to reduce recombination after SEE. The two outer shielding layers are grounded. RMS Sensor and accelerating layers are divided into 7 parts (110 × 75 mm, with a layout which is similar to IT silicon sensors size). The RMS consists of 4 modules (Top, Cryo, Bottom, Access) containing 7 sensors each (in total 28 sensors), which are located at IT-2 station (∼ 8.4 m from interaction point) around the Beam Pipe. Due to IT-boxes overlapping the Top-module is shifted up on ∼ 5 cm from the Beam Pipe.

The RMS readout electronics consists out of the six 5-channel sensitive ChIs [6] and 32-channels LVDS VME-scaler (C.A.E.N. V830 LC). The ChIs were developed at INR (Kyiv, Ukraine) and have been modified at MPIfK (Heidelberg, Germany). The ChI's principle of operation includes a current-to-frequency converter allowing to

achieve high dynamic range (up to 10^6). A current from the stable external source (250 pA) is injected to the ChI's inputs to make base lines (25 kHz). The tipical features of the RMS is presented in Table 1. The RMS is designed for the monitoring of charge particle fluxes exceeding ~ 2500 MIP/s per sensor.

Table 1: Typical Features of the RMS

Name	Value
ChI conversion factor	10 fA—1 Hz
SEE factor	~ 25 SE/MIP
RMS response	30 MIP/cm^{2}s—1 Hz

RESULTS

During the year 2010 LHC has provided colliding proton beams at 7 TeV (c.m. energy) delivering 42 pb^{-1} at LHCb, in total. The charged particle fluxes high enough to evoke a signal in the RMS were during high intensity beams (starting from the 20$^{\text{th}}$ of September'10) which contributed 29 pb^{-1} into the total delivered luminosity. As it is shown in Fig. 1 RMS response is linear correlated with the LHCb measured luminosity. This has been used to calibrate the RMS for measuring luminosity in future as well as to extrapolate RMS measured data on low intensity beams colliding which usually occur at the beginning of the LHC operation after shutdowns.

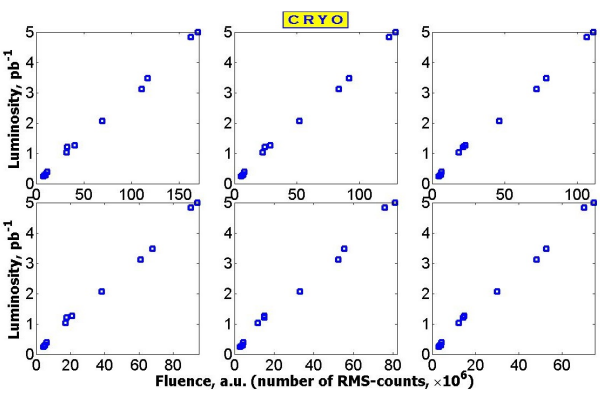

Figure 1: Correlation between the RMS response and the LHCb measured Integrated Luminosity in 2010. The response from 6 sensors of the RMS's Cryo module is presented for illustration.

LHCb Integrated Luminosity Measured by the RMS

In 2011, the first protons collisions at LHCb occurred on the 14$^{\text{th}}$ of March. Till 18$^{\text{th}}$ of March low intensity beams collided producing charged particle fluxes insufficient to evoke a response in the RMS. Total integrated luminosity of these first collisions has not exceeded 3% of the annual one.

Due to power cut the RMS had not been operating 10 days in July missing 41 pb^{-1} of data which correspond to $\sim 6\%$ of annual integrated luminosity.

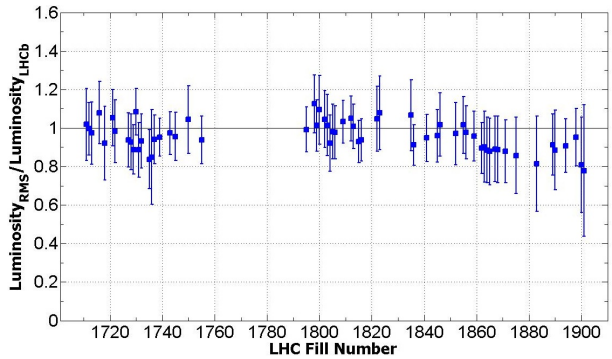

Figure 2: A Ratio of the luminosity measured by RMS to the LHCb one.

So, the RMS measured about 90% of the total integrated luminosity. The uncertainty of those measurements is about 10%. This accuracy is sufficient for the on-line monitoring of the integrated luminosity during pp-collisions at the LHCb.

The RMS data agrees well with the LHCb ones [7]. Figure 2 presents a ratio of the integrated luminosity measured by RMS to LHCb's one calculated for the 61 LHC Fills (~ 400 pb^{-1}, April-May'11).The uncertainty of the on-line LHCb's luminosity data is about 10%.

Radiation Load over IT Si-sensors Measured by the RMS

As it was mentioned above, RMS's main goal is monitoring of the radiation load on LHCb Inner Tracker sensors. During the 2011 year RMS performance allowed to measure 90% of the radiation load. Perfect linearity of the RMS response with respect to the integrated luminosity (see Fig. 1) makes it possible to extrapolate data into the 'unmeasured zone.

In total, over 1 fb^{-1} integrated luminosity has been delivered to the LHCb in 2011 year. Dose Distribution over IT Si-sensors measured by the RMS corresponding to this integrated luminosity is shown in Fig. 3.

An absorbed dose varies from 100 to 400 Gy depending upon the sensor. Sensors closest to Beam Pipe get higher doses then peripheral ones. These doses correspond to $(0.4\text{–}1.5) \times 10^{12}$ MIP/cm^2 which results in 50–200 µA leakage currents increase over Si-sensors, respectively. This requires Si-sensors cooling down and bias voltage tuning to keep reliable operation of the IT. The uncertainty of the measurements does not exceed 10%.

The leakage currents data evaluated by the RMS are in good agreement with a direct leakage current measurements as well as with the Monte-Carlo predictions for the charged particle fluxes (see below).

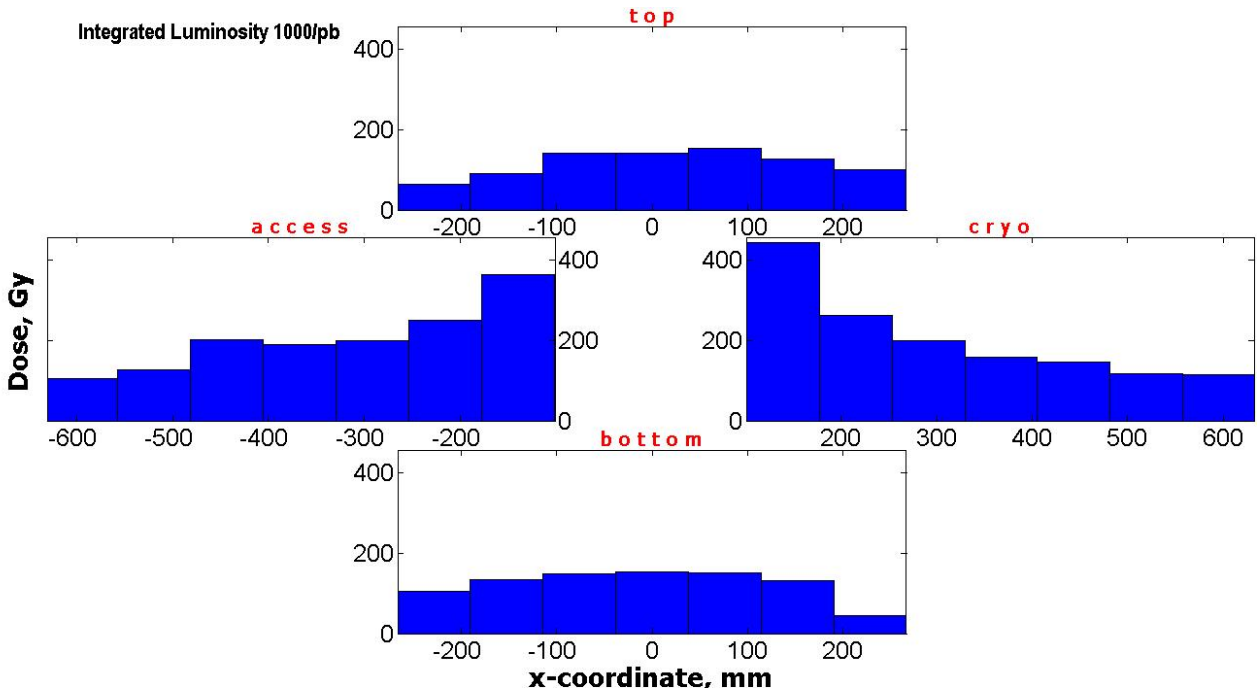

Figure 3: Dose Distribution over the IT Si-sensors measured by the RMS in 2011.

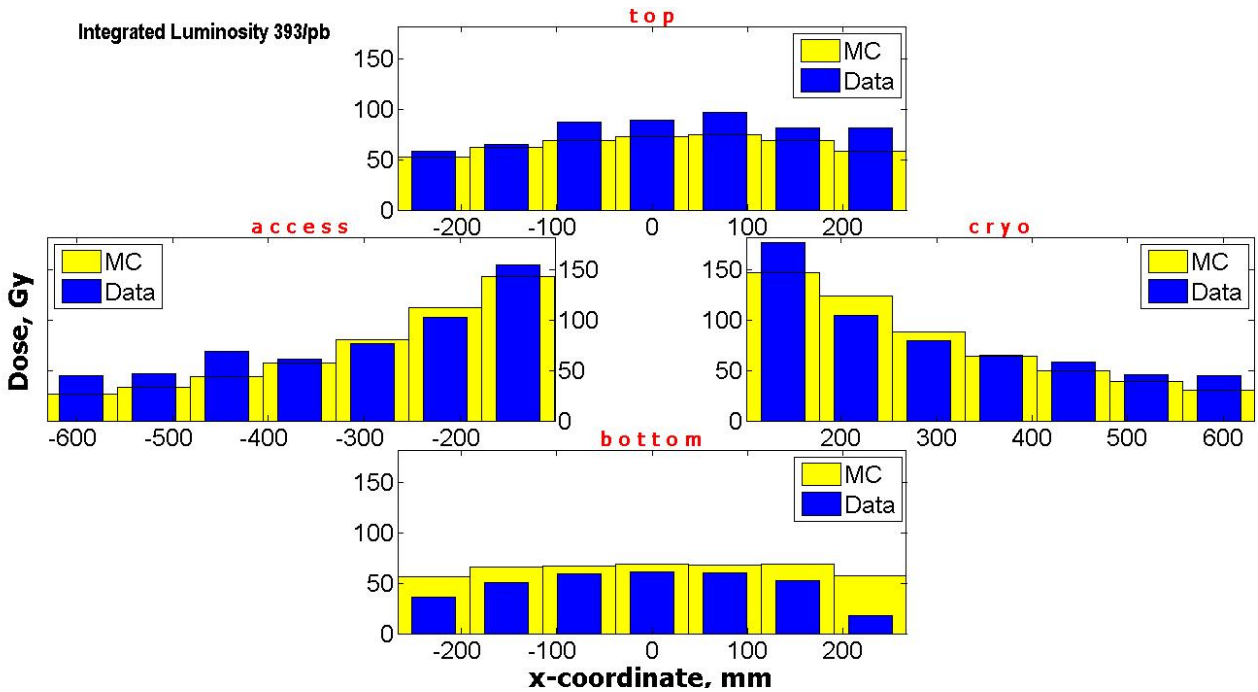

Figure 4: Comparison between real and MC simulated RMS data.

Comparison Between Real and Monte-Carlo Simulated RMS Response

Using standard LHCb software (Gauss v38r9) [8], 10k events under following condition were generated:

- a center of mass energy of the colliding proton beams—7 TeV,
- the average number of pp-interaction (including elastic which is not visible in the detector) per bunch crossing (ν) is 2.5,
- different LHCb Dipole Magnet polarity—up and down,
- charge particle, only, were included.

These conditions are very similar to the real one during 2011 LHC operational year.

The resulting particle fluxes distribution over sensors in comparison with the data measured by the RMS is shown in Fig. 4.

Good agreement is observed for all modules but the 'Bottom' one. This disagreement is under study and might be caused by the Beam Pipe supporting tools located just in front of the RMS not included in the MC simulations.

CONCLUSION

During the LHC operational year 2011 the Radiation Monitoring System has provided monitoring of the radiation load on Si-sensors of the LHCb Inner Tracker. RMS data have allowed also to determine the integrated luminosity as well. The RMS data are in good agreement with data obtained by other detectors as well as with Monte-Carlo simulations. These data are planned to be included into the on-line monitoring of the radiation load and integrated luminosity.

EQUIPMENT AND MACHINE PROTECTION SYSTEMS FOR THE FERMI@Elettra FEL FACILITY*

F. Giacuzzo, L. Battistello, L. Fröhlich, G. Gaio, M. Lonza, G. Scalamera, G. Strangolino, D. Vittor, Sincrotrone Trieste, Trieste, Italy.

Abstract

FERMI@Elettra is a Free Electron Laser (FEL) based on a 1.5 GeV linac presently under commissioning in Trieste, Italy [1]. Three PLC-based systems communicating to each other assure the protection of machine devices and equipment. The first is the interlock system for the linac RF plants; the second is dedicated to the protection of vacuum devices and magnets; the third is in charge of protecting various machine components from radiation damage. They all make use of a distributed architecture based on fieldbus technology and communicate with the control system via Ethernet interfaces and dedicated Tango device servers. A complete set of tools including graphical panels, logging and archiving systems are used to monitor the systems from the control room.

INTRODUCTION

The protection systems are based on Siemens S7 PLCs with an extensive use of Profibus to connect several distributed I/O peripherals and LCD operator panels. The communication between systems is realized either by means of Profibus or digital I/O signals, while Ethernet-TCP/IP is employed to interface to the FERMI@Elettra control system [2] using the Send/Receive protocol and dedicated Tango servers.

In all, the protection systems make use of five 315-2DP and 16 IM151 CPUs, 30 operator panels and 31 Profibus nodes. The systems manage in total about 1900 digital inputs, 500 digital outputs and 250 analog inputs.

LINAC RF PLANTS INTERLOCK SYSTEM

As shown in Fig. 1 each RF modulator is equipped with one PLC (CPU_MU), which guarantees the required performance in terms of reaction time. The goal is to allow no more than one linac shot after an interlock alarm is detected; given that the linac maximum repetition frequency is 50Hz, the protection action must be accomplished in less than 20 ms. This has also been achieved with an accurate design of the software architecture and a thorough programming. It has been necessary, for example, to avoid pre-compiled functions in favour of very primitive home-made functions and, whenever possible, to make extensive use of "jump" instructions. With a Siemens IM151 CPU controlling about 18 digital I/Os and eight analog inputs, the maximum reaction time is 12 ms.

Each RF plant has one touch-screen operator panel manufactured by UNIoP. A number of synoptic panels display the modulator interlock states and the analog input values, such as temperatures and klystron focalization currents, and allow the operator to set the corresponding interlock values.

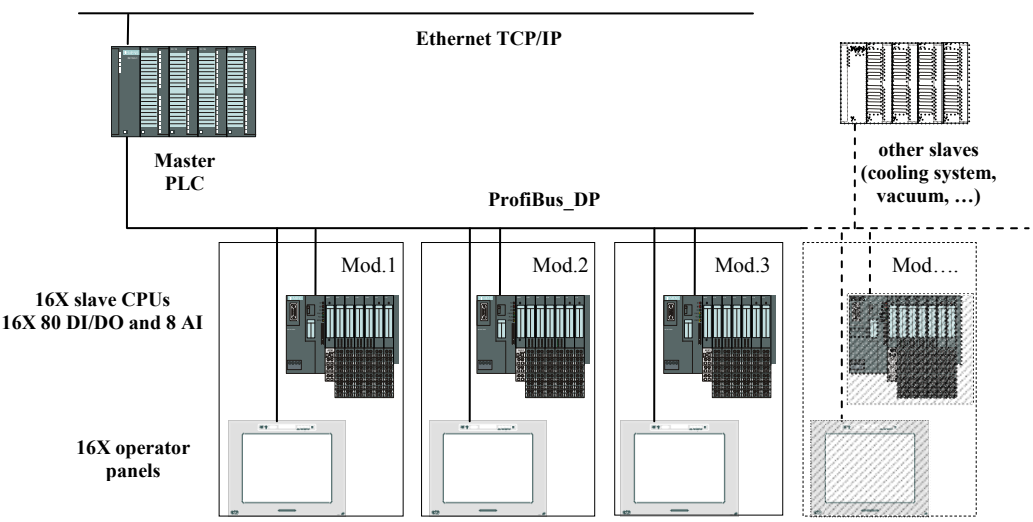

Figure 1: Block diagram of the linac RF plants interlock system.

* This work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3.

An example of panel representing the logics of the signals that enable the various RF plant subsystems is shown in Fig. 2.

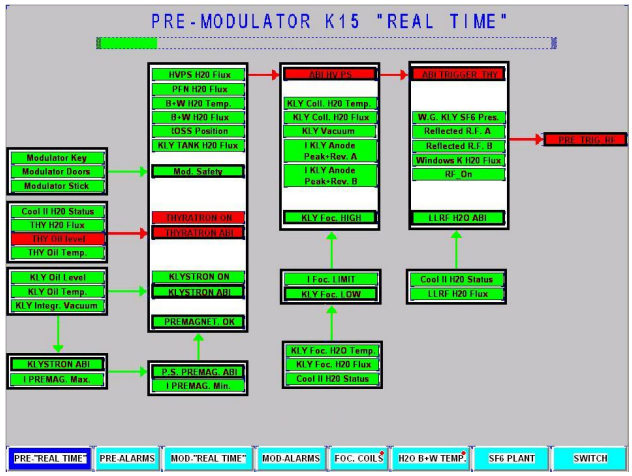

Figure 2: A page of the RF interlock operator panel.

All the CPU_MUs and the operator panels are connected through Profibus to a "Master PLC" configured as Profibus master, which does the following:

- Distribute to the CPU_MUs some common interlock alarms related for example to the general water cooling system, which don't need a short reaction time;
- Collect all the data from the CPU_MUs and send them through Ethernet to the Tango server; the same data are also sent to the local operator panels.
- Receive control commands from the Tango server and send them to the proper CPU_MU.

With this architecture the interlock system of each RF plant is independent from each other. If one of them fails the others can continue working. Within some functional limitations the systems can also work without the "master PLC".

During the first period of the machine commissioning, we suffered from a few interruptions of the communication between the master and slaves probably due to electromagnetic noise from klystron modulators. The problem has been solved by modifying the default DP Profibus profile; in particular, we have increased from one to ten the number of connection attempts from master to slave.

MAGNETS AND VACUUM INTERLOCK

The interlock for the protection of the accelerator electromagnets switches off the power supply in case of alarm from the cooling system of the corresponding magnet. Depending on the magnet type, alarms can be generated by flux-meters and thermo-switches. For safety reasons a lamp driven by the interlock system in placed on the magnets with potentially dangerous voltages. Moreover, the interlock system is also used to safely inhibit the power supplies in case of personnel access in the tunnel.

The purpose of the vacuum interlock is to avoid the propagation of possible leaks along the vacuum chamber. In the accelerator the PLC receives vacuum alarms from ion pump and vacuum gauge controllers by means of voltage-free contacts; the alarm thresholds (set points) are set on the controllers. In the machine front-end, instead, also analogic signals are acquired from temperature sensors, turbo-ionic pumps and vacuum gauges.

According to the coded protection logics, the PLC closes at least two valves in order to isolate the segment of vacuum chamber where an anomalous pressure increase has been detected; at the same time the PLC disables the electron beam to avoid damages of the valves. The vacuum valves can be remotely controlled (status reading and open/close command) either by using the local operator panels (Fig. 3) or via the Ethernet TCP/IP interface.

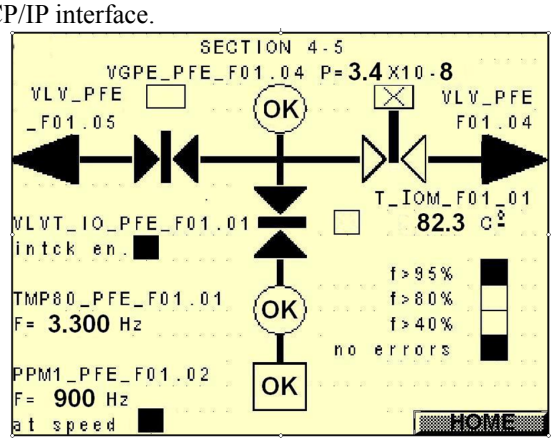

Figure 3: An operator panel display dedicated to the frontend vacuum interlock system.

MACHINE PROTECTION SYSTEM

The Machine Protection System (MPS) protects the FEL undulators from the deposition of excessive radiation doses caused, for example, by bad alignment of the electron beam. Several diagnostics are used to detect radiation, including ionization chambers, charge loss monitors and Cherenkov fibres [3]. The block diagram of the MPS is shown in Fig. 4.

In order to guarantee the required reaction time, a specific PLC has been dedicated to the MPS. It directly receives the alarm signals from the ionization chambers electronics. The analog signals generated by charge loss monitors and Cherenkov fibres are acquired by a VME system running Linux and the Xenomai real-time extension [4], which performs the signal processing and generates the alarms. The connection of the VME system with the PLC is realized by means of digital outputs and a heart-beat signal that synchronizes the communication.

Other signals not needing a fast response are collected by the PLC via Profibus from the interlock system.

In case of alarm, the PLC closes a shutter that stops the laser of the photo-injector, thus switching off the electron beam. The measured reaction time is less than 10 ms, so only one shot could eventually be fired after the alarm is received.

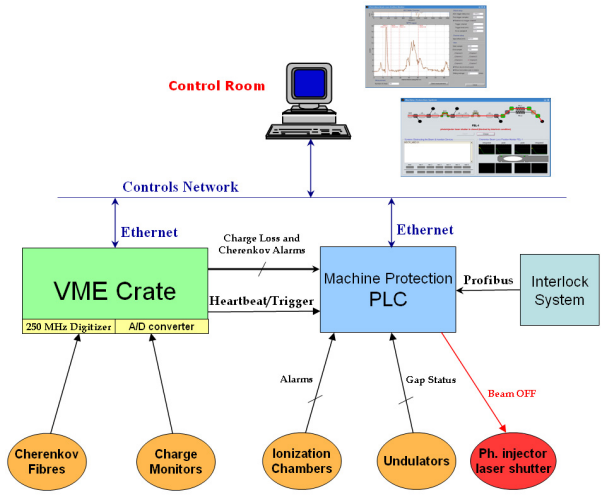

Figure 4: Block diagram of the Machine Protection System.

Since incorrectly inserted multi-screens hit by the electron beam can cause the release of huge radiation fields, the screens position is detected by means of micro-switches and the beam is disabled when they are moving. When a given screen arrives in the final position, the beam is automatically enabled only if that screen can be safely hit by electrons.

The reading of the undulators gap status (open/closed) is used to stop the beam only if the alarm is coming from a location were the undulator gap is closed. Moreover, the state of the bending magnets power supplies are used to determine the real path of the electron beam, so that only screens that can actually be reached by the electron beam are taken into account. A future upgrade of the system will provide analog readings of the bending currents.

In order to allow machine operations in the presence of anomalous situations during the machine commissioning, a feature has been implemented to selectively "bypass" some alarms. This possibility is only permitted to expert people.

The PLC cycle is synchronized with the linac trigger (up to 50Hz). At each linac shot the PLC compile a portion of a Data Block (DB) containing all the alarm states and adds to it a time stamp. When the DB is fully compiled with 50 shots, it is sent via Ethernet to a Tango server which stores it into a database. With this feature every event detected by the MPS is recorded and made available for analysis.

THE SUPERVISION SYSTEMS

Supervision applications run in the FERMI@Elettra control systems and are developed using the Tango framework. The interlock systems communicate with the control system through Ethernet links and dedicated Tango servers, which acquire alarms and send commands.

At every cycle each PLC compiles a DB with the data acquired from the field, both digital (true/false) and analog (floating point) values. If the PLC detects the variation of at least one of the values with respect to the previous cycle, it adds a time-stamp and sends out the DB via the Ethernet port. This is called "Real-Time DB".

In order to detect and memorize fast events that normally could be lost, a second DB called "Alarm DB" similar to the first one, latches the active alarms until an acknowledge command is received via the external interface. Also the Alarm DB is sent on variation.

A Tango Device Server for each PLC is in charge of receiving the DBs and saving them into a MySQL database. A second level of Tango servers communicating with the first level has been developed to extract data from the DBs and export every single value as a meaningful Tango attribute. The servers also receive commands from Tango client applications and forward them to the PLCs.

A number of graphical interfaces have been developed using Matlab and QTango, a C/C++ graphical library for the Tango control system. They display the status of the systems and warn operators of interlock alarms. Fig. 5 is an example of a synoptic panel representing the status of the vacuum interlock.

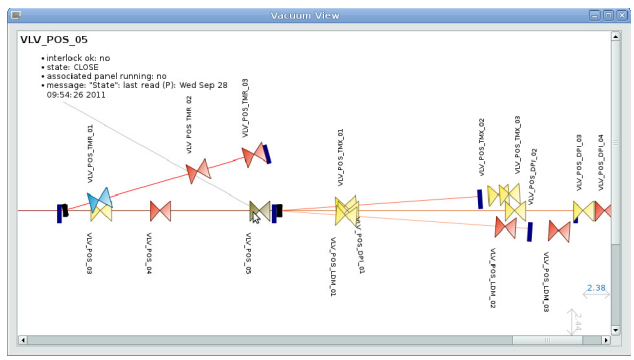

Figure 5: Synoptic panel of the vacuum interlock system.

Abstract

ALICE (A Large Ion Collider Experiment) is one of the big LHC (Large Hadron Collider) experiments at CERN in Geneva. It is composed of many sophisticated and complex detectors mounted very compactly around the beam pipe. Each detector is a unique masterpiece of design, engineering and construction and any damage to it could stop the experiment for months or even for years. It is therefore essential that the detectors are protected from any danger and this is one very important role of the Detector Control System (DCS). One of the main dangers for the detectors is the particle beam itself. Since the detectors are designed to be extremely sensitive to particles they are also vulnerable to any excess of beam conditions provided by the LHC accelerator. The beam protection consists of a combination of hardware interlocks and control software and this paper will describe how this is implemented and handled in ALICE. Tools have also been developed to support operators and shift leaders in the decision making related to beam safety. The gained experiences and conclusions from the individual safety projects are also presented.

INTRODUCTION

The Large Hadron Collider (LHC) at CERN is the most powerful accelerator ever built. A top energy of 360 MJ will be stored when two counter-rotating proton beams, containing up to 2808 bunches of 1.1 x 10^{11} protons, will collide every 25 ns at a centre of mass energy of 14 TeV in each of the four experiments distributed along the 27 km accelerator ring.

Local beam losses at various levels may induce a quench of the super-conducting magnets or even a physical damage to machine components and experiments detectors. Such losses can be the consequence of various instabilities (beam failures) happening during beam injections or with circulating beams.

Depending on the nature and amount of beam loss, several kinds of damages can be produced: high voltage trips and accelerated ageing in gaseous detectors, single event upsets in front-end electronics or even permanent damage to semiconductor devices and electronics components.

In order to prevent such damages a complex protection system has been developed comprising numerous diagnostic systems and passive protection elements [1]. The ALICE experiment [2] is protected by a dedicated Beam Condition Monitor (BCM) system connected to the LHC Beam Interlock System (BIS) [3]. In addition safe states have been defined for all sub-detectors to establish the best conditions implying the smaller risk of damage in given beam operating modes.

BEAM CONDITION MONITOR

The Beam Condition Monitor system provides real-time monitoring of the radiation level in the ALICE experimental area. In order to protect the detectors against multi-turn beam failures it triggers a beam dump if the instantaneous radiation level crosses a certain threshold.

Used Components

The ALICE BCM design was based on the Beam Condition Monitor system of the LHCb experiment [4].

The beam background is measured using pCVD (polycrystalline Chemical Vapour Deposition) diamond sensors that are grouped in two stations located close to the beam pipe on both sides of the interaction point. The readings from these sensors are digitized by CFC (current-to-frequency converter) cards and then sent to a TELL1 board [5] via optical links. The TELL1 board calculates running sums (RS) over 1, 2 and 32 CFC data frames with corresponding integration times of 40 µs (RS1), 80 µs (RS2) and 1.28 ms (RS32), respectively. In addition "RS32 Sums" are calculated by summing up the RS32 values of 5 out of 8 sensors of one station discarding the two highest values and the lowest value.

Access to the registers of the TELL1 board is provided via an on-board credit card-sized PC (CCPC). The CCPC can communicate via DIM (Distributed Information Management System) with the SCADA software package PVSS. The DIM server is running on the CCPC and a DIM client is part of the PVSS project.

Interface to BIS

ALICE provides three flags (user permits) to the LHC Beam Interlock System via the TELL1 board:

- Beam permit - inhibiting/allowing the beam circulation (acting on both beams simultaneously),
- Injection permit for beam 1 – injected via the TI2 transfer line from SPS (Super Proton Synchrotron) to LHC,
- Injection permit for beam 2.

A beam dump is triggered by the TELL1 firmware via removal of the beam permit if values of monitored running sums exceed defined thresholds.

The injection permits are controlled by the central Detector Control System (DCS) [6] and they are set when ALICE is prepared for incoming beam.

Control Layer

A dedicated PVSS project is used to supervise and control the performance of the TELL1 board and auxiliary devices such as CAEN power supply and VME crate. The designed panels provide experts and DCS operators with all important information including status of BIS flags, the beam background level and reasons of beam aborts.

In case of emergency, the control and monitoring of the CCPC can be continued by the DCS operator (even without the PVSS layer and DIM) via emergency command line scripts, based on the SSH connection tool PLINK.

The values of the BCM thresholds are changed dynamically depending on the state of the most sensitive ALICE sub-detectors and a "beam mode" published by the CCC (CERN Control Centre). The more strict limits are activated before turning on the selected subsystems.

Post Mortem

The causes of emergency beam aborts have to be revealed to improve protection systems and operational procedures. In such cases, analysis of data registered shortly before the dump is essential.

The incoming data stream from the CFC cards is written into a circular buffer on the TELL1 board. This buffer is frozen when a Post Mortem (PM) signal is received via the LHC machine timing system.

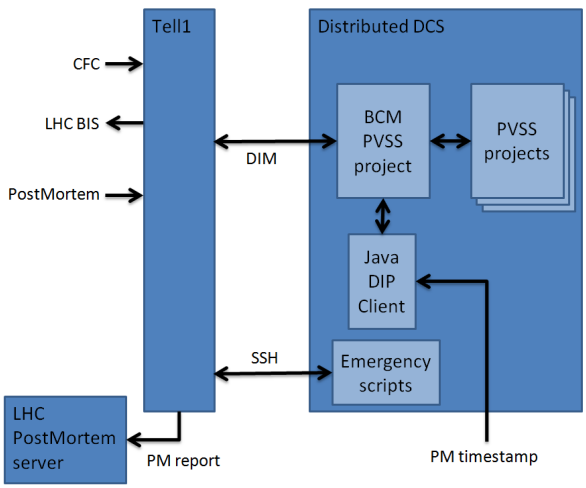

Figure 1: Beam Condition Monitor - the control layer.

The content of the circular memory buffer is marked using the published timestamp of the latest PM event and then sent to the LHC central PM server, from where it can be further analyzed.

The timestamp is distributed over Data Interchange Protocol (DIP) in nanoseconds. Since the PVSS DIM client does not support such accurate time resolution, a specialized client was implemented in Java for retrieving it.

The main communication flow in the BCM system is presented in Fig. 1.

OPERATING THE DETECTORS

ALICE consists of many subsystems integrated via a distributed PVSS project. The DCS shifter operates through a central User Interface (UI), which is connected to all sub-detectors and to the common systems like electricity, environment monitoring etc. The User Interface collects all the system states and alerts, and is able to send commands to change the status of the detectors.

The UI panels are designed with the goal of simplifying the actions and minimize the time and risk of mistakes. The most frequent procedures have been coded into scripts and panels, and the operator is asked to activate an existing procedure when needed, instead of interacting with the single detectors following their different and dynamic requirements

The SAFE and SUPERSAFE States

Certain LHC operations require detectors to be in a compatible, so called SAFE condition. During the LHC Injection, TI2 setup or beam adjust, the sensitive detectors typically lower their voltages to protect the electronics against excessive charge deposits.

During certain operations (such as testing of new LHC filling schema etc.) the detectors put even more restrictions on their settings. This condition is called SUPERSAFE.

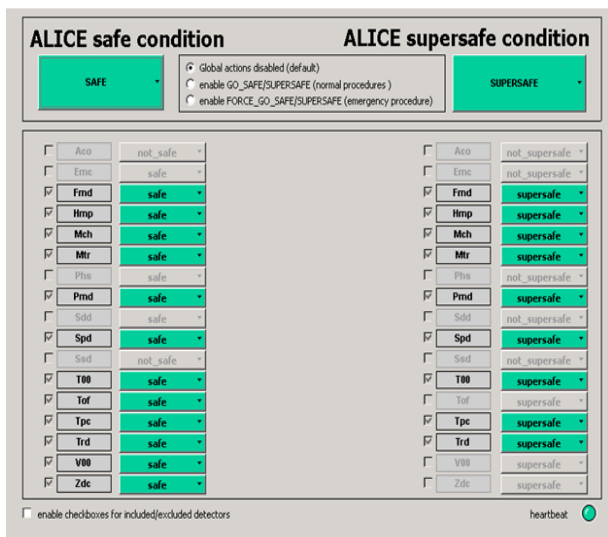

Figure 2: The SAFE/SUPERSAFE panel.

Each detector declares if it meets the SAFE and SUPERSAFE conditions. The central system collects this information and sends to the subsystems the GO_SAFE or GO_SUPERSAFE command through a PVSS datapoint to obtain the required level of safety. If a detector is in a SUPERSAFE condition, it can be brought

back to SAFE using the RESTORE_SAFE action. The commands are available to the DCS operator from the SAFE/SUPERSAFE panel presented in Fig. 2.

The shifter can also send global commands (GO_SAFE, GO_SUPERSAFE and RESTORE_SAFE) that trigger relevant actions on side of all the detectors. When all the detectors are SAFE (or SUPERSAFE), the global state of ALICE is declared as SAFE (or SUPERSAFE).

An exclusion matrix is introduced to temporarily ignore individual detectors from the calculation of the global state. This matrix can only be changed under the supervision of the shift leader and the detector expert. The exclusion/inclusion from/to the safety matrix is also set via the SAFE/SUPERSAFE panel.

The GO_READY Matrix

When the beam condition requiring the SAFE/SUPERSAFE state is not present anymore, the detectors are sent, on request of the shift leader, to the READY state via the GO_READY command to start the data taking.

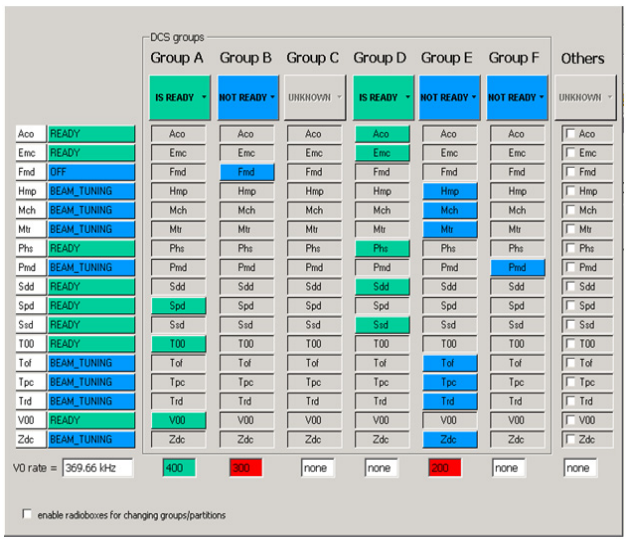

Figure 3: The GO_READY panel.

Different detectors will switch on the HV in different phases of the beam operation (the so-called luminometers right after injection, the gaseous detectors only at stable beams).

In order to minimize the risk of a mistake of the DCS operator and the time needed to send to READY the relevant detectors, a panel has been prepared which groups the subsystems and allows sending the GO_READY command in parallel to the different groups (Fig. 3).

The V0 Rates

The risk of HV trips and potential sub-detectors damage can be estimated using the V0 subsystem. This detector is based on two disks of segmented plastic scintillator (76 cm in diameter) located asymmetrically with respect to the ALICE interaction point (+340 cm, -90 cm).

Due to its enhanced timing performance V0 can detect both beam-beam and beam-gas collisions, thus providing separate numbers of collisions (rates) for luminosity and background. The sum of these rates lets the experiment monitor the amount of charged particles crossing the sub-detectors.

Right after the beam injection and the energy ramp, ALICE and the LHC usually agree on a desired luminosity level. If the sum of luminosity and the background rates is above a fixed threshold for some sensitive gaseous detectors then they should not be sent to READY until the V0 rates decrease below the threshold.

A control is then implemented in the GO_READY panel to alert the DCS shifter not to send to READY the detectors until this condition is valid. The decision to continue or abort the GO_READY command is then left to the shift leader.

If the V0 rates are too high and the detectors are READY, a severe alert is raised and again the SL takes the responsibility to ramp down the different sub-detectors.

THE HANDSHAKE MECHANISM

The Handshake is a communication protocol between the CERN Control Centre (CCC) and the LHC experiments. Its purpose is to inform the shift crews of the experiments about any beam activity to be performed by the machine. Another goal of the Handshake is to obtain permission from the experiments before starting actions like injection, adjust or beam dump. After receiving the notification about the beam activity, the experiments should take necessary actions to prepare the detectors for this activity, to avoid damages that the beam may cause.

The Handshake mechanism is based on the exchange of messages (“LHC commands” and “ALICE responses”) between the CCC and ALICE via DIP. On the ALICE side, the logic of the Handshake is implemented as a finite state machine using SMI scripts from the fwFSM component developed within the JCOP project.

Injection Handshakes

From the point of view of safety, the most critical are Injection Handshakes. Their main purpose is to make all the subsystems SAFE (and if required SUPERSAFE) and to remove the injection interlock. The relations between different phases of the Injection Handshake and protection mechanisms are illustrated in Fig. 5.

When the CCC is ready to inject the beam they publish the “WARNING” message. The ALICE DCS operator, using dedicated control panel (Fig. 4), confirms it by executing the “INJECT_PREPARE” action and then starts to prepare for the injection. During the next 5 minutes the ALICE experiment should be moved to the global SAFE (or SUPERSAFE) state. The operator executes the “CONFIRM_INJECT” action when the experiment is prepared. This command also sends a request to the BCM system to grant the injection permits.

After all the experiments report they are ready the CCC sends the "READY" command and only then the beams can be injected into the LHC. When the injection is completed the CCC publishes the "OK" message, which triggers removal of the injection permits. Starting from this moment ALICE no longer needs to be in the SAFE/SUPERSAFE state.

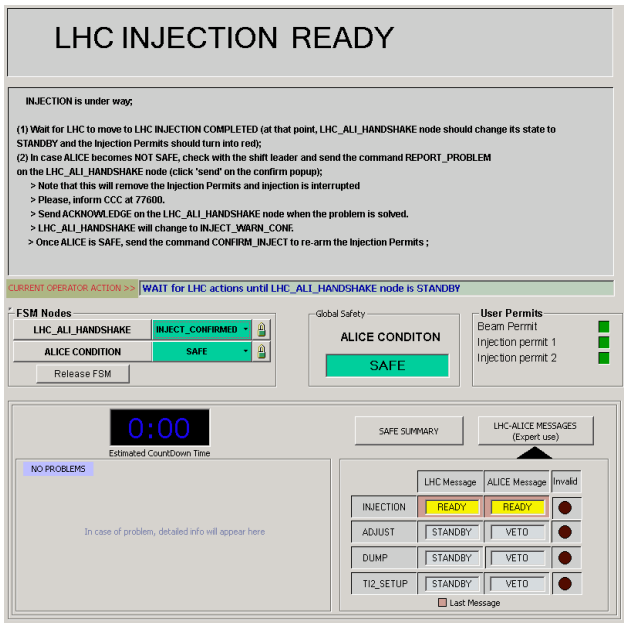

Figure 4: The Handshake control panel.

Emergency Situations

The handshake protocol can also handle exceptional situations, like violation of the SAFE state or a communication problem in DIP. In such situations the state of handshake is changed automatically to emergency state "PROBLEM_REPORTED" in which the injection permits are not granted. This state can also be set manually by the DCS operator upon the shift leader request in justified cases.

CONCLUSIONS

The main task of the central DCS team was to design a system to keep detectors in the safest condition during the most dangerous machine modes (from injection up to adjust) and a monitoring system able to react to anomalous beam conditions. These goals were achieved and the experience gained during 1.5 years of operation has been used to better define the safe states of each detector and values of the BCM dump thresholds.

At the moment, the most dangerous for ALICE are fast beam losses produced during injection by kicker magnet failures since the reaction of the BCM and LHC Beam Loss Monitor systems is too late. Therefore, the proper definitions of the SAFE and SUPERSAFE states are essential. Wrong definitions can lead to serious incidents, like during big beam losses in July 2011, when part of a calibration system of Silicon Drift Detector was damaged and the safe policy had to be reviewed for this subsystem.

On the other hand slow losses related to circulating beams can be detected in due time and beams can be dumped typically within 2-3 orbits before any damage is produced.

Abstract

In the IFMIF/EVEDA Project, the prototype accelerator experiments to produce a deuteron (D^+) beam with the beam current of 125mA accelerated up to 9MeV at the CW mode are planned. The Personnel Protection System (PPS), which has two functions of radiation safety management and accelerator operation management, has to protect the personnel against unnecessary exposure, electrical shock hazard and the other dangerous phenomena. Since the radiation safety management during and after beam operation is a critical issue for the IFMIF/EVEDA accelerator, PPS with high reliability is indispensable. To realize the high reliability, for PPS design policy, we decided to use and customize proven systems and hardware, and applying dual PLC system [1]. This article presents the PPS design for the radiation safety management.

INTRODUCTION

The International Fusion Materials Irradiation Facility / Engineering Validation and Engineering Design Activities (IFMIF/EVEDA) Project is carried out at the BA site in Rokkasho, Aomori, Japan. The prototype accelerator consists of Injector extracting D^+ beam energy of 100keV, a 175MHz RFQ (4-vane type; output beam energy up to 5MeV), the first section of superconductive linac (SRF Linac; output beam energy up to 9MeV), beam dump, and the other accelerator subsystems [2].

Personnel Protection System (PPS) is a part of the control system for the IFMIF/EVEDA prototype accelerator. The PPS has two functions, which are radiation safety management and accelerator operation management in order to protect the personnel against unnecessary exposure, electrical shock hazard and the other dangerous phenomena.

Because the D^+ beam of 125mA/9MeV at the CW mode operation will be produced for the engineering validation, the radiation safety management is very important since the high radiation environment in the accelerator vault is assumed during and after beam operation. Therefore, the development of PPS with high reliability is indispensable for the radiation safety management for the personnel entering/leaving of radiation controlled area. In order to obtain the high reliability, we decided to use and customize the proven system and hardware to eliminate risks by initial failure, and apply dual PLC system to prevent malfunction.

*kojima.toshiyuki@jaea.go.jp

CONFIGURATION OF PPS

Fig. 1 shows a general configuration of the PPS. The PPS consists of a couple of PLCs, the PPS console, personal key boxes, door control boxes, emergency stop buttons, cameras for monitoring etc. In order to centralize status of the PPS equipments, all signal paths are hardwired from equipments to the PLCs.

One PLC system consists of one set of PLC and signal path which is composed to cables, limit switches and so on (for example, PLC-A and signal path for PLC-A in Fig. 1). The PPS consists of PLC-A system and PLC-B system and each system is configured separately and works independently.

The dual PLC system is adopted for higher reliability because the PPS only permit some actions when both PLC systems make same judgement. For example, workers can only operate the accelerator subsystems when both PLC-A and PLC-B system permit the operation.

The PPS console is used for monitoring and operating at the control room. The personnel entering/leaving of the radiation controlled area is managed by taking/returning personal keys. Access doors on the controlled area can be opened by the personal keys.

In the accelerator vault etc., some emergency stop buttons are installed. The beam operation is stopped by pushing the button.

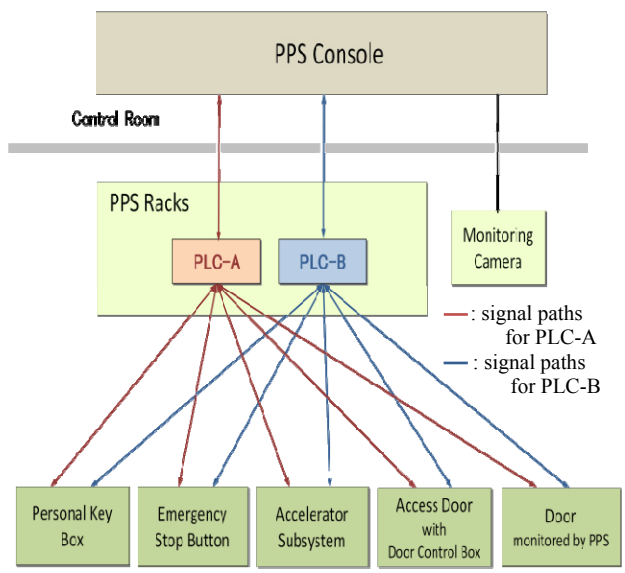

Figure 1: General configuration of PPS for the IFMIF/EVEDA prototype accelerator.

RADIATION CONTROLLED AREA

Fig. 2 shows the radiation controlled area of the PPS and the layout of main equipment for the PPS. The controlled area consists of the accelerator vault (yellow part in Fig. 2), radiation hot area (blue part in Fig. 2) where nuclear HVAC system and heat exchangers for cooling water etc. are installed. The PPS manages the entering/leaving of the radiation controlled area according to the classification of the access mode described in Tab. 1.

Table 1: Access Mode of PPS

Access Mode	Status
No Access	"No Access" means a prohibition against all access to the accelerator vault. * On beam operation * While radiation dose is too high to enter the radiation area after beam operation.
Controlled Access	"Controlled Access" means accessible to the accelerator vault and radiation hot area, when the supervisor gives permission. * During preparation for beam operation. * Interval of beam operation. * Maintenance at the radiation hot area
Authorized Access	"Authorized Access" means possible to access to the accelerator vault and radiation hot area, without permission. * Under suspension of accelerator subsystems * During maintenance works

During beam operation, "No Access" mode means prohibition against all access to the accelerator vault. Only when no person in the accelerator vault is confirmed and "No Access" mode is selected, the beam operation is permitted by the PPS. When the access door is opened or the lock is released, the permission for beam operation is immediately cancelled by the PPS.

In the "Controlled Access" mode, the access to radiation hot area for maintenance etc. is possible on beam operation when the permission is given by supervisor, but the access to accelerator vault is prohibited. During preparation for beam operation, access to both areas is possible when the permission is given by supervisor.

To let two status modes of "No Access" and "Controlled Access" on beam operation distinguish surely, two personal key boxes are prepared. One is used for entering to the accelerator vault, and the other is used for entering to radiation hot area, so that it is possible to enter to hot radiation area during beam operation under the management of PPS. The key for the accelerator vault is impossible to pull out during beam operation by the PPS.

For "Authorized Access" mode, the access to both controlled area for maintenance etc. is possible. In this mode, two kind of personal keys are also needed to access the both area, because the access mode of PPS is never changed to "Controlled Access" or "No Access" before all personal keys are returned to key boxes.

EQUIPMENTS LAYOUT

PPS Racks

The PPS consists of four racks; Uninterruptible Power Supply (UPS) rack, PPS control rack (PLC-A), Cable connection rack, and PPS control rack (PLC-B), arranged from left to right in Fig. 2 (1). These racks are installed in RF & Power Supply Area.

PLCs are installed in the PPS control racks (A and B) with same composition, and the PPS is full duplication including signal paths. The UPS has capacity of 5kVA and ability to supply the PPS equipments without electric power interruption during 10 minutes until startup by a backup generator.

PPS Console

The PPS console is used for monitoring and operating against personnel entering/leaving for controlled area from the control room. The PPS console consists of PPS control panel, an intercom, LCD monitors etc., as shown in Fig. 2 (2). In the PPS console, it is possible to survey the situation in the accelerator vault and shipping bay area by monitoring cameras and intercoms. In addition, the console is also used for monitoring the important points for radiation boundary, for example "Door monitored by PPS" in Fig. 2.

The PPS control panel provides the follow switches; Access Mode switches, permission switches for personal key boxes and door control boxes, an emergency stop switch, etc. By using these switches, the supervisor can manage the access doors for personnel entering/leaving for controlled area.

Personal Key Boxes

Personal keys are used for unlocking access door in the controlled area. When workers enter into the controlled areas, each worker has to take a personal key. Unless all keys are returned to the key box, the beam operation is not permitted.

Two personal key boxes are installed in the access room for entering the accelerator vault (yellow key panel) and for entering the radiation hot area (blue key panel) as shown in Fig. 2 (3).

The workers cannot take the keys on the yellow key panel during the beam operation, while they can take them on the blue key panel, when the supervisor gives permission by the PPS to enter to the radiation hot area.

Door Control Boxes

For the access doors (indicated red circles in Fig. 2) to enter the controlled areas, access door control boxes are installed near the door. When permission to release the access door lock is given by the PPS console, the door lock is released and the access to controlled area is possible.

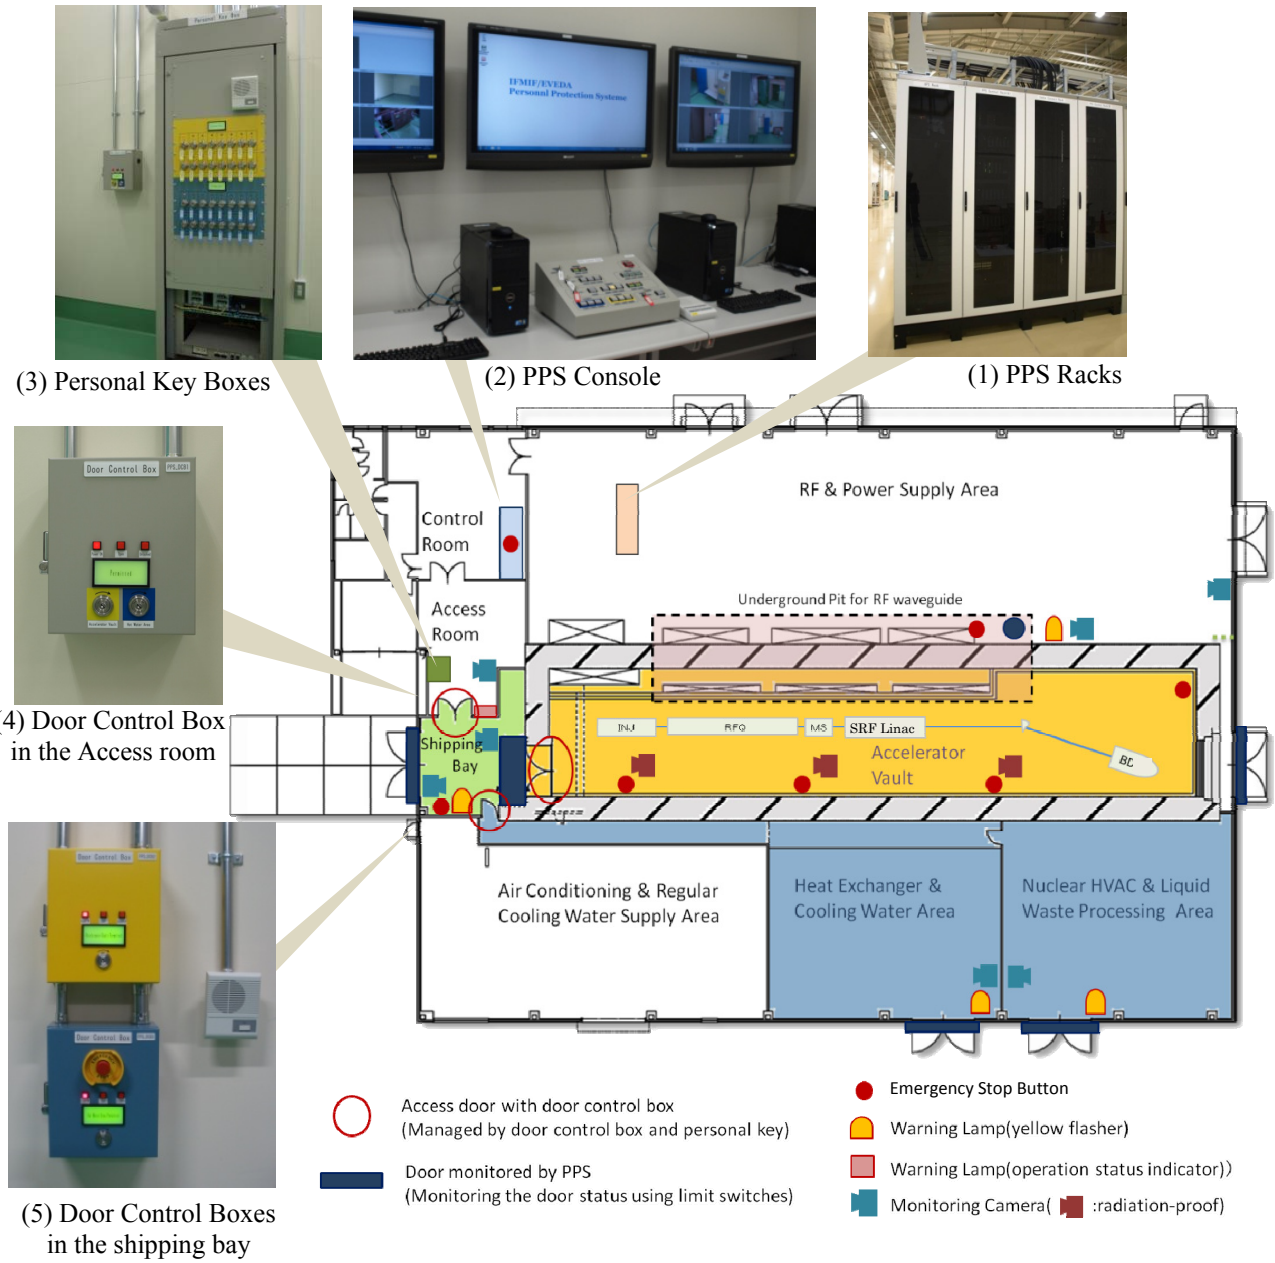

Figure 2: Radiation controlled area and Layout of main equipment for the PPS.

As indicated in Fig. 2, the workers have to access to the accelerator vault or the radiation hot areas from access room through the shipping bay. In the access room, the door control box is set, and the door lock can be released by yellow or blue keyhole as indicated in Fig. 2 (4). In the shipping bay, two access door control boxes are set for each access door (Fig. 2 (5)). After the supervisor can confirm the number of workers in the shipping bay by the monitoring cameras, a permission signal to the PPS is given by the supervisor, each door lock can be released by each personal key and person can enter to each areas.

(1) Emergency Stop Button (2) Monitoring Camera in the radiation proof box

Figure 3: Emergency stop button & Monitoring camera.

Emergency Stop Buttons & Monitoring Cameras

Four emergency stop buttons (Fig. 3 (1)) are installed in the accelerator vault in front of the accelerator subsystems; Injector, RFQ, SRF Linac, and Beam Dump.

When an abnormal or an emergency phenomenon happens, it is possible to stop or cancel for the beam operation by pushing the nearest button. The emergency stop button has a built-in alarm. The alarm rumbles loudly during the emergency stop button is pushed and also does during 5 minutes before starting beam operation to alert.

To monitor the important area for radiation safety at the control room, the monitoring cameras are installed in of the accelerator building. In the accelerator vault, 3 cameras are installed in the radiation proof box with lead shielding (Fig. 3 (2)). The 3 web cameras installed in the shipping bay and the access room make it possible to monitor views of the personnel entering/leaving for the controlled area. Some web cameras to monitor the radiation boundary are also installed in the RF & Power Supply Area and the hot radiation area.

SUMMARY

The PPS for the IFMIF/EVEDA prototype accelerator has been designed. In order to manage workers for maintenance, three status modes of "No access", "Controlled access" and "Authorized access" are applied for the accelerator vault area and the radiation hot area. For each status modes, management of workers for the entering/leaving is carried out by the personal keys, the monitoring system.

In the present status, sequence logics and programmed ladder on PLCs are applied, and the PPS has already performed the equivalent radiation safety management.

According to the interface signals between PPS and the accelerator subsystems, the responsible officers both JAEA and European Institutes are discussing details. Each interface signal will be performed at the linkage test with the accelerator subsystems in Europe, before they will be delivered to Rokkasho site [3].

ASSESSMENT AND TESTING OF INDUSTRIAL DEVICES ROBUSTNESS AGAINST CYBER SECURITY ATTACKS

F. Tilaro, B. Copy, CERN, Geneva, Switzerland

Abstract

CERN (European Organization for Nuclear Research),like any organization, needs to achieve the conflicting objectives of connecting its operational network to Internet while at the same time keeping its industrial control systems secure from external and internal cyber attacks. With this in mind, the ISA-99 [1] international cyber security standard has been adopted at CERN as a reference model to define a set of guidelines and security robustness criteria applicable to any network device. Devices robustness represents a key link in the defense-in-depth concept as some attacks will inevitably penetrate security boundaries and thus require further protection measures. When assessing the cyber security robustness of devices we have singled out control system-relevant attack patterns derived from the well-known CAPEC [2] classification. Once a vulnerability is identified, it needs to be documented, prioritized and reproduced at will in a dedicated test environment for debugging purposes. CERN - in collaboration with SIEMENS - has designed and implemented a dedicated working environment, the Test-bench for Robustness of Industrial Equipments [3] ("TRoIE"). Such tests attempt to detect possible anomalies by exploiting corrupt communication channels and manipulating the normal behavior of the communication protocols, in the same way as a cyber attacker would proceed. This document provides an inventory of security guidelines [4] relevant to the CERN industrial environment and describes how we have automated the collection and classification of identified vulnerabilities into a test-bench.

INTRODUCTION

The Internet has become essential for any organization or company that would like to conduct any sort of business. On one hand, in Industry this results in an improvement of the communication from the fabric floor network to the business level one; but on the other hand, the Internet has brought a lot of security problems which cannot be ignored because of the resulting damages and disasters. Thus, it is necessary to identify methods and procedures for achieving the dual mission of both exploiting the advantages provided by the Internet and at the same time keeping their industrial systems secure from external and internal attacks.

As we know, the number of hostile applications, worms and viruses is continuously increasing and hackers are more and more interested at exploiting common industrial control systems vulnerabilities [5]. As the well-known industrial control security expert Joe Weiss testified to the US Congress, in 2010 more than 180 security incidents were reported; it is worth to mention the Deepwater Horizon (BP Mexican Gulf oil spill) counting 11 casualties or the San Bruno gas pipeline explosion, with 8 casualties.

It is evident that industrial security cannot rely only on IT security techniques and properly configured network architectures (like firewall, network segmentation, antivirus software, access management, etc…) which, however, can provide only a partial protection for the entire system; this is easily explained if we consider the fundamental differences in the deployed hardware but also in the concepts of availability and manageability between IT and Industrial Systems. On the contrary, new methodologies aimed at securing industrial systems must be integrated into IT security standard practises.

This paper mainly focuses on testing industrial Ethernet-connection-based devices without going into details on network security configurations.

COMMUNICATION ROBUSTNESS

Any communication between two or more hosts is regulated by a protocol whose specification defines the formats, syntax and semantic rules for exchanging messages – called Protocol Data Units (PDUs) [6] - over a network. Protocol specifications are typically written in natural - not deterministic - language and sometimes cannot state how to handle all the possible faulty inputs; so many decisions are left to the implementer. Hence it is clear that distinct implementations of the same protocol handle PDUs in different ways.

Due to this heterogeneity, each implementation could present many issues related to services availability, performance and even security: once a hacker has figured out some malformed PDUs or sequences of them which are not properly handled, the entire system is under risk [4]. Ideally all these defects affecting the protocol implementations should be detected and fixed by the manufacturers, but they are sometimes actually detected and reported by external communities. This explains the need of performing automated testing of protocol implementations, especially for critical systems.

In this paper we present a methodology for automated testing of protocol implementation robustness, which must be seen as the ability of the system to handle exceptionally malformed PDUs and stressful network conditions, while maintaining the normal operational behaviour. This evaluation proves a greater ability of analyzed networked systems to survive in the face of

malformed input due to possible involuntary mistakes or explicit attack attempts.

As explained in the following section of the document, the enumeration of all possible faulty PDUs for each protocol is exponential in the number of protocol fields; so it is necessary to devise a strategy to reduce the number of possible malformed PDUs to generate, while still detecting security issues accurately. This can be achieved by exploiting the knowledge of communication experts to distinguish the test cases which could be really interesting, from the ones that are redundant and maybe even duplicated. The approach we are proposing is used to generate individual malformed PDUs or sequences of them in a systematic manner according to a specific grammar definition. Grammars define a set of syntactic and semantic rules to cover a specific domain of tests (generally related to a specific communicational protocol header); if the protocol implementation cannot handle invalid packets correctly, anomalous behaviour may occur and needs to be detected.

The approach, we are proposing, must be generic enough to be applied to all protocols even to industrial ones which exhibit really specific properties and features.

ANALYZED TOOLS AND SECURITY STANDARDS

In the recent years the increasing number of cyber security related incidents affecting industrial control systems has made vendors of critical infrastructure to pay more attention to security issues. Unfortunately, there are no complete and comprehensive standards whose specifications can be followed to protect any critical system; nonetheless several initiatives have been started with the objective of improving the security level and the robustness of industrial systems.

The ISA Secure Program [7], on the basis of ISA 99 Standards specifications, has produced a certification program with three levels of recognition for a device security assurance.

Among the commercial products - that we have already tested and used in our initial testing phase - Wurldtech Achilles [8] must be mentioned; it is an all-in-one vulnerability scanner specifically designed for suppliers of industrial process automation, control and safety systems such as: Programmable Logic Controllers, Supervisory Control and Data Acquisition (SCADA) Devices, Distributed Control Systems and Critical Systems. Wurldtech has also developed a proprietary certification with the purpose of evaluating and assuring the robustness and resilience of industrial products. However, to overcome the Achilles platform's proprietary aspects and limitations in terms of supported network protocols and attack techniques customization support, we have designed and implemented the TRoIE test-bench [4]. Moreover Wurldtech Inc. is also providing a valuable contribution to the preparation of industrial cyber security standards, such as ISA99.

In the wide range of open-source security frameworks and tools we have integrated into our test-bench the Open Vulnerability Assessment System [9] (OpenVAS); born as a branch of the popular Nessus2, OpenVAS provides a flexible environment for the development and deployment of new vulnerability scanning techniques. So far this framework does not offer a real wide range of tests developed specifically for industrial and process control environments. This field has been attracting more and more interest in the last few years: for instance, the Nessus vulnerability scanner has recently introduced an internal package finalized to industrial protocols and systems tests.

ENHANCED PROTOCOL FUZZING TESTS WITH GRAMMAR DEFINITION

When assessing the cyber security robustness of devices, *attack patterns* [10] can be used to categorize the discovered vulnerabilities. An attack pattern is expressed as "a series of repeatable steps simulating an attack against a system".

Such classification is useful to identify the cause of vulnerability and the potentially related well-known solution. In our experience we focused on Fuzzing and Grammar tests because of their effectiveness at probing devices for security vulnerabilities.

Protocol Fuzzing is a very effective testing technique generally deployed to generate valid and invalid packets with "randomized" header field values; its main purpose is analyzing the behaviour of a specific protocol implementation or functions of the protocol stack by injecting unexpectedly malformed input parameters values.

Fuzzing, according to the first, narrower definition, might be characterized as a blind fishing expedition that hopes to uncover completely unsuspected problems in the software under test. However it must be also admitted that for many interfaces, the idea of simply injecting random bits works poorly generally because of the wide domain of test. For example, injecting a web interface with randomly generated strings will have the only effect to detect only invalid URLs: they will be mainly rejected suddenly, perhaps by a simple parser - acting a sort of protection - checking for valid URLs. This is why completely random fuzzing is a comparatively ineffective way to uncover problems in a generic system. On the contrary Fuzzing acquires more efficiency when it is combined with "intelligent" techniques. Microsoft refers to this as "smart fuzzing" [11]: it is not a random testing anymore, but the generation of the tests is led by the target specifications; hence an initial knowledge of the system under test is required. In our case the fuzzing system is fed with some grammar rules which specify the part of the protocol headers to fuzz and the strategy we want to follow for the generation of the injected packets. One of the most important benefits coming from this kind of testing strategy is the ability to systematically and

predictably explore the input space, instead of having to rely on randomly generated noise.

Our final strategy is a mix of fuzzing and syntax testing: syntax is used to translate the knowledge of security experts into rules, which determine the packets generation and injection. In any case, the creation of effective syntax tests requires a deep understanding of the multiple protocols under test and their possibly stateful interconnections.

A PROTOCOL FUZZING SYSTEM IMPLEMENTATION

In the initial phase of the project, we analyzed a wide range of available specialized fuzzing utilities. Some of them exhaustively iterate through a designated protocol, whose specification are known in advance; so they could be used to stress test a variety of applications that support that protocol. We then opted for other generic fuzzers capable of fuzzing arbitrary protocols and file formats by performing simple, in principle non-protocol-aware, data mutations such as bit flipping or byte transposing. Although these fuzzers are effective against a wide range of common applications, we often have a need for more customization and thorough fuzzing for proprietary and previously untested protocols (we remind that our main targets are industrial control devices with proprietary specifications). This is where fuzzing frameworks become extremely useful. Among them we explored three open source fuzzing frameworks: SPIKE, Sulley Fuzzing Framework and Peach. Eventually the last framework has been selected for its flexibility and simplicity at developing specific customized protocols fuzzing tests. Nonetheless Peach provides some utility to convert Wireshark captured network traffic file into its protocol model format. It also includes several modules for target faults detections; but unfortunately they cannot be used in our scenarios where a custom monitoring system has been developed to observe the behaviour of the industrial devices under tests.

Peach Fuzzing framework [12] is an open source cross-platform fuzzing framework written in Python. It provides with a well designed software components, like mutators, transformers, protocols definitions, publishers, groups, etc... These components can be extended and chained together to simplify the generation of customized complex data types. As underlined before, Peach offers a very high object oriented abstraction level through the definition of pure python classes: it allows a tester to focus on the individual subcomponents of a given protocol, later tying them together to create a complete fuzzer scheme. As a result this approach generously promotes the code reuse for the development of new fuzzers. We have customized this framework by defining:

- new publishers tailored at injecting the generated data into the specific protocol formats we want to test;
- new mutators responsible for the generation of data ranging values and types;
- new transformers to encode the data values in a proper way;
- new mutation strategies which establish the algorithm to follow at combining the protocol fields values;
- new agents and monitors to integrate the fuzzing system with the external monitoring one: in case of target failure detection the fuzzing test saves its current state to restart it later from the last point.

Once the framework has been customized through the implementation of the previously described components, we have started the creation of so called “PeachPit” files: they are XML files containing all of the information necessary to run a fuzzing test:

- the data model defines the structure, information type, and relationships in the data to be fuzzed;
- the state model: It additionally allows for the configuration of a fuzzing run including selecting a data transport (Publisher), logging interface, etc.
- Generic configuration to specify the publishers, agents and monitors to use, including their specific initial parameters values.

In line with the ISA-99 security standards specifications we have defined an independent testing and certification system for industrial control devices. The PeachPit file definition is not totally arbitrary, but aims at fulfilling the ISCI Communication Robustness Testing (CRT) requirements. In practises we have implemented within the Peach fuzzing framework a list of security tests classified by protocol and scope of test. However it must be said that this certification does not cover the industrial protocols yet; so, to overcome this limitation, we have defined our own tests by applying the same security concepts and guidelines used for the open protocols.

MONITORING

In any testing procedure it is essential for the tester to be able to determine if the behaviour of the system under test is symptomatic of vulnerability or anomalies either in the software or hardware.

This examination can be harder in security testing than in traditional functional testing, because the tester is not necessarily comparing actual program behaviour to expectations derived from specifications. Rather, the tester is often looking for unspecified symptoms indicating the presence of unsuspected vulnerabilities. Furthermore monitoring must be integrated into several automated procedures, which can be used to evaluate test outcomes and identify only the anomalous ones: this is especially true during high-volume test activities like fuzzing. Unfortunately there are no third-party test automation tools able to monitor generic industrial devices’ outputs and internal behaviour; so we have been forced to design and implement our own monitoring strategy. At least the “essential services” - following the ISCI CRT [6] naming convention - must be observed

during the testing activities. In our specific case the monitoring system should check and track any of the following effects: extension of the current PLCs scan cycle, excessive use of memory, CPU overuse, delays in the physical outputs and consistent delays in the periodic communication.

Once an anomaly has been detected, it becomes relevant to identify its cause, the specific packet or sequence of packets. Because of its complexity it is not generally easy to achieve this task: one anomaly could be the result of different environment variables, and the device's behaviour could not be affected by the single factors, but only by a specific combination of them.

ACHIEVEMENTS

The described strategy has already proven to be effective at detecting device robustness issues. Thanks to the performed testing analysis, it was possible to detect critical anomalies in the devices' software protocol stack implementations. These research findings have been directly reported to their proper industrial vendors in order to be patched and incorporated in subsequent firmware releases. These initial encouraging results have motivated the team to continue following and expanding this approach for the future of the collaboration between CERN and the automation industry.

CONCLUSIONS AND FUTURE WORK

The entire article is based on the assumption that any network protocol implementation is susceptible to accidental or malicious corrupted communication. For this reason, it is essential to perform robustness testing of these implementations for critical industrial systems. Our approach consists of analyzing protocol implementations by injecting malformed PDUs to corrupt the normal behaviour of the system. As a PDU typically has many fields, the number of possible syntactically faulty PDUs grows exponentially with the number of fields. In this document, we proposed a strategy to explore this huge test domain using a hybrid approach of fuzzing and syntax techniques, specifically developed to evaluate industrial device communication robustness. So far, not all the tests can be integrated into automatic tools, human analysis and management is necessary to discover and investigate specific possible failures.

Moreover it should be remembered that security analysis must be seen as a dynamic process which should be adapted according to new requirements, constraints and technological changes. So the testing techniques and methodologies defined in this document should be adapted and modified to fit incoming features and evaluate new functionality.

In the future, we will extend the scope of our analysis to the industrial supervision layer: the targets of our tests will not only be the individual devices but also SCADA systems in order to estimate the potential impact of malicious PDUs within the entire industrial network architecture.

CERN SAFETY SYSTEM MONITORING - SSM

T. Hakulinen, P. Ninin, F. Valentini, CERN, Geneva, Switzerland
J. Gonzalez, C. Salatko-Petryszcze, Assystem, France

Abstract

CERN SSM (Safety System Monitoring) [1] is a system for monitoring state-of-health of the various access and safety systems of the CERN site and accelerator infrastructure. The emphasis of SSM is on the needs of maintenance and system operation with the aim of providing an independent and reliable verification path of the basic operational parameters of each system. Included are all network-connected devices, such as PLCs, servers, panel displays, operator posts, etc. The basic monitoring engine of SSM is a freely available system-monitoring framework Zabbix [2], on top of which a simplified traffic-light-type web-interface has been built. The web-interface of SSM is designed to be ultra-light to facilitate access from handheld devices over slow connections. The underlying Zabbix system offers history and notification mechanisms typical of advanced monitoring systems.

INTRODUCTION

This paper presents, Safety System Monitoring (SSM), a framework for monitoring the computing infrastructure of CERN safety-related systems, such as the LHC and PS access and safety systems. While other monitoring tools exist at CERN, none of them is able to easily monitor control systems as heterogeneous as the access and safety systems.

The main purpose of SSM is to present the access and safety maintenance teams an accurate overall picture of the functioning of the various parts of the monitored systems. While the monitoring system is primarily aimed at the maintenance teams, some elements are still available to access operators and safety personnel.

MOTIVATION

In order to ensure the best possible service to their clients, access and safety maintenance teams need to know what is going on with their systems before their clients tell them. The goal of SSM is to provide the teams a straightforward remotely accessible user interface, which can help to anticipate major problems by early detection of failures. The following access and safety systems are the target of the SSM system:

- **LACS** (LHC Access Control System) – who enters the LHC and when?
- **LASS** (LHC Access Safety System) – is it safe for beam or access?
- **PACS** (PS Access Control System) – idem for the PS complex.
- **PASS** (PS Access Safety System) – idem.
- **SPS PSS** – integrated personnel safety system for the SPS complex.
- **SUSI** (Surveillance des Sites) – who enters CERN sites and areas other than the accelerators.
- **CSAM** (CERN Safety Alarm Monitoring) – alarms for the fire brigade.
- **Sniffer** – gas detection and alarm.
- **SIP** (Site Information Panels) – display relevant info at access points.
- **SSA** (Safety System Atlas) – Access and personnel safety system for the ATLAS detector.

The systems themselves have normally some internal tools giving at least info on the operational status and internal state of health, as well as synoptic displays for operators and maintenance. However, there is little coherence between the different systems due to their often different approaches and levels of abstraction. The native interfaces also tend to be difficult to use requiring expert knowledge, their information cannot always be trusted due to too many layers and black-box implementation of those systems, and not everything is necessarily monitored – particularly in systems composed of many diverse components. CERN access and safety system typically consist of:

- Servers (Windows / Linux).
- Operator posts (PCs at control rooms / access service).
- Panel-PCs (local displays / information panels).
- PLCs / UTLs (local special purpose control units).
- Various other local control units.
- Video cameras / recorders.
- Biometry units (iris-scan).
- Interphones (at access points and operator rooms).
- Card readers.
- Key distributor units.
- Databases / web-servers.

These various devices come from many different vendors, and they are nowadays mostly directly network connected. Access systems reside mainly in the CERN Technical Network (TN) but some equipment reside also in the General Purpose Network (GPN) and the most important systems, in particular safety systems, have their own private networks.

It is to manage this complexity in a unified manner that the SSM system was conceived: The goal was to build an integrated system for monitoring all safety and access systems managed by the CERN access and safety teams in a coherent and reliable manner. The following basic requirements for the SSM system were identified:

- SSM would need to target directly all network-connected devices and subsystems of the systems being monitored.
- SSM needed to be easily accessible from individual PCs inside and outside of CERN.

- The adopted approach was a simple system of traffic-light style indicators (green/yellow/red) to give a quick indication of problems without going into too much detail.
- The SSM interface had to be well adapted to fixed information panel displays.
- SSM had to be easily usable with handheld devices.
- The underlying monitoring engine was to be kept separate from the visualization interface.
- It should be possible to distribute information to other systems, such as the CERN Technical Infrastructure Monitoring (TIM) [3], when this information is not available elsewhere.

A small on-paper comparison of the monitoring systems currently in use at CERN was made, and monitoring system Zabbix came out as the tool of choice [4]. The main reasons were the openness and easy configurability of Zabbix, its out-of-the-box support for both Windows and Linux/Unix systems, SNMP and IPMI support, Oracle support, it being free of charge, and the fact that it was already known by the access and safety teams thereby making it easily acceptable.

A development project was initiated together with Assystem to develop the basic SSM application infrastructure and user interface.

DESIGN PRINCIPLES

The general design of the SSM system is based on the following basic principles:

- **Simplicity**: Use well-defined interfaces with clear functional separation. Use existing systems and CERN standard services whenever possible (example: Oracle, web-services, authentication).
- **Reliability**: Put in place self-diagnostic checks to tell if the displayed information is trustworthy.
- **Independency**: Look at the system to be monitored from the outside and avoid using information produced by that system. Go to the source whenever possible (example: access PLCs directly).
- **Maintainability**: Keep scripts and database structure simple and easy to understand with up to date documentation.
- **Accessibility**: Must work with all major web-browsers and handheld devices from anywhere.
- **Confidentiality**: Access is to be limited to a well-defined group and a login with CERN password required.

A division of responsibilities between system layers is based on a functional separation:

- **Collect** function: The underlying monitoring engine Zabbix carries out the actual monitoring tasks (management of local agents, connections, item logging, events, notification).
- **Synthesize** function: The integration and synthesis layer consists of a separate "scratch" Oracle database, which has access to Zabbix database tables. The database imports parts of the internal group-machine-item-trigger structure from Zabbix. All the synthesis rules for properly combining the information are defined as Oracle procedures.
- **Visualize** function: The visualization layer consists of the SSM web site [1], which accesses the synthesis database using a PHP-Oracle interface. The site is designed to be as light and simple as possible and to support both interactive and static displays.

SSM visualization layer presents information to users based on a 3-tier approach, where the roles of the different tiers are well defined:

General System Availability Tier

The general system availability tier is a generic web-based top tier presenting general status-information in the form of a synthesis of the states of various subsystems. This interface is designed to be extremely simple and light to facilitate viewing with any web browser or hand-held device (see Fig. 1).

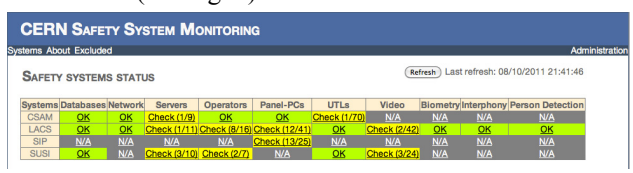

Figure 1: SSM main system synthesis view. Every monitored system is presented on a line of its own, with different subsystem categories shown as columns. Green **OK** means that everything is fine with every equipment of the subsystem, yellow **Check** means that the system continues to function but in a reduced state (non-critical failure of some equipment, with the number of failing equipment given in parenthesis), red **Down** would signify a critical failure rendering the subsystem non-operational, and grey **N/A** means that this item is not applicable to the system in question.

Subsystem Availability and Diagnostic Tier

The subsystem availability and diagnostic tier is a more detailed web-based 2nd tier allows access to a selected set of availability and diagnostic information of the various subsystems. This is simply an extension of the top tier pages allowing one to dig more deeply into the system. Similarly to the top tier, viewing of the pages is possible with the same kinds of devices (see Fig. 2).

Low-Level Diagnostic Tier

The 3rd tier comprises access to native diagnostic and configuration tools of the various subsystems. In most cases this means simply a direct link to a web-based interface of the underlying monitoring tools like Zabbix (see Fig. 3).

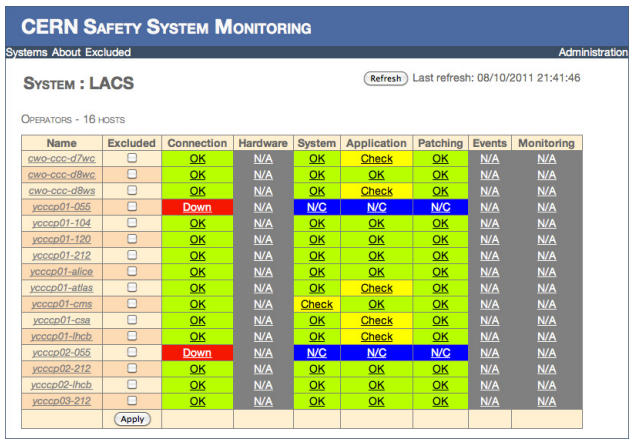

Figure 2: SSM subsystem view. All the devices of a subsystem are shown on a line of their own. The significance of the colours is the same as in the main view with addition of blue **N/C** meaning that the equipment is not communicating the information in question. The special item **Excluded** gives the possibility to mark some equipment to be excluded from the synthesis calculation (thereby not being visible in the main synthesis view) to prevent equipment undergoing maintenance or some known failures from polluting the synthesis view.

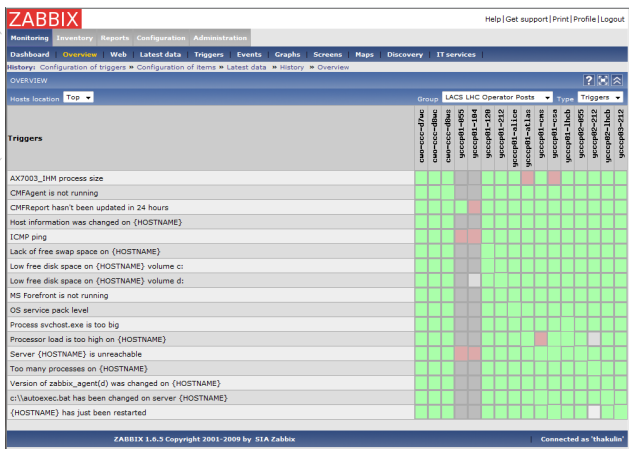

Figure 3: The native Zabbix interface. This interface permits a full access to all the features of the Zabbix tool including trend graphs, host configuration information, and email and SMS notifications. This interface is only accessible from the CERN network.

Target Audience

The expected audience of the monitoring system can be roughly divided in three categories depending on the roles and needs of each. Access to the system can be tailored to each case separately:

- **Access and safety maintenance and operation teams**. By virtue of their functions and being the main target of the monitoring system, the maintenance and operation teams have full access to all of the information and functionalities of the monitoring system.
- **Access operators, safety personnel, operational personnel, and registration service**. As the main "clients" of the access and safety systems, the operational personnel can benefit from certain elements of the monitoring system, but will probably not need access to the underlying tools.
- **CERN users and general public**. There is no interest to expose an internal monitoring system to the general public. However, some information provided by the system might become available via indirect routes, such as the information panels visible in publicly accessible areas.

Since access to the monitoring system is generally restricted to the members of the access and safety system teams and operators, an access control scheme has been implemented. This was achieved by controlling access to the web pages. There are two complementary authorization mechanisms:

- The web-server checks the ip-address of the machine where the request is coming from and if it is on the list of machines authorized to access the pages directly, access is given. These machines would include the machines running the safety information panels in stand-alone mode and possibly certain operator posts, access control configuration workstations, and dedicated terminal servers under direct control of the maintenance team or operation.
- Otherwise, a personal CERN login is requested. If the person is on the list of authorized persons, access is given. To use any configuration or diagnostic utilities with other powers besides a simple display of information, personal login is always required.

NETWORK ARCHITECTURE

The overall network architecture of SSM is presented in Figure 4. It consists of the following components:

- **Main Zabbix server**: The main monitoring engine resides in the Technical Network.
- **Proxy Zabbix server(s)**: A proxy server is a slave monitoring server for a private network able to act as an information gateway for the monitoring system between the TN and the private network segment.
- **Zabbix database:** The main monitoring data repository residing on the CERN central Oracle servers.
- **SSM database:** A "scratch" database with access to the Zabbix database and containing the synthesis rules and the data visualization logic of the SSM web interface.
- **SSMTIM database:** A second scratch database accessing the Zabbix database to distribute selected data to the TIM framework.
- **SSM web site:** A dynamic web site based on PHP scripts, which provide access to the SSM database for visualization. The web scripts contain no other logic except what is required to format and visualize the information.

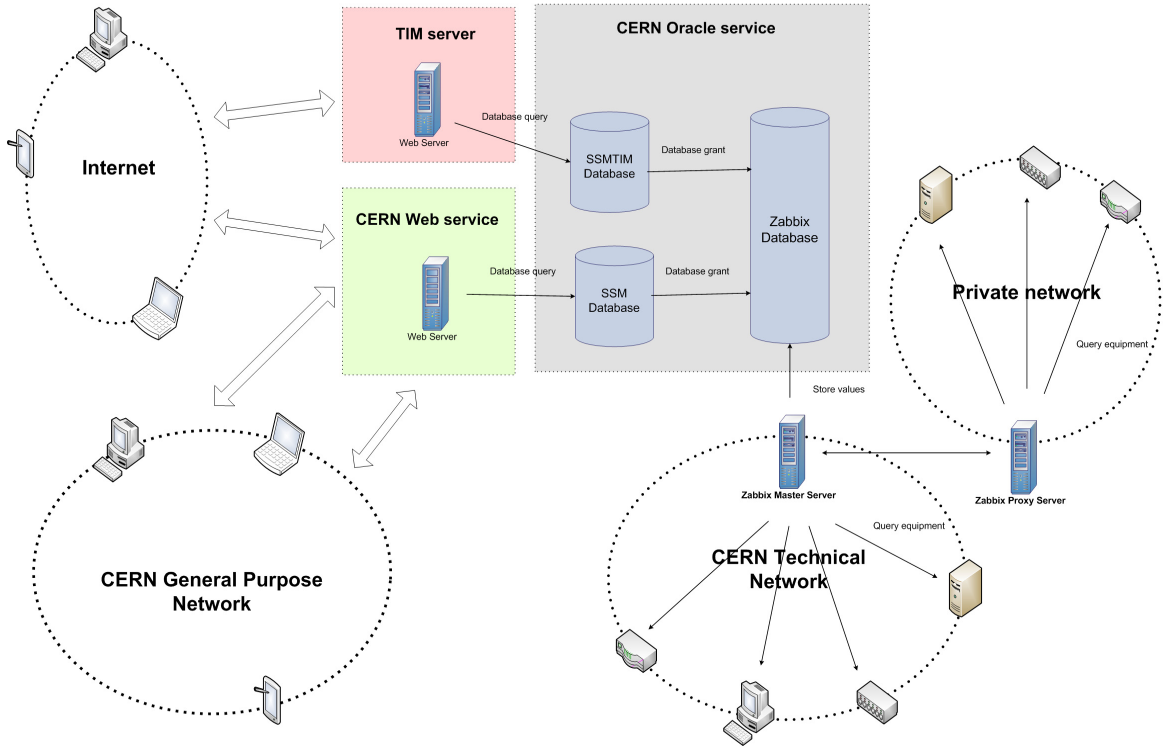

Figure 4: The overall SSM network architecture.

CURRENT STATUS

After a pilot phase of several months, SSM is in production at CERN since summer 2011. The systems integrated into the SSM are: LACS, CSAM, SUSI, and SIP. Work continues to integrate the remaining systems, SPS PSS, Sniffer, and SSA. The PS complex access and safety systems (PACS/PASS) will be integrated into the SSM framework once the renovation of those systems is final during the CERN accelerator shutdown of 2013-2014. Below are some current statistics of the SSM system today:

- 700 network connected equipment of the various systems are now monitored:
  - LACS: servers, operator posts, panel-PCs UTLs, interphones, biometry, video recorders, person detection units, network switches.
  - CSAM: servers, operator posts, panel-PCs, PLCs, network switches.
  - SUSI: servers, operator posts, UTLs, video recorders, video cameras, network card readers.
  - SIP: info screens.
  - Some small safety-related systems by other CERN teams monitored as a free service to those teams.
- 5900 monitoring items (180 new values / second).
- The full history of all values is kept for 30 days and trend data for 6 months.
- The access and safety team members have personal SSM and Zabbix user accounts to allow personal notifications via email / SMS. The authentication is via standard CERN login.
- The system has turned out to be very robust: (almost) no glitches in over a year of server uptime.

CONCLUSIONS

The CERN Safety System Monitoring (SSM) system has been designed to offer a robust and easily accessible tool for the monitoring of large scale heterogeneous systems made of numerous industrial components. It is currently under deployment on most of the CERN safety-related systems, but its open, pragmatic, and ergonomic approach based on a 3-tier user interface could be used also for the monitoring of industrial or accelerator related systems.

VIRTUALIZATION IN CONTROL SYSTEM ENVIRONMENT

L.R.Shen, D.K.Liu, T.M.Wan, SSRF Shanghai, China 201800

Abstract

In large scale distribute control system, there are lots of common service composed an environment for the entire control system, such as the server system for the common software base library, application server, archive server and so on. This paper gave a description of a virtualization realization for control system environment include the virtualization for server, storage, network system and application for the control system. With a virtualization instance of the epics based control system environment that built by the VMware vSphere v4 [1], we tested the whole functionality of this virtualization environment in the SSRF [2] control system, include the common server of the NFS, NIS, NTP, Boot and EPICS base and extension library tools, we also virtualization the application server such as the Archive, Alarm, EPICS gateway and all of the network based IOC. Specially, we test the high availability (HA) and VMotion for EPICS asynchronous IOC successful under the different VLAN configuration of the current SSRF control system network.

THE SSRF CONTROL SYSTEM ENVIRONMENT

A uniform environment which based on PC Linux system had been set up for the system development and operation in SSRF control system [3]. It composed with sets of server system that running Centos system and supplying the EPICS development and high level physics application environment. NIS and NFS server were used to manage user account and share resource. As part of runtime environment, the database server, boot server, Soft IOC server and EPICS application server such archive and alarm handler were installed at the server room.

Several versions (from v3.13.x to v3.14.8.2) of EPICS based with cross-compiler support were installed in the runtime environment and the base 3.14.8.2 is used currently. The target include the Linux-x86 and ppc-604_long architecture which is defined in EPICS.

Moreover in this environment, the EPICS extensions had been installed includes all the tools we needed like the EPICS tools like sequencer, ALH, EDM, MEDM, archive engine and so on. A standard directory structure of the entire environment was defined for all users in a centre NFS server, looks like the "/usr/local/epics/base-3.xx.xxx" for epics base, "/opt/matlab" for the MatLab.

During the operation in past years at SSRF, there were several times of the server system crash in control system environment and brought the accelerator shutdown accident. At the once of most serious it generated the shutdown more than 24 hours waiting for resume the server system normal at the once of most serious. Especially, there were many centralized IOC servers used for large amounts of asynchronous devices in SSRF control system. It will cause the beam lost frequently when these IOC servers down. A step further, the server crash will cause the data lost permanently and consume more time to reinstall the IOC server.

Based on these problem above, we think about the virtualization of the whole control system environment to reduce the failure rate and increase the MTBF of control system environment though the high availability and auto migration on fault brought by the virtualization.

VIRTUALIZATION OF SSRF CONTROL SYSTEM ENVIRONMENT

SSRF controls system environment was used for operation, management and maintenance of the whole SSRF facility. The server system achieved the application of control system and the user management. For the long time stability of server system and satisfy of the requirement of 7X24 hour running, we adopted the virtualization technique and tested in control system environment [4] Include the server system virtualization and the application virtualization.

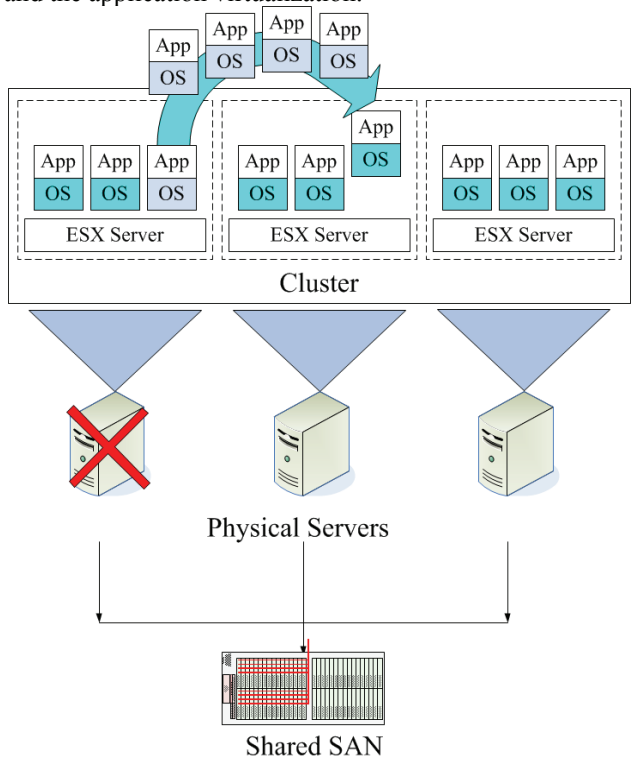

Figure 1: Structure of the virtual server system.

The SSRF virtual server system composed with 16 Dell PowerEdge 2950 PC rack server and a EMC CX-320 SAN storage system, every server used a HBA card connect to the centralized SAN storage system that realized the high availability virtual machine system with online migration capability (see Fig. 1). Another thing

need to noticed was that all the virtual machines operation system also must be installed on the SAN storage system to get the auto migration ability when the hardware fault. Cause we did not need the 100% availability. We did not use dual HBA link connection redundancy, just keep a SAN switch and some HBA card as the replacement part. The only risk is the replacement time of SAN switch when it on fault. The estimated time of change of SAN switch is about 10 minutes.

Hardware Resource Allocation Principle of Virtual Machine

According to the current status of the SSRF server system, the CPU and memory utilization is very low. For some typical system in SSRF, the memory used of archive engine is 484M, YUM and NFS is 1.2G, IOC Server is 338M. So we make the hardware resource allocation rule as below:

- Type1：1 CPU, 2G memory, 20G hard disk;
  Used for NIS, IOC server
- Type2: 2 CPU, 4G memory, hard disk based on requirement;
- Used for NFS, Archive server
- Type3: custom type, hardware resource was custom defined on demand.
- Used for some application such as Yum server, not need the high CPU and RAM utilization but may be need more hard disk.

For some special requirement for example the CA gateway, all the virtual machines used a single network adapter (virtual network adapter).

The Template of the Virtual Machine

According to the principle of hardware resource allocation above, we made several different kinds of virtual machine template so that we can create new virtual server on demond. The frequently used templates were the application server and IOC server that help the administrator make a new application or IOC server quickly and easily. Because all the EPICS base library, IOC software and environment were preinstall and configured in the template, so do not need any install and configured process, the administrator just need to click mouse several times then a new application or IOC server was created and operation immediately.

The template also carry with the storage and network information so we can add new application server has specially depended and dive into use immediately, such as add new EPICS gate way or the archive server when expand the system.

The VLAN setting for the IOC virtual machine

SSRF control system use VLAN to instead of device subnet. There are many asynchronous IOC server used for different sub system in different VLAN, such as the MPS IOC and the Vacuum IOC [5]. Before the virtualization, we need to run multiple IOC servers at one physical server, so we need to config VLAN setting for every physical server. After the virtualization we can run IOC on virtual server one by one. The VMWare HA characteristic need to move these IOCs move from one physical machine to another physical machine, so we need to configure virtual switch with multiple VLAN on same physical server. In the physical machine network configure, we add virtual switch port group one by one and assigned with different VLAN ID of subnet to the virtual switch (see Fig. 2).

Figure 2：VLAN configure in virtual switch.

Except the IOC server, the EPICS gateway server is also across two different VLAN and need to configure virtual network switch that suit for different VLAN so that the virtual machine of EPICS gateway can migration between the different physical machine.

The Implement of the Virtual Control System

We install the VMware vSphere v4 on all of the physical machines and build a virtual cluster system. On the virtual machine system, we created some storage group for virtual machine for different type of application in centralized storage, typically one special small IOC storage group for all virtual IOC servers, two big storage group for NFS server and the Archive server. Before the storage group created, we built the virtual machine templates and installed the EPICS and application software with system configure of SSRF control system environment, include the EPICS environment, network with VLAN setting. Finally we create all of virtual server in the current SSRF control system from the template, include the Yum, NFS, NIS, Boot, Archive, Database, IOC and so on.

Testing of virtual control system environment

We have tested the virtual control system environment at the SSRF machine study time successful. All the functionality of control system environment can be operated normal and virtual IOC servers also work fine

with large numbers of network data transfers through the virtual network adapter, the maximal number of packets can reach about ten thousand per second. Except the mainly target of the virtual machine system, we also

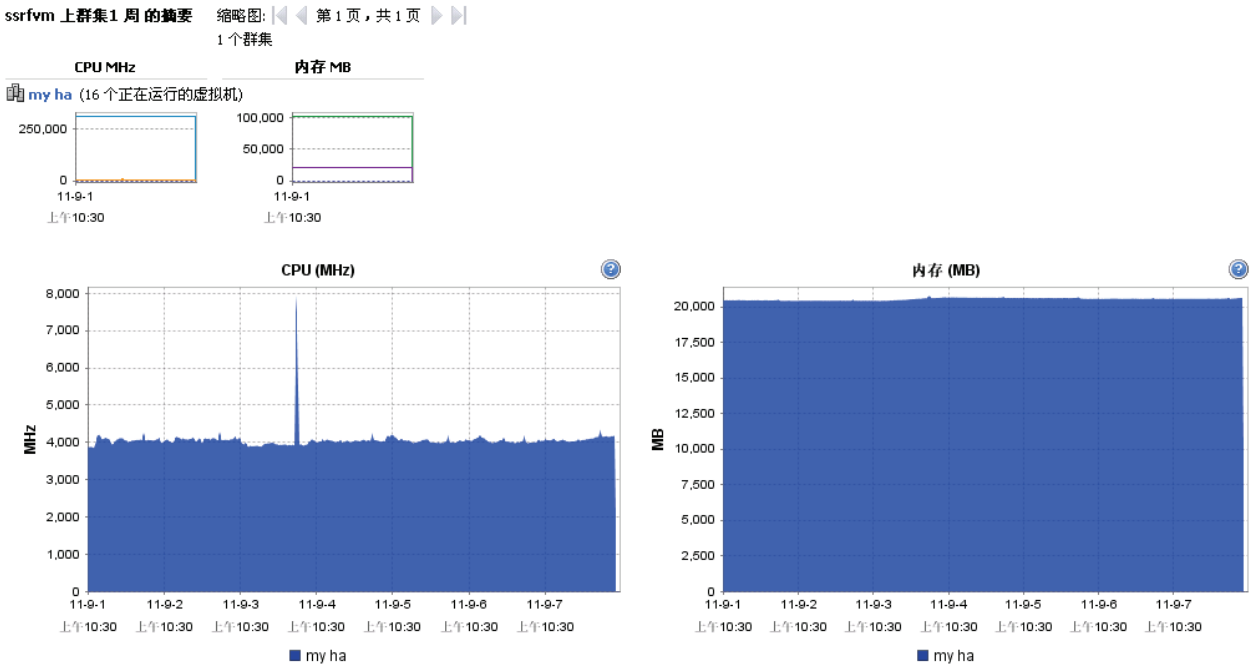

Figure 3: The resource average utilization of virtual machine cluster in one week.

tested the NFS and Archive disk read/write speed and all of results indicated the good performance of the virtualization, Fig. 3 shows the CPU and memory utilization in one week period. Include all the virtual server and application system, the online migration and physical machine crash simulation were tested and the fault migration ware successful. The virtual machine and application all can be moved from the crashed physical machine it existed to other normal physical machine.

During the running in couple of month, we met some of hardware failure situation such as the hard disk and network fault, even cause the physics server crashed, all the virtual servers were still work continually and the virtual control system environment also keep normal running. After fixed the physical server, it can add to the virtual cluster quickly and seemed nothing happened.

THE BENEFIT

The control system environment virtualization can integrate the hardware resource and raise the hardware utilization such as CPU and memory. The most direct results are we saved the servers and consume of power through the virtualization, we reduce the numbers of server in SSRF control system from more than 40 to 16.

The most import point is it can large improves the reliability of the control system environment and the MTBF of the whole facility by the high availability (HA) and VMotion characteristics of virtual machine system.

Other benefit is we can deploy virtual machine from the preconfigured virtual machine template easy and rapidly, that's bring more flexibility for the control system environment, all the work are the configuration of virtual system and no more any hardware work.

CONCLUSION

We have built a virtual control system environment with high availability and auto migration on fault characteristics and used in normal operation of SSRF successfully. From the beginning to now, it works more than half of year and got the result of very stable operation with good improvement of MTBF for control system.

Used virtualization for EPICS IOCs of many asynchronous devices and application server in SSRF control system got the more flexibility and stability.

The virtualization bring benefits such as save hardware resource and achieve the high availability goal and demonstrated the virtualization technical that applied in the larger scale control system environment.

MONITORING CONTROL APPLICATIONS AT CERN

F. Bernard, M. Gonzalez, H. Milcent, L. B. Petrova, F. Varela#, CERN, Geneva, Switzerland.

Abstract

The Industrial Controls and Engineering (EN-ICE) group [1] of the Engineering Department at CERN has produced, and is responsible for the operation of around 60 applications, which control critical processes in the domains of cryogenics, quench protection systems, power interlocks for the Large Hadron Collider and other sub-systems of the accelerator complex. These applications require 24/7 operation and a quick reaction to problems. For this reason the EN-ICE group is presently developing the Monitoring Operation of cOntrols Networks (MOON) tool to detect, anticipate and inform of possible anomalies in the integrity of the applications. The tool builds on top of Simatic WinCC Open Architecture (WinCC OA) [2] SCADA and makes usage of the Joint COntrols Project (JCOP) [3] and the UNified INdustrial COntrol System (UNICOS) [4] Frameworks developed at CERN. The tool provides centralized monitoring and software management of the different elements integrating the control systems like Windows and Linux servers, PLCs, applications, etc. Although the primary aim of the monitoring tool is to assist the members of the EN-ICE Standby Service, the tool may offer different levels of detail, which also enables experts to diagnose and troubleshoot problems. In this paper, the scope, functionality and architecture of the tool are presented and some initial results on its performance are summarized.

INTRODUCTION

The LHC accelerator complex and its associated Experiments rely on many critical auxiliary systems for their safe operation. The EN-ICE group at CERN develops solutions and provides support in the domain of medium and large control systems covering the Experiments, as well as the technical infrastructure and accelerator systems. The group was born in 2009 following a major reorganization of the controls groups at CERN, which aimed at centralizing in a single group the experts and the knowledge on industrial control systems existing at CERN. EN-ICE currently provides an ample portfolio of solutions and actively participates in the development of two successful controls frameworks at CERN that build on top of the WinCC OA (formerly PVSS): the JCOP and the UNICOS frameworks. The utilization of these two frameworks is promoted by the group in all WINCC OA-based applications in order to reduce the development and maintenance efforts.

Moreover, the group also develops and maintains a large variety of turn-key applications in various fields like cryogenics, power interlock systems and safety. These applications are wide-spread around the CERN facilities and although many of them are operated by separated groups, EN-ICE is the ultimate responsible for their correct operation and maintenance over the lifetime of the LHC.

A quick response to abnormal situations or misconfiguration of the systems is crucial to maximize the physics usage of the LHC. Two main actions were taken by EN-ICE to ensure the maximum availability of these control applications, namely:

- A standby service was put in place to guarantee the availability of an expert 24/7.
- A tool was developed to centrally manage software upgrades and to monitor the integrity of the applications, which provides an efficient troubleshooting strategy to both, members of the standby service and application developers. This is the Monitoring Operation of cOntrols Network (MOON) tool and it is described in the rest of this contribution.

MOON

Why Yet Another Monitoring Tool at CERN?

In the last few years, a wide spectrum of monitoring tools has flourished at CERN. Although these tools provide many similar functionalities, this variety is, to some extent, justified by the peculiarities of the applications that are imposed by the technologies used, and the operational environment. Prior to deciding on the development of a new tool, an evaluation of various existing monitoring applications was carried out. The following were some of the main criteria that could not be satisfied by the tools evaluated and that led to the development of MOON:

- Integrated software configuration management and application monitoring allowing for quick correlation between mis-configuration of the monitored applications (e.g. wrong versioning of a component or configuration parameters) and run-time anomalies.
- Centralized deployment of software components on sets of WinCC OA-based applications.
- Detailed light-weight access to the run-time databases of the remote WINCC OA-based applications exploiting the native interfaces and protocols of the product.
- Need to combine in a single tool the monitoring of all elements integrating control applications, namely: hosts, WINCC OA-based applications and their associated front-end devices, like PLCs and FIP [5] buses, as well as the supervision of the technical infrastructure, e.g. electrical distribution, status of the network devices, etc.
- Graphical representation of the components of the control application and of their interconnections and dependencies.

#fernando.varela.rodriguez@cern.ch

- Support of multiple views presenting different levels of detail of the applications depending on the role of the user, e.g. a standby-service user with a limited knowledge of the applications as opposed to an expert or a developer.
- Multiplatform: given the extensive usage of Microsoft Windows and Linux for the control applications at CERN, detailed monitoring of hosts running these operating systems is required.
- Minimization of the development and maintenance efforts.
- Alarm system to list the current faults affecting the monitored systems. In addition the fault history to detect the recurrent problems.
- Long term storage of alarms and monitored parameters.
- Trending of online and historical values.

Moreover, it is very important to underline that MOON is not a complete new development as it is largely based on existing tool and reuses many components of the EN-ICE Frameworks as it is explained in the next section.

Architecture

MOON is an integrated monitoring and software management tool based on WINCC OA which exploits the following two main components of the JCOP Framework, which were originally developed for the control systems of the LHC Experiments:

- The Component Installation Tool [6] for centralized deployment of software components onto sets of WINCC OA-based applications.
- System Overview Tool [7] for farm and application monitoring.

The main building blocks of the application are shown in Figure 1. MOON extends the functionality of the JCOP System Overview Tool to also provide the monitoring of the PLCs and FIP agents. In addition, the demanding requirements of MOON in some specific areas like alarm handling and nightly reports called for a number of enhancements to the original functionality of the components that were successfully ported back to the base utilities. Moreover, the utilization of the UNICOS tools and concepts for the graphical interfaces provides an intuitive and powerful navigation schema for users with different technical backgrounds.

Functionality

The main graphical interface of MOON is shown in Figure 2. The panel is organized into multiple tabs that containing tree-like views of the applications and monitored equipment. These trees are implemented using the JCOP Finite State Machine (FSM) [8], which models each monitored component according to a well-defined set of states and possible transitions amongst them. Moreover, the FSM toolkit organizes these applications in a hierarchical fashion where the state of a node is calculated based on the state of its children where the leaves of the tree represent the actual monitored equipment, i.e. the PLCs, the hosts, the WINCC OA projects, etc.

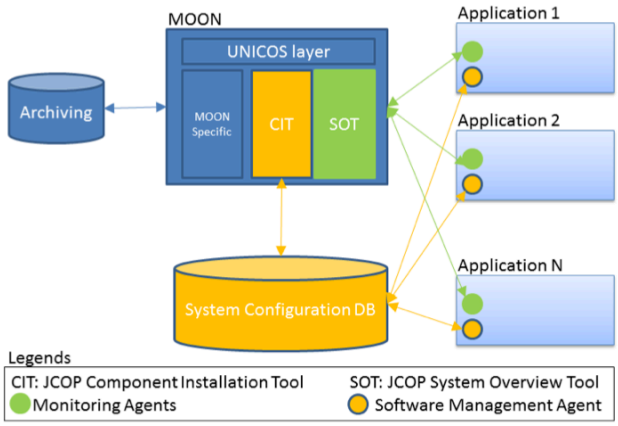

Figure 1: MOON main building blocks.

The state of each node in the tree is characterized by an associated colour. The propagation of the states and associated colours upwards in the FSM hierarchy summarizes the overall state of all monitored applications in a view and provides an intuitive method to locate the components of the control systems experiencing anomalies.

The selection of a node in a tree causes a dedicated panel to be displayed on the right-hand side of the graphical interface. The information displayed in those panels depends on the mode of operation of the tool: run-time monitoring or configuration management. Figure 4 shows an example panel in the former mode where a synoptic view providing a graphical representation of the monitored components, as well as their dependencies and connectivity is shown. In the configuration management mode, the panels display and allow modifying the configuration of the remote applications in a centralized fashion (Figure 5). This mode is restricted to experts by means of a strict access control policy and it is heavily used during technical stop periods of the LHC to upgrade sets of components in groups of applications. The arrangement of the applications in the FSM tree is preserved when toggling between the two modes of operation of the tool.

Each FSM view shows a different level of detail and logical organization of the equipment. As an example, the main view presented to the members of the standby service contains a coarse and simplistic representation of the control applications (e.g. current state and basic information of a device) whereas the expert view holds all required information for an expert to understand the behaviour of the application (e.g. statistics, performance counters).

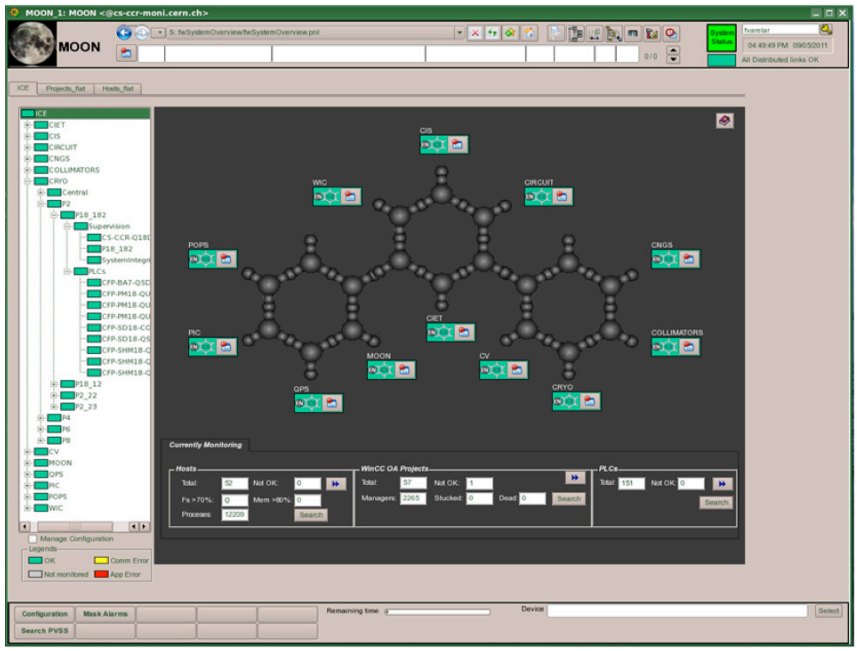

Figure 2: Main graphical interface of MOON showing a summary of the states of the EN-ICE controls applications.

At each level of the trees corrective actions on the remote applications can be taken by experts, e.g. to restart a process or reboot a host.

Problem identification is also complemented by the powerful alarm-handling schema featured by the tool. Besides an overall alarm screen, at each level of a FSM tree, the user can access a preconfigured alarm panel that restricts the alarms displayed to those raised by the equipment and applications in the local FSM sub-tree. Data gathered and alarms raised by MOON are archived to an ORACLE database for offline analysis. Alarms triggered by misbehaving sensors or problems in the readout can be masked by experts. This feature can also be used to prevent alarms from a particular set of applications during planned interventions. In this case, experts may define an expiration date for the masking such that the tool automatically unmasks these alarms at the due date.

MOON also provides a direct link from its alarm screen to the web help procedures written by experts that are associated with an alarm. Moreover, the tool also provides users with access to an electronics logbook to report an incident.

Web reports are generated daily for each application. These reports contain detailed information of the state of the different components integrating the control applications during the last 24 hours. In order to help analysing errors and predicting possible faults, the reports also include statistical data, like the number of occurrences of particular alarm.

System Size and Performance

The system which is currently in production has a considerable size and it is expected that it will grow in the near future (see Table 1). Currently, the parameters monitored by MOON are refreshed every few tens of seconds. However, this interval may be increased as system grows in size. Figure 3 shows the distribution of incidents per application domain over a week. Despite of the high number of incidents detected by the tool, an intelligent filtering schema is applied so that the standby service is notified only in the event of major faults.

Table 1: Monitored Items

Item	Current number	Estimated number	Refresh interval
Application Domains	12	20	N/A
Hosts (cores)	52 (544)	100	30s
PLCs	151	400	30s
WinCC OA applications	57	300	30s
Processes	12177	25000	30s

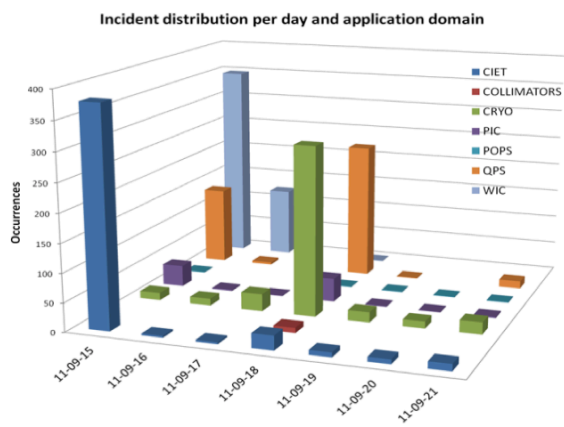

Figure 3: Incidents distribution.

NEXT STEPS

Currently, MOON monitors and provides views for the standby service for most of the EN-ICE WINCC OA applications in the accelerator and technical infrastructure domains. The development plan foresees a continuous upgrade of the tool with an incremental addition of new functionality whilst avoiding any interference with the monitored applications. In particular, a major milestone has been set for the unusually long stop scheduled at the end of 2011 beginning of 2012. During this period, it is planned to complete most of the functionality envisaged for the tool and to extend the range of monitored applications to Experiments. Specific actions include the completion of the expert views, enabling email notifications in the event of alarms, as well as the monitoring of devices and peripheral technical infrastructure, such as network equipment and electrical distribution that, although they are not a direct responsibility of EN-ICE, are vital for the correct operation of the control applications. Moreover, an effort will be made to extend the monitoring to the LabVIEW - based applications developed by the group. Finally, EN-ICE also foresees to offer the tool as a service to other groups at CERN having similar requirements in terms of application monitoring.

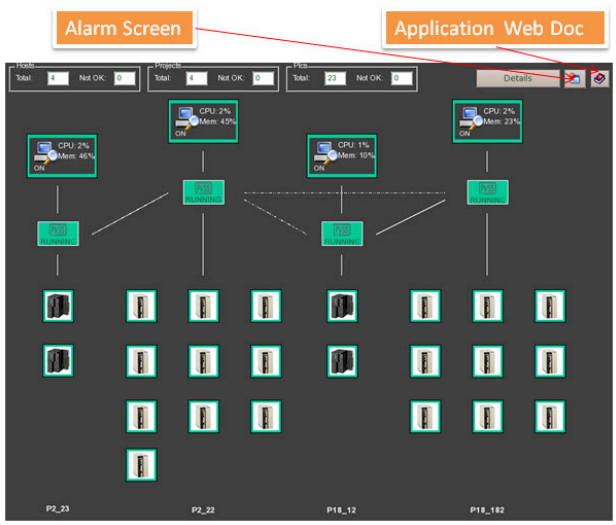

Figure 4: MOON user interface showing the layout of the cryogenics control applications for Point 2 of the LHC.

CONCLUSIONS

The modular design approach of the EN-ICE Frameworks, the clear definition of the user requirements gathered at the initial phase of the project, as well as the consistent model of abstraction the control applications has enabled a rapid development of MOON with limited resources. Although the tool has only recently entered the production phase, it has already shown its power to assist experts and members of the standby service in their daily work. A number of centralized upgrades have been successfully performed using the tool leading to a significant reduction of the time required for these interventions thus increasing work efficiency. Moreover, MOON has now become the primary tool for the members of the standby service to understand the behaviour of the control applications. The tool has successfully operated with no interference on the monitored applications since its initial deployment. For these reasons, MOON is already contributing its grain to maximize the Physics usage of the LHC by reducing the reaction time in the event of problems in the EN-ICE applications that control critical processes for the operation of the machine and the experiments.

INFRASTRUCTURE OF TAIWAN PHOTON SOURCE CONTROL NETWORK

Y. T. Chang, C. H. Kuo, Y. S. Cheng, Jenny Chen, S. Y. Hsu, C. Y. Wu, K. H. Hu, K. T. Hsu
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

A reliable, flexible and secure network is essential for the Taiwan Photon Source control system which is based upon the EPICS toolkit framework. Subsystem subnets will connect to control system via EPICS based CA gateways for forwarding data and reducing network traffic. Combining cyber security technologies such as firewall, NAT and VLAN, control network is isolated to protect IOCs and accelerator components. Network management tools are used to improve network performance. Remote access mechanism will be constructed for maintenance and troubleshooting. The Ethernet is also used as fieldbus for instruments such as power supplies. This paper will describe the system architecture for the TPS control network. Cabling topology, redundancy and maintainability are also discussed.

INTRODUCTION

Taiwan Photon Source (TPS) [1] will be the new 3 GeV synchrotron radiation facility to be built at National Synchrotron Radiation Research Center, featuring ultra-high photon brightness with extremely low emittance. The construction began in February 2010, and the commissioning is scheduled in 2014.

The control network is used for the operations of accelerators and beamlines. TPS control system will be implemented using the Experimental Physics and Industrial Control System (EPICS) [2] software toolkit. Control devices are connected by the control network and integrated with EPICS based Input Output Controller (IOC). The control network will be a 1-Gbps switched Ethernet network with a backbone at 10-Gbps.

INFRASTRUCTURE

The main goal of this planning is to build a reliable, agile and secure network for TPS control system. The design will provide enough flexibility and scalability for future expansion. [3]

Accelerator operators are the principal users of the control system. Control consoles with remote multi-display will be used to manipulate and monitor the accelerator through network. For remote monitoring and control Taiwan Light Source (TLS) facility, dedicated control consoles are planned to be installed in TPS control room.

Control System Computer Room contains EPICS control servers, database servers, control console computers, and network equipments. Network services will be available at the control room, control system computer room, 24 Control Instrumentation Areas (CIA), linear accelerator equipment area, transport lines, and main power supply equipment room which are distributed along the inner zone just outside of the machine tunnel. Each CIA serves for one cell of the machine control and beamline interface. Major devices and subsystems connected to the control system are installed inside CIAs.

Control network connects to NSRRC campus network through a firewall with Network Address Translation (NAT) function. Segregating the network will strengthen the security for those devices that need additional protection and high availability. Network traffic burden will also be lowered by isolating from general purpose network. Remote access mechanism will be constructed for maintenance and troubleshooting.

Connection to TLS control network is required for remote operations of the TLS facility. Control system laboratories for software development and hardware maintenance are also connected with the control network. The TPS control network infrastrcture is shown in Figure 1.

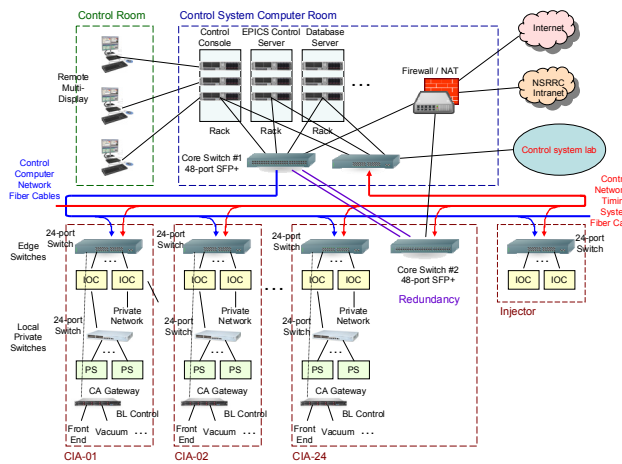

Figure 1: TPS control network infrastrcture.

A high performance switch with 48 10-Gbps fiber ports will be defined as the core switch. Two core switches will be used for redundancy, one is located inside the Control System Computer Room and the other is located inside CIA #24. Optical fiber links between core and edge switches are matched up with redundant cabling structure.

There are two types of switches be used in every CIA. The first type is defined as the edge switch which is used to connect IOC nodes and uplink to the high-speed backbone through 10-Gbps fiber uplinks. A 24-port 100/1000BASE-T switch with 2 10-Gbps fiber uplink ports wil be selected as the edge switch.

The second type is defined as the local private switch which is used for local private network to connect control devices such as power supplies and uplink to the IOC nodes. Depending on the needs, a variety of low cost Ethernet switches will be used as the local private switch.

Considering the budget, only one core switch will be used in Phase I. The redundancy structure will be implemented later in Phase II. But the fiber cabling for redundancy will be ready in Phase I. Figure 2 shows the baseline plan of the TPS control network.

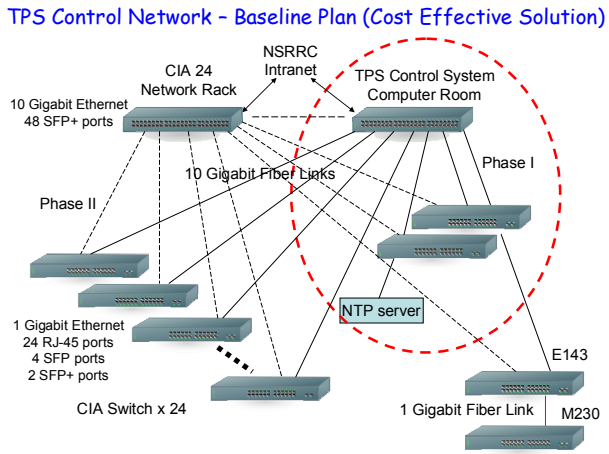

Figure 2: TPS control network – baseline plan.

SUBSYSTEM SUBNET

One Class B private network will be used for IOC network. Because there is a huge number of netwroked devices which scatter over a vast area (e.g. 24 CIAs), the IP addressing schema will be easy to identify the locations of IOCs and devices. This will be helpful to speed up finding the devices for maintenance and troubleshooting. This Class B private network will use IP range 172.20.xx.yy which xx represents locations (e.g. number of CIA) and yy is for functional groups.

There are multiple Class C private networks for respective subsystems, such as BPM IOCs, power supplies, motion controllers, GigE Vision, etc. These Class C private networks will use IP range 172.21.xx.yy which schema is also the same as above. Access of these Class C private networks might connect to the the VLAN router to provide access possibility.

Highly reliable Ethernet will be heavily used as fieldbus in the TPS control system. Power supplies for dipole, quadrupole and sextupole are connected to the EPICS IOCs by Class C private Ethernet within the CIAs.

Miscellaneous instruments will connect to the control system IOC located at each CIA via Ethernet also, such as LXI instruments, temperature/voltage monitors, etc. All of these devices might comply with LXI standard or not.

Orbit data is the most important operation information and should be captured in 10 Hz rate without interruption. In order to provide better service for this, a dedicated Class C subnet is planned for BPM IOCs. A CA gateway will connect with the BPM network to the TPS control network.

EPICS based CA gateway will provide necessary connectivity and isolation. Its functionality is to forward channel access to different network segments. It can also reduce network traffic and provide additional access security.

GigE Vision for diagnostics is based on the Internet Protocol standard and can be adapted to EPICS environment. Also, the images can be easily accessed through network for machine studies. The GigE Vision cameras can connect to control system through Ethernet with the data transfer rate up to 1000 Mbits/s. For decreasing traffic loading, one Class C private network and one CA gateway will also be used for the GigE Vision cameras to connect with the control system.

Subsystems such as vacuum, front-end, beamline control, and utility can access process variables of accelerator control system via CA gateways. It is expected that every beamline will have a Class C private network for their control system, data acquisition, and endstation applications. The beamline EPICS control environment will connect to the machine control system via CA gateway at each CIA. This design will provide necessary connnectivity between the machine control system and beamline control system and also restrict unnecessary network traffic across different network segments. The relations between the machine control system and beamline control do not clearly defined at current stage.

IP technology will be heavily used in the TPS control system. For providing more convenient environment for system maintenance, IP based cameras for area monitoring, phones, pagers are planned to attach to a Class C private network. This network will connect to the control network via a CA gateway and/or VLAN mechanism to the NSRRC intranet for saving network bandwidth.

For miscellaneous devices, the same principle will be adopted. The cabling scale will be downsized by using CA gateways and VLAN routing mechanism.

CABLING

For the long distance (> 100 m) networking, single-mode fiber (SMM) in the category G652.D will be used for cost consideration. There are two SMM cabling distribution links. One of the links is for control computer network only, the other is for control network and timing network dual function fiber pairs in one fiber cable.

The fiber cables for the control computer network will distribute from the Control System Computer Room and surround half of the ring clockwise and counterclockwise to every CIA. Then Copper STP/UTP cables are used to connect CIA edge switches to various IOCs and network attached devices within the same CIA. The fiber cabling for control computer network is shown in Figure 3.

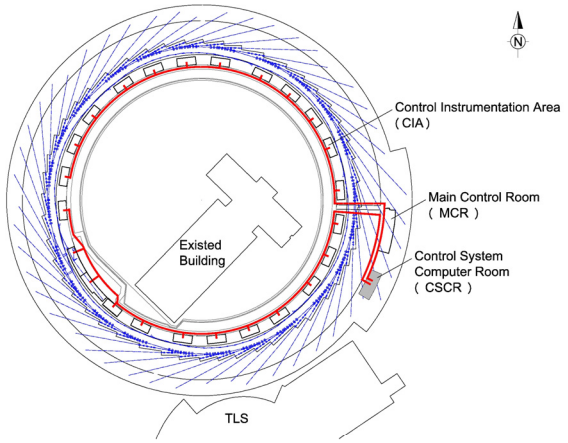

Figure 3: Fiber distribution for control computer network.

Since the timing master is located inside CIA #24, the fiber cables for control network and timing system will distribute from the CIA #24 to every CIA and Control System Computer Room. For receiving timing signals synchronously, the length of fiber cables will be equal. Besides, one fiber pair will be used as the redundancy for the control computer network. The fiber cabling for control network and timing system is shown in Figure 4.

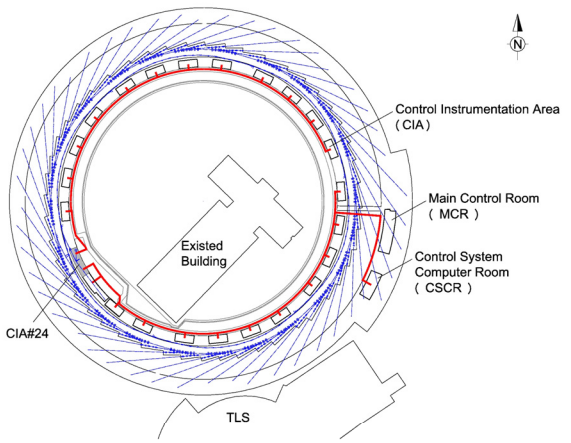

Figure 4: Fiber distribution for control network and timing system which strated form CIA #24.

NETWORK MANAGEMENT

Spanning Tree Protocol (STP) or Rapid Spanning Tree Protocol (RSTP) will be configured to implement redundancy. Network monitoring software (e.g. MRTG) will be used to show traffic and usage information of the network devices. By collecting and analyzing the packets, it can measure the traffic and usage to avoid bandwidth bottlenecks..

It is necessary to access the control system from outside in case of machine problems. Remote maintenance or troubleshooting has the advantages of convenience and time-saving. There are many ways to configure the network to enable remote access. Network tunneling tools, such as Virtual Private Network (VPN), can be used to penetrate the firewall system of the protected network. It can establish an encrypted and compressed tunnel for TCP or UDP data transfer between control network and public networks inside or outside the TPS. Providing a reliable authentication mechanism is also essential to remote access the control network.

The Network Time Protocol (NTP) servers are needed for timekeeping. NTP is used for synchronizing the clocks of computer systems over the TPS control network within 10 ~ 100 millisecond performance.

Using Simple Network Management Protocol (SNMP), the behaviour of network-attached devices can be monitored for administrative attentions. Since the TPS control system is based upon the EPICS framework, a dedicated EPICS IOC with SNMP support will be used to monitor the status of control system components such as CompactPCI (cPCI) IOC crates, network switches, servers, Uninterruptible Power Supplies (UPSs), etc. The equipment room environment such as temperature and electric power will also need to be watched. [4]

CYBER SECURITY

Current accelerator control systems are commonly based on modern Information Techonolgy (IT) hardware and software, such as Windows/Linux PCs, PLCs, data acquisition systems, networked control devices, etc. Control systems are correspondingly exposed to the inherent vulnerabilities of the commerial IT products. Worms, viruses and malicious software have caused severe cyber security issues to emerge.

It is necessary to use network segregation to protect vulnerable devices. Combining firewall, NAT, VLAN… technologies, control network is isolated to protect IOCs and accelerator components that require insecure access services (e.g. telnet).

Firewall only passes the packets from authorized hosts with pre-defined IP addresses outside control network and opens specific service ports for communications. But firewall is not able to resist the spread of worms. Worms are not only designed to self-replicate and spread but also consume the network bandwidth. Thus security gateway or IPS (Intrusion Prevention System) is needed to block worm attacks and quarantine suspicious hosts. IPS can detect and stop network threats such as worms, viruses, intrusion attempts and malicious behaviors.

Remote access mechanism needs network tunneling applications to bypass the firewall. It will provide a private tunnel through the public network for remote access to the control network. The remote access mechanism also requires appropriate types of protection and control. It must be enhanced with a reliable user authentication mechanism for full security.

Security will always put at the highest priority for the TPS control system. Security policy for control network is essential. Regulations should be defined for the accelerator scientists and engineers to access the control system. It's everyone's responsibility to protect the

infrastructure. However, balance between security and convenience will be addressed also.

SUMMARY

This report describes the infrastructure of the TPS control network. An adaptive, secure and fault-tolerant control network are essential for the stable operation of the TPS. The control network will be separated from the NSRRC campus general purpose network for imposing security. Subsystem subnets will connect to control system via CA gateways for forwarding data and reducing network traffic. Two fiber cabling distributions are described. Network management tools will be used to enhance productivity. Remote access mechanism with proper authentication will be implemented for system maintenance or troubleshooting. An infrastructure monitoring system is planned to adopt the EPICS and SNMP. Cyber security will be the most concern.

DISTRIBUTED MONITORING SYSTEM BASED ON ICINGA

C. Haen*, E. Bonaccorsi, N. Neufeld, CERN, Geneva, Switzerland

Abstract

The LHCb online system relies on a large and heterogeneous IT infrastructure: it comprises more than 2000 servers and embedded systems and more than 200 network devices. Many of these equipments are critical in order to run the experiment, and it is important to have a monitoring solution performant enough so that the experts can diagnose and act quickly. While our previous system was based on a central Nagios server, our current system uses a distributed Icinga infrastructure. The LHCb installation schema will be presented here, as well some performance comparisons and custom tools.

INTRODUCTION

LHCb [1] is one of the four large experiments at the Large Hadron Collider at CERN. The infrastructure of networks and servers deployed in order to manage the data produced by LHCb and control the experiment are critical for its success. While for the control and monitoring of detectors, PLCs, and readout boards an industry standard SCADA system PVSSII has been put in production, at a lower level the network infrastructure and resources used by each server in the LHCb Cluster need to be monitored. This is because the PVSSII in the ECS (Experiment Control System) depends already on a lot of systems such as the shared storage, the network, DNS (Domain name Server) and others. In monitoring terminology, one uses 'host' to refer to a machine such as a server, and 'service' to refer to all kind of software, application or resource like CPU or disk space, etc. A 'service' is then applied to an 'host'. Over time, the amount of services and hosts to be monitored increased up to the point where the previous monitoring system shown on Fig. 1 based on Nagios [2] did not perform sufficiently, and we decided to search for a more scalable solution.

INSUFFICIENT PERFORMANCES

Nagios monitors hosts and services with tiny single-purpose programs called plugins that are executed periodically in order to get the status of a monitored entity [3] (host or service). Basically, executing a plugin consists in forking, creating and closing a socket. Thus, monitoring 40 000 entities induces a huge load on the central server running Nagios [4]. The result is a big latency in the checks and then in the alerts received by the experts.

* christophe.haen@cern.ch

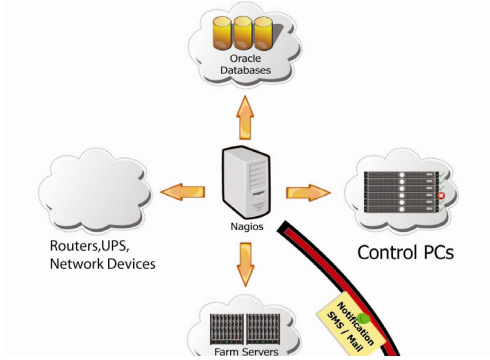

Figure 1: The previous Nagios installation.

NEW INFRASTRUCTURE

In order to improve our system, two changes took place: replacing Nagios by Icinga [5]; and going from a central to a distributed architecture.

Icinga is a fork of Nagios. There are several reasons to motivate the choice to switch:

- The support of the Icinga community is better.
- Extra features [6]: among them, the possibility of using a database as backend which can be queried with an API. This is particularly interesting regarding some other projects on going at LHCb.
- Nagios configuration files are compatible with Icinga.

Going for a distributed system is an obvious solution to avoid the bottleneck presented in the previous section. Three different possibilities to distribute our monitoring have been explored.

Independent Icinga Instances

The first option is to have several independent Icinga instances running, each of them monitoring a specific group of entities. The major drawback of that solution is the difficulty to have a redundancy in the checks: having the same checks executed by different instances would mean having all the alarms several times, since there is no information sharing between the instances.

Central Instance with Distributed Instances

In this setup, several instances would monitor specific entities, but they would all report to a central instance, whose goals are only to gather the check results, display it to the users, and trigger the notifications. This setup is possible with Icinga core [7]. If one of the distributed instance is dead, the central server will actively do the test,

thus ensuring redundancy for the distributed nodes. This solution has been seriously considered, but the configuration becomes complicated when you have many entities to monitor: the central server has to know all the entities, but each distributed server has to know only its own. In order to balance the drawback of this setup we developed a few tools to ensure consistency and dependencies:

- Oracle database backend: the database schema can be used to store a complete configuration for Icinga.
- Web frontend: based on symfony [8], this tool provides a global overview of the configuration, and allows non experts to use the monitoring services, by defining their own entities.
- Generation tool: thanks to a set of perl scripts, the configuration is extracted from the database, written in files readable by Icinga, and properly shared between the Icinga instances.

Even by using these tools, the management of large amount of entities was difficult: the frontend performances were not good enough to cope with our large installation. For this reason, we decided to give up that solution.

Central Icinga Instance with Distributed Workers

The third option is to have a single instance of Icinga which would schedule the checks and deal with the results, but having other servers (called 'workers') actually perform the checks. This is made possible by mod_gearman [9], an Icinga/Nagios broker module. The load induced on the worker is negligible, whereas the central server is fully busy. Mod_gearman is a module based on Gearman [10], a generic framework to distribute applications. It uses a client/server model as shown in Fig. 2. The server manages queues that clients use to get their tasks and give their results.

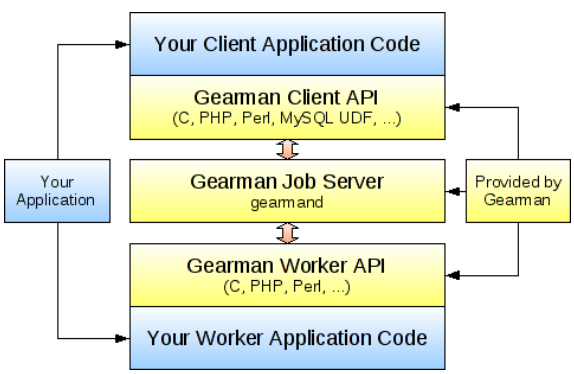

Figure 2: Gearman Stack.

Mod_gearman intercepts the checks triggered by Icinga, and puts them into queues managed by Gearman. The client side is a light weight program which simply gets the path of the executable, runs it, and put the result back in a result queue on the server side. Note that the executables need to be present on all workers. The elements in the result queue are then passed to Icinga, which processes them as if it had executed the checks itself.

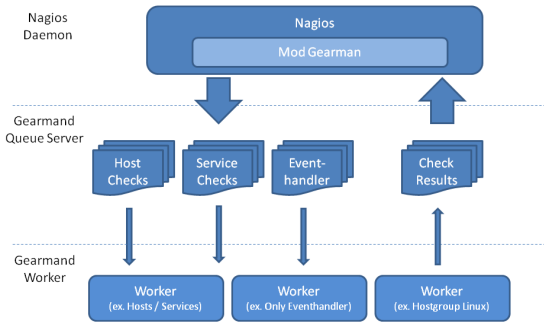

Figure 3: Mod gearman.

By default, all the checks are put in the same default queues showed in Fig. 3. This can be a problem if some workers cannot access the machine they should check, for network security reasons for example. To solve this issue, mod_gearman offers to put checks in separate custom queues, according to the group they belong to. These groups are groups of hosts or services defined in the Icinga configuration files: one can define one group for each separate network, and configure workers to fetch checks only from appropriate queue.

This is the solution we decided to implement in LHCb, and coupled it with a configuration schema described in the next section.

The other interesting feature proposed by Icinga is the database backend. With the idomod and ido2db modules [11], Icinga will log the result of every action and check-result in a database. The information can then be queried using a PHP API. This is a remarkable tool to use the Icinga results as input for other projects. Unfortunately, we found a deadlock in ido2db, for which a ticket has been open, which make it unusable for the moment.

Finally, to make sure we can always access our monitoring services, the server running Icinga is connected to the LHCb network and to the CERN network. Thus, even if a big network problem occurs in LHCb, the monitoring information can still be accessed through independent networks.

NEW SCHEMA

The whole LHCb infrastructure is made up of thousands of machines. We can divide in groups which are doing the same tasks, and thus must be monitored the same way.

Rewriting all the time the same complete configuration file for the different machines would be extremely tedious and error-prone. Fortunately, one can use two features offered by Icinga to avoid that:

- Hostgroup: an hostgroup simply defines a group of hosts. A host can be in several hostgroups, and a hostgroup can be member of another hostgroup.
- Inheritance: a host can inherit the configuration of another host, in the manner of the object oriented programming paradigm. The inheritance will only carry over the host monitoring options, not the services applied on the parent host. For example, the child will inherit the check frequency from its parent, but the service checks that are applied to the parent will not be applied to the child.

Thus by defining precisely the roles of all the machines, one can come up with a complete logical tree like in Fig. 4, which is then implemented as two separate but homeomorph trees. The first one is made of hostgroups: each node is member of the parent node. The service checks are always applied to a hostgroup in this tree, and never to a single host. The second tree is implemented with hosts, and each node inherits from its parent node: each level brings more specialized options, and the leafs of the tree are the machines themselves.

- Adding a new host consists in defining a name and an address, assigning it to the right hostgroup and inheriting from the right template (both being at the same in the logical tree). It will then be monitored exactly the same way as all the machines having the same role.
- Changing the way a functional group of machine is monitored is done by changing a single configuration file: for example, one can add a new service check on all of the file servers by adding this check only once to the hostgroup containing all the file servers.

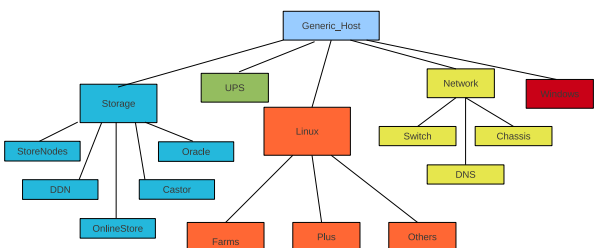

Figure 4: Part of the tree used to define configuration.

NEW PERFORMANCES

The new installation shown in Fig. 5 is now running 36000 service checks on 2100 hosts, with 50 gearman workers, and the performances are now on average 2760% better, as shown in Tables 1 and 2:

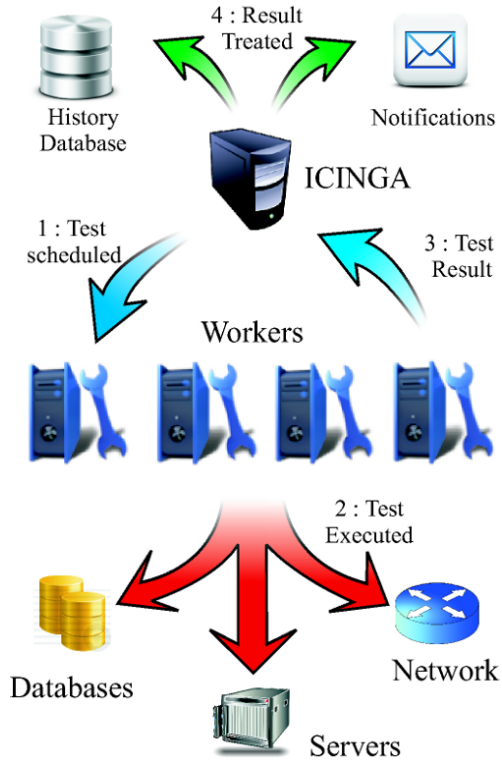

Figure 5: The new LHCb Icinga infrastructure.

Table 1: Single Nagios Instance Performances

	Min.	Max.	Average
Service checks latency	320 sec	578 sec	328 sec
Host checks latency	0 sec	401 sec	318 sec

Table 2: Central Icinga Instance and Distributed Workers Performances

	Min.	Max.	Average
Service checks latency	0.03 sec	57 sec	14 sec
Host checks latency	0 sec	35 sec	12 sec

The latency represents the difference of time between the scheduled execution time of the check, and the actual execution time.

CONCLUSION

Icinga has been running for two months in parallel with Nagios. The notifications have always been quicker and more up to date. We retired Nagios a month before this paper has been written.
In addition to that, the way our workers are spread over

the LHCb network, and the way the central Icinga server is connected to the external network ensures to have in almost any case access to our monitoring information.
Nevertheless, the central Icinga instance is still a single point of failure. A solution for this could be to set up a cluster of identical machines running in active-passive mode: if the server running the central Icinga instance crashes, a fail-over will happen and another server will take over.

EFFICIENT NETWORK MONITORING FOR LARGE DATA ACQUISITION SYSTEMS

D.O. Savu, B. Martin, CERN, Geneva, Switzerland
A. Al-Shabibi, Heidelberg University, Heidelberg, Germany
R. Sjoen, University of Oslo, Norway
S.M. Batraneanu, S.N. Stancu, UCI, Irvine, California, USA

Abstract

Though constantly evolving and improving, the available network monitoring solutions have limitations when applied to the infrastructure of a high speed real-time data acquisition (DAQ) system. DAQ networks are particular computer networks where experts have to pay attention to both individual subsections as well as system wide traffic flows while monitoring the network. The ATLAS Network at the Large Hadron Collider (LHC) has more than 200 switches interconnecting 3500 hosts and totaling 8500 high speed links. The use of heterogeneous tools for monitoring various infrastructure parameters, in order to assure optimal DAQ system performance, proved to be a tedious and time consuming task for experts. To alleviate this problem we used our networking and DAQ expertise to build a flexible and scalable monitoring system providing an intuitive user interface with the same look and feel irrespective of the data provider that is used. Our system uses custom developed components for critical performance monitoring and seamlessly integrates complementary data from auxiliary tools, such as NAGIOS, information services or custom databases. A number of techniques (e.g. normalization, aggregation and data caching) were used in order to improve the user interface response time. The end result is a unified monitoring interface, for fast and uniform access to system statistics, which significantly reduced the time spent by experts for ad-hoc and post-mortem analysis.

INTRODUCTION

At the core of the ATLAS DAQ infrastructure there are 3 distinct computer networks responsible for the data transfers between the system's subcomponents. More than 200 switches and routers interconnect around 3500 hosts to build a real-time filtering system for particle collision events.

The ATLAS Networking Team's operational goals are to prevent network downtime and to be able to track down ad-hoc or post-mortem network issues as fast as possible. A complex software solution has been developed to help networking experts accomplish their goal while providing relevant and up-to-the-minute system information for other related DAQ teams.

The network monitoring software is designed as a modular solution around a central database (N-CDB). The N-CDB acts as a shared data structure for the various modules and is implemented as a core relational database with external binary file extensions. The most important software modules (Figure 1) are:

- **Topology Consistency:** responsible for keeping an up-to-date database representation of network devices, computers, connections and geographical location;
- **Statistics Collection:** gathering any network traffic related statistics and making the data available to other modules through the N-CDB;
- **The ADAM API:** a programmatic way of accessing the database data by external programs or scripts;
- **The User Interface:** a set of web-based applications to make all the information available in a structured and easy to navigate way;
- **Self-check module:** a warning mechanism sending detailed mail messages to experts about any module not functioning as expected.

TOPOLOGY CONSISTENCY

An accurate representation of installed devices and network connections in the N-CBD is assumed by every module and is critical for the system's operation. To keep the topology representation up to date, a full network discovery process is run periodically and is complemented by additional data. The discovery is then deployed in the production system through a semi-automatic procedure involving expert approval for topology changes.

The network discovery is primarily MAC address based, being able to identify network device uplinks and end node connections by inspecting the MAC address tables of network devices. Since the MAC address tables are dynamically populated by the traffic traversing network devices, it is essential to run the discovery when all the devices have generated traffic. Thus it is most efficient to run a discovery either during data taking, when almost all devices have network activity, or immediately after an induced ARP* broadcast event.

A network discovery based on MAC address tables or LLDP[#] does not reveal the nodes' function or geographical location. To extend the discovery knowledge with such complementary data, information from external databases is used and cached by the N-CDB. The purpose of the N-CDB cache is to avoid any run-time dependency and overloading of external databases.

*Address Resolution Protocol
[#] Link Layer Discovery Protocol

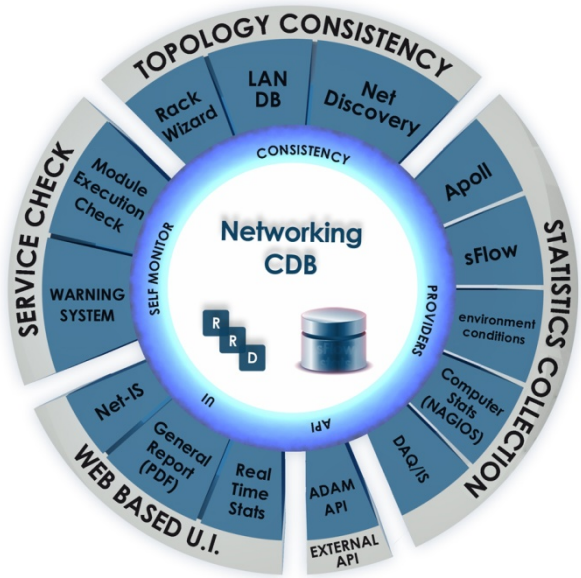

Figure 1: Diagram of the network monitoring software modules.

Such external databases include Atlas RackWizard, for geographical location, Sysadmin ConfDB, for functional host name mappings and IT LanDB, for auxiliary host mapping.

STATISTICS COLLECTION

Gathering statistics about traffic flows and network state is mandatory for monitoring the system's performance. The network overview statistics are the primary source of information for investigating most network problems. These statistics are collected by APoll, an internally developed software which polls SNMP counters from switches and routers every 30 seconds. Once a network issue is isolated, an in-depth analysis is performed by looking for relevant traffic samples collected via the sFlow protocol.

APoll, the high speed SNMP poller, has been developed by the networking team to address the limitations of commercial software used in production. It is implemented as a multi-threaded C++ application that dynamically adapts its number of threads to the number and responsiveness of the network devices. The run mode can be configured either as standalone, dumping basic traffic log files, or integrated mode when last minute statistics are synchronized with the N-CDB.

The SNMP* counter statistics, due to their time-series format, are stored in a structured set of Round Robin Database (RRD) binary files. The files are referenced by the metadata in N-CDB and accessed directly via the RRD library. A copy of the RRD files for the last 72 hours is also stored on a ramfs partition to reduce the I/O to non-volatile storage and improve application response. Additionally, the last SNMP counter values are stored in a N-CDB in-memory table. The table is used as a shared resource between all the applications that need or provide real-time data.

The sFlow sample data, on the other hand, does not resemble a standard time-series format. To efficiently store the sFlow gathered data, a tool is used to aggregate it over 1 minute time intervals and store it in a MySQL relational database. Then, various database tuning techniques are used to improve the response time.

Sometimes external factors, such as environmental conditions or faulty systems, affect the network's normal behaviour. Making information from directly related systems available to network monitoring modules gives the networking team an advantage in understanding and limiting the impact of an external event. Currently, full or partial information from NAGIOS (computer monitoring), PVSS (environmental conditions database) and DAQ/IS (data-taking information service) is accessible through the same user interface used for network monitoring. Examples of such external factors include rack power failure causing device crash events or DAQ data-taking process causing network discarded packets.

THE ADAM API

The information stored in the N-CDB is also of interest to shifters and system analysts. To facilitate programmatic access to information, a generic interface for data exchange has been implemented. The creation of a generic interface has been a joint effort between several ATLAS teams and lead to the definition of the ADAM (ATLAS Data API Mechanism) data exchange interface.

The ADAM API is fully implemented in the network

* Simple Network Management Protocol

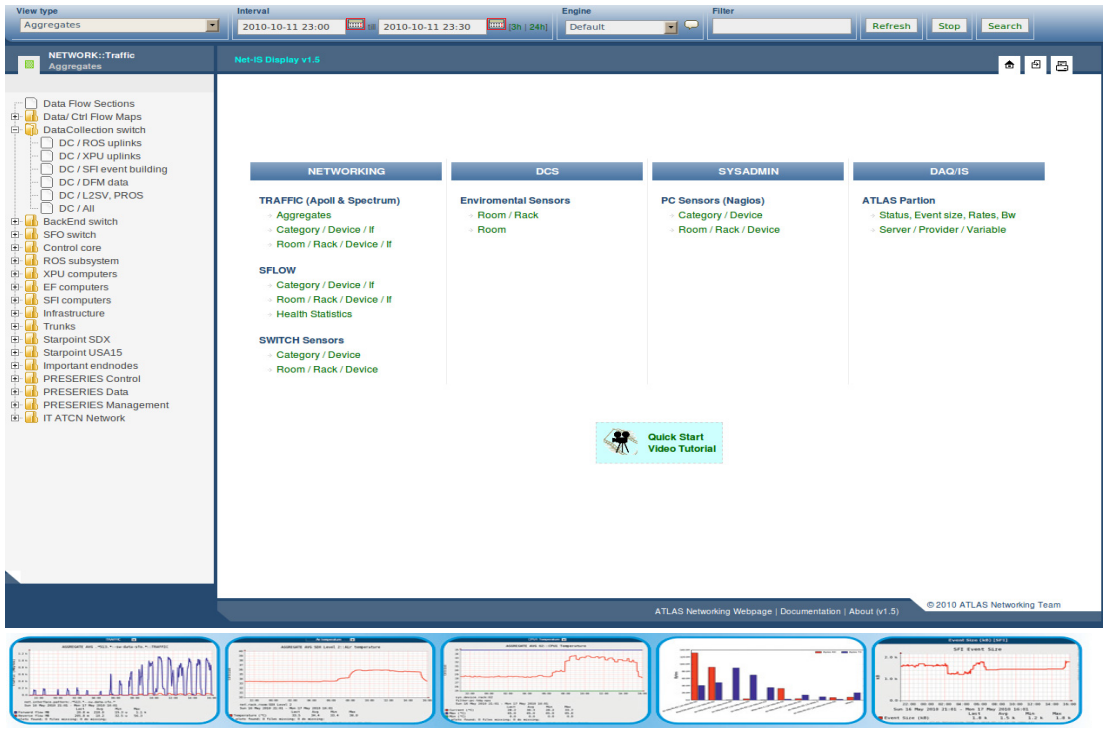

Figure 2: Main page of the Net-IS user interface providing access to historical statistics.

monitoring solution and provides network traffic, computer statistics and environmental conditions to external applications on demand. Through this API the network monitoring software can be a data provider for other external data analysis applications, and is currently used in the ADAM User Interface project.

THE USER INTERFACE

The user interface is designed to provide all the data an expert needs to investigate a problem and yet be simple to use for non experts. A set of web-based applications, integrated as a portal, offers access to real-time reports and historical statistics about network state and complementary systems. For offline visualization of the current topology a comprehensive PDF report is generated daily and made available for download.

The Net-IS web application (Figure 2) is the main networking interface used by experts and shifters. It provides direct access to any historical statistics through a single interface with the same look and feel regardless of the data source. The statistics can be grouped to match predefined or custom rules via an aggregation layer based on regular expressions.

The Net-RT web application provides real-time statistics about any network device or network traffic. Various table-based reports, as well as a 2D map displaying network uplinks load, are updated in real-time according to the N-CDB in-memory table.

A different option to access the N-CDB data is through a Command Line Interface (CLI). The CLI tool was developed to allow experts to access and change the N-CDB data manually without the risk of affecting its low level consistency.

The user interface has been described in more detail in the "Integrated System for Performance Monitoring of the ATLAS TDAQ Network" paper, published in the Proc. Computing in High Energy Physics 2010.

SELF-CHECK MECHANISM

The reliability of the system may be affected by a misbehaving module. The purpose of the self-check mechanism is to identify and inform experts in real-time about any faulty modules. To make the self-check mechanism more robust, the checking of module execution status and the mail reporting have been implemented as two distinct components.

The execution status check is implemented using a set of scripts that monitor each module's functionality and expected results, and then report the status to the N-CDB. If a check script fails to execute within a timeout period, it will flag this problem to the warning component. A module can also flag a warning and send a detailed message if it anticipates an imminent problem likely to require expert intervention.

The warning component then checks all the active module status information and sends error-triggered and daily service status mail reports.

CURRENT STATUS AND FUTURE PLANS

Started as an independent network monitoring software, the current ATLAS DAQ network monitoring solution has grown by integrating additional system information.

This extension improved the understanding of overall system behaviour by enabling the correlation between networking events and external factors. Two years after its deployment it is the main tool used by both experts and non experts to analyze network problems. It has proven to be more efficient compared to the alternate commercial solution when it comes to performance monitoring.

Future plans to improve the current solution include the extension of the N-CDB by storing network event logs from multiple sources and the addition of an event processing engine. Such a feature will bring together the network events signalling a state change, with the collected statistics that provide a more complete picture of the circumstances associated with the generated event.

VIRTUALIZATION FOR THE LHCB EXPERIMENT

E. Bonaccorsi, L. Brarda, M. Chebbi, N. Neufeld, CERN, Geneva, Switzerland
F. Sborzacchi, INFN, Laboratori Nazionali di Frascati, Italy.

Abstract

The LHCb Experiment, one of the four large particle physics detectors at CERN, counts in its Online System more than 2000 servers and embedded systems. As a result of ever-increasing CPU performance in modern servers, many of the applications in the controls system are excellent candidates for virtualization technologies. We see virtualization as an approach to cut down cost, optimize resource usage and manage the complexity of the IT infrastructure of LHCb. Recently we have added a Kernel Virtual Machine (KVM) cluster based on Red Hat Enterprise Virtualization for Servers (RHEV) complementary to the existing Hyper-V cluster devoted only to the virtualization of the windows guests. This paper describes the architecture of our solution based on KVM and RHEV as along with its integration with the existing Hyper-V infrastructure and the Quattor cluster management tools and in particular how we use to run controls applications on a virtualized infrastructure. We present performance results of both the KVM and Hyper-V solutions, problems encountered and a description of the management tools developed for the integration with the Online cluster and LHCb SCADA control system based on PVSS.

INTRODUCTION

LHCb is an experiment set up to explore what happened after the Big Bang that allowed matter to survive and build the Universe we inhabit today, in the specific is a dedicated heavy-flavour physics experiment designed to perform precise measurements of CP violation [1]. The experiment is located at point 8 of the LHC particle accelerator.

The LHCb online system has been designed to run completely isolated and independent, as an autonomous system, it consist of ~2000 physical servers and embedded systems interconnected through 3 main high density routers and ~100 distributions switches.

Hosts are organized in two different local area networks: the Experiment Control System (ECS) [2], illustrated in Figure 1 and the Data Acquisition System (DAQ). The access to the CERN General Purpose Network (GPN) and consequently to internet is provided by Linux and Windows gateways which are secured by a three tier firewall setup.

While the DAQ hosts have been designed to discern the "potentially interesting event" from the huge amount of data produced by the hadrons collisions, zero-suppressed in the front-end electronics [3], the ECS network has been designed to control the experiment, mainly using open sources software wherever possible and the standard LHC SCADA system PVSS in order to control and monitoring high and low voltages, gas and temperatures, etc.

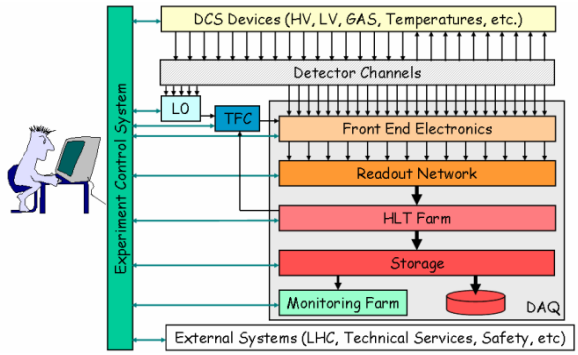

Figure 1: ECS Diagram.

Unlike the DAQ hosts the ECS hosts most of the time underuse resources (with some peak time to time) in terms of memory, network, power, cooling and space.

Taking into account that servers are becoming increasingly powerful, the use of the many-core CPUs accentuates this issue.

Virtualization has in principle a great promise for a control system like ours. It can save power and space and in the long run also money. At the same time it increases the availability and serviceability by abstracting software services from the underlying hardware. However, as we had to learn, the initial investment is rather high and many things have to be taken into account.

The LHCb online team has performed an evaluation of available clustered virtualization implementations focusing mainly on the free edition of Microsoft core Hyper-V [4].

The first part of the project was focused on the virtualization of the public web services and the essential infrastructure services summarized in Table 1.

In this paper we describe further work were we had add a virtualization implementation based on Linux KVM and Red Hat Enterprise Virtualization (RHEV).

Our plan is to migrate from the Microsoft Hyper-V infrastructure to the RHEV infrastructure as well as the deployment of virtual "experiment control PCs", in charge of controlling the detector hardware.

Table 1: Virtualized Systems

Category	Virtualized Systems
Public available	Web Services
Common infrastructure	Firewall, DNS, Domain Controllers, Cron system, DHCP
ECS	Control PCs
Test systems	Dedicated control PCs for testing software and procedures

HYPERVISORS

The hypervisor, also called virtual machine monitor, is a virtualization platform that allows multiple operating systems to run on a single host at the same time.

In the initial part of the study Microsoft Hyper-V had been chosen as hypervisor mainly because the virtualization technology offered by Red Hat/Scientific Linux was in a transition state from XEN to KVM.

A three nodes RHEV cluster has been tested and put into production in parallel with the Hyper-V cluster. The RHEV architecture is illustrated in Figure 2.

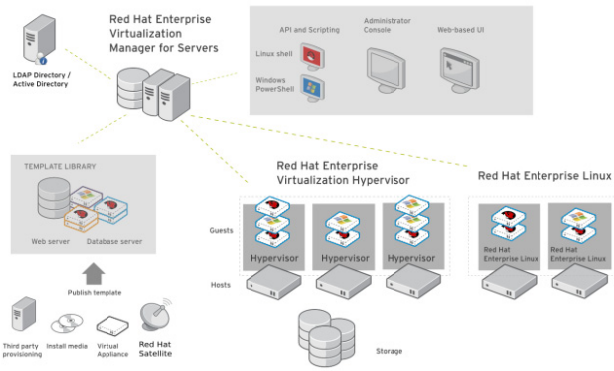

Figure 2: RHEV Architecture.

HARDWARE

The RHEV implementation has been deployed on the same hardware used for the first one and upgraded in terms of memory. The specifications about the memory and the I/O cards are summarised in Table 2.

Table 2: Hardware Specifications

CPU	2 x E5530 @ 2.4 GHz (8 real cores + Hyper Threading)
Memory	6 x 8 GB = 48 GB RAM
Network adapters	2 x 10 Gb network interfaces (for VLAN sharing, 1 linked to ECS) 2 X 1 Gb network interfaces (1 linked to CERN GPN, 1 used for cluster communications)
Fibre channel adapters	2 X 8 Gb Fiber channel switches (linked to two isolated fabrics)

STORAGE AREA NETWORK (SAN)

Virtual disks are stored on a DDN 9900 shared storage system as logical volumes (LV) interconnected through a redundant multipath fibre channel.

The DDN 9900 storage controllers can reach a high level of throughput using a proprietary RAID level called "Direct RAID": each RAID set consist of 10 spindles (disks), of which 8 are used for the data and 2 for the parity.

Three SATA RAID sets ("tiers") and one small SSD RAID set have been exported to the RHEV cluster and configured as a single Volume Group (VG).

The preferable block size for the Logical Units (LUN) in the RAID set is a multiple of 4 Kilobyte (512 Bytes times 8 disks), but unfortunately this value is not supported either by both Hyper-V nor by RHEV, which force us to use a LUN block size of 512 Bytes with the consequential lost of performance in terms of bandwidth and random Input Output Operation per Seconds (IOPS)

STORAGE IOPS

The reason why the DDN9900 is very fast in terms of throughput is the simultaneous access to all the disks in the same RAID set. While this makes the storage extraordinarily fast for sequential I/O operations, the access to all disks at the same time drastically reduces the number of random IOPS.

Considering that each SATA RAID set can perform ~200 random IOPS and that a virtual machine (VM) for standard operations needs at least an average of 30 IOPS, the current storage implementation limit the maximum number of VMs to ~50 using 4 RAID-sets. The effect of adding IOPS is clearly visible in Figure 3.

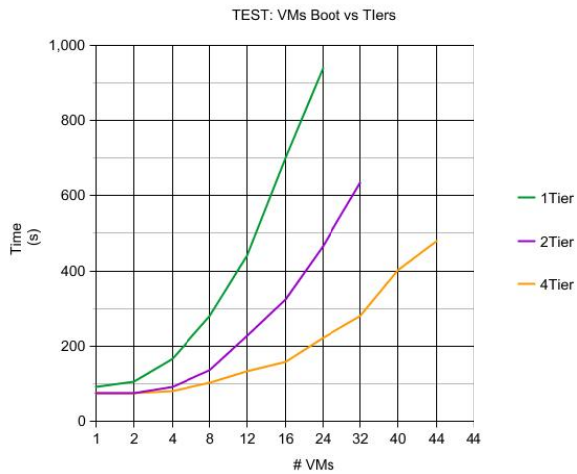

Figure 3: shows how increasing the number of RAID sets (IOPS) improves performances measured in "boot time".

TUNING

Even though there is a fundamental limitation in our current storage hardware a lot of improvement can be obtained by carefully tuning various parameters described in the following.

The main improvements, after having increased the number of RAID sets to the maximum available, have been achieved by switching the VMs default scheduler to NOOP:

By default Red Hat/Scientific Linux uses the CFQ [5] scheduler configured to balance the IO request and it aggregate them to a smallest number of large requests. While the idea of adding "intelligence" to the scheduling of the IO requests is great for a real PC, in a virtual machine this kind of scheduling will just add an additional delay since the smart scheduling will be done

twice: one time by the virtual machine and one time by the hypervisor in which the virtual machine is running.

Significant improvements have been measured as well adding to the default mount options of the VMs filesystems the "noatime,nodiratime" option as well as mounting the /tmp as tmpfs. This last measure keeps temporary files on a local RAM disk rather than soliciting external storage.

By default in ext3 for each read-request a write request will be triggered in order to update the file and directory access time.

Starting a "Name Server/LDAP" caching daemon and disabling IPv6 improved the users experience for the kind of virtual machines which are dedicated to general log-in. In this way the virtual machine does not need to do a request to the DNS and LDAP servers every time an hostname, an IP address or a UID/GID needs to be resolved.

For the virtual machines that are creating a lot of IOPS a solution based on moving the ext3 metadata away from the data in a dedicated SSD RAID set has been put in place. The details of this will be described in a forthcoming, dedicated publication.

This solution which is order of magnitude faster in terms of IOPS compared to the SATA RAID set works also for real machines and is achieved through LVM moving the physical extents in which the metadata is stored to an SSD RAID set.

Regarding the tuning of the hypervisors particular attention was given to the fiber channel interfaces in which we decreased the frame size to 512 Bytes allowing a more number of frames and consequentially of IOPS to the storage in the same interval time.

LHCB VIRTUAL NETWORKS

Live migration of VMs is one of the main advantages of having a virtual infrastructure making the machines less vulnerable to HW failures.

This put same constraint on the network configuration and according to common security procedures three virtual firewalls based have been put in place in order to isolate virtual networks and demilitarized zones. These are shared between the real machines using VLAN through a 10 Gb/s link.

The two 1 Gb/s links are dedicated respectively to cluster management communications and as up-link to CERN network/Internet.

For high-availability reasons the LHCb networks have been linked through a 10Gb/s connection per server with a switch uplink the LHCb core router of 20 Gb/s made by two link on two different linecards using the Link Aggregation Control Protocol (LACP).

A logical map of the virtual network is illustrated in Figure 4.

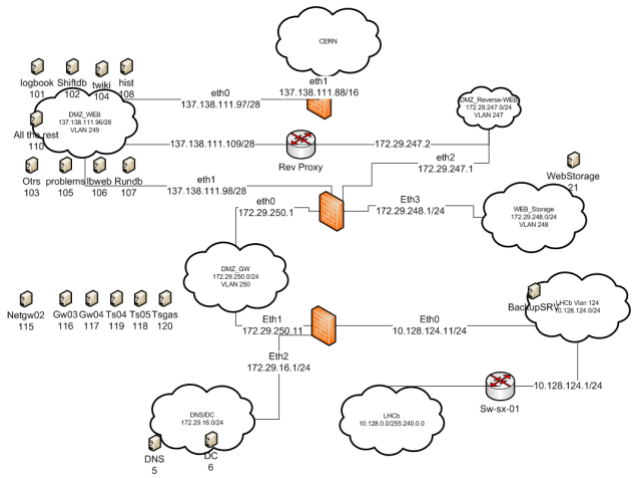

Figure 4: Logical Virtual Networks.

NETWORK PERFORMANCES

We measured the network throughput and the network latency from a KVM and a hyper-v virtual machine with the paravirtualized drivers installed, to a real server inside the LHCb network linked to the core router.

The tests have been done with iperf [6] and ICMP echo requests/replies.

The results are for KVM respectively ~1.50 Gb/s of throughput and ~0.3 ms of latency and for Hyper-V ~900 Mb/s of throughput and ~0.2 ms of latency.

In both hypervisors when the network traffic is filtered and routed by an additional virtual machine the latency time increases to ~0.6 ms and the bandwidth decrease to ~250 Mb/s

INTEGRATION WITH QUATTOR CLUSTER MANAGEMENT TOOL

The main problem in deploying OS on a Hyper-V virtual machine is the lack of pre execution environment (PXE) support when paravirtualized driver are used.

This is not the case for the KVM based VMs because the paravirtualized drivers called VIRTIO are included in the main vanilla kernel since version 2.6.20 and ported back by RedHat/Scientific Linux to version 2.6.18.

The virtual machines are now installed using QUATTOR, a system administration toolkit that provides a powerful, portable, and modular set of tools for the automated installation, configuration, and management of linux clusters and farms, like any real machine in the experiment [7].

ISSUES

Unlike the first study done on Microsoft Hyper-V we did not find any problems with networking, multicast and ACPI, also licensing problems with PVSS are not present. The main problem is the current storage backend, whose RAID system is not optimized for random IOPS.

CONCLUSIONS

The LHCb virtual infrastructure is now based on RHEV. Careful tuning allowed us to achieve very good latency and network and storage throughput.

The current system is however affected by a bottleneck in terms of random IOPS limiting the number of VMs to be executed at the same time.

A new storage solution will be chosen and bought in Q4 2011. The requirements derived from studies conducted for this paper will guarantee a maximum number of concurrent VMs of at least 180.

Once the acquisition will be completed we will continue to deploy more VMs focusing on the control PCs of the experiment.

NETWORK SECURITY SYSTEM AND METHOD FOR RIBF CONTROL SYSTEM

A. Uchiyama#, R. Koyama, SHI Accelerator Service Ltd., Shinagawa, Tokyo, Japan
M. Komiyama, M. Fujimaki, N. Fukunishi, RIKEN Nishina Center, Wako, Saitama, Japan

Abstract

A closed network is more reliable for accelerator control from the viewpoint of information security. The control system of RIKEN RI Beam Factory (RIBF) based on EPICS is also constructed on a closed network that is completely disconnected from all the other networks including laboratory intranets used for daily research activities. However, there are several inconveniences in exchanging information between the network of RIBF control and others. To solve the conflicts, we designed and implemented the network security system. This proceeding describes the design policy of the system and the method used for the exchange information between the intranet in RIKEN and the closed network used for RIBF control system.

INTRODUCTION

The control system of RIKEN RIBF adopted the EPICS (Experimental Physics and Industrial Control System) that used LAN-based protocols [1] and was constructed on its own network (ACC-LAN). E-mail services and Internet accesses unrelated to accelerator operations utilize the RIKEN virtual LAN (RIKEN-VLAN) which is a major network system in RIKEN Wako campus. In the RIKEN-VLAN, Wireless Fidelity (Wi-Fi) routers have been installed in all of the buildings, and all visitors including beam users can access the Internet using the Wi-Fi with DHCP services in RIKEN.

ACC-LAN, however, should not be connected directly to the RIKEN-VLAN because there are possibilities of illegal accesses of intruders to ACC-LAN via Wi-Fi services of the RIKEN-VLAN, even if illegal accesses from wide area network (WAN) is denied with a firewall.

Although the use of the network disconnected from RIKEN-VLAN and WAN is effective for network security of RIBF control system, there were several inconveniences. In this network system, it is difficult for members of the accelerator group to monitor the status of accelerator operation in real time from their offices because access ports of ACC-LAN are not prepared for the offices of the members. The members were hence required to use a storage device, such as USB flash memory, to extract logged data of accelerator operation from ACC-LAN. It was also impossible to transfer E-mail alerts, which are widely used for server management. In addition, RIBF beam users frequently request wide varieties of information, such as accelerator operation status. For these reasons, we decided to improve the inconvenient situation without risking information security.

NETWORK ARCHITECTURE

The ACC-LAN consists of Ethernet switches, optical fibres and metal cables, which are all commercially available. The control system comprises two different systems: an accelerator control system based on EPICS and the other is a system for non-EPICS-based utility control (see Fig. 1). The controllers, servers, and client PCs are installed on the EPICS-based network system. On the other hand, some digital measurement instruments, video servers, and network cameras are connected to the network for non-EPICS-based utility control.

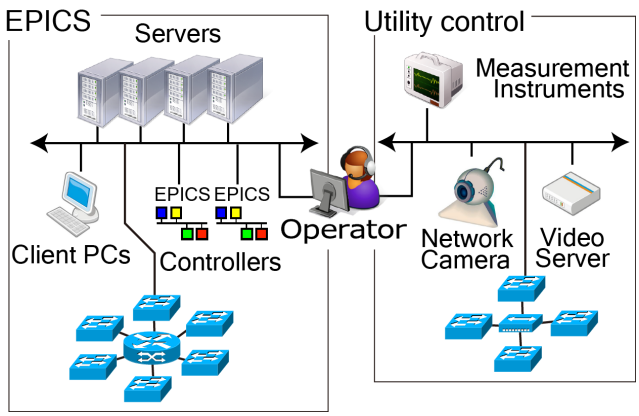

Figure 1: Outline of the ACC-LAN.

PROTECTION AGAINST MALWARE

Nowadays, spread of malware, such as warm, becomes one of the serious issues on the Internet. For example, according to Adobe.com report, systems using Microsoft Windows, Macintosh, Linux and Solaris are possibly infected by malware due to critical vulnerability in old versions of Adobe Flash Player, Reader and Acrobat [2]. Usually the accelerator operation does not require Internet connections and E-mail services. Since major parts of malware infections are caused by Web browsers and E-mails, communications to the Internet or RIKEN-VLAN from client PCs used in accelerator operation are strictly prohibited.

#a-uchi@riken.jp

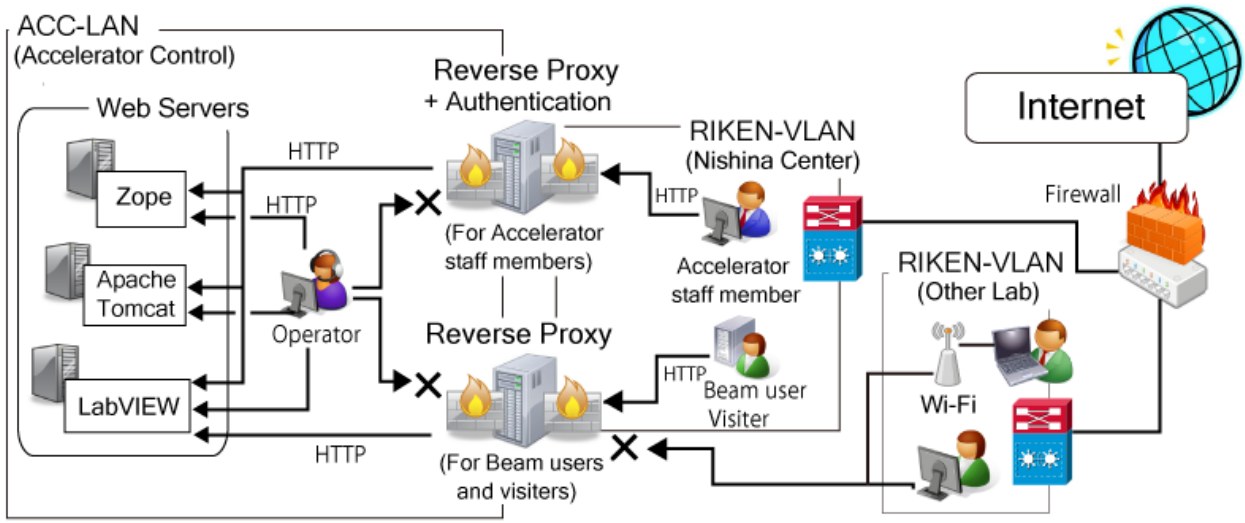

Figure 2: Network diagram in the web communication using reverse proxy servers between ACC-LAN used for RIBF control system and RIKEN-VLAN for office network.

WEB COMMUNICATION USING REVERSE PROXY

System Construction

From the view points of the system management and easiness of system construction, web communication is a suitable to provide information stored in ACC-LAN to many people. To meet the requirements, a combined system with reverse proxy servers for web communication and a firewall has been constructed for providing accelerator information to RIKEN-VLAN with ensuring secured access. Installation of reverse proxy servers, in front of real web servers, is widely used prescription for security and caching.

In order to implement the system, the standard package of CentOS 5.5 has been used as the operating system. Further, Iptables [3] for the firewall and Squid [4] for the reverse proxy server are installed. The system chart and basic concepts are shown in Fig. 2. The significant feature of our system is that accesses from RIKEN-VLAN are masked by the web servers behind the reverse proxy servers. As a result, our system is protected from attacks.

Access Control of Information

In order to restrict unnecessary accesses from beam users and visitors to critical information of accelerator control, such as operation log and raw data, we have adopted an authentication system. In order to control the access of users by authentication, our system consists of two reverse proxy servers. To manage the username/password and denial or allowance to hosts from each user easily, accelerator staff members and beam users/visitors use different reverse proxy server. Therefore, the environments that allow users to access web sites are different for accelerator staff members and beam users/visitors, because the content of information is different. Beam users/visitors are permitted to access only some specific website without the authentication, while accelerator staff members can access all the registered web servers in ACC-LAN with authentication. Consequently, single sign-on (SSO) authentication has been achieved by choosing the accessible reverse proxy server for the accelerator staff members, because SSO has a mechanism whereby a single action of user authentication and authorization can permit a user to access all computers and systems.

Protection against Illegal Access

In order to prevent illegal accesses using SSH and other protocols, the revers proxy system opens only a minimum number of ports to the reverse proxy servers by installing firewall. Additionally, access control based on network addresses was implemented, that is accesses using HTTP protocol required from the PCs having Nishina Center's network addresses in RIKEN-VLAN. Furthermore, the authentication system is used not only for the access control but also play an essential role for the protection against illegal access. Actually, it is difficult to test vulnerabilities against all the type of attacks, for example cross site scripting, for all of the web sites inside ACC-LAN. However in this case, the administrator needs to test only a small number of web sites which visitors can access without authentication.

Result of Access Test

The following software and devices, which support a web interface or the HTTP protocol, have been used inside ACC-LAN.

- Zlog (Zope based Operational Log System) [5]
- MyDAQ2 (MySQL based Archive system) [6]

- Wiki-based log system for 28GHz Ion Source [7]
- Wiki-based documents for RIBF control system
- RIBFCAS (RIBF control data archive system) [8]
- Video server (produced by AXIS using ActiveX)
- Network camera (produced by Sony using ActiveX)
- Digital oscilloscope (produced by Agilent)
- Digital measurement instrument (MW100 produced by Yokogawa Electric Corporation)

We executed access tests to check if the ones listed above in ACC-LAN can be accessed from RIKEN-VLAN via the reverse proxy servers. As a result, it was confirmed that all of them except the digital oscilloscopes and MW100, which have web interface using Java applet, can be accessed successfully.

Other Web Services

The present method enables us to develop a new type of software of RIBF control system with HTTP protocol because process variables (PVs) of EPICS can be accessed from RIKEN-VLAN via reverse proxy server. PVs are converted into XML and JSON formats by our frame-work, which run on the apache and is written in PHP by using PHP EPICS module developed by PSI [9]. Since many application programming interfaces, such as web application have been adopted XML and JSON format recently, it has scalability for the system development. For this reason, using PVs converted XML and JSON formats, we can develop EPICS clients running on RIKEN-VLAN without the use of EPICS channel access protocol.

Additionally, some applications have been provided by using LabVIEW's HTTP service after construction of this revers proxy system. One example of these applications is "Beam Transport Map" developed by R. Koyama et al. [10]. This web application provides real-time operation status of RIBF accelerators with members, users of RIKEN Nishina Center via this reverse proxy. Consequently, various types of monitoring data and status in ACC-LAN become commonly communicated in RIKEN-VLAN by using HTTP protocol (See Fig. 3).

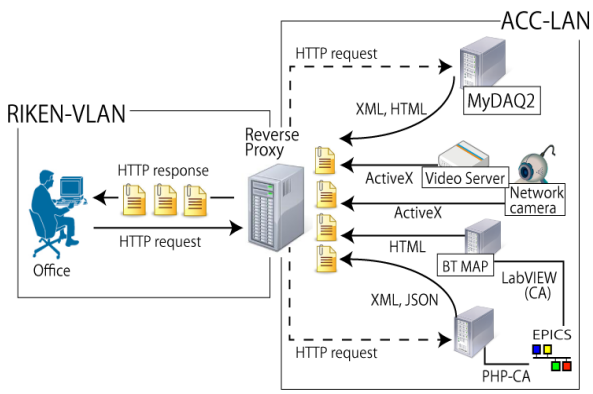

Figure 3: Integrated communication with HTTP protocol.

SOFTWARE UPDATE

Generally, almost all Linux distributions are updated by using YUM and APT. However, it is not easy to update software in a closed network, when it is required to fix security bugs. In the RIBF control system, almost all servers and clients have adopted CentOS and Scientific Linux based on Redhat Enterprise Linux. Therefore, we constructed our own YUM server inside the ACC-LAN. When a serious security hole will be reported, we will install an updated package in our YUM server as soon as possible.

E-MAIL ALERT

Although, it was successfully proceeding to implement the reverse proxy system in RIBF control system. The present work is not completed and the introduced system is not a perfect risk-free system from the view point of information security. As an example of perfect risk-free system in sending information from a completely closed network system, we introduced a new E-mail alert system. It is also important to notify administrators via E-mail automatically on serious failures for management of servers and systems. Since RIBF control system did not have this feature, we designed and implemented a system to send E-mail alerts from EPICS. The present alert system sends E-mail by using on-off control action of EPICS-based mechanical switches without a connection between the networks.

The system consists of an E-mail auto-sender embedded board (mailer board, See Fig. 4) manufactured by TriState ltd. [11], Yokogawa FA-M3 as Programmable Logic Controller (PLC) and Linux Input/Output Controller (IOC). The system chart is shown in Fig. 5. The main characteristic of the mailer board is sending E-mail to a specified mail address that is determined by 16 DIs. The mailer board is installed as a standalone E-mail client in the RIKEN-VLAN. The PLC is installed as one of EPICS control devices within ACC-LAN. As a result, the E-mail alert from EPICS IOC installed in ACC-LAN was sent to RIKEN-VLAN with secured access, though the each network is separated completely. In RIBF control system, it has been used as E-mail alert to administrators in case of system troubles, such as interruption of important services, and reboot of EPICS IOCs.

We have succeeded in sending information using hardware signal in a perfectly closed network. Currently, the reverse proxy system and E-mail alert system are being weighed from the view point of ensuring security.

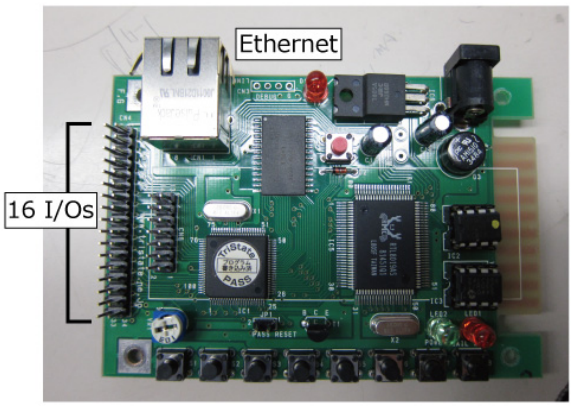

Figure 4: Photograph of the E-mail auto-sender embedded board manufactured by TriState Ltd.

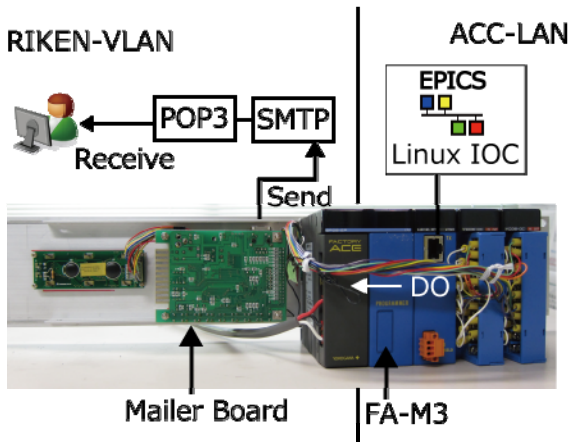

Figure 5: The system chart of E-mail alert.

SUMMARY

Reverse proxy servers, which interconnect the RIBF control network and the RIKEN-VLAN for providing various types of services in the RIKEN Wako campus, were designed and constructed. The HTTP protocol was adopted for the reverse proxy servers to allow accelerator staff members, beam users and other staff members to access the real-time information on operational status of accelerators with ensuring security against possible attacks via the RIKEN-VLAN. In addition, an E-mail alert system has been constructed by using an E-mail auto-sender board on the RIKEN-VLAN and a PLC-based IOC, prepared in ACC-LAN. The E-mail alert system helps the administrators to notice quickly when serious problems occur. It was confirmed that reverse proxy system is an effective method to provide information ensuring secured access in RIKEN RIBF. The usefulness of E-mail alert system without network connection was also proved by operational experience.

ACKNOWLEDGEMENT

One of the authors (A.U) would thank to Prof. K. Furukawa of KEK for useful discussion and valuable comments.

Abstract

The control system for J-PARC accelerator complex has been developed based on the EPICS toolkit. About 90 traditional ("real") VME-bus computers are used as EPICS IOC's in the control system for J-PARC MR (Main Ring).

In 2010-2011, we demonstrated a "virtual" IOC using Xen, an open-source virtual machine monitor. Scientific Linux with an EPICS IOC runs on a Xen virtual machine. EPICS records for oscilloscopes (network devices) are configured. Advantages of virtual IOC are discussed.

In addition, future directions are discussed. Plan view of virtual IOC's for MR operation will be given.

INTRODUCTION

The J-PARC Main Ring (hereafter MR) is a high-power proton synchrotron with beam-energy 30GeV. The beam commissioning of MR started May, 2008. Since then, various machine studies as well as beam deliveries to physics experiments have been carried out [1]. The control system for MR has been developed based on EPICS (Experimental Physics and Industrial Control System) [2], where EPICS is a toolkit for large accelerator controls developed and supported by an international community [3].

Table 1: Types of IOC used in J-PARC MR

Type	Number	Comment
VME-bus GE and Sanritz	~90	Traditional styles
Yokogaw PLC F3RP61-2L	~30	Embedded EPICS [4] with PLC I/O modules
Cosylab microIOC	3	Industrial PC [5] with serial lines (RS485)

In EPICS, signals are handled by an in-out controller (hereafter IOC). Traditional EPICS systems use a VME-bus computer as an IOC. In MR, we have about 90 VME-bus-type IOC's among 120 IOC's in total (Table 1). A snapshot of IOC status overview during operation is given in Fig. 1.

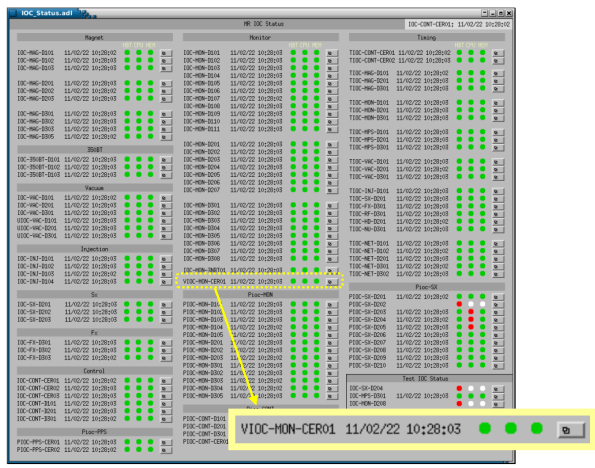

Figure 1: Overview for J-PARC MR IO-Controllers.

In J-PARC MR, 60 of 90 VME-bus-type IOC's do not use VME-bus. They are used for network-based devices: such as PLC with ladder sequences, intelligent measuring systems (WE7000 [6]), oscilloscopes, etc [7,2]. Typical topology found in MR is shown in Fig. 2.

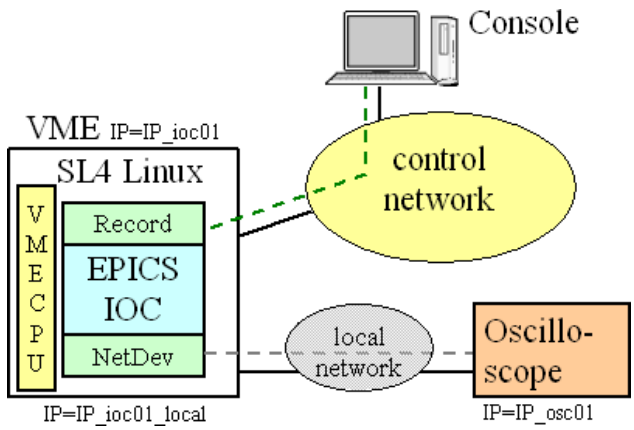

Figure 2: Typical topology with a network device.

STUDY OF VIRTUAL IOC

Idea of Virtual IOC

Recent IT technology has provided various types of virtualization of a computer: for example, Xen, VMware, VirtualBox, and KVM. Among them, we firstly interested in Xen [8], an open-source virtualization technology. The start procedures of a "vioc - virtual IOC" is given below (see also Fig. 3):

(1) Prepare a host OS. In our case, it is a blade-type server running Scientific Linux 5 (SL5).

(2) Run a guest OS using Xen. The guest OS is assigned 512MB memory, running SL5, with an independent IP address from the host.
(3) Start an EPICS IOC on the guest OS. The EPICS IOC's in Fig. 2 and Fig. 3 are identical.

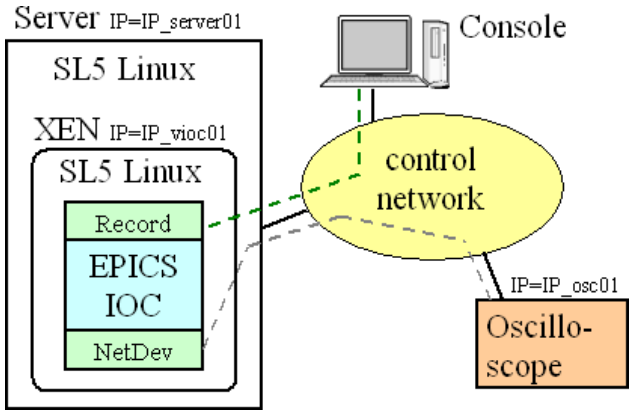

Figure 3: Topology with a virtual IOC.

Demonstration of VIOC at J-PARC MR

In order to demonstrate a vioc at J-PARC MR, we selected an extinction-monitor setup [9]. It consisted of oscilloscopes, and not EPICS-based. Thus, we developed an EPICS-based system using vioc in October, 2010. The system controls Tektronix DPO4054 and TDS3054 oscilloscopes. Setting parameters as well as waveform signals (four input and 1 output) are configured as EPICS records. Typical waveform is 10,000 elements, 10 us with 1G/s sampling rate.

The vioc for extinction monitor setup started operation since November, 2010. It was used in machine studies very successfully. Moreover, the vioc was included in our IOC surveillance monitor with the name "VIOC-MON-CER01" (Fig. 1). It had been stable over a few months. It is worth noting that nobody can find it a "virtual", not a "real" VME-bus-type, unless using it remotely (Fig. 4).

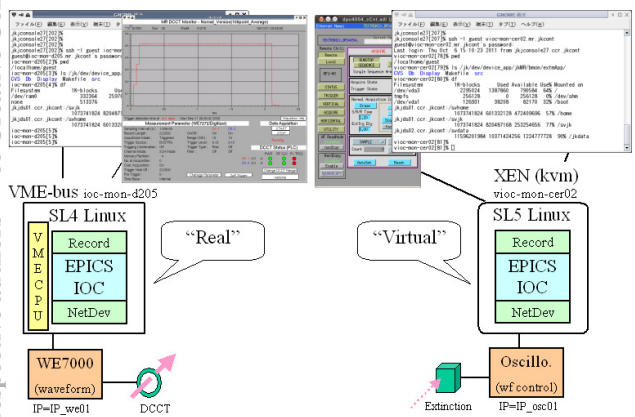

Figure 4: virtual IOC (right) and real IOC (left).

Discussion

Based on our successful experience, a scheme that running multiple vioc's (guest OS's) on limited number of servers (host OS's) seems promising. It is efficient and flexible: (a) adding new vioc is easy, (b) customization for each vioc (i.e. small memory size for small function) is possible. When a server has a trouble, one can move vioc's to another server.

However, we must pay attention to network traffic. Unless network amount is small, vioc scheme works well. When waveform signals are handled at a considerable high repetition rate, "real" scheme has an advantage. More studies are needed.

FUTURE DIRECTIONS

Xen to KVM

We have demonstrated a vioc using Xen. However, recent trend of virtualization technology suggests KVM. KVM functions were merged into Linux kernel after 2.6.20. Now Scientific Linux 6 (SL6) has native supports for KVM.

When we run multiple vioc's on servers, it is apparent that we need a management tool. In the early phase, we looked for a tool for Xen, but could not find an appropriate one. For KVM, a default "virt-manager" is available with SL6. We have checked that it is good and stable enough for our purposes.

Toward mass introduction of vioc's in the future, we decided to use KVM instead of Xen. A plan view of vioc's, using KVM and SL6, is shown in Fig. 5. We will start operation with the new scheme after December, 2011.

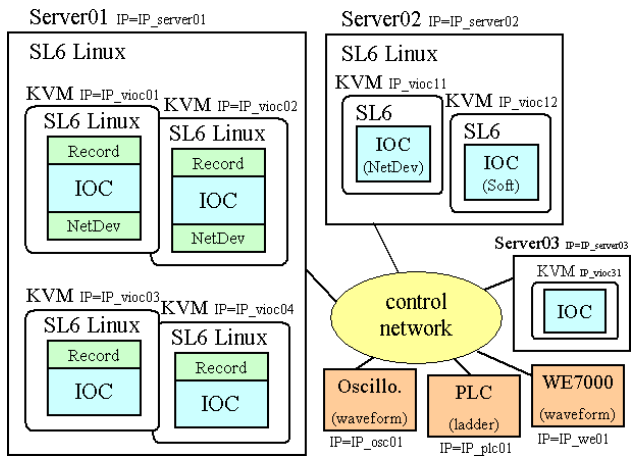

Figure 5: Plan view of vioc's for future MR operation.

Virtual Terminal

We also studied a possibility to use virtual desktop infrastructure (VDI) under KVM environment. The idea of "vterm - virtual terminal" is similar to vioc. Instead of an EPICS IOC, we run a SPICE server on a virtual machine. SPICE is a remote-desktop protocol supported by recent Linux kernels [10]. On a SPICE server, we run GUI applications developed in our EPICS-based control system.

We have an operator's console system using commercial thin-client terminals [11]. We expect higher reliability when we run a SPICE client on a thin-client terminal, since system load (CPU and memory) is always constant. Number of GUI applications does not affect to

stability of a thin-client terminal. Studies are under progress.

CONCLUTION

We have demonstrated a virtual IOC (vioc) on a Xen virtual machine. A vioc was configured for parameter settings of oscilloscopes. It has been used very successfully in studies of extinction monitors. In addition, it was stable over a few months.

Recently we decided to usie KVM virtualization technology instead of Xen. After December, 2011, we will start to run multiple vioc's in our operation.

PACKAGING OF CONTROL SYSTEM SOFTWARE

Abstract

Control system software consists of several parts – the core of the control system, drivers for integration of devices, configuration for user interfaces, alarm system, etc. Once the software is developed and configured, it must be installed to computers where it runs. Usually, it is installed on an operating system whose services it needs, and also in some cases dynamically links with the libraries it provides. Operating system can be quite complex itself – for example, a typical Linux distribution consists of several thousand packages. To manage this complexity, we have decided to rely on Red Hat Package Management system (RPM) to package control system software, and also ensure it is properly installed (i.e., that dependencies are also installed, and that scripts are run after installation if any additional actions need to be performed). As dozens of RPM packages need to be prepared, we are reducing the amount of effort and improving consistency between packages through a Maven-based infrastructure that assists in packaging (e.g., automated generation of RPM SPEC files, including automated identification of dependencies). So far, we have used it to package EPICS, Control System Studio (CSS) and several device drivers. We perform extensive testing on Red Hat Enterprise Linux 5.5, but we have also verified that packaging works on CentOS and Scientific Linux. In this article, we describe in greater detail the systematic system of packaging we are using, and its particular application for the ITER CODAC Core System.

INTRODUCTION

The principal challenges of today's control systems for large experimental physics facilities are complexity and quality assurance.

By this we mean the fact that a large number of software components – executing either on the same host or in a distributed set-up – need to be integrated into a functioning whole while performing according to performance and reliability expectations. The complexity challenge stems both from the inherently distributed, large-scale nature of a control system, as well as the trends in component-based software engineering and systems engineering, where monolithic systems are giving way for those that are integrated from smaller, more manageable subsystems.

With limited development, maintenance and integration resources – in particular skilled staff – it is important that as many tasks as possible are automated, and that common problems have common solutions – i.e., that standardization takes place to the extent that it is economically feasible.

The ITER CODAC [1] control system is also facing these challenges. CODAC integrates software packages that are a product of two decades of work, and which have been developed in diverse environments by different teams. Not surprisingly, each of these packages takes a different approach on how the software is built, and what quality assurance process is in place during its release.

We have decided to standardize at least the interface with which the developer (or maintainer) interacts with the build system. To achieve this, we have wrapped the diverse approaches and technologies for building (Makefile [2], Ant [3], shell scripts, Eclipse builder [4], etc.) into one tool. Since many software packages share the same approach (e.g., EPICS base [5] and all of its extensions rely on Makefile, while Control System Studio [6] and all of its plug-ins rely on Eclipse), we were looking for a way to re-use our effort: for example, specify integration with the EPICS Makefile system in a single place, and "invoke" it with a one-line stanza in all software packages where it is needed.

As we are not the first to have come across this challenge, a market survey revealed that build tool frameworks already exist (for example, Maven [7] and Gradle [8]). After our evaluation, performed in late 2009, we have settled to use Maven 2 as the platform, and we have chosen to solve our challenges by implementing a plug-in for this tool.

Another challenge is managing deployment across the many hosts that will eventually constitute the control system. However, this challenge is not uncommon in the IT industry, where large corporations also have thousands of computers that need to be managed with the limited IT staff. To leverage existing solutions, ITER had decided to take an off-the-shelf approach: using Red Hat Enterprise Linux and its automated installation and update capabilities enabled with the Red Hat Satellite software [9].

Managing installation, un-installation and updating of software packages on an individual host is a rather complex task in itself. The most trivial step of it is to place the files constituting a software package (executables, scripts, configuration files and data files) to the right places in the file system. As un-installation and update need to be able to clean-up those files, meta-data must be associated with each file to specify which software package had installed it. Installation/un-installation might require that some actions are taken (e.g., adaptation of configuration files of other software components, creation of database schemas, population of databases, etc.). And finally, software package might have dependencies, and other software might depend on: installing a package might thus have a precondition that

Figure 1: Example of a SPEC file that provides meta-information and build instructions for an RPM package.

other packages are installed beforehand, and uninstalling it may have a consequence that those depending on it should be uninstalled as well.

This problem, too, has already been solved by the IT community. On Linux platforms, the Debian package management (APT/DEB) and Red Hat Package management (YUM/RPM) are commonplace. As ITER has chosen Red Hat Enterprise Linux as the operating system, we have opted for the YUM/RPM technology.

To provide a RPM, the developer must provide a so-called SPEC file. The SPEC file contains (see Figure 1):

- meta-information about the package (name, version, description, etc.),
- instructions in form of an executable script on how to build the package (unpack the sources, run configure/make or other tools, etc.)
- which files to package, and what default permissions to assign to them
- the scripts to execute before and after installation, and before and after un-installation.

CONSTITUENTS OF A CONTROL SYSTEM

In case of ITER CODAC, the control system consists of the following kinds of software packages:

- EPICS IOC applications.
- Configuration files for the BEAST alarm server.
- Configuration files for the BEAUTY archiving system.
- Kernel modules, e.g., for implementation of kernel-mode device drivers.
- User-mode device drivers and libraries.

The EPICS IOC applications are standard EPICS applications, built with the EPICS' Makefile system. They consist of the binary compiled for the target platform, the `st.cmd` start-up script, and EPICS database files.

These files are packaged in an RPM package, and an `init.d` script is automatically generated that allows for starting up and shutting down of the IOC as a system service. The `init.d` script also provides a console through which developers and maintainers can access the EPICS shell of the IOC process (via the `screen` tool).

For security reasons, it is not advisable to run services as the `root` user. Therefore, a system user called "`codac`" is provided, and all services run under that account. This raises some issues with permissions (e.g., the `codac` user by default doesn't have permissions to interact with kernel-mode device drivers, nor does it have permissions to set its real-time attributes such as scheduling priority and CPU affinity). The packaging ensures also that these permissions issues are properly addressed.

Packaging of configuration files for BEAST and BEAUTY involves putting the configuration files in the RPM package, and running the database import tools upon installation of the RPM to populate the BEAST and BEAUTY configuration databases with their content. In CODAC, the content of these configuration files is automatically generated by the SDD tools [1], thus they are in-sync with the contents of the EPICS configuration database.

Kernel modules are built with standard tools for kernel modules. Currently, kernel modules can be built for two targets:

- A regular kernel.
- A real-time kernel.

```
<package name="MCioc">
  <include name="MC-ICHCore" type="ioc"/>
  <include type="boy" file="*"/>
  <include type="databrowser" file="power.plt"/>
</package>
```

Figure 2: Excerpt from Maven's POM XML file responsible for generating RPM SPEC file from Figure 1.

For each build, a separate RPM package is provided, which then has its dependency set as required (either to the `kernel` or to the `kernel-rt` package).

THE MAVEN PLUGIN

The packaging of control system's constituents described in the previous section into RPMs is performed by the a Maven plugin we have developed.

The Maven plugin is designed to execute the packaging task during the "`package`" phase of its lifecycle – i.e., after compilation and testing, but before installation and deployment.

The description of the packaging is very concise. Figure 2 shows an example of the Maven configuration that results in RPM SPEC file shown in Figure 1.

The RPMs thus produced allow installation of several versions of the ITER CODAC system simultaneously. E.g., version 2.1 and 3.0 can be installed at the same time, with the first residing in `/opt/codac-2.1` and the latter in `/opt/codac-3.0`. The developer can then switch between the two versions with a command `codac-version`, which redirects all the softlinks from the system's paths accordingly (via the *alternatives* system) and reconfigures environment variables.

In addition, the Maven plugin provides command-line options that facilitate generation of Maven's project definition file, the `pom.xml`. Thus, even developers not familiar with syntax of this file can configure their projects to be packaged.

USAGE EXAMPLE

The developer might use the Maven-based tools as follows.

Firstly, the developer would create a *project* (a *unit* in ITER's CODAC terminology) by executing:

```
mvn iter:newunit -Dunit=my-unit
```

This results in a subdirectory *m-my-unit* (the *m-* prefix is prepended due to ITER CODAC's naming convention for units). The directory structure conformant to CODAC's standards, and Maven's `pom.xml` file, are also created by this command.

The following sequence of commands creates an EPICS application, and then configures an IOC process to run that application. The type of the application here is "psh", referring to ITER CODAC's *Plant System Host*:

```
cd m-my-unit
mvn iter:newapp \
    -Dapp=PlantSystemHost \
    -Dtype=psh
mvn iter:newioc \
    -Dioc=PlantSystemHost \
    -Dapp=PlantSystemHost \
    -Dtype=psh
```

Now, the RPM can already be prepared by executing:

```
mvn package
```

It is also possible to conveniently start the resulting IOC:

```
mvn iter:run
```

CONCLUSION

The Maven-based tools that have been developed to facilitate the development process greatly simplify development of software for the control system – from input/output controller processes to extensions of the operator's graphical user interfaces.

The interface provided to developers is simplified so that even those who had no prior exposure to EPICS, Maven or RPM are able to create new EPICS-based, CODAC-compliant projects, build them, and ensure that results are packaged in an installable RPM.

While the tools have been developed for ITER, they can be adapted to other projects as well. For example, currently an effort to adapt ITER CODAC for the needs of the European Spallation Source's control system.

TAILORING THE HARDWARE TO YOUR CONTROL SYSTEM*

E. Björklund, S.A. Baily, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

Abstract

In the very early days of computerized accelerator control systems the entire control system, from the operator interface to the front-end data acquisition hardware, was custom designed and built for that one machine. This was expensive, but the resulting product was a control system seamlessly integrated (mostly) with the machine it was to control. Later, the advent of standardized bus systems such as CAMAC, VME, and CANBUS, made it practical and attractive to purchase commercially available data acquisition and control hardware. This greatly simplified the design but required that the control system be tailored to accommodate the features and eccentricities of the available hardware. Today we have standardized control systems (Tango, EPICS, DOOCS) using commercial hardware on standardized busses. With the advent of FPGA technology and programmable automation controllers (PACs & PLCs) it now becomes possible to tailor commercial hardware to the needs of a standardized control system and the target machine.

In this paper, we will discuss our experiences with tailoring a commercial industrial I/O system to meet the needs of the EPICS control system and the LANSCE accelerator. We took the National Instruments Compact RIO platform, embedded an EPICS IOC in its processor, and used its FPGA backplane to create a "standardized" industrial I/O system (analog in/out, binary in/out, counters, and stepper motors) that meets the specific needs of the LANSCE accelerator.

BACKGROUND

The 800 MeV proton accelerator at the Los Alamos Neutron Science Center (LANSCE) was designed and built in the 1960's. The original design included a custom-built computer control system based on a custom-built data acquisition system that we called RICE ("Remote Information and Control Equipment") [1]. In the 1980's, with the advent of the CAMAC standard, we adapted our control system to use both CAMAC and RICE. Then, in the 1990's, we introduced both VME and EPICS into our control system. This required a lot of adaptation – old control systems to new hardware, new control systems to old hardware, and new and old control systems to each other.

While it is nice to keep up with new technology, unfortunately it did not mean that we got to eliminate any of the old technology. And so, in the 2000's we found ourselves supporting a control system that included three generations of hardware technology (RICE, CAMAC, and VME) and two generations of software technology (EPICS and the legacy control system).

Now, at last, we have the opportunity to start phasing out our old hardware and software. The only way to make this economically feasible, however, was to use hardware that could a) interface with the accelerator the way the accelerator equipment was designed, and b) provide a straightforward interface to the new software (EPICS). And so we began exploring the use of programmable hardware solutions.

THE NEW LANSCE INDUSTRIAL I/O SYSTEM

For our first test case we decided to replace the Industrial I/O (IIO) portion of one RICE module with a commercial programmable logic controller (PLC). We defined "Industrial I/O" to encompass the basic, non-time-critical, non-closed-loop, and non-safety-critical functions of the control system. The PLC system worked well, but we discovered that it was not fast enough for some of our IIO binary output channels. It also could not time ADC reads to avoid the noise induced on the system by the accelerating RF.

For our next iteration, we traded the PLC for a National Instruments Compact RIO system, which is about as environmentally rugged as a PLC, but can also be several orders of magnitude faster. In the Compact RIO system, I/O cards plug directly into an FPGA. The FPGA can be programmed using LabVIEW, which gets translated into VHDL and then into the FPGA bitmap.

The standard RICE-replacement system we constructed is an 8-slot Compact RIO system that features 64 binary input channels, 32 sinking binary output channels, 8 solid state relay binary output channels, 32 analog input channels, 16 analog output (DAC) channels, and 4 stepper motor channels. The analog inputs can be triggered in order to avoid RF noise. Variants of the standard system are possible, and may replace some functionality (e.g. stepper motors) with other functionality (e.g. counters). In most cases, one (IIO) chassis can service all the industrial I/O channels in one RICE module. Details of the specific implementation can be found in the companion paper [2].

ADAPTING THE COMPACT RIO TO RICE

The specific features of the RICE system that we wanted to emulate in our new IIO controller were:

- Timing the ADC reads to avoid RF-induced noise
- Multiple protocols for binary output commands.
- Knob-friendly stepper motors.
- Easy on-line reconfiguration

*Work supported by the US Department of Energy under contract DE-AC52-06NA25396

Binary Output Protocols

The LANSCE control system uses four different command protocols for binary output channels. These are:

- **Command Only:** The simplest protocol. Turn it on and it goes on. Turn it off and it goes off.
- **Command With Latchback:** The most complex protocol and the most common protocol used by RICE. Each command channel has an associated readback channel. The command value tracks to the value of the readback channel until a command is issued. The command value is held for a specified "hold time", allowing time for the readback to reflect the new command value before the command channel starts tracking it again. Latchback channels are useful when a device can be commanded from multiple sources.
- **Momentary Normally Open:** The command channel is normally low. Writing a 0 to the channel has no effect. Writing a 1 to the channel causes the device to change state. When a 1 is written, the command channel will be held high for the specified hold time, after which it reverts to low. A "momentary normally open" channel with a latchback is useful for implementing fault/reset logic.
- **Momentary Normally Closed:** The same protocol as "momentary normally open" except that the command output is inverted.

CAMAC and VME systems require a different card type for each of four binary output protocols. Even more card types are required if the hold times are implemented in hardware. By programming the protocol into the controller, we were able to implement all the binary command channels with only two card types.

Control Knobs and Stepper Motors

One of the unique features of our original control system is its heavy reliance on stepper motors as the primary analog output device and assignable control knobs as the primary analog output interface. This was a problem when we started to integrate EPICS into the control system because EPICS is not very good at implementing control knobs and particularly bad at controlling stepper motors with control knobs. Consequently, we spent a lot of time adapting our EPICS system to work well with control knobs [3].

A problem that can occur when knobbing a stepper motor is that the pulses can accumulate faster than the motor can turn, resulting in overshooting the intended target. We avoid this problem by limiting the output of the control knobs to only the number of pulses that can be accumulated in a fifth of a second. We also programmed the stepper motor controller to preempt the current pulse stream whenever a new pulse stream is received. In this way we guarantee that the device will stop moving when the knob stops turning.

Instead of using a stepper motor card, we chose to implement our stepper motor controller with a simple binary output card. This allowed us to program in the exact pulse width, speed and ramping characteristics that the accelerator equipment expected from RICE.

Stem Cells and Reconfiguration

In the RICE system, when you needed to change the protocol of a binary output channel, or give it a different readback, you simply moved a jumper or re-routed a wire. Typically this could be accomplished in a matter of minutes and did not disturb any of the other equipment controlled by that RICE module. To accomplish this same task with an FPGA, first the FGPA source code must be changed. Then (in the case of Compact RIO) the source code must be translated into VHDL. Then the bitmap needs to be reconstructed from the VHDL (a potentially lengthy process). Finally, the Compact RIO system must be taken off-line while the bitmap is re-flashed and the Compact RIO rebooted.

Reconfiguration occurs more frequently than one who is not accustomed to the workings of an accelerator laboratory might think. In order to minimize the amount of time it takes to reconfigure our FPGA systems, we adopted a "Stem Cell" approach. Under this approach, the FPGA code for a binary output channel (for example) resembles a biological stem cell. A binary output "stem cell" has the possibility of becoming any command type (command only, latch-back, momentary open, or momentary closed), using any binary input for its readback, and having any hold time between 0 and 65 seconds (in millisecond intervals). The "stem cell" does not take on a specific function until it receives instructions from a configuration process. The configuration process reads a configuration file and assigns the specified functions to the stem cells. Configuration runs at startup, but can be invoked again at anytime. Thus it is possible to completely reconfigure the action and behavior of a binary output channel "in vivo" without any interruption of service.

The chief drawback of the "stem cell" approach is that it requires more FPGA real estate per channel. When we first tried this approach on a Virtex 2 FPGA, we only had enough space to implement 11 binary output channels. After upgrading to a Virtex 5, however, we had more than enough room for 40 binary output channels and 64 binary input channels.

Binary outputs are not the only stem cells in our system. We can also dynamically configure the dynamic range and trigger of our analog input channels, the pulse rate and (to some extent) the ramp up rate of our stepper motor channels, and the integration time of our counter channels.

EMBEDDING THE CONTROL SYSTEM IN THE HARDWARE

Perhaps one of the most dramatic ways to tailor the hardware to your control system is to actually embed it

within the hardware. Many commercial products such as PLCs, PACs, Serial Controllers, and beam diagnostics employ an embedded processor running a real-time or "near" real-time operating system. This raises the possibility of actually embedding the control system (or at least the "front end" part of the control system) in the device's processor and letting it interact directly with the vendor's code. One of the strengths of belonging to a control system collaboration is that vendors have been willing to entertain and even market this ability. We have already seen this with products from Instrumentation Technologies [4], Moxa [5], National Instruments [6], Yokogawa [7], and ZTEC Instruments [8].

The Compact RIO uses a power-PC running the vxWorks real-time operating system. National Instruments and CosyLab collaborated with us to install a complete EPICS I/O Controller (IOC) on the Compact RIO. The EPICS software runs concurrently with the National Instruments software and communicates with it using a shared memory interface concept originally pioneered at the Spallation Neutron Source [9].

One immediate advantage of embedding the control system is that data displayed on the operator screens now comes directly from the Compact RIO. With the PLC, the data had to go from the PLC to an EPICS IOC and then to the operator screen. Another advantage is that the Compact RIO is now able to take advantage of all the EPICS utilities such as archiving, bumpless reboot, access security, alarm handling, performance diagnostics, and our local software for making control knobs work well with EPICS. A final advantage is that the Compact RIO system may also access other local devices that have Ethernet interfaces – such as, for example, a PLC.

One final topic worth mentioning is that FPGAs are now coming equipped with hard and soft-core processors, making it possible to embed the control system right on the FPGA. Some examples can be found in [10], [11], and [12].

CONCLUSION

Not only has the Compact RIO IIO controller worked well as a replacement for RICE, but with some minor tweaks we found it also works well as a replacement for CAMAC. To date we have replaced two RICE modules and two CAMAC crates with our standard Compact RIO IIO systems. The three things that have contributed to this success have been 1) the ability to program the controllers, which allowed us to interface with existing accelerator equipment, 2) embedding the control system in the controller, which simplified the software interface, and 3) the ability to reconfigure the interface on-line.

ACKNOWLEDGEMENTS

The authors would like to thank David Bonal, Thierry Debelle and Ryan King of National Instruments for their invaluable support and assistance with the initial implementation of the Compact RIO IIO Controller. We would also like to thank Rok Šabjan of Cosylab for his initial work on getting EPICS to run on the Compact RIO as well as for the initial implementation of the shared memory library.

SUITABILITY ASSESSMENT OF OPC UA AS THE BACKBONE OF GROUND-BASED OBSERVATORY CONTROL SYSTEMS

W. Pessemier*, G. Raskin, H. Van Winckel, Institute of Astronomy, K.U.Leuven, Belgium
G. Deconinck, P. Saey, ESAT-ELECTA, K.U.Leuven, Belgium

Abstract

A common requirement of modern observatory control systems is to allow interaction between various heterogeneous subsystems in a transparent way. However, the integration of off-the-shelf (OTS) industrial products - such as Programmable Logic Controllers (PLCs) and Supervisory Control And Data Acquisition (SCADA) software - has long been hampered by the lack of an adequate interfacing method. With the advent of the Unified Architecture (UA) version of OPC (Object Linking and Embedding for Process Control), the limitations of the original industry-accepted interface are now lifted, and also much more functionality has been defined. In this paper the most important features of OPC UA are matched against the requirements of ground-based observatory control systems in general and in particular of the 1.2m Mercator Telescope. We investigate the opportunities of the "information modelling" idea behind OPC UA, which could allow an extensive standardization in the field of astronomical instrumentation, similar to the efforts emerging in several industry domains. Because OPC UA is designed for both horizontal and vertical integration of heterogeneous subsystems, we explore its capabilities to serve as the backbone of a dependable and scalable observatory control system, treating industrial components like PLCs no differently than custom software components. Performance measurements and tests with a sample of OTS OPC UA products are presented.

INTRODUCTION

Context and Motivation

Similar to the efforts in industry, control system engineers for astronomical observatories are continuously seeking to reduce development and maintenance costs and to increase system dependability. One of the most prominent trends is to foster software reusability, by creating frameworks which separate infrastructure code (i.e. the common *technical* aspects) from application logic (i.e. project-specific *functional* aspects) [1]. Another trend is the continued effort to integrate OTS (either commercial or public domain) software and hardware into these control systems [2]. Today, generic frameworks exist which meet both requirements to a large extent, even though some issues persist. Firstly, deeply involving frameworks may impose too strong constraints on the freedom of developers to choose the best fitting or best known technology for a given problem [3]. A "one size fits all" framework may exhibit code bloat and a lack of scalability, especially towards smaller and less demanding (embedded) applications. Secondly, as most generic frameworks to date rely on CORBA or DDS[1] as middleware to "glue" all subsystems together, integration of mainstream OTS industrial products remains inconvenient. As will be elaborated in this paper, OPC UA may offer a solution to these issues.

Methods

For this assessment we have compiled a list of qualitative and quantitative properties that are commonly required by observatory software frameworks, and in particular for the Belgian Mercator Telescope (a 1.2m optical telescope based at La Palma and currently being refurbished). The approach is twofold: not only do we want to verify if the OPC UA specification can satisfy these requirements, but we also want to test whether OTS implementations are complete and mature enough to build a functional infrastructure. For this purpose we have created a test set-up as depicted in Fig. 1, consisting of a small sample of commercial products with OPC UA connectivity. Naturally, many more products[2] of many more vendors are available on the market. Particularly important in the set-up is the SDK that we used to develop code for an experimental framework based on OPC UA. For this purpose we evaluated the C++ SDK by Unified Automation.

OPC UA BASICS

OPC UA is the successor of the suite of "classic" OPC standards that were developed by the OPC Foundation to interface industrial PLCs with SCADA and HMI (Human Machine Interface) systems. Besides the specification [4], a collection of code deliverables has been released to speed up application development and to facilitate compliance to the standard. Among these code deliverables are communication stacks in ANSI C/C++, JAVA, and C# .NET, which implement common lower level functionality. Two transport mechanisms are defined: the simple but high performance *UA TCP* and the Web Services standard *SOAP/HTTP*. Optional message signing and encryption is based on the *WS-SecureConversation* specification, and authentication is controlled by X.509 certificates. The stacks also implement data encoding via an efficient binary scheme or via XML. Built on top of the stack, an SDK is responsible for higher level functionality such as service handling and address space management. SDKs are offered by the OPC Foundation and by third party companies.

One of the most characteristic aspects of OPC UA is the extensive support for *information modelling*. Information entities (*Nodes*) and the relationships between them (*References*) can be defined, and exposed to the network in the *address space* of a server. Not only data itself but also meta-data can be exposed and transported over the wire. The semantics of the information model can be described formally in a *namespace*. A Node has several attributes and can represent an object, a variable, a method, an object/variable/data/reference type or a view (see [5]). A full mesh network of Nodes and References, representing a fictitious information model of METIS (the proposed Mid-Infrared E-ELT Imager and Spectrograph, see [6]) is shown in Fig. 2. The example is not meant to be optimal or complete, but attempts to illustrate some features of OPC UA. Object-oriented concepts such as data abstraction, encapsulation, polymorphism and inheritance are supported, as well as dynamic model changes, extensible references types, and cross-server referencing.

REQUIREMENTS

Table 2 lists a number of essential requirements [7], and whether they are met by the OPC UA specification and the tested SDK (second and third columns respectively). Only general comments are given, even though many requirements have more in-depth technical aspects which were verified by developing code snippets on top of the Unified Automation SDK. A recurring observation is the level of detail that is present in the OPC UA specifications and the derived stacks and SDKs. A substantial amount of these built-in features are distinctive for heterogeneous distributed control systems. For instance, data changes can be monitored asynchronously via the *MonitoredItems* services, which include standard arguments so that clients can request (and negotiate) the interval to sample the underlying data source, the publishing interval to minimize bandwidth overhead, an optional filter to deal with noisy data sources, and even a flag to request resampled data from the server. Dependability mechanisms are also strongly built into the OPC UA specification. For instance, OPC UA clients need to send "publish requests" to a server in order to keep the latter informed about the readiness of the client to receive events.

Quantitative requirements are more difficult to assess since they may vary strongly between projects and depend largely on the used hardware. We therefore use the set-up from Fig. 1 to measure the performance of a few typical service calls (*read* in this case) between a client and a server built with the Unified Automation SDK, see Table 1. The server is running on a Linux laptop and the client on a Windows PC. The UA Binary protocol is used to transmit the unencrypted and unsigned data via the gigabit network.

Table 1: Performance Measurements

Variables per call	Single UInt32 variable	1K*1K UInt32 matrix
1	0.37 ms	181 ms (∼22.1 MB/s)
10	0.68 ms	1784 ms (∼22.4 MB/s)
100	3.18 ms	
1000	23.26 ms	

The results indicate that the binary protocol of OPC UA is capable of high performance transmission of data (or meta-data) between components running on computer platforms. The performance in a more heterogeneous set-up (including embedded and real-time devices) is less useful to assess since it depends even more on the particular hardware and software configuration. Besides a priority mechanism for event handling on application level, no Quality of Service (QoS) features are specified by OPC UA. And, even though throughputs of around 22 MByte/s can be achieved when transmitting messages of several MByte (see Table 1), no special services are defined to exchange large data volumes. While other middleware technologies such as CORBA and DDS can meet strict real-time and data streaming requirements, OPC UA is clearly tailored for system architectures with complementary, special-purpose bus systems. These could include real-time fieldbuses, a bus for large data volume transport, an IEEE1588 timing bus, a safety bus, ... on a dedicated or shared medium (with managed switches to preserve QoS if needed).

FEASIBILITY

Besides accommodating special purpose frameworks (such as LabVIEW or PLC systems), an OPC UA-based infrastructure should provide a comfortable framework to develop applications in a popular language, on common platforms. Although SDKs provide useful high level functionality that is normally not part of a general middleware like CORBA, an extra software layer and tools are needed to simplify application development and deployment.

Table 2: Qualitative Analysis

Requirement	Spec.	SDK	Comments
Platform independence	Yes	Yes	No reliance on platform specific technology; SDKs are available for most platforms (non-real-time, real-time, and embedded).
Scalability	Yes	Yes	OPC UA is designed for vertical integration from sensor level up to mainframe level. Applications expose well defined *Profiles* to describe which services they support. In our test set-up, UA applications could be developed for embedded devices with few supported profiles (such as PLCs) to rich-featured servers on Linux PCs.
Reusability	Yes	Yes	OPC UA facilitates and encourages the definition and standardization of information models that extend the standard namespace. This is exemplified in Fig. 2: standardization can be achieved on a low level (e.g. by representing all sensor values according to the standard *AnalogItemType*), on a high level (e.g. by deriving a *DetectorControllerType*) or even on a system-wide level (by referencing Nodes in other servers in order to facilitate the organization of complex systems and avoid unnecessary aggregation).
Communication paradigms	Yes	Yes	Services are defined to read and write data, to invoke methods on remote objects, and to subscribe to events and data changes (monitored items). Multiple operations (e.g. method calls) can be invoked in one request. The tested SDK provides both a synchronous and asynchronous API for the service calls. Processes requiring a longer execution time should be modelled as *Programs* (standardized state machines) instead of methods.
Complex data	Yes	No	Servers need to expose the structured variable instances, their type definition and their encoding details (so that clients can discover how to interpret them). The SDK we tested required manual encoding of these user-defined types, but both stub/skeleton code generators (for types known at compile time) and generic helper classes (for types known at runtime) were due to be released with the next minor update.
Lifecycle management	No	No	Due to scalability and platform independence, OPC UA systems may be very heterogeneous. Therefore transparent starting, stopping and killing of client and server processes is complicated or (in case of embedded devices) may be impossible. Lifecycle management of objects similar to the container-component model can be accommodated well by OPC UA, but the central "manager" (or a hierarchy of managers) needs to be developed on top of the SDK. When a manager references Nodes in other servers, clients can easily resolve these Nodes by using standard OPC UA services.
Alarms	Yes	Yes	*Alarms* and *Conditions* (representing the state of a system) are standardized in OPC UA by extending the event mechanism. Advanced features such as "shelving" (to prevent operators from being flooded by alarms) are built-in.
Logging	Yes	Yes	Straight-forward to implement by extending the *BaseEventType* (containing fields for the timestamp, priority, description, ...) or one of its subtypes (e.g. for auditing purposes).
Location transparency	Yes	Yes	OPC UA foresees *Discovery Servers* at well known locations, to which other servers can register. Clients can query them to find the location of the server they need. More advanced discovery of applications is feasible via a *Global Directory Service*.
Historical archive	Yes	Yes	OPC UA does not define how historical information is stored, but does specify how it can be accessed. An attribute is assigned to variables and event notifiers to specify whether historical data or events are available. Clients can invoke standard services to read or modify raw (or even resampled) historical data at given timestamps and intervals.
Dependability	Yes	Yes	A wide range of mechanisms to increase reliability and availability are offered on a low level (e.g. sessions handlers can deal with network interruptions) and on a high level (e.g. compliance tools are available to test servers and clients). Security measures (confidentiality, integrity, authentication and authorization) are part of the stack and are therefore implemented by most OPC UA products. Due to the extensible design of OPC UA (e.g. new encodings and transport protocols can be added) and the wide support from industry, OPC UA is likely to be future proof. However, due to the lack of a standardized API, a system infrastructure may strongly depend on a particular stack or SDK.

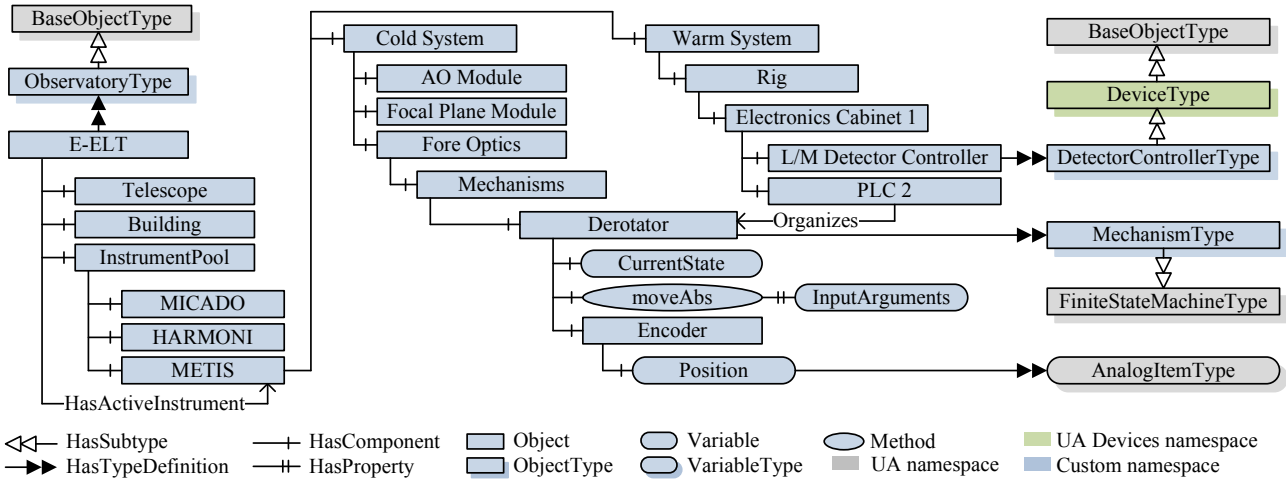

Figure 2: Example of a full mesh information model in the context of METIS.

An important difference with CORBA is the poor availability of stub and skeleton code generators. Similar to CORBA Interface Definition Language (IDL) compilers, OPC UA code generators can be used to convert XML namespace definitions into stub and skeleton code. Unfortunately, only a few OTS code generators existed at the time of writing this article. Those we did find were either inaccessible or too inflexible for us. Therefore we decided to estimate the expense of a homemade solution. For this purpose we wrote a few Python scripts which were able to convert XML namespace definitions (designed in UML [1] by one of the available graphical tools) into C++ server skeletons with rudimentary introspection and dispatching functionality. Application developers can derive classes from these skeletons and include business logic. When the corresponding objects are instantiated and registered to our server implementation, both the object instance and type definition are automatically exposed. On the client side we opted for a design with a narrow interface, in order to accommodate multiple actions in one service call. While it's clear that our experimental code is unsuitable to be used outside our test environment, we expect that it will take less than a man-year of work to prepare and commission a basic framework for the Mercator Telescope.

CONCLUSIONS AND OUTLOOK

In conclusion, we consider OPC UA suitable to serve as the "backbone" technology of ground-based observatory control systems. We estimate that the specification and available implementations are sufficiently mature and complete to cover the requirements of many projects. Even so, at this moment an infrastructure built around OPC UA cannot take full advantage from all opportunities offered by the specification, since the adoption by industrial products is still limited. For instance, UA Binary connectivity is generally supported, but SOAP/HTTP is not.

With respect to a "general purpose" middleware such as CORBA, OPC UA is naturally more tailored to facilitate interaction between the components of a heterogeneous and distributed control system. In effect, much of the basic functionality (alarms, logging, monitored items, ...) required by infrastructures for astronomical observatories is already standardized by the OPC UA specification. As a result, development efforts are reduced (because this functionality is offered by SDKs), and more importantly, industrial software and hardware can be integrated much more seamlessly since they comply to the same standard.

More effort and a more rigorous approach are certainly needed to create a framework which streamlines and facilitates application development for PCs, but we consider the investment worthwhile even within the constraints of a project on the scale of the 1.2m Mercator Telescope. For the refurbishment of this control system we aim to host most software on industrial PLCs and Linux PCs. We will thereby try to benefit as much as possible from technology advancements such as powerful and dependable soft-PLCs, flexible (object-oriented) PLC programming environments, and OPC UA as the universal control interface.

SNS ONLINE DISPLAY TECHNOLOGIES FOR EPICS*

K.U. Kasemir, X. Chen, J. Purcell, E. Danilova, ORNL, Oak Ridge, TN 37831, U.S.A.

Abstract

The ubiquitousness of web clients from personal computers to cell phones results in a growing demand for web-based access to control system data. At the Oak Ridge National Laboratory Spallation Neutron Source (SNS) we have investigated different technical approaches to provide read access to data in the Experimental Physics and Industrial Control System (EPICS) for a wide variety of web client devices. We compare them in terms of requirements, performance and ease of maintenance.

INTRODUCTION

Traditional control system operator interface tools were often standalone applications for a specific operating system [1]. Recent developments emphasized operating system portability, allowing users in their offices or even at home to run the same applications that are used in the control room [2]. These new tools are highly integrated, offering a workflow that previously required switching between multiple standalone programs [3]. While there is a continuing need for such feature-rich applications, there is at the same time a desire for web-based control system access. This online view of the control system might be read-only, at a limited update rate and restricted to a subset of the machine, but it should be accessible from any web browser, be it a desktop computer, laptop, netbook or cell phone, without need to install any additional software on the client device.

CONTROL SYSTEM DATA

The following examples refer to EPICS, but the fundamental ideas apply to any control system. The control system allows network access to data points called Process Variables (PVs). Certain PVs might change at a known rate, but the most common case is data that changes at arbitrary times. "Set point" PVs for example will stay constant until adjusted by an operator. PVs for temperature readings might vary slowly over time, while other machine parameters can change rapidly.

Polling vs. Event-Driven

A control system display tool should be event-driven, reflecting changes as they occur. If the display is polling the PVs for updates, resources are wasted polling data points that stay constant while at the same time missing updates that are faster than the poll rate.

BASIC WEB TECHNOLOGY

The Hypertext Transfer Protocol, HTTP [4], is the basis of all web technology. It typically functions as follows:

1) Web client establishes a network connection to the web server.
2) Web client requests a web page by sending GET /some_web_page.html HTTP/1.1
3) Web server returns the web page content.
4) Server and client close the network connection.

The request as well as the response can include additional parameters. Server and client may keep the network connection open for follow-up requests, but the protocol remains a request-response pattern.

There is no method in HTTP that is implemented by all web clients to support a "push" of updates from the server to the client. Every data transfer needs to start with a request sent by the client. This makes HTTP fundamentally unsuitable for event-driven updates as desired for control system displays! Users would have to manually initiate a request by pushing the "Reload" button on their web browser to update the display to the most recent data.

There are several commonly used approaches to work around this limitation in a way that is supported by the majority of web browsers.

Web Browser Plug-Ins

Most web browsers allow the installation of plug-ins to extend their functionality. The CAML project uses a WebCA plug-in to add native support for EPICS Channel Access to several web browsers [5]. This solution offers the best possible performance because the web client directly receives updates from the control system.

The approach is, however, specific to certain web browsers. The direct network traffic between the client and the control system is also often blocked by firewalls that only allow access to the standard web server port TCP 80, or generally restrict access to the control system to computers on the plant network.

Consequently, this approach cannot offer generic web access to control system displays from a wide range of devices, including cell phones.

Ajax

Ajax [6] uses JavaScript code running inside the web browser to create XMLHttpRequest (XHR) objects [7] that in turn perform requests to a web server. The JavaScript code then handles the response, typically by updating the web page with the received data. Ajax still uses the HTTP request-response pattern, but it no longer requires the user to *manually* initiate requests because the JavaScript code inside the web browser itself can initiate the requests.

Ajax can be used to implement a polling web client that periodically requests updates from the web server.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy

Long Poll

A "Long Poll" [8] uses a polling Ajax web client as just described with the additional agreement between server and client that the server can delay its response until updates are available:

1) JavaScript in client starts XHR to request.
2) Web server waits until updates become available.
3) Once there are updates, web server returns the data.
4) Web client displays the data and immediately starts another XHR, i.e. repeat step 1.

Technically, this is still a polling request-response mechanism. In a true event mechanism the client would not have to re-issue any request. The server would simply send updates via a once established network connection.

Performance is lower than a true event mechanism because of the additional network traffic for sending the requests. The client or server might even close their network connection at the end of each transaction, requiring a new connection for each long poll.

To the end user, there is hardly a difference: The display can be updated as soon as the server sends new data.

SNS STATUS WEB SITE

The SNS Status web site is a Java Server Page (JSP) project running on a Tomcat web application server [9].

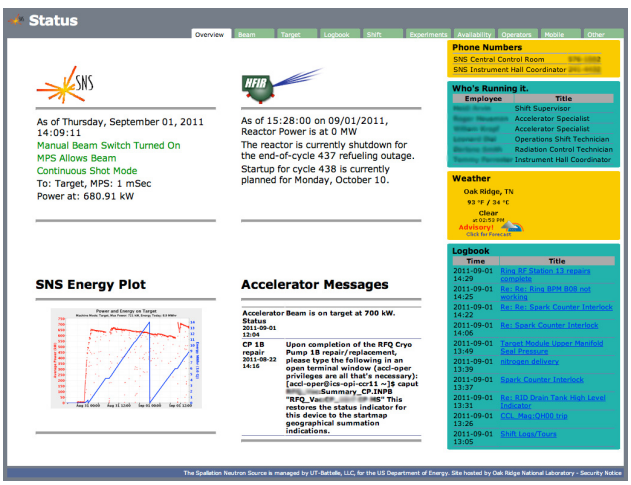

Figure 1: SNS Status Web Page.

It displays a fixed set of pages, arranged in "tabs", to summarize the recent history of SNS operation, including beam power, state of beam lines, availability statistics, recent logbook messages, and shift summaries.

Certain sections of these web pages are periodically updated via Ajax. The beam power in the upper left section of Fig. 1 for example is refreshed every 3 seconds, while other sections of the page are updated at intervals of 30 seconds or even minutes.

Java code on the web server, i.e. Tomcat, subscribes to a predefined, fixed list of PVs and maintains a table of their current values. Ajax requests from web clients invoke Tomcat servlets, which then read the current PV data and format it to for example generate the beam status information shown in Fig. 1.

The SNS Status Web site has been online since July 2010. It has been very stable. It can be accessed by any web client, and requires only a few CPU and memory resources. Sections of this web site are displayed on hallway monitors throughout the SNS facility. The beam history information from this web site is a key component of daily status meetings.

The majority of its content, however, is based on data read from a relational database, not online PVs. Only about 50 PVs are monitored by the Tomcat application, updating sections of the web page at comparably slow periodic rates as mentioned.

The web site offers a common denominator of data that is of interest to many users. The overall content and its layout are fixed. End users cannot customize it to meet their specific, individual needs.

SNS DASHBOARD

The SNS Dashboard was created to provide more flexibility. Users can choose from a list of widgets, some of which are customizable. Widgets can be opened and closed; they can be "dragged" to the desired position on the web page.

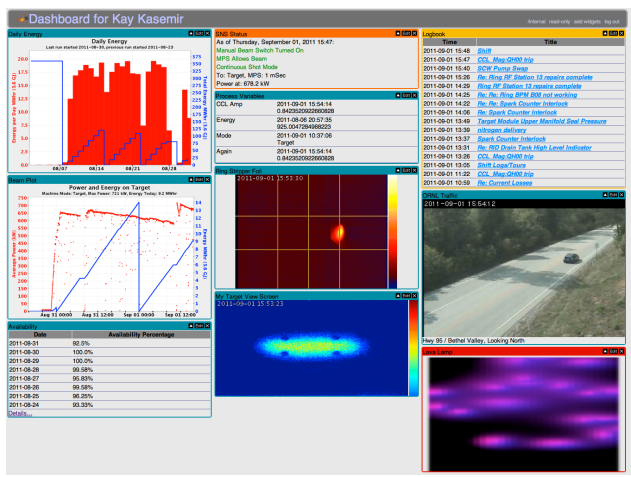

Figure 2: SNS Dashboard.

At this time there are about 20 widgets. Some duplicate information that is already offered on the SNS Status web site, but users can now consolidate the information of interest on their personal dashboard. There are also widgets for a user base that was too small to warrant inclusion in the SNS Status web site. Examples include a widget that lists the devices affected by scheduled power outages, or a widget with indicators for the status of certain groups of front-end computers.

Widgets that rely on PV data utilize a Long Poll, updating as events are received from the control system. The PV pool is not fixed as in the SNS Status web site. Some widgets allow the user to configure which PVs to display. The web client will invoke a subscription servlet

for these PVs. The web server subscribes to the control system PVs and returns updates as they arrive from the control system in the next Long Poll.

In our initial implementation, each widget that depends on PV updates would issue a Long Poll, but we learned that most web browsers limit the number of parallel XHR requests to 6 or even 2. To adjust for this limitation, our dashboard software performs only one Long Poll for the whole dashboard page of a user. The data returned by the web server contains tags, which are used by the client to dispatch the data to the widgets that requested it.

The achievable Long Poll update rate varies. 10 Hz are often possible, but we throttle it to 1 Hz because it was considered fast enough for a generic online display. The web server tracks the PV subscriptions of each web client. If a PV changed, it is marked for update. Adding a 1 second delay to the Long Poll means that the web server can often return the accumulated updates for multiple PVs within one Long Poll, reducing the network traffic.

The Dashboard software is more complex than the SNS Status web page. The dashboard configuration for each user is persisted in a relational database. It is read by the web server when a user logs on, then duplicated in the web client. This duplication in the web client allows the user to efficiently edit the configuration inside the web browser. When the user relocates a widget inside the web browser or adds a PV name to a widget, the web client does not need to communicate each mouse click or key press to the web server. The web client only sends the end result to the web server, for example the new widget location or the added PV name, thereby minimizing the network traffic and optimizing the responsiveness of the web page.

Keeping the dashboard data consistent between the web server and client requires attention to detail. To complicate the implementation, this has to be done in two very different programming environments: Java on the server, but JavaScript, a Document Object Model (DOM) and Style Sheets in the web client. The JQuery scripting library [10] simplified the client-side implementation, especially the Ajax handling for different web browsers.

The Dashboard was published in June 2011 and is gaining acceptance. Users can create multiple setups, for example one for the desktop and one for the cell phone. We have been adding new widgets based on user requests. At this time, however, users can not create their own widgets or contribute them to the list of available widgets.

CSS WEB OPI

Most of our recent developments for control room and office computer user interfaces were based on the Eclipse Rich Client Platform (RCP) [2, 3]. RCP is a powerful Java framework that allows the implementation of applications, which then run on different operating systems like Microsoft Windows, Apple Mac OS X and Linux. The RCP Standard Widget Toolkit (SWT) library implements the actual user interface components like windows, buttons and other graphical elements that the end user sees on her computer screen.

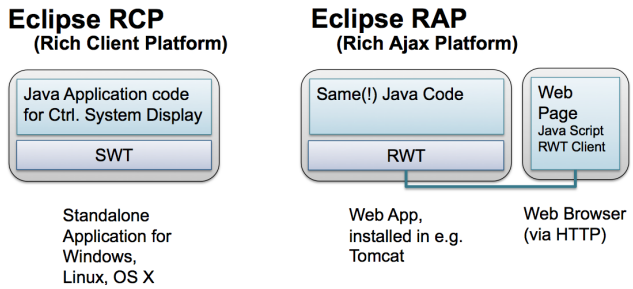

Figure 3: Comparison of RCP and RAP.

The Eclipse Rich Ajax Platform (RAP) project offers an RWT library that replaces SWT [11]. Ideally, the same Java application code that was originally developed for SWT will also run with RWT, but instead of creating a display on the local computer screen, as was the case for RCP, the RAP application is acting as a web server. Web clients that connect to this web server will see a display in their web browser that mimics the original SWT display.

The RAP application is typically installed in a web container like Tomcat. The RWT library creates HTML and Java Script code for the web client, using a Long Poll mechanism to send updates to the web client. An important point, however, is that the application developer can almost completely ignore the details of Tomcat, HTML, JavaScript, Ajax, Long Poll, because this is handled by RAP.

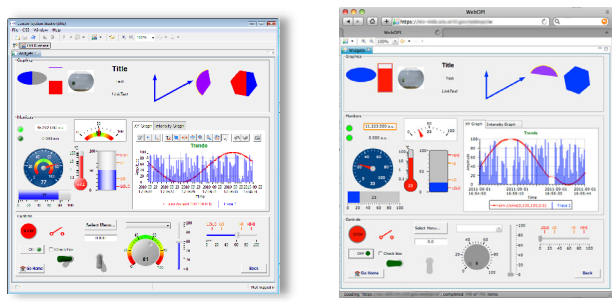

Figure 4: CSS 'BOY' display (left) and corresponding Web OPI representation.

The CSS operator interface BOY [12] was modified to execute not only with RCP but also RAP. As shown in Fig. 4, existing display files that were created with BOY can now also be executed in a web browser, providing an almost identical look and behavior. Users can develop any type of BOY display and then not only use that in the control room or their office computer but also at home and on portable device, including smart phones.

To port the existing RCP version of BOY to RAP, code for reading display files, connecting to EPICS network channels and handling control system events remained the same. This code is now executed within the web server. Its performance is naturally identical to the same code running in the RCP version.

Calls into SWT, which originally updated a physical display, now go into RWT, which in turn generates JavaScript that is queued for delivery to the web client via Long Polls. The JavaScript generated by RWT causes the web client to update the display inside the web browser.

The direct display update as performed by RCP is naturally more efficient than the RAP implementation necessitated by the shortcomings of HTTP. On a computer where an RCP display for 100 text widgets updating at 10 Hz uses about 12% of the CPU and 50MB of RAM, the combination of RAP under Tomcat with Firefox as a web browser used about 40% CPU and 80MB of memory.

When increasing the number of text widgets to 1000, the RCP display would continue to update at 10Hz, while the RAP version would degrade to 3Hz.

In an operational setup, the CPU load is of course spread across different computers. The web server can be a high-performing server machine, while the clients can be an office PC as well as a much simpler smart phone. The server handles most of the logic except for the actual display. As long as there are not too many events from the control system that require display updates, small devices like smart phones can display operator screens of considerable complexity.

The RAP design aims to allow "single sourcing". The same source code should seamlessly compile for both RCP and RAP. The main difference between the two is the fact that RCP code targets a single display, while RAP needs to handle multiple (virtual) displays. Since the SWT programming interface associates fonts, colors and other user interface resources with a display, the BOY code needed to be extended to track such resources for multiple (virtual) displays.

The network traffic between web server and client adds a certain delay to RAP that is not present in an RCP application, including the extreme case that the web client can be closed without directly notifying the web server. RAP can only detect this via time-outs.

While the BOY RCP code and the Web OPI RAP code are currently not fully single-sourced, the majority of the source code is shared by both approaches. Most important, the Web OPI offers all the features of the RCP BOY display without having to perform any coding on the HTML or JavaScript level.

We presented the web OPI to SNS users in August 2011. Its current implementation relies on certain pre-release snapshots of RAP code because RAP is still maturing technology, but our initial experience has been very good.

SUMMARY

The core web technology, HTTP, is less than ideal for online control system displays. Appropriate use of Ajax, especially the Long Poll paradigm, can alleviate fundamental HTTP limitations.

The SNS Status web uses basic Ajax technology to generate generic displays for a wide audience. The Dashboard uses Long Poll and more client-side JavaScript to offer more customization and faster updates for users that need specialized displays. The Web OPI uses RAP for web access to any BOY display, offering utmost flexibility because users can create their own BOY displays in CSS.

These three approaches complement each other. Users can access generic status displays with zero effort, invest time in creating their fully customized displays for the Web OPI, or use the Dashboard as an intermediate solution.

The Web OPI explores the limits of HTTP-based control system displays. A true event mechanism that can transfer binary data could encode the display updates more efficiently. In the future, WebSockets [13] might be available in all web clients, allowing for more efficient control system displays.

Abstract

ALICE is one of the experiments at the Large Hadron Collider (LHC), CERN, Geneva, Switzerland. Composed of 18 sub-detectors each with numerous subsystems that need to be controlled and operated in a safe and efficient way. The Detector Control System (DCS) is the key to this and has been used by detector experts with success during the commissioning of the individual detectors. During the transition from commissioning to operation, more and more tasks were transferred from detector experts to central operators. By the end of the 2010 data-taking campaign, the ALICE experiment was run by a small crew of central operators, with only a single controls operator. The transition from expert to non-expert operation constituted a real challenge in terms of tools, documentation and training. A relatively high turnover and diversity in the operator crew that is specific to the HEP experiment environment (as opposed to the more stable operation crews for accelerators) made this challenge even bigger. This paper describes the original architectural choices that were made and the key components that enabled the DCS to come to an homogeneous control system that would allow for efficient centralized operation. Challenges and specific constraints that apply to the operation of a large complex experiment are described. Emphasis will be put on the tools and procedures that were implemented to allow the transition from local detector expert operation during commissioning and early operation, to efficient centralized operation by a small operator crew not necessarily consisting of experts.

INTRODUCTION

ALICE (A Large Ion Collider Experiment) is a general purpose heavy–ion detector installed on the 27 km Large Hadron Collider (LHC) at CERN. The experiment is designed to study the physics of strongly interacting matter and the quark–gluon plasma in nucleus–nucleus collisions. Data-taking during proton-proton runs provides reference data for the heavy-ion programme and addresses a number of specific strong-interaction topics for which ALICE is complementary to the other LHC experiments.

The experiment (Fig. 1) is composed of 18 sub-detectors and the collaboration currently involves over 1300 physicists, engineers and technicians from 116 institutes in 33 countries. The overall dimension of the detector is 16x16x26m3 with a total weight of approximately 10 000 tons.

The operation of the experiment relies on several independent online systems, each responsible for a specific domain of the operation:

- The Detector Control System (DCS) for the control and safety of the experiment; this paper will concentrate on this system
- The Data Acquisition (DAQ) system is responsible for the readout of the physics data, for event building and for data transport.
- The Trigger (TRG) system selects the interesting events and triggers the readout of the experiment.
- The High-Level Trigger (HLT) system performs online reconstruction of data in order to reject or tag events and to allow for data compression.

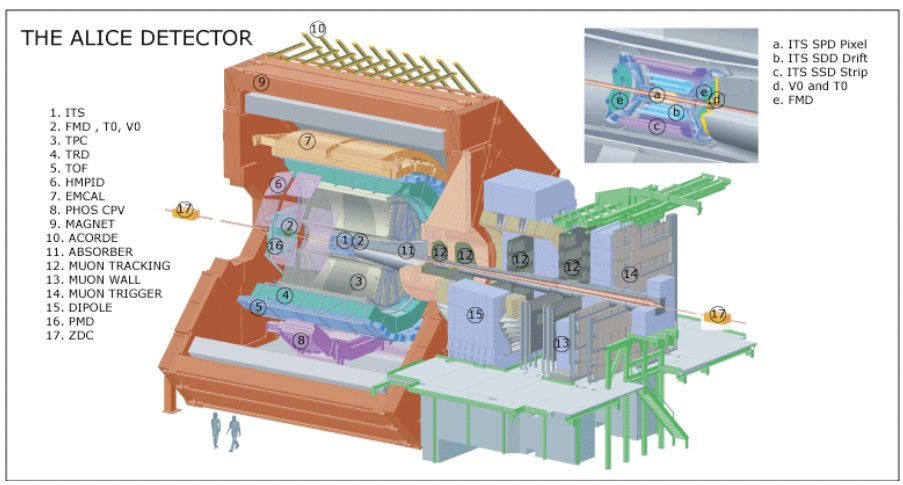

Figure 1: The ALICE detector at the LHC.

THE DCS IN ALICE

The main task of the Detector Control System in ALICE is to ensure safe and efficient operation of the experiment [1]. It provides configuration, remote control, and monitoring of all experimental equipment to allow the entire experiment to be operated from the ALICE Control Room (ACR) at LHC point 2, through a unique set of operator panels. The DCS provides the optimal operational conditions so that the physics data taken by the experiment is of the highest quality. The control system has been designed to reduce the downtime of the experiment to a minimum and hence contribute to a high running efficiency. It also aims to maximise the number of readout channels operational at any time.

The sub-detector control systems are provided by the contributing institutes; this work of over 100 developers from all around the world and from various backgrounds is coordinated by a small central controls team. The core of the controls system is a commercial Supervisory Control and Data Acquisition (SCADA) system: PVSSII [2]. It controls and monitors the detector devices, provides configuration data from the configuration database, and archives acquired values in the archival database. It allows for data exchange with external services and systems through a standardized set of interfaces.

In order to complement the PVSSII functionalities, a software framework has been built around PVSSII. It provides tools and guidelines for simplified implementation of the detector control systems. The core of this framework is built as a common effort between the LHC experiments, in the context of the Joint COntrols Project (JCOP) [3]. The main tools cover Finite State Machine (FSM), alarm handling, configuration, archiving, access control, user interfaces, data exchange, and communication. To cater for specific ALICE needs, the JCOP framework is complemented by components specific to ALICE. The complete ALICE framework is used by the sub-detector experts to build their own control applications, such as high voltage control, front-end electronics control, etc. Well over 100 such applications are finally integrated for a large and global ALICE control system.

FROM INSTALLATION TO ROUTINE OPERATION

After a long design, R&D and construction phase, installation of the first sub-detectors at the experiment site started in 2006. With this also the installation of the DCS infrastructure started, allowing the sub-detector groups to install their control systems.

From this moment, the time up to 2008 was heavily used to test and commission all sub-detectors to prepare for the first collisions in the autumn of 2008.

The year before resuming operation, late 2009 was used to install and commission more sub-detector modules, with the associated equipment and controls. This time was also used to gain experience in all aspects of running the experiment. The experiment collected cosmic ray data during several months, gearing up for the restart in October 2009.

After the end of year stop, operation resumed early 2010 to finish with a dedicated heavy-ion run. The last end of year stop saw again major installation work, notably the installation of a complete sub-detector (EM calorimeter).

Early this year, 2011, operation resumed, and in parallel, the commissioning of the newly installed detector equipment commenced.

Up to and including the start of 2009, the operation of the experiment was in the hands of the numerous sub-detector experts. It was only after several months of operation in 2010 that operation started to become more centralized. The transition to a fully centralized operation, where the whole experiment was run with a handful of people in a shift crew, took nearly 1 year. From early summer this year, the experiment is routinely run with a shift crew of 5.

It is clear that the evolution of the experiment has an impact on the DCS. The DCS has to follow the evolution to be able to fulfil its task of ensuring safe and efficient operation. The following sections will describe some of the challenges.

THE EVOLUTION CHALLENGE

Evolution in the Use and Users of the DCS

The early years of operation concentrated on detector debugging and commissioning. The DCS was used, and still developed, locally by the various sub-detector groups, providing all the functionality needed by the experts to operate their equipment for their test programs. The main task of the DCS at that moment was remote control of equipment, with only little emphasis on protection (e.g. from operator errors) since the system was exclusively used by system experts. The user interfaces used in this phase give access to the level of single channel operation of the equipment, and give the user a very detailed view of the system.

With the start of data-taking, the emphasis shifted more on operational aspects than pure remote control. Rather than manipulating individual channels, the simultaneous operation of groups of channels or whole sub-systems became important. Although several sub-detectors were operated at the same time, the actual operation was performed locally by the various sub-detector operators. These operators usually had a good knowledge of their sub-detector, but were not necessarily experts. Due to this, the need arose to present these operators with dedicated interfaces that would allow grouped operation and present information in a more concise form. At this point the protection against operation errors also became more important.

With the transition to more centralized operation, the tasks previously executed locally by the sub-detector operator were now carried out by a central operator.

Because of the large number of sub-detectors, it was obvious that the central operator would need additional tools to efficiently operate all sub-detectors. In addition, these operators usually have very little experience in sub-detector operation, so the tools shall also hide any complexity in sub-detector operation.

DCS Follows the Evolution of the Experiment

Another challenge for the DCS is that it has to cope with a continuously evolving experiment.

- Regularly, additional detector modules are installed that need to be integrated into the existing controls.
- Existing equipment is exchanged or upgraded. The DCS will have to be able to integrate this with minimal effort.
- While gaining experience in operation, the DCS might have to adapt to the newly gained insights.

The architecture of the DCS allows for meeting these challenges. The system was built with scalability in mind; new systems can easily be added. The notion of partitioning (taking control of a sub-tree in the controls hierarchy) was a key feature of the system to allow concurrent independent operation of sub-detectors.

THE SINGLE OPERATOR CHALLENGE

With the transition to a central operation of the experiment DCS, there were several challenges. Up to this point each detector was operated by a sub-detector operator; people with good knowledge of their sub-detector. This mode of operation required a shift crew of 25, which is not sustainable for the collaboration in the long term. More and more operation responsibilities were transferred to the central shift crew and currently a crew of 5 is running the experiment.

Unlike the accelerator sector, where shifts are usually covered by a reduced team of professionals, large HEP experiments face a specific challenge. It is common practice to encourage a maximum number of people to experience the operation of an experiment. In this way, people that will analyse physics data gain a better understanding of how operational issues can influence data quality. Nowadays large experiments are collaborations of a large number of institutes, and covering experiment shift duties are expected to be fairly shared between the collaborating institutes. This is the reason that the experiment is run with a relatively large pool of people that will only cover a small number of shifts. To illustrate, for 2011, the 926 8 hour ALICE DCS operator shifts are covered by about 80 different operators. So, an average operator will not do more than 11-12 shifts, making it difficult to gain solid experience.

This fact has a clear impact on the experiment DCS.

Training

The large number of new operators that need to be trained by the DCS experts puts a non-negligible load on the limited resources of the central team. For the future, a partly web based operator training might be envisaged, given the positive experience with such training courses at CERN.

Documentation and Instructions

Clear, extensive, and explicit documentation is fundamental to guide the majority of operators that have only limited experience. Classical (word processor produced) documentation is used for static documentation, and for more volatile instructions, Twiki is used.

As the central operator is responsible for the operation of all sub-detectors, the recovery of anomalies and errors is the primary task of the central operator. To facilitate this, sub-detectors have to provide a set of instructions for events that can be recovered by the central operator. One can easily understand that collecting these instructions from such a large number of sources is a managerial challenge.

This large collection of instructions shall be made easily accessible for the operator. To achieve this, context sensitive access to instructions is integrated into the main tools and interfaces used by the operator.

Hiding Complexity

Obviously, the central DCS operator cannot have the detailed knowledge of all the operational details of all sub-detectors, therefore central operation is only possible when the complexity and specificity of each sub-detector is hidden for the operator.

Each sub-detector is represented by a limited set of states (e.g. ready for data-taking, standby, etc.) and a limited set of generic commands (e.g. go ready, switch off, etc.). The calculation of the state and the internal processing of the generic commands are programmed in Finite State Machine logic by the sub-detector experts.

Experience has shown that it is nowadays relatively uncommon to operate a single sub-detector; they are typically operated in 3-4 groups. Therefore, recently, a new tool (Fig. 2) has been introduced to allow the operator to operate groups of detectors; the configuration of the groups can be done by experts.

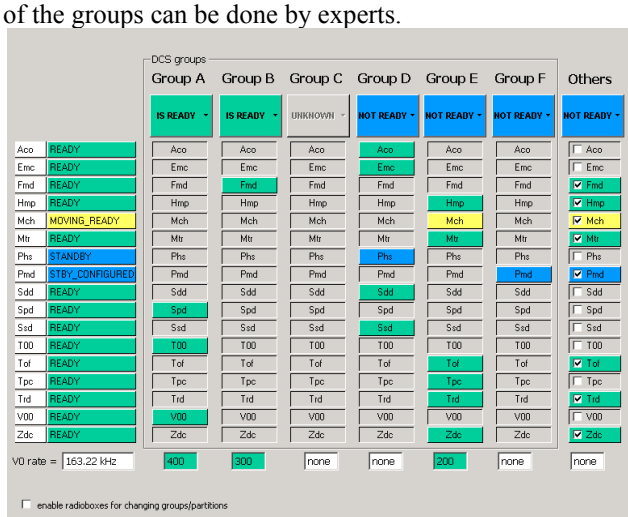

Figure 2: Group operation.

Automation

The majority of tasks the operators must perform currently require active intervention. This implies the operator has to judge when and what action to perform (e.g. switching off certain sub-detectors when beam conditions change). In order to aim for a more coherent operation we try to automate as much as possible in any routine operation.

Currently a tool is being prototyped that allows an expert to define automatic actions triggered by external events (such as a beam mode change). The tool will be accompanied with an interface where the operator can follow the automatic actions that are performed.

THE COORDINATION CHALLENGE

Integration

Each sub-detector DCS is developed under the responsibility of that sub-detector, by their experts. In order to guarantee integration of all these separate developments into a single, homogeneous control system, a strong coordination of the developments and integration is needed. At a very early stage - with the start of the first developments - strong guidelines were issued and regular reviews performed to monitor the progress.

Also now, as development still continues, the strict coordination continues to ensure the correct integration of all sub-detector systems.

Maintenance and Development

All control applications are developed and maintained by the sub-detector teams. As with many of these projects in the HEP community, application development is often done by programmers with limited duration contracts, or that spend only a limited time in the project.

With the original author no longer available, long term maintenance or new developments are more and more delicate. In some projects, the applications are now maintained by the 3rd or 4th generation developer.

FUTURE

The sub-detector details are hidden from the central operator, and all standard operations are done with dedicated tools or interfaces. However, for error recovery procedures, the operator might be instructed to access more detailed sub-detector interfaces. In order to ease the navigation through such expert interfaces, and to limit the risk of operator errors, an effort shall be undertaken to encourage further uniformity of these interfaces (e.g. same look and feel).

Error recovery instructions are created by the relevant sub-detectors using templates, so that at least the form is homogeneous. However, there is currently only a limited check on the content of these instructions. A more systematic quality assurance of these instructions is currently under study.

CONCLUSION

The Detector Control System of the ALICE experiment was designed with flexibility in mind. It was with the start of a more centralized operation that the full power of the architecture of the DCS was unveiled and this architecture allows it to cope with the challenges it faces. Some of these challenges are typical for HEP experiments (as opposed to accelerator control), such as a relatively dynamic environment, and many inexperienced operators due to the high turnaround. The challenges are not only technical, but also managerial; a strong coordination closely following the activities in the sub-detectors is the key to preserving the homogeneity of the DCS.

PURPOSE AND BENEFIT OF CONTROL SYSTEM TRAINING FOR OPERATORS

Elke Zimoch, Andreas Luedeke, PSI, Villigen, Switzerland.

Abstract

The complexity of accelerators is ever increasing and today it is typical that a large number of feedback loops are implemented, based on sophisticated models which describe the underlying physics. Despite this increased complexity the machine operators must still effectively monitor and supervise the desired behavior of the accelerator. This is not alone sufficient; additionally, the correct operation of the control system must also be verified. This is not always easy since the structure, design, and performance of the control system is usually not visualized and is often hidden to the operator. To better deal with this situation operators need some knowledge of the control system in order to react properly in the case of problems. In this paper we will present the approach of the Paul Scherrer Institute (PSI) for operator control system training and discuss its benefits.

INTRODUCTION

For the scope of this paper a machine operator is someone who monitors and supervises the behavior of one or more accelerators from a control room. Typically, the only connection between the operator and the physical machine (which can be hundreds of meters away) is the control system with the computer network it is implemented on. In the case of PSI the operators are responsible for four different accelerators each with its own control systems, most of them based on EPICS.

The general task of the operators is to remotely control the accelerators. During normal machine operation this narrows down to setting up and optimizing the accelerator settings according to the scientific needs on one hand and handling system misbehavior and faults on the other hand.

As there is no other connection between the operator and the accelerator all this has to be done through the control system, or more precisely through the user interfaces of the control system.

MENTAL MODELS

In a perfect world the control system is transparent to the operator. The operator would only need to know about the accelerator. All relevant information would be provided by the control system, correctly and in the right way. Unfortunately, there is no perfect world. Even the "right way" to display data is different from one user to the next and from one use case to the next.

If the control system can not represent the accelerator correctly, it is not transparent to the operator. This implies that information is changed on its way from the accelerator through the control system to the operator. The data is distorted by the control system like a picture is distorted by a colored lens. Therefore, the operator needs some knowledge about the control system and how it works in order to be able to recognize the distortion and clean up the information.

In cognitive science and psychology the internal human representation of a complex external system is called a "mental model" [1]. We develop such models to help us handle the complexity of the real world. They assist us in simulating alternative behavior before applying it. And in addition, they allow reasoning about the way the systems will behave or develop [2].

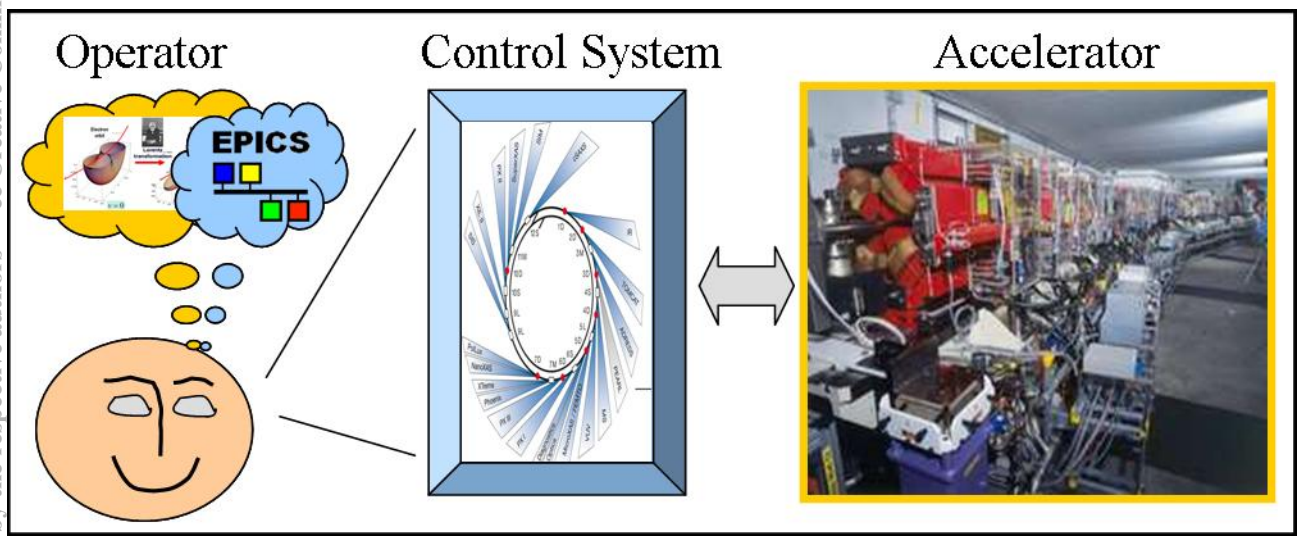

Figure 1: Operator relationship to Accelerator and Control System.

Unfortunately, to make a mental model work and fit into the "working memory" of a human brain, it has to be simplified. The aspects that are represented are influenced by background knowledge and developed over time with experience.

In the context of accelerator control the operator has to maintain two mental models: one for the accelerator and another for the control system of that particular accelerator. As the main task of the operator involves operating accelerators the mental model of the accelerator is usually acknowledged by everyone. For the majority of operator tasks this might be sufficient but as soon as some unusual situations appear the mental model of the control system gets more important. Especially during error diagnosis and recovery it is vital for the operator to distinguish between errors in the accelerator and errors in the control system.

CONTROL SYSTEM TRAINING

The question is how to influence the mental model operators have about the control system in such a way that it represents the actual reality. Fortunately, mental models are not static but change over time through learning and experience [3]. This led us to a twofold approach for operator training for the Swiss Light Source (SLS) at PSI.

EPICS Training Course

The first step prepares the ground and provides the theoretical background information. This is done in the "EPICS Training at PSI" course [4]. It consists of a lecture part and afterwards hands-on training. The lecture concentrates on an overview of the control system and informs about technical terms and general ideas.

We found that it is important to provide this lecture in German, the native language of the operators at PSI. Presenting unfamiliar concepts in a foreign language makes it more difficult to learn and accept these concepts. For scientists who do not speak German fluently the same course is available in English as it is not feasible to provide it in the native language for everyone.

Directly after the lecture a hands-on training is provided. Each operator has a dedicated control system console available as well as some hardware connected to a server. They are tutored to configure the server so that they can remotely control the hardware from the console. Some exercises are provided in order to channel the training but there are no constraints to what the operators can do.

It has been proven crucial for the success of the training to provide a safe playground and make the operators aware of it. Otherwise the fear of doing something wrong or making a mistake hobbles the playful approach. Without pressure the operators can find out how the control system reacts to faults and discover what to do in fault situations in their own speed of learning.

As the speed of learning can vary a lot given the diverse backgrounds of course participants, it is important for the trainer to have small groups. The PSI EPICS Training is provided once per month but only for four people at a time. This ensures that the trainer can concentrate on each student. In addition, each student having his own computer and hardware does not allow hiding behind someone who knows more or is quicker to understand.

Training through Experience

As mental models change over time they can decay. This happens if the knowledge of the operator is no longer up to date due to changes in the system, or if knowledge simply gets forgotten. In addition the build up of a mental model is quite slow for new operators if there is no possibility to gain experience.

In this aspect the excellent availability of the SLS has proven to be a problem. Faults occur too seldom to keep the mental models up to date. Because of this, mental models of operators (both, the accelerator model as well as the control system model) are subject to decay. But as the accelerator model gets some stimulation from change of setups and optimization of the facility it is less affected.

To counteract this knowledge decay we have introduced the "SLS Operator Training": once per month during scheduled machine time the trainer creates a problem with the actual accelerator facility. The problem is created by a dedicated program called "sabotage" that randomly selects one of several possible error sources and applies it to the accelerator or control system. One operator is chosen to solve the problem while the other operators and the trainer watch and provide help if needed.

In addition to providing experience in fault handling, the operator training allows to reflect on the way problems appear through the filter of the control system. Even if the induced fault is not connected to the control system the operator gets practical knowledge on how the control system shows problems and where to look for indications of misbehaviour.

The operators that observe these problem solving sessions have the possibility to compare the approach of their colleague to their own approach.

WHAT ELSE CAN BE DONE

To support mental models about the control system the functionality and status of the system itself should be visualized. Such user interfaces allow the operator to supervise the control system more explicitly than only through the behaviour of accelerator parameters.

Examples could be the status of network connections or hardware servers (called IOCs in EPICS). The EPICS framework provides already some tools for this purpose: the connection status of each parameter is available to the client automatically (but still needs to be displayed) and the vxStats package evaluates the status of an IOC. But error messages and status information of control system internals are often obscure. To avoid confusion, explanations or a glossary has to be displayed as well.

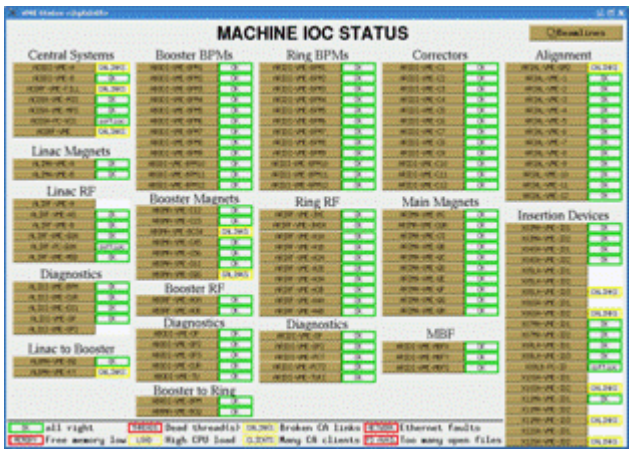

Figure 2: Example of a status screen for visualisation of Control System functionality.

Including control system information in error messaging systems like the EPICS "alarmhandler" can help the operators to distinguish between accelerator errors and control system errors. But it can hide the difference as well. Therefore, the implementation has to be thought through carefully.

CONCLUSION

Operators need mental models of the control system to recognize fault states and react appropriate to errors and misbehavior of both, the accelerator and the control system itself. Mental models gained only on infrequent experience can be imprecise or plain wrong in worst case. Control system training can provide a foundation to build better mental models and therefore help to enhance operator responses and machine availability.
For a refinement of the mental model repeated experience is needed. This can be provided by trainings sessions at the real accelerator. Reflection and discussion of the monitored error handling approach can optimize the impact.

ACKNOWLEDGEMENTS

We would like to thank

- Detlef Vermeulen and Anton Mezger for their support of the different trainings.
- The whole Controls Section for help and feedback.
- The PSI Operators for their patience.

JDDD, A STATE-OF-THE-ART SOLUTION FOR CONTROL PANEL DEVELOPMENT

E. Sombrowski, A. Petrosyan, K. Rehlich, W. Schütte, DESY Hamburg, Germany

Abstract

Software for graphical user interfaces to control systems may be developed as a rich or thin client. The thin client approach has the advantage that anyone can create and modify control system panels without specific skills in software programming.

The Java DOOCS Data Display, jddd [1,2,3,4], is based on the thin client interaction model. It provides inclusion of panel components and channel address inheritance for the creation of generic displays. Wildcard operations and regular expression filters are used to customize the graphics content at runtime, e.g. in a dynamic list component the parameters have to be painted only once in edit mode and then are automatically displayed multiple times for all available instances in run mode. This paper will describe the benefits of using jddd for control panel design as an alternative to rich client development.

INTRODUCTION

DESY is currently building a new 3.4 km-long X-ray free electron laser XFEL. This facility will deliver ultra-short light pulses with a peak power up to 100 GW and a wavelength down to 0.1 nm. The commissioning is planned in 2014. The software development has already started and concepts are currently being evaluated and improved at the FLASH FEL facility.

Jddd is developed as the main tool for the creation of graphical displays for the XFEL accelerator. It uses the thin client concept. In the following paragraphs advantages and disadvantages of thin and rich clients will be discussed.

THIN CLIENT VERSUS RICH CLIENT APPROACH

When implementing a client/server architecture it has to be determined if it will be the client or the server that handles the bulk of workload.

In a rich client system, a significant amount of data processing is done on the client or desktop system, while relatively little is done on the server. In contrast, a thin client generally does as little processing as possible on the client side and relies on accessing the server each time input data needs to be processed or validated.

Each of these approaches has its own benefits:

Advantages of Thin Clients

- The interface between client and server is clearly defined.
- Control system panels are rapidly developed using a set of predefined components/widgets.
- No programming skills are needed. Engineers, technicians and operators are able to design their own control panels. This reduces the commissioning time because the hardware and software development is in one hand.
- Panels are easily adapted to changing server properties and new hardware. The design has high flexibility to later modifications.
- Thin client software provides a standard look&feel and uniform functionality for all control panels independent from the developer.

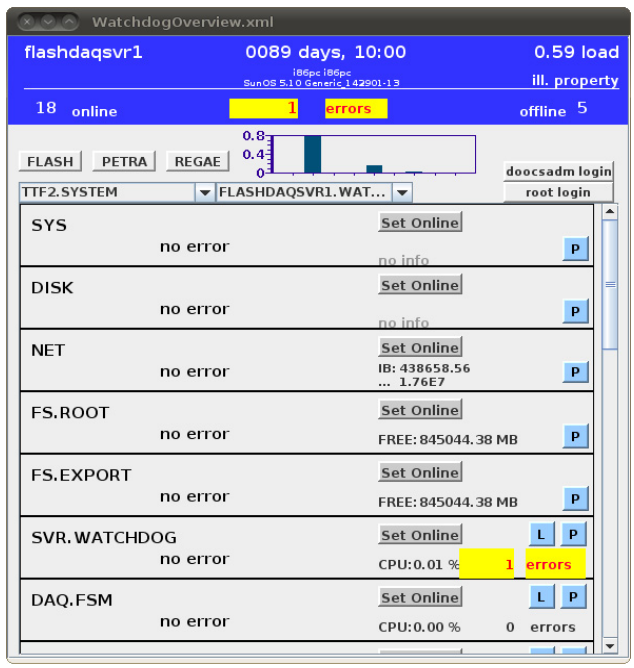

Figure 1: Screenshot of the watchdog overview panel in run mode. A dynamic list component in the lower part of the panel displays the status of all available servers on a selected CPU. A location chooser component, which is placed above the list, allows to change the facility and CPU address and therefore the list content. The buttons labelled FLASH, PETRA, REGAE switch between the different facilities.

Advantages of Rich Clients

- The functionality is not restricted to generic possibilities of thin client software. The display design is more user-friendly. Graphical components can be adapted to special use cases.
- Sometimes it's difficult to put all functionality in a server. Using rich clients, simple mathematical operations or even complex data analysis might be included on the client side.

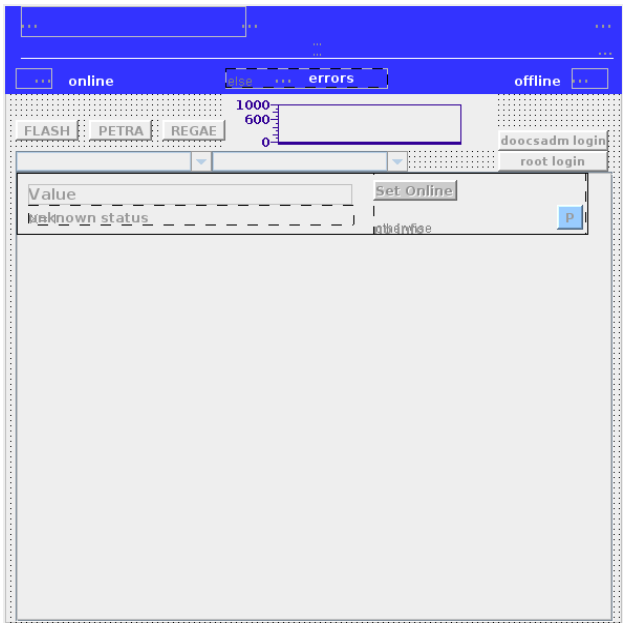

Figure 2: Screenshot of the watchdog overview panel in edit mode. The lower part of the panel contains a dynamic list component. This list is filled in run mode as displayed in Figure 1.

ADVANCED COMPONENTS AND FEATURES

To compensate the disadvantages of thin clients, to reach more flexibility in control panel design and to implement data manipulation, jddd uses different approaches:

- Dynamic components, which change their graphical content according to server properties.
- Logic components (if and switch component) switch the view between different layered panes (cases) depending on a user defined control system value.
- Buttons with “Set Component Property” function change e.g. include files or the panels base address at runtime.
- Wildcard operations, regular expression filters and JavaScript are used for mathematical data operations.

DYNAMIC COMPONENTS

Dynamic Lists

The dynamic list is a layered pane which can be filled with any jddd components in edit mode. It is assigned a base address with a wildcard for the facility, device, location, or property. At runtime the wildcard is replaced by all available addresses and the list is automatically filled with the required number of components. Figure 1 and 2 show an example for using the dynamic list in a watchdog overview panel.

Dynamic Includes

The dynamic includes component is a transparent layered pane which displays automatically multiple include components at dedicated positions according to their Z_POS and X_POS. In the FLASH orbit feedback example (Figure 4) the dynamic includes component shoes all available BPMs and steerer magnets.

LOGIC COMPONENTS

If and Switch Component

The if component contains two cases which consist of two different layered panes. The switch component contains an arbitrary number of cases. Depending on a user defined control system value one of these layered panes is displayed at run mode.

The condition for each case of a logic component is displayed in the jddd component inspector. Any case may contain nested logic components (see Figure 3).

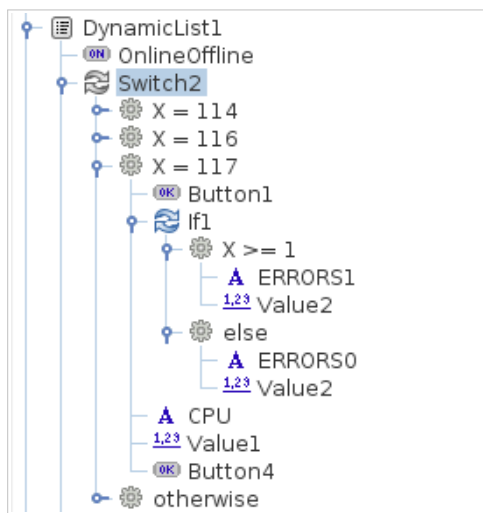

Figure 3: Example for nested switch and if components displayed in the jddd component inspector.

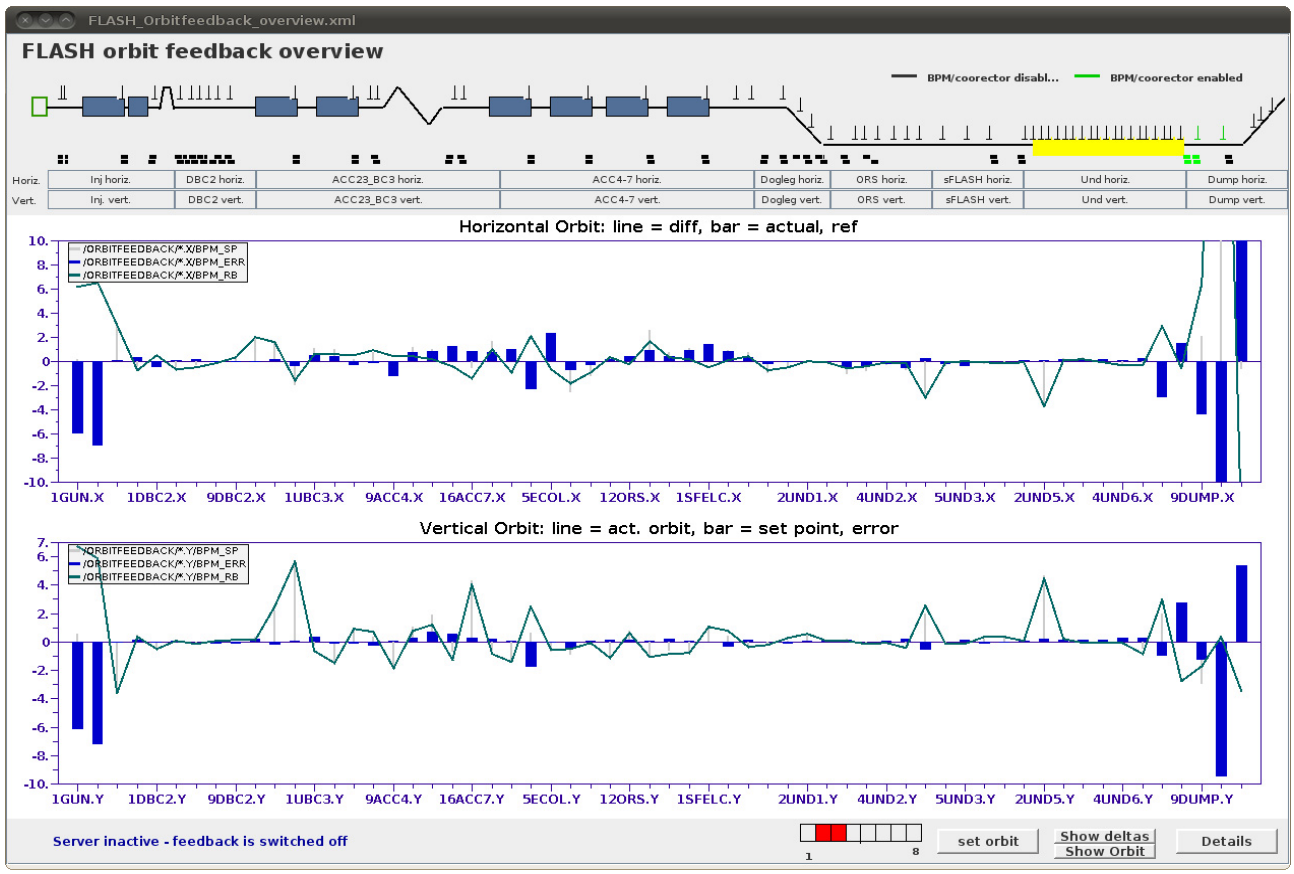

Figure 4: Screenshot of the FLASH orbit feedback panel. In the upper part of the panel dynamic include components are used for displaying BPMs and steerer magnets. The buttons “Show Deltas” and “Show Orbit” use the “Set Component Property” function to switch between orbit and delta plots.

SPECIAL BUTTON FUNCTIONALITY

A jddd button can have different functions. One of them is the “Set Component Property” function. Pressing this type of button one or multiple properties of any component in the panel are changed.

One possible use case is to modify the XML file of an include component. This changes the graphical content of the panel at runtime. In the FLASH orbit feedback (Figure 4) this button function is used to switch between delta and orbit view.

Another use case is to set the panels base address at runtime. In Figure 1 the FLASH, PETRA and REGAE buttons change the base address of the Watchdog panel and therefore switch the view between the different facilities.

WILDCARDS AND FILTERS

To allow the creation of dynamic control panels, which adapt the displayed information according to the selected server properties, jddd uses wildcard operations and regular expression filters.

Wildcards

To specify the content of dynamic lists, dynamic includes and location plots, wildcard operations in the address string are used. For example: If the address of a location plot is

TTF2.DIAG/ORBITFEEDBACK/*.X/BPM_XYZ_RB

all available locations ending with “.X” will be displayed in the plot (see upper location plot in Figure 4). For further filtering regular expression filters may be used.

Filters

For dynamic lists, dynamic includes, location chooser and the properties table a regular expression filter is available to filter the displayed data. It uses standard Java syntax for regular expressions, like *(?<!_SVR) to remove all locations ending with the letters “_SVR”. This filtering mechanism allows to display a dedicated subset of data.

JAVA SCRIPT

The "dataOp" property is used to perform mathematical operations with control system values using JavaScript syntax. It is available for the jddd components button, value, progress bar, coloured indicator, status register and switch. An example how to use this property is e.g.:

dataOp = $address1*2+$adddress2

At runtime "$address1" and "$address2" are replaced by the current values read from the specified addresses.

CONCLUSION

Jddd is more than an editor for simple thin clients. With logic components, “Set Component Property” buttons, filters and JavaScript support it offers advanced possibilities for nearly rich client development. Most panels with complex display logic can be implemented with this software and only a few high-level displays have to be created as rich clients.

Dynamic components and the use of wildcards ensure that displays do not have to be reworked if new devices are added to the control system.

Using jddd with its easy-to-use editor the development time for graphical displays is minimized. Engineers, technicians and operators are able to design control panels themselves, which reduces the workload of the control group. All panels will have a common look and feel and functionality independent from the developer.

Abstract

The Wide-area Remote Experiment System (WRES) at SPring-8 has been successfully developed [1]. The system communicates with remote users on the basis of SSL/TLS with bi-directional authentication to avoid interference from unauthorized access to the system. The system has a message-filtering system to allow remote users access only to the corresponding beamline equipment and safety interlock system. This is to protect persons inside the experimental station from injury from any accidental motion of heavy equipment. The system also has a video streaming system to monitor samples or experimental equipment. We have tested the system from the point of view of safety, stability, reliability etc. and successfully performed the first experiment from a remote site, i.e., RIKEN's Wako campus, which is 480 km away from SPring-8, at the end of October 2010.

INTRODUCTION

Remote experiments brings many benefits to the users of a publicly opened experiment facility. One of the benefits is that the system frees users from travelling to and from the facility and users can spend that time on their creative work. Additionally, the system enables international collaboration during its 24-h operation: collaboration teams can operate their experimental equipment for 24 h, despite each collaborator working only during his or her day-time.

To realize a remote experiment system, we have to take into radiation and other safety and security issues. As previously reported [1], we have built a safe and secure Wide-Are Remote Experiment System (WRES) for remote experiment infrastructure. We have built a remote-experiment graphical user interface (GUI) and experiment control server for protein-crystallography experiments on the WRES, and after many tests, we have successfully completed the first operation from a remote site, i.e., RIKEN's WAKO campus 480 km far from SPring-8, at the end of October 2010. In this paper, we describe the remote experiment control system and summarize the first and following remote experiments.

WIDE-AREA REMOTE EXPERIMENT SYSTEM (WRES)

The wide-area remote experiment system (WRES) has been developed for safe and secure remote experiment at SPring-8 [1]. For safe and secure remote experiments, we have to take into account 1) radiation safety, 2) other human safety, i.e., human physical safety, and 3) security for access over the Internet.

During a remote experiment, the situation for radiation safety is no different from ordinary experiments at SPring-8; therefore, we do not require special treatment for a remote experiment on radiation safety issues.

If a remote experiment user, who has limited information on the experimental station, operates experiment equipment while SPring-8 staff is accessing the equipment, heavy or high-speed equipment might hurt the staffs. This leads to the issue of human physical safety. To prevent this, we use the fact that when an X-ray beam is introduced into the experimental hutch that covers the equipment to shield users from X-rays in the hutch, the radiation-safety interlock system ensures there are no people in the hutch. We built a local interlock for human physical safety. The local interlock system only permits remote experiments when the hutch is "normally closed," i.e., the hutch is ready for introducing X-rays.

For network security we use Secure Sockets Layer / Transport Layer Security (SSL/TLS) communication with bi-directional authentication (Fig.1). SPring-8 staff issues an authentication certificate including a beamtime ID for the remote experiment and sends it to the remote user by e-mail. The authentication certificate is an electric file locked by a randomly generated password. The password is also sent to the remote user by postal mail. The user who has both the authentication certificate and password can start the communication with the remote experiment connection server at the SPring-8.

The connection server verifies the certificate and passes the messages from the remote user during the beam-time. From the beam-time ID included in the certificate the connection server obtains the allocated beam-time.

The messages exchanged between the remote user and the SPring-8 station control system are formatted as SVOC which is used in the SPring-8 control system "MADOCA." The connection server filters the messages and passes only permitted messages to the station control system.

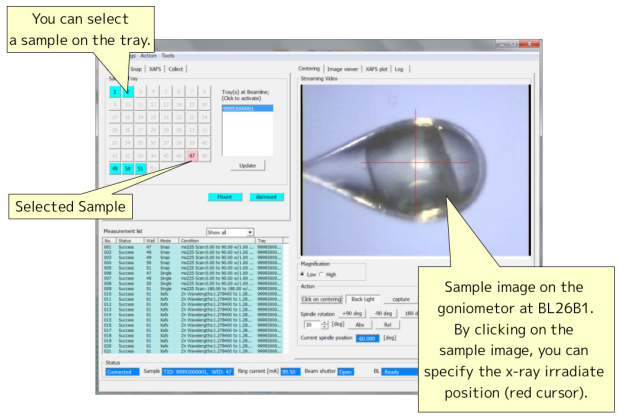

Figure 2: A graphical user interface for the remote user.

PROTEIN CRYSTALLOGRAPHY BEAMLINE BL26B1

In this section we briefly describe the SPring-8 protein crystallography beamline, BL26B1 [2]. The BL26B1 is one of the standardized protein crystallography beamline in SPring-8. The X-ray source is a bending magnet and the beamline optics consist of a double crystal x-ray monochromator, slits, X-ray mirrors. A monochromatized X-ray beam is introduced into the experimental hutch, which encloses the experimental equipment, consisting of X-ray slits, shutters, a goniometer, an X-ray CCD detector, and a sample changer. The sample changer is called SPACE [3].

The beamline and experimental station are highly automated, containing a sample changer. After users set their sample tray, which can contain up to 52 crystals on the sample changer, they can operate all their experiments from the software, called BSS [4], including sample screening, X-ray absorption spectra measurement, and automatically obtaining diffraction data.

Collected data are stored at a common data storage location for the protein crystallography beamlines and users can access their data via the Internet on the Web-based data distribution system called DCha [5].

Crystal growth becomes difficult as protein crystallography advances; therefore crystals become smaller and heterogeneous. It becomes important that the researcher who has grown the crystal specify the X-ray irradiated position for obtaining data because selection of the X-ray irradiated position determines data quality.

We focused on how a remote user can specify the X-ray irradiated position for the sample in a remote experiment. As shown in Fig.2, users select a sample number and SPACE mounts the selected sample. The sample image is then displayed on the remote user's GUI using a video streaming system, as shown at the top left on Fig.2.

By clicking on the video image, the remote user can specify the X-ray irradiated position. After taking several diffraction images, the user decides whether the sample quality is good enough for obtaining data. After the user sets the parameters for obtaining data, including the judgement of sample quality and the X-ray irradiated position, BSS starts automatic data collection. After all the data has been collected, the remote user can obtain the collected data using DCha.

FIRST OPERATION OF THE REMOTE EXPERIMENT

The first operation was made from RIKEN Wako campus, which is located 480 km from SPring-8 as shown in Fig.3. SPring-8 and RIKEN's Wako campus were connected to SINET-3 [6], which was the Japanese academic Internet backbone with 40-Gbps bandwidth[1]. RIKEN Wako campus was connected to SINET-3 at 10-Gbps bandwidht, and SPring-8 was connected to SINET-3 at 1-Gbps bandwidth.

The first experiment was successful and all the functions required for the remote experiment mostly worked well. The video streaming went down several times but this was later improved by upgrading ffserver and ffmpeg, which were used for the video streaming.

Latency from clicking on the video image to sample motion was less than 1 s. This was not dependent on the geometric distance because most of the latency was result of video encoding.

Video streaming was VGA size, 10 fps and streaming data rate was up to 800 kbps. Message exchanging data rate was much smaller than the video streaming data rate.

We confirmed that the quality of the collected data was the same as that of the data collected during an ordinary experiment.

[1]SINET was upgraded SINET-4 in March 2011 and SPring-8 connection bandwidth to the SINET will be increased up to 10 Gbps later.

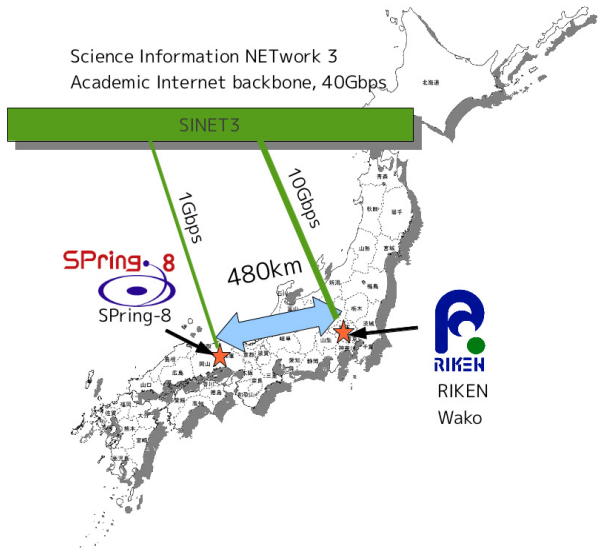

Figure 3: Location of RIKEN Wako campus and SPring-8.

CURRENT STATUS

The remote users interface was improved according to suggestions from the first experiment and opened for public protein crystallography users. We conducted training for the remote protein-crystallography experiment at the end of July 2011. We can now perform remote experiment on six beamlines.

We are now preparing for the first international remote experiment from Taiwan on BL12B2, which was constructed by the National Synchrotron Radiation Research Center (NSRRC) in Taiwan for protein crystallography.

We are also preparing a remote experiment for the another X-ray experiment field, X-ray Absorption Fine Spectra (XAFS) and plan to start testing coming April.

CONCLUSION

The first remote experiment based on the Wide-area Remote Experiment System was successful, and this indicates that the system is not only safe and secure enough but also efficient enough for conducting remote experiments. The SPring-8 remote experiment system will be expanded to include international remote experiments and other X-ray experiment fields.

COGNITIVE ERGONOMICS OF OPERATIONAL TOOLS

A. Luedeke, PSI, Villigen, Switzerland

Abstract

Control systems have become increasingly more powerful over the past decades. The availability of high data throughput and sophisticated graphical interactions has opened a variety of new possibilities. But has this helped to provide intuitive, easy to use applications to simplify the operation of modern large scale accelerator facilities? We will discuss what makes an application useful to operation and what is necessary to make a tool easy to use. We will show that even the implementation of a small number of simple application design rules can help to create ergonomic operational tools. The author is convinced that such tools do indeed help to achieve higher beam availability and better beam performance at all accelerator facilities.

INTRODUCTION

A "tool" is something that helps you to achieve a goal. It is called an "ergonomic tool" if it has been tailored to be used by humans, taking into account our physical and cognitive limitations. These days the operator in an accelerator control room pursues his goals exclusively by means of computer applications. The discipline that deals with the design of ergonomic computer applications is human-computer interaction (HCI). For the software industry this field has continuously gained in importance over the last few decades. The branch of human-computer interaction that deals specifically with the analysis of cognitive processes is known as cognitive ergonomics. It deals, for example with diagnosis, decision making and planning: all required of operators in modern industries. At the same time human-computer interaction has been widely ignored in the development of modern control systems for accelerators. The intention of this article is to advertise the basic methods of cognitive ergonomics to develop ergonomic operational tools for the control of accelerators.

MOTIVATION

One of the most important figures of merit for accelerator operation managers is beam availability. Figure 1 shows the contributions of the different systems to beam interruption time for the Swiss Light Source (SLS) in 2009. There appears to be no contribution from "bad operational tools", but "operator faults" do account for 3% of the downtime. The operational applications at the SLS are the only means of the operator to interact with the accelerator; therefore an operator fault is most likely an unintended action of the operator: he did not properly predict the consequence of his action. Or we could say that the application failed to communicate the risks of the action to the operator in a timely manner.

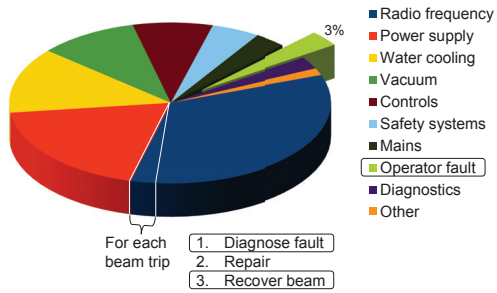

Figure 1: Beam failure statistics of the Swiss Light Source for 2009. Operational tools do affect the number of operator faults and the time to diagnose faults and recover beam.

The design of ergonomic operational tool does not just help to prevent operator faults. Every beam interruption is handled by the operator in three phases: first, he has to diagnose the fault; then he takes care that anything preventing him from making beam gets repaired and finally the operator has to recover the beam. The actual repair is often not in the responsibility of the operator, only the delegation of the repair. But as well for the proper diagnosis before as for the beam recovery after the repair he is in charge. He'll depend on his operational tools to solve these tasks quickly and efficient. If the actual repair time is on average in the same order as the time required for failure diagnosis and beam recovery, then the quality of the operational tools for these two tasks can have a significant impact on the operation statistics.

THEORY

Human-Computer Interaction

Three aspects needs to be understood for the design of good user interfaces. They are shown in Fig. 2: the goals to be achieved (the tasks), the user that has these goals (the operator) and the technology to build the user interface (the control system).

A thorough understanding of the user of operational tools, the operator, is vital to create ergonomic tools for the accelerator operation. Unfortunately many developers of operational tools are not aware that this knowledge is important. Therefore this should be the main focus of this contribution.

In some cases the operation of an accelerator facility suffers from an inappropriate specification of the tasks of the operators. The operational tools are often developed for the

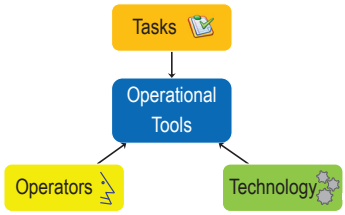

Figure 2: Tasks, operator and control system technology need to be understood for the design of operational tools.

commissioning of the facility, and therefore are optimised for the flexibility required for this phase. The tasks of the operator for the operation of an accelerator facility can differ significantly from those required for the commissioning. Problems of this type are often solved by developing new applications specifically for operation later on. A formal task analysis can help to prioritise on the development of operational tools. The task analysis section will introduce into this technique.

The technology to develop the operational tools compromises all aspects of the user interface of the control system: from input devices like a mouse, over GUI development software to the means of visualisation. This is generally among the core competence of the application developers and rarely a problem. Therefore we will omit it here.

Interaction Design

Figure 3 shows a simple model of the interaction of the operator with his tools. The operator will act on his tools by

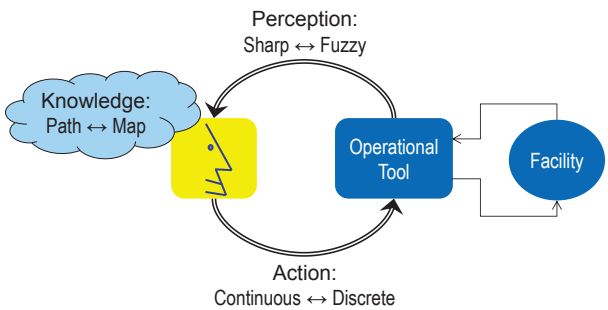

Figure 3: Simple interaction model of the operator, his operational tools and the accelerator facility.

the means of discrete control, like buttons, and continuous handles, like sliders. His actions are driven by his goal and his knowledge on how to achieve it. This knowledge can be like a path, where the operator follows step-by-step a defined procedure, or rather like a map, if the operator has a deeper understanding of his task, making him autonomous to find the way to his goal based on his knowledge. The information presented by his tool will be perceived by him either as a sharp picture, showing exactly the information he needs or rather fuzzy with room for interpretation.

A good tool should support the operator in all aspects: it should present a selection of actions appropriate to the task and easy to use by the operator, it should present all information relevant to the task in a way appropriate for the perception by the operator and it should provide all necessary knowledge required to perform the task such that they are comprehensible by the operator.

Human-computer interaction research used the theory of perception to derive guidelines for the design of effective and efficient user interfaces. The cognitive limitations of humans defining how user interfaces needs to be designed to support the user in pursuing his goals.

USER INTERFACE DESIGN GUIDELINES

While guidelines for user interfaces are formulated differently in different reference publications for user interface design, they have a great overlap in their concepts [1]. We will briefly introduce these concepts in the following, as shown in Fig. 4. Simple strategies will be provided to apply them to the design of operational tools.

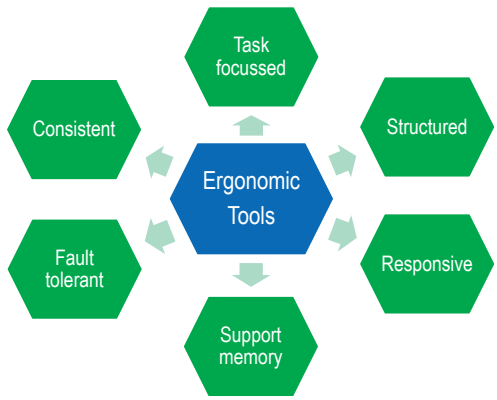

Figure 4: Design concepts for ergonomic user interfaces.

Consistency and Structure

It is obvious that consistency of the user interface has many advantages for the user. Exceptions are difficult to remember and variations in the style and layout can easily lead to confusion. Consistency is often reached without special measures, when the operational tools are created by a small number of people working closely together. If a larger number of people are involved, then a style guide helps to implement consistency in the design of the operational tools (See Fig. 5). A style guide documents a desired common style for all applications designed in a given context, like all operational tools of an accelerator facility. A variety of style aspects can be documented: the general layout of screens, the types and styles of handles and buttons to be used, the standards for the display of data, the general usage and meaning of colour and symbols or the vocabulary to be used.

The benefit of standardisation derives from the limitations of our perception. People are unlikely to mix up a picture of a close friend with the picture of a similar looking stranger, but we do confuse sometimes buttons labelled

"edit" and "exit", in particular if they are at the same location in two similar looking screens. Colour can be spotted very easily, for example a red word in a black on white text, but we have difficulties to distinguish different shades of red. We can spot relevant information quickly if it is presented in a clear, visual structure, but to find a specific word buried in a long text is very hard. The reasons for this are simple: we are good at things that helped our ancestors over the past hundred thousand years to survive. Reading text was no such thing within that time scale. And a red apple had a different shade of red anyway, depending on the light. This needs to be taken into account in the style guide: have a standardised layout and few defined handles and formats to provide structure [2]. Define few colours with specific meanings and select colours that are easy to distinguish [1]. Have a glossary of button and text labels following the simple rule: *"same name, same thing, different name, different thing"* [3]. In addition the vocabulary should be simple and unambiguous to the operators. Reading requires us to concentrate on the text, that will hinder us to concentrate on the task [1]. Use structure, colour and symbols to minimise the amount of text the operator has to read while performing his task. Many symbols have a known meaning, like a red triangle with an exclamation mark. Using them, e.g. for error messages, will catch the eye of the operator. Be careful to use "eye-catcher", like blinking text or pop-up windows: they do get the attention of the operator, but they can distract him from the task [1].

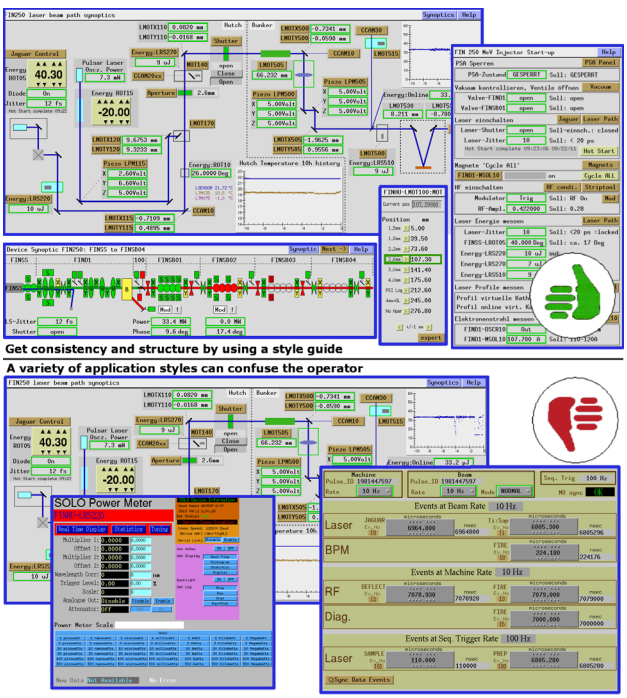

Figure 5: Use a style guide to make all operational tools similar to use. This increases the confidence of the operator in his tools and reduces the number of operator faults.

A style guide should best be ready before you start developing applications. Then it is not much extra work to adhere to it. But even after all applications have been developed, it is still a good idea to create and implement a style guide. Because many changes, like button labels or colours are very easy to change and the effort will pay off compared with the long term benefit for operations.

Task focused

A good tool should help you to achieve a goal. All your concentration should be on the task to accomplish the objective. People get easily distracted and an operator has many possible distractions: alarms to handle, telephone calls to receive, staff coming into or leaving from the control room. Therefore the tool should help the operator to stay focused on the task despite the distractions. There are several methods to help the user to focus on the task. In multi-step procedures it is useful to show which steps have been done and which still have to be done. The application should appear focused: display only actions relevant for the task and show all information useful for the task but no unrelated information.

The application itself should never distract the user from the task. Therefore it should use the task specific vocabulary, not the terminology of the application programmer. A message "division by zero, abort" will likely confuse the operator, while "the selected scan range of the measurement is zero, please select a valid scan range and retry" tells him clearly what went wrong and what he needs to do to continue his task.

Fault Tolerant

Even the best tool cannot fully prevent the operator from making errors. But ergonomic operational tools should make it hard for the operator to create significant failures and they should make it easy for him to recover from his errors. That way the operator will not just do less errors significant to operation. He'll as well feel more secure in using his tools. And his learning curve, while he's trying out new tools, will be much steeper, if he feels secure to try things out.

The confidence in his tools will even have an impact on the performance of the machine. Lets consider an SLS operator who tried to optimise the pre-accelerator with no success. He then decides to restore a saved machine setting from last week. This turns out to produce zero transmission, because - he then remembers - something had been changed yesterday on the pre-accelerator. He then learns that nobody saved the new setting. He'll be busy for an hour to restore transmission. Everyone will tell him afterwards that he should have followed the proper procedure by saving the machine settings before making many changes. This kind of stress is likely not helping him to learn the proper procedure, it is rather probable to make the operator reluctant to optimise the pre-accelerator again. It happened at the SLS, too. But we introduced an "Undo" button at the application to restore a machine setting. This allows

the operator to recover to the state before the machine settings were loaded from the file. When restoring the saved settings does not produce the desired result, he can easily get back to the previous setting. In the example he would have saved the new setting after the "Undo": this would have prevented a significant fault of the accelerator, would have reminded him of the proper procedure and would have increased his confidence in continuing the optimisation.

Responsive

Our brain has time requirements in order to perceive causality. If we click a button and nothing happens for ten seconds, then we will not be confident that things that happen afterwards are related to our actions. The following time requirements have been identified for human-computer interaction [1]:

- *0.1 sec*: immediate reaction to user input, e.g. a button appears "pressed" or a wheel-switch "turns".
- *1 sec*: status feedback if a process has not completed.
- *10 sec*: estimate time, if a process takes longer.
- *100 sec*: the typical time to make critical decisions.

A tool does not need to be fast in performing the task to meet those time requirements. It just needs to respond quickly to user input and if the task takes longer it needs to keep the user informed about the process. Human-computer interaction scientist found that responsiveness has a high impact on user satisfaction. More important for the control room is, that a responsive application clearly tells the operator what it is doing and if his attention is currently required. If it is not he can use his time for something else: fix problems to improve the performance, return phone calls to improve communication or have a cup of coffee to improve operator satisfaction.

Some examples to implement reactiveness in applications are shown in Fig. 6.

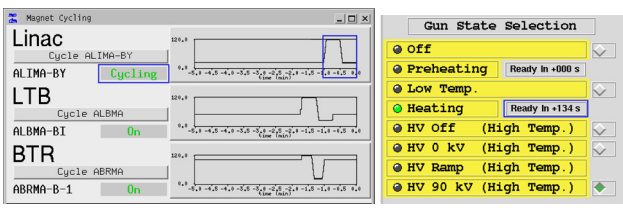

Figure 6: The magnet cycling application on the left shows the magnet current as visual feedback to the operator and the status "Cycling" while the process is still ongoing. The control panel of the electron source on the right shows a count down to forecast the end of the heating process.

Support Memory

The obvious approach to support the long term memory of an operator in performing a task is to have a thorough documentation of all the steps necessary to perform it, with a direct link from the tool to the document. Practice shows, that this works initially, most operators will read the documentation to learn the task. Some will prefer to learn the task from other operators. Once they learnt the task, only very few will read the documentation again. That should be taken into account when the documentation is updated: the operator needs to be informed about what parts have been updated and when.

There are additional methods to support the memory of the user. Each tool should clearly state it's purpose, e.g. by a descriptive title. It is often useful to provide links to related tools, to help the operator to find the tool he's looking for. Our memory works by association, therefore it will be much easier for the operator to select the proper action from a list of choices, than to recall the proper action from memory. If the number of choices is very large it is often useful to sort them by the expected frequency of usage: make those choices most visible that will be needed frequently.

A tool should provide the operator with all information required for the task. Do not expect the operator to collect the necessary information from other tools. This is particularly important during critical decision making: under stress the operator will base his decision on the available information, if the decision needs to be collected from several tools he'll may miss important information and make a bad decision.

If a tool is used to recover from a failure, then it should support documenting the failure. Do not expect the operator to type in the failure information into the electronic logbook after the failure! It is error prone and a waste of the operators time. Figure 7 shows how the magnet power supply control application at the SLS allows to save the information of the fault into the electronic logbook. This procedure is convenient for the operator but will at the same time assure that the fault is documented with complete and consistent information.

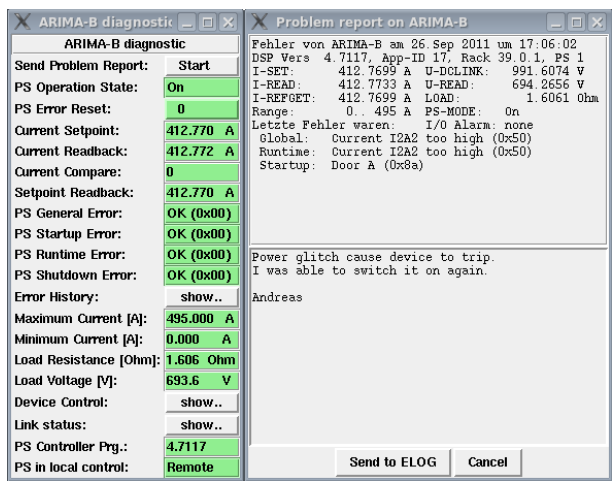

Figure 7: A problem report can be issued from the magnet power supply diagnostics application. It collects all information of the last failure and allows the operator to add a comment and save it the the electronic logbook.

TASK ANALYSIS

The method of task analysis has been developed in applied behaviour analysis and is not specific to human-computer interaction. It is the process of observing and analysing the steps of the performance of a specific task. There are different methods of task analysis and many books delve into this topic [1] [4]. We will just give a motivation here, how to use task analysis for the design of ergonomic operational tools.

Task analysis starts with observation: you watch the operators performing a task and record the steps they take to achieve their goal. The recorded steps are then organised, e.g. in the hierarchical task analysis as a tree of tasks and sub-tasks. One of the primary utilisation for task analysis is the creation of good documentation: you can use the recorded, organised steps to document the task. If you have documented the most frequent tasks of the operators, you can analyse the tools he is using for the task: Which tools are used frequently for the operator tasks? Are they appropriate for these tasks? What steps are difficult for he operator? Where are risks involved, like pressing the wrong button could cause beam interruption? Is the usage of these tools consistent or do they differ significantly?

Once you've answered these questions for the set of your operation tasks you probably know already which tools would need to be modified most urgently. But instead of starting to adapt your tools you should now start to develop a conceptual model of the operation of your accelerator. That is an idealised view on how operation should work: what tools would be useful for operation, what devices would they be used on, what are the relationships between the devices and the tools, how should they be used by the operators? Make the conceptual model as simple as possible and focused to the operator tasks, and you'll get a good starting point to prioritise your work on your operational tools.

USABILITY TESTING

Regardless on the amount of planning you've spend on the design of your operational tools: they will likely fail to meet some requirements of the users. The only way to find out is to test them on your users: the operators. Usability testing is a common method in application design [5].

A usability test will start, like a task analysis, by observing the operator using the operational tools. Here the focus is on how the operator is using the tool: Does he use it the way it has been intended? What time does he need to perform the intended task? At which point is he uncertain, where does he need guidance?

Industry builds specialised usability laboratories where hundreds of users are tested for a new product and even all eye movements of the users are recorded and analysed with special software: how long does the user look where at the screen, where does he moves the mouse pointer and when does he click where. But there is a very simple but powerful alternative for accelerator facilities with limited resources: the "think aloud" technique [2]. Tell the operator to think aloud while he's using the tool to perform the desired task. Sit behind, watch the operator and take notes. A variation of this technique is to have one operator explain to another what he's doing to perform the task. Since he is forced to explain what he is doing it will produce more information about what's going on in his mind while he's using the tool.

We use this technique frequently at the SLS. We call it "operator training": at least once a month we dedicate 90 minutes of beam time to the training of the operators. A special application called "sabotage" generates randomised system failures on demand. While one operator is responsible to fix the problem, several others are watching. His duty is to fix the problem and recover beam, to explain what he does or attempts to do and to document his actions. While the primary goal of the operator training is to exercise failure analysis and beam recovery with the operators, it serves at the same time as usability testing. Even if an experienced operator uses the tools quick and efficient, the questions from the observing operators often help to find possible improvements of the tools for novice operators.

SUMMARY

In order to design effective and efficient tools for the operation of an accelerator one needs a thorough understanding of the operational procedures. The well established user interface design guidelines of human-computer interaction theory can then be utilised to create operational tools that are intuitive and easy to use.

The optimisation of the operator interface should be an ongoing process. The techniques of task analysis can help to get a better understanding of your operational procedures. Usability testing is a proven method to improve the user interface of your operational tools. Both techniques can be implemented by regular operator training exercises on the real machine: by watching the operator actually performing his operational tasks.

The creation of ergonomic operational tools can help to achieve higher beam availability and better beam performance at all accelerator facilities.

MULTI-PLATFORM SCADA GUI REGRESSION TESTING AT CERN

P.C. Burkimsher, M. Gonzalez-Berges, S. Klikovits, CERN, Geneva, Switzerland

Abstract

The JCOP Framework is a toolkit used widely at CERN for the development of industrial control systems in several domains (i.e. experiments, accelerators and technical infrastructure). The software development started 10 years ago and there is now a large base of production systems running it. For the success of the project, it was essential to formalize and automate the quality assurance process. This paper will present the overall testing strategy and will describe in detail mechanisms used for GUI testing. The choice of a commercial tool (Squish) and the architectural features making it appropriate for our multi-platform environment will be described. Practical difficulties encountered when using the tool in the CERN context are discussed as well as how these were addressed. In the light of initial experience, the test code itself has been recently reworked in object-oriented style to facilitate future maintenance and extension. The current reporting process is described, as well as future plans for easy result-to-specification linking. The paper concludes with a description of our initial steps towards incorporation of full-blown Continuous Integration (CI) support.

INTRODUCTION

Many of the systems of the CERN Large Hadron Collider (LHC) accelerator [1] and the sophisticated physics experiments placed around its circumference are controlled using commercial Supervisory Control and Data Acquisition (SCADA) technology [2]. These production control systems have an expected lifetime upwards of 20 years, nevertheless are in general implemented by an ever changing stream of developers who frequently work on many other different sub-systems too. The CERN Joint Controls Project's JCOP Framework [3] was introduced into this mix to minimize the regular hurdles faced by new developers. The JCOP Framework strives to hide much of the complexity of the underlying SCADA tool used (WinCC-OA from Siemens, previously known as PVSS [4]). The Framework further aims to provide a level of consistency in the final application, in order to minimize the cost of long term maintenance as well as for operational safety reasons. The Framework comprises not only code segments (libraries) but also a substantial amount of Graphical User Interface (GUI) [5] software. This paper outlines the deliberate steps taken to ensure that the GUI implementations are rigorously tested.

QUALITY ASSURANCE

A strict quality assurance strategy is necessary not only to deal with the long project lifetime and staff rotation issues, but also with upgrades of the JCOP Framework itself and the packages upon which it depends (e.g. operating system version, SCADA tool, compilers, database clients and servers).

GUI TESTING

Early on in the Framework project it was recognized that the GUI mechanisms comprised a significant proportion of the software being generated. Programmers are used to testing library software in an automated fashion, but GUI regression testing is often not included [6]. To have full confidence in all of the modules of the Framework package, it is necessary to automate testing of their GUI aspects also. Considerable effort has therefore been invested in GUI regression testing – on a daily basis ensuring that the individual packages and components still behave the same way they did yesterday. This approach has proved to be very fruitful, especially when new developers first start maintaining code. Inadvertent side-effects of any changes made have been identified within 24 hours.

IMPLEMENTATION

In practice, we are testing WinCC-OA panels. An initial investigation using the tool "Rational Robot" [7] was dropped when ETM [8] switched the WINCC-OA windowing system to Qt [9]. A specialised product for the automated testing of Qt GUI interfaces was selected called Squish [10], marketed by Froglogic. Like Qt itself, Squish is available on many platforms, including those used in control systems at CERN, namely Windows and Linux. Out of the box, Squish allows you to record GUI input and test the properties (including existence) of screen objects.

Squish Recording Facility

Our first implementation made extensive use of the Squish recording facility. Squish generates human readable source code that, when executed, will replay mouse gestures and keyboard input. We opted to produce Python [11] code and have grown to appreciate the power and flexibility of this language. Although Python is interpreted, for this application domain there has never been a performance issue.

In practice though, our first implementation was very hard to maintain. Our surrounding environment was in a state of constant and uncomfortably rapid flux. WINCC-OA is upgraded to a new version each year or so. Although ETM strove very hard (and were successful) in

maintaining functional backwards compatibility, their underlying implementation did change and this unfortunately was visible to Squish and the testing software. Underneath WINCC-OA, Qt itself has been undergoing a major version change also. As our test suites grew in size, more and more code needed to be changed to keep the test system working with each new version. Similar issues presented themselves with each new version of Squish. Although in general each new Squish version would bring highly desirable functional enhancements, it was usually necessary to modify and sometimes completely regenerate sections of Squish code. Our naive approach simply did not scale.

Code Refactoring

It became clear that we needed to refactor our code to make it more robust. We tackled this problem by extracting repeated sequences of recorded code into libraries, Fig. 1.

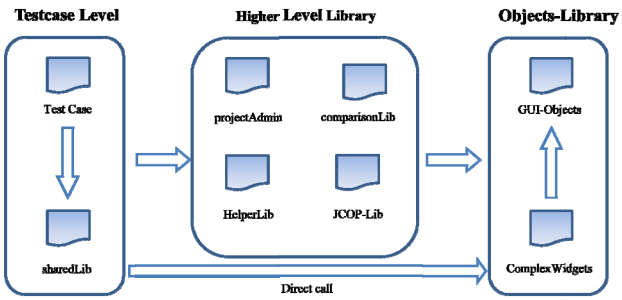

Figure 1: Library Structure.

The first step was to extract all of the routines which interact with GUI-widgets into their own library. The library was implemented in object-oriented style [12]. This programming paradigm makes it easy to define an instance of a GUI-widget once and to re-use it in several places. Our library contains several classes (one for each GUI-widget).

We then extracted all duplicate code from the test scripts into several higher-level application libraries dependent only on the above GUI-widget library. One example of an application level library would be the "Project Administration" library. This library contains a class with methods for creating, starting, stopping and deleting WINCC-OA projects, namely the functionality made available in ETM's "Project Administrator" panel. The code of these application library routines is used in nearly every test case. Extracting this code into a library makes test cases more robust and maintainable in case of changes of WINCC-OA.

The test case scripts themselves were thus reduced to library calls and verifications. Development of new tests is now quick and easy, as test creators can build on pre-existing functionality.

ENVIRONMENT

An important aspect of testing the Framework relates to the fact that the Framework runs on 2 major platforms, Windows and Linux.

One System Running On 2 Platforms

Our initial implementation attempted to validate the software on both platforms by producing a system that would execute on each of them. We opted to invoke our tests (with all of their file-system specific definitions) from within the Bash shell [13], running natively on Linux [14] but using Cygwin [15] on Windows, Fig. 2.

Figure 2: Platform commonality through Bash.

Although Cygwin is extremely powerful, the two Bashes are not identical and cause significant problems. Regularly updated versions of Cygwin provoked us into looking for an alternative solution.

One System Controlling A 2nd Platform

Squish itself is implemented as a client-server architecture, Fig. 3.

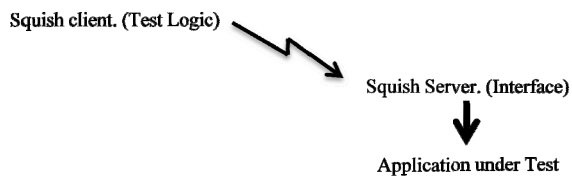

Figure 3: Squish is Client-Server.

A squish client executes the logic of the test scripts and a server executes the program being tested. This alternative arrangement was deemed to be appropriate for our multi-platform target scenario. We learned the hard way that this was not a particularly good idea. We decided that the client code would always run on Windows and would connect to the server on Windows or Linux as appropriate. Although this superficially meant that there was only one single body of testing code to maintain (always on Windows), in practice the code differed rather significantly depending on which was the target platform. As before, our problems derived from file system issues: Where was the program that was being tested going to get its data from and write its results to? These issues were not insurmountable, but they certainly made the code somewhat messy.

We encountered another much more practical problem which finally sounded the death knell to the "client-server on different machines" approach. The CERN Windows networked file-server environment was insufficiently stable to be able to work in this way. From time to time

network connections from Windows to Linux would receive a very slow response, slow enough to cause the applications and particularly their display (through the Exceed tool [16]) to decide that the network had broken. All of the windows on the target machine(s) would collapse and all of the state of the system would be lost. Any test had to be restarted from scratch – and there was no guarantee that the new attempt would not suffer a similar fate. We even tried displaying in a virtual session and viewing with VNC [17] - but this was only of partial help.

Time For A Re-think

We therefore took advantage of the code rewrite opportunity described above to revert to an architecture where the Squish client (the test logic) and the Squish server (executing the code being tested) were once again executed on the same target machine. We abandoned Bash and rewrote the test harness completely in Python, which not only made it more compatible across platforms but also made it consistent with our use of Python for the Squish test scripts.

At the beginning of the project, we were using physical Windows and Linux machines as targets for testing. We are now migrating to using Virtual Machines, hosted in the CERN Computer Centre. The advantage for us is in regard to the provision of space to house, power and cool the machines. The advantage for CERN is that our virtual machines run their jobs once per day and then go idle, releasing VM server capacity for other useful work. Thus far, our experience of this service has been excellent, with our virtual machines being functionally indistinguishable from real hardware.

The move to virtual machines has neither improved nor made worse another problem we have commonly encountered: GUI testing can be very sensitive to timing issues. Running Emu in a different environment can introduce significantly different timing behaviour. Even though Squish implements a waitForObject() function which can deal with many of the synchronisation issues, we frequently see examples where the screen update is out of step with internal data. Clicking to open up a tree structure can appear to have completed, but pressing the next mouse click too quickly can still cause problems. It is tempting to sleep for a couple of seconds or so to give the system time to catch up – but how many seconds is enough? And how many seconds is enough on all platforms, so that the code doesn't suddenly break when you change to a new operating system (Windows XP to Linux or Windows 7) or to a new software release?

ORCHESTRATING THE TESTS

At the time of the code rewrite, we stepped back, took a wider view of the system and decided to incorporate a Continuous Integration (CI) tool [18][19] that would manage execution of our tests across multiple machines, operating systems and versions. We considered using Bamboo [20] from Atlassian as a CI tool as it integrates cleanly with the other Atlassian tools (Jira, Confluence) already in use at CERN. Bamboo however needs a license and initial investigations showed it to be rather rigid in its implementation. Instead, a more configurable (and free) Open Source equivalent was selected called Hudson [21].

Hudson offers us the possibility to centrally manage the testing whilst physically distributing it to multiple machines with different operating systems and software versions installed. Tests are triggered from a central (Windows) "Hudson Master Machine" onto one or more dissimilar remote platforms, Fig. 4. The Master machine runs a web server and Hudson is configured and controlled through any browser.

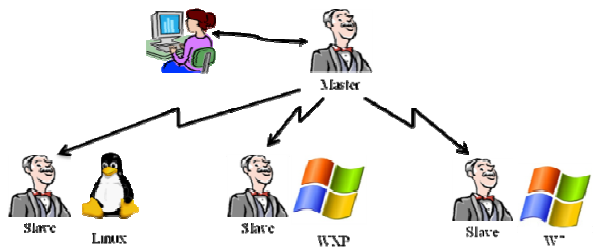

Figure 4: Hudson Master-Slave architecture.

An added bonus is that Hudson provides us with a convenient interface for having results returned to one central machine from where reports can be generated for sending to interested parties, Fig. 5.

Emu Summary (Full details here)

Topic (Test Suite)	Overall Result	OK Program Runs (Test Cases)	OK Booleans (Tests)
suite_createAVirginPvssProject	OK	1/1	0/0
suite_deleteProject	OK	1/1	3/3
suite_exerciseAnalogDigitalComponent	OK	1/1	2/2
suite_exerciseCaenComponent	OK	5/5	9/9
suite_exerciseWienerComponent	OK	3/3	6/6
suite_firstRunOfFwInstallationTool	OK	1/1	0/0
suite_installFwComponents	OK	1/1	0/0

Extract of the 14 error lines in PVSS_II.log:

Figure 5: Example result email with hyperlinks.

To date, the same central team that developed the Emu harness has also implemented the tests according to specifications drawn up with the Framework Component developers. This mode of working has several advantages:

1. The tests are prepared independently of the developers by a different individual, who is therefore unlikely to be aware of some of the implicit assumptions in the minds of those same developers. As such it is considered that these tests may be more likely to find errors than tests prepared by the developers themselves.
2. There is a written specification for the test scenarios – and consequently these are well documented. This may not always be the case in a situation where tests are written by the developers themselves.

Unfortunately this approach has a cost. The testing team becomes a bottleneck as all test code must first be written by them. For this reason we are planning to move to a scenario where the developers themselves will be able to plug their own tests into the Emu harness. Whilst alleviating the bottleneck, this comes at the cost of negating the advantages just described as well as having implications for the licensing of the software tools being used!

STATUS REVIEW

The theoretical advantages [18] of finding issues (bugs, incompatibilities, etc) before software is released, have once again been achieved in practice. New problems (side-effects) inadvertently introduced by new programmers joining the Framework development team have been spotted during the very next overnight run. We are able to test the JCOP Framework against new versions of WINCC-OA very readily by creating a new test target machine. This work is currently being extended to include the testing of a greater number of components from the JCOP Framework and also with new tests for the UNICOS Framework [22].

CONCLUSIONS

A scalable testing architecture has been defined and implemented. Automatic tests are executed every night on a variety of platforms. The architecture is not restricted to JCOP and is already being rolled out to encompass other frameworks at CERN.

ASSESSING SOFTWARE QUALITY AT EACH STEP OF ITS LIFECYCLE TO ENHANCE RELIABILITY OF CONTROL SYSTEMS

V. Hardion, A. Buteau, N. Leclercq, G. Abeillé, S. Pierre-Joseph Zéphir, S. Lê
Synchrotron Soleil, Gif/Yvette, France

Abstract

A distributed software control system aims to enhance the upgradeability and reliability by sharing responsibility between several components. The disadvantage is that it makes it harder to detect problems on a significant number of modules. With Kaizen in mind we have chosen to continuously invest in automation to obtain a complete overview of software quality despite the growth of legacy code.

The development process has already been mastered by staging each lifecycle step thanks to a continuous integration server based on JENKINS and MAVEN. We enhanced this process, focusing on 3 objectives: Automatic Test, Static Code Analysis and Post-Mortem Supervision.

Now, the build process automatically includes a test section to detect regressions, incorrect behaviour and integration incompatibility. The in-house TANGOUNIT project satisfies the difficulties of testing distributed components such as Tango Devices.

In the next step, the programming code has to pass a complete code quality check-up. The SONAR quality server has been integrated in the process, to collect each static code analysis and display the hot topics on summary web pages.

Finally, the integration of Google BREAKPAD in every TANGO Devices gives us essential statistics from crash reports and enables us to replay the crash scenarios at any time.

We have already gained greater visibility on current developments. Some concrete results will be presented including reliability enhancement, better management of subcontracted software development, quicker adoption of coding standards by new developers and understanding of impacts when moving to a new technology.

INTRODUCTION

Building, operating and maintaining a control system are complex operations. When the SOLEIL Control Group chose Tango as the distributed control system for the SOLEIL synchrotron, they firstly thought about upscaling good practices from previous laboratories to a big facility. De facto, a distributed system allows:

- Sharing between programs, as opposed to monolithic applications.
- Load-balancing to scale the number of devices to control.
- A standard communication protocol to focus development on the "business" code.

A new technology can afford the adoption of good practices only if we consider that resistance to change is an important task to manage. While we didn't call the acceptation of Tango at Soleil Kaizen, it was.

Our Kaizen : A Lean Quality

The main objectives at SOLEIL are to improve productivity and quality. Our Kaizen is inspired from the "Toyota way" or "Lean", meaning that rapid production is not possible without managing quality, and vice versa. The benefit is to detect any problems as soon as possible in the software lifecycle to reduce the cost of resolving them, which increases exponentially as production progresses.

Moreover our client has asked the Control Group to supply just-in-time solutions to their problems. So we have managed this quality project like an agile project focused on developer productivity with limited time resources.

This philosophy is based on good practices revealed by the open source community and our own experience:

- "Bottom-Up": Only the developers know how to work better. The quality process aims to generalise isolated good practices
- "Agility": We prefer modify our tools to prevent us from the non-quality instead of write documentation.
- "Don't Repeat Yourself" or DRY: We want to eliminate all small repetitive actions with no business value for the developer's job.
- "Keep It Simple, Stupid" or KISS: We won't specify our quality like a "silver bullet" with "tunnel effect" but rather by building slowly by small iterations (lasting weeks) from the actual requirement and supplying new automatism, new monitoring, new checks ASAP.
- Standardisation: Priority on components that follow our standard which can benefit from all advantages of the system. All deviations are clearly identified in our Wiki.

Only when the tools can't make a rule transparent for the developer, writing reference documentation is mandatory. But experiences show that maintenance time increases as there are many interpretations of each quality document.

Software Factory With Continuous Integration

So our quality system is mainly embodied in a Software Factory deployed in early 2008. This system integrates all tools and automation to build and monitor each piece of software. The functional perimeter includes registering new projects, building, testing and integration for deployment. The installation of the Continuous Integration principle [1] has rationalised much of the Control group's business process. This setup allowed time to be leveraged to focus on quality.

With a "just-in-time" job scheduler like Jenkins [2], the aim was to deal with automated actions at the most appropriate time. This is the case with a change in the

source code that triggers a compilation job. It's more convenient to debug code from one change than a nightly build which will compile several changes.

All our software components follow the same lifecycle defined in Figure 1, where each step is associated with a quality check.

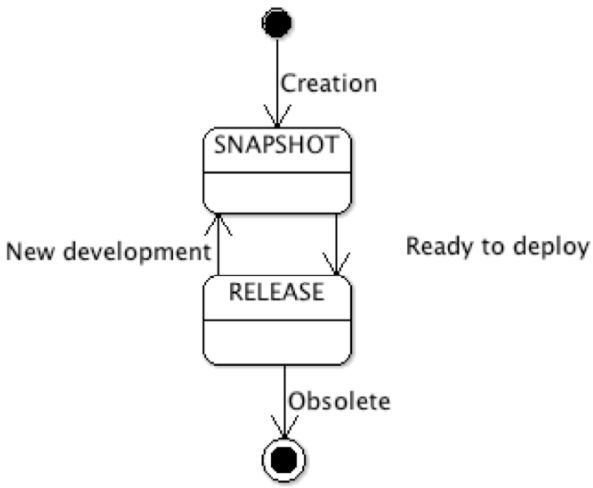

Figure 1 : Lifecycle.

In this kind of system, every new process or new tool should have the ability to be non interactive. This system is quite stable because the developers prefer to benefit from its advantages rather than use non standard tools. Even if they choose a new tool, the quality project could integrate new requirements.

The sections below will describe the extension of the Software Factory. With this new version, we chose to focus on 3 main axes: Automatic test, Continuous Quality Control and Monitoring production life.

AUTOMATIC TEST

The tests can guarantee the expected behaviour for end users as this is an important part of final quality. Although this could be the most important axis, it's also the most difficult to apply:

- No transparency: Developers have to write automatic tests themselves.
- Technically: Some difficulties with Client/Server paradigm or Graphical software
- Hardware: Equipment is often not available for automatic tests.

TangoUnit : Test For Tango Devices

TangoUnit aims to reproduce an environment for software that integrates Tango Devices. With TangoUnit, the goal is to supply a small framework to abstract registration, execution, deletion of Tango devices when the developer creates their testing environment. Tests using TangoUnit are considered as part of Integration Tests.

Simulation

An analysis made in 2010 on some beamlines reveals that only ~20% of deployed devices are directly connected to equipment. Others are process devices or from a higher layer based on the hardware equipment. It means that simulation should only consider equipment devices. This enables integration tests to be implemented for processes (high layer) devices. In the same time, some simulated devices have been created and one generic device called Transformer allows the behaviour to be changed dynamically to completely mock a real device.

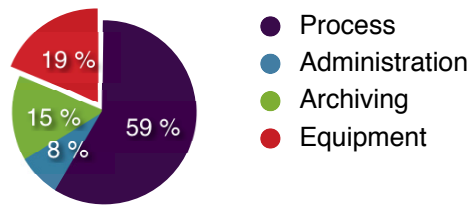

Figure 2 : Device usage.

For the ~20% of low level devices, an internal simulation mode is necessary.

Experience

How do the unit tests help to manage the recent reorganisation of projects responsibilities?

When S.Pierre-Joseph Zéphir, an ICA software engineer, took over the responsibility of the supervision project [11], she knew a little about the internal organisation of source code and the functionalities already implemented. On the other hand, the users needed to retain confidence in the one of their main tools to monitor the machine and the beamlines. If you added the current stabilisation of the new underlying graphical library and the migration of legacy components, you obtain an "explosive cocktail".

The right way to guarantee stability was to invest in unit tests especially for graphical software. Thanks to Ordinal [3], the editor of the supervision framework, which brings expertise with JFCUnit [4] a graphical testing tool, the feasibility was quickly assessed. By successive iteration, the acquired experience allowed us to better understand these black box tests on components used directly from final users.

This project cost 80% of the time spent for enhancing the tool over a period of 4 months. Initially difficult to estimate, the Return On Investment gave us more confidence in the user trust level and the comfort of portability.

A good side effect is that the rest of the team also benefited from integration tests, because the supervision software is one of highest in the dependency tree.

Next Steps

The adoption is very slow but for new project. We learned a lot from our initial success about how we can

benefit from major changes to implement tests in a project.

Today some Java projects use JUnit and a few JFCUnit for graphical tests. Some Tango Devices have a little test coverage with TangoUnit. But automatic tests are not the default practice and we will have to interest developers by training or with friendly tools.

STATIC CODE ANALYSIS

Continuous Quality Control is a process which aims to evaluate the compliance of projects to the Control Group's Quality Assurance criteria. One category specifically addresses the issue of the code quality, this is Static Code Analysis. Java developers are required to define a standard way to write code, from style to good practices.

The difficulty of obtaining a complete overview of all modules, understanding the metrics and to determining priorities from the huge metrics almost caused this project to fail.

Sonar

Sonar is an Open Source Software (OSS) developed and supported by SonarSource [5]. It aims to analyse the quality of components and report on them with a web server. The main functionality is to aggregate metrics to show only the essential data, with the possibility of monitoring metrics trends. It comes with preconfigured compliance levels for each rule.

Each new release of component triggers a complete analysis (see Lifecycle). The developer can also trigger an analysis during the development phase to allow them to anticipate the quality and correct it before the Release.

Java

Today, the Java side has been in production since late 2010 and some critical projects are actively monitored with:

- the dependency structure provides information about the abstraction level,
- the code duplication information gives maintainability level,
- the highest level violations help focusing on possible bugs.

C++

Sonar has no built-in functionality for C++. Thanks to the plugins system, it had been possible to extend Sonar. In this context, we studied the OSS market place with these constraints: multiplatform, easily parse report, no false positives and standard in the community [6]. Some tools stand out without reaching the level of Java tools.

Today the C++ analysis is integrated to Sonar through the CXX extensions co-developed by Soleil. All results come from CppCheck [7] for bug detection and Vera++ [8] for the syntax and the style of coding analysis. But we still have to invest time in determining the compliance level of each rule.

Experience

When Synchrotron Soleil decided to update the Java implementation of Tango device, G.Abeillé, the ICA engineer who has been in charge of this project, was able to check that her implementation was compliant with the OSS standard and that her unit tests were efficient.

Tango defines a standard protocol for communication between Servers and Clients. A Tango Device has some complexity with the number of execution paths with the different input and output types.

Although unit testing has a cost, we can monitor the code coverage thanks to Sonar, associated with the measure of the Cyclomatic Complexity [9]. Thus to know the effective coverage allows us to reduce the number of unit tests to the most efficient level. Others metrics like number of comments, duplication of code lines, rules compliance was useful to be OSS compliant.

Unit tests cost 2 weeks compared to the 2 months of code phase. Subsequently the unit testing cost could have been integrated in the initial time if they were written first.

Next Steps

Now the experience has benefited other projects to enhance the maintainability or recently to choose subcontractors who can comply with new ICA best practices. Sonar is also ideal to help the integration of young software developers with an accurate explanation of all rules and associated good practices. We are trying to define the monitoring process for all projects with global metrics but in an efficient way with the "Sonar Views" plugin.

POST-MORTEM MONITORING

Crash Reporting

Certainly the third success experience of this article. N.Leclercq, who is in charge of the Machine control system, enhances the quality by heading the Crash Reporting project, an "accelerators post-mortem"-like system but for Tango Control System. This process, which has been set up in production since late 2010, was motivated by the difficulty in debugging low occurrence and non-repeatable software crashes. Our accelerators operators didn't use to report these kind of events so our statistics were poor on it.

The only valuable solution was to invest in a Crash Reporting system and after evaluating the market we chose Google BreakPad [10] as the only open source and multi-OS implementation. By monitoring the current threads with another static thread able to catch all exit events, its operating principle is really non-intrusive. This library is encapsulated into the in-house CrashReport library to adjust our own parameters, such as output format or to retrieve some Tango Device informations. Then main 3rd party libraries are compiled with this CrashReport library. With the software factory, we added small pieces of code in main.cpp file of all Tango Devices used at SOLEIL. After deploying a new version of

common build parameters, the activation was carried out for all libraries and devices.

Crash Assessment is computed with each log of each Tango Device. The developer is able to replay the context thanks to the associated debugging information, although the programs are compiled with optimised options, mandatory for production deployment. Also no code instrumentation is necessary.

Quick Win

Not straightforward. This project cost approximately 80 man hours mainly due to the lack of documentation of the BreakPad project. But the ROI was immediate with working log and objective feedback each time the origin and type of failure was questioned. With this process we solved the obvious crashes caused by 30 out of the 300 Tango Devices.

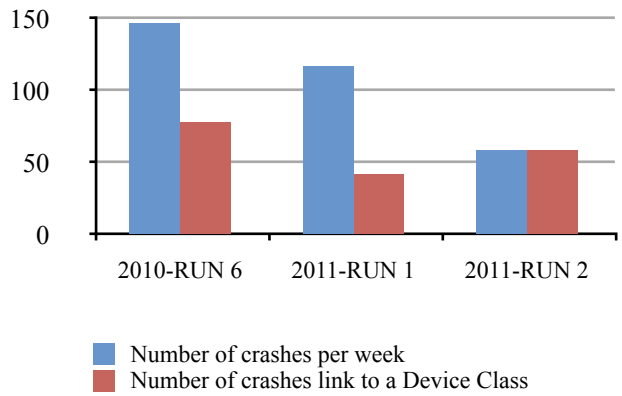

Figure 3 : Software crashes figures per Beam run (Accelerators and Beamlines).

Now we have stabilised the deviation and a maximum of crashes. Graph reports bottom out the natural law where as 80% of the crashes were caused by around 20% of the devices which corresponded with the maintenance of the global Tango Device legacy. The Crash Reporting has increased the quality of production such that the Machine's staff has clearly seen a "skyrocketing" progression.

Next Steps

This process is well monitored and maintained, but some manual operation are costly. Actually the report is made globally by hand. Other points also consist of the replay of crash context that needs the debugging info supplied with the compilation. The size of the whole distribution of binary was 5 times bigger than before. In fact, the evolution of this process will eventually be centralised like Firefox is with the Socorro project in which all crash notification will go to a server that also keeps the debugging information.

CONCLUSION

Besides of these main axis, several others monitors developed at Soleil gives us quick win results :

- Report project in activities (i.e in snapshot Status) notify developers about forgotten to release theirs projects.
- Report failed projects from dependency change is useful to analyse impact for any library evolution. This report had helped a lot to identify blocking point when we migrated all our component to the new version of Tango 7.
- Report on versions changes from the last official deployment. This report is transmitted to users to show where are the risks for the next deployment.

Obsolescence

Another point in progress we have been working on is how to target the unused Java components from the supervision software written by end-user [11]. These old components carry a lot of weight in major evolution of software. Here a simple graph analysis had allowed us to focus unit test only on used component and didn't waste our time. Cleaning the legacy should be valuable.

Human Touch

The position of the quality software manager implies good knowledge as well in software development to understand the requirement of developers than in system administration to deal with software installation. This allows to be agile with requirements.

It's important to imply the developers to these software quality processes. Sharing knowledge is also necessary for the communication and the dynamic of the team. For this purpose, we organise each month an internal regular meeting for software developers . These so-called "Café Java and C++" aims to create a dynamic for the continuous improvement of our software developments.

SYSTEM DESIGN TOWARDS HIGHER AVAILABILITY FOR LARGE DISTRIBUTED CONTROL SYSTEMS*

S. M. Hartman†, Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA

Abstract

Large distributed control systems for particle accelerators present a complex system engineering challenge. The system, with its significant quantity of components and their complex interactions, must be able to support reliable accelerator operations while providing the flexibility to accommodate changing requirements. System design and architecture focused on required data flow are key to ensuring high control system availability. Using examples from the operational experience of the Spallation Neutron Source at Oak Ridge National Laboratory, recommendations will be presented for leveraging current technologies to design systems for high availability in future large scale projects.

INTRODUCTION

The Spallation Neutron Source (SNS) at Oak Ridge National Laboratory is an accelerator-driven pulsed neutron source for scientific research and industrial development. The accelerator is a high intensity H^- linac operating at 60 Hz with superconducting RF. The accelerator control system, built using the Experimental and Industrial Control System (EPICS) toolkit, consists of over 300,000 process variables on a dedicated network of approximately 1,200 nodes, including over 500 EPICS input-output controllers for controls and diagnostics, and over 100 programmable logic controllers (PLCs).

After construction, which was completed by a partnership of six US Department of Energy National Laboratories, the SNS began a simultaneous ramp up of beam power and operational hours coupled with higher availability goals. At present, the SNS has demonstrated repeatable operation at 1 megawatt of beam power (Fig. 1), and over 5000 hours of total operating time per year including over 4500 hours of neutron production time for the user program, with availability of greater then 90% (Fig. 2).

For the 2012 fiscal year, the accelerator availability goal is 90% with a 4500 hour production schedule. For the accelerator controls system, this translates to an availability requirement of approximately 99.5%

MANAGING COMPLEXITY

Large-scale, high-expense experimental science projects are increasingly undertaken as collaborative projects in response to funding pressures and system complexity. For the SNS, the partners were all US Department of Energy National Laboratories. In this case, there was a single funding agency, with all partners responsible to the same organizational and budgetary authority. For projects such as the European Spallation Source or ITER, there is the added complexity of partner contributors belonging to separate nations with responsibility for "in-kind" contributions rather then a central budget authority and organizational structure.

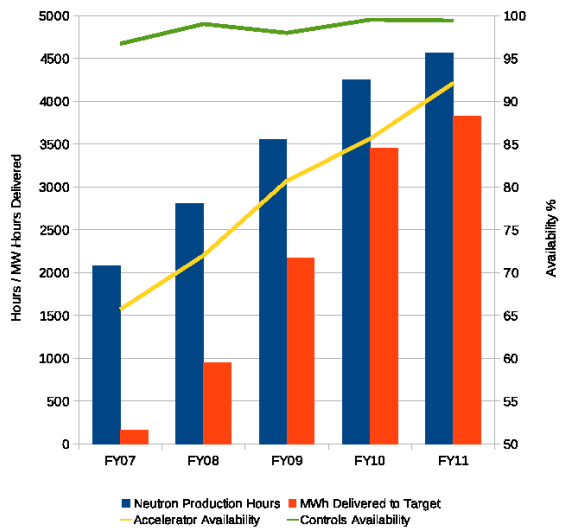

Figure 2: SNS accelerator and accelerator controls (excluding safety systems) operational performance, October 2006 to mid-September 2011.

*SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy.

†hartmansm@ornl.gov

For projects of this scope and complexity, a systems engineering approach with a holistic view of the final requirements and operational needs is critical to success. The control system serves as the interface between the various subsystems and between hardware and humans. As such, it is a key for managing this complexity. By standardizing interfaces, protocols and data handling, the control system provides the structure for bringing together the disparate parts into an overall system.

Accelerator Controls

For the SNS project, the accelerator control system group was involved early in setting standards to unify the activities of the contributing laboratories [1]. An early key decision was to standardize on a common, well developed toolkit and network protocol for use for all subsystems, namely the EPICS toolkit and the EPICS Channel Access protocol. This provided a common framework for diverse technical systems and for contributors during construction. For an operational facility, the benefit is a common set of tools and operator interfaces for accelerator controls, beam instrumentation and diagnostics, and safety systems.

Additionally, the scope for the accelerator control system was broadly conceived. The control system for conventional facility services for technical buildings, typically within the scope of the facilities or site service department, was instead included in the scope of the accelerator control system. The benefit of this decision for operations is that it becomes a simple matter to correlate, for example, the operation of a chiller or the temperature of a building with an accelerator RF structure and its impact on the beam.

Another area where the SNS control system succeeded was in the early standardization on hardware formats. Limiting the number of supported field buses and process control equipment types has resulted in simplification of long term support and maintenance. The benefit is in simpler spares management and maintenance, and fewer skills sets for which ongoing expertise is needed. Although such hardware standardization is likely to result in increased costs during the construction period, over the multi-decade life of the project, the reduced maintenance and support cost will more then offset this.

There are a few areas where early design and planning for the SNS control system has resulted in ongoing challenges for the operational period. The control system naming standard continues to be a problem. Legal names for the control system relational database are not legal in the equipment tracking and maintenance system. Names for networked devices as represented in the relational database are not compliant network host names, and it is not possible to derive the device name from a known host name. The SNS naming standard's flexibility regarding capitalization and attempts to improve readability for humans resulted in names which are neither computer parseable nor human guessable. Related to this problem is the incomplete realization of using a relational database as the definitive data source for control system tools. A lack of sufficient tools to facilitate support for early buy-in and use of the database resulted in incomplete, missing or incorrect data in the database; this still presents problems years later for control system configuration. It is critical to ensure that data entered in to the database is used from the start for actual system configuration. This ensures full investment into the system and provides the impetus to ensure data entered is correct and useful.

In recent years of the operational period for SNS, a concerted effort has been made to address control system problems that do occur at their source [2]. Review of incidents causing accelerator downtime with emphasis on identifying recurring problems and patterns has resulted in impressively high availability for the past two years. Understanding how a component, whether software or hardware, failed and how this impacted operation of accelerator systems can lead to proper fixes and long term improvements in availability.

Looking forward, an issue which needs to be addressed is obsolescence. Even though the facility has only been in operation for about five years, some custom hardware designs rely on parts which are no longer commercially available. Timing system hardware redesign is already in process [3]. At this point, industrial bus components such as VME hardware and PLCs do not appear to be a problem, or have clear upgrade paths using commercially available products. Likewise, software (such as EPICS), operating systems (Linux and VxWorks), and computing hardware (servers and workstations) have a clear path forward with reasonable compatibility available across upgrades.

The network, however, may become a problem in the future. Even after five of years of operation, the quantity of network devices on the dedicated control system network continues to grow. The initial network design resulted in a relatively flat network with a very large broadcast space for EPICS Channel Access searches. Currently, there are no significant performance issues with the network, but as the number of devices continues to increase a limit may eventually be reached. Additionally, the address space has reached a point where manual cleanup was required to allow for new devices. It would be far preferable to have the control system network more internally segmented with capacity for additional growth built in. However, such a migration would be quite disruptive at this point in the project.

Beam Line Instrument Controls

In recent months, the SNS has undertaken a review of the data acquisition and beam line controls system. Initially, this system was not included within the scope of the accelerator controls group and development took a separate path. While the accelerator control system was developed with industrial hardware (VME bus, PLCs), a mature control system toolkit (EPICS), and commercial embedded real-time (VxWorks) or open-source (Linux) operating systems,

the beam line controls were developed primarily as custom software running on commodity computers using a desktop operating system, interfacing to custom hardware. Additionally, there was less standardization on hardware, software, and system design.

Operational experience indicates a greater maintenance effort is required for this system compared to the accelerator control system. A redesign of the beam line controls system is currently in the design phase. Lessons from experience with the accelerator control system, along with beam line instrument control and data acquisition systems for other neutron sources and synchrotron sources, will be used in planning the new system (see, for example [4] [5] [6]).

The design requires a systems based approach. Beam line controls integrates a number of different subsystems including sample environment, choppers, motion control, and detector systems, and must output data in a format compatible with data analysis tools. Unlike an accelerator with a central control room and an operations staff, the experiments need to be controlled by users who may not have expertise in experiment control or data analysis. Experiments are typically scripted to allow for automated control and acquisition with minimal supervision. Nonetheless, there is significant overlap in system needs and required skill sets between accelerator controls and beam line controls.

CONCLUSION

With large user facility development projects, such as a spallation neutron source or a synchrotron light source, there is a natural progression from developing and implementing controls and diagnostics for the accelerator system to the controls and data acquisition for the experimental beam line systems. Standardization in hardware and software architecture across these systems provides numerous benefits. During the many years of project operation, the greatest expense for the controls group will be people. By sharing common technologies and skill sets for both the accelerator systems and the experimental systems, a core group can support both systems. This strategy also has the added benefit of leveling of resources between the early phases of the project focusing on accelerator development and the later phases of the project focusing on the experimental user program.

THE SOFTWARE IMPROVEMENT PROCESS – TOOLS AND RULES TO ENCOURAGE QUALITY

K. Sigerud, V. Baggiolini, CERN, Geneva, Switzerland

Abstract

The Applications section of the CERN accelerator controls group has decided to apply a systematic approach to quality assurance (QA), the "Software Improvement Process", SIP. This process focuses on three areas: the development process itself, suitable QA tools, and how to practically encourage developers to do QA. For each stage of the development process we have agreed on the recommended activities and deliverables, and identified tools to automate and support the task. For example we do more code reviews. As peer reviews are resource-intensive, we only do them for complex parts of a product. As a complement, we are using static code checking tools, like FindBugs and Checkstyle. We also encourage unit testing and have agreed on a minimum level of test coverage recommended for all products, measured using Clover. Each of these tools is well integrated with our IDE (Eclipse) and give instant feedback to the developer about the quality of their code. The major challenges of SIP have been to 1) agree on common standards and configurations, for example common code formatting and Javadoc documentation guidelines, and 2) how to encourage the developers to do QA. To address the second point, we have successfully implemented 'SIP days', i.e. one day dedicated to QA work to which the whole group of developers participates, and 'Top/Flop' lists, clearly indicating the best and worst products with regards to SIP guidelines and standards, for example test coverage. This paper presents the SIP initiative in more detail, summarizing our experience since two years and our future plans.

BACKGROUND

When LHC moved from the intense preparation and commissioning phases to operations, a consequence was increased requirements on the integrity and availability from the operations crew on the released software for controls provided for by us, the Applications (AP) section of the Controls group of the Beams department. We were at the same time facing a large and ever-growing code base, demanding more and more of our time to maintain and debug with less time to focus on new functionality. Even though some quality assurance (QA) techniques, like unit testing, were being applied in several projects, no general guidelines or standards existed. Therefore, in view of improving the quality and integrity of the products released in operations, we decided to apply a systematic approach aiming to introduce quality improvement as an integral part of the development cycle and to standardize and unify between the projects with regards to deliverables and deployment and release procedures. We call this initiative SIP, the Software Improvement Process.

OBJECTIVES

The objectives set for this initiative are:

To think of and organize us as one big team, not many small ones. This means that everybody and nobody own the software produced by the section. It should therefore adhere to the standards and guidelines agreed by all of us, not follow the personal preferences of one developer. This is important in an environment where many developers collaborate on the same software and where the turnover resulting from short-term contracts are fairly high.

To achieve better quality of products that is measurable based on predefined metrics and with an agreed set of deliverables. Metrics are important as they give us the means to measure progress, which helps encouraging the developers to apply the standards and guidelines.

To reduce code base growth by promoting the development and use of common frameworks, libraries and components, avoiding duplication.

To provide better and more comprehensive documentation of the process and components.

To achieve a better software production process through incremental improvements. We don't claim to have all the answers as we start therefore we will adapt as we go and as we learn what works and what does not work, following the evolution of the industry recommendations and tools available to us.

The process focuses on three areas: The development process itself, the QA tools available to automate the process as much as possible, and how to encourage developers to include QA in their everyday work.

DEVELOPMENT PROCESS AND TOOLS

In the AP section we apply a systematic approach, a development process, to ensure a timely delivery of software corresponding to the clients needs and requests while ensuring improved productivity and software quality. It is an iterative process, where for each iteration the project goes through the stages 'Design', 'Implement, Test and Document', and 'Deploy and Maintain' as depicted in Figure 1.

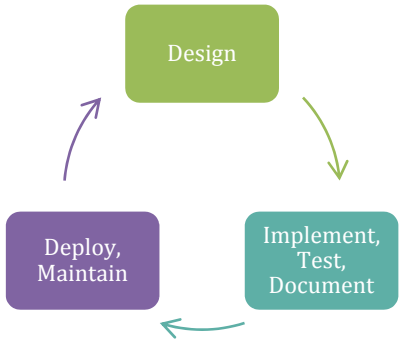

Figure 1: The stages of the development process.

For each of the stages depicted in Figure 1 we have in SIP defined the recommended or mandatory activities and deliverables. We have also identified tools that will help us automate the process as much as possible and agreed on their configuration. To ensure that each developer has these tools available and uses the same configuration, they have been integrated into an AP-specific distribution of our recommended IDE, Eclipse [1].

Design

In the design stage we have agreed to do more design reviews for new and existing projects. The purpose is twofold: firstly, it verifies the soundness of the design and propose improvements at an early stage of the iteration, i.e. before the developers invest much time in the actual coding and testing; secondly, it promotes knowledge sharing and collaboration between different development teams in the AP section, and help identify overlapping functionality, in view of reducing redundancy from our existing code base.

These reviews are at the detail level of sub-components. To discuss the design, we use UML class diagrams with the main classes and design patterns, and sequence diagrams with the interactions between these classes.

Implement, Test, and Document

In this stage the SIP focuses on three areas: the code, the documentation and the testing.

Code reviews go into more detail than design reviews. They aim at finding bugs, at making sure the code is maintainable and at verifying that our development conventions are met. However, as code reviews are very time consuming, we have decided to focus only on the most critical parts of our code (e.g. core libraries or multi-threaded code) and on code written by junior developers that need mentoring. This is done in an interactive way with person-to-person reviews of the code, but also in a lightweight, offline manner relying on the Atlassian tools FishEye+Crucible [2] integrated with Eclipse. Through this tool a committer can set up a review for a change-set, invite a number of fellow developers, which are then notified via email and can review the code changes in Eclipse and comment inline.

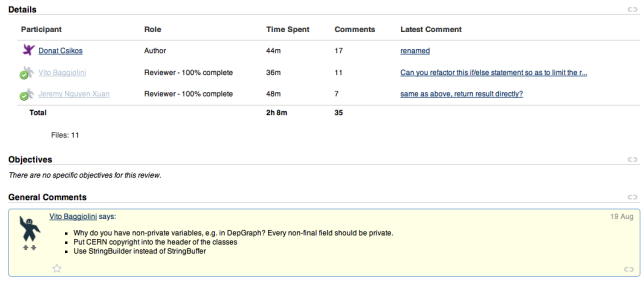

Figure 2: Code review using FishEye+Crucible.

In addition to code reviews by humans, we rely on static code analysis tools to automatically spot the most common mistakes and bug patterns. In the beginning of the SIP we performed an investigation and comparison of several tools and agreed on using FindBugs [3] and Checkstyle [4]. Plugins for these tools are distributed with our tailored Eclipse distribution, and we have agreed on a common configuration for each, also distributed with the Eclipse distribution. In addition to these external tools, we have settled on a common configuration of the Eclipse warnings, also pre-configured in our Eclipse distribution.

The benefit of having the tools integrated with the IDE is that they show up as other compilation errors, giving immediate feedback to the developer about potential problems.

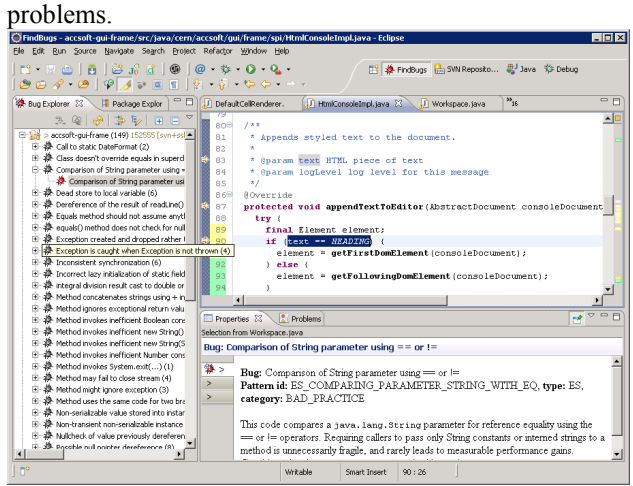

Figure 3: FindBugs report in Eclipse.

Another area the SIP focuses on is the level of testing in the projects. Even though most developers agree on the benefits of unit testing, not all take the time to implement unit tests as new functionality is added. To improve on this situation we have agreed to make unit tests a mandatory deliverable of a project: a minimum coverage of 30% for non-trivial classes must be achieved before a project can be released. We use Clover [5] from Atlassian to check the level of unit test coverage and again there is a plugin integrated with our distribution of Eclipse, giving immediate feedback to the developers of the level of coverage and the high-risk classes. Tested code appears in green, while untested code is highlighted in red (c.f. Figure 4).

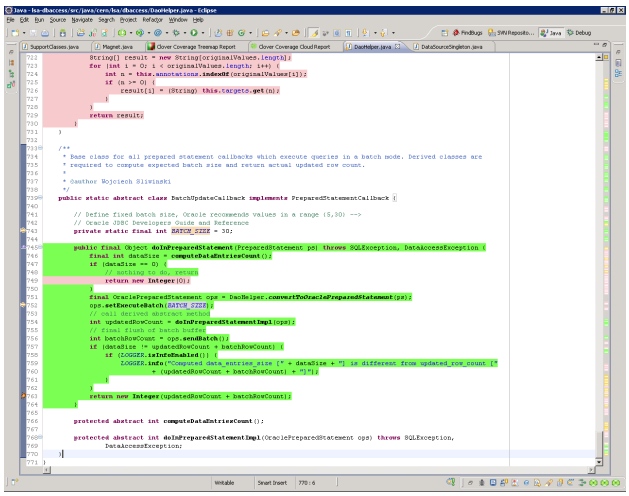

Figure 4: Test coverage indicated using Clover.

To make sure that changes in one project do not break other projects that depend on it, we have put in place a Continuous Integration (CI) server using the Atlassian tool Bamboo [6]. Whenever a developer commits changes to the source code repository, this tool checks out the new sources, compiles them and runs the unit tests. It then does the same with all dependent projects, in a cascading way, to assure that everything still compiles and all the unit tests still succeed.

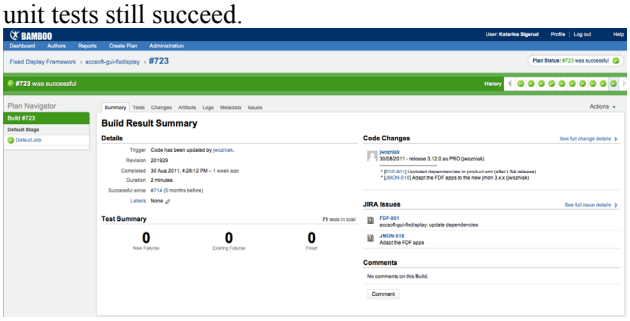

Figure 5: Bamboo build plan summary.

Documentation in SIP concerns two areas: to document the process itself and as a project artifact mandatory before a release.

To document the process, we have put in place a wiki page, detailing the set of project artifacts, best practices and standards that we have agreed on. It also lists the tools we have decided to use and their configuration.

Regarding documentation as a mandatory artifact of a project, we believe that for the documentation to be kept up to date, it should be as close to the code as possible. We therefore rely in first place on documenting the code, using the Javadoc [7] tool. At least for the base java source package(s), there should be a clear description in a file called *package-info.java,* summarizing the functionality of the package and sub-packages. As needed and for more details regarding specific sub-packages, there can be one *package-info.java* per sub-package.

Regarding documentation inside the code, we have agreed on common file and class headers, containing items like the copyright statement and SVN variables.

At least all public classes and interfaces must be documented with Javadoc following the agreed guidelines, and there should be Javadoc links to other packages (e.g. JDK).

We have also agreed on a common code formatting, available by default in our Eclipse distribution.

Both the Javadoc and the code formatting are checked using Checkstyle.

For all documentation that cannot be done using Javadoc, we are relying on Atlassian's wiki Confluence [8] to document the process and project-specific information.

Deploy and Maintain

In the deployment and maintenance phase, we have focussed on introducing a common build, release and deploy procedure using tools developed in-house. We have made a particular effort to standardize the deployment of Java server-side processes. For this we have agreed on a common naming, location and directory structure, supported by tools that enable us to easily deploy a new version of our products into operations, but also to roll-back to the previous version if necessary. The benefit is that the processes are now easily recognized and located by most members of the AP section, and allows them to intervene on processes of their colleagues, e.g. to restart or roll-back a process if necessary.

Once a process has been deployed operationally, the follow up of issues and new requests is important. We have chosen to rely on Atlassian's issue tracking tool JIRA [9] for this as it gives us the transparency we are looking for and is easily configurable to our needs. Being an Atlassian tool it also integrates well with the other tools in our development process, like the CI server Bamboo and FishEye+Crucible for code reviews where an issue number is the traceable item across all three, as shown in Figure 6.

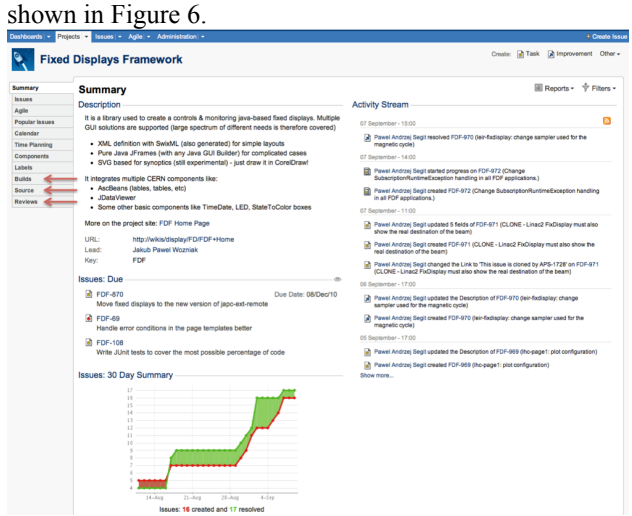

Figure 6: JIRA project summary page with links to Bamboo builds and to sources and reviews through FishEye+Crucible.

CHALLENGES

The two major challenges of SIP have been (1) to agree on the common standards and configurations, such as the common code formatting and Javadoc documentation guidelines described previously and (2) to encourage the developers to do QA.

For the first point, the approach we have taken is summarized in the first objective described above: *Think of and organize us as one big team, not many small ones*. As the code belongs to the section, not to a project or an individual developer, it should adhere to the guidelines and standards agreed by everybody not the preferences and habits of a single person.

For the second point, most members of the AP section saw the benefits of the QA techniques discussed here, and many projects already applied some of them consistently. However, they felt that their priority was to sort out issues and to provide new functionality requested by the users, and hence, they felt they did not have time for more QA work. To address this issue, we have decided to 'officialise' the time spent on QA and make the artifacts it produces mandatory deliverables of a project before release. QA objectives are part of a project's yearly objectives and prioritized and reported on regularly as with more traditional objectives. The progress for each project to adhere to the agreed guidelines is also tracked and 'Top/Flop' lists are presented on our wiki showing the best and worst projects. Finally, we have introduced "SIP days", approximately one every 3 months when everybody in the section works on a common goal, e.g. to increase the test coverage, to complete documentation or to standardize deployment configurations. This is to encourage the developers who might still have difficulties to find the time for QA activities to apply the guidelines, standards and tools in their work.

FUTURE PLANS

As for our development, we are also for the SIP applying an iterative process and continuously considering how to improve and move forward with QA related work.

Inside the section, there is still some work to finalize the list of guidelines but the main focus will be on improving the tool integration and the tracking of the progress through Top/Flop lists. As well as developing our own tool, we are also considering tools like Sonar [10], a platform to manage code quality that integrates many of the tools mentioned above, displaying the results in a clear manner.

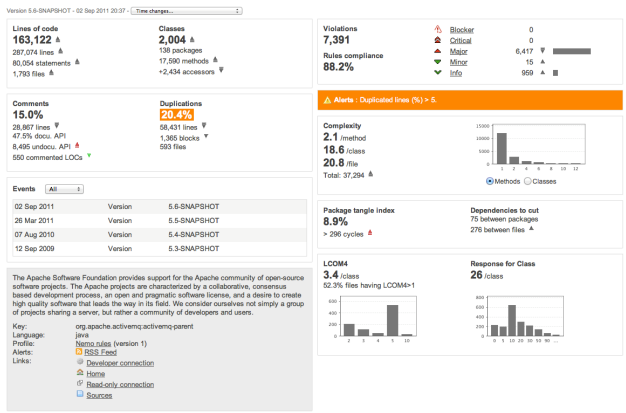

Figure 7: The Sonar dashboard.

At the group level, there is also an increased interest in QA, most particular in extending the SIP principles to C/C++ projects.

LARGE SCALE DATA FACILITY FOR DATA INTENSIVE SYNCHROTRON BEAMLINES

R. Stotzka, W. Mexner, T. dos Santos Rolo, H. Pasic, J. van Wezel, V. Hartmann, T. Jejkal, A. Garcia, D. Haas, A. Streit, Karlsruhe Institute of Technology, Karlsruhe, Germany

Abstract

ANKA is a synchrotron light source located at the Karlsruhe Institute of Technology, providing light from hard X-rays to the far-infrared for research and technology. It serves as a user facility for the national and international scientific community, currently producing 100 TB of data per year. Within the next two years a couple of additional data intensive beamlines will be operational producing up to 1.6 PB per year. These amounts of data have to be stored and provided on demand to the users.

The Large Scale Data Facility LSDF is located on the same campus as ANKA. It is a data service facility dedicated for data intensive scientific experiments. Currently, storage of 4 PB for unstructured as well as structured data and a HADOOP cluster, used as a computing resource for data intensive applications, are available. The campus experiments and the main large data producing facilities are connected via 10 GE network links. An additional 10 GE link exists to the internet. Tools for an easy and transparent access allow scientists to use the LSDF without having to bother about the internal structures and technologies. Open interfaces and APIs support a variety of access methods to the highly available services for high throughput data applications. In close cooperation with ANKA, the LSDF provides assistance to efficiently organize data and meta data structures, and develops and deploys community specific software running on the directly connected computing infrastructure.

DATA INTENSIVE SCIENCE AT ANKA

ANKA was designed and constructed by Forschungszentrum Karlsruhe in 2003 and is now operated by the Karlsruhe Institute of Technology (KIT). As a large scale research facility, ANKA provides beamtime for fundamental and application–oriented research to users from Germany, Europe and beyond [1]. Fourteen beamlines at ANKA are operational. The beamlines for analytic service cover techniques from spectroscopy to diffraction over a large spectral range from far infrared to hard X–rays. At the moment a high–resolution X–ray diffraction beamline (NANO) and an imaging beamline (IMAGE) are under commissioning and construction.

The Next Generation of Ultra Fast Tomography Beamlines

The substantial progress made in recent years, in fields like mechanics, X–ray optics and detector systems as well as the tremendous increase of processing speed and I/O bandwidth gives rise to a paradigm shift in the design and execution of tomography experiments. A new type of smart experimental station becomes possible using the vast computational power of massively parallel computation units. The process under study as well as the measurement procedure itself can be actively controlled by data driven feedback loops in direct dependence on image dynamics and spatio–temporal contrast.

Digital area detectors are an essential component for high–speed X–ray imaging experiments. A widely used X–ray detector type is the so–called indirect detector, which X–rays converts into visible light by a thin scintillating crystal. The resulting image is then magnified onto the CCD (or CMOS) camera by a diffraction limited optical system. The use of highly absorbing scintillation crystals with high light yield and optimized detector optics that are able to withstand the intense broad–band radiation produced by modern synchrotron sources has permitted a significant reduction of exposure times. High frame rates are achieved by employing column–parallel or block readout active pixel detectors, which reduce the read–out time for a full frame substantially, compared to classical high-dynamic range CCDs.

Commercially available, scientific grade cameras produce projection data at a rate of up to 750 MB/s. A detailed description of the reconstruction algorithm and its speed–up in comparison to a CPU implementation can be found in [2].

A smart experimental station for high-speed and high–throughput tomography is currently designed for the IMAGE beamline, which is constructed at the ANKA storage ring. The photon source employed for tomography will be a superconducting wiggler, which covers an energy range up to 100 keV. Compared to the bending magnet beamline Topo–Tomo [3], the flux density will be increased by more than one order of magnitude, yielding a reduction of exposure time on the same scale.

The Need for High Performance Data Management

Processing and storing the data of high–speed and high–throughput imaging beamlines are challenging tasks. Using robotic sample changers, the sample throughput is increased substantially. For instance, raw data rates presently produced at the Topo–Tomo bending magnet beam line, with a sample changing time of 15 seconds and a total scan time of 30 seconds, are 350 MB/s averaged over a daily run.

A raw reconstructed volume has a size of 50 GB, which needs to be stored alongside the raw projection data.

Data analysis is often a laborious manual process that includes several steps that cannot be automated easily, for instance finding optimal parameters of segmentation routines or even selecting pre–processing algorithms to present suitable data for post–processing. Thus, large amounts of data need to be accessible for long periods of time with high bandwidth and low latency for data processing and visualization.

The management of large scale data, its secure storage and archiving, fast and reliable access as well as high performance processing are essential for cutting edge beamline research. Usually, costs caused by growing infrastructures, reliability and sustainability of large scale data are limiting the extension of current beamline experiments.

STATE-OF-THE-ART IN DATA MANAGEMENT FOR DATA INTENSIVE BEAMLINES

The Topo–Tomo Beamline

The data management of the Topo–Tomo beamline has evolved over the years with its construction and each technical extension. Most data storage and access operations are directly steered by the user.

Samples are mounted on a rotary stage that allows a precise rotation with typical 5–10 kHz depending on the used camera. The whole detector and sample positioning setup is controlled via TANGO [4, 5] and SPEC [6, 7]. In a first step, the image data are temporarily stored on a local high performance 30 TB SAN. To check the quality of the acquired data, radiograms are monitored. Then the acquired data are processed with a dedicated four Nvidia Tesla GPU server. The final visualization for tomography is performed by VG Studio MAX [8]. It runs on a dedicated visualization server with 196 GB RAM, which allows a high performance processing of the whole tomography in memory.

Finally, the 3D tomogram plus the raw data are stored as unstructured data at the Large Scale Data Facility (LSDF). Most of the sample specific meta data that could not registered via the control application is still archived via the old fashioned laboratory book.

Data Management Systems for Beamlines

The maturity level of the data management seems to be very diverse across a variety of institutions and beamlines, and this heterogeneity is partly caused by different problems and requirements. The crucial point in beamline data management is indeed the amount of generated data and the desired throughput. In case of very data–intensive experiments the data management becomes challenging [9]. Nevertheless, beamlines with a primitive data management, where the user seems to be the main data management component and is responsible for all kinds of data storage, processing, transport and archiving, are still widespread.

An example of a data intensive beamline with complete data management during the whole data life cycle can be found at the National Ignition Facility (NIF), a research device located at the Lawrence Livermore National Laboratory [10]. The most important highlights are automatic data ingest, automatic triggering of analysis upon new data arrival, data provisioning from various data sources, policy–based automated hierarchical storage management, long term storage architecture and employment of HDF5. It is designed for beamlines with a fixed configuration that rarely needs adaptions for new scientific experiments.

Another data management system was developed and employed at SOLEIL [11]. The main idea is to produce individual data sets in form of a single and well defined atomic package containing all the relevant contextual information (including informations about the experiment itself, instrumentation, sample, user, etc.). The logical file format NeXus [12] with HDF5 as underlying physical data format is used.

The software architecture reflects the natural separation of different concerns, including hardware–layer and software–layer components for DAQ on device level, data collections and transformations and the data storage. It employs a TANGO based modular control system, so the data management components for data collection, transformation and storage, are mainly treated and integrated as TANGO devices.

Due to the required flexibility for continuously adapted beamline experiments, we think the SOLEIL Experimental Data Storage Management could be a great foundation for a sophisticated data management system, coupled with the Large Scale Data Facility infrastructure at KIT.

THE LARGE SCALE DATA FACILITY

The Large Scale Data Facility (LSDF) comprises on–line storage, data analysis computing cores, archival capacity and data management services, initially funded by the Helmholtz Association and the state of Baden–Württemberg in order to facilitate data–intensive science. Based on the experience in designing and continuously enhancing and the documented excellence of the WLCG Tier–1 centre GridKa [13] at KIT for the high-energy physics community, the LSDF is not limited to single scientific communities — instead it aims to be open for all scientific disciplines requiring large scale data storage, analysis and archiving on a regional, national and international level. Detailed plans and budget allocations exist to enhance the LSDF, in accordance with the requirements of the scientific user community.

The project has currently 4 PB of storage available, together with a compute cluster for data processing and a high speed dedicated network infrastructure, Figure 1. Access protocols, like GridFTP and the data management system iRods [14], are provided by dedicated servers attached through GPFS to the storage systems. For internal use CIFS and NFS access are offered for unstructured data.

An 10 Gigabit Ethernet network is spanned between all servers and the internet. Through dedicated high–speed network links the LSDF is connected to the research network and data sources, like ANKA inside KIT, allowing a rapid data taking. It enables scientific communities to work with and share the data in collaborations of global scale.

Based on the described infrastructure, several high level services for structured data are provided. The KIT Data Manager KDM consists of data and meta data management and repository components especially designed for large scale scientific data. The KDM DataBrowser [15] allows meta/data ingest and access using a graphical user interface that can be easily adapted for special needs. Additional services for organizing the data life cycle and data support are offered to the user communities. Open interfaces and APIs support a variety of access methods to the highly available services for high throughput data applications.

To process the experimental data a compute cluster with 60 nodes equipped with Hadoop [16], an implementation of Google's MapReduce [17] programming paradigm is directly attached to the storage. This allows for data intensive computing with excellent scalability, but requires adapted applications which run in a predefined environment. LAMBDA [18] – the LSDF Execution Framework for Data Intensive Applications — simplifies large scale data processing for scientific users by reducing complexity, responsibility and error–proneness. The description of an execution is realized as part of LAMBDA administration in the background via meta data and can be steered by the KDM DataBrowser.

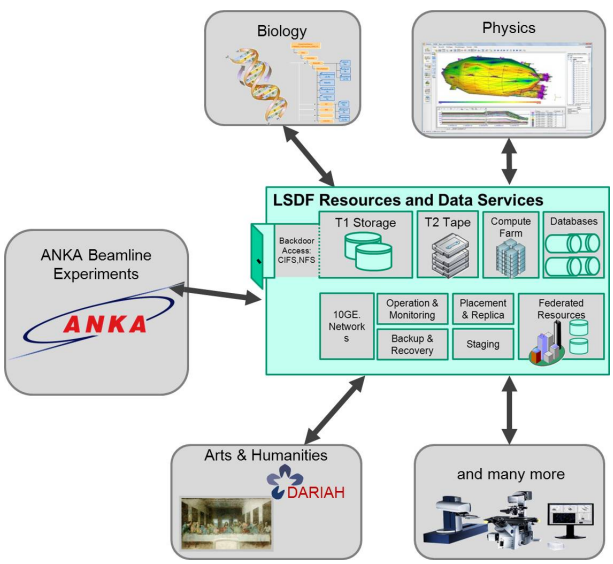

Figure 1: The Large Scale Data Facility and connected scientific communities.

If processing of experimental data requires a dedicated software environment, (for instance Windows, or specific software versions or licences) the OpenNebula [19] Cloud environment is foreseen.

In close cooperation with the user communitites, the LSDF provides assistance to efficiently organize data and meta data structures, and develops and deploys community specific software running on the directly connected computing infrastructure.

COMPONENTS OF A NOVEL DATA MANAGEMENT SYSTEM

Figure 2 depicts the conceptual data flow within a imaging beamline (left) to the storing and processing components within the LSDF. All beamline components are steered by a Control System with various user interfaces (UI). Control & monitoring data are exchanged with the components as well as user information administrated by the "User Office" for e.g. authentification and authorization.

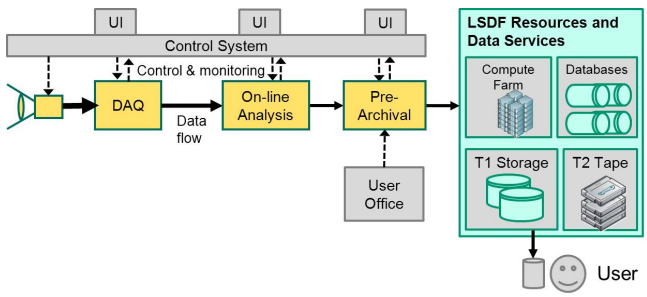

Figure 2: Data flow from the camera to the LSDF.

Starting from the detector or camera, a massive flow of data is piped to the data acquisition system "DAQ". In "DAQ" relevant measurement data are selected and annotated for further processing and storage.

"On–line Analysis" processes the data in various preprocessing steps, reconstructs tomographic images and volumes using a GPU–accelerated system and visualizes the results. Based on the visualization, the user will select promising data sets for further processing and archiving.

In the "Pre–Archival" step the date is prepared by adding meta-data for the storage, archival and processing in the Large Scale Data Facility LSDF. Additional meta data about the experiment and user data will be added from the "User Office".

Within the LSDF the data will be stored, processed and archived. The data ingest process is mostly standardized, including data transfer and meta data storage, via APIs or the KDM DataBrowser. Since the LSDF has also provided computing resources, a variety of sophisticated and computationally expensive processing algorithms can be applied automatically. For tomography beamlines algebraic reconstruction will provide high–quality images and volumes for further scientific analysis. The results will be enriched with additional meta data for data provenance and stored with the corresponding measurement data sets. Users will access their data sets on the LSDF directly via the KDM DataBrowser or a Web interface. External users will be provided with a temporary user account, according

to ANKA's policies.

It is planned to use NeXus as a primary file format for all scientific data sets written to persistent storage. The CDM technologies [20] will provide an abstract interface for accessing NeXus.

The whole architecture is designed to fulfill the requirements for continuously adapted experiments and enhanced hardware components.

CONCLUSION

The ANKA Synchrotron facility is part of KIT, a world-leading engineering institution with top ranking Faculties of Informatics, Electrical Engineering and Information Technology, and Mechanical Engineering. KIT supports a broad research palette ranging from astro–particle physics over biology to supercomputing with superior infrastructures. The modern data storage and processing infrastructures enable cutting edge research with high measurement data rates. Because the infrastructure is shared among several institutes investments are also shared. This takes some pressure off the financial budgets of ANKA and the beamline experiments.

Very economically the large scale data facility offers nearly unlimited storage, cluster computing, high throughput networks, transparent yet secure access services, and is still easily adapted to the changing requirements of the users. The unique possibilities of this facility for data intensive computing opens a new dimension for data intensive beam-ine experiments and subsequent data analysis.

ACKNOWLEDGEMENTS

Many thanks to the fruitful discussions within the High Data Rate Initiative HDRI of the German Helmholtz Association research program PNI, and with Alain Buteau and his crew from SOLEIL. Special thanks Francesca Rindone for revising and improving the texts.

COMMON DATA MODEL ACCESS; A UNIFIED LAYER TO ACCESS DATA FROM DATA ANALYSIS POINT OF VIEW

S. Poirier, A. Buteau, M. Ounsy, C. Rodriguez,
Synchrotron SOLEIL[1], France
N. Hauser, T. Lam, N. Xiong, ANSTO[2], Australia

Abstract

For almost 20 years, the scientific community of neutron and synchrotron institutes have been dreaming of a common data format for exchanging experimental results and applications for reducing and analyzing the data. Using HDF5 as a data container has become the standard in many facilities. The big issue is the standardization of the data organization (schema) within the HDF5 container. By introducing a new level of indirection for data access, the CommonDataModelAccess (CDMA) framework proposes a solution and allows separation of responsibilities between data reduction developers and the institute. Data reduction developers are responsible for data reduction code; the institute provides a plug-in to access the data.

The CDMA is a core API that accesses data through a data format plug-in mechanism and scientific application definitions (sets of keywords) coming from a consensus between scientists and institutes. Using a innovative "mapping" system between application definitions and physical data organizations, the CDMA allows data reduction application development independent of the data file container AND schema. Each institute develops a data access plug-in for its own data file formats along with the mapping between application definitions and its data files. Thus data reduction applications can be developed from a strictly scientific point of view and are immediately able to process data acquired from several institutes.

THE GENESIS OF THE PROJECT

Working independently, ESRF, SOLEIL, DESY and ANSTO software development has focused on the design of frameworks for data processing, operating on top of a NeXus [1] data storage layer.

The central issue for collaboration was related to using the same tool independent of the data container and schema. Work at ANSTO on the GumTree Data Model [2] abstracted data file access of the underlying NeXus files (the standard data format at ANSTO) by designing a data model with a set of Java interfaces. This seemed to be a very promising development to share.

SOLEIL became interested in the concept as it was coincidentally looking for a unified data access layer based on NeXus (the standard data format used at SOLEIL) to build on top of it its COMETE [3] project, a Java framework that aims to ease data visualization and data analysis applications programming.

The collaboration started between ANSTO and SOLEIL in January 2010, after a meeting between the authors at ICALEPCS 2009. The work started from the data access layer of ANSTO's GumTree project [4], written in Java.

In Q4 2011, DESY will join the collaboration and help us developing the C++ port of CDMA.

BACK TO OUR MOTIVATIONS

The important thing we must understand is that the data format is not an issue. The issue is how to allow users of our institutes to use the same tools regardless the origin of the data?

We notice that even in the same synchrotron or neutron facility, data schemas are not the same across the beamlines. The NeXus standard is useful, but not strong enough to ensure uniformity. Interpretation of the standard allows two identical beamlines to have different data schemas.

The aim of the CDMA is to offer an abstract data access layer in order to build analysis/reduction applications regardless of the data schema.

HDF-like formats allow the recording of any kind of data using an API; the physical file organization is abstracted. The NeXus-like specification is a set of logical data organizations in a standardization effort. This kind of standardization may be applicable to various tree-oriented data formats (such as HDF or XML). The problem of this approach is that facilities must produce data files that strictly comply with the specification. This is a huge challenge because each facility's staff (mostly scientists & engineers) has its own view on acquisition systems and experimental and contextual data. Also the hardware and the acquisition process are rarely driven by the data recording system.

The idea behind the CDMA is to reverse the data point of view. Rather than desperately try to standardize the data files across institutes, is it not easier to introduce a layer able to hide the different way the data is stored? We think the answer is *yes*!

We encourage the use of the NeXus standard. We believe that in the future, as the standard matures, the NeXus API may replace CDMA. We encourage facilities to take part in the NeXus standardization process. However, CDMA allows now to deal with the various standard interpretation.

1. http://www.synchrotron-soleil.fr
2. http://www.ansto.gov.au/

Each institute will continue to produce data using the most suitable format. There is no need to wait for the ultimate data organization specification before running acquisitions, and sharing data and applications!

INTRODUCTION TO THE CDMA

The CDMA comprises

- a client layer API for writing data reduction and analysis applications.
- a developer API to build the data access plug-in.

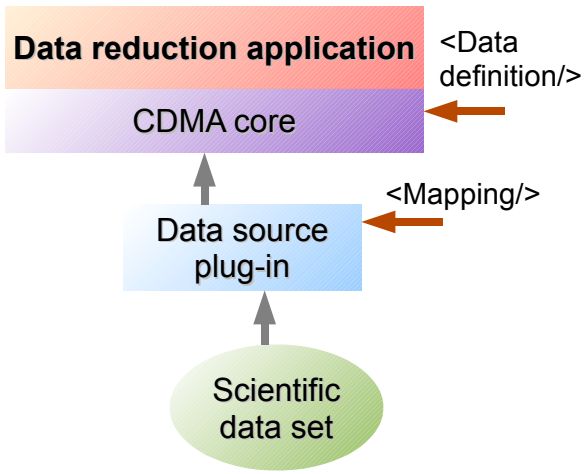

Figure 1: CDMA general usage schema.

Client API

Using the client API, the data reduction applications developer doesn't have to know anything about the file formats because the API uses an abstract data access layer that hides the data file specification.

Data Source Plug-In

The data file specification is embedded through a plug-in mechanism. It is therefore the institutes' responsibility to develop their data access plug-ins in order to open datasets acquired in their institutes through the CDMA.

Classical Navigation API

Nevertheless, using the navigation API, the data reduction developer has to know precisely the data schema in each data file their application will access. We think it's a useless waste of time. This is a roadblock to these projects being used outside of the organization where they are being developed.

Dictionary Mechanism

To solve this issue the CDMA introduces a new, innovative way of accessing data. This is the dictionary mechanism.

Using this mechanism, the data reduction application developer no longer has to know the data schema. The data is accessed using keywords. A keyword is a short character string naming a scientific measurement or a generic technical data item. Thus the data access part of data reduction applications' source code is simpler and (this is the most important) more stable.

Considering this mechanism, scientists have to agree on key names, regardless of the way the data is physically organized. Moreover, the data may have different units (wavelength vs. energy for example) for the same measurement; the CDMA provides a mechanism to perform conversions at run-time.

Please note that the old-style navigation API is still available but we strongly recommend considering the dictionary API.

CLIENT API

The client API defines interfaces that abstract the data sources. There are three levels of abstraction:

- The top level is the *IDataset* interface which represent a handle all the data of an experiment.
- *IGroup* (or *ILogicalGroup* if using the dictionary mechanism, see below) defines a group of related data. There is at least one root group for each dataset; a group may contains sub groups and data items.
- *IDataItem* defines a single value or measurement which can be a scalar or a multidimensional array.

Along with the data access layer, the Array class allows an efficient manipulating of multidimensional arrays. It is is more than a primitive Java or C++ array. It is a scientific data object allowing you to slice and dice arrays and to do math.

The CDMA provide also an class that allows error propagation, the *Error* object, that provides propagation of count uncertainties based on Poisson statistics with every math operation. This is extensible to other uncertainty calculations.

DATA SOURCE PLUG-IN SYSTEM

Using the CDMA library, the data reduction developer doesn't care about data schemas. The plug-in mechanism dynamically loads the plug-in (a dynamic library) that accesses data from the data file. Thus this mechanism allows a user to open files acquired from different institutes, in the same session.

DICTIONARY MECHANISM

The dictionary mechanism relies on two XML documents.

Data Definitions

The first document is a set a keywords matching scientific or technical data items. For instance a key named current should refer to the effective current in a storage ring at acquisition time. These keywords may be just listed by this document or organized through a tree hierarchy. In the latter case, this document describes a particular a view on the data, like a NeXus application definition.

This document is intended to be independent of the way the data is physically organized. There are (at least) two ways of writing this document:

- it may be written for a specific data analysis application which already exists and is adapted to use the CDMA,
- or it may be written independently of any application, like the NeXus application definitions.

```
<data-def name="Example">
  <group key="detectors">
    <group key="detector">
      <item key="camera"/>
      <item key="distance"/>
      <item key="exposureTime"/>
      <item key="shutterCloseDelay"/>
      <item key="xBin"/>
      <item key="yBin"/>
    </group>
  </group>
  <group key="data">
    <item key="images"/>
    <item key="spectrums"/>
  </group>
</data-def>
```

Figure 2: Data definition example.

Keywords Mapping

The second document is the dictionary itself. It's the mapping between keywords and real paths..It needs an exact knowledge of the data schema in the file.

```
<map-def name="Example" version="1.0.0">
  <item key="distance">
    <path>
      /{NXentry}/{NXinstrument}/detector/distance
    </path>
  </item>
  <item key="exposureTime">
    <path>
      /{NXentry}/{NXinstrument}/detector/Exposure
    </path>
  </item>
  <item key="shutterCloseDelay">
    <path>
      /{NXentry}/{NXinstrument}/detector/CloseDelay
    </path>
  </item>
  <item key="xBin">
    <path>
      /{NXentry}/{NXinstrument}/detector/Xbin
    </path>
  </item>
  <item key="yBin">
    <path>
      /{NXentry}/{NXinstrument}/detector/Ybin
    </path>
  </item>
<map-def>
```

Figure 3: NeXus file mapping example.

Responsibilities

Given a keywords list, the institutes that produce experimental data must write the mapping document corresponding to their data files organization.

CURRENT STATUS

There are two implementations of the CDMA, in Java and C++.

The Java implementation is mature (in operation) and already available on the SVN Codehaus repository [5].

ANSTO has developed a data browser based on the Java version of the CDMA, and uses CDMA on 4 neutron beam instruments as part of the Gumtree ecosystem.

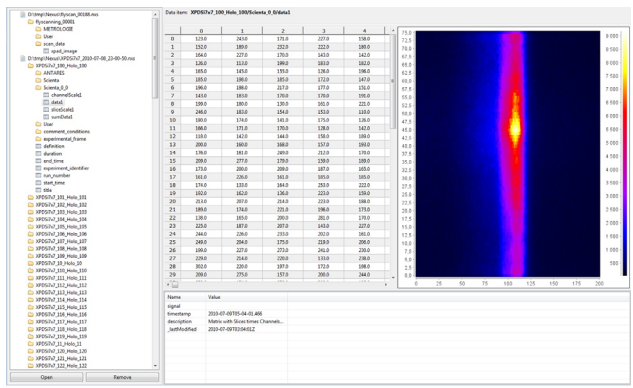

Figure 4: CDMA based data browser at ANSTO.

On SOLEIL side, two data reduction applications written in Java and based on the CDMA are currently in production, on SWING (SAX acquisitions) and ANTARES (EXAFS, Photo-emission measurements).

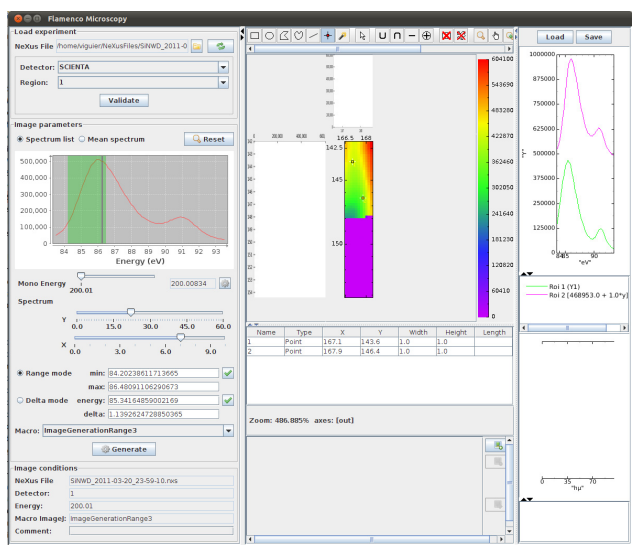

Figure 5: Flamenco, a data reduction application using CDMA at SOLEIL.

We are working on the C++ implementation which is scheduled to be available in early 2012. Then a Python port will be developed based on this C++ implementation.

CONCLUSION

The first results on using the CDMA are very promising. We have found that the time required to develop a new data reduction application has been significantly reduced, because the developers naturally no longer have to take care of the data format.

On the technical side , with the arrival of new participants (DESY, ANKA, ...), we have a community that will be able to quickly evolve this project, by enlarging the number of data reduction applications and data source plug-ins to allow cross institutes experimental files exchanges.

Last but not least, our conviction is that the CDMA project is a valuable technical answer to the Data Management issues that European projects like PANDATA, HDRI, NFFA, etc are willing to address, as CDMA provides a solution now to the old dream of able exchanging in a transparent way data files and data analysis applications between institutes.

MANAGEMENT OF EXPERIMENTS AND DATA AT THE NATIONAL IGNITION FACILITY*

S. Azevedo#, R. Beeler, R. Bettenhausen, E. Bond, A. Casey, H. Chandrasekaran, C. Foxworthy, M. Hutton, J. Krammen, J. Liebman, A. Marsh, T. Pannell, D. Speck, J. Tappero, A. Warrick
Lawrence Livermore National Laboratory, P.O. Box 808, Livermore, CA, 94551, U.S.A.

Abstract

The National Ignition Facility (NIF) consists of 192 pulsed laser beams fired simultaneously at a stationary target in a 10-m diameter vacuum chamber. During a typical 4-8 hour NIF shot cycle, culminating in a nano-second scale laser firing, thousands of adjustments are performed on the target (type, composition, shape), laser (beams used, their power profiles, pointing), and diagnostics (configuration, calibration, settings). It is imperative that we accurately define all equipment prior to the shot. Following the shot, and the data acquisition by the automatic control system, it is equally imperative that we archive, analyze and visualize the results within the required 30 minutes post-shot. Results must be securely stored, approved, web-visible and downloadable in order to facilitate subsequent publication. To-date NIF has successfully fired over 2,500 system shots, and thousands of test firings and dry-runs. We present an overview of the highly-flexible and scalable campaign setup and management systems that specify all aspects of the experimental NIF shot-cycle, from configuration of drive lasers all the way through archival and presentation of analyzed results.

EXPERIMENTS AT NIF

Experiments, or "shots", conducted at the National Ignition Facility (NIF) [1,2] are discrete events that occur over a very short time frame – up to 500 terawatts of instantaneous laser power are delivered to a target in tens of nanoseconds – separated by a few hours. The 192 beams of pulsed laser energy are directed at the mm-sized target centered in the NIF vacuum chamber. Each shot generates hundreds of gigabytes of data from over 30 diagnostics that measure optical, x-ray, and nuclear phenomena from the imploding target.

Most shots are part of a larger group, or campaign, of shots to advance a specific scientific goal in the understanding high-energy-density physics. One such campaign, the National Ignition Campaign, employs 1.8-Megajoules of 351-nm laser energy to implode a hydrogen-filled target as a demonstration of controlled nuclear fusion with gain. The campaign goal of fusion ignition and gain, the primary reaction that fuels stars, could potentially lead to a limitless clean energy source.

Often, in order to achieve efficient usage of precious target chamber time, shots from one campaign are interleaved with those of other campaigns. Each experiment can have very different needs from the facility including the laser controls and restrictions, target chamber controls, target positioning and cooling, industrial controls and safety subsystems.

Following each shot, the control system systematically stores the state of the entire system and all the raw diagnostic data for subsequent analysis. Extraction agents make them available outside the facility. These diagnostic data represent the principal scientific output of NIF, so a shot is not considered "complete" until they are safely archived in a secure database. Only then can the control system be reset and all subsystems can be quickly reconfigured to prepare for the next shot.

Careful planning and efficient execution of NIF shots is paramount to achieving a high volume of high quality science results. In this paper, we describe a set of integrated web-based enterprise tools that have been designed and fielded for NIF experiment support—from shot planning through presentation of final analyzed results. These tools, or follow-on designs, are expected to be employed for the projected 30-year experimental lifetime of NIF, during which many thousands of pulsed-laser shots will occur and many peta-bytes of data will be acquired and processed.

SHOT TIMELINE

NIF can fire only one experiment at a time—there is only one target, and a single chamber. For this reason, the control system [3] is designed around a "shot cycle" that executes all setup procedures for countdown to a shot as well as post-shot activities. Figure 1 shows a typical ignition shot timeline using an exponential time scale. The delivered 192-beam laser power has a very well-defined and repeatable pulse shape that is a few tens of nanoseconds in length. Prior and subsequent shots have the same tasks to perform, but their timelines are shifted by several hours. Therefore, many of the timeline activities occur simultaneously for dozens of shots, so coordination and communication among many teams are essential. Complicated campaigns can require months to years of planning for a few microseconds of total shot time, and the results are expected to be available for many years.

For the purposes of this paper, we can breakdown the pre-shot and post-shot tools into the six major categories shown in the figure and described in the following subsections—planning, setup, configure, archive, analyze, and visualize. The control system has been described elsewhere [3,4].

* This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.
#azevedo3@llnl.gov

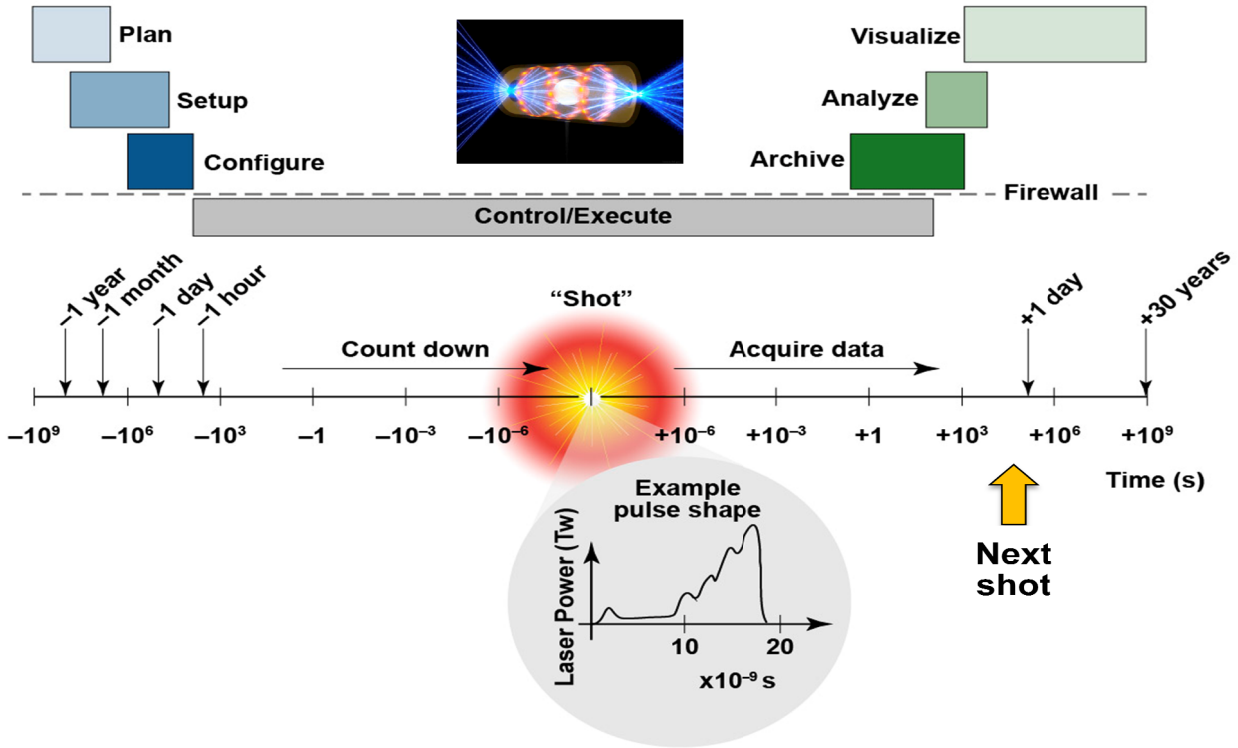

Figure 1: Shown on an exponential timeline, active control and execution of each NIF shot spans a few hours of facility time. To maximize facility usage, NIF must be rapidly reconfigured for the next shot a few hours later. Web-based tools have been developed for planning, setup, configuration, archiving, analysis and visualization of shot data.

Planning Tools

Campaign and shot planning tools provide a high-level view of upcoming experiments and facility schedules, as well as informing production and procurements. Where formerly a large shared spreadsheet was used to manage the complex decisions that dictate when and which shots will be fired, the new Shot Planning and Analysis Tool is now an on-line suite of applications that allow NIF Operations for making informed shot planning decisions based on:

- Shot dependencies, such as laser energy needed, target availability, and diagnostics required,
- Facility availability, for example, around scheduled maintenance periods or installation of new equipment,
- Predicted demand on optics, which have an expected lifetime based on cumulative laser fluence they experience, and
- Potential radiological hazards and delays caused by exposure of the facility to fusion by-products (gammas, neutrons).

Committees of NIF stakeholders use these decision support tools to evaluate the proposed shot plans, approve them and communicate that plan to the NIF community. Off-site warehouses and factories that supply the needed equipment receive advanced notice of what is needed and when. These tools help ensure that the necessary targets and diagnostics are available when needed.

The tools also enable the optimization of expensive optical consumables (lenses, mirrors, wavelength conversion crystals, etc.). NIF has an extensive optics inspection, repair and recycling program that detects and tracks micron-sized laser-induced damage sites on optics well before they can grow to impact laser performance. A rules engine is employed to predict when an optic will need replacement based on the laser energies of upcoming shots. On a single beam line, operators can intentionally block a few percent of the cross-sectional pre-amplified beam area to protect those sites, or the optic can be exchanged. In this way, the planning tools help minimize the cost of experiments by maximizing the life cycle of the optics.

Setup Tools

Once a shot or campaign is scheduled into the planning tools, a Campaign Management Tool suite (CMT) allows the experiment principle investigator (PI) to define all the necessary setup parameters for the control system to conduct the shot. This suite consists of fourteen integrated software applications that manage the preparation, validation, review, approval and configuration readiness for NIF experiments. The CMT suite manages all shot details (laser, target, diagnostics, facility), enforces the operating envelope of the laser to ensure facility safety, and provides shot setup reports and installation orders. It compares the requested facility setup to the current actual NIF configuration and notifies the PI of changes needed.

Over 15,000 setup items and over 100,000 serialized parts are monitored and controlled. The primary output of CMT is the full set of controls documentation with detailed experiment definitions to successfully perform a shot. If the entire setup documentation were to be printed as a report, it would be well over 200 pages for each shot.

Configuration Tools

When an approved shot is ready to be performed, an integrated configuration and work control suite of tools helps the on-site team ensure that NIF is ready to execute it. The tools support shot operations and data analysis by helping to enforce policies and procedures while providing a data repository to characterize the facility configuration over time. Web-based integrated applications serve to define, build, operate, maintain, and configuration-manage all components and assemblies in NIF. A transactional database monitors all installation and removal orders, while a content management database called the Location, Component and State tracking system (LoCoS) maintains the historical record of the millions of parts installed in NIF at any time.

Calibration information is also maintained in LoCoS for parts that are important to the data analysis (filters, attenuators, detectors, cameras, oscilloscopes, etc.). Re-calibration and maintenance plans are included in scheduling software. As parts are exposed to laser fluence or neutron radiation, operations personnel are notified to plan for replacement or retrofit. Work orders for part installation and removal can be automatically generated.

A NIF "Seating Chart" shows the current state of the laser, target and diagnostics on a web page that allows drill-down to every installed part and its component drawings. All drawings are under strict document control. The Shot Director will not initiate the shot cycle control system without a "green light" from the configuration tools indicating that state of the facility matches the setup request.

NIF Shot Archive

Immediately after the shot, any data potentially used in the analysis of scientific results are collected and stored in the NIF Shot Archive. This archive includes raw data and metadata, shot configuration, device calibrations and analysis parameters. In addition, the archive is also the permanent repository for experimental results produced by shots. It is meant to be the authoritative, consolidated resource for studying science at NIF. [5]

Requirements for this archive are that the data and automated results must be web-visible within a few minutes post-shot, reviewable by the scientific team for release, downloadable to authorized personnel, and secure for 30 years.

Archived data are stored in a relational Oracle Real Application Cluster (RAC) database with a software interface layer written on top of a content management framework that performs transparent object-relational mapping. This data architecture provides a powerful and flexible way that data is accessed and presented using a combination for object-relational queries or standard relational queries using SQL. Arrays of data such as waveforms and images are stored in a common Hierarchical Data Format (HDF), and are downloadable in other formats.

One key aspect to the archival of scientific data is to maintain data "pedigree" or traceability throughout all processing steps. The archive was designed to carefully maintain and validate the chain-of-custody that starts with raw data through each step of the analysis including the routines used. Pedigree is a form of metadata and is archived whenever data is refined at each step of analysis.

Analysis Tools

The Shot Analysis and Visualization (SAVI) System is an integrated set of tools for the analysis, validation and approval of science results from NIF shots. An analysis framework initiates messages to a workflow engine that launches a predefined set of analysis steps based on diagnostic type [6]. The analysis is initiated by the data as it arrives, and is performed by a highly-parallel distributed set of software components on a Linux cluster. Robust signal processing analysis tools, under version control, are customized to accommodate unique properties the each diagnostic signal or image. Results are placed back in the Shot Archive with new pedigree.

Not all analysis steps can be automated into SAVI for all diagnostics. Some, like film or trace-gas sampling, require off-line processing. Other types of new or more exotic high-speed digital systems may require specialized non-routine processing that necessitates user interaction. Also, "what-if" analysis scenarios that involve analyzing data with new, minimally-tested algorithms do not fit into the automation paradigm. In any of these cases, an alternative desktop analysis interface has been developed. Analysts can download relevant input data and pedigree, compute results using a desktop analysis code, and finally upload the results to the archive with annotations regarding their source. When both automated and desktop results appear for a particular experiment, the SAVI system provides tools to select the "authorized" results.

SAVI uses the archive to proactively validate the pedigree chain of all results in near real-time. Many different scenarios can result in a "bad" pedigree chain. For example, an improved or corrected calibration can be applied retroactively, a configuration error (e.g., wrong serial number) may have been recorded at the time of the shot, or a prior calculation step may have been re-executed whereas the final result relied on the earlier version. Any change to the quality of data inputs impact the entire pedigree chain from that point forward. Within seconds of these occurrences, the archive flags the appropriate chain of data as having bad pedigree quality, and that flag is displayed through the visualization tools. If desired, the user can then reprocess the analysis workflow with the most up-to-date inputs. Any new results created this way are stored as new versions; i.e., prior results are not overwritten.

Visualization Tools

Visualization of experimental data and results must provide a "quick look" summary of results, cross-shot analysis and trending, and collaboration tools for scientists. The web-based Archive Viewer employs rapid queries and displays to access the data in numerous ways. Additionally, collections of data can be viewed in tabular or grid formats. Hierarchical data can be traversed via hyperlinks along data relationships including between dependent results using pedigree. Scientists may download data and perform off-line desktop analysis. The application also provides an upload feature where scientists can archive desktop results to become part of the official shot record.

In 2010, the Viewer has been enhanced to include rapidly-deployable web "widgets" onto summary dashboards. Example dashboards are shown in Figures 2 and 3. Each widget loads in a separate browser thread using calls to data services hosted by visualization servers for responsive displays. Widgets in the dashboard act as windows that can be dragged, minimized, or maximized. Each widget hosts a menu of options such as data export features or actions that can performed on the data. Many of the dashboard widgets include powerful interactive data plots. Using this technique, any combination of data from the archive can be very quickly assembled into a dashboard. This method provides a current view of the data not possible with off-line tools.

The dashboard provides a collaborative environment for scientific working groups focusing on various areas of physics. Scientists view their results live (often via videoconference) from various perspective, compare results across many shots or campaigns, contrast them with simulated expectations, and select "authorized" values to be published externally.

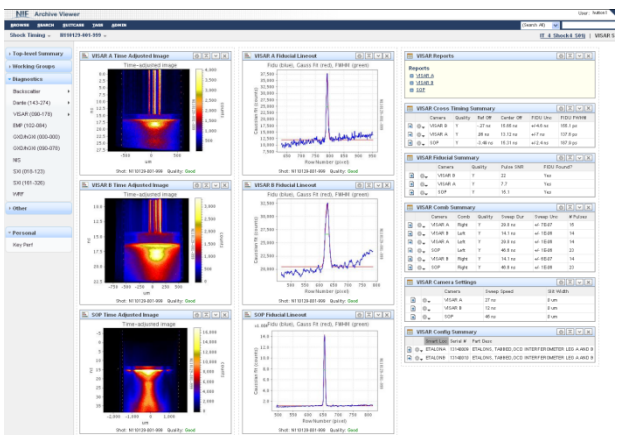

Figure 2: An example of dashboard page providing a single-shot perspective of the VISAR diagnostic.

Figure 3: An example of a multi-shot dashboard containing simulation vs. experimental data. Interactive plots allow each data series to be toggled on or off.

SUMMARY

Since the start of NIF shot operations in 2009, many hundreds of shots per year have been successfully fired. To optimize the usage of precious target chamber time, shot-based operations need flexible, high-performance tools to plan and analyze experiments. We now have over 40 integrated collaborative tools that routinely support dynamic, data-driven, high-quality shots on NIF. They also provide secure and transparent access to data, analysis and results. Shots are now being planned by many international partners, who are using these tools, for 2015 and beyond. Our future goals, as NIF transitions into a user facility in 2013, include improving the efficiency and availability of the facility. We plan to use the latest application support software to enhance the intuitive user experience, as well as to include mobile applications.

LHCB ONLINE LOG ANALYSIS AND MAINTENANCE SYSTEM*

J.C. Garnier†, L. Brarda, N. Neufeld, F. Nikolaidis, CERN, Geneva, Switzerland

Abstract

History has shown, many times computer logs are the only information an administrator may have for an incident, which could be caused either by a malfunction or an attack. Due to the huge amount of logs that are produced from large-scale IT infrastructures, such as LHCb Online, critical information may be overlooked or simply be drowned in a sea of other messages. This clearly demonstrates the need for an automatic system for long-term maintenance and real time analysis of the logs. We have constructed a low cost, fault tolerant centralized logging system which is able to do in-depth analysis and cross-correlation of every log. This system is capable of handling O(10000) different log sources and numerous formats, while trying to keep the overhead as low as possible. It provides log gathering and management, Offline analysis and online analysis. We call Offline analysis the procedure of analyzing old logs for critical information, while Online analysis refer to the procedure of early alerting and reacting. The system is extensible and cooperates well with other applications such as Intrusion Detection / Prevention Systems. This paper presents the LHCb Online topology, problems we had to overcome and our solutions. Special emphasis is given to log analysis and how we use it for monitoring and how we can have uninterrupted access to the logs. We provide performance plots, code modification in well-known log tools and our experience from trying various storage strategies.

INTRODUCTION

LHCb [1] is one of the four large experiments at CERN which takes data from proton-proton collisions at the LHC. The control of the experiment and the data acquisition from the detector electronic channels to the permanent storage is managed within the Online Cluster. It is separated from the CERN IT infrastructure and managed entirely by LHCb people. The cluster is made of about 2000 Linux machines, 200 Windows machines and 60 switches and routers. Windows machines are the controllers of the detector systems. The Event-Filer farm [2], and all the other Data Acquisition (DAQ) servers are running under Linux. DAQ Software is controlled and monitored via the Farm Monitoring and Control System (FMC [3]). We use a uniform control interface for the detector and for DAQ software: the SCADA system PVSS [4].

*This research project has been supported by a Marie Curie Initial Training Network Fellowship of the European Community's Seventh Framework Programme under contract number (PITN-GA-2008-211801-ACEOLE).

† jean-christophe.garnier@cern.ch

The readout boards [5] are the interface between the detector links and the network links. An embedded computer allows the user to access and configure the entire board. It is running the Scientific Linux at CERN distribution [6].

Most of our machines are equipped with Baseboard Management Controllers (BMC) and accepts the Intelligent Platform Management Interface (IPMI [7]).

All these systems - Operating Systems, PVSS, DAQ software, IPMI, etc. - are generating numerous logs. They are traditionally consolidated locally on the system producing them. There are some limitations:

- Investigating problems can lead to correlating numerous log files from numerous locations.
- Once a machine is down, the local logs are unreachable and the problem investigation can only starts once the machine is up again.
- In case of hard drive failure, logs are lost.

We therefore implemented a central logging system, highly reliable and available, which collects logs from every system, consolidates them hierarchically and distributes them so that they can be reachable from numerous locations. Logs are then processed for indexation and analysis.

The first section presents the study and the deployment of the central logging system. The second presents the purpose of log analysis at LHCb, the tool we chose and its configuration. The third presents the status and the performance of the system, its limitations and its future.

CENTRAL LOGGING

Linux traditionally uses the *syslog* daemon [8] to manage logging from the applications and from the system. Logs are identified by a facility and a severity. The facility is usually used to define the source of the message. There are 20 facilities; hence several sources have to share the same facility in large systems. It is up to the system administrator to configure this correctly. The severity is an eight-level ladder used to classify the message importance. The daemon task is then to write different files for any combination of facility and priority. *Syslog* can be run as a client / server application. A node will send its messages to a remote node.

Syslog's features are sufficient to design a central logging system, but they were not flexible enough for us. Sharing 20 facilities amongst one node is acceptable, but not among 2200 nodes. Our system has to be able to differentiate a large number of systems, it should be able to write

several files per nodes. A few thousand files are expected. Figure 1 illustrates the file system architecture.

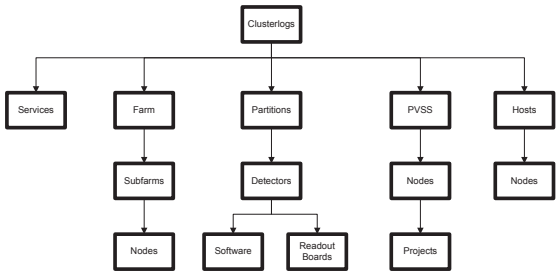

Figure 1: Log File System structure. The directory is divided first by themes. Then there are sub-categories corresponding to subsystems, then nodes, and then projects or software.

Rsyslog [9] is an enhanced *syslog* daemon. A few noticeable features are:

- A more complex analysis of the log message, using tags, regular expressions, sources, etc.
- The possibility to convert files to the *syslog* protocol, hence to get the logs from applications which are not using *syslog*.
- Multiple queues and multiple threads.
- Aggregate log lines into batches before to write them, to maximize IO performance.
- Message discard according to watermarks and log severity.

From these features, one can notice that *rsyslog* is oriented for setting up a centralized logging system. *Rsyslog* uses the *syslog* protocol so it is compatible with the *syslog* daemon. We deployed *rsyslog* on most of our cluster as client instances, except on embedded computers where it is preferable to run only *syslog*, which is much lighter.

The logging system is implemented with a few Linux servers and thousands of clients. It is described in figure 2. The log servers are configured as a cluster. The cluster nodes are identical commodity servers. Processing is not a critical issue here so they have only a single processor chip of four cores. They are equipped with 8 GB of memory. They have two SATA II hard drive disks of 2 terabytes configured as mirrors in *RAID 1*. Each node has two network interfaces. The first is used for control, for receiving the log messages and for exporting the log file system to log clients for analysis. The second is used for meta-data transfer and for cluster synchronization.

Corosync [10] manages the communication between the nodes of the cluster. On top of it, *pacemaker* [11] manages the applications that are critical for the cluster, like the various logging mechanism, virtual IP addresses, etc. It makes sure that the nodes and the services that they provide are running correctly, and distributes them amongst the cluster. Logs are written in a common area for all the cluster nodes, using *gluster* [12]. This is a file system that we use to replicate the information between all the nodes of the cluster, in order to increase the reliability of our system. Hence, if we have four machines with 2 terabytes hard disk space, our cluster area will only have a maximum of 2 terabytes space. *Rsyslog* is running as a server on every cluster nodes. This particular daemon is not managed with pacemaker as it has to run on every instance. It is simply managed via *chkconfig*. This is the main logging software, but there are a few more custom software. They are managed by pacemaker, and they process custom logging protocols developed for LHCb. The cluster is configured an Active/Active way. All nodes are processing logs coming from clients in parallel. In order to do that, we use a virtual IP address that every node recognizes as theirs. This IP address is bounded to a multicast Ethernet address that the switch uses to send data to all servers. Each server receives every log messages, but they will only process a subset of them, according to a hashing algorithm managed by *netfilter* [13, 14].

The log servers all share the same configuration for *rsyslog*. The current configuration is awfully complex, but it is interesting to stress that it currently does not rely on multi-queuing and multi-threading as we observed that performance were decreasing so much that no logs were written in the end. We suspect a deadlock or live-lock issue and further investigations are required before to report about that to the developers. The daemon is configured to write batches of several lines, in order to improve IO performance, trying to do not delay the log information too much for the user.

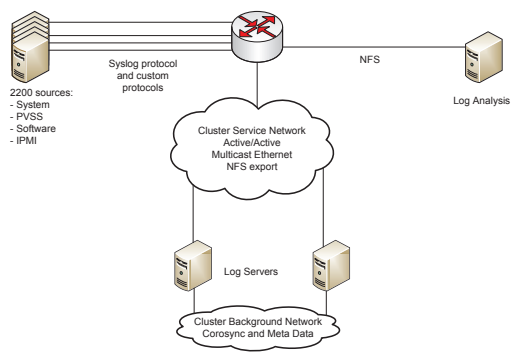

Figure 2: Architecture of the logging system. 2200 clients are logging information using the *syslog* protocol into an Active/Active cluster. This cluster exports the log files via NFS for log analysis. Log analysis is then performed by user applications and a host based intrusion detection system.

Clients are running both Windows and Linux. Under Linux, *rsyslog* sends the system logs, most application

logs, PVSS and IPMI logs to the log cluster. Our farm and our data acquisition servers are however running applications which are not logging to *syslog* but to FIFOs which are then read by FMC loggers. These loggers can then directly write a file or forward logs to a remote FMC logger. The log cluster runs FMC loggers, but some of their proprieties prevent them to run Active/Active like *rsyslog*, so pacemaker makes sure that only one server runs one instance of *rsyslog* for a same system. The event logging system of Windows is slightly different and does not rely on *syslog*. The system relies there on *Snare* [15] and *Epilog* [16] to respectively send event log messages and PVSS logs to the cluster using the *syslog* protocol.

The log cluster exports the log file system via NFS to some servers, so that users can access all logs easily. A special server is performing log analysis.

LOG ANALYSIS

Log analysis consists in reading the log files to look for patterns or sequences of lines. Most of the lines will not be interesting and nothing will be produced, in some cases a message is written in a dedicated log file which is a summary of what was important. Really important log messages will trigger alarms, sent by e-mail or text message, and they could also trigger automatic responses to fix the problem.

Several tools exist and are open source, but our choice is the Open Source Host-based Intrusion Detection System OSSEC [17]. Performing log analysis using a Host-based Intrusion Detection System (HIDS) comes along with a wider strategy of security in LHCb. It will be peered with an IDS performing network analysis.

OSSEC brings numerous features as it is a client server HIDS, but our primary use here will be to configure it as a log analyzer. It consists in defining decoders, which are templates that a log line can match or not. If a line matches a decoder, then OSSEC can apply rules to this line, in order to study it, to define its degree of importance, and to decide if the administrator should be warned, immediately or later, and whether to run or not an automatic action to fix the problem.

The OSSEC configuration is complex for our cluster, and there is still a lot of tuning to be done. In order to keep tracks of old configurations, the OSSEC rules and decoders are written into a GIT [18] repository.

RESULTS

We successfully implemented a central logging service with log analysis. It collects most of the identified logs of the LHCb Online system and writes them in more than 12000 files. Figure 3 shows the performance of a node over one month. The network is not overloaded but some peaks can make performance quite weak. The scalability, the reliability and the high availability requirements are fulfilled. There are however a lot of improvements to implement.

The typical issue of such system is the “split brain” issue. It happens when one or more members of the cluster cannot communicate with the other members for a while, and are starting to work independently from each other. Pacemaker can make sure that such situation does not happen, whereas it occurred with gluster a few times. It is not a critical issue at all there, as once the cluster is unified, gluster will recover files which were written by both sub-clusters. Figure 4 shows the IO performance of the hard drive of a node when such recovery occurs. The nodes are basically unable to write any log messages for a while as their hard drive disks are monopolized by gluster to check the 12000 files of our system and to merge data from the sub-clusters. At first the log servers were designed with 4 GB of memory and the recovery was a critical moment as all log messages are cached in memory. Doubling the memory made this situation more comfortable. If the gluster area size increases much more, this recovery might take much more time and the caching might not be enough to overcome it. In that case, upgrading the hard drive disks to formats which can support a larger number of IOs would improve the situation.

Another issue comes from the Active/Active configuration of the cluster. Netfilter is a standard module of the kernel. Its project which manages the virtual IP address and the multicast Ethernet address is however written with a hard-coded debug logging. It prints a line for each packet received. The log files for the log servers are basically polluted with these messages. There are two solutions. The first is to use another netfilter module, more recent and not integrated into pacemaker yet. The second, that we adopted, is to patch the kernel module to remove the disturbing lines.

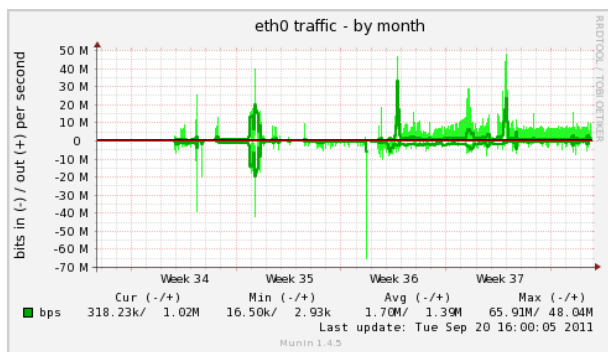

Figure 3: Log server throughput for one month. The input rate are log lines coming to *rsyslog* or custom loggers. The output rate is the NFS rate.

The system would ideally be real time, users could read logs remotely as soon as they were written locally by the nodes, and the log analysis would be performed at this moment as well. It is not possible yet for several reasons. In order to maximize IO performance, *rsyslog* is configured to write batches which produces a slight delay. Thereafter, our current system is unable to export the *gluster* file sys-

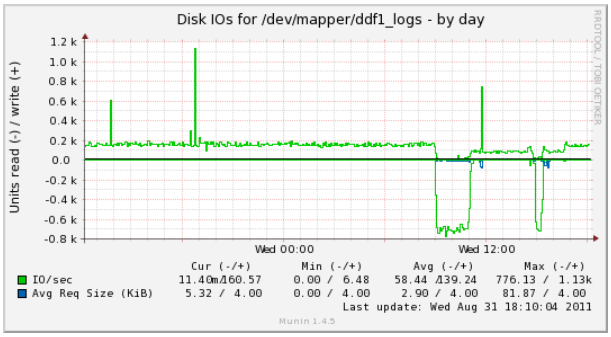

Figure 4: Disk IOs on the RAID file system. The read peaks around Wednesday 12:00 were gluster split brain recovery situations. During these periods, all IOs operations are allocated for gluster and rsyslog cannot write most of the logs. It still performs caching.

tem via NFS, so it exports the real file system. Hence, the log analyzer and the users have to wait for the *gluster* cache to be flushed to disk. An alternative could be to user a *gluster* client instead of NFS.

LHCb, and more particularly Fotis Nikolaidis, contributed to the *rsyslog* module *imfile* which manages the translation of files to syslog. With this module, *rsyslog* polls files periodically, and logs the difference between the previous poll and the current poll. The new version of the module provide the option to use *inotify* [19] under Linux instead of polling. This tool allows applications to register in order to be informed when changes happens to files. Hence, changes in the log files are directly reported to *rsyslog*.

INSTRUMENTATION OF THE CERN ACCELERATOR LOGGING SERVICE: ENSURING PERFORMANCE, SCALABILITY, MAINTENANCE AND DIAGNOSTICS

C. Roderick, R. Billen, D. Dinis Teixeira, CERN, Geneva, Switzerland

Abstract

The CERN accelerator Logging Service currently holds more than 90 terabytes of data online, and processes approximately 450 gigabytes per day, via hundreds of data loading processes and data extraction requests. This service is mission-critical for day-to-day operations, especially with respect to the tracking of live data from the LHC beam and equipment.

In order to effectively manage any service, the service provider's goals should include knowing how the underlying systems are being used, in terms of: "Who is doing what, from where, using which applications and methods, and how long each action takes".

Armed with such information, it is then possible to: analyse and tune system performance over time; plan for scalability ahead of time; assess the impact of maintenance operations and infrastructure upgrades; diagnose past, on-going, or re-occurring problems.

The Logging Service is based on Oracle DBMS and Application Servers, and Java technology, and is comprised of several layered and multi-tiered systems. These systems have all been heavily instrumented to capture data about system usage, using technologies such as JMX.

The success of the Logging Service and its proven ability to cope with ever growing demands can be directly linked to the instrumentation in place.

This paper describes the instrumentation that has been developed, and demonstrates how the instrumentation data is used to achieve the goals outlined above.

INTRODUCTION

Born out of the LHC Logging project, and operational since 2004, the CERN accelerator Logging Service (herein referred to simply as the "LS") is used to store and retrieve billions of data acquisitions per day, from across the complete CERN accelerator complex, related sub-systems, and experiments [1].

The LS is considered a mission critical service, heavily relied upon to support day-to-day operation. As such the availability and performance of this service are paramount.

ARCHITECTURE OVERVIEW

Figure 1 shows a basic overview of the LS which is essentially comprised of:

- Two Oracle databases: A so-called Measurement database (MDB) where raw data from Java processes and other Oracle databases is persisted during seven days, and a Logging database (LDB) where a sub-set of MDB data and pre-filtered data from industrial SCADA systems are stored on-line indefinitely.
- Distributed Java APIs are responsible for loading data into the databases.
- A sub-set of MDB data is transferred to the LDB using in-house developed PL/SQL code that uses a comprehensive set of metadata to dynamically filter the data of long-term interest.
- A powerful distributed Java API is the sole means of extracting data from the databases, which includes a command line interface. Applications wishing to use the API must be pre-registered. At the time of writing there are 100 applications registered to a heterogeneous client community. Direct SQL access is not permitted.
- A generic Java GUI called TIMBER is also provided as a means to visualize and extract logged data. The tool is heavily used, with more than five hundred registered users.

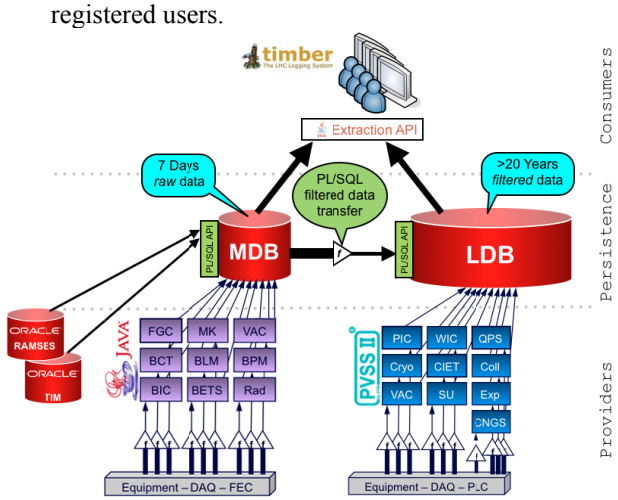

Figure 1: Logging Service architecture overview.

The Java APIs for both logging and extracting data are significantly optimized, and run on Oracle application servers. For data extraction clients, the fact that database access is actually made in a distributed manner via an application server is hidden within the Java API.

PERFORMANCE, SCALABILITY, STABILITY … AND USERS

The LS is a high performance service, which needs to deal with very high data throughputs. At the time of writing the MDB has to process approximately 5.4 billion records/day, which equates to around 270GB/day (annual throughput of approximately 100TB). Meanwhile the LDB needs to persist around 4 billion records/day for

some 850 thousand signals. This boils down to storing 140GB per day (50TB/year) and keeping it available online beyond the lifetime of the LHC.

The success of the LS leading to an increase in scope beyond the LHC, together with unforeseen events requiring more data to be available, has meant that the current data throughput levels far exceed initial expectations, which predicted 1TB/year during LHC operation.

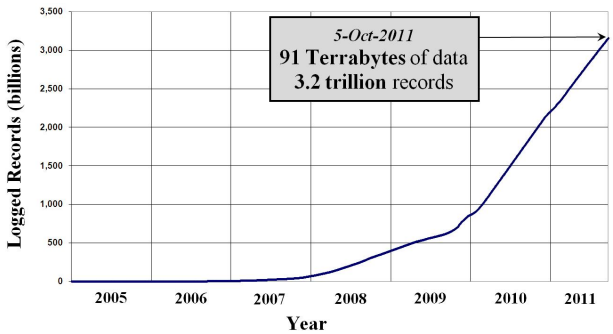

Figure 2: Evolution of logged data.

Figure 2 shows the evolution of logged data, and clearly illustrates how the LS has had to scale to satisfy evolving requirements. The ability to scale in such a manner is in no small part down to the design of the LS [2], however instrumentation also plays an important role, as will be explained later in this paper.

The amount of data logged only tells one side of the story, since data is actually logged in order to be extracted later on to support operational decisions, which often have to be made within short time constraints; therefore data extraction must be as fast as possible.

It is perfectly legitimate for users to ask for data spanning long time periods and/or from long ago. Therefore the LS must satisfy such diverse requests not only as quickly as possible, but also whilst remaining stable such that is can support other operations in parallel.

The determining factor in how a service performs is *always* how the service is used. Experience has shown that there is often a big difference between how service providers *think* the service will be used, how users *claim* they will use the service, and how users *actually* use the service. This is where instrumentation comes in…

WHAT IS INSTRUMENTATION?

In this paper, instrumentation refers to capturing information about service activity in real time, and over time, in order to know who is doing what, from where, how things are being done, and how long various actions take.

Who?

This should always indicate the *real* end-user of the service – somebody who can be contacted. In other words, in an n-tier environment, it should not just be the directly connected OS user on one of the tiers.

What?

In its simplest form, this could be the name of a method / function / procedure etc. A more comprehensive solution would also capture details of all of the dimensions that can affect the outcome of an action and/or the performance of the service. These details are domain specific, but an example from the LS when querying data would be: the API method, the names of the signals concerned, the time window, and any additional data manipulation parameters (see Figure 4).

Where?

This should be a host name or IP address, and process id, which can be used to physically locate calls being made to the service.

How?

This means identifying which application (by name) is using the service, and if the service is accessed via libraries – which versions of the libraries are being used.

How Long?

Knowing the amount of time spent doing something is an essential ingredient in understanding how a service is performing, and why problems may have occurred. Therefore it is necessary to capture the elapsed time for each significant action executed within the service.

Besides these key elements, it is also important to instrument if actions finish successfully or throw exceptions in order to understand unexpected behaviour.

WHY INSTRUMENT?

Instrumentation is often considered an unnecessary overhead, especially by developers who want their code to run as fast as possible. However, this is a rather shortsighted view on things.

Knowing the answers to the questions above enables service providers to understand how a service is really being used (or misused), and how it is performing in terms of both throughput and response times. In turn, this allows to pre-empt problems, identify potential bottlenecks, plan system upgrades, and when issues inevitably occur – diagnose and react swiftly and effectively.

Collectively, these benefits far outweigh any perceived run-time overhead of having instrumentation in place.

The rest of this paper will focus on particular examples of instrumentation deployed in the LS, and how it has helped meet the requirements for performance, scalability, and stability.

DATA LOADING

Every day, the LS treats millions of data loading requests, coming from hundreds of client processes. The distribution of these requests across clients is heavily skewed. For example, one client may be responsible for

sending up to 40% of the data, and other just 1%. In order to know how the systems are being used, it is important to capture these data distributions.

Likewise, the data distribution within data loading requests may be heavily skewed across clients, or over time. In other words a fixed size data loading request may contain a lot of data for a few signals, or a small amount of data for many signals. This distribution can have a significant impact on performance, and therefore also needs to be captured to support performance analysis.

The other factor impacting performance of data loading in the LS is whether or not a request contains duplicate data (same timestamp received for the same signal), which requires a special treatment taking 4 times longer to process than a request without duplicate data.

Initial Implementation

The instrumentation in the LS has evolved significantly over many years. Initially most of the above details were just captured in log files. The problem with this approach is that they were very difficult to analyze, especially as the parallel load on the LS began to increase, and non-related log entries become more and more interleaved.

To understand the data distribution across clients, an internal database job ran queries against the logged data, making aggregates of the amount of data received per client. This approach was not scalable, and as the data rates increased the aggregate queries were continually adapted to use increasingly smaller sample periods of data. A new approach to instrumentation was required.

Evolution

A well-structured instrumentation framework was developed and put in place at the level of the data loading API running on the Oracle application servers. This framework captures all details of all data loading requests, performs on-the-fly in-memory data aggregations, and writes the results into the database on a daily basis.

This approach is extremely accurate (since aggregates are based on actual data rather than data samples), and avoids the need to use significant database resources to estimate system usage. In addition the time spent on each action (parse, check, prepare, load) within each data loading request is captured and aggregated to facilitate analysis of system performance, and identify bottlenecks and bad clients.

The other major advantage with the instrumentation framework is that all information is well structured and exposed via JMX using Java *managed beans* (MBeans), which can be consulted in real-time via any JMX (Java Management Extensions) interface. This allows service providers to easily see what the systems are currently doing, and diagnose on-going problems.

INTERNAL DATA TRANSFER

The majority of the data logged in the MDB are candidates to be transferred to the LDB for long-term storage. What data actually gets transferred is governed by a comprehensive set of metadata defining things such as deltas, smoothing, fixed logging, precision etc. for each of the defined signals. The act of applying the metadata to the raw data, and filtering and transferring the results to the LDB are carried out using in-house developed PL/SQL code which is executed in parallel by 8 internal database jobs running every 5 minutes. The signals whose data is treated by 1 of the 8 jobs are distributed across the jobs according to a predefined category for each of the signals.

Knowing how each execution of the data filtering and transfer jobs performs, in terms of number of signals, number of candidate values per data type, number of logged values per data type, and times taken for each internal action is essential.

Data Capture & Diagnostics

The PL/SQL data filtering and transfer code captures all of the above information in memory, and writes the results into dedicated database tables after each execution.

This detailed information remains available for 7 days (lifetime of MDB data) and is extremely useful for diagnosing performance problems – identifying if long executions times are isolated to particular groups of data, specific data types, certain times of the day or a specific type of action (such as data collection and filtering in the MDB, or data transfer to the LDB).

The detailed information is also aggregated on an hourly basis (Figure 3), and results are stored long-term in the LDB. This aggregate data helps identify trends in system performance such as correlations with accelerator performance, or gradual performance decreases as demands on the system increase (e.g. requests to log data for more signals and / or at higher frequencies.

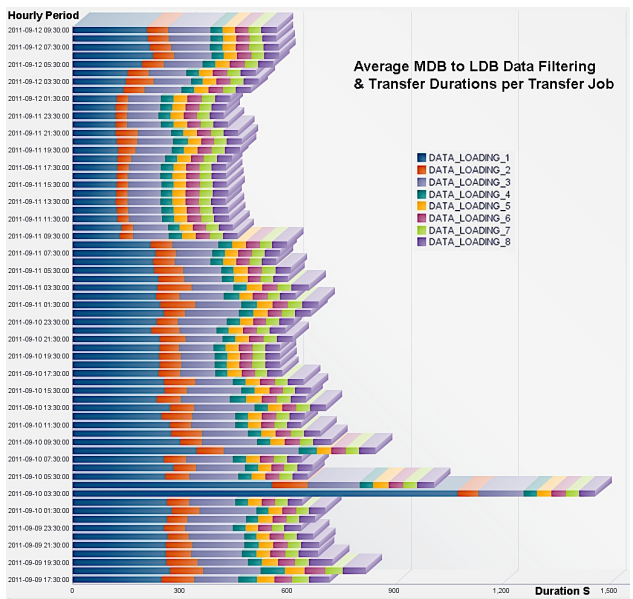

Figure 3: Example MDB to LDB instrumentation data.

DATA EXTRACTION

With up to 2 million requests per day to extract data for one or more signals over greatly varying time periods – data extraction from the LS represents a significant portion of overall activity.

Data rates vary significantly from one signal to another, and from one time period to another (e.g. according to whether or not there is beam present in the LHC).

In such an environment, users are often unaware of the amount of data that they are implicitly requesting, or of the best methods to use to extract with.

Aiming for Service Stability

As part of an attempt to assure service stability, every request to extract data is transparently instrumented, exposed, and logged using a framework similar to that for data loading, based on JMX. For each user: the running, last added, last finished, and last unsuccessful requests are always accessible via any JMX console. The *Who*, *What*, *Where*, *How*, and *How Long* information is embedded in each request, including signals involved, the extraction time window, invoked method, elapsed time, library versions, and the result (see Figure 4).

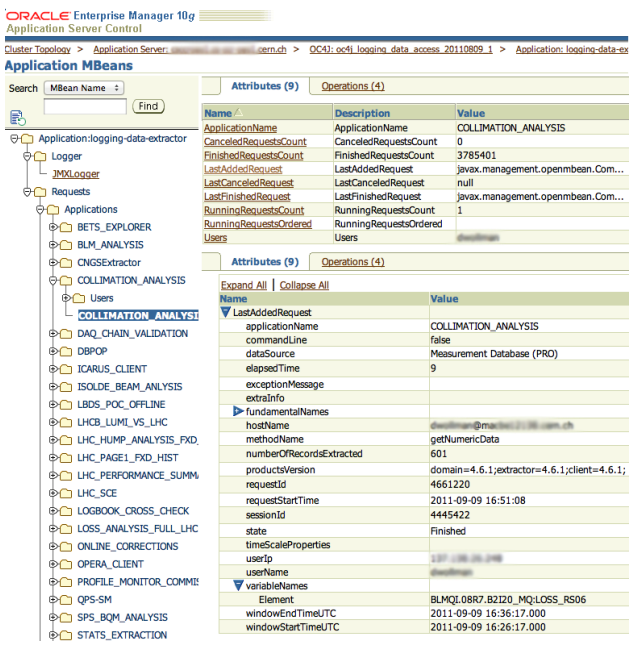

Figure 4: Data extraction instrumentation via JMX.

The ease of access of this information greatly facilitates following up support requests, since service providers can quickly access the full set of details of what the user is trying to do. Furthermore, because this information is accessible in real-time, a JMX agent connects every 5 seconds to the remote data extraction server, assesses the current situation, and can take various actions:

- If a request has been running for too long, a warning is first sent to service administrators, and if the situation continues – the request will be terminated. In such situations, it is common practice for the service administrators to diagnose the problem and pro-actively contact the user. More often than not – the users just need to be advised about which alternative methods to use or attribute values to apply.
- If any centralized data extraction server fails, service administrators are notified of the failure, together with details of all requests running prior to the failure, such that they can diagnose the cause, inform the user responsible, and adapt the service to be more resilient in the future.

Another way in which the captured data is used is related to backwards compatibility during upgrades to the API. Because all method calls are logged, it is possible to deduce whether or not certain users will be affected by necessary API changes, and contact them in order to adapt their code, or delay the changes.

SUMMARY

Instrumentation should not be considered as an overhead, but rather as an integral component of any software infrastructure. Once in place it quickly becomes part of the backbone of the system, allowing service providers to quickly and confidently diagnose problems, tune system performance, and plan upgrades.

The Logging Service instrumentation data is constantly used to support users, and has helped unravel otherwise impossible to diagnose problems in a complex and distributed environment.

The Logging Service is a stable, high performance, and heavily used service. The performance, proven ability to scale, and overall stability are testament to the value of the significant instrumentation in place.

CONTROL SYSTEM FOR CRYOGENIC THD/DT LAYERING AT THE NATIONAL IGNITION FACILITY*

M.A. Fedorov, O.D. Edwards, E.A. Mapoles, M.Y. Mauvais, T.G. Parham, R.J. Sanchez, J.D. Sater, B.A. Wilson, Lawrence Livermore National Laboratory, P.O. Box 808, Livermore, CA 94550, USA

Abstract

The National Ignition Facility (NIF) is the world largest and the most energetic laser system for Inertial Confinement Fusion (ICF), located at the Lawrence Livermore National Laboratory (LLNL). In 2010, NIF began ignition experiments using cryogenically cooled targets containing layers of tritium-hydrogen-deuterium (THD) or deuterium-tritium (DT) fuel. The 68 μm-thick ice layer is formed inside of a 2 mm target capsule at temperatures of approximately 18.3 Kelvin. The ICF target designs demand sub-micron smoothness of the THD/DT ice layer. Precise formation and characterization of such layers is a challenging task and still an active research area. It requires a flexible control system capable of executing evolving layering protocols. At NIF, this task is performed by the Cryogenic Target Subsystem (CTS) of the Integrated Computer Control System (ICCS). ICCS is a large-scale, distributed control system which integrates scientific instruments, control hardware and computing platforms under a common object-oriented architecture. The CTS provides precise cryogenic temperature control, advanced x-ray imaging capability, and monitoring of vacuum and gases. Equipped both with automatic software engines and an interactive development environment, the recently deployed control system has enabled first NIF cryo-layered target campaigns and supported layering research.

INTRODUCTION

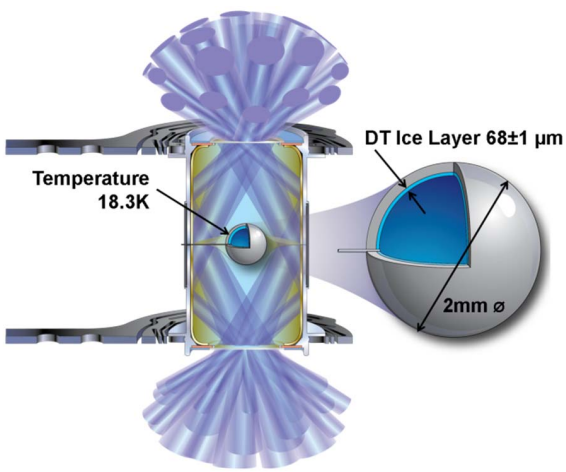

Figure 1: NIF cryogenic layered target.

The National Ignition Facility at Lawrence Livermore National Laboratory is a 192 beam, 1.8 MJ, 351 nm laser designed to conduct Inertial Confinement Fusion (ICF) experiments. Construction of NIF was completed in March of 2009. While NIF was conducting its first hohlraum energetics campaigns, the facility was also preparing for cryo-layered target experiments [1]. The key systems commissioned in the first half of 2010 included the Cryogenic Target Positioner (CryoTARPOS) with the Ignition Target Insertion Cryostat (ITIC) and the Load, Layer and Characterization Station (LLCS). Along with installation of hardware, the software for the Cryogenic Target Subsystem (CTS) of the Integrated Computer Control System (ICCS) was deployed and qualified for operations [2]. Precise cryogenic THD/DT layering was the main capability delivered with this new hardware and software.

An ignition target consists of four essential components: the hohlraum, the thermal control hardware, the capsule and the ice layer, see Fig. 1. The THD/DT ice layer is formed inside of the 2 mm target capsule at temperatures of approximately 18.3 K. In ignition experiments, the ice layer is 68 μm thick. Most of the target parts are precisely manufactured and calibrated in dedicated facilities, weeks and months before the shot. The ice layer is formed in the target mounted at the end of the target positioner, next to the NIF target chamber, just hours before the shot. Furthermore, the ice layer is cryogenic and is not accessible for direct inspection. However, the quality of the ice layer formation (or "manufacturing") is essential for the success of the ignition experiment.

THD/DT LAYER FORMATION

The THD/DT ice layer is formed by executing a cryogenic layering protocol. The layering protocols are first developed and proved in the R&D lab to accommodate a variety of target designs and fuel mixes. The protocols consist of several melting-freezing phases and last 17-24 hours. The x-ray images of the developing ice layer are periodically acquired in three imaging directions. The images provide the feedback on the layering process.

The goal of the layering protocol is to produce an ice layer which is both symmetrical and smooth. In a high-quality layer, the ice is distributed into a perfect sphere. The sphericity is measured by calculating the power spectrum of the unwrapped image in three directions. In addition, the ignition-quality layer must be free of local defects, such as boundary grooves and thermal stress cracks.

The formation of a spherical shape and elimination of local defects require application of different techniques.

* *This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.* LLNL-CONF-505491.

Beta-Layering

The general spherical shape is formed using the beta-layering process [3]. The beta-decay of tritium generates volumetric heat in the THD/DT ice. Thick regions of the ice layer have higher surface temperatures. The THD/DT fuel evaporates from the thick regions which are warmer and condenses in thin areas which are cooler. Given a symmetrical capsule, a uniform thermal environment and some time, the beta-layering will produce a spherical ice layer. The time constant of this process is about 27 minutes. Unfortunately, this technique is not efficient in preventing local defects.

Single Seed Crystal Growth

It was noticed that most of the local defects are due to the boundaries between ice segments grown from multiple seeds. Thus, a technique was developed which attempts to isolate a single seed and then grow the entire spherical layer from that seed [4,5]. The procedure involves several hours of precise temperature manipulations using x-ray image analysis as feedback. First, the capsule is rapidly cooled. The resulting ice layer formed inside of the capsule has an irregular shape and many defects. Next, the temperature is gradually increased to melt most of the ice inside the capsule. The melting process is monitored with the x-ray imaging system and is stopped when almost all of the fuel is liquid again. The remaining ice speck serves as a seed for the new layer formation. The temperature is decreased slowly, and the new layer grows as a single crystal over several hours.

CRYOGENIC TARGET CONTROL SYSTEM

Temperature Control

Both the beta-layering and the single seed crystal growth techniques require a highly uniform, and precisely controlled, thermal environment. At NIF, the Ignition Target Insertion Cryostat (ITIC) provides such a controlled environment [6], see Fig. 2. The ITIC is two meters long and it is mounted at the end of the NIF target positioner, as shown in Fig. 3. The target positioner is a large mechanical structure of approximately 15 meters long. The cryogenic operations start with the positioner fully retracted from the target chamber into an isolated vacuum vessel. The vessel is equipped with a three-axis x-ray target imaging system.

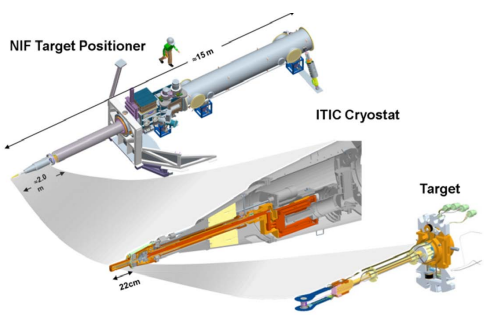

Figure 2: Ignition target cryostat system.

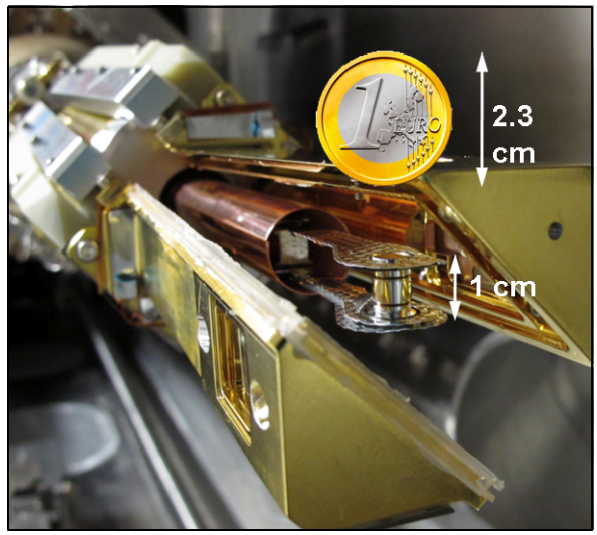

Figure 3: Front view of the ITIC shroud and the target.

Target temperatures are controlled down to 1 mK precision at multiple points. The top and bottom of the target have independent sets of controls. There are two additional shimming heaters in the middle section of the hohlraum. By adjusting these temperature control points, a highly uniform thermal environment can be created for the ice layer, even when the external environment or the target components are not perfectly symmetrical. The ice layer itself serves as a precise indicator of the temperature field. When the x-ray characterization of the layer reveals that it is asymmetric or not concentric, a calculated adjustment of the heaters is performed and beta-layering brings the layer into desired spherical shape.

The target base and the DT fuel reservoir are also precisely controlled. This is needed for filling the target with fuel. The reservoir and the target capsule are connected by a thin (10 μm OD, 5 μm ID) fill tube. The fuel is transferred by adjusting the temperature gradient between the target and the reservoir. Another important feature of the cryogenic system is the helium tank which provides thermal capacitance sufficient to maintain temperatures even when the mechanical cryogenic cooler is turned off for several minutes. This thermal capacitor capability is utilized to reduce vibration blur during the ice layer characterization.

Each experiment at NIF is conducted with a new target. There are several designs of cryogenic targets. They have different sets of control points. Each sensor comes with a unique calibration file. Therefore it is essential for the control system to be data-driven and support different control topologies.

X-ray Imaging System

The distribution of DT fuel inside of a target capsule is monitored and measured using a three-axis x-ray imaging system. The phase contrast, computer enhanced imaging reliably detects boundaries of solid and liquid DT inside of the beryllium and plastic capsules.

The imaging system includes three sets of x-ray sources and x-ray cameras arranged as three perpendicular axes.

The vertical axis is aligned with the hohlraum laser entrance hole and provides an unobstructed full view of the capsule. The two side views are taken through the starburst-shaped apertures in the hohlraum walls.

The image acquisition engine controls and monitors imaging hardware, see Fig. 4. It configures hardware settings, such as x-ray source voltage and beam current.

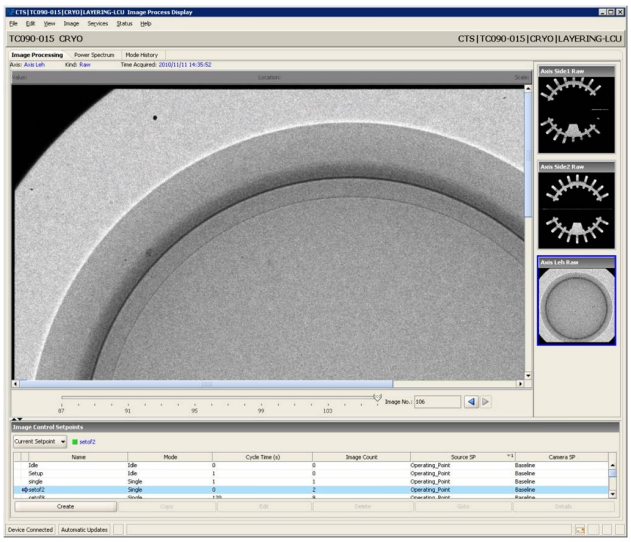

Figure 4: Control panel for x-ray imaging engine.

Because of the proximity of the target to the mechanical cryogenic cooler, the vibration blur distorts fine features of the images. To reduce blurring, the image acquisition engine times camera exposures to pauses in the cooler operations. The signal-to-noise ratio of the images is enhanced by taking multiple exposures and computing summed images. The capsule drift between the exposures is compensated by aligning images through image registration.

Interactive Layering Environment

In addition to automatic, data-driven software engines, the cryogenic controls are equipped with an interactive analysis and development environment. The environment is based on MATLAB and is implemented as a MATLAB Layering Toolbox extension. The environment enables real-time interaction with the growing ice layer, see Fig. 5.

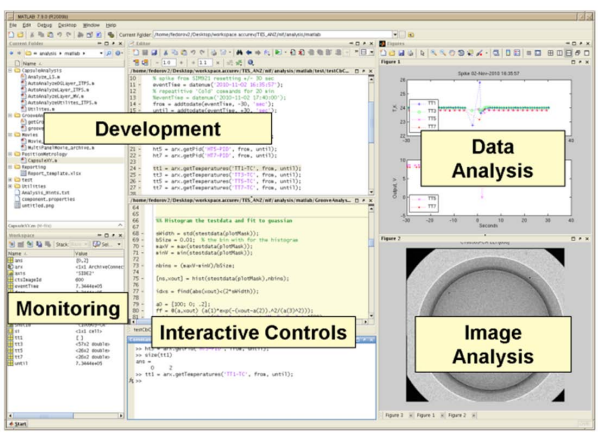

Figure 5: Interactive layering environment.

Implementation of the Layering Toolbox is based on the standard ICCS frameworks and CORBA middleware. Through this distributed control system infrastructure, the interactive environment automatically benefits in network connectivity, process concurrency and data sharing. The layering specialists at multiple workstations can monitor and support the ongoing layering process. Interactive sessions co-exist and communicate with the automatic software engines. The cryogenic process can be switched between automatic and interactive execution based on the complexity and novelty of a specific procedure.

Isolation of the interactive environment from the low-level hardware controls was one of the key design goals. The cryogenic target specialists preferred to avoid dealing with the specifics of the hardware configuration. The control system operators demanded that interactive environment actions are always entirely contained within a well-defined scope. The isolation goal was achieved by introducing the layering recipe controls abstraction. The minimalistic interface provides only a few virtual control points relevant to the physics of layering. It hides dozens of configuration settings which are managed by the core control system. The x-ray imaging is abstracted into named acquisition patterns and a flow of images. The low-level settings and sequencing of the x-ray imaging hardware are handled by the automatic software engines. The mapping of the virtual layering control points to hardware is data-driven and is managed by the core control system.

The development of the interactive layering environment was greatly simplified by choosing a well known scientific and technical computing product (MATLAB) as a COTS platform. While the Layering Toolbox codifies our domain expertise, the COTS component supplies a user-friendly IDE for code editing, debugging and version control. Extensive selection of data visualization and image processing tools for MATLAB is readily available, both commercial and open-source.

The rich toolset and flexibility of the layering environment have simplified evaluation of the new target designs and supported layering research.

COORDINATION WITH NIF LASER SHOT

Layering Report

When the ice layer is completely formed, an extended set of image analysis routines is run to produce the Layering Report., shown in Fig. 6. The Report contains metrics and checks whether the layer meets the ignition specification. The Layering Report is a key decision point, when the scientific review board meets to decide whether to proceed with a NIF shot.

For visual inspection, the layering report contains unwrapped images of the ice layer in three dimensions. These images help evaluate the general spherical shape and severity of local defects. The power spectral density of the unwrapped ice surface is calculated for three axes

and it is plotted against the ignition target specification. In the Layering Report section shown on Fig. 6, the spherical shape is within the specification for all three directions. For local defects, a cumulative metric is calculated based on the total surface area affected by the defects.

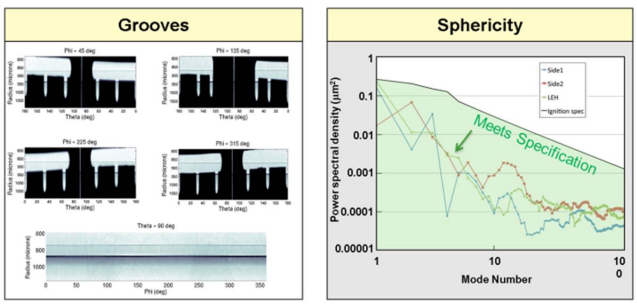

Figure 6: Section of a Layering Report.

The summary of the Layering Report includes a recommendation to proceed with the shot or to re-attempt the layering.

Cryogenic Activity and NIF Shot Sequence

Formation of the high-quality ice layers is a long process. It takes many hours, see Fig. 7. Including retries and supporting operations, it can take days. All cryogenic operations are coordinated under the Cryogenic Activity. The Cryogenic Activity is a sequence of steps similar to a NIF Shot [7]. Due to its extended duration, the Cryogenic Activity starts independently from a NIF shot. When the layer is close to completion, the NIF shot sequence starts. The Cryogenic Activity communicates to shot controls and joins the NIF Shot cycle.

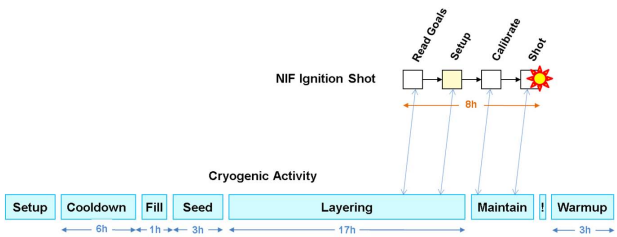

Figure 7: Timeline of Cryogenic Activity and NIF Shot.

Final Pre-shot Cryogenic Target Operations

The cryogenic target subsystem continues to monitor target temperatures during target insertion into the chamber and during target alignment. Seconds prior to the main laser shot the cryogenic controls perform final temperature adjustments and open the shroud.

Ignition target specifications require that the final target temperature is ~1.5K lower than the temperature at which the ice layer is formed and maintained [4]. At lower temperatures, the ice layer quickly develops roughness and cracks. To minimize the degradation of the ice surface, the cryogenic controls perform final temperature adjustment, called quench, only 30 seconds prior to the main laser shot (T-30). To further reduce the thermal stress, the quench is performed as a smooth linear ramp.

From the beginning of the cryogenic activity until the laser shot, the protective shroud surrounds the cryogenic target. This shroud shields the target from infrared radiation and prevents undesirable condensation on the outer surfaces of the target. The NIF shot control software commands mechanical opening of the shroud eight seconds prior to the main laser shot (T-8). The cryogenic system has adequate control authority to maintain precise temperatures for several minutes after the shroud is open. This is sufficient to handle normal and off-normal shot cases.

Normally, at T-0 the main laser shot is fired and the cryogenic target is consumed. Next, the cryogenic controls proceed to the warm-up sequence. If the laser shot is aborted during the final seconds, the cryogenic controls quickly revert the quench and return the target to temperatures at which the ice layer can be maintained safely until the next attempt.

RESULTS

Since 2010, the Cryogenic Target System supported 72 NIF experiments, including 13 with layered targets. The integrated hardware-software system provided a robust and accurate platform for cryogenic target experiments. The automatic data-driven process consistently executed complex layering protocols. Finally, the flexible interactive environment simplified evaluation of new target designs and supported layering research.

CONTROL AND TEST SOFTWARE FOR IRAM WIDEX CORRELATOR

S. Blanchet, D. Broguiere, P. Chavatte, F. Morel, A. Perrigouard, M. Torres
IRAM, Grenoble, France

Abstract

IRAM[1] is an international research institute for radio astronomy. It has designed a new correlator called WideX for the Plateau de Bure interferometer (an array of six 15-meter telescopes) in the French Alps. The device started its official service in February 2010. This correlator must be driven in real-time at 32 Hz for sending parameters and for data acquisition. With 3.67 million channels, distributed over 1 792 dedicated chips, that produce a 1.87 Gbits/sec data output rate, the data acquisition and processing and also the automatic hardware-failure detection are big challenges for the software. This article presents the software that has been developed to drive and test the correlator. In particular it presents an innovative usage of a high-speed optical link, initially developed for the CERN ALICE experiment, associated with real-time Linux (RTAI) to achieve our goals.

INTRODUCTION

After the installation of its new generation of receivers in 2006, IRAM has started to build a new correlator called WideX that can process up to 64 GHz of total analog bandwith [1]. It is a big machine with 3.67 million channels, distributed over 1 792 custom[2] chips. With such a number of components, powerful programs for automatic testing are crucial, otherwise the project fails. Real-time driving at 32 Hz and data processing is also a serious software challenge because the total device output data rate is about 1.87 Gbit/s.

TECHNICAL CHOICES

Data Transmission

For technical convenience the correlator is divided into four identical sub-units (Fig. 1), driven by four computers. It means that it requires 4 data links at 448 Mbit/s. Finding a way to transfer data at such rate, was a headache for engineers. Fortunately CERN had already developed such a high-speed serial link for its own needs[3] and it was possible to buy this technology jewel at a very affordable price. The CERN solution is called Detector Data Link (DDL) [2]. It is a versatile high-speed optical link, that can transfer up to 1.5 Gbit/s. It is composed of:

[1]Institut de Radioastronomie Millimétrique

[2]The correlator chip is a 250 MHz application-specific integrated circuit (ASIC) designed under IRAM specifications [1].

[3]CERN has developped DDL for the LHC/ALICE experiment.

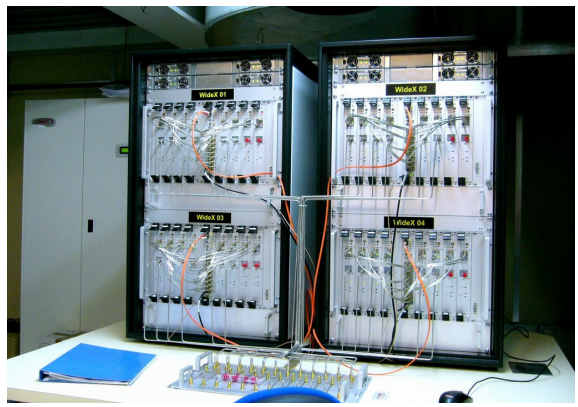

Figure 1: IRAM WideX on the observatory site. Note the four orange fibers that connect the four sub-units.

- a *Source Interface Unit* (SIU) to plug into the correlator (Fig. 2).

Figure 2: CERN Source Interface Unit board.

- a *Destination Interface Unit* (DIU) hosted on a readout receiver card (Fig. 3) to connect to a computer.

Figure 3: CERN Read-Out Receiver Card (PCI-X slot) with 2 Destination Interface Units.

- a fiber optic to link directly the SIU and the DIU (orange fibers on Fig. 1).
- a Linux driver with the source code.

This optical link is very easy to use: the data are sent to the SIU through a parallel bus, then they appear automati-

cally in the computer memory at the address that has been provided to the driver.

Real-time Operating System

While processing large amounts of data, the computer must drive the data acquisition at 32 Hz, therefore a real-time operating system is required. Linux-RTAI[4] was chosen because it has already been successfully used at IRAM, for critical tasks like the antenna control.

This real-time engine guarantees that the data acquisition runs at 32Hz, without losing any data, whatever the computer load is. Among the different RTAI running modes, LXRT[5] was prefered, because it allows hard real-time programs to run in user space: the software development is easier and programs can be written in C++ instead of C only.

The only small drawback is that the CERN driver and libraries are not directly compatible with RTAI, but a modification of the CERN source code has solved this problem.

Software Libraries

Because electronic engineers need very fast and responsive testing tools, the fastest software libraries have been carefully selected to build the programs:

- Qt: *a free C++ cross-platform framework* [4]. It provides fast and nice graphical widgets and also many other very useful classes. It is developped by Nokia Corporation.
- Qwt: *Qt Widgets for Technical Application* [5]. It is a Qt extension, that provides nice technical widgets like a plotter (QwtPlot) with built-in zoom and autoscaling. It is a community project.
- FFTW: *Fastest Fourier Transform in the West* [6]. It is a free library to compute the Discrete Fourier Transform in one or more dimensions. It uses code-generation and runtime self-optimization techniques to achieve a very high level of performance. This software library was developed at the Massachusetts Institute of Technology (MIT).

SOFTWARE

The different pieces of hardware impose some constraints on the time diagram (Fig. 4) that should be explained to understand the most interesting details of the software design.

1. The correlator data output is scheduled on an internal 32 Hz clock[6].
2. To read data, the computer sends a `RDYRX` (Ready-to-Receive) command before the 32 Hz pulse. The transfer starts with the 32 Hz pulse.
3. The data transmission is long and uninterruptible. Therefore it allows only a small sending window after `EOBTR` (End Of Block Transfer).
4. The CERN board generates no hardware interrupts: a polling is required to detect the end of transmission (`EOBTR`).
5. The CERN board writes data directly in memory without using the central processor, therefore it is the best moment to process data from the previous acquisition period.

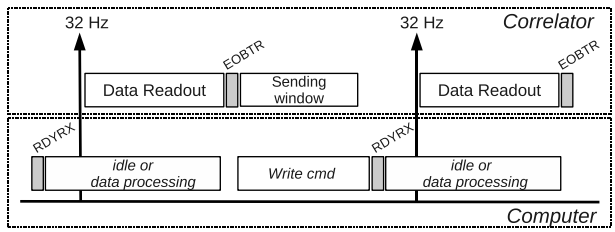

Figure 4: Time diagram.

Time Synchronization

Like the antenna position, the correlator acquisition parameters change relentlessly with the Earth rotation. Unlike the correlator that synchronizes itself directly on the time signal of the observatory maser, the computer has no particular hardware for clock synchronization. However a software-only solution works very well:

1. Because the transmission duration is constant and starts always on a 32 Hz pulse (Fig. 4), the computer considers the end-of-block-transfer (`EOBTR`) event as a faithful image of the correlator clock. Therefore the real-time tasks are synchronized on this event. The polling loop starts only when required, at the very last time, and exits after only few iterations. In this case, it makes sense to use a high-frequency[7] loop.
2. To know the absolute time associated to each `EOBTR` event, the computer uses the Network Time Protocol[8] server that depends on the observatory maser.

Software Architecture

There is only one real-time program: `CONTROL` (Fig. 5). It has two real-time threads: `DRIVE` and `PROCESS`.

[4]RTAI: RealTime Application Interface [3]. It is a real-time extension for the Linux kernel from the *Department of Aerospace Engineering, Politecnico di Milano, Italy*.

[5]LXRT: Linux Extension for Real Time. It is a special RTAI scheduler.

[6]The 32 Hz frequency is dictated by the Walsh functions that are used to reduce the effects of electrical crosstalk between antenna signals.

[7]In our case, the polling loop runs at 1 kHz, but it could be higher.

[8]Network Time Protocol (NTP) is a protocol for synchronizing the clocks of computers over variable-latency networks.

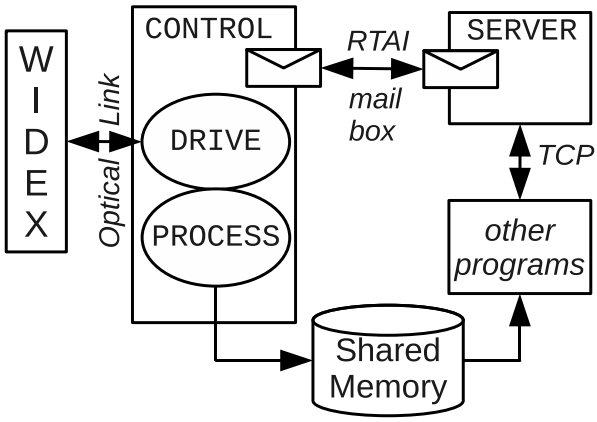

Figure 5: Software architecture.

- `DRIVE` drives the data acquisition. It has the first real-time priority to avoid any data loss. It executes the following loop of instructions:
  1. Get a free memory page[9], and send its address to the CERN driver.
  2. Send a `RDYRX` command to the correlator, and then sleep[10] until just before the next `EOBTR` event.
  3. Poll until `EOBTR` occurs.
  4. Push the page of the just-arrived data into the waiting queue of the `PROCESS` thread,
  5. Send any pending parameters to the correlator.
  6. Sleep until just before the next 32 Hz pulse.
  7. Repeat the loop.
- `PROCESS` processes the raw data from the correlator. It has the second real-time priority to guarantee that the processing is finished in the expected time. It executes the following loop of instructions:
  1. Take the first data page from its waiting queue.
  2. Process the data and write the result into the shared memory.
  3. Push back the memory page to the pool.
  4. Repeat the loop.

Because of the chosen priorities, the Linux kernel and all the other software run only when `DRIVE` and `PROCESS` are asleep. To send specific command to the correlator, programs must pass through `SERVER` (Fig. 5) to transform TCP requests into RTAI messages. The command will be really sent to the correlator during the next sending window (Fig. 4).

[9]The memory page comes from *physmem*: it is a reserved memory area for CERN DDL direct memory transfers. A realtime-compatible memory allocator has been specifically written for this area because the Linux kernel does not manage it.

[10]The sleeping and the transmission last exactly the same time, but the sleeping ends before, because it starts before.

RUNNING MODES

There are different running modes, one for each testing stage.

Simulation Mode

The target of this mode is to test software without needing hardware, and also to prove that the processing algorithms are correct. The simulation mode changes the behaviour of the driving task: instead of reading the CERN driver output, the thread calls real-time functions that generate custom simulation data.

There are several simulation patterns, one per kind of tests. For example, Fig. 6 shows a simulation pattern for chip failure detection.

Chip Debugging Mode

The goal of this mode is to check that all the correlator chips work as expected. This mode modifies the processing task: instead of analyzing spectrum, it compares together the raw outputs of the chips. A special program displays the results as a 448-cells matrix (Fig. 6). When a problem is detected in a chip, the cell color changes. The user can click on the chip to display its channel values (Fig. 7).

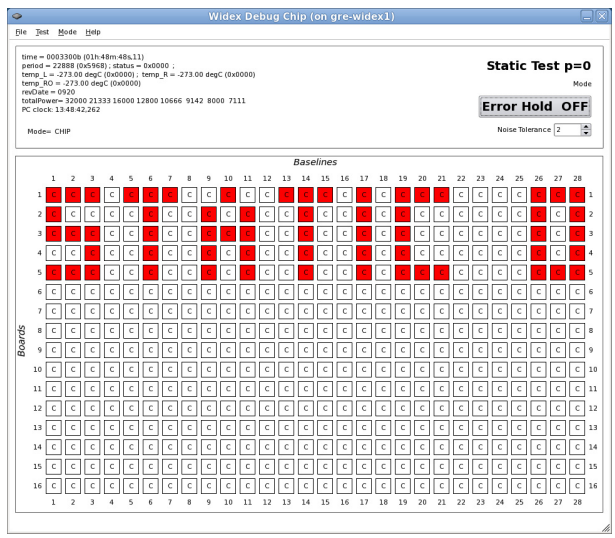

Figure 6: Chip debugging window. A simulation pattern is printing messages on the chip matrix.

Observing Mode

The purpose of this mode is to show that the correlator can extract the hidden signal from the noise. Therefore it implements almost all the operations for real observing. This mode modifies the processing task to analyze the spectrum in real-time. These signal processing operations are organized in sequence: Fast Fourier Transform followed by several corrections of levels and phases. Each pipeline stage can be enabled or disabled in order to measure its

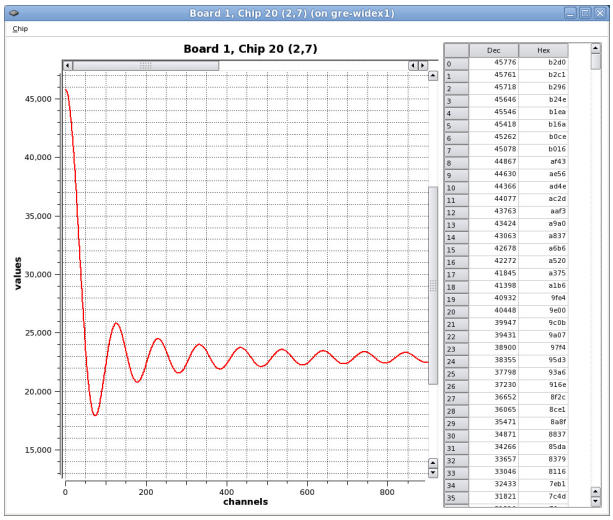

Figure 7: Content of a chip. The curve is plotted with QwtPlot [5].

individual effect and its contribution to the total execution time. A fast viewer (Fig. 8), with direct buttons to control signal processing, has been written to display the results. It heavily uses Qt [4], Qwt [5], and FFTW [6].

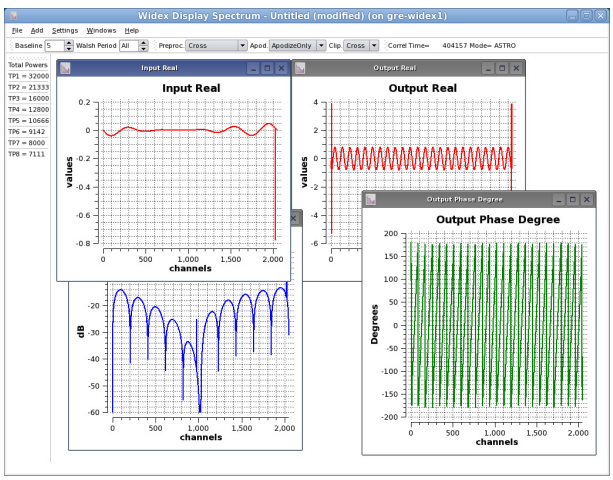

Figure 8: Dedicated viewer for correlator spectrum.

CONCLUSION

Thank to the innovative pair CERN DDL – RTAI, it is possible to build a very high-performance control software. It drives in real-time a complex scientific device, while processing large amounts of data. The icing on the cake is that the solution is built with free open-source software only.

ACKNOWLEDGMENT

The authors would like to thank Ervin Dénes, Csaba Soós and Pierre Vande Vyvre from CERN: we are grateful for their free hardware loan and their precious help at the early stage of the project.

A NEW FAST DATA LOGGER AND VIEWER AT DIAMOND: THE FA ARCHIVER

M.G. Abbott, G. Rehm, I.S. Uzun, Diamond Light Source, Oxfordshire, UK

Abstract

At Diamond Light Source, position data from 174 Electron Beam Position Monitors (BPMs) and a number of X-Ray BPMs is distributed over the Fast Acquisition communications network at an update rate of 10 kHz; the total aggregate data rate is around 15 MB/s. The data logger described here (the FA Archiver) captures this entire data stream to disk in real time, re-broadcasts selected subsets of the live stream on demand to interested clients, and allows rapid access to any part of the saved data. The archive is saved into a rolling buffer allowing retrieval of detailed beam position data from any time in the last four days. A simple socket-based interface to the FA Archiver allows easy access to both stored and live data from a variety of clients. Clients include a graphical viewer for visualising the motion or spectrum of a single BPM in real time, a command line tool for retrieving any part of the stored data by time of day, and Matlab scripts for exploring the dataset, helped by the storage of decimated minimum, maximum, mean, and standard deviation data.

INTRODUCTION

Diamond uses Electron Beam Position Monitors for electron beam diagnostics and orbit position feedback. Each BPM button block is connected to a Libera [1] beam position processor, comprising RF processing for each of four pickup buttons, with ADCs and an FPGA which reduces the data to streams at a variety of data rates, and an embedded processor providing an EPICS interface [2].

In the Libera FPGA the sampled button intensities are converted to X, Y positions and reduced by decimation and filtering to machine revolution frequency (534 kHz) and then to the "Fast Acquisition" (FA) data rate of 10 kHz and the "Slow Acquisition" rate of 10 Hz for EPICS clients. The FA data is broadcast through the Diamond Communication Controller (CC) network [3, 4] which makes this data stream simultaneously available to all connected machines. The CC network allows machines to be freely added as receivers or transmitters with little or no impact on the operation of the network; the FA Archiver is one such machine.

The FA archiver receives CC updates at the FA data rate of 10 kHz, each update consisting of position information for all connected BPMs together with data from a handful of other data sources. This data is stored to disk in a rolling multi-day buffer and made available to client applications throughout Diamond.

The archiver runs on a dedicated server and writes to local disks; at Diamond we use a 6 Terabyte archive (two dedicated 3 TB disks as a 6 TB RAID 0 volume) giving us just under 4½ days of archive of 182 CC ids. The archiver acts as a socket server supporting a simple command language; commands are provided for subscribing to any subset of the live data stream, and for retrieving any part of the archived dataset.

Live data is available from the FA archiver both at the full 10 kHz data rate and decimated by filtering down to 1 kHz. Archived data is available at the full data rate or decimated binned by factors of 128 or 16384 (by default) to provide an overview of the stored data.

FA ARCHIVER AND CC NETWORK

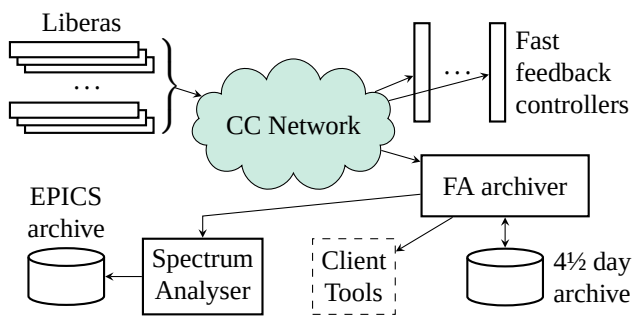

Figure 1: FA Archiver and CC network in context.

The Communication Controller network was originally constructed to make the 10 kHz FA data from each Libera BPM available for the operation of the fast feedback controllers which maintain position stability of the electron beam. The network synchronously distributes beam position X and Y coordinates every 100 µs with a propagation delay of around 50 µs.

The design of the CC network with a highly redundant topology broadcasting by storing and forwarding makes it easy to add new nodes to the network, both as contributors and as passive listeners. Other sources contributing to the network are a handful of X-ray BPMs and power pick-ups from the RF cavities. The FA archiver acts as a passive listener and makes the FA data freely available, see Fig. 1.

The archiver stores data at the full data rate, referred to here as the "FA" rate, and at two decimated rates, "D" data decimated by a factor of 128, and "DD" "double decimated" data decimated by a factor of 16834.

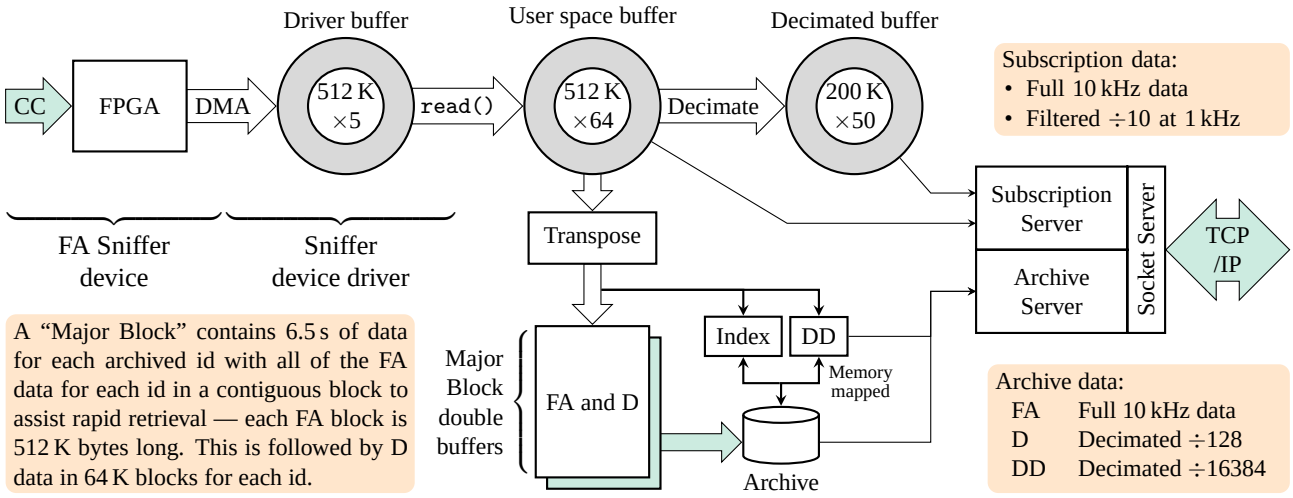

Figure 2: Architecture of FA archiver showing device, driver and archiver process writing to disk and serving clients.

ARCHIVER ARCHITECTURE

The FA archiver consists of the following components:

FA Sniffer. This is an implementation of the Communication Controller on a Virtex-5 FPGA PCI Express (PCIe) board. The sniffer captures communication frames and transfers them by DMA to memory.

Sniffer device driver. The device driver communicates with the sniffer card and makes the data stream available as a Linux device node, `/dev/fa_sniffer0`.

Archiver process. The archiver process reads frames from the device driver, saves them to disk after processing to optimise subsequent reading, and provides a socket server for client access to both the live data stream and a ÷10 decimated stream, see Fig. 2.

Client tools. A variety of client tools are able to connect directly to the archiver server, including a data visualisation tool (`fa-viewer`) for viewing the live data, a general purpose command line tool (`fa-capture`) for reading from the archive, and a Matlab script (`fa_zoomer`) for exploring the archive.

FA Sniffer

The FA Sniffer is so called because it passively "sniffs" FA data from the communication controller network. The FPGA design integrates the Diamond Communication Controller [3] into a bus master PCI Express architecture using the commercially available Xilinx Virtex-5 FPGA ML555 development platform [5]. The design, see Fig. 3, consists of target logic, DMA initiator logic, status/control registers and the Virtex-5 endpoint core for PCI Express. Target logic is responsible for capturing single double-word memory write and memory read PCIe Transaction Layer Packets (TLPs) for control and status register access. The DMA initiator logic generates memory write TLPs to transfer 2 K byte frame data from the communication

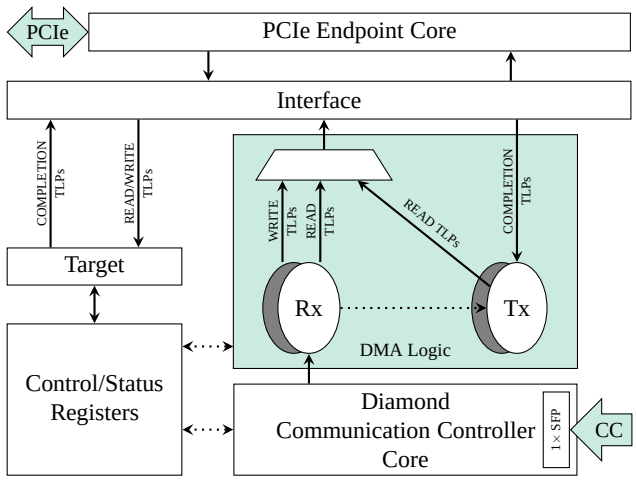

Figure 3: Architecture of the FA sniffer FPGA.

controller core to the host's system memory. The complete design occupies 30 % of bit slices and 20 % of block RAMs available on the FPGA.

The communication controller core captures a complete frame from the CC network on every communication controller cycle, with a new cycle starting every 100 µs. The frame transferred to memory by the sniffer is 2048 bytes consisting of 256 samples, each a pair of four-byte numbers corresponding to measured X and Y positions for FA ids 1–255 together with a 32-bit timestamp counter repeated in position 0 as "id 0".

The sniffer card maintains a queue of up to two DMA targets, address and frame count, one being written to, the next to be loaded when the first target is filled, at which point an interrupt is raised to the host machine. At this point the device driver is responsible for setting up a fresh buffered DMA target, otherwise the sniffer will halt.

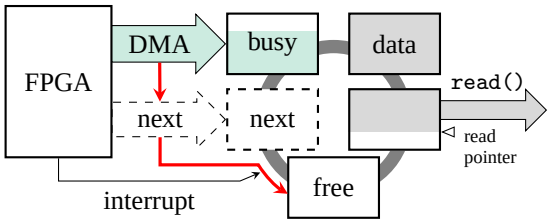

Figure 4: Architecture of the sniffer device driver.

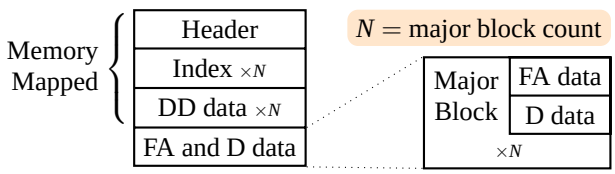
Sniffer Device Driver

The sniffer device driver, see Fig. 4, maintains a circular pool of buffers for the FA sniffer to write to, by default five buffers of 512 K bytes each, enough storage for 40 ms of data per buffer. When the sniffer is running, two buffers are allocated to the sniffer and the remaining buffers contain data for the user space program to read or are free for the next DMA transfer. On each interrupt the pool cycles round by one buffer unless there is no free buffer, in which case the sniffer is allowed to halt.

Data capture is also interrupted during CC network synchronisation or if a communcation error occurs. Any interruption is signalled by the driver as "end of file" and recorded by the archiver as a gap in the archive.

The Archive on Disk



Per major block, repeated for each archived FA id:

FA data:	x, y	$\times 65536$
D/DD data:	$\overline{x}, \overline{y}, \lfloor x \rfloor, \lfloor y \rfloor, \lceil x \rceil, \lceil y \rceil, \sigma_x, \sigma_y$	$\times 512/\times 4$

Figure 5: Layout of archive store on disk.

The FA data stream from the sniffer is uniform, with constant sized updates received at an unchanging interval. The only variation in this structure is the occasional presence of gaps in the data stream where synchronisation of the communication network has been performed.

This uniform data format allows the archive to be stored as a simple fixed-format file, see Fig. 5. For performance it is better for the archive to be stored directly on the underlying block device, as filesystem block management otherwise adds a significant overhead for very large files.

Early experiments with the archive revealed that the optimum block size for transfers to and from disk is around 512 K bytes and so the layout of the archive on disk is optimised for reading by placing the data for a single FA identifier into blocks of 512 K bytes or 65536 samples each, or around 6½ seconds of data.

At the same time, to help with generating an overview of the entire archive, data is binned into 128 and 16384 sample bins in which the mean, minimum, maximum, and standard deviation values are computed. The decimated $\div 128$ data is stored together with the FA data as a "major block", the $\div 16384$ data is stored separately in a memory mapped area.

These major blocks are indexed by timestamps recorded in the index which is searched by binary search when an archive read request is processed.

A fixed size (4096 byte) header defines all of the operating parameters of the archiver (block sizes, decimation factors, etc.) together with the list of FA ids archived, and also records the current active block.

Data Processing

Two major blocks are maintained in memory, one being prepared as frames are received from the FA sniffer, the other being written to disk. FA sniffer frames are transposed (in blocks of 256 frames) into the major block layout.

To ensure that reads from the archive do not delay writes there is a limit on the number of reads that can be requested simultaneously, and there is also an interlock to prevent a read being initiated while writing to disk is in progress.

Filtered Decimation

For some applications of the archiver live FA data feed at the full 10 kHz data rate is too much; for example most of the environmental disturbances on the beam have their main effects in the bottom few hundred Hertz. In particular, the full orbit Spectrum Analyser (described below) only covers frequencies up to 320 Hz.

Thus the archiver decimates the entire FA data stream by a factor of 10 using a compensated CIC filter [6, 7], and this data stream is available as an alternative data source for subscribers. The spectrum of the decimated data is flat to ± 0.25 dB with better than 100 dB alias rejection up to 350 Hz.

APPLICATIONS

Archive Retrieval. A command line tool `fa-capture` provides full access from the command line to the dataset stored on the FA archiver, allowing any part of the archive to be retrieved and saved in either raw or Matlab format. Start and end times or start and sample count can be specified in a variety of formats.

Archive Exploration in Matlab. A Matlab tool called the `fa_zoomer` allows the archive to be explored interactively. An interactive window displays the current selection and allows any part of the selection to be zoomed and retrieved in more detail from the archive. The initial window uses "double decimated" data to show an overview of either the last 24 hours or the entire available archive (4½ days), and the decimation is reduced as zooming is refined.

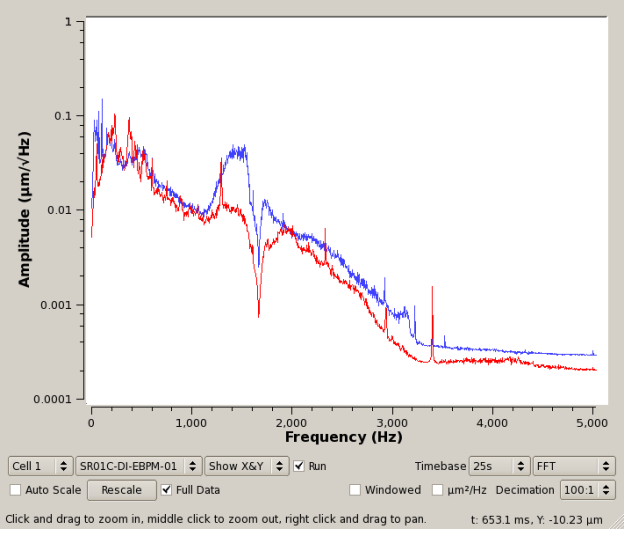


Figure 6: FA viewer application showing beam motion power spectrum of selected BPM over the last 25 seconds.

Live Visualisation. Figure 6 shows the `fa-viewer` tool, a Python Qt application which visualises the motion of the beam at any location. The user can choose to observe any available FA identifier which is then displayed as either a live history display (for up to 60 seconds of history) or a variety of spectral displays: FFT on log y or log xy scales, or an integrated power spectrum. Graphing is done using PyQwt [8] which is both fast and flexible, making it straightforward to develop a large variety of visualisations.

Audio Playback. As the beam disturbance frequencies as processed by the FA archiver are comfortably audible it was natural to try playing back the beam position as sounds. This turns out to work very well, and is occasionally quite instructive. Both topup and injection have very distinctive sounds, but what is more interesting is the variety of very odd sounds that appear to be superimposed on the beam by disturbances in the RF system.

Long Term Spectral Analysis. A dedicated server subscribes to the 1 kHz complete live orbit data and computes averaged power spectra in 1 Hz bins averaged every five minutes covering the spectral range from 1 to 320 Hz. Complete waveforms for all frequencies and all 174 BPMs are generated as EPICS PVs, both as power density spectra for each BPM and orbit disturbance for each frequency, and a limited selection of these waveforms is archived in the long term EPICS archive.

This allows a detailed examination of changes in the spectral behaviour of the machine over extended periods; it is easy to look at the spectrum for a week's operation of the machine and identify long term changes in disturbance.

Other Users. The sources for the archiver and driver can be downloaded from the Diamond web site [9], and the FA archiver has been used at Soleil since May 2011.

CONCLUSIONS

The motivation for the FA Archiver has been to gain access to longer periods of synchronously recorded position data from all channels (the whole orbit) at FA data rate. Previously our setup had only been able to capture ten seconds of this data using buffers inside the fast feedback processors. Having access to records of up to several days of this data facilitates the following:

- Identification and detailed investigation of any orbit events that happened in the recent past. To this end, the maximum/minimum/standard deviation calculations on the ÷16384 decimated data are invaluable.
- Correlation of orbit events with other measurements by adding X-ray BPMs and RF cavity voltage readings to the FA network [10].
- Modal analysis of orbit motion over longer periods. This is useful for the optimisation of the fast orbit feedback and for the identification of BPMs or correctors with subtle malfunctions.

Together with the long term spectral analysis all these methods allow monitoring and improvement of the reliability and performance of the fast orbit feedback system and ultimately the beam stability.

FREE AND OPEN SOURCE SOFTWARE AT CERN: INTEGRATION OF DRIVERS IN THE LINUX KERNEL

Juan David González Cobas, Samuel Iglesias Gonsálvez,
Julian Howard Lewis, Javier Serrano, Manohar Vanga, CERN, Geneva, Switzerland
Emilio G. Cota, Columbia University, NY (formerly at CERN), U.S.A.
Alessandro Rubini, Federico Vaga, University of Pavia, Italy

Abstract

Most device drivers written for accelerator control systems suffer from a severe lack of portability due to the *ad hoc* nature of the code, often embodied with intimate knowledge of the particular machine it is deployed in. In this paper we challenge this practice by arguing for the opposite approach: development *in the open*, which in our case translates into the integration of our code within the Linux kernel. We make our case by describing the upstream merge effort of the `tsi148` driver, a critical (and complex) component of the control system. The encouraging results from this effort have then led us to follow the same approach with two more ambitious projects, currently in the works: Linux support for the upcoming FMC boards [1, 2] and a new I/O subsystem.

TSI148 DRIVER INTEGRATION IN THE KERNEL

Rationale

The VME bus is a central component of the Controls System at CERN. We rely on 1140 FECs (Front End Computers), 710 of which are VME crates with SBC (Single Board Computers). A process of renovation is in course, involving the migration from

- CES RIO2/RIO3 SBCs with PowerPC CPUs runing LynxOS (around 605 crates by August 2011), to
- MEN-A20 SBCs with Intel CPUs running real-time Linux (around 105 by August 2011).

The MEN-A20 SBC incorporates a TSI148 VME-to-PCI-X bridge chip. To support the functionalities required, and for maximum backward compatibility with the legacy CES API, a device driver was developed by CERN's BE/CO group in spring 2009. Clearly, this is a critical component of the controls system: every VME device relies on the provided programming interface to the VME bus. The CERN-developed driver offers, therefore, a CES compatibility API to facilitate the transition during the renovation process and a new API more in line with what is common practice in the Linux kernel.

Work on the inclusion of the driver in the Linux kernel started in late 2010 and is currently nearing completion. This effort, along with its motivations and consequences, is documented in the remainder of this Section.

Benefits

There are many reasons that make the insertion of code in the mainline kernel a desirable target.

- Smoother maintenance in the (frequent) event of kernel API changes. [3]
- Very strict process of peer review of the code by knowledgeable and specialised maintainers.
- Widespread distribution of the code base, which can then be enhanced and get contributions by researchers working on similar problems.
- Input from the topmost experts in the field.
- Best practice and use of bleeding-edge tools selected by experienced programmers, *e.g.* git [4], sparse [5] and Coccinelle [6].
- Avoidance of suboptimal, *ad hoc* solutions in favour of the best ones from the technical point of view.
- Contributing back in return to the many benefits the FOSS community gives us.
- Being able to drive a critical hardware component with software in the vanilla kernel, with no local, idiosyncratic modifications.

It is worth noting that the importance of the last point only became apparent once the merge effort was well underway. In our control system, renovated FECs are *diskless* machines that boot a custom *rt* kernel [11], carefully configured and patched to match local needs. The upstream merge of the *tsi148* driver allows us to deploy off-the-shelf kernels packaged by linux distributions, thus largely reducing the kernel maintenance burden.

Caveats

Some of the caveats herewith enumerated will be elaborated further in the description of the integration process, but we summarize here the most important ones.

- It is hard, frustrating at times. One should be ready for the peculiar culture of the Linux Kernel Mailing List.
- Design, APIs and coding practice that are customary or simply acceptable locally must be adapted or rebuilt to comply with the strict standards imposed by the Linux kernel developers. The morale is that the end product will most certainly be different to (and better than) the original.

- One must be prepared to compromise. The most practical, short-lived solution might not be the technically perfect one kernel maintainers aim at.
- Maintainers are occasionally hard to deal with.
- The review process may be long; several iterations are usually necessary when merging significant changes.
- Small, incremental changes are more likely to be accepted than big, hard-to-digest ones. The rule of thumb is to "Separate *logical changes* into a single patch file." [7]
- Having a good history of prior contributions gives more respectability and ease of acceptance: the system is based on meritocracy.

The Process

Submission of source code for acceptance in the kernel is done by means of patches subject to a process of peer review before acceptance. The reviews are sometimes daunting, and much editing and re-submissions can result. This process of strict code review is another good practice our team adopted for its development process, a practice that has proved very beneficial.

Our fist attempt of integration of the `tsi148` driver was initiated in late 2010 by one of the authors (Emilio G. Cota).

By that time, a `tsi148` driver had recently been admitted in the `staging` [8] area of the kernel, its maintainer being Martyn Welch. This driver brought a tentative support for the VME bus that covered two VME-to-PCI bridges:

- The Tundra Universe chips, with work derived from VMELinux by John Huggins and Michael Wyrick.
- The Tundra TSI148 chip, inspired in the above.

The set of patches initially submitted provided improvements in several areas, esp. in orthodox implementation of the Linux bus/device model concepts. Acceptance by the maintainer was partial, and modifications related to the device model implementation remained controversial and not accepted.

In 2011, another of this paper's authors, Manohar Vanga, took over the submission effort. Some bugs in the staging driver were fixed, and the bulk of modifications concerning the device model were partially acknowledged. This led to several review iterations; at the time of this writing, the definitive submission and acceptance of the last set of patches concerning the core device model is in its final stage, and will be applied by the corresponding kernel maintainer in the next merge window.

Although the whole set of patches concerning bug fixes and device model of the `tsi148` VME bridge driver is finally accepted, there is still a long way before reaching the final desideratum, *i.e.,* driving our `tsi148` devices with stock software from the mainline kernel tree.

- The outstanding goal should be now getting the VME driver out of the `./staging/` tree. For this to happen, the overall quality of the code must improve significantly. [8]
- There are API incompatibilities with the driver currently used at CERN; this implies that a transient kernel module must adapt interfaces if driver code has to remain untouched.

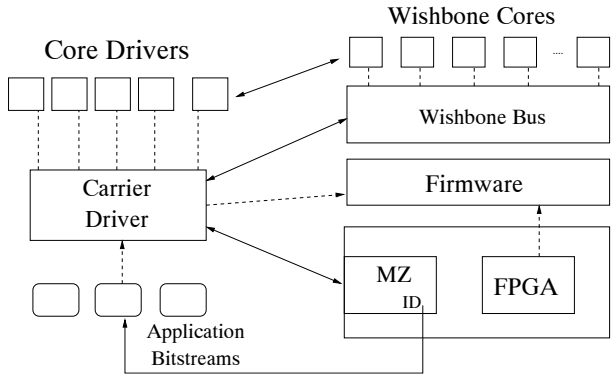

Figure 1: Wishbone bus driver architecture.

DRIVERS FOR THE FMC FAMILY

A family of carrier/mezzanine modules compliant with the ANSI VITA 57 FMC standard [2] is described in [1]. This kit of boards, developed by the BE/CO Hardware and Timing section at CERN is another case in point for the benefits of a Linux kernel-centric approach. The hardware concept and architecture are described in the aforementioned paper [1]; the key point is that the mezzanine provides basic circuitry, and the core of the application logic is implemented in the FPGA of the carrier board. The cores inside this FPGA are interconnected via a Wishbone [9] bus.

From the software point of view, a particular instance of this family behaves like a PCI-to-Wishbone or VME-to-Wishbone bridge. The Wishbone bus interconnects a set of cores providing functionalities that are either common to the whole family of mezzanines, or specific to the application board actually plugged in the FMC slot. We show in figure 2 the block diagram of the FMC 100MS 14 bit ADC, a typical example of an FPGA application comprising cores for, among others

- Basic I^2C interfacing to the mezzanine board.
- Wishbone mastering.
- DMA access to DDR3 memory in the carrier board.
- Mezzanine-specific control logic (*e.g.* ADC programming/setup).
- Interrupt control.

The consequence of this modular design of the application FPGA is that the device driver architecture reflects the structure of this set of cores (see figure 1). The driver for the carrier board performs essentially the following basic functions

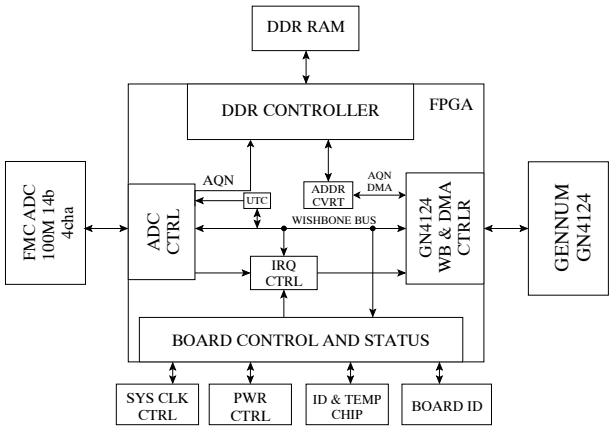

Figure 2: Block diagram of the FMC slow ADC application.

- Identify the carrier board and initialize it.
- Perform a basic identification of the mezzanine(s) installed in the FMC slot(s), and their configured applications.
- Load the application firmware into the carrier FPGA.
- Register a Wishbone bus with the kernel.
- Enumerate the cores in that firmware (to wit, the inner blocks in figure 2).
- Register the devices those cores implement and install the drivers associated to them.

The process is directly implied by how the Linux kernel device model is implemented as described in [10] or in chapter 14 of [12]. Conceptually, it amounts to the provision of a bus driver for Wishbone, plus a PCI-to-Wishbone bridge driver for the carrier board.

Modularity and reusability of cores and drivers are not the only rationale behind this design. Actually, the drivers for the FMC family are the second family of drivers planned to be integrated in the mainline kernel. Given that boards and their applications will be manufactured by external companies and available to the general public and not only to CERN, having their drivers and the Wishbone bus integrated upstream is the logical step to take. The Wishbone enumeration is made possible through the definition of an FPGA configuration space developed in [13], that will be the basis for the integration of all drivers of this family in the kernel.

DATA ACQUISITION DRIVERS: KERNEL FRAMEWORKS

The third family of drivers considered for integration upstream is less homogeneous than the FMC family. The BE/CO group supports a standard kit of hardware modules for data acquisition and general analog and digital I/O, some of whose characteristics can be compared in table 1. Linux drivers for these modules were developed in different stages of the renovation process, leading from legacy LynxOS drivers to Linux; therefore, there is a varying degree of adherence to standard practice among the Linux kernel developers, because of the LynxOS coding practice formerly prevalent.

Two needs arise here clearly, in the light of our intention of having our whole set of drivers incorporated upstream:

- Proceed to a more homogeneous, Linux-only code base.
- Provide a general framework for data acquisition and control devices.

Concerning the latter, there are two candidate Linux kernel frameworks: Comedi [14] and IIO [15]. Both are in `./staging/`, and careful analyses show that they prove insufficient for our needs. Therefore, the development of a more complete and acceptable framework for industrial data acquisition and analog/digital I/O becomes part of our effort of integrating our supported device drivers in the Linux kernel. This effort is motivated both by the requirements of legacy drivers and by the requirements that the FMC family will impose in driver design, esp. in the area of operating system interface.

Such a framework, codenamed `zio`, intends to cover all the relevant aspects of data acquisition devices, far beyond the existing frameworks, such as

- Digital and analog input and output.
- One-shot and streaming (buffered) data acquisition or waveform play.
- Resolution.
- Sampling rate.
- Buffer management and timing for streaming conversion.
- Support for DMA.
- Calibration, offset and gain.
- Bit grouping in digital I/O.
- Timestamping.
- Triggering of acquisition/output.
- Clean design conforming to Linux kernel practice.

At the time of this writing, prototype versions of the framework software are under development phase [16].

FORTHCOMING STRATEGY

The strategy for inclusion of our driver kit in the kernel relies now on a handful of key milestones

1. Initiate upstream integration of the Wishbone bus driver.
2. Make the in-tree and our local API for `tsi148` converge.
3. Get the VME driver out of `staging`.
4. Develop the `zio` framework as a competitive alternative to Comedi and IIO.
5. Initiate integration of the `sis33xx` drivers into the `zio` framework and the mainstream kernel.

Points 1, 2 and 4 are short-term priorities that should come out as quite straightforward.

Table 1: BE/CO Data Acquisition Modules

Module	Type	Channels	Resolution	Max. Speed	Bus
VMOD-12E8/16	Analog input	8/16ch	12b	15us/sample	VME/PCI
VD80	Analog input	16ch	16b	200kS/s	VME
SIS3300	Analog input	8ch	12/14b	100MS/s	VME
SIS3302	Analog input	8ch	16b	100MS/s	VME
SIS3320	Analog input	8ch	12b	250MS/s	VME
"Fast" FMC ADC	Analog input	4ch	14b	100Ms/s	VME/PCIe (Wishbone)
"Slow" FMC ADC	Analog input	8ch	16b	100kS/s	VME/PCIe (Wishbone)
CVORB V4	Analog output	16ch	16b	5us/sample	VME
VMOD-12A2/4	Analog output	2ch	12b	10us/sample	VME/PCI
CVORG	Analog output	2ch	14b	100 MS/s	VME
VMOD-TTL	Digital I/O	20ch	1b	n/a	VME/PCI
CVORA	Digital I/O	32ch	1–32b	100Mhz	VME

LESSONS LEARNED

The main lessons we got from this process, that we will have to take into account in the course of the forthcoming integrations, are

- Being there first gives competitive advantage. However technically sound a proposal might be, it is better to get it accepted when it is new, and not contending with other more entrenched positions.
- Getting input and enhancements from Linux peer developers is tremendously beneficial to improve the quality of the code, of the design and of the working environment (tools, policies and style being naturally given by what the Linux kernel developers have already tried and tested over many years).
- There is a change of thinking when it comes to development after a while in the kernel community. The mindset changes from thinking of the short term goals to thinking of solutions that can scale to a larger set of problems. One starts to think of more generic solutions rather than quickly hacking together the fastest solution to the problem at hand.

CONCLUSIONS

Contrary to what conventional assumptions dictate, low-level software and development need not be intimately linked to, nor closely shaped after, the peculiarities of a single control system. Developing with a wider scope in mind is possible, as our experience proves. But not only that: it results in technically superior, more scalable and maintainable solutions.

Last, but not least, peer review, advice and a bleeding-edge set of tools created by top level programmers contribute to the efficiency and quality of the development process; a priceless gift we also owe to the community of Linux kernel developers.

THE CASE FOR SOFT-CPUS IN ACCELERATOR CONTROL SYSTEMS

W. W. Terpstra, GSI Helmholtz Centre for Heavy Ion Research GmbH, Darmstadt, Germany

Abstract

The steady improvements in Field Programmable Gate Array (FPGA) performance, size, and cost have driven their ever increasing use in industry, science, and IT. As FPGA sizes continue to increase, more and more devices and logic move from dedicated chips to FPGAs. For simple hardware components, the savings in board area and chip count are compelling. For logic involving dynamic memory and complicated control flow, the trade-off is not as clear.

Traditionally, this has been the domain of CPUs and software programming languages. In hardware designs already including an FPGA, it is tempting to remove the CPU and implement all logic in the FPGA. However, if that logic is then be implemented in the more constraining hardware description languages, it cannot be as easily debugged or traced, and typically requires significant FPGA area. For performance-critical tasks, this trade-off can make sense. However, for the myriad slower and dynamic tasks, software programming languages remain the better choice.

One great benefit of a CPU is that it can perform many tasks. Thus, by including a small "Soft-CPU" or softcore inside the FPGA, many low performance tasks can be aggregated into a single component. These tasks may then reuse existing software libraries and debugging techniques, while retaining ready access to the FPGA's internals.

This paper discusses requirements for using Soft-CPUs in this niche, especially for the FAIR project[1]. Several open-source alternatives will be compared and recommendations made for the best way to leverage a hybrid design.

BACKGROUND

FPGA chips allow developers to implement custom circuitry. A developer designs his desired circuit in a Hardware Description Language (HDL), and a compiler translates this into the underlying gates and wires required by the design. The target FPGA chip can then be programmed with the resulting bitstream. A given FPGA has a limited number of wires and gates and when a design is loaded, it consumes some of the *area* on the chip.

Developers organize their HDL project into components. A component corresponds roughly to a chip design, with internal logic and input/output pins. For example, a component might implement a memory chip with address and data pins. Each component can be instantiated multiple times, like placing several chips with the same specification. These instances can in turn be wired together to produce a larger component, akin to wiring several chips together on a card. The resulting amalgam component will have it's own input/output pins. This hierarchical composition results in a tree of nested component instances.

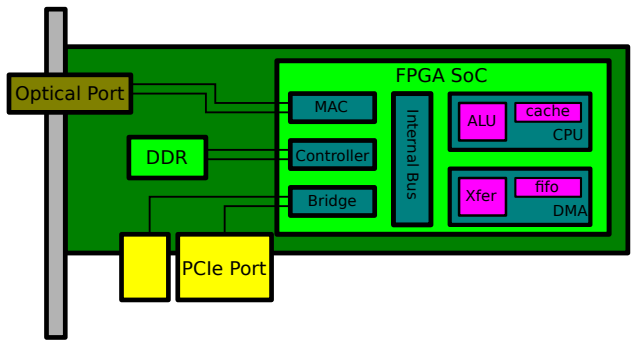

Figure 1: A SoC including a Soft-CPU.

Typically, the top-most component or root has its input/output pins mapped to the physical pins on the FPGA. The FPGA's pins are then physically wired to external chips mounted on the board and the connectors required by the type of device manufactured. For example, in the FAIR project, our control devices have FPGA pins connected to a DDR memory chip, an optical network transceiver, and a PCI express connector.

Within the FPGA, to ease interconnection of several components, developers often use a bus protocol. Just like the PCI express bus of a PC, this allows developers to plug together multiple components without needing to modify their designs. The resulting FPGA is called a System on Chip (SoC), because it is effectively an entire computer in a single chip. The key advantage of a bus is that it allows multiple logical connections. Where a simple wire between components only connects those two components, a bus allows n master components to control m slave components, resulting in nm logical connections. Figures 1 and 2 illustrate two SoC designs.

Within a SoC system, one can include a CPU. This CPU is typically a bus master which controls the slave devices on the SoC bus. As the CPU is not a physically distinct chip, and is implemented in HDL within the design, it is called a Soft-CPU or SoftCore.

This paper will cover: when it makes sense to include a Soft-CPU, what they require from the memory subsystem, an analysis of the best available Soft-CPUs, and our recommendations.

[1] A new international accelerator facility for antiproton and ion beams.

WHEN TO USE A SOFT-CPU

Soft-CPUs are often, but not always, a good thing to include in a SoC design. On a modern FPGA the area they consume is relatively minor; an LM32 Soft-CPU uses 2-4% of a EP2AGX125, depending on selected features. However, they typically impose a hefty memory cost, discussed later. Furthermore, they introduce another master running on the bus, which may not be desirable due to arbitration.

Comparison to Custom HDL

Any functionality one can implement in software, one can also implement directly in HDL; it's just more work. For example, `memcpy(dst, src, len)` run on a Soft-CPU can move data from one slave device to another. In HDL one could implement a DMA controller to perform the transfer. Broadly speaking, the advantage of HDL is raw speed and software is ease of development. More specifically, the strengths of a Soft-CPU are:

- ✓ Soft-CPUs can run traditional C/Fortran/Java code. They can re-use existing libraries and applications.
- ✓ A single Soft-CPU can implement many features with one component; one processor can run multiple programs. In HDL each feature requires more circuitry.
- ✓ Execution order is easier in software. In HDL a state machine tracks the current operation. In software this is implicit in the program's instruction pointer.
- ✓ Dynamic resource management is easier in software. Software systems have a stack and a heap. Hardware only has static (in the C/C++ sense) variables.
- ✓ Software debuggers can single-step programs and inspect/modify every variable. Hardware signal tapping captures execution after matching crude triggers and can only inspect new variables with a recompile.
- ✗ Software is *much* slower. Hardware is always parallel, executing many things at once. However, Soft-CPUs can leverage this parallelism with custom instructions.
- ✗ Soft-CPUs require a memory subsystem.
- ✗ Soft-CPUs require an additional developer toolchain.

It is important to understand that Soft-CPUs and custom HDL are not mutually exclusive; the above pro/con list presents a false dichotomy. One of the key strengths of a Soft-CPU compared to an external CPU is that it is directly connected to customizable hardware. The question is not whether or not to use custom HDL. When using an FPGA that is a given. The question is if any of the required functionality could benefit from a Soft-CPU. If a Soft-CPU is useful, then a hybrid design should be used.

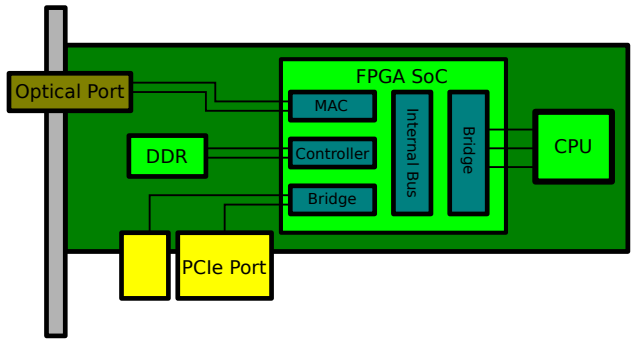

Figure 2: A SoC connected to an external CPU.

Comparison to an External CPU

If a CPU is required, instead of putting it inside the FPGA, one can attach it as an external chip. See, for example, Figure 2. All of the same trade-offs for custom HDL that apply to a Soft-CPU apply to an external CPU. However, Soft- and external CPUs have their own trade-offs.

The main advantage of an external CPU is performance. Soft-CPUs are as simple as possible to minimize the FPGA area required. Generally, their designs mimic RISC architectures from the mid 1980s. Modern superscalar CPUs are significantly more complex and much faster clock for clock. Furthermore, the fairly decent EP2AGX125 FPGA run an LM32 Soft-Core at 200MHz compared to the typical 3GHz clock rates of a modern CPU. Thus, an external CPU will dispatch over 30 times as many instructions as a Soft-CPU. Nevertheless, for a particular problem, custom hardware can be faster still and a Soft-CPU will be directly connected to that hardware.

Since the main advantage of an external CPU is raw performance, it will be run at a faster clock rate than the FPGA. Otherwise, one might as well use a Soft-CPU and save money. In this configuration, the trade-offs are:

- ✓ The Soft-CPU solution costs one less chip.
- ✗ An external CPU issues instructions $> 30\times$ faster.
- ✓ The Soft-CPU can use custom instructions.
- ✗ The external CPU runs a standard OS and toolchain.
- ✓ A Soft-CPU operates synchronously with the FPGA.
  - It is directly connected to the internal bus. There is no bridge, no variable latency.
  - It is in the same clock domain as the devices.

When money is no object, the main advantage of a Soft-CPU is deterministic execution speed; the Soft-CPU executes instructions at a known rate. In a hybrid design, it is possible for a custom HDL component to dispatch work to the Soft-CPU and be guaranteed to receive the result after a fixed number of cycles. Similarly, when the Soft-CPU pushes data to a device known to use 5 cycles, it doesn't

need to synchronize or check for completion. It just burns 4 cycles before reading the result. This tight integration makes it possible for a Soft-CPU to fill the not-easily-done-in-HDL gaps of a mostly custom HDL solution.

MEMORY ARCHITECTURE

The real cost of adding a Soft-CPU to a design is not FPGA area, but memory. The more complex the logic that the Soft-CPU executes, the larger the executable it must run. While it is true that a single Soft-CPU can implement many features in one component, the hidden cost is this increasing memory foot print.

Unfortunately, a larger memory footprint comes with decreased determinism. As the memory requirements grow, the memory must move further from the CPU. As the memory moves further from the CPU, the memory hierarchy deepens. Caches make an otherwise straight-forward program take an unpredictable amount of time. This weakens the greatest strength of a Soft-CPU. Unfortunately, if the problem requires more memory, this is unavoidable.

Certainly, one could imagine running a Soft-CPU with an SRAM chip for memory and no cache. An SRAM chip will take at least 4 cycles to provide each instruction to the Soft-CPU. FPGA internal cache memory could provide it in 1 cycle. If one runs the Soft-CPU with no cache or prefetch, it is exactly 4 times slower. With cache, it is at worst 4 times slower and at best full speed. Omitting the cache doesn't improve the deadline behaviour of the Soft-CPU; it just makes it (much) slower on average. Thus, when the Soft-CPU's memory footprint exceeds the memory available at one level in the memory hierarchy, that level becomes cache for the next, larger level.

The important message is that one size does not fit all problems. A good hybrid design uses the smallest amount of memory possible, and thus the least levels of cache.

Another factor which can impact determinism is the bus itself. If the Soft-CPU must share access to the memory with other devices, it may need to wait for those devices to finish their access. We strongly recommend that a hybrid design dedicate a memory port exclusively to the Soft-CPU's instruction bus. The data bus is much less frequently used (only on load/store instructions) and can share access with other devices as long as access is carefully scheduled.

MMU: Yes or No

A common feature found on modern CPUs is the Memory Management Unit (MMU). This introduces a level of indirect addressing which is needed by modern operating systems to implement inter-process memory protection. Some Soft-CPUs always include an MMU, some don't, and for some it is configurable. An MMU implementation is typically tightly integrated with the CPU cache system. Usually a Translation Lookaside Buffer (TLB) maps virtual addresses to physical addresses. When the TLB cannot find an entry needed, it must be refilled, introducing an additional source of non-deterministic delay. The trade-offs:

✓ Standard OS supported, meaning more compatability.

✓ Supports efficiently garbage collected languages.

✓ Fault isolation and memory error detection.

✗ TLB misses add non-deterministic execution delay.

✗ Memory required for page table management.

The main advantages of an MMU only apply to large software systems. Both a standard OS and a garbage collected runtime entail significant memory consumption. Furthermore, both of these scenarios make steep concessions in pause times. If one uses a Soft-CPU with an MMU, one has almost given up the main advantage of a Soft-CPU compared to an external CPU. Both the MMU and attendant cache system introduce execution pauses, as does a standard OS and/or garbage collected runtime. Aside from cost, little remains to recommend a Soft-CPU + MMU.

SOFT-CPU SHOWDOWN

To choose a Soft-CPU for use in the FAIR project, we made a list of requirements that candidate Soft-CPUs should fulfill. In order of decreasing importance:

- Open source HDL: port to many FPGA manufacturers, add required features, trace and debug problems.
- Toolchain support. No compiler, no point.
- Configurable memory subsystem.
- Mature and well documented.
- Size and Speed.
- Debugger support.

We only considered CPUs which met at least the first two requirements. The surviving candidates we investigated are summarized in Table 1.

RECOMMENDATIONS

Inspecting Table 1 makes pretty clear that the only reasonable options are the LEON3, LM32, and OpenRISC processors. All three processors are RISC and have similar area and performance. The other open source offerings are either incomplete, poorly documented, or too large for an FPGA (S1). Of the runner ups, the ZPU is probably the most interesting due to its smaller foot-print. However, it is significantly slower clock-for-clock than the three main candidates which issue most instructions in one cycle.

For a hybrid design, the LM32 is the clear winner. It has very clearly specified instruction timings and is designed to work without an MMU. It's memory subsystem is very configurable; the instruction bus can use either internal FPGA memory, an 1/2-way instruction cache, or direct bus access. This makes it easily accommodate designs

Table 1: Feature Breakdown of Available Open Source CPUs as Synthesized on an Arria2

CPU	Memory Subsystem	Documentation	Area	Speed	Debugger
LM32	optional(I+D cache)	Very Good [4, 5]	2000	200MHz	yes
LEON3	optional(I+D cache + MMU)	Excellent [1, 2, 3]	3000	150MHz	yes
OpenRISC	I+D cache + MMU	Adequate [6, 5]	3300	150MHz	yes
ZPU	none	Poor	1000	200MHz	no
ZET	none	Poor	3000	60MHz	no
S1	I+D cache + MMU	Sparc [3]	45000	-	-
CPU86	none	Non-existant	3800	100MHz	no
Plasma	none	Non-existant	-	-	no
Navre	none	Non-existant	1000	200MHz	no
pavr	none	Poor	2400	120MHz	no
aemb	none	Non-existant	1100	140MHz	no
openfire	none	Non-existant	1300	160MHz	no
pacoblaze	none	Poor	650	200MHz	no
yasep	none	Poor	-	-	no
dspuva16	none	Non-existant	340	250MHz	no

with different memory requirements. Finally, it is architecturally much simpler than a sparc. A hand-crafted operating system can easily fit in under 1kB of memory, or it can just be used directly as a micro-controller.

Both the LEON3 and the OpenRISC are well suited to running a full Linux operating system. However, the only thing which recommends them over using a much faster external CPU is cost. When running linux, the operating system, MMU, and cache all conspire to eliminate the benefit of a direct connection to the FPGA bus. An SoC bridged over PCIe to an external CPU would likely meet tighter real-time deadlines.

In conclusion, given the low area cost of a Soft-CPU and the many potential benefits, it seems wise to plan on including a Soft-CPU in most SoC designs. As long as the executable code can fit in FPGA memory, the design impact is low. At the GSI, we have now used the LM32 in several designs and found it very useful not only in offloading low-priority tasks from custom HDL, but also in debugging attached hardware devices.

APPENDIX: LM32 FEATURES

A quick overview of our recommended Soft-CPU:

- 6-stage pipelined RISC architecture
- 32-bit data path and instructions
- 32 general-purpose registers and interrupts
- Optional instruction and data cache
- Wishbone [5] memory interfaces (instruction+data)
- Debug unit with breakpoints+watchpoints
- Can both be debugged over JTAG or internally

THE FAIR TIMING MASTER: A DISCUSSION OF PERFORMANCE REQUIREMENTS AND ARCHITICTURES FOR A HIGH-PRECISION TIMING SYSTEM

M. Kreider, GSI Helmholtz Centre for Heavy Ion Research, Darmstadt, Germany
Hochschule Darmstadt, Darmstadt, Germany
Glyndŵr University, Wrexham, UK

Abstract

Production chains in a particle accelerator are complex structures with many interdependencies and multiple paths to consider. This ranges from system initialisation and synchronisation of numerous machines to interlock handling and appropriate contingency measures like beam dump scenarios. The FAIR facility will employ WhiteRabbit, a time based system which delivers an instruction and a corresponding execution time to a machine. In order to meet the deadlines in any given production chain, instructions need to be sent out ahead of time. For this purpose, code execution and message delivery times need to be known in advance. The FAIR Timing Master needs to be reliably capable of satisfying these timing requirements as well as being fault tolerant. Event sequences of recorded production chains indicate that low reaction times to internal and external events and fast, parallel execution are required. This suggests a slim architecture, especially devised for this purpose. Using the thread model of an OS or other high level programs on a generic CPU would be counterproductive when trying to achieve deterministic processing times. This paper deals with the analysis of said requirements as well as a comparison of known processor and virtual machine architectures and the possibilities of parallelisation in programmable hardware. In addition, existing proposals at GSI will be checked against these findings. The final goal will be to determine the best instruction set for modeling any given production chain and devising a suitable architecture to execute these models.

INTRODUCTION

In an accelerator, machines need to execute their actions at predefined moment, as part of an overall master plan. Magnets need to be run through current ramps, kicker assemblies need to be triggered at the right moment for beam transfer between accelerator rings, and similar matters. Most accelerators use some form of middle ware to convert physical scenarios into the necessary machine commands, like the production of a beam with a given energy and isotope. In theory, it would be possible to compute all necessary instructions and their times of execution in advance and then just go with this program. For such a scenario one would only need a very simple timing control, executing this precomputed value table.

However, more flexibility is needed in a real world scenario, since circumstances can change. From simply waiting for a machine to report ready status over changing demands from operators up to occurring interlocks and engaging machine protection circuits, all of these require changes to the planned scenario. Given a certain deadline, satisfying the timing requirements depends on several factors: The time to detect the condition and compose the message in the data master, transmission time through the distribution network, composed of switch traversal and time on the line, and decoding time in the endpoint.

TIMING CONSTRAINTS

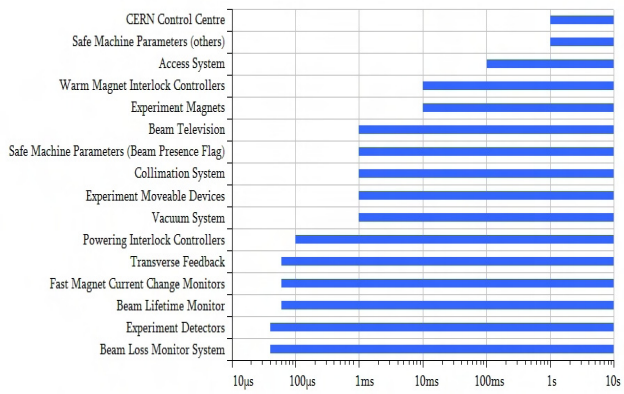

Figure 1: Reaction Times of CERN Interlock systems.[1]

The system timing constraints are to be deduced from hardware parameters like the minimum possible reaction time of a magnets power supply or the synchronisation requirements with RF systems and kicker assemblies as well as interlock systems, subdivided into beam protection, machine protection access control and operating. For all accelerators, interlock handling comes in several speed categories, depending on the kind of system to be monitored. from fastest to slowest these are: beam diagnostic equipment, magnet power supplies, vacuum system, temperature control, access control and finally operating.

Figure 1 shows a comparison between various systems employed at CERN's LHC. Interlock deadlines are spread here from 40μs over the low millisecond range up to several hundred milliseconds [2].

While many of these seem to require comparatively slow reaction achievable with a Real Time Operating System (RTOS), the fastest reaction times possible are always desired. The reason is, the quicker the system reaction time,

[1] B.Todd, A Beam Interlock System for CERN High Energy Accelerators

the less beam dump scenarios are to be expected. This means less ionisation of beam guides and Faraday cups, reducing radiation emmanating from the facility and therefore cooldown time in the beginning of maintenance shutdowns. It also causes less damage to beam diagnostic equipment. Availability for hands-on-maintenance goes with an overall decrease in maintenance time and cost. The most critical machine protection system shown here is the quench protection system for superconducting magnets. As to underline the importance of this system, the most prominent example is the 2008 incident at CERN. A quench led to the explosive discharge of about two tons of helium from a magnet housing into the LHC tunnel, damaging the equipment so severely, that the LHC was shut down for repairs until the end of 2009.

As an example from the planned GSI/FAIR facility, the shortest period to be served by the timing system is about 3ns for the kickers. This is obviously too fast for a reaction over the timing and controls network, but there is mixed approach to meet requirements and enhance system safety at the same time. The kicker timing depends on the RF frequency currently present on the accelerator ring, and this frequency is also sampled at the data master. Phase is therefore known to the whole system. After the kicker signals readiness, the event is scheduled to an absolute time 3ns after a future RF edge. The edge is chosen in a way to allow for transmission time of the control message trough the timing network plus a safety margin. Because transmission and processing time is somewhere around 100 μs, the kicker can safely be assumed to be unchanging in the interim. Until now, the kicker at GSI was triggered on a local basis without regard for other circumstances in the system, while said approach would shift back control to the timing master.

TRANSMISSION TIME

For an example of transmission and decoding times over a WR [1] network, we took a closer look at the future timing system of two accelerators, GSI/FAIR and CERN. The following estimates from the White Rabbit Robustness evaluation [3] show the time for transport of command messages on the network.

Table 1: Elements of Control Message Frame Delivery Delay Estimation [2]

Name	**Value** μs Min	**Value** μs Max
Eth Frame TX Delay	0	$(13 + B_{tx} t_{FECpck})$
Switch Routing Delay	0	13
Link Delay	$5[\frac{\mu s}{km}]$	$5\,[\frac{\mu s}{km}]$
Eth Frame RX delay	t_{FECpck}	t_{FECpck}
FEC Encoding	2	2
FEC Decoding	2	2

Both GSI/FAIR and CERN will employ a tree topology with three layers of WR switches between master and end-points. The main difference between systems in the calculation is in the estimated length of fiber links used. The value is 2 km for GSI/FAIR and 10 km for CERN. The following values are calculated under the assumption that switches have a cut-through option to preempt command messages.

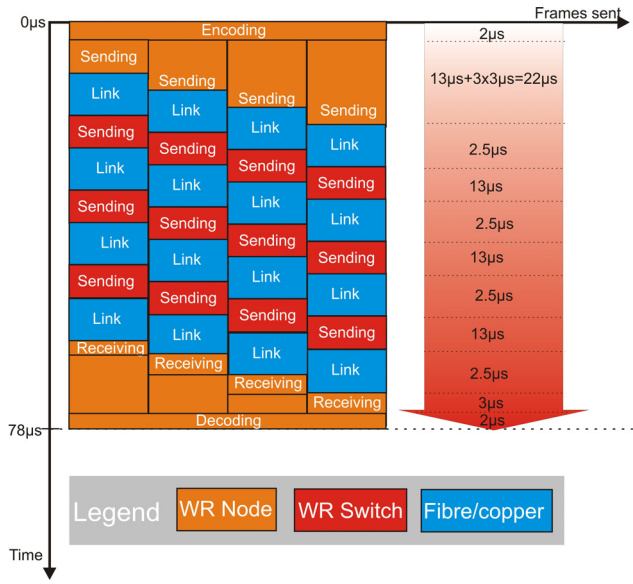

Figure 2: Delivery Delay of Control Message using cut-trough.[2]

Table 2: Control Message Delivery Delay

Control Message size	**Delay**	
	GSI	CERN
500 bytes	78μs	118μs
1500 bytes	102μs	142μs
5000 bytes	162μs	202μs

The figures show that for interlock servicing, it would be advantageous to connect time critical devices to the upper switch layers in order to reduce transmission time. For fastest respone, connection to the topmost layer would reduce latency by about two thirds. From a practical point of view however, since the tree is fanning out, this will of course be limited by number of ports available on the first switch layer or even the timing data master.

MODELING THE ACCELERATOR

Command messages sent over the timing network supply event codes to the machines paired with execution times. The machines are preprogrammed with a certain reaction upon reception, which should also be done by the same means. The accelerator has sequential processes with synchronisation points. While the sequences are simple in themselves, their interdependencies can be quite complex,

[2] M.Lipinski, C. Prados, White Rabbit Robustness

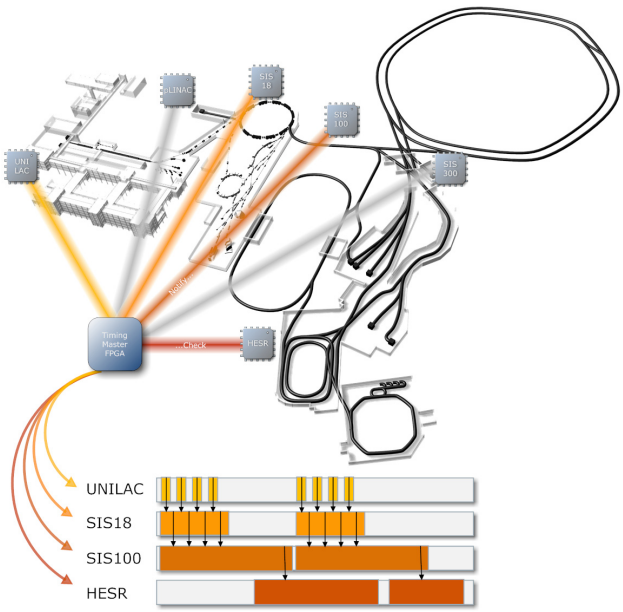

Figure 3: Machine sequences in a production chain.

depending both on external events like interlocks and internal synchronisation. Sequence architecture include jumps, conditional branching, IO handling, loops, real time clock waits and fast synchronisation between sequences. The sequences must be exchangable in parameters or completely during run time. For the GSI/FAIR accelerator, about 20 of these sequences are expected to run in parallel, 32 are aimed for to be future-proof.

PROCESSING TIME

CPU

With increasing complexity and number of processes, keeping code execution and synchronisation deterministic becomes ever more challenging. Fast modern CPUs, especially multicore architectures, offer vast processing power. Their drawback is that they require a managing OS to unlock most of their advanced features, which have worst case interrupt service latencies in the low millisecond range, making it an inapt choice for a Timing Master architecture. Real time Operating Systems are deterministic and can offer ISR latencies in the low microseconds range and most them are made for embedded CPUs (MCU). There are no RTOS systems targeting Hi-End-Multicore architectures available today.

Table 3 shows the latency measurements for a PowerPC 604 CPU (300MHz) on a MVME2306 board [4]. The discussed timing constraints could possibly be achieved with an MCU running an RTOS system, but as shown in Table 3, jitter is in the range of several microseconds. There are also strong peaks under load (which would be common, since the RTOS has to handle all machines and IO sources in the system) which go as high as 200μs. This disqualifies the solution for all fast interlock systems. We must also bear in mind that transmission time through the timing network ranging between 80-200μs must be added to the total reaction time, restricting the use even further. This leads to the assumption that an MCU with RTOS would probably be capable of running the required number of machine agents, but as figures show, could hardly cope with timing requirements for IO service requests.

Table 3: RTOS Latency Measurement Results[3] Times in μs

	Interrupt Latency		Context Switching	
	max	**avg** $\pm$	**max**	**avg** $\pm$
Idle System				
RTL	13.5	(1.7 $\pm$ 0.2)	33.1	(8.7 $\pm$ 0.5)
RTEMS1	14.9	(1.3 $\pm$ 0.1)	16.9	(2.3 $\pm$ 0.1)
RTEMS	15.1	(1.3 $\pm$ 0.1)	16.4	(2.2 $\pm$ 0.1)
vxWorks	13.1	(2.0 $\pm$ 0.2)	19.0	(3.1 $\pm$ 0.3)
Loaded System				
RTL	196.8	(2.1 $\pm$ 3.3)	193.9	(11.2 $\pm$ 4.5)
RTEMS1	19.2	(2.4 $\pm$ 1.7)	213.0	(10.4 $\pm$ 12.7)
RTEMS	20.5	(2.9 $\pm$ 1.8)	51.3	(3.7 $\pm$ 2.0)
vxWorks	25.2	(2.9 $\pm$ 1.5)	38.8	(9.5 $\pm$ 3.2)

FPGA Based Soft-CPU

This leaves programmable hardware for investigation. Field Programmable Gate Arrays (FPGA) can be configured by Hardware Description Languages (HDL) to function like every digital circuit from a simple FlipFlop over a counter to a full blown embedded CPU. The major advantage is in their huge degree of flexibility. There are several open source Soft-CPUs (Soft-CPU) as well as a couple commercial ones available today. Soft-CPUs in FPGAs are a fast, lightweight alternative to real hardware CPUs. Their most interesting aspect is that it is possible to have enough instances inside an FPGA to actually assign one Soft-CPU to each task. They also do not accumulate wait times for bus arbitration and memory access in operation, because they do not need to share their memory resources. A modern FPGA not only hosts logic units, but memory cells as well. Creating an instance of a memory controller template with matching RAM block for each Soft-CPU inside the FPGA makes them independent of their peers. In addition, this RAM block is natively capable of Dual Port access, providing the capability for on the fly change of sequence programs. Due to the fact of the one Soft-CPU-per-task policy, sequence programs can be blocking instead of using ISR, saving the time consuming context change. Assuming 125MHz system frequency and therefore 8 ns period per cycle, response times to external IO are well below 0.5μs, beating all competition. Due to the given flexibility, building a complete custom Soft-CPU tailormade for the given scenario is possible. The major drawback of a custom processing unit, wielding its own instruction set, is the total lack of toolchains. Virtually everything in a toolchain

[3] T. Straumann, Open Source Real Time Operating Systems Overview

that makes a productive workflow possible, that is, assembler, linker, compiler, debugger etc must be created from scratch. There will most likely be no community support, since the application is very narrow. Since the scenario requires standard functionality like basic math, counters, loops and RTC support, it will be a lot of redundant work.

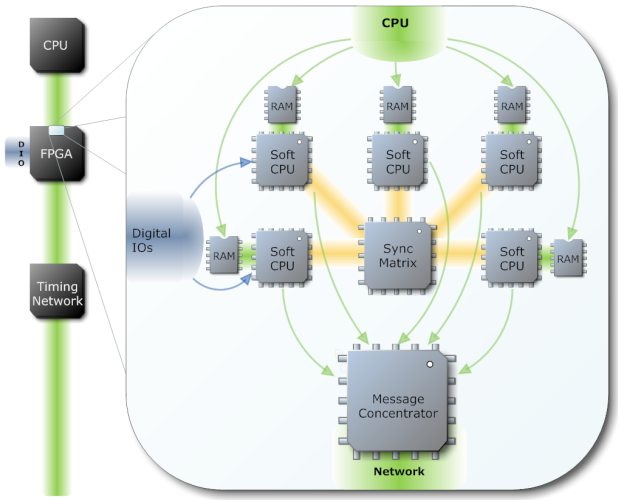

Figure 4: FPGA based Soft-CPU Cluster.

Soft-CPU Evaluation

A more promising approach is therefore to use a tried and tested open source soft CPU and enhance it with custom instructions. In our case, those are mainly ones used for quickly synchronising of soft CPUs.

Soft CPUs like the LM-32 are at around 2000 logic cells and therfore very lightweight [5]. Today's high end FPGAs range in the $>$ 250000 logic cells and can therefore easily instantiated several tens of those CPUs. According to early tests, the limiting factor is more likely to be the amount of RAM present in an FPGA than the number of logic units. Assuming around 2.5MB internal memory cells for a modern FPGA, this equals to about 80kB for each of the 32 soft-cores desired for the FAIR accelerator, more than enough to execute quite big programs. As an example, running a GNU debugger on system currently consumes around 1 kB memory.

The idea is then to create a Soft-CPU for each machine handler as well as one or more instances dedicated to IO signal and high level communication handling, as shown in figure 4. So instead of solving a complex scheduling problem in software to maintain deterministic system behavior, parallel tasks each get assigned their own Soft-CPU. Their synchronisation can be done by a custom HDL block, an $n * n$ matrix for synchronisation messages, making sync possible within less than five processor cycles ($<$ 40 ns) for checking of simple flag bits.

In the field of experimental electronics, a multi author situation should also be considered. It makes sense to let people working with the actual experiment write the software, which is another point in favor of existing toolchains.

CONCLUSION

In sight of time availabe to react to system interlocks and signals, it is evident that a pure CPU solution will not be able to satisfy the requirements. A pure custom hardware solution probably would satisfy the requirements for any given constraint, but prove difficult when it comes to follow changes at the operating level. Soft-CPUs are a good compromise between both worlds, with the added benefit of readily available development tools. To provide more IO speed and better scalability in face of system load, the choice falls to a multi core architecture from Soft-CPUs with dedicated internal memory. This setup shall be completed by a fast synchronisation mechanism and the possibility to dedicate Soft-CPU to specific sequence programs and IO handling.

OUTLOOK

The first steps will be the implementation of customized Soft-CPUs in a small scale test system in order to measure actual response times. An mechanism for safe on-the-fly change of the sequence programs in Soft-CPUs has to be devised, and several Soft-CPUs will be tested in a small cluster to demonstrate fast synchronisation between sequence programs. A prototype system is planned to be set up in 2012 to drive the first component to be comissioned to the FAIR extension of the GSI accelerator, a proton linear accelerator module.

MODERN SYSTEM ARCHITECTURES IN EMBEDDED SYSTEMS

T.Korhonen, PSI, Villigen, Switzerland

Abstract

Several new technologies are making their way also in embedded systems. In addition to the FPGA technology which has become commonplace, multi-core CPUs and I/O virtualization (among others) are being introduced to the embedded systems. In this paper we review the trends and discuss how to take advantage of these features in control systems. Some potential application examples are discussed.

THE DOMINANT TRENDS

Many of the technical advances in the computing industry are driven by the needs of the applications in the general information technology, Internet and the web, telecommunication and the entertainment industry. Common for these markets are that the data volumes are increasing, as well as need for of data communication bandwidth and processing power. To respond to these demands, the computer and electronics industries have come up with several technology solutions.

The embedded and control system applications are in some areas in the leading edge of technology, but in other areas the technology used in the general computing is coming into the applications with a delay. This delay is to a large extent due to the nature of the embedded market: the application life cycle is much longer than in the general computing market.

The general trends of the computing market are not essentially new but have practically always been to a) provide more computing power and communication bandwidth and b) use the hardware investment in the most efficient way. In the next chapters we take a look at these solutions and what they could bring to the field of control systems. This is not always obvious and it is a time-consuming process to implement this into the embedded infrastructure.

NEED FOR SPEED

Computers are never fast enough. Each advance in the processor technology has taken us a step further, but as soon as a solution has become available, a number of applications have arisen that use up all the available power and require even more.

As increasing speed just by making the CPU clock rates higher has become impractical, the major method is now increasing the parallelism. This is happening in a number of ways, most apparent is putting multiple processors in one unit. However, this is not the only way to implement parallelism.

Speed by Parallelization

Starting at the lowest level of parallelization, FPGAs have been around for some time and have become very common in embedded applications, too. The recent applications have started to use them as processing engines instead of glue logic. An FPGA can be the ultimate tool for fine-grained parallel processing if the tasks in hand match the model. The downside of using FPGAs is that the application development is work-intensive, as the abstraction level of the tools is low. To implement an application in a FPGA the problem needs to be well constrained. FPGA is also a fairly expensive solution in many cases.

In the processor world the obvious way of introducing parallelism is to increase the number of processing units and divide the computing tasks between them, Multi-core CPUs have emerged in the recent years, being now the standard in server and desktop machines but have also recently entered the embedded market. There are essentially two different directions in multicore implementations: having a number of identical cores (typical in desktop computers) or having a mix of general and special purpose processors on the same chip, like the TI OMAP[1], which combines a (dual-core) ARM CPU,DSP and GPU on the same chip. This kind of heterogeneous multicore processors could be very interesting in applications that need floating-point and mathematical operations in the embedded level.

As an example of a multicore CPU targeted for the embedded market, the QorIQ SoC series by Freescale [2] is displayed in Fig. 1. In addition to a variable number of processor cores, it also integrates specialized function accelerators on the same chip, for instance a TCP packet accelerator that implements a part of the TCP packet processing in hardware. It also integrates Gigabit Ethernet transceivers and three PCI express endpoints plus a number of specialized function controllers like an encryption engine.

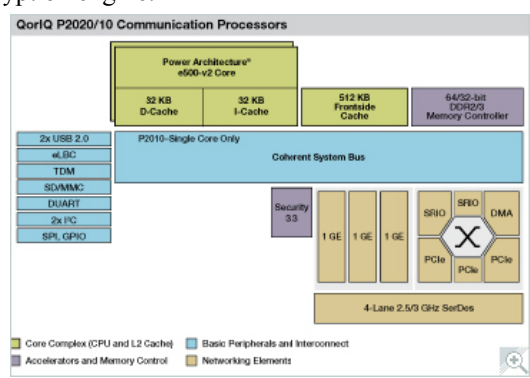

Figure 1. Freescale QorIQ® P2020 block diagram

Interconnects

To make advantage of the multiple processing units, the units need to communicate efficiently with each other. This has traditionally been implemented with multidrop buses. However, a bus scales very badly with the increasing number of processing units. For this reason, the

interconnects are more and more going to the direction of serial point-to-point links. In dedicated applications these links have been used already a long time. General-purpose interconnect protocols are now being included directly in processors so it makes a lot of sense to use them in embedded applications, too. The most prominent interconnect protocols are Ethernet (obviously) and PCI Express. The other protocols cater for specialized needs and what will happen with them in the long term is not that obvious. The two prominent protocols are however likely to have a large share in applications and be widely supported long into the future.

Controls Applications

A typical embedded application consists of tasks for I/O and some level of processing. As the processing power in the low level has grown, more and more applications have migrated to the low level. This has several advantages, as the data can be pre-processed right down at the source and only the relevant data needs to be passed on to the higher level. To achieve this in a low level embedded processor, there are a number of options. One can implement applications in a FPGA and take advantage of the real parallelism possibilities and very hard real time capabilities. This can however be very labour-intensive.

For the processing with a CPU, the obvious way is to try to take advantage of the multiple cores. A relatively simple way is to take advantage of a symmetric multiprocessing (SMP) OS and let it take care of distributing the load between processors. This can work quite well when the workload consists of different tasks that have little or no relation to each other. However, for embedded applications this is often not the case. The other possibility is then to dedicate computing cores for different tasks, or define certain tasks to run on different cores. This can help in management and partitioning of the workload.

The SoCs that provide different specialized cores can also have interesting possibilities. For instance the OMAP processors with their special processors could be efficient when the workload is a mixture of heavy floating point and matrix operations plus running general purpose tasks (I/O handling, network tasks etc., for which a general purpose core like an ARM is well optimized. Dedicating coprocessors for different tasks would also enable applications where a tight connection between a modelling environment and an embedded controller is useful. The modelling can happen in an workstation and the modelled application can be run on a dedicated core, where it would not need to disturb the general purpose tasks, and restarted as wanted.

Using GPUs as coprocessors for doing intensive matrix manipulations is also a possibility that is becoming more and more common.

QUEST FOR EFFICIENCY

Even if the price of computing equipment has come down, it still always costs too much. One of the long-standing ideas (and implementations) of taking the most benefit of the installed equipment has been to share the computing resources between several applications. Instead of each service running on its own machine, sharing the time of the hardware by running several things in parallel can improve the utilization of the hardware.

Virtualization

However, even more than optimizing the use of the hardware the problems facing IT departments now are physical space in the data center, power/cooling costs, system maintenance and management. The performance of servers has also increased to a point where there is a large amount of idle capacity. With virtualization, IT departments can utilize that spare capacity rather than adding a new physical server to support a new environment.

Virtualization is traditionally implemented with the help of a hypervisor that controls and shares the computing resources at a low level. The hypervisor is usually a thin software layer below the guest operating system. As the number of cores in CPUs increases, the task of a hypervisor gets more and more demanding and it self starts to become a bottleneck for the effective load sharing. Thus the functions of a hypervisor are increasingly being implemented in hardware. The need is most obvious and pressing in the area of I/O.

I/O Virtualization

The concept of I/O virtualization [3] is fairly recent and its meaning may not be immediately obvious. What this means is the implementation of the tasks of a software hypervisor in hardware to improve the efficiency. When many guest systems want to share the access to I/O modules the supervisor becomes a bottleneck when all the accesses have to be arbitrated. For instance, the SR-IOV standard within PCI express defines so called virtual functions in the devices. The guest systems can be given direct access to the hardware and the need for data manipulation by the hypervisor is eliminated.

SHARE AND CONQUER

Being a discipline with long development cycles, most of the software infrastructure in the control systems field is still oriented towards the single-processor model. Only recently activities to address have been initiated; some of them presented also in this conference. For instance the handling of timing of real-time processes: in a single-core system

The rise of open-source software has had a big impact on the way systems are built. Direct access to the source code has enabled implementation of functionality that was previously an area where only proprietary solutions existed. In addition, several working groups are defining open standards to make the utilization of multi-core systems easier. A notable standardization body is the Multicore Association [4], which has several working groups working on standardization of APIs in different

areas. For instance MCAPI working group provides a standardized API for communication and synchronization between closely distributed cores and/or processors in embedded systems. The working group has formed two subgroups. One is working on 'zero copy' functionality, including bidirectional interaction between 'application and application' using shared memory and bidirectional interaction between 'application and driver'. A second subgroup is focused on interoperability.

The MTAPI™ working group is charged with creating an industry-standard specification for an API that supports the task coordination on embedded parallel systems.

The Tools Infrastructure Working Group's key objective is to improve the interoperability between the different tool solutions for the development of embedded multicore systems, has been predominantly continuing its work on the Common Trace Format (CTF) specification. The goal of this work is seamless correlation of data coming from different types of tracers (e.g. software instrumentation, hardware instruction/data trace) as well as divergent execution contexts on multiple cores or systems.

PUTTING IT TOGETHER

Case for Parallelization and Multi-Core

There is no other way than going to multi-core – practically all modern CPUs have more than one core and the number will increase. However, the (real-time) control system software that runs on embedded processors has been written using single-core machines and while one can introduce operating systems that provide SMP support out of the box, just letting the OS to do the task assignment will cause some surprises in how the system behaves. The timing of tasks will inevitably change if tasks that have been assumed to be sequentially scheduled, are running truly parallel in separate cores.

Having said that, there are several cases where having multiple cores available can bring true advantages.

Data Streaming Application

One of the applications we are working on is a processing system for a low-level RF controller. The basic structure of the system is as shown in Fig. 2. The system collects data from several ADCs, processes them and does feedback of the RF system. The platform to do this is the IFC_1210 board that has recently been developed in collaboration between PSI and IOxOS SA [5]. The board is based on a PCI express communication infrastructure, on which several processing units are connected. The board has a powerful Virtex-6 "Central" FPGA, a dual-core Freescale P2020 QorIQ SoC CPU unit. The board in in VME format, to be compatible with the large existing installation base at PSI, but with an innovative use of the P0 connector allows PCI express links to be routed through the backplane, allowing us to create a multi-board system by connecting several boards together. The VME bus can be used as a control plane interface, but the system is not limited by the bus speed.

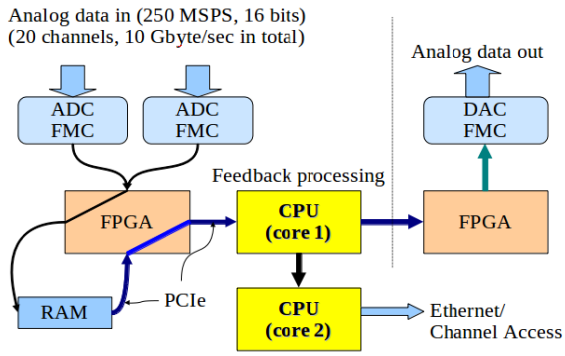

Figure 2. A data streaming and processing application for low-level RF control

The bulk of the raw data processing in this system takes place in the FPGA, however the control algorithms are at least in the first stage planned to be run on the general purpose PowerPC cores, that are much more suitable for interactive development. This makes the prototyping cycle much shorter. FPGAs do not easily lend them for scripting, even with the most modern tools.

The idea here is to take advantage of the multi-core CPU by clear partitioning of the tasks. At least in the development stage one could even take advantage of virtualization in the sense that the algorithms could run on a desktop machine which is connected to the field hardware via a long-distance PCI express link. The plan is to accelerate the development cycle by supporting direct access from modelling tools for developing and testing the feedback algorithms. The preferred tool for this is Matlab/Simulink. We plan to integrate it with the IFC_1201 board that we can directly download code from the tool to the system under test.

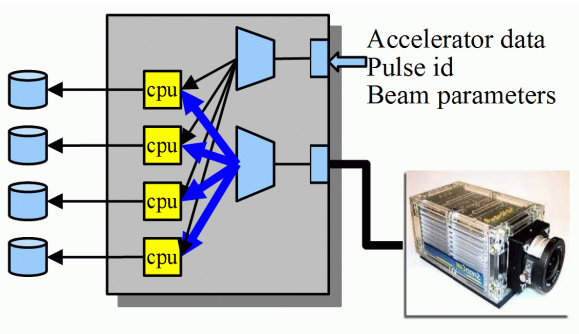

Figure 3. Striping data acquisition

Striping Data Acquisition

One conceivable application could be high-speed acquisition of data, e.g., images from a high-speed sensor to be processed in parallel. When the data cannot be processed fast enough by a single unit, it can be streamed to multiple units and the results stored in parallel (see Fig. 3). Many experiments in physics and X-ray FELs could fit this kind of model where each "event" is in principle an individual unit. If the imaging device would support I/O virtualization, the load could be effectively shared between multiple units. Usually the sensor data

needs also to be merged with data from the accelerator (e.g., pulse number, beam characteristics, etc.) to enable later analysis of the data.

Case for Virtualization

For controls applications, configuration management is probably the most compelling reason why one would consider virtualization.

The trend has been to put the computing closer to the equipment. With the fast interconnects and protocols available, one could think of revising the trend. It might be feasible to put the computing infrastructure together in a server room instead of spreading it out on the field. This would have the advantages that the management becomes easier, granularity of allocating processing power to the applications can be improved: not all I/O processors need to be the dimensioned according to the highest requirement, and on the other hand more power can be allocated where it is needed. In a sense this has already been happening since the EPICS software has allowed us to run the IOC core software on a server machine. Moving from the "soft IOC" would involve adding the direct (virtualized) I/O to the system and one could even implement real-time systems on a remote server. Using PCI express as the interface protocol, the infrastructure for device drivers would be easily usable in such an environment.

CONCLUSIONS

The advances in computing sometimes enter the embedded world with a delay. It is also often not obvious how to take advantage of the technologies that have been targeted to a different domain. However, after all the requirements are not that different, and by embracing the technology they can bring a lot of benefits to the embedded applications.

AN ERLANG-BASED FRONT END FRAMEWORK FOR ACCELERATOR CONTROLS

Dennis J. Nicklaus, Charlie Briegel, Jerry Firebaugh, Charlie King, Richard Neswold, Ron Rechenmacher, Jianming You. Fermilab, Batavia, IL 60510, U.S.A.

Abstract

We have developed a new front-end framework for Fermilab's Acnet control system in Erlang [1]. Erlang is a functional programming language developed for real-time telecommunications applications. The primary task of the front-end software is to connect the control system with drivers collecting data from individual field bus devices. Erlang's concurrency and message passing support have proven well-suited for managing large numbers of independent Acnet client requests for front-end data. Other Erlang features which make it particularly well-suited for a front-end framework include fault-tolerance with process monitoring and restarting, real-time response, and the ability to change code in running systems. Erlang's interactive shell and dynamic typing make writing and running unit tests an easy part of the development process. Erlang includes mechanisms for distributing applications which we will use for deploying our framework to multiple front-ends, along with a configured set of device drivers. We've developed Erlang code to use Fermilab's TCLK event distribution clock and Erlang's interface to C/C++ allows hardware-specific driver access.

INTRODUCTION

Our front-end computers are responsible for acquiring control system signals from the hardware or field bus and making this data available to the Fermilab control system. The front-end framework is a software architecture that is deployed to provide common central functions to serve the variety of devices or bus systems that we acquire data from. The primary requirements of this front-end framework are:

- Communicate readings, settings, etc. via the Acnet protocol
- Enable a mapping between the a device's name in the control system and the hardware channel.
- Manage the connections between control system requests and the data channel.
- Check for and report device alarms.
- Respond to the timing system to ensure prompt collection
- High degree of reliability.

We began discussing developing a new framework as an alternate path forward, replacing our vxWorks-hosted, C-language MOOC framework, with a stated goal of running under the Linux operating system. Initially, we were expecting to develop the new framework in C++, but the Erlang language caught our attention and we soon realized it would be a great candidate for our project.

ABOUT ERLANG

Erlang is a functional programming language originally developed for telephony applications. It was built to support soft real-time systems with a high degree of reliability and fault-tolerance. Erlang is designed to be scalable to very large distributed systems.

Functional Programming

Functional programming emphasizes the application of functions to get results, as opposed to the more familiar imperative paradigm which emphasizes changing state and side-effects of subroutines. The elimination of side-effects in functional programming makes predicting and testing function results more straightforward.

Properties of Erlang include dynamic typing, single assignment, and extensive support for pattern matching in assignment. The initial hurdle that new Erlang developers must jump is figuring out how to program when you can't change the value of a variable once it has been assigned. As you would expect from a functional language, there is considerable support for list creation and processing, as well as structured concepts built on lists.

Erlang has excellent support for concurrent processes and for message passing between processes. Spawning a new process is a relatively inexpensive operation in Erlang. There is a built-in process supervisor behaviour model, where the supervising process gets notified of the termination of the subordinate and can act to restart it.

WE ADOPT ERLANG

Once we started looking at Erlang, we realized it was very well-suited for our front-end framework. Reliability of front-ends is a key concern, and Erlang is designed from the ground-up with reliability in mind. It supports the soft real-time that we need and is available on a variety of platforms, including linux that we were specifically targeting. High level data structures, such as the Erlang dict offer a painless way to implement mappings between database devices and specific controls code. Easy availability of Erlang processes, and high level language support for message passing make Erlang a natural fit for handling all the various Acnet data requests at a large variety of frequencies. Standardized process behaviours, such as supervisor or generic server, have proven useful in supporting the modularity of our design. Utilizing multiple processes and the supervisor behaviour allows us to build in overall reliability even if the implementer of a particular device's driver code has made mistakes which might cause that driver code to crash. Erlang provides an interface to C/C++ that allows us to

use C++ when we are required to read/write hardware registers that aren't accessible to Erlang.

FRAMEWORK DETAILS

One can divide our Erlang framework into several relatively independent modules: Acnet Protocol Handler, Sync, Data Acquisition Core, and Device Drivers.

Acnet Protocol Handler

We have a library of routines for connecting with the acnetd daemon which transports Acnet traffic in and out of the Erlang framework. In order to hide the details of the Acnet binary network protocols, we've developed sets of marshalling and unmarshalling routines that convert between the Acnet binary packet and Erlang records (structured lists). With a separate set of these functions for each particular Acnet message (e.g. read, set, post alarm, get plot data,...) used in conjunction with the Acnet library functions for sending or receiving messages, the rest of the Erlang code is freed from any worries about the Acnet packet protocols.

Sync

Our Erlang Sync library is our general purpose triggering system for data acquisition or other periodic tasks in Erlang. A unified interface handles read requests for periodic updates, updates on our hardware clock events, or other requests, such as on Acnet state changes. For instance, if the Erlang front-end receives a request to read data at 1 Hz, the framework registers its generic ''read data callback'' function with the Sync library and thus gets notification to run at the desired period.

Data Acquisition Core

The data acquisition tasks are the main function of the front-end. At the core here is a server process waiting on new read or set requests to arrive via Acnet. This server keeps a local mapping of the local device drivers and the database identifiers which will access those drivers. At system startup, the drivers in use are registered with the data acquisition server. Currently this is accomplished with a configuration file, one for each front-end to indicate the device types it owns, but we envision this information one day being stored in the global device database and sent to the front-end from the database at startup time.

When the data acquisition server receives a new reading request, it will generally spawn a separate process to handle that request at its desired update rate, thus keeping the central server free to receive new messages and insulating it from any buggy behaviour in the device drivers.

Alarm limit checking is also done with processing similar to a simple read, but with the obvious added limit checking added on.

Device Drivers

We refer to the code which contains the details of reading or setting any particular device as its ''device driver''. These aren't necessarily traditional linux device drivers, although that may be a part of our Erlang device driver. There is a standard Erlang programming interface that each driver conforms to. Each device driver in an Erlang front-end is registered with its local data acquisition server in order to connect to Acnet requests. This interface sends the device driver routine the details of the access request, a container of information shared throughout that device driver, and the triggering event specification.

Some controls tasks require accessing hardware which isn't reachable from Erlang code. For these tasks, we've also developed a standard method of calling from Erlang to C++, using standard Erlang-C interfaces. Our C++ programming interface lets the C++ compiler do much simple type and error checking to ensure reasonable parameters are passed to the C++ code.

PROGRAMMING IN ERLANG

Everyone on our development team is used to programming in imperative languages such as C/C++ and Java. In addition to mastering the new syntax, functional programming requires a fundamental mind-shift by the programmer. This shift is somewhat similar to changes one must make when going from a serial, procedural C program to an event-driven Java graphical user interface. The functional tools provided by Erlang also allow one to consider different solutions to a programming problem.

Two paradigms used extensively in Erlang include message passing between processes and tail recursion. Erlang's message passing is built into the language, and passing indicator atoms or message data can be done without much thought by the programmer. Since Erlang passes copies of the data, the programmer doesn't need to worry about issues like semaphore locks around shared data. Because Erlang variables are single assignment, many tasks which might be done by iteration in C are done by recursion in Erlang. The run-time system is highly optimized for tail recursion, where a function calls itself recursively and the last thing the function does is make the recursive call.

Many features of the Erlang language and run-time system only become useful as one gains some expertise with the language, for instance, the generic server (gen_server) behaviour. A novice Erlang programmer will probably spend some time writing some simple message receive loop functions. As the functionality of that loop expands, the utility of the predefined gen_server package becomes more apparent.

Functional languages by their nature encourage unit testing. Since pure functions don't have side effects, effective test routines can prove that your code works. The Erlang development system provides tools that explicitly tell you which lines of you code are tested by your unit testing functions. These coverage maps obviously help demonstrate well-tested code. The interactive Erlang shell also speeds testing because you can construct test vectors and interactively call your functions.

With reasonably modern 1-2 GHz processors running linux, Erlang's performance has been sufficient for us The Fermilab linac runs at 15Hz, so 15Hz response has been our baseline for testing Erlang system response. Using Erlang and its command-line shell, it is easy to create stressful load tests of the system, for example, setting up requests for hundreds of device readings at once. Erlang provides run-time profiling tools that help point out performance bottlenecks and show how a programming or data structure choice can influence the run-time performance.

We have not yet made use of the "hot-swap" feature that lets one upgrade a software module of a running Erlang system, but we look forward to taking advantage of this in the future.

SUMMARY

We have developed a new front-end data acquisition and controls framework in Erlang. Adapting to the functional programming paradigm has been well-worth the effort and some early deployments of Erlang front ends include control commercial motor controllers over UDP and monitoring the status of the near detector of Fermilab's Nova experiment. A few other example device drivers have also been written. We've found Erlang very suitable for this type of application and are looking at implementing other control system infrastructure in Erlang.

THE FERMI@Elettra DISTRIBUTED REAL-TIME FRAMEWORK *

L. Pivetta, G. Gaio, R. Passuello, G. Scalamera, Sincrotrone Trieste, Trieste, Italy

Abstract

FERMI@Elettra is a Free Electron Laser (FEL) based on a 1.5 GeV linac. The pulsed operation of the accelerator and the necessity to characterize and control each electron bunch requires synchronous acquisition of the beam diagnostics together with the ability to drive actuators in real-time at the linac repetition rate. The Adeos/Xenomai real-time extensions have been adopted in order to add real-time capabilities to the Linux based control system computers running the Tango software. A software communication protocol based on Gigabit Ethernet and known as Network Reflective Memory (NRM) has been developed to implement a shared memory across the whole control system, allowing computers to communicate in real-time. The NRM architecture, the real-time performance and the integration in the control system are described.

INTRODUCTION

FERMI@Elettra is a light source based on a linear accelerator designed to operate two FEL undulator chains covering the wavelength range from about 100 nm to 4 nm. Designed to work at 50 Hz repetition rate, FERMI@Elettra requires the control system to be able to track and tag each shot with a unique timestamp called bunch number. Any relevant data must be tagged with the same timestamp eventually allowing to correlate machine parameters with the electron and photon beams characteristics. Moreover, a number of control loops are required to stabilize the main parameters of the beams. The control system must guarantee the mechanism, the performance and the reliability necessary to acquire all the relevant sensors, perform the feedback calculations and drive the actuators in real-time.

LINUX AND REAL-TIME

Linux, as a general purpose operating system, historically belongs to the server application field and typically privileges throughput over responsiveness. Thus, the *vanilla* linux kernel is not suitable to predict precisely the execution of a task, neither the scheduling time nor the real duration. Three different approaches have been tested to improve the real-time behaviour.

* The work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3

Performance Tuning

A number of methods are availabile in the plain Operating System (OS) to tune the behavior and obtain a better timing of the tasks:

- Increase the scheduling priority via the `nice` command:
  `nice -20 ./executable`.
- Change scheduling policy programmatically:
```
sched.sched_priority = \
        sched_get_priority_max(SCHED_RR)-1;
sched_set_scheduler(0, SCHED_FIFO, &sched);.
```
- In multicore processors, reserve a core to a task via the `taskset` command:
  `taskset -c1 ./executable`.
- Avoid memory pages of the process to be swapped via the `mlockall` system call.

A quick and dirty solution could be rewriting some Interrupt Service Routine (ISR) to include the desired code. The ISR cannot be scheduled and preempts any other task, except other ISRs, assuring the real-time execution. Good candidate ISRs to be modified could be those related to:

- A *data availabile* interrupt request (IRQ): when data are availabile an interrupt is raised and the critical task code could run in the end of the ISR code.
- A timer IRQ: the critical code runs on a timer period.

It is even possible to reserve a core to just one IRQ.

This approach has nevertheless an important drawback: code running in the ISR is required to be short and fast and not all applications could fit.

Preemptible Kernel

A better solution relies on the adoption of a fully preemptible kernel based on the PREEMPT_RT patch [1] and availabile on the mainline since release 2.6.23. This patch reduces the kernel code protected by *big locks*, implements the priority inheritance mechanism for in-kernel spinlocks and semaphores, adds the possibility to perform deferred operations and enables the support for High Resolution Timers (HRT). This approach leads to a much more responsive kernel/system altough it cannot guarantee an unfailing respect of the deadlines: the system is still not real-time.

Real-time Subsystem

A real-time subsystem environment cooperating with the GNU/Linux kernel provides a pervasive hard real-time support to both kernel-space and user-space applications and allows for the best performances.

For FERMI@Elettra the Adeos/Xenomai [2] real-time subsystem has been adopted. It supports several processor architectures on embedded systems, such as ARM, Blackfin, NiosII, PowerPC, x86 and, of course, runs also on standard workstations and servers. To port and optimize the Adeos/Xenomai subsystem to the embedded platform selected for the FERMI@Elettra control system [3] some work has been outsourced [4].

A complete set of Application Programming Interfaces (API) to develope real-time applications in kernel/user space, such as Inter-Process Communication (IPC), synchronization, mailboxes, etc. are availabile.

To exploit all the performance of the real-time subsystem some care must be taken: standard GNU/Linux system calls should be avoided in the real-time application and the device drivers must be eventually patched in order to use the API availabile in the real-time domain.

REAL-TIME PERFORMANCE

A laboratory testbench, shown in Fig. 1, has been set up to measure the performance of a VME based system consisting of an Emerson MVME7100 CPU and a couple of digital I/O boards.

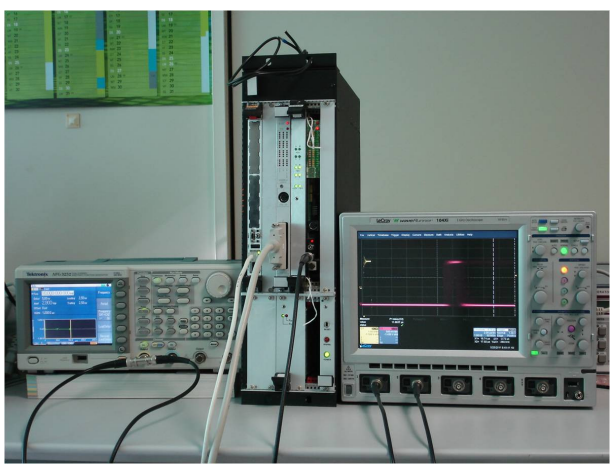

Figure 1: Real-time measurement testbench.

A pulse, referred below as *input pulse*, produced by a signal generator is acquired by a digital input board which rises an interrupt on the VME bus. The IRQ is then managed by the ISR and the digital line of an output board is driven producing an output pulse. The system has been loaded with tasks involving a large volume of interrupts: multiple *ping flood*, processes generating network activity and high-speed serial I/O traffic. Two scenarios have been analyzed.

Running the Code in the ISR

Some measurements have been carried out to characterize the performance of the described setup with the application code running inside the interrupt service routine of both GNU/Linux kernel domain and Adeos/Xenomai domain. A digital oscilloscope, triggered on the input pulse, measures the latency of the output pulse.

Table 1 and Table 2 show the results of the test for 50 Hz and 10 KHz input pulse repetiton rate respectively.

Table 1: Latency at 50 Hz Repetition Rate

	Min	Max	Mean	Std
Linux ISR	10μs	33μs	15μs	1.5μs
Xenomai ISR	11μs	23μs	16μs	1.4μs

Table 2: Latency at 10 KHz Repetition Rate

	Min	Max	Mean	Std
Linux ISR	10μs	29μs	11μs	0.8μs
Xenomai ISR	11μs	14μs	12μs	0.2μs

Measurements show that the worst case latency decreases when running at higher repetition rates, as the probability of the ISR code generating a *cache miss* decreases.

As already noticed, anyway, inserting the application code into the ISR is not good practice. The ISR must always be as fast and light as possbile.

Running the Code in an OS Task

Either the GNU/Linux kernel or the Adeos/Xenomai real-time scheduler have complete synchronization primitives that allow to execute a specific task triggered by an asynchronous event. In both cases the ISR code, servicing the IRQ, releases a semaphore that unlocks the execution of a suspended task.

A GNU/Linux task running in user space is blocked on a `ioctl` waiting on a semaphore. A GNU/Linux ISR, triggered by the IRQ generated by the digital input board, unlocks the semaphore. The GNU/Linux task generates a pulse driving a digital output line. An oscilloscope acquires both the input pulse and the output pulse. Table 3 shows the resulting measurements for a repetition rate of 10 Hz.

Table 3: GNU/Linux Task Latency Measurements

	Min	Max	Mean	Std
No load	15μs	48μs	23μs	2.5μs
Heavy load	196μs	37180μs	175μs	1374μs

As expected, the system shows outstanding performances without machine load. No guarantee,

even at 10 Hz repetiton rate, to meet the deadline when the system is heavily loaded.

In the Adeos/Xenomai case the IRQ is serviced by a Xenomai ISR. A Xenomai task is pending on a `ioctl` waiting on a Xenomai semaphore. The ISR releases the semaphore unlocking the task that drives the digital output line. The results are shown in Table 4.

Table 4: Adeos/Xenomai Task Latency Measurements

Rep. rate	Min	Max	Mean	Std
50Hz	17μs	69μs	42μs	5.7μs
10KHz	16μs	49μs	21μs	3.2μs

The real-time behaviour is guaranteed and is not affected by the laod on the system; the performance suffers a slight degradation with respect to the code running into the ISR but with a big advantage: the task runs in user space.

The Fig. 2 summarizes the measured overall latencies of the testbench. The GNU/Linux heavy load measurements are not shown.

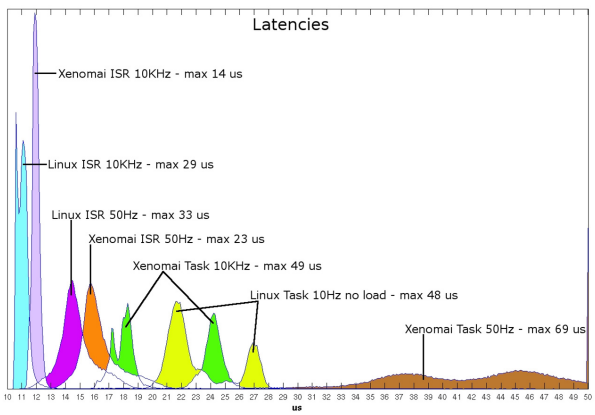

Figure 2: Overall system latency distributions.

HARDWARE

Two hardware platforms are currently supported and could be integrated into the real-time framework. VME crates, designed in accordance to the VME64x extensions, host the front-end computers; on this bus, double-edged source-synchronous transfer (2eSST) compliant boards can reach transfer rates up to 320 MB/s [5].

Emerson MVME7100 PowerPC single board computers (SBC) featuring 1.3 GHz CPU clock, 2 GB ECC RAM, 8 GB soldered flash disk, 4 Gb/s Ethernet interfaces, 5 RS232 serial lines, 2 user configurable hardware timers are used as main processors on the VME.

Intel-based processing servers have been adopted for the acquisition of digital cameras (CCD) based on Gigabit Ethernet, because of the closed-source binary-only proprietary support libraries. Two Xeon QuadCore 3.0 GHz processors, 4 GB of DDR3 RAM and up to six Gb/s Ethernet interfaces allow an effective acquisition and processing of up to three CCDs on each Gigabit link.

NETWORK REFLECTIVE MEMORY

A real-time framework tightly integrated in the control system has been implemented. Every control system cabinet is reached both by a standard control/supervisory network and by an Ethernet network dedicated to real-time. The standard Ethernet device driver has been customised in order to be able to transmit and receive raw Ethernet packets from the real-time domain. All the machines involved in real-time activities connect to this network using an additional Ethernet port.

To share the real-time data in a simple end effective way, a software infrastructure called Network Reflective Memory (NRM) has been developed. It consists of dedicated real-time device drivers and threads together with a dedicated API, availabile in both kernel space and user space, which implement the mechanisms of data-transparent memory shared among computers. Currently the device drivers of two families of Ethernet chipsets have been modified to support the NRM: the four channel Gianfar Ethernet Controller used on the MVME7100 and the Intel PRO/1000 used on the 1U rack-mount CCD acquisition servers [6].

The system topology is star shaped. At the centre a master system is in charge of collecting the packets coming from each slave and broadcasts them to all the stations. In order to guarantee the consistency of the shared memory the master broadcast is used as the trigger: upon reception, each slave syncronizes its local copy of the NRM with the data belonging to the master packet and at the same time starts sending its specific data to the master.

The NRM packets are handled in kernel space; the modified Ethernet device driver allows raw access to the interrupt handler and the transmission routines. Two First In Firts Out (FIFO) queues serve the write operations to the NRM coming from kernel space and user space respectively.

The raw packet is forged to comply to the link layer of the TCP/IP model; the header contains the MAC address of the sender and the destination, the timestamp, the sequence number and the CRC followed by the data. The data starts with a 4 bytes header containing the data type, the segment size, and the shared memory offset; the minimum payload size is therefore 4+4=8 bytes. To safeguard the availabile bandwidth shared among all stations, currently 1 Gb/s, the maximum packet size is fixed to 256 bytes for the slaves and could be increased up to the jumbo packet size for the master. Also, the address space of the NRM is limited to 1 MB.

Repetition rates up to 10 KHz are sustainable when the master and the slaves are all connected to the same network switch; otherwise, when the packets have to cross two switches the maximum repetition rate lowers to roughly 5 KHz.

An approximate calculation of the sustainable data traffic could be done considering the size of the master data packet and the usable repetiton rate; the maximum on a single Gbit Ethernet connection spanning at most two hops is roughly 9000 bytes × 5 KHz = 45 MB/s. Without using the jumbo packet payload and at the actual repetition rate, the NRM maximum data exchange rate through for the FERMI@Elettra control system is 1500 bytes × 3.3 KHz ≈ 5 MB/s.

The actual size of the NRM data currently in use is 12 KB at the Linac repetiton rate of 50 Hz, thus the data rate is 12 KB × 50 Hz = 600 KB/s. Moreover, with a NRM refresh rate of 3.3 KHz and a Linac repetition rate of 50 Hz the number of availabile NRM cycles between two shots, e.g. 20 ms, is 65. Considering the worst case of the data payload, 4 bytes data plus 4 bytes header, the number of NRM cycles used in the FERMI@Elettra control system is 12 KB / 1500 / 2 = 16 over 65, i.e. about 25% utilization.

USE CASES

A large number of devices are currently interfaced, i.e. acquired and/or driven, shot by shot:

- Electron/photon beam diagnostics: electron beam position monitors (BPM), photon beam position monitors (PHPBM), current monitors (CM), CCDs, bunch lenght monitors (BLM), beam arrival monitors (BAM), laser power meters, i0 monitors (photon counters), experimental station detectors.
- Power supplies: corrector power supplies, quadrupole power supplies.
- Radio frequency systems: linac low level RF.
- Machine protection systems: Cherenkov optic fibers, ionization chambers.

An example of a real-time FERMI@Elettra application is the Machine Protection System (MPS)[7][8]. An Equipment Controller [9] is in charge of monitoring the radiation levels along the undulator chain to avoid damaging the permanent magnets. For this purpose a number of Cherenkov optic fibers have been placed into appropriate grooves along the undulator magnets.

The waveform signals coming from the Cherenkov fibers front-ends are synchronously acquired shot by shot by a Caen V1720 VME digitizer at 250 MHz sampling rate.

A signal processing algorithm, running in real-time, analyzes the waveforms and, when over a predefined threshold, drives a digital output line requesting the switching off ot the electron beam to the MPS PLC.

Moreover, in order to monitor the operation of the software routines inside the VME system, a keep-alive signal with the repetition frequency of 50 Hz is transmitted from the VME to the PLC.

The same VME system is also in charge of the acquisition of the current monitors in real-time through a dedicated Ethernet network. Also in this case the algorithms to calculate the charge loss run in real-time on a shot by shot basis and the results are used to drive the inputs of the MPS PLC.

CONCLUSIONS

The Adeos/Xenomai realtime subsystem has been adopted to achieve hard real-time performances on GNU/Linux based systems running on PowerPC and x86 processor architectures. The measurements show that even loaded systems behave very well with the advantage of the programming API availabile in user space. The NRM has beed designed to share small amounts of data in real-time, i.e. with a known and reproducible latency, in a transparent and cheap way, leveraging the standard Gigabit Ethernet hardware. The hardware, the network topology, the software implementation of the data transmission make the NRM a good candidate for real-time distributed applications with repetition rates in the range of some hundreds of Hz and data size of tens of KB.

Abstract

FPGAs are now large enough that they can easily accommodate an embedded 32-bit processor which can be used to significantly extend the capability of an FPGA system. Running embedded Linux gives the user many more options for interfacing to their FPGA-based instrument, and in some cases this enables removal of the middle-person PC. It is possible to manage the instrument directly by ModBus (130 Hz poll rate and 6.6ms latency) and StarkStream (42 MB/s transfer and 83 MB/s raw throughput), and use these protocols as a low level layer to communicate with EPICS or TANGO. Additionally it is possible to use the embedded processor to facilitate remote updating of firmware which, in combination with a watchdog and network booting ensures that full remote management over Ethernet is possible.

INTRODUCTION

Embedded Linux is a very powerful tool on FPGA instruments. The reason for this is that the embedded processor is directly coupled to the FPGA logic thus giving full control using Linux. By using high level tools it is possible to create very complex systems that do not require VHDL or verilog code to be written. With a soft processor all of the logic is embedded in the FPGA, thus abstracting the design from the hardware and making it more portable helping to prevent system obsolescence.

This paper demonstrates the versatility of embedded Linux combined with two protocols: i) a low latency UDP protocol called StarkStream, ii) the widely used Modbus TCP PLC protocol. Also discussed is the strategy for inclusion to complex control systems.

EMBEDDED LINUX

Many devices now incorporate embedded Linux. The main reason for this is access to a large amount of open source software supporting a large number of hardware devices. Embedded Linux has existed on FPGA devices for at least 5 years with the Xilinx Microblaze processor currently supported in the mainline Linux kernel tree and the Altera Nios II also having a Linux port. Recent developments in the last year include support for the AXI bus which has enabled much faster data rates coupled with the use of DMA enabled drivers thus making embedded Linux more powerful than it has been before.

HIGH LEVEL TOOLS

High level tools are a very significant timesaver in developing FPGA applications and likely justify their cost. They allow access to complex DSP logic blocks such as FFT, CORDICs, etc. We have found that the MATLAB Simulink environment is very good for producing FPGA products as it has a completely open environment in which it is possible to access all the pins of the FPGA and use them in any way desired. For Xilinx FPGAs the tool is called System Generator and for Altera FPGAs the system is called DSP builder. System Generator even allows you to compile a portion of logic code and compile it as a hardware component (PCORE) of the embedded processor. This extremely useful function greatly simplifies the integration with the processor - the result is that this can be done without writing any code but solely through the use of a GUI.

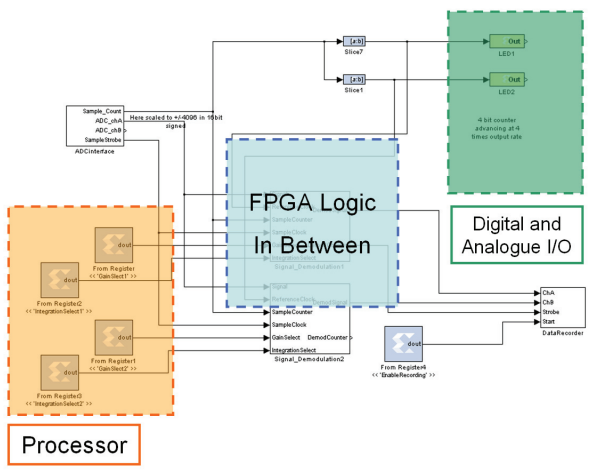

Figure 1: The high level MATLAB Simulink environment used for developing FPGA logic. In this figure the processor logic drives the FPGA logic which in turn drives the digital and analogue I/O. The digital flow can also be reversed to feed back or run completely independently of the processor.

* This work was part-funded by the RCUK Energy Programme under grant EP/I501045 and the European Communities under the Contract of Association between EURATOM and CCFE.

AXI BUS

The AXI bus is an open on-chip bus. It is used by ARM, Xilinx and becoming more widely supported on Altera FPGAs. It is a very fast bus with separate read and write channels thus allowing uninterrupted data flow in both directions. It can be driven at beyond 200 MHz at 256+ bits wide which allows 51.2+ Gbps transceivers.

It is only with the AXI bus that we have been able to achieve high speed on compact systems - achieving up to 10 GB/s in our continuous data streaming application.

STARKSTREAM

StarkStream is a high speed UDP protocol. It runs on embedded Linux, and sits inside a DMA ethernet enabled driver. With interrupts on both the transmit and receive lines it is very quick to respond to sending and receiving input packets. The principle for systems using this protocol is that the FPGA board must respond as quickly as possible to any read/write requests over StarkStream.

Despite the fact that the Microblaze is only running at ∼83 MHz it is still able to achieve very high raw throughput (83 MB/s) and continuous data transfer rates (42 MB/s) that may not be expected with a soft processor. The reason for the high speed is an AXI DMA bypassing the processor for memory transfer.

Even faster speeds could be achieved by embedding the UDP packet header around the data to be transmitted. This would require FPGA logic change to add this header (no more than 64 bytes) to each 1kB up to 8kB data payload. But then the consideration has to be that the net throughput rate also depends on the receiving side, which may become the limiting factor.

REMOTE MANAGEMENT

Remote Reboot Control

Remote power control of an FPGA system is crucial for two reasons: i) Many FPGA boards are designed such that the new firmware will only be loaded once a power cycle has been performed. ii) An FPGA system with an embedded processor may have a processor which crashes (as can happen to a standard PC running an operating system). In order to be able to have full control over this we take advantage of the ATX power supply which has two critical elements, a permanent standby low current (∼100 mA) supply when the power is off and circuitry for enabling/disabling the power.

Watchdog

An Embedded Linux controlled watchdog with the poll code implemented in the heartbeat section of the kernel ensures that in the event the Linux crashes the system will automatically reboot in 5 minutes.

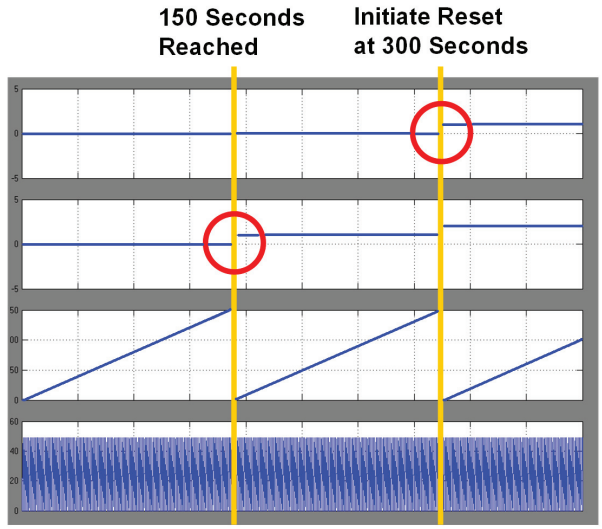

Figure 2: A Simulink simulation of the FPGA watchdog code which shows the counting ramp with a reset/reboot signal initiated after the processor has failed to poll the watchdog for 300 continuous seconds.

REMOTE FIRMWARE UPDATES

The remote firmware update uses the embedded Linux to access the storage area of the firmware (generally flash). Using embedded Linux on the FPGA provides a standard interface for updating FPGA firmware. By relying on the Linux drivers it is not necessary to develop custom drivers thus saving a lot of development time. A standard script is used to write to the specific flash locations to perform the firmware update. The system is then power cycled using the remote reboot control capability.

PLC MODBUS CONTROL

On Linux one can use the Modbus library [1] to create Modbus compatible systems. Modbus is one of the most widely supported PLC communication protocols but other protocols can similarly be adapted to the embedded Linux in a similar way.

Having embedded Linux on an FPGA systems allows it to behave as either a PLC master or slave. This gives a huge amount of flexibility to an FPGA systems adding yet another remote management interface. Since the FPGA system is running embedded Linux there is the possibility to perform other communications (HTTP/SSH/etc) in addition to PLC communications.

Latencies of 6.6ms with 0.38ms deviation (with 995 tests) have been achieved. An error rate of 3.4×10^{-6} errors/write found after approximately 35 million writes. An error is not a catastrophic failure in that the PLC master will just attempt the write again if a failure (such as a timeout) occurs. An average poll rate of 130 Hz is achieved over a period of 72 hours, resulting in a long term polling rate of at least 100 Hz.

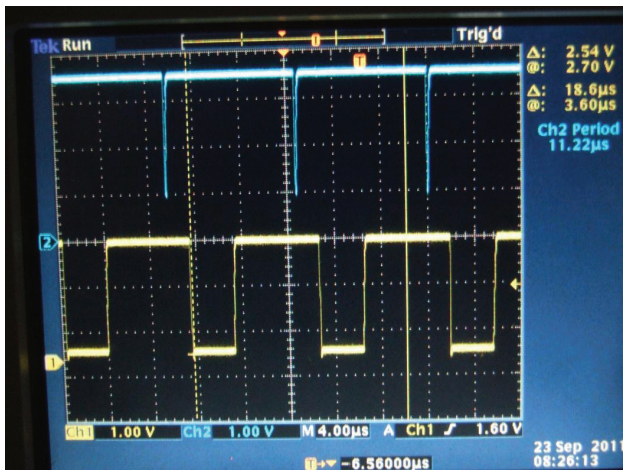

Figure 3: An oscilloscope screenshot of the Modbus FPGA System, with a configurable pulse delay and length controlled by a Schneider Modicon Quantum 140-CPU-651-60 PLC using Modbus.

DEVELOPMENT STRATEGY

EPICS and TANGO

EPICS and TANGO [2] are widely used control systems so developing an FPGA system with this capability would be useful. Some control systems have been designed to communicate over Modbus to EPICS [3, 4, 5] and TANGO [6, 7]. On an FPGA system with a soft processor the limiting factor is the processor speed since EPICS and TANGO are not lightweight. As such future development will initially involve an intermediate protocol (such as Modbus or StarkStream).

Embedded System Development

Using a generic layer between the processor and FPGA logic, it will be easier to create systems that incorporate embedded Linux with minimal effort. The goal is to have a capability to easily "drag-in" embedded Linux and synthesis the system in one step.

CONCLUSIONS

Embedded Linux has been used as a powerful tool for developing more capable FPGA systems using a standard operating system to integrate with custom FPGA logic easily using high level tools such as the MATLAB Simulink environment with the FPGA front end tools (Xilinx System Generator or Altera DSP Builder).

The AXI Bus has been used to achieve fast streaming rates (up to 10GB/s) with memory shared between the FPGA logic and the processor. Remote management has been achieved using embedded Linux to communicate over the StarkStream and Modbus protocols. In future these protocols can be incorporated with standard control systems such as EPICS and TANGO. Full remote system control has been improved by enabling firmware updates and power cycling using embedded Linux and an ATX power distribution board.

Abstract

A low-level RF controller has been developed for the accelerator controls for SuperKEKB, Super-conducting RF Test facility (STF) and Compact-ERL (cERL) at KEK. The feedback mechanism will be performed on Virtex-5 FPGA with 16-bit ADCs and DACs. The card was designed in the form-factor of an advanced mezzanine card (AMC) for a MicroTCA shelf. An embedded EPICS IOC on the PowerPC core in FPGA will provide the global controls through channel access (CA) protocol on the backplane interconnect of the shelf. No other mechanisms are required for the external linkages. CA is exclusively employed in order not only to make the AMC cards to communicate with each other, but also to communicate with central controls and with an embedded IOC on a Linux-based PLC for slow controls.

INTRODUCTION

The low level radio frequency (LLRF) is one of the crucial facilities to enable the high precision and high stability of the particle accelerator beams. There are several accelerator projects planned at KEK. New projects are always demanding to achieve higher experimental results, and the LLRF control should play an important role there. After the recent development at KEK the digital LLRF controls are well accepted, and three accelerator projects began to share the developments, namely Compact ERL (cERL) as a demonstration machine for the future energy recovery linac (ERL), SuperKEKB for B-physics study, and Superconducting RF Test facility (STF) for the international linear collider (ILC). They are sharing a single LLRF controller design.

In order to achieve a higher stability for better beam quality fast digital feedback or feed-forward mechanisms are utilized on those LLRF controllers. A field programmable gate array (FPGA) is employed to carry those tasks with high precision ADCs and DACs, and it would maintain the stability of RF cavities that are covered by the controller.

On the other hand, global controls are indispensable in order to achieve overall performance of those accelerators. Sensor signals from beam instrumentation are analyzed and applied to actuators along the accelerator to improve the beam quality. Among those actuators LLRF is the fastest and the most important. Thus, the LLRF controller needs to be designed with global control capability in mind from the beginning. Globals controls are provided by EPICS (experimental physics and industrial control system) in these accelerators [1].

We designed the LLRF controller for three accelerator systems with MicroTCA platform and embedded EPICS. Even a single LLRF controller card can perform the same EPICS control functions as other I/O controllers.

* < kazuro.furukawa @ kek.jp >

LLRF CONTROLLERS AT KEK

Digital LLRF controllers were developed at KEK since 2003, and it was applied for J-PARC linac at first [2]. It was based on CompactPCI platform, and has been performing well. Based on the experiences at the J-PARC linac, LLRF controller on an advanced telecommunication computing architecture (ATCA) platform was designed for STF, because ILC chose ATCA as a possible control platform [3]. Management facilities provided by ATCA were indispensable to achieve reliable controls even with large number of accelerator components. Actually, the large board area provided by ATCA standard was adequate to accommodate a number of analog control and monitor circuits which were required by the baseline clustered klystron scheme of ILC.

The ATCA standard includes the advanced mezzanine card (AMC), and for example LLRF controllers at DESY employed AMCs on ATCA carrier card, instead of a direct ATCA card. When the LLRF controller for cERL was designed, the standard of MicroTCA was just finalized, based on AMC. The size of the standard AMC card was just enough for the small number of analog circuits at cERL. Then, MicroTCA was chosen for cERL LLRF [4]. It aimed at the future stability of 0.01 % in amplitude and 0.01 degree in phase.

It turned out that the LLRF controller at SuperKEKB shared the same requirements as one at cERL, and it was decided at SuperKEKB to employ the same design of LLRF controller [5].

Later, a new RF system configuration of distributed RF system (DRFS) was adopted at STF in the framework of S1 Global. It does not require a large card size any more compared with the clustered klystron scheme. Thus, the same LLRF card will be utilized at STF as well [6]. The choice of the controller platform at three projects above followed the synergy of the previous developments, and MicroTCA was chosen.

Computing Platforms and MicroTCA

The ATCA standard was defined in 2003 for a new computing standard for telecommunication and industry as a descendant of CompactPCI standard which was used since 1993. ATCA employed a large card area for high-performance computing, many serial interconnects on the backplane, 2.5 Gbps each, for larger bandwidths and IPMI surveillance and remote management facility for higher reliability. Even though it was designed for telecommunication and industry, the design approach of ATCA was considered adequate for ILC controls.

AMC mezzanine card was included in the ATCA standard, and AMC itself inherited many of good part of ATCA. Later in 2008, MicroTCA was standardized with direct slot-in AMC cards. As embedded controllers became smaller with the evolution of FPGA technologies, MicroTCA is considered one of the proper embedded platforms.

Both of the ATCA and MicroTCA backplanes allow fast serial communication such as Gigabit Ethernet (GbE) and PCIe. If we choose GbE as a communication media, a switch module in the box can transfer packets directly to the external networks. In MicroTCA the switch is called MCH (MicroTCA Carrier Hub), and it connects the serial backplane interconnect to an external network through a layer-2 switch.

GLOBAL CONTROLS WITH EPICS

The accelerator control architecture in KEK evolved in several steps in the past. Some time ago several control systems were standardized with a combination of several fieldbuses, VME field computers, and Unix computers. In order to consolidate the efforts on the development and maintenance some of the fieldbuses were gradually removed and many controllers were directly attached on to IP networks [7].

At the same time EPICS (Experimental Physics and Industrial Control System) control software framework was employed at several control systems at KEK. Eventually, many controllers evolved to embed the same EPICS software as on VME field computers. The EPICS component on those field computers is called IOC (Input/Output Controller), and it communicates with others using a common protocol called Channel Access (CA). We call this embedded EPICS framework as "CA Everywhere", and it enabled the both rapid development and smooth maintenance.

Several different kinds of controllers have been developed in the framework of CA Everywhere, and they greatly reduced the control efforts and improved the reliability [8].

LLRF CONTROLLER WITH EPICS CA EVERYWHERE

As described above MicroTCA can accommodate GbE and TCP/IP on the backplane interconnect directly. In addition, many field controllers recently employ the idea of CA Everywhere to embed EPICS IOC software at KEK. Thus, it was rather natural to design the new LLRF controller with embedded EPICS IOC software, and make it connect with the global control network with EPICS channel access protocol directly through the backplane as in Fig. 1.

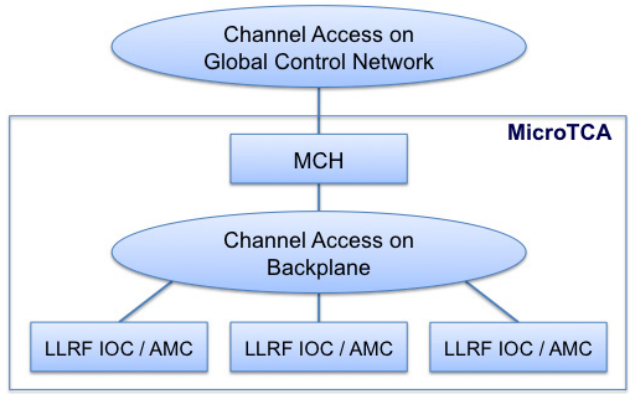

Figure 1: EPICS IOC software is embedded in controller cards and EPICS channel access protocol is used everywhere.

The PowerPC CPU in Virtex-5 FPGA on the LLRF controller runs Linux 2.6.21, and EPICS IOC 3.14.9 is embedded. The Linux kernel is booted from the on-board flash memory. On the other hand EPICS IOC software is loaded from a NFS file server, as the software can be improved frequently. Device support software to link between FPGA and IOC was developed using mmap() interface.

Hardware Features

The controller module was fabricated in a single-width full-height AMC module with two analog boards and a digital board, as shown in Fig. 2. The analog boards comprise four channels of 16-bit 130 Msps ADCs, four channels of 16-bit 500 Msps DACs. The digital board accommodates a Xilinx Virtex-5 FXT FPGA with PowerPC-440 hardcore CPU, 640MB RAM, 64MB flash memory, digital I/Os, IPMB, and GbE. IPMB (intelligent platform management bus) is used to manage the AMC in order to improve the reliability.

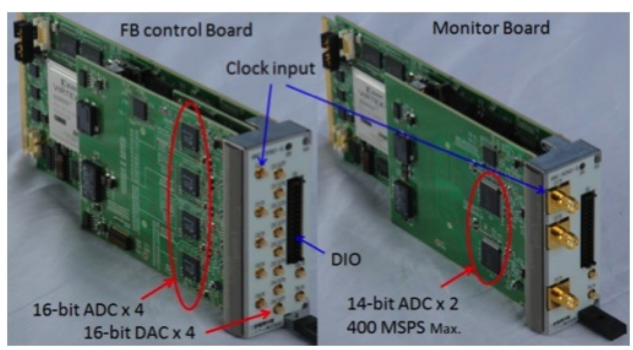

Figure 2: LLRF controller and monitor cards.

The digital part was designed based on the evaluation board of Xilinx ML507. The software for the controller was initially developed on ML507, and the main part of Linux implementation was provided by Wind River Linux 2.0.

Besides the feedback controller card, a LLRF monitor card was designed with the same digital board but with another analog board of two channels of 14-bit 400 Msps ADCs.

Other EPICS Embedded Controllers

Slow controls for cavity vacuum and so on are provided by a PLC system. It is equipped with Yokogawa's F3RP61 CPU with Linux 2.6.26, and EPICS IOC 3.14.11 is embedded on it.

The machine protection system at cERL employed a modular system which is served by a commercially available FPGA card. The card consists of Xilinx Virtex-4 with PowerPC and Linux 2.6, that embeds EPICS IOC 3.14. This card is used for other controllers as well.

The same protocol and the same software environment are shared between LLRF controllers and external servers and clients. That enables a reliable control system. The system structure is described in Fig. 3.

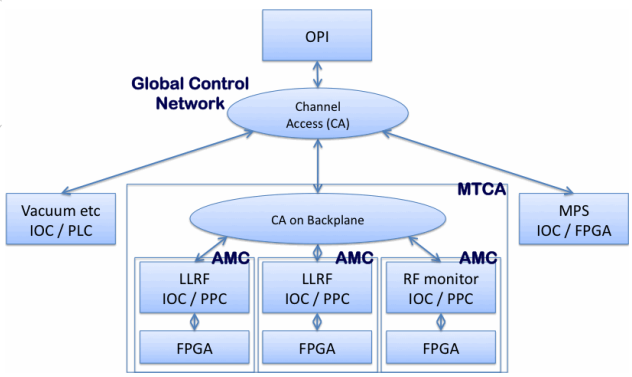

Figure 3: LLRF controller AMC cards can communicate locally on the MicroTCA backplane interconnect and globally through normal IP networks both using EPICS channel access protocol.

Enhancement Possibility

MicroTCA inherits several mechanisms from ATCA to enhance the availability, which can be utilized in order to improve the reliability of the LLRF system. Redundant power supplies, MCHs and CPUs are being evaluated as in Fig. 4. Presently, processes in LLRF system is carried on the IOCs on controllers. Additional CPU modules can be introduced into MicroTCA box to facilitate local processes among several controllers. We may run EPICS redundant IOCs on those redundant CPUs to enhance the reliability further [9].

After this controller was developed, the MicroTCA physics extension (MTCA.4) was defined. This platform may relieve the busy set of three circuit boards in the controller. We may utilize this new standard in the future.

Figure 4: Redundant CPUs, MCHs and power supplies are evaluated as a possible future extension.

The combination of fast ADCs, DACs and FPGA may serve as a general controller. As a connection to global EPICS controls was also provided, this controller can be applied for many different purposes in machine controls. Actually, the same controller card is evaluated for a specific beam monitor at SuperKEKB.

CONCLUSION

As a natural consequence of several developments at KEK, a LLRF controller in MicroTCA AMC with EPICS CA protocol on the backplane interconnect was developed. All controllers embed EPICS IOC to share the same software and protocol both locally and globally for rapid developments and smooth maintenance, including auxiliary controllers with PLCs and FPGA modules. This LLRF system is being applied to three accelerator projects of SuperKEKB, cERL and STF at KEK.

Abstract

The Multi-threaded Application Real-Time executor (MARTe) is a C++ framework that provides a development environment for the design and deployment of real-time applications, e.g. control systems. The kernel of MARTe comprises a set of data-driven independent blocks, connected using a shared bus. This modular design enforces a clear boundary between algorithms, hardware interaction and system configuration.

The architecture, being multi-platform, facilitates the test and commissioning of new systems, enabling the execution of plant models in offline environments and with the hardware-in-the-loop, whilst also providing a set of non-intrusive introspection and logging facilities. Furthermore, applications can be developed in non real-time environments and deployed in a real-time operating system, using exactly the same code and configuration data.

The framework is already being used in several fusion experiments, with control cycles ranging from 50 microseconds to 10 milliseconds exhibiting jitters of less than 2%, using VxWorks®, RTAI or Linux. Codes can also be developed and executed in Microsoft Windows® and Solaris®.

This paper discusses the main design concepts of MARTe, in particular the architectural choices which enabled the combination of real-time accuracy, performance and robustness with complex and modular data driven applications.

INTRODUCTION

MARTe [1] is a framework tailored at the design and development of real-time control systems. The kernel of MARTe uses a C++ multi-platform library named BaseLib2 [2]. The main ideas behind the original design of the framework were the modularity and portability of its applications. In particular, a strong effort was made in order to allow a robust simulation environment that allows both the models to be simulated with the hardware in the loop and the control algorithms to be validated offline.

This is achieved by providing a clear development boundary between the algorithms, hardware and system configuration. Being multi-platform it also allows to debug and develop in non-real-time environments, where better developing tools are usually available. Currently the framework runs in Linux, Linux with RTAI [3], VxWorks® for PowerPC®, Solaris® and Microsoft® Windows™.

The framework components are configured using a common language, designed to be as simple as possible, but complete enough to provide a clear way of describing the problem. The structure is similar to XML, where the syntax rules are validated by a BaseLib2 parser, whereas the actual validity of the arguments is performed by the component (i.e. no validation schema is available). An example of a configuration is shown in Listing 1.

The configuration file is translated into a database of named objects that can be browsed using the object addresses in the database. By parsing the configuration file, the framework automatically creates and configures instances of all the declared objects. A messaging mechanism uses the database to provide a standard interface for communication between objects. This is the preferred

mechanism to interface MARTe objects with other systems and protocols.

MAIN COMPONENTS

A MARTe application is designed by configuring and connecting a series of blocks named Generic Application Modules (GAM). These modules contain an entry point to receive data driven configuration and a set of data-driven optional input and output channels to interface with other GAMs. Each of these channels has a unique name and is connected to a generic memory data pipeline, named Dynamic Data Buffer (DDB). Before starting the execution of the application, MARTe guarantees the coherency of the DDB by checking that all GAMs have the requested inputs being produced by another GAM. This scheme enables to design interchangeable and generic modules, that can be used in different projects without knowing any details or imposing any restrictions in the data producer. Moreover, this is also the key design concept which enables to replace a part of the system by a set of simulation GAMs, without changing the other modules, a very important feature when testing and designing a new control system, before introducing the hardware in the loop, and later in the commissioning of new hardware if good models of the plant are available. An example is shown in Fig. 1. A large set of generic GAMs is available to be used in any MARTe application (e.g. PID, waveform generation, live data view, data collection, data statistics).

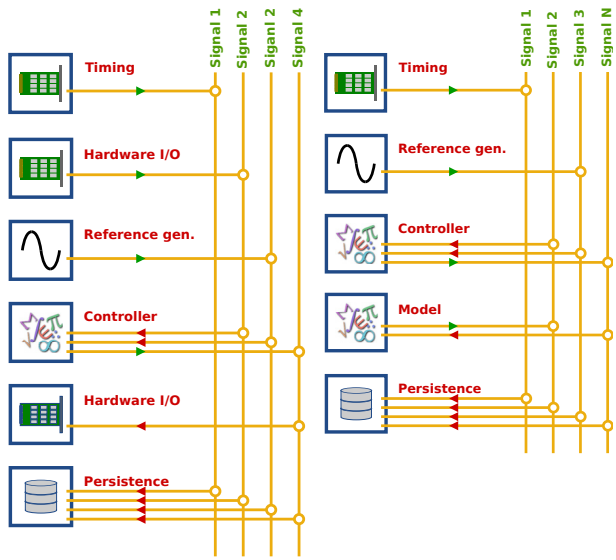

Figure 1: Example of a set of GAMs connected to the DDB. A timing and an hardware GAM provide the I/O interface to the outside world, whereas a generic waveform GAM inputs the reference for a PID controller. Finally, the output is sent to a DAC and the data is stored for analysis by a collection GAM. The picture in the right shows how the same system can be developed using a model of the plant. It should be noticed that the reference generation and the controller GAM are not aware of the changes in the data providers and data consumers.

A special GAM, named IOGAM, enables the connection of any hardware to the DDB, as long as a MARTe high level driver is developed to provide the connection between the IOGAM and the hardware interface (usually through an operating system low level driver). GAMs are sequentially executed, at a given frequency, by a real-time thread. Several real-time threads can be connected, both synchronously and asynchronously, and executed in parallel.

A real-time thread cycle is triggered by an entity named external time triggering service (ETTS). The ETTS is connected to a time provider and checks that the current time is a multiple of the configured MARTe cycle time. When this condition holds true a new cycle is signalled. Two types of ETTS are available: one based in hardware interrupts and another based in the polling of a resource (e.g. shared memory entry). The synchronisation scheme will issue an alarm if a timeout occurs, either due to a slow execution of the control cycle (e.g. a GAM is consuming too much time and the cycle finishes after its period has already elapsed) or if the jitter in the timing source is very high. MARTe

provides some ready to be used synchronisation schemes based in CPU timers and in network inputs.

Taking advantage of the new multi-core processors, the framework enables all of its tasks to be allocated to a specific subset of cores. In Linux, using the special *isolcpus* kernel parameter, it enables to have an isolated real-time execution environment for the real-time threads with jitters in the order of the microseconds [4].

INTERFACING WITH MARTE

All MARTe objects are setup using the configuration mechanism described above. The framework makes no assumptions on how these files are produced and does not impose any communication protocol on how these should be transmitted. A standard C++ interface, with all the infrastructure from the MARTe side implemented, is available for the development of new communication mechanisms. Currently, for systems outside JET, the only ready to be used configuration mechanism is based in the HTTP protocol, although the preferred way of interfacing with MARTe components is to use the message mechanism introduced before. In order to integrate the framework in different environments, the required protocols are translated into messages and broadcast to the destination objects. An example of such integration can be found in [5].

The framework also provides its own HTTP server, capable of browsing and introspecting any of the installed objects. The server was designed to minimise any impact with the real-time activities, by carefully executing all of its activities in low-priority tasks and, in the case of multi-core environments, in cores not allocated for the real-time threading. This scheme enables GAMs to publish run-time execution information about the internal state of algorithms and data.

MARTE SYSTEMS

As shown in Table 1, a large number of control systems is already using MARTe to solve different control problems [6]. These systems are key to the operation of large experiments, and some have an active role providing a first line of defence for the protection of the machine itself. The framework is installed in different experiments, with different configuration and data retrieving protocols.

The most frequent operating systems are Linux, running in Intel® and AMD® processors with isolated cores, and VxWorks® running in PowerPC®. The frequency of execution spans from 100 Hz to 20 kHz. Some modules, like the waveform generation, data collection and data statistics are shared by all projects.

The COMPASS control system [8], depicted in Fig. 2, was the first to exploit the capability of running multiple real-time threads at different frequencies. The fastest thread executes at 20 kHz and starts by reading the data from the analogue input channels, followed by a drift compensation (due to the use of integrators). Data is then filtered and sent to the second, slower, thread running at 2 kHz. In parallel, the fastest thread controls the horizontal and vertical magnetic fields, while the slower thread is responsible for the control of the plasma current and position. Since the hardware is the same used by the JET vertical stabilisation, the only GAMs that had to be developed concerned the plasma control.

Table 1: Systems using MARTe

Name	Cycle time	O.S.
JET Vertical Stabilisation [1]	50 µs	Linux-RTAI

JET Plasma Wall Load System	10 ms	Linux

CONCLUSIONS

MARTe is C++ real-time framework designed for the development and deployment of control-systems. It is already being used in several experiments to solve different problems that require different operational frequencies and hardware interfaces. Currently it is only being used in magnetic confinement nuclear fusion experiments, but there is not reason why it cannot be deployed in any context where a real-time control system is required.

DEVELOPMENT OF THE MACHINE PROTECTION SYSTEM FOR LCLS-I*

J. Dusatko#, M. Boyes, P. Krejcik, S. Norum[1], J. Olsen
SLAC National Accelerator Laboratory, Menlo Park, CA 94025, U.S.A.

Abstract

Machine Protection System (MPS) requirements for the currently operating Linac Coherent Light Source (LCLS-I) demand that fault detection and mitigation occur within one machine pulse (1/120th of a second at full beam rate). The MPS must handle inputs from a variety of sources including loss monitors as well as standard state-type inputs. These sensors exist at various places across the full 2.5Km length of the accelerator and beam lines. A new MPS has been developed based on a distributed star network where custom-designed local hardware nodes handle sensor inputs and mitigation outputs for localized regions of the LCLS accelerator complex. These Link-Nodes report status information and receive action commands from a centralized processor running the MPS algorithm over a private network. The individual Link-Node is a 3u chassis with configurable hardware components that can be setup with digital and analog inputs and outputs, depending upon the sensor and actuator requirements. Features include a custom MPS digital input/output subsystem, a private Ethernet interface, an embedded processor, a custom MPS engine implemented in an FPGA and an Industry Pack (IP) bus interface, allowing COTS and custom analog/digital I/O modules to be utilized for MPS functions. These features, while capable of handling standard MPS state-type inputs and outputs, allow other systems like beam loss monitors to be completely integrated within it. To date, four different types of Link-Nodes are in use in LCLS-I. This paper describes the design, construction and implementation of the LCLS MPS with a focus on the Link-Node, which has proven to be a very useful and flexible component for the MPS.

HISTORICAL PERSPECTIVE

The SLAC National Accelerator Laboratory accelerator complex has hosted several different Machine Protection Systems throughout its varied history. The original 1960s era SLAC Linac contained two protection networks [1]. The primary one, capable of responding within 1ms, consisted of a transmitter broadcasting two tones through a network of series connected Tone Interrupt Units (TIUs) to a receiver unit, which gated beam production on/off at the injector. The TIUs used mechanical relays actuated by various system sensors, so that if a sensor tripped, the tone signal path would get interrupted, inhibiting triggers and indicating a fault alarm.

The SLAC Linear Collider (SLC) era in the 1980s ushered in a more sophisticated MPS [2] where programmable logic algorithms and more sophisticated sensors allowed automatic limiting and control of beam repetition rates without switching off the entire accelerator. This system was based on both CAMAC and VME bus platforms and used the MIL-STD-1553 serial bus standard as a fast, dedicated link between the sensor units and fault processor units. This became known as the "1553 MPS". It interfaced with the accelerator timing system, dictating beam rates to it. The 1553 MPS was largely independent and parallel to the TIU MPS.

The development of LCLS-I presented a unique opportunity and challenge to replace both of these legacy systems by combining and integrating their functionality. The new LCLS-I MPS had to connect to legacy accelerator systems as well as to completely new installations built solely for LCLS-I. The development effort also provided the opportunity to use modern technology.

THE LCLS-I MPS

SLAC is building a second facility, LCLS-II, so we now refer to the present machine as LCLS-I. The LCLS-I Free Electron Laser is a pulsed machine with a maximum repetition rate of 120Hz. LCLS-I uses the last 1/3rd of the SLAC LINAC, the existing switchyard beamline and then extends this to a newly constructed undulator hall e-beam dump, photon transfer lines and experimenter areas. An overview of the LCLS-I MPS is given in [3]. The system requirements for the LCLS MPS [4], state that the MPS will only turn off the electron beam and not any other devices. In addition to turning off the beam, this system also needed to be capable of rate limiting beam production upon certain conditions. System inputs include standard (mechanical and electronic switch state) sensors (e.g. valve position) as well as direct input from beam loss detectors. Presently the input device count is approximately 2100.

The LCLS MPS has outputs to control beam mitigation and shutoff actuators. These devices are mechanical shutters at the photoinjector laser and laser heater, as well as the gun timing trigger permit. Another mitigation device is a fast pulsed kicker magnet located just prior to the undulator magnet string.

The minimum required response time (sensor in to mitigation out) is 8.3mS. As implemented, the system actually samples, processes and acts on sensors at 2.78ms.

The architecture is that of a star network with a central MPS Link Processor connecting to individual Link-Node units. The interconnect channel is a private Gigabit Ethernet network which uses commodity Ethernet switches (Cisco Catalyst 3750). The Link Processor (LP)

*Work supported by U.S. Department of Energy under Contract Nos. DE-AC02-06CH11357 and DE-AC02-76SF00515.
[1]Now at Varian Medical Systems, Palo Alto, CA
#jedu@slac.stanford.edu

implements the MPS algorithm and is responsible for all decision making based on the states of device inputs it receives from each of the Link-Nodes (LN). The LNs provide the I/O interface between the MPS and the outside world; with a LN connecting to sensors (input devices) and mitigation units (output devices). The LP (a Motorola MVME-6100 CPU) also communicates rate limiting commands to the LCLS Timing System [5] via a point-to-point Ethernet link. It receives timing pattern and fiducial information from the timing system by way of a connected timing Event Receiver (EVR) module. The EVR (MicroResearch Finland PMC-EVR-200) generates an interrupt to the LP at the timing system 360Hz fiducial rate. The LP also connects to the regular control system Ethernet network (via a second Ethernet port) for status and control communication.

Communication between the LP and LNs over the private Gigabit Ethernet network uses the UDP protocol. The upper layers of the Ethernet protocol were not used in order to keep the overhead low. The communications sequence is as follows: 1) The LP is woken up by the 360Hz interrupt generated by the timing fiducial received by the EVR. 2) The LP sends a sync broadcast message to all LNs, asking them to return their status. 3) The LNs then send their device state status information to the LP. 4) The LP sends a permit command message telling specific mitigation devices to actuate based on the previous (one 2.78ms tick) sensor status. 5) The LP processes the new status and sends out a status clear message back to the LNs, telling them to clear any latched faults. 6) The LP, based on its algorithm, processes the current sensor states and decides if mitigation devices need to fire on the next fiducial. 7) The LP then waits for the next interrupt. Software and FPGA watchdogs ensure a fail-safe communications link. A maximum of 254 LNs can be connected to the LP. The LN IP address is set with DIP switches. Packet size is modest (< 1000 bytes) and the data payload is small enough to handle communications at 360Hz without dropped or split packets. Maximum link communication times were calculated and later empirically confirmed (< 1ms). The LNs also connect (via its embedded CPU) directly to the control system network for control, status and housekeeping.

THE LINK-NODE

The Link-Node is the central functional element of the LCLS MPS and its unique design merits further elucidation. In order to accommodate a variety of input signals distributed across the full accelerator complex, a local signal collection and processing point was required. It was desirable to develop a solution that could accommodate a variety of inputs, which led to the idea of a modular platform. Several crate-based platforms were considered including VMEbus and micro-TCA. The chassis design ultimately won out based on cost and the need for customizability. This gave a common platform that could be configured in multiple ways with low overhead. A block diagram of the Link-Node chassis is given in Fig. 1. The chassis consists of several circuit boards, and depending upon the flavour of LN (Mitigation, BLM, PIC, ByKIK) the configuration and types of these boards varies. The general functions of each of these boards will now be described

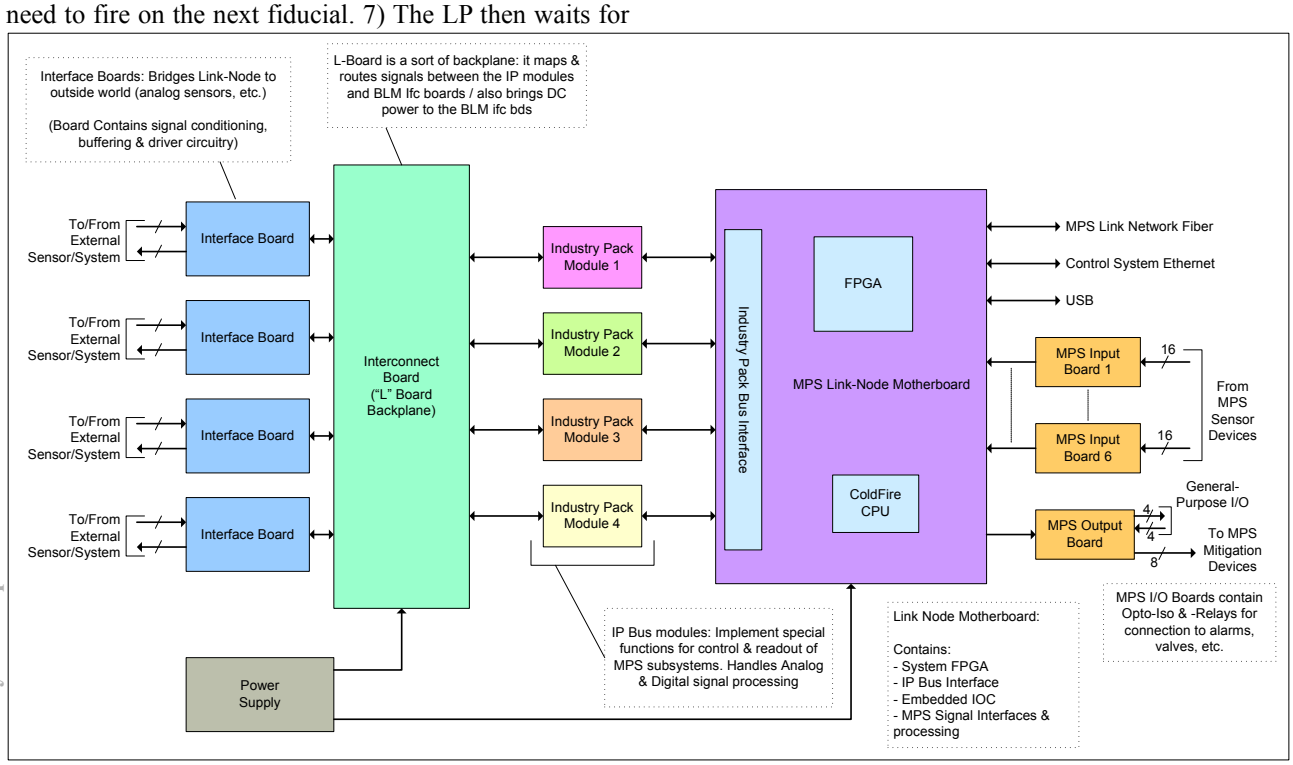

Figure 1: MPS Link-Node Block Diagram.

Motherboard

The Motherboard (MB) contains the main functions of the LN chassis. It contains a Xilinx XC4VFX20 Virtex-4 FPGA, a ColdFire embedded CPU (Arcturus Networks uC5282), the MPS digital I/O interface, a USB 1.0 interface and the Industry Pack bus interface. The USB interface permits local control and status readout for development and maintenance purposes. The FPGA implements the MPS engine, the private Ethernet interface (using its embedded MAC and Rocket I/O cores), the USB interface and the IP bus interface. The MPS sensors and mitigation devices connect to the motherboard via the MPS Digital Input and MPS Digital Output boards, respectively.

Input and Output Boards

The MPS Digital Input Board accommodates 16 optically-coupled inputs. It is capable of supplying up to 2A of fuse-protected standard +24VDC for interface logic. A total of six Input Boards can be installed into the MB, giving the L-N chassis up to 96 digital inputs.

The MPS Digital Output Board contains eight optical relay outputs for driving mitigation devices. It is also provides up to 1A of fused +24VDC for interface logic. The MB can accommodate only one Output Board. This board also contains four each, general-purpose digital inputs and outputs; available on Lemo connectors. The inputs are 50Ω terminated TTL compatible schmitt-trigger types, while the outputs are high current TTL drivers, capable of driving up to 67mA into 50Ω. These I/Os are configurable for different functions inside the MB FPGA and are used for dedicated I/O in the BLM, PIC and ByKIK L-N models.

Industry Pack Interface and Modules

A standard Industry Pack (IP) Bus interface is available on the MB that can accommodate up to four IP modules. This interface allows the use of custom and COTS IP modules to enable a signal processing, status and control path between sensor elements and the MPS. With this capability we can completely integrate a sensor readout subsystem within a LN chassis. This enables the MPS to directly connect to the beam loss and pulsed kicker magnet systems. The IP bus side of the IP modules connect to LN MB, while the I/O side of the IP modules connect to the L-board. The IP modules receive their power from the MB. The type of IP board used depends on the flavour of LN, and can be analog and/or digital I/O.

L-Board and Interface Board

The L-Board, so named for its physical shape, is essentially a backplane that provides interconnect and power between the IP modules and the interface boards. There is one L-Board per chassis. It contains mostly connectors for power, the IP and Interface boards and I/O of key IP module signals. To date, two L-boards have been designed: the BLM and PIC L-boards.

The Interface Board contains signal conditioning, receiver, driver and protection circuitry that bridges the LN to external devices. It receives its power from the L-board. The Interface Board is application-specific and to date, two Interface Boards have been designed: the BLM and PIC Interface Boards.

Motherboard FPGA

The MB FPGA implements the core functions of the LN. A block diagram of the FPGA is given in Fig. 2.

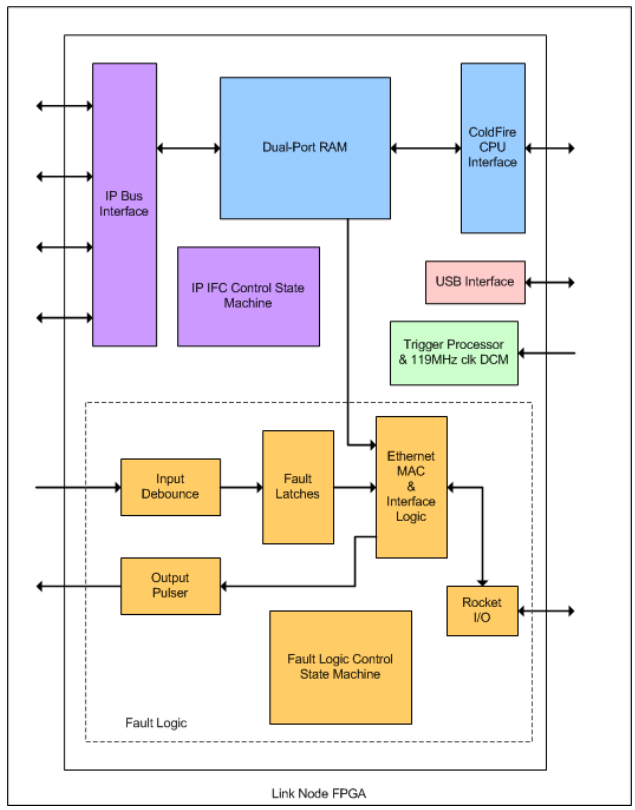

Figure 2: LN Motherboard FPGA Block Diagram.

Conceptually, the FPGA is divided into sections. The Fault Logic, inside the dotted box, implements the MPS engine. This logic contains all of the fault processing and communications functions including the Ethernet interface. The sensor inputs are passed into a debouncer block which has eight programmable debounce times ranging from 10µs to 5s; this block helps filter out noise (e.g. bubbles on waterflow switches), preventing false trips. The debouncer feeds the fault latch logic, whose output is sent to the LP. The output logic consists of a pulse generator which generates a 9ms pulse when a mitigation command is received. This output must be refreshed at each communications sequence, otherwise it will time out. This is done to avoid a latched failure mode in the case of a link failure. The fault logic is controlled by a state machine which sequences operations and communication. The fault logic also receives inputs from the IP interface dual-port RAM block. For certain applications, the IP modules can provide fault information. This fault data is passed to the Ethernet

interface so that the LP can receive it. The ColdFire interface is used to control the IP modules and other LN chassis housekeeping, control and status functions. In addition, the ColdFire has access to the fault latch data in a read-only manner.

LINK-NODE FLAVORS

This section describes each of the types of Link-Node currently being used in the system. It should be noted that in all configurations, the MPS Digital I/O boards can be installed.

Mitigation Link-Node

The Mitigation LN is the simplest configuration. It consists of just the motherboard and MPS Digital Input/Output boards. The configuration of I/O boards is done on a per-instance basis depending upon device requirements.

BLM Link-Node

The Beam Loss Monitor LN is the most complicated. It is part of the BLM readout system [6]. This LN can connect to up to eight undulator BLM detector head and front end electronics box pairs. It is a triggered device, receiving triggers from the timing system [5]. A custom eight-channel IP module, the IP-QINT-ADC (QADC), was developed at SLAC to digitize and process the detector signals. The BLM LN sets and reads back the PMT high voltage power supplies (located in the front end electronics) using COTS DAC and ADC IP modules. The LN also generates a test pulse to exercise the BLM PMT & readout chain. The BLM's high voltage and fault thresholds are setup and controlled from EPICS via the ColdFire CPU. Detector analog readout data is also sent over EPICS. Thus, the BLM LN can also be used as a radiation monitoring instrument.

PIC Link-Node

The Protection Ion Chamber LN is similar to the BLM LN. It interfaces the PIC loss monitors to the MPS. The output of the PIC chamber is connected directly to the LN. The chamber signals are digitized and processed using the same custom QADC module, operating in PIC mode. The LN can accommodate up to four IP-QINT-ADC modules, allowing for a total of 32 PIC chambers to be connected to a single PIC LN. This LN is a triggered device and also controls the PIC high voltage power supply chassis. Fault thresholds and analog data are setup and read out respectively over EPICS via the ColdFire.

ByKIK Link-Node

A single bunch beam dumper magnet, called ByKIK, is located upstream of the Undulator. This magnet interfaces to the MPS through the ByKIK LN. This LN receives Standby and Abort triggers from the timing system and provides a conditioned trigger to the kicker pulse generator, qualified with an MPS permit signal. The kicker outputs an analog waveform that indicates the quality of the kick pulse. This waveform, is digitized (using a COTS IP ADC) by the ByKIK LN and the sampled waveform is compared against thresholds. If the comparison exceeds these thresholds, an MPS fault is generated and the beam is disabled. Specially configured PIC L- and Interface Boards connect the kicker signals to the ADC.

LINK-NODE SOFTWARE

The LN code is EPICS running on the RTEMS RTOS. EPICS applications code is written in C. Information from the LN is available as EPICS Process Variables (PVs) displayed on specialized EDM panels. The PVs are read out of the LN at a 0.5Hz polling rate. Critical PVs are save/restored, archived and connected to the alarm handler.

OPERATIONAL EXPERIENCE

The LCLS MPS was commissioned in 2009. Currently, there are a total of 32 Link-Node chassis in the system. Prior to commissioning, an interim MPS was setup using legacy hardware. By summer of 2010, all of the legacy TIU and 1553-MPS inputs were moved over to LCLS MPS Link-Nodes; fully transitioning MPS functionality for LCLS to the LCLS MPS. The system has been running satisfactorily for almost two years now.

FUTURE DIRECTIONS

This same system will be used for machine protection in the upcoming LCLS-II machine. Plans exist to upgrade the LN ColdFire CPU with a more powerful COM Express platform unit. Based on recent needs, the design of two more flavours of LN are being considered: thermocouple input and general-purpose analog input units. The flexibility of the platform makes these latter items relatively easy to implement.

STUXNET AND THE IMPACT ON ACCELERATOR CONTROL SYSTEMS

S. Lüders, CERN, Geneva, Switzerland

Abstract

2010 has seen wide news coverage of a new kind of computer attack, named "Stuxnet", targeting control systems. Due to its level of sophistication, it is widely acknowledged that this attack marks the very first case of a cyber-war of one country against the industrial infrastructure of another, although there is still much speculation about the details. Worse yet, experts recognize that Stuxnet might just be the beginning and that similar attacks, eventually with much less sophistication, but with much more collateral damage, can be expected in the years to come. Stuxnet was targeting a special model of the Siemens 400 PLC series. Similar modules are also deployed for accelerator controls like the LHC cryogenics or vacuum systems as well as the detector control systems in LHC experiments. Therefore, the aim of this presentation is to give an insight into what this new attack does and why it is deemed to be special. In particular, the potential impact on accelerator and experiment control systems will be discussed, and means will be presented on how to properly protect against similar attacks.

DAWN OF A NEW ERA

In June 2010, repeated reports of a major wave of infected Windows PCs in Iran hit the news. Initially triggered by a report of a Belarus security company called VirusBlokAda on a new Windows zero-day exploit*, a deeper analysis by Symantec, another security company, revealed that this exploit targeted specifically the SCADA (Supervisory Control And Data Acquisition) systems manufactured by Siemens.

Such SCADA systems have been deployed in thousands of instances worldwide, e.g. in the car manufacturing industry, in facility management, oil & gas industries as well as for accelerator control systems. However, in this particular instance, it seemed that this exploit targets the control system of the nuclear facility of Natanz in Iran. This plant is used for the enrichment of uranium. For Siemens, it was an unfortunate coincidence, that their systems were used there.

Named "Stuxnet", as derived from some keywords buried in the exploit code, this is the first documented exploit which deliberately attacks control systems. Due to its level of sophistication, there was much speculation whether this is a case of cyber-war of a particular country against the industrial infrastructure of another, namely the U.S. and Israel against the Natanz nuclear facilities in Iran [1]. Indeed, the sophistication of Stuxnet is very impressive, and this level of sophistication and complexity makes it most unlikely that Stuxnet was produced by an average attacker, but instead required significant investments, engineering skills and intelligence gathering. However, due to the nature of the attack, it is impossible to obtain confirmed information.

The media quickly labelled Stuxnet as "a new kind of cyber-attack" [2], but it was not. In the 1980's, the U.S. CIA provided a Russian energy provider with manipulated valves which eventually led to the explosion of a Siberian natural gas pipeline [3]. Also, the inherent weaknesses exploited by Stuxnet have been reported before, like the CERN TOCSSiC tests conducted in 2005 and later which found 39% of 35 tested devices being susceptible to malicious packages [4] and that many of these devices lack basic access protection allowing them to be manipulated and/or stopped easily. It took five more years for an ultimate proof.

THE INNER WORKINGS

The Stuxnet attack proceeds in two steps: in a first step Stuxnet infects random Windows PCs, in a second it attacks the controls process. A general overview of the different phases is given in Figure 1.

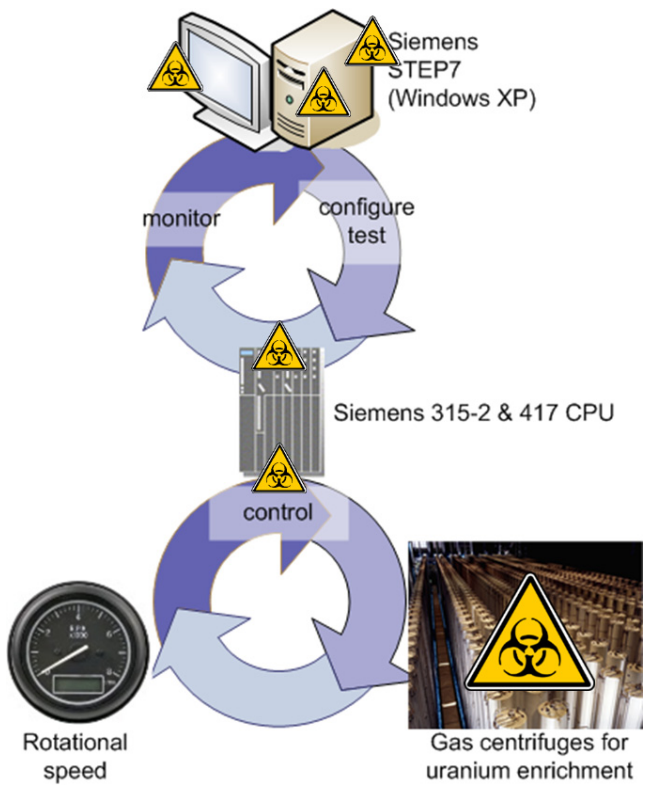

Figure 1: Sketch of a possible control system. Components which were attacked and compromised by Stuxet have been marked explicitly.

* A "zero-day exploit" is an exploit targeting a currently unknown vulnerability. Hence, no fix or patch exists.

Phase 1: Infect a SCADA PC

The PC attack was taking advantage of four (4!) initially unknown vulnerabilities in the Windows operating system. These vulnerabilities are quite valuable since they might be traded on the black market for more than $100 000 each [5]. Most likely, Stuxnet has been introduced via an infected USB stick by either a malicious insider, a saboteur or by means of social engineering luring an employee to insert the stick into a PC.

Once having successfully infiltrated the PC, Stuxnet hides itself using so-called root-kit functionality. This functionality takes benefits of two certificates stolen by the adversaries from a Taiwanese company. This gave the root-kit the air of legitimacy. This makes it neither visible to any local user who browses the infected program folders nor to any local anti-virus software. It then scans the local network and tries to infect further hosts. Using peer-to-peer functionality, all nodes are kept up-to-date and in contact with two remote command and control servers, one in Denmark, the second in Malaysia.

So far, Stuxnet behaves like a sophisticated and expensive worm harvesting compromised PCs and waiting for a command to unleash its malicious power. Up to five different versions with different functionalities have been identified, the oldest dating back to June 2009. In the end, Stuxnet has infected approximately 100.000 PCs worldwide (60% in Iran, 18% in Indonesia, 5% in India) [6].

Phase 2: Compromize the Control Process

But Stuxnet is special. Once established on a PC, it checks for the presence of the Siemens "STEP7", "WINCC" or "PCS7" software suites [7][8][9]. The STEP7 software is essential to program the control system in so-called programmable logic controllers or PLCs. The control system software consists of a series of software "blocks", e.g. "Function Blocks" (FB/FC), "Operational Blocks" (OB), or "Data Blocks" (DB) which are combined into a "project". WINCC and PCS7 are two types of Siemens SCADA applications displaying information relayed from the PLC and allowing values to be changed interactively in the PLC.

If one of these software suites is present, Stuxnet plants a copy of itself into any STEP7 project which can be found on the PC. This will open a further vector of propagation, should the project is copied and transferred to another PC by the corresponding system expert.

In addition, Stuxnet replaces the so-called S7 communication libraries (DLLs) such that it can fully control any data exchange between the SCADA PC and the PLC (see Figure 2). It acts now as a "Man-in-the-Middle" which can hide certain information from the operator looking at the SCADA display like out-of-bound values or alarms, and inhibit commands issued by an operator to the PLC.

Next, Stuxnet scans for PLCs which are reachable from that SCADA PC and "fingerprints" those PLCs: The PLC hardware must be of a certain type of hardware module and the software must contain a number of user-defined blocks with a certain byte-pattern and length. If the fingerprint does not match certain criteria, the worm stays idle and would expire on June 24th 2012.

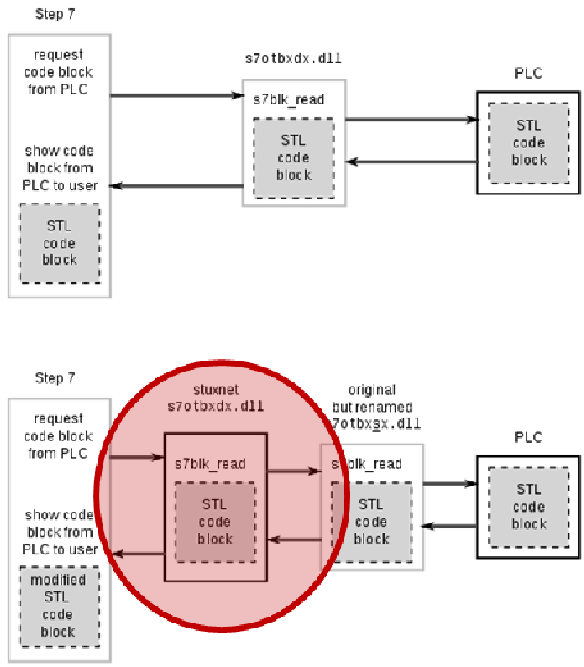

Figure 2: The Siemens S7 communication before (above) and after (below) Stuxnet has inserted its malicious libraries [10].

Phase 3: Game Over

Finally, if the control process matches what Stuxnet is looking for, Stuxnet downloads 17 to 32 additional software blocks to the PLC (depending on the PLC type). This new software blocks change the local control process such that, over the course of several months, the rotational speed of the gas centrifuges deviate from their nominal 1400Hz up to 1410Hz or down to a few hundred hertz [10]. Due to this, the uranium enrichment process was hampered, and the centrifuges wear out more quickly.

Due to the "Man-in-the-Middle" controlling the data flow from and to the SCADA system, operators in front of their SCADA displays will not have noticed anything. Thus, the production of highly enriched uranium became spoiled, and hence delayed.

PROTECTIVE MEANS

Stuxnet is targeting only one particular control system allegedly located in Iran. Therefore, given the aforementioned fingerprinting, it is very unlikely that accelerator or experiment control processes match these patterns. But in the course of the attack, Stuxnet also infects Windows (SCADA) PCs, which are employed in accelerator or experiment control processes, too.

However, not being affected *this* time should not imply that taking no action is an option. On the contrary, Stuxnet

should be considered as a wake-up call to raise the barriers, if not done yet, and deploy measures for properly protecting controls systems.

Protecting a Siemens PLC

While not broadly discussed in the media nor explicitly publicized by Siemens, their PLC come with two basic protection means: a local firewall and an intrusion detection system.

Sophisticated Siemens PLCs, as well as PLCs from other manufacturers, too, come with rudimentary firewall functionality based on IP access protection lists. For proper protection, only IP addresses of remote devices (PLCs, PCs) with a need to communicate with that particular PLC should be permitted by this firewall. All other connections should be dropped[†].

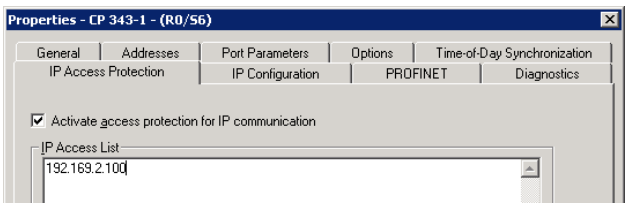

Figure 3: Configuration window of a Siemens S7-343 communication processor. The "IP Access Protection" tab allows configuring a local firewall based on IP addresses.

Special to Siemens STEP7 software is the provisioning of a so-called "Checksums" functionality which can be used as a simple intrusion detection system. Checksums are quasi-unique numbers ("hashes") which change drastically once a bit of the PLC's software blocks or its hardware is modified[‡]: STEP7 allows calculating such a hash over all software blocks, i.e. FB/FC/SFB/SFC/DB/OB, of a STEP7 project. A second hash is calculated over the hardware configuration. These values can be compared to those computed directly on-line by the PLC's CPU (see Figure 4).

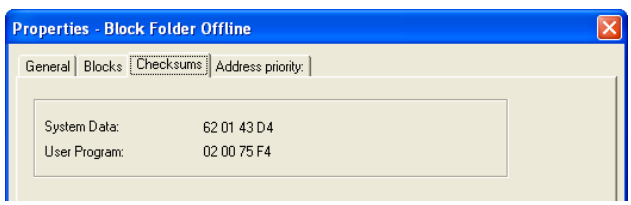

Figure 4: Information box giving the checksum values of a STEP7 project.

Mismatches indicate that software blocks in the PLC or its hardware has been altered. In such cases, the PLC or an attached display can raise an alarm (alarm e-mail, alarm sound, warning message). Important is, however, that the display can and is not compromised through a "Man-in-the-Middle" attack as the SCADA PC was[§].

Defence-in-Depth

The general strategy for the protection of control systems (as for any other computer system) must follow a "Defence-in-Depth" approach. This implies that protective measures have to be deployed on every level of the hardware and software stack[**]:

- On the network level by proper network segregation and compartmentalization of the controls network into security cells;
- On the hardware level by increasing the robustness and resilience of the device itself. Physical outlets like USB ports or CD drives should be disabled if not essential for operation;
- On the level of network services by disabling those services which are not essential for operation. A device should not be susceptible nor fail to a simple network scan issued by e.g. Nessus [11] or nmap [12];
- On the firmware and operating system level by applying software upgrades and patches in a timely manner. If possible, the device should run anti-virus software with up-to-date virus signature files. All default passwords must be changed and not disclosed to any other third party;
- On the application level by removing all applications which are no essential for operation. All remaining applications must be kept up-to-date and patched in a timely manner;
- On the social level by providing appropriate training to the system experts and operators. Particular focus should be put on awareness raising and the risks of social engineering[††].

More details on any "Defence-in-Depth" approach can be found in the "Good Practise Guidelines" of the U.K. CPNI [13] or in the ISA SP99 series of documents [14]. Other good standards are [15][16][17][18]. Usually, it is sufficient to choose any one standard or guideline and cross check later with a second one.

For example, long before Stuxnet, CERN set up a working group on the protection of control systems [19]. Since then, all control systems at CERN must adhere to the "Computer and Network Infrastructure for Controls (CNIC) Security Policy for Controls" [20] and to the

[†] However, since the Stuxnet comprimized PC was directly linked to the PLC, a local firewall wouldn't have prevented Stuxnet from connecting to that PLC.

[‡] Since this checksum is only four bytes long, there is a residual risk for finding collisions, i.e. the same checksums for a completely different set of software blocks or hardware configuration. However, to the author's knowledge, Stuxnet has not been designed to produce such a collision.

[§] There is still the risk of a "race-condition" where the malicious block downloaded to a PLC competes with the regular execution of the calculation of checksums. Depending on the exact time the malicious block gets enabled on the PLC, it might be able to inhibit raising an checksum alert.

[**] Admittedly, not all those measures would have helped to protect against Stuxnet. In particular, Stuxnet's zero-day exploits were not patchable at that time. Also, Stuxnet's sophistication bypassed the installed anti-virus software.

[††] Other good practices would require regular screening of experts and operators with view of their financial, social, family, and psychological situation, and whether they are addicted to drugs, gambling or alcohol. However, in the academic environment of high energy physics, this would be impossible.

"CERN Security Baselines" [21] which both give basic recommendations on how to protect control systems as well as computing services at CERN.

Whilst following a standard is definitively a good practise, it also must be stressed that any investment in cyber-security must be balanced. Consciously accepting the risk is a valid alternative, too.

CONCLUSIONS

Stuxnet should have been the wake-up call for all those who never believed that control system could and would be attacked. Indeed, the media was quickly interested and created an unprecedented hype about the protection of the critical infrastructure which strongly relies on control systems. They called out the new "Era of Cyber-War" [1]. In parallel, attackers as well as security researchers became interested in analysing control system hardware. Standard IT security companies joined and now provide technical solutions for protecting control systems, even if their technical knowledge in control systems might be limited.

Most importantly, vendors are also concerned. Siemens, for example, has started an elaborative initiative on securing their control systems [22]. This should, however, not serve as an argument to users not to take any action. On the contrary, users should review the security protections put in place. Deploying a "Defense-in-Depth" approach is mandatory and corresponds to good practise. Continuing to ignore control system cyber-security is grossly negligent.

A new era has begun. Stay tuned.

DEVELOPMENT OF THE DIAMOND LIGHT SOURCE PSS IN CONFORMANCE WITH EN 61508

M.C. Wilson, A.G. Price, Diamond Light Source, Oxfordshire, UK.

Abstract

Diamond Light Source is constructing a third phase (Phase III) of photon beamlines and experiment stations. Experience gained in the design, realization and operation of the Personnel Safety Systems (PSS) on the first two phases of beamlines is being used to improve the design process for this development. Information on the safety functionality of Phase I and Phase II photon beamlines is maintained in a hazard database. From this, reports are used to assist in the design, verification and validation of the new PSSs. The data is used to make comparisons between beamlines, to validate safety functions and to record documentation for each beamline. This forms part of a documentation process demonstrating conformance to EN 61508 [1].

INTRODUCTION

The Diamond Light Source is a 3rd generation synchrotron, a particle accelerator that accelerates electrons close to the speed of light and uses insertion devices to cause the electron beam to produce intense beams of X-rays. It is used for research by the science community and industry. Inherent in the process is the risk of harm to personnel from ionising radiation, i.e. X-rays generated by design and neutrons and gamma radiation generated by collisions of high energy electrons with hard surfaces. As a result Diamond is subject to the UK's Ionising Radiation Regulations, IRR99 [2] and must provide an engineered safety system to manage the hazards. Diamond elected to adopt the safety system standard EN 61508 to guide the process. It is a generic international standard for the design of electrical / electronic and programmable electronic safety systems, which is applicable to environments without specific safety standards of their own, such as accelerators. Diamond has now been producing Personnel Safety Systems (PSS) to protect personnel from ionising radiation and other hazards since the project began in 2002. Protection against "Other hazards" may include crush hazards caused by robots, eye damage from lasers and any additional hazards which require a rigorous access control system.

The Diamond PSS includes:

- a Linac zone,
- 3 booster zones,
- 10 storage ring zones,
- 7 phase 1 beamlines
- 14 phase 2 beamlines

Phase 3 will consist of a further 10 beamlines.

Each system is an independent safety system which contributes to the overall safety system for the facility. This type of architecture allows for the addition of new systems and the removal of old without undue reconfiguration of the overall system. However, this amounts to a lot of safety systems to manage. As part of the safety management under EN 61508, a database of hazards was established. This has proven to be of little direct benefit, and so it was decided to extend its function to help manage the EN 61508 process. This paper describes the database and its role in the Diamond Personnel Safety System.

EN 61508 IMPLEMENTATION

Diamond identified the desire to apply EN 61508 to the PSS early in the realisation of the project. An external contractor was employed to set up the process and, due to pressures of the programme, the first iterations of the design and conformance processes were established at the same time. Diamond safety management requires formal identification of hazards in a HAZard IDentification process (HAZID). The technique, in common with many others, identifies the hazards that fall within a specific area and for each hazard the initiating event that might lead to an incident, the consequences, the likelihood of the incident and the safeguards that will protect against it.

The information collected in the HAZID is used to generate a safety requirements specification and as a basis of a safety model.

The safety requirements specification lists and describes the safety measures required and allocates them to subsystems, where appropriate, using Safety Integrity Levels (SIL), derived from the safety model. SIL indicate the rigour required from the safety system with 1 the least and 4 the most rigorous requirement. The system is built and tested so that each safety requirement is tested against a functional performance test. The remaining EN 61508 implementation concerns the quality of the process, involving verification and validation and cross-checks to ensure what was built meets the SIL requirement and is as designed, that the design is as specified and that the specification mitigates the hazards.

DATABASE OBJECTIVES

Diamond has an EN 61508 process which augments a traditional manufacturing process used to design, build and test the PSS. The EN 61508 process provides the means of managing the design and manufacture; however the manufacturing process is typical of manufacturing processes used elsewhere without the requirement for EN 61508. Hence, there was a possibility that the two processes could operate largely independently and on different timescales, undermining the safety design process. A means of consolidation was therefore sought, such that the manufacturing process should be able to

receive timely information from the EN 61508 process in a readily useable form. The EN 61508 should be able to accept data from the design process and provide cross checks to ensure that the design is complete. The EN 61508 process should be able to provide calculations which support the design prior to the detailed analysis being undertaken.

There are three main elements that make these requirements appropriate to a database:

- the large number of similar and comparable systems at Diamond,
- the quantisation of qualitative information,
- the ability to structure reports based on a common data set in many different arrangements for cross referencing and validation of the various stages of EN 61508

Having a large number of systems allows the comparison of data between systems. This is a valuable benefit, as the start point of the process requires human expertise and judgement, which is fallible. Cross referencing between systems helps to identify omissions and irregularities by requiring justification of the differences.

Entering information into a database provides the opportunity to put similar interpretations and numbers to qualitative assessments. This is the first stage of processing data to provide probabilistic assessment of risk.

Producing reports that contain the pertinent information in an appropriate order is a great help to verification and validation. Information from different points in the process can be brought together to generate new information and data, including calculations.

DATABASE STRUCTURE

The database is built using Microsoft Access 2007 from the Microsoft Office suite. It consists of tables of hazards, safeguards, frequencies of opportunity and outcome severities. These are linked to interlocks and control measures by a logic table. Preliminary assessments can be undertaken and reports generated to support the EN 61508 process. Documentation is also included by linking the database into the SharePoint document repository. The following sections identify the processes and reports generated for the various stages.

HAZARD IDENTIFICATION

The Diamond Safety Management plan requires hazard identification to be undertaken early in the project. As soon as the preliminary beamline layout has been established, it is reviewed for hazards, and the potential frequency and severity of incidents is assessed. Safeguards to prevent the incident are identified. The results are recorded in the "Preliminary Hazard Analysis" report. The records of the review are collated and recorded in the database. In entering the information, steps are taken to convert the qualitative results into quantitative values:

- Frequency of opportunity is commonly expressed as an interval during discussion and is converted into an explicit number of events per annum.
- Severity is allocated by table to provide a risk of fatality per event as a percentage. This provides common allocation of severity for similar hazards on different systems.
- The effectiveness of the safeguard is assessed and probability is assigned to the control measure.

The first output from the database is a report for checking the database records against the Preliminary Hazard Analysis report. The report is formatted to present the data in the same arrangement as the HAZID table for ease of comparison

"Sore Thumb" Checks

The benefit derived from implementing a system to structure the design of a safety system can only be as good as the identification and analysis of the hazards presented. At Diamond we have the benefit of having built many safety systems and have records of the hazards identified on those systems. The database is used to generate two reports that compare hazards, frequency, severity and safeguards, in different formats, allowing the comparison and rationalisation of differences between hazards on different beamlines. The first format arranges the initiating event with consequence and frequency of opportunity grouped by beamline and beamline area. This allows comparison of hazards identified in similar areas on different beamlines. The second format arranges the data by cause, which generates a report that allows comparison of the treatment of a particular hazard on different beamlines.

Hazard and Safeguard Cross Reference

Once the appropriate and correct data is in the database a cross-reference report is generated and appended to the Preliminary Hazard Analysis report.

PRELIMINARY NUMERICAL ANALYSIS

Undertaking some preliminary analysis is a useful exercise, as iterations "around the EN 61508 loop" are quite time consuming.

Risk of Fatality Report

Given that most safeguards contribute to additional safety, a very basic preliminary calculation can be undertaken that combines the safeguard contributions as a logical AND function of all the individual safeguards that contribute to the mitigation of the risk. It should be noted that accuracy of this calculation is limited by the simplicity of the model, which ignores the independence and common-mode failures of the safeguards, and does not replace the need for a more thorough analysis. However it does provide a useful early warning that more

safety measures may be required to provide adequate mitigation for a particular hazard.

SIL Rating Report

Most of Diamond's safety systems have similar safety requirements and similar solutions; this allows the use of common analysis between safety systems. It is not unreasonable to assume that an equivalent system on similar safety systems will have the same SIL requirements and that the equivalent solution will achieve a similar SIL. The database also holds references to the evaluation of the solution.

The SIL report provides a list of SIL evaluations, SIL ratings and the Probability of Failure on Demand (PFD) for the function. This allows the development of safety models using consistent values.

SAFETY REQUIREMENTS SPECIFICATION

The safety requirements specification contains definitions of the safety functions that the system will implement. It is derived from the safeguards and control measures defined in the database. The first report in this section lists the safety requirements for inclusion in the specification. It includes legal requirements and Diamond safety policy functional requirements, which may not be direct "safety" requirements placed upon the safety system. It should be noted that the report lists an occurrence of a particular safety function for each hazard that it mitigates. The safety function is incorporated only once in the design as it is effective for all of the hazards it mitigates, but the complete list of references is an important record in case of future changes of requirements.

The list of safety functions produced from the database is a significant element in the composition of the safety requirement specification, which is the document that specifies in detail the function of the personnel safety system and its components.

SAFEGUARD COMPARISON REPORT

Again, as we have a history of safety systems design at Diamond, it is prudent to compare the current system with previous similar systems. A report listing the safeguards for particular hazards allows comparison and justification of differences between beamlines and assumptions made at the time of hazard identification.

NON-PSS SAFETY REQUIREMENTS REPORT

Some of the safety functions required to achieve adequate safety fall outside the scope of Electrical / Electronic / Programmable Electronic (E/E/PE) systems and are managed by others. This report lists all Non-PSS safety requirements. Its use provides an effective mechanism for communicating and discharging responsibilities.

LOGIC DESIGN

Safety functions translate into interlocks and control measures, or "permits". Often, the same control measures are required for several interlocks, and so logic functions are required to combine interlocks and provide permits to equipment. Generally the control measure is asserted only if the logical AND combination of the interlocks is present. By processing the beamline data in the database to produce a report of interlocks by control measure, a comprehensive design-checking tool becomes available. The database provides a method of recording the logic design so that each safety function is implemented and is recorded.

VERIFICATION AND VALIDATION

The database allows the safety functions to be listed for the each system. A report can be generated which lists each safety function, its interlock and its permit. This is a valuable tool for checking that all safety functional requirements are tested in the functional test procedure. Further, the reference for the functional test for each safety function can be recorded to provide a cross-check that all safety functions have been included and are tested.

DOCUMENTATION

The documents associated with a beamline are referenced from the database into the document repository. This allows generic documents and system-specific documents to be used for each safety system and the documents to be recalled simply and efficiently.

CONCLUSIONS

The ability of the database to produce reports sorted and filtered on different criteria allows the production of reports tailored for specific stages of the EN 61508 process. Presenting similar data in different formats enhances the ability to check and compare data. Cross referencing and filtering on specific criteria provides valuable information for assisting audits. The database is a useful tool for checking validity, assisting design and verifying the safety system, but should not be employed blindly.

FUTURE DEVELOPMENT

The database contributes to the processes involved with the development of safety systems, during which assumptions are made about the frequency of operation and reliability of components in the system. The database could be developed to accommodate data collected from operational experience allowing the assumptions to be validated. In practice, frequency-of-operation information is relatively simple to collect; however there are often other considerations to be taken into account and some sort of normalisation may be required before the number becomes useful. Reliability of components is a study that is likely to be too complex for a database of this type, and

is probably better studied elsewhere. Consolidation of failure data into subsystem failure and safety requirement failure would be of interest. Safety requirement failure rates could be added to the database for validation of SIL ratings. Subsystem failure data could be collected elsewhere for comparison with Failure Modes, Effects and Consequence Analysis (FMECA) and subsequent studies.

Abstract

The JET ITER-like wall project (ILW) replaces the first wall carbon fibre composite tiles with beryllium and tungsten tiles which should have improved fuel retention characteristics but are less thermally robust. An enhanced protection system using new control and diagnostic systems has been designed which can modify the pre-planned experimental control to protect the new wall. Key design challenges were to extend the Level-1 supervisory control system to allow configurable responses to thermal problems to be defined without introducing excessive complexity, and to integrate the new functionality with existing control and protection systems efficiently and reliably. Alarms are generated by the vessel thermal map (VTM) system if infra-red camera measurements of tile temperatures are too high and by the plasma wall load system (WALLS) if component power limits are exceeded. The design introduces two new concepts: local protection, which inhibits individual heating components but allows the discharge to proceed, and stop responses, which allow highly configurable early termination of the pulse in the safest way for the plasma conditions and type of alarm. These are implemented via the new real-time protection system (RTPS), a centralised controller which responds to the VTM and WALLS alarms by providing override commands to the plasma shape, current, density and heating controllers. This paper describes the design and implementation of the RTPS system which is built with the Multithreaded Application Real-Time executor (MARTe) and will present results from initial operations.

INTRODUCTION

The main experimental control of the JET[1] machine is provided by five real-time control systems, or actuators, which govern : plasma position and current control (PPCC [2]), fuelling, via the plasma density local manager (PDLM) and additional heating, via the local manager systems for neutral-beam heating (NBLM), radio frequency heating (RFLM) and lower-hybrid current drive (LHLM).

JET machine protection has been provided historically by three systems. The Central Interlock and Safety System (CISS) provides basic hardwired plant protection. Higher level protection with limited configurability is provided by the Pulse Termination Network (PTN[3]). This is triggered if key systems fail, or if protection signals move outside of predefined limits. The PTN output is a latched stop signal to each of the control systems, which execute a fixed shutdown sequence in response. Finally, additional heating systems require enable signals from the Plant Enable Window System (PEWS) which are conditioned by real-time protection signal validation algorithms.

The design of these systems is characterised by a high degree of configurability in respect of detecting machine fault conditions, but extremely limited control over stop strategies which are constrained to be fixed throughout the duration of an experiment. The stops are designed to minimise the global damage to the machine but are unable to take account of any localised heat flux limits on plasma facing components (PFCs).

The ILW project[4] has rebuilt the plasma facing surfaces of the machine with all-metal tiles which should have improved fuel retention properties. However, their temperature needs to be carefully controlled to avoid damage. The Protection of the ITER-like Wall (PIW) project was launched in late 2009 to upgrade the protection systems to address this need.

CONCEPTUAL DESIGN

The PIW system design aimed to augment the diagnostic monitoring of wall component temperatures and to provide a new protection system which could intervene to keep these temperatures within limits. The new system should act early, to prevent PTN or CISS from following a global stop strategy that might cause excessive energy loads on the walls. However, the basic machine protection provided by PTN and CISS had to be retained. The structural archi-

* See the Appendix of F.Romanelli et al., Proceedings of the 23rd IAEA Fusion Energy Conference 2010, Daejeon, Korea.

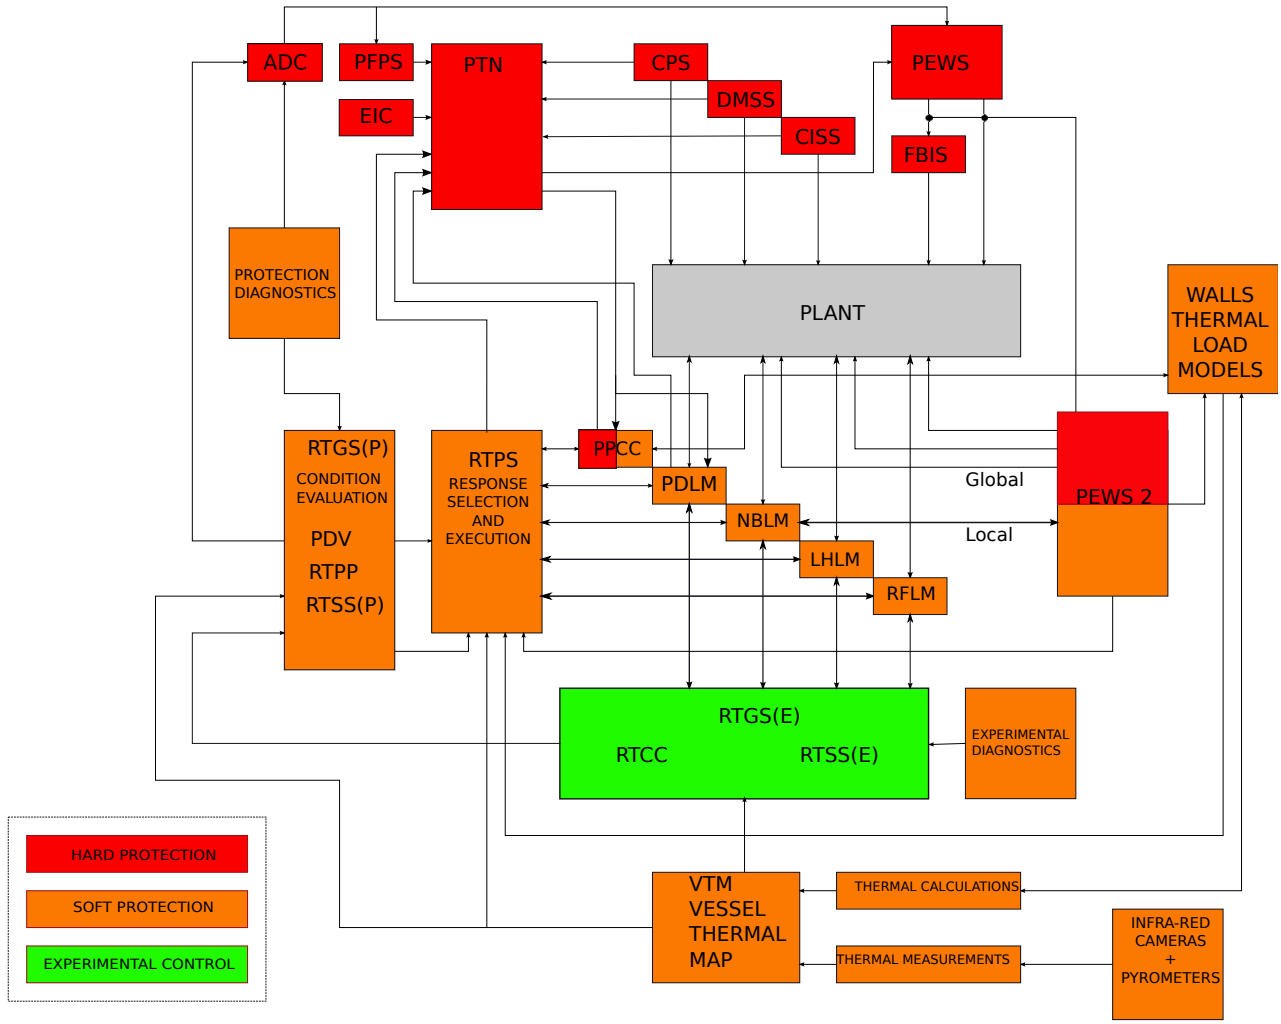

Figure 1: JET protection of the ITER-like wall system architecture. The experimental real-time control links to the density and heating local managers (PDLM, NBLM, RFLM and LHLM) is expanded to allow protection overrides from the new RTPS system which receives alarms from VTM, WALLS and also from the real-time plasma protection (RTPP) and real-time central controller (RTCC) systems. The original higher level protection systems of CISS, PTN and PEWS are retained.

tecture was clear and is outlined in figure 1. The density and additional heating real-time controllers already had interfaces which allowed for real-time modification of plant control. PPCC would be similarly updated. A new system, called the Real-Time Protection Sequencer (RTPS) would provide protection override commands to adapt the experimental control as required to keep temperatures under control, or to achieve a safe termination when necessary.

Temperature monitoring is provided based on real-time measurements from new infra-red camera and pyrometer diagnostics[5] which are analysed by a new system called the Vessel Thermal Map (VTM[6]) in order to generate alarms where limits are reached. The plasma wall load system (WALLS) may also generate alarms if modelled predictions of temperature or energy load become excessive. WALLS required to be updated to take account of the new component geometry and materials.

The design distinguishes between *local* and *global* events. Local alarms are limited in location or time, or may be set at lower thresholds and trigger a protection response which allows continued operation with dynamically controlled limits on further injection of heating with fine granularity. If this fails to bring checks back into tolerance, global alarms are raised which result in control overrides which truncate the experiment and land the plasma safely.

The significant design challenge was to make the new system practical to configure. The best control to provide a soft landing in the event of a fault condition depends on the state of the plasma. This is a function of the experiment design, the phase within a particular discharge, and the type of fault detected. Potentially, this represents a large number of possible paths. This was addressed with a fault and response classification scheme which confines the complexity to a manageable level, and by providing a way to define response actions generically, such that a library of reusable stop responses may be applied to many similar experimental scenarios.

RTPS IMPLEMENTATION

Local Protection

Local alarms and local protection are defined in relation to the additional heating systems. Each heating system comprises several individual units, and under certain conditions, particular heating units may directly heat a specific plasma facing component. For example, the neutral-beam heating system has 16 positive ion neutral injectors (PINIs). Depending on the plasma density, a proportion of beam particles pass through the plasma and strike the surface of the machine, a condition known as shine-through. Each PINI has a shine-through footprint on a specific set of components. Therefore, when a local hotspot alarm occurs for such an element, the relevant PINI should be turned off to prevent further overheating. This should not preclude the neutral-beam system as a whole from continuing to deliver the total requested power to the plasma, as other PINIs can be turned on to compensate. Similar relationships and control rules can be determined for the RF antennae, and the LH klystrons.

Global Protection

If local protection is not adequate to keep the machine safe the experiment must be curtailed. To manage the potential complexity of the design, the key observation is that although there are many hundreds of individual fault conditions, most require similar reactions, and we introduce the term *stop trigger* to classify the types of threat.

Seven stop triggers have been identified. Three represent thermal problems. These are hot spots in the main chamber (inner and outer walls), in the divertor (the base region where particles are exhausted from the machine) or which occur in both regions. Two are associated with magneto-hydrodynamic (MHD) instabilities. Two more allow for generic conditions requiring either a slow or fast termination of the pulse.

Each stop trigger is associated with a corresponding *stop response*, which defines the required override control strategy to mitigate the effects of the related alarm. There are three kinds of stop response. If a fault occurs early in the discharge before main heating phase, it can be sufficient to trigger the PTN system. During the heating phase, the real-time controllers require overrides which are fully programmable, termed *RTPS* stops. In some cases, the best possible way to end a pulse is to execute the control waveforms that would have come into force had the experiment reached a natural conclusion. This is termed a *jump-to-termination* (JTT) stop. Table 1 illustrates the matrix that links stop triggers to stop responses, as a function of experimental phase. The full control matrix is a key part of the protection system configuration interface.

The system also takes account of the possibility that one class of fault (and corresponding stop response) might be followed soon after by another. For example, a magnetic instability followed by a hotspot, or vice versa. This is addressed, by allowing for two levels of stop response, *primary*, and *secondary*. Not all possible combinations of control are allowable, since in some cases, once a primary stop response has begun, the best outcome is achieved by allowing it to run to completion.

Table 1: The primary stops table configures the mapping between stop triggers and stop responses as a function of experimental phase. A subset of the possible stop triggers are shown, including mode lock (MHD), main chamber hotspot (MCHS) and divertor hotspot (DHS).

Phase	Slow	MHD	MCHS	DHS
Breakdown	PTN	None	None	PTN
Ip Rise	|	|	|	|
Limiter	PTN	|	|	|
X-point	PTN	|	|	|
Heating 1	RTPS	|	RTPS	PTN
Heating 2	RTPS	|	RTPS	JTT
Plasma Termination	PTN	|	PTN	PTN

Stop Responses

A particular stop response is defined by a set of override references for each of the five actuator systems, each of which has one or more control signals. For a given control signal, the override is specified as a waveform which is parameterised as a set of steps, where for each step, the reference value to achieve and the time in which to make the transition are defined.

There are many ways of specifying these parameters. Reference values can be defined in absolute terms, or relative to the control value at the beginning of the stop, or in proportion to any other control signal. e.g. If 10MW of neutral-beam total power were being delivered and a stop response was initiated, the new reference could be set to 6MW (absolute mode), 60% (relative mode) or proportional to plasma current, in which case the reference would be calculated dynamically. Step durations can be defined as an absolute time, as a ramp rate (where the duration will be computed from the difference between the reference values) or to be synchronised to another control signal.

Software and Hardware

To achieve the required degree of configurability and reliability, the software is constructed using a component based approach, based on the Multi-threaded Application Real-Time executor (MARTe[7]). A MARTe application is organised as a chain of processing objects instantiated from Generic Application Modules (GAMs) interconnected by a software bus called the dynamic data buffer (DDB). A supervisory level set of tasks implements a state machine

distinguishing background operation, preparation for an experiment (pulse), pulse on, and post-pulse actions (including data collection). The set of GAMs and their attributes are data driven, which allows a powerful separation of source code and binary modules from experimental parameters. This allows the application to be comprehensively configured from the JET Level-1 system.

The standard MARTe library provided the key infrastructure, driver modules for the peripheral electronics and data collection modules. The RTPS software was completed by writing custom MARTe modules. These include the *Stop Selector* GAM which implements the state machine and alarm processing logic, and the *Stop Manager* GAM which defines and executes the stop responses. The application is executed on a PowerPC processor hosted in a VME rack, with digital IO modules providing links to the PTN system.

MARTe has been used with several operating systems and was ported to VxWorks 6.8 to develop the online real-time version of the RTPS application. A major benefit of using MARTe was the possibility of recompiling the application to run on Linux to allow development and offline testing with access to powerful debugging and checking software tools.

Communications with the alarm generator and control actuator systems is via the JET real-time data network (RTDN[8]) which provides low latency, high reliability exchange of fixed size datagrams over permanent virtual circuits. The processing rate is 500Hz, with inputs from the VTM at 100Hz.

Ensuring Reliability

Alarm systems such as the VTM define blind stop alarms to handle loss of critical signals during a shot. If RTPS detects communication or status faults with the alarm source systems, or real-time controllers, it can trigger the PTN system. A hardware watchdog signal to PTN ensures that RTPS is operational itself. Detection of PIW system failures needs to be reliable and appropriate. The Level-1 user interface provides intelligent conditioning of these checks so that features or subsystems which are not in use cannot cause problems.

The PIW system overall relies on distributed interaction between simpler, smaller systems. This reduces the cost of developing, commissioning and testing of each subsystem, but demands correct communications. To ensure this, all messages between systems are defined in a central database. Each message is allocated a unique identification number which is used to allow run-time verification that all systems on a virtual circuit are coherent and operating correctly.

OPERATIONS

JET recommenced operations with the ILW on 24 August 2011 and initial plasma performance has exceeded expectations. Unusually following a JET shutdown, the experimental and restart commissioning activities are interleaved. The restart programme has included sessions dedicated to the commissioning of the PIW systems.

The basic protection logic has been tested thoroughly, and the response of the PPCC and PDLM systems for a number of stop response types has been verified. End to end testing of alarm generation from camera systems through to RTPS response has been demonstrated. This was done initially without heating the wall, by using the cameras without infra-red filters. Calibration parameters and the visible plasma light intensity levels were tuned to simulate high temperature signals. Similar tests will be repeated using real temperature signals when the infra-red filters have been fitted, and the additional heating systems commissioned. RTPS has been used successfully to override a plasma discharge by requesting PPCC and PDLM to execute the jump-to-termination response in JET pulse number 80500.

CONCLUSIONS

The impact of plasma fault conditions which risk damage to the JET ITER-like wall will be mitigated by the action of a new, highly flexible protection system. This allows safer and more efficient exploitation of the new machine by expanding the operational space available, and by gently landing the plasma when necessary, without making the task of session preparation excessively onerous.

HIGH-INTEGRITY SOFTWARE, COMPUTATION AND THE SCIENTIFIC METHOD

Les Hatton*, CISM, Kingston University, UK

Abstract

Computation rightly occupies a central role in modern science. Datasets are enormous and the processing implications of some algorithms are equally staggering. With the continuing difficulties in quantifying the results of complex computations, it is of increasing importance to understand its role in the essentially Popperian scientific method. In this paper, some of the problems with computation, for example the long-term unquantifiable presence of undiscovered defect, problems with programming languages and process issues will be explored with numerous examples. One of the aims of the paper is to understand the implications of trying to produce high-integrity software and the limitations which still exist.

Unfortunately Computer Science itself suffers from an inability to be suitably critical of its practices and has operated in a largely measurement-free vacuum since its earliest days. Within CS itself, this has not been so damaging in that it simply leads to unconstrained creativity and a rapid turnover of new technologies. In the applied sciences however which have to depend on computational results, such unquantifiability significantly undermines trust.

It is time this particular demon was put to rest.

BACKGROUND

High-integrity systems are fundamentally those systems which on failure, have a significant impact on humans, organisations, society or the environment. It is traditional to split these into two categories

- Safety-critical systems. Such systems on failure, have a direct impact on human safety or indirectly by damaging the environment. Examples of these include aircraft active avionics, railway signalling software or medical imaging software.
- Mission-critical systems. Such systems on failure, are typically associated with financial loss. In an organisation this could be failure of its accounting systems, customer information or other enterprise systems. However, in the context of science, such systems on failure would be directly associated with unintentionally misleading results. Indirectly, this may lead to financial loss but the essential issue here is untrustworthiness of the results.

In the context of Accelerator and Large Experimental Physics Control Systems, both categories will be represented. The failure of Control Systems is frequently safety-critical whilst data acquisition and processing is mission-critical in that failure here may well lead to misleading results.

The processes involved in producing Safety-Critical Systems are well-rehearsed, well-documented by numerous standards, both military (DO-178B, DO-254, DEF STAN OO-55/56) and civilian (CENELEC EN 50126, EN 50128, EN 50129, IEC 61508) and strongly associated with legal liability. In this paper, therefore, I will restrict myself to the latter of these issues, viz. the risk of unintentionally misleading results and the potential impact on scientific research.

SOME ISSUES IN HIGH-INTEGRITY SOFTWARE

The Scientific Method

The highly influential 20th century philosopher Karl Popper was instrumental in delineating the scientific method by laying down the notions of deniability. Deniability in an experimental context is fundamentally linked to openness of technique and reproducibility of result. We make progress by ruthlessly eliminating those experimental results which cannot be reproduced within some suitable bound of error when an identical experiment is performed. Such methods have served science well and have come to embody the very essence of the scientific method.

I will now restate deniability in a software context as

- Truth cannot be verified by software testing, it can only be falsified,
- Falsification requires quantification of computational modelling error,
- Deniability is at the heart of progress in scientific modelling. We are always seeking to deny the truth of a result and continued failure simply adds weight to a result but not verification,

In this context, Computer Science has not done well.

Software Defect

The principle enemy of the programmer is software defect. In the absence of a well-defined set of categories, I will define a defect as a fault or mistake in the software which then causes the software to fail. Software failure occurs when the behaviour of a computer program departs from its expected behaviour. Every failure is associated with at least one fault but not all faults fail.

There are many kinds of fault and there are many kinds of failure.

* lesh@oakcomp.co.uk

Fault categories Although by no means exhaustive or independent, these might include

- The use of ambiguous programming language features as described for example by [4],
- Mistakes in logic, for example an incorrect programming branch,
- Errors of omission, (i.e. something important left out such as initialisation statement),
- Errors of commission, (i.e. something put in which should not be there),
- Various abuses of floating-point arithmetic, [11],

Fault occurrence rates have been thoroughly examined by many researchers, for example the seminal contributions of Basili, [2]. Such faults are typically identified as occurring in the range 1-10 per thousand executable lines of code for typical software with arguably the best software around 0.1 on this scale.

Where computer scientists have made little progress is on *quantifying the effects these faults have on the actual output values of the computation, in other words on how they fail.* Let me then consider different kinds of failure.

Failure categories Examples of these might include

- An unintended program halt. These can occur for many reasons in programming languages. For example, an incorrectly dereferenced pointer or a pointer alignment problem in languages like C and C++; a divide by zero which causes a run-time exception; overflows; underflows and so on. Such errors although traumatic for a safety-critical system because service is interrupted perhaps during a critical phase, they tend not to be particularly serious in scientific computation because the scientist is immediately alerted that there is something wrong.
- Wildly incorrect results. These are results which are so far wrong that they cannot be correct as for example the rather surprised Malaysian man who received a $218 trillion dollar phone bill in 2006, (http://www.msnbc.msn.com/id/12247590 /ns/world_news-weird_news/t/think-your-phone-bill-high-try-trillion/, accessed 30-Sep-2011). These are not serious in scientific computing either as they are readily identifiable as spurious. Such a result is extremely unlikely to mislead.
- Subtly incorrect results. These are results which are profoundly dangerous in scientific computing. It may be thought if they are subtle, they cannot mislead but this was profoundly disproved by [7] who showed that the presence of previously undetected software faults in a comparison of 9 seismic data processing packages independently developed to the same mathematical specifications effectively destroyed the level of agreement to the point where the data became highly misleading. This is exemplified in Figure 1. Although some 17 years old, the programming language used is still in widespread use (Fortran), the packages are still in widespread use, the software processes used are effectively unchanged today and scientific programmers still make mistakes, so its relevance is undiminished.

The experiment of [7] is known as an N-version experiment. Although independent versions of software written to the same specifications do not fail independently, [12], [14], they fail sufficiently independently to provide important insight into quantifying the effects of failure.

Another effective way of achieving this is to release all source code so that it can be independently checked. This is very similar to N-version experiments in that source code is subjected to many analysing minds in parallel. In N-version work, this leads to N versions. In open source work, this will usually lead to one version, independently checked by N persons.

There have been many attempts to build models which can predict unreliability based on some statically measurable property of software, for example the cyclomatic complexity, (a graph theoretic measure of decision complexity), first proposed by McCabe [13] but these have not been very successful, [3].

A typical example of a correlation between recorded defects and the cyclomatic number in a study by Hopkins and Hatton [8] illustrates the unfocused relationship between them with no statistically significant patterns.

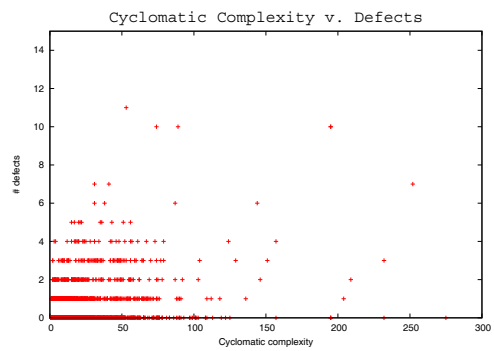

Figure 2: Recorded defects over a period of several years in the NAG Fortran library plotted against the cyclomatic number of the component in which the respective defects were found.

Programming Languages

Problems with ambiguity in programming languages have been reported on many occasions and regularly occur in scientific software in multiple languages, [4]. These include very simple issues like the use of uninitialised variables to far more subtle aspects of computation such as any reliance on a specified order of evaluation, (which is not defined for the majority of programming languages).

Recent research suggests that there are implementation and language independent properties which can be exploited. In [6] I used information theoretic arguments in the

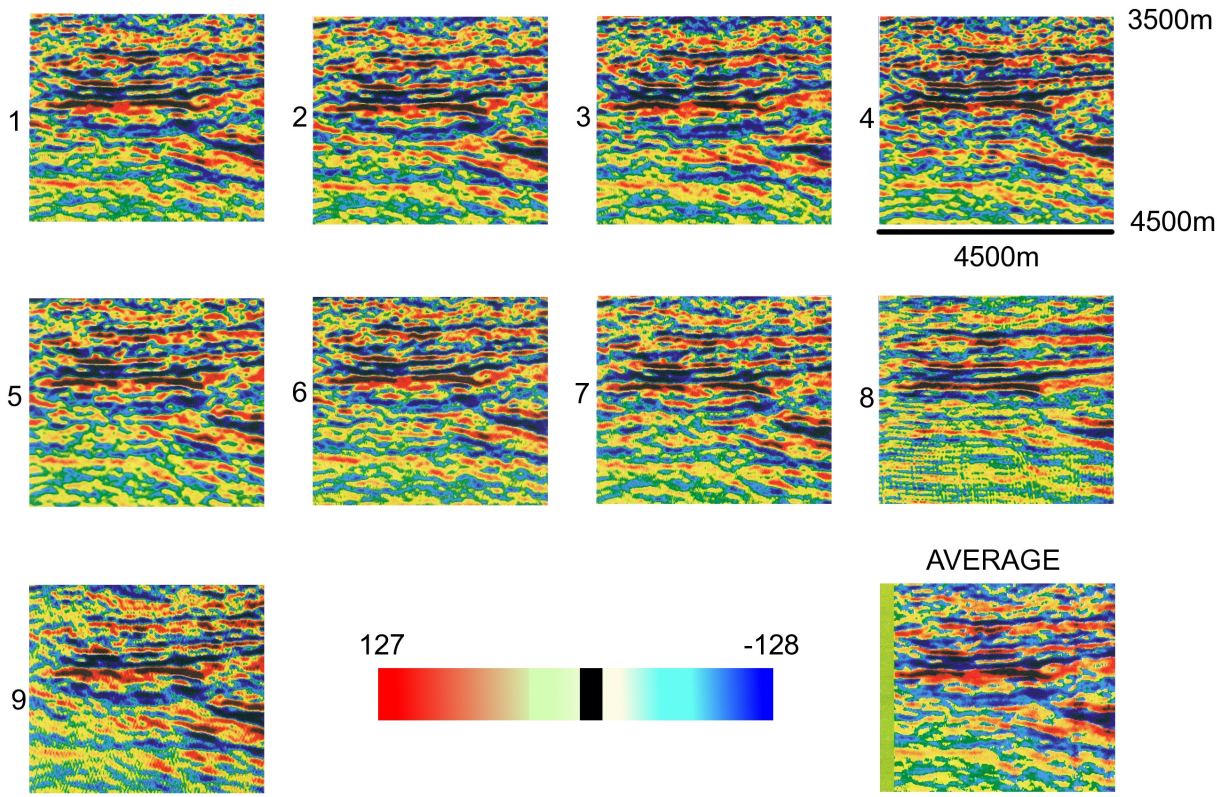

Figure 1: A comparison of nine independently developed packages in the same programming language on the same input seismological data shown by [7]. The y-axis is depth of burial in the earth and the x-axis is distance along the surface of the earth. The outputs vary in the second and sometimes first significant figure. The data needs about three significant figures of accuracy to resolve the geological features (in this case an unconformity trap for a gas field in the North Sea) sufficiently accurately for statistically reliable positioning of a well. The differences were demonstrated to be entirely due to software faults which had been present in the packages in some cases for years. This is by no means unusual as shown by Adams, [1] who demonstrated that a significant number of faults took hundreds and in some cases thousands of execution years to fail for the first time.

context of statistical mechanics to show that the probability p_i of the i^{th} software component in a system containing say, t_i programming tokens in total, obeyed a power-law in the alphabet of *unique* tokens a_i used to build it *independently of the programming language or its application area.* A token here is a keyword, identifier name or operator of a programming language.

$$p_i \approx (a_i)^{-\beta} \tag{1}$$

This in turn leads to a simple prediction that defects will also obey a power-law. One important property of power-law distributions is *clustering* so this gives some theoretical support for the widely-observed phenomenon that defects in software systems do in fact cluster. This can clearly be seen for example in the NAG Fortran scientific library as demonstrated by Hopkins and Hatton [8] as shown in table 1 where all reported defects cluster in only 30% of the executable lines.

Table 1: Defects in NAG Fortran Library

Defects	Components	XLOC
0	2865	179947
1	530	47669
2	129	14963
3	82	13220
4	31	5084
5	10	1195
6	4	1153
7	3	1025
> 7	5	1867

As I pointed out in [6] however, this appears to be a statistical phenomenon with little to be gained by asking the question why are almost 80% of all components defect free. This is akin to asking why somebody has won the lottery, the answer being of course that everybody else didn't.

Clustering is of real value in software testing because if a defect is found, then there is an increased probability of finding another if the same component is re-examined. In other words test effectiveness is improved.

Software Process

Software process in its many forms has become synonymous with High-Integrity developments thanks to initiatives such as the CMMi (Capability Maturity Model Integration) at the Software Engineering Institute of Carnegie-Mellon. This in turn was based on the pioneering work of Humphrey, [9], [10]. The principle notions of this maturity process enabling an organisation to progress through various levels towards full defect management, tracking and prevention have proven to be of great importance.

As with all good things though, there is no question that some implementations of these ideals have become poisoned by bureaucracy and it is all too easy for complacency to creep in, [5]. Nowhere is this more tragically seen than in the events leading up the Afghanistan crash of a RAF Nimrod in 2006, (http://www.official-documents.gov.uk/document/hc0809/hc10/1025/1025.pdf, accessed 01-Oct-2011). In his summing-up, Charles Haddon-Cave QC, author of the independent review stated:

> "Unfortunately, the Nimrod Safety Case was a lamentable job from start to finish. It was riddled with errors. It missed the key dangers. Its production is a story of incompetence, complacency and cynicism."

As important as management of software process is, it should be noted that it makes no guarantees and can shed little light on the effect that residual delivered defects can have on the output of a computation.

Specific Issues in High-Integrity

In the preparation to this paper, I was made aware of a number of issues of relevance in the sphere of Accelerator and Large Experimental Physics Control Systems and I will list these here and make comments on them based on the background above.

Risk versus ingenuity The LHC (Large Hadron Collider) is novel and ingenuity figures large even to get the machine realised. However, risk has always accompanied ingenuity. An ingenious solution is almost by definition new. However new solutions carry risk far more than well-tried solutions because not all of their potential side-effects have been realised. As I stated at the beginning, in terms of dealing with potential safety, this remains a well-rehearsed process with a number of techniques available such as FMECA (Failure Modes, Effects and Criticality Analysis).

Ingenious software solutions are a little different. Ingenuity in software can and often has been associated with obscurity. Obscurity in software is usually a menace because it reduces the power of peer review. Peer review is one of the main weapons in the battle against software defect.

Knowledge transfer and Education This is a vital area. Many of the ways that the problems described earlier in this paper manifest themselves, would be ameliorated with education. Problems with programming languages; the acceptance of basic training in software engineering methods for scientists; engineering technologies such as software redundancy; the imperative for reproducibility; fundamental notions of how to test software and the realisation that software testing is Poppperian in the deniable sense I defined at the beginning of this article, and so on.

In terms of the accuracy of the results of a computation, it is not only the specification, often resident in just a few minds, which is of value. Ultimately, the results depend on the code. The code must therefore be disseminated with the specification to maximise the chance of reproducibility.

At the risk of causing a little upset, I personally have found some scientists highly resistant to the notion that their code is almost inevitably in error. Amongst such scientists, there seems to be the notion that in comparison to scientific research, software implementation is in some sense 'easy'. I have been a practising scientist for much of my career and am a competent mathematician but the formidable difficulties presented by trying to verify the results of a scientific computation are enough to beat humility into anyone who realises just how difficult it is.

Consequently, I would like all people who deal with scientific software to respond to being faced with 100,000 lines of code in the same way, *if we've done a really good job, there will only be around 100 defects in this of which a significant number may well undermine the accuracy of the results.* That is a refreshing, pragmatic and above all, justified approach and I sincerely hope that education will enable this.

Approaches to Design It is commonly thought that High-Integrity systems are specified, built, tested and released. This rather comfortable viewpoint is still frequently taught in universities. In my experience, it could not be further from the truth. In contrast, *every* stage of the implementation of a trustworthy system is accompanied by iteration or prototyping to make sure ideas are feasible before cementing them into a system.

As a very simple recommendation, it is not common for software testers to be included at the design stage. They *must* however be included from the earliest days because testability is an excellent brake on vaulting and frequently unimplementable ambition.

Dealing with technological leaps In High-Integrity systems, the ideal case generally is to ignore them on the grounds that they carry too much risk as described in the section above. However, each must be taken on its own merits recognising that some technological leaps carry great benefit. A very simple example arises from the interoperability and openness of the Internet protocols. The Internet was not designed and no doubt if we had tried, we would have failed. However, from these tiny beginnings of portability and openness allowing cooperating but disparate development, the vast complexity and indeed reliability, of the Internet evolved to everybody's benefit.

CONCLUSIONS

In this essay, I have tried to present some background on why it is so difficult to quantify the inevitable inaccuracy in the results of scientific computation and why the notions of Popperian deniability demand that we make more progress in this vital area.

I have pointed out a few areas in which we are making progress, for example by designing N-versions systems but these are very expensive. Ultimately, there seems no alternative than to open all source code to public scrutiny and hope to garner the same benefits that open source has brought for example to the world of operating systems, where the Linux kernel is now one of the most reliable complex pieces of software the human race has ever built.

Perhaps we can do the same with scientific computation.

FEED-FORWARD IN THE LHC

M. Pereira, X. Buffat, K. Fuchsberger, M. Lamont, G.J. Müller, S. Redaelli
R.J. Steinhagen, J. Wenninger, CERN, Geneva, Switzerland

Abstract

The LHC operational cycle is comprised of several phases such as the ramp, the squeeze and stable beams. During the ramp and squeeze in particular, it has been observed that the behaviour of key LHC beam parameters such as tune, orbit and chromaticity is highly reproducible from fill to fill. To reduce the reliance on the crucial feedback systems, it was decided to perform fill-to-fill feedforward corrections. The LHC feed-forward application was developed to ease the introduction of corrections to the operational settings. The LHC Feed-Forward software has been used during LHC commissioning and tune and orbit corrections during ramp and squeeze have been successfully applied. As a result, the required real-time corrections for the above parameters have been reduced to a minimum. In parallel, successful trials have been made to apply feedforward corrections before commissioning with beam which are based on MAD-X simulation scans over the unused setting functions. In this paper we present the evolution of feedforward for the LHC and discuss further improvements of this software.

INTRODUCTION

The performance of the LHC is highly dependent on the capability to keep under control some key beam parameters (tune, chromaticity, orbit, ...). These parameters must be kept within acceptable limits to allow safe and efficient operation of the accelerator. Early conclusions pointed out that this challenging task would require the implementation of a real-time control system for satisfactory operation of the LHC. Such system, also known as feedback, would correct perturbing effects on the beam reducing beam loss inside the accelerator. However, the prevailing idea was that the mitigation of external effects on the beam should be done by both feedback and feedforward control [1]. The feedforward control would use the past experience from previous fills and apply corrections to the subsequent ones, eliminating some of the observed effects. The feedback systems would then correct the remaining effects through real-time corrections.

Feedforward is seen as a succession of corrections being applied which become progressively smaller, provided a certain degree of reproducibility exists. Consequently, the measurements obtained will gradually tend to the expected result. In the LHC, feedforward corrections are very similar. Corrections are retrieved from measurements of previous fills and then applied to settings to be used in subsequent fills. Currently, both feedback and feedforward control have been successfuly implemented ensuring safe and performant operation of the LHC. This paper presents implementation details of the LHC Feedforward application, results obtained and discusses future improvements.

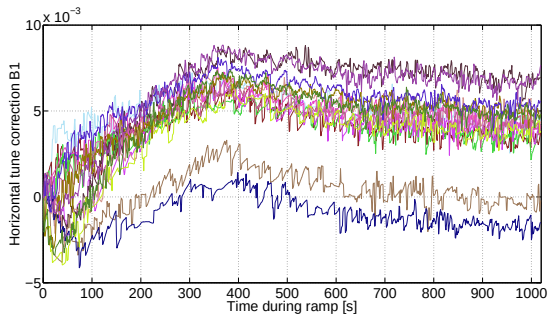

Figure 1: Feedback correction on beam 1 tune on the horizontal plane over 15 fills.

FEEDFORWARD IMPLEMENTATION

Feedback System

Real-time corrections are typically based on a feedback loop. In the case of the LHC one single feedback controller is responsible for correcting tune, chromaticity, orbit, coupling and energy [2]. The hardware receives measurements from the beam position monitors and tune diagnostics systems and calculates the corrections. These are then sent to corrector circuits and RF systems which should stabilize the beam around the established reference value for the beam parameter being corrected. The input data and corrections of the feedback controller are then re-published to be logged in the Logging Database or to be reused in other applications.

Reproducibility

The success of the feedforward correction approach is highly dependent on the reproducibility of the machine on a fill to fill basis. In the case of the LHC, the high level of reproducibility was evident early in beam commissioning. The reproducible behaviour was first observed in tune measurements during ramp. Through the analysis of successive tune corrections made by the feedback systems it was evident that the discrepancy between measurements was quite small. Figure 1 compares feedback corrections of beam 1 tune in the horizontal plane over 15 fills.

The high reproducibility of the LHC came as a pleasant surprise to those who before had seen quite the opposite in LEP. The lack of reproducibility in the machine was evi-

dent and only after 8 years of operation the first feedforward corrections were made.

Logging Database

The Logging Service [3] is responsible for logging all major activity related to the accelerator. This includes a wide range of heterogeneous data ranging from cryogenic temperatures and magnetic field strengths to beam positions and intensities. Data queries are performed either through a dedicated Java API or a desktop tool called *TIMBER*. While the former allows other software applications to access data programatically, the latter is aimed at users who want to explore and visualize the data or eventually export the data to a file.

Smoothing & Sampling

Real-time corrections stored in the Logging Database cannot be directly introduced into LSA. The feedback system logs data at a frequency of 1Hz which translates into a large number of data points that LSA simply does not support. Moreover, the data contains a reasonable amount of noise, which if not removed, would most certainly produce erroneous trim functions. Smoothing is a well known method used in signal processing for mitigation of noise and capture of patterns in data.

There is a wide variety of algorithms but the most commonly used is the ”moving average”. Two variants have been tested during the development of feedforward software: simple or unweighted moving average (*SMA*) and the weighted moving average (*WMA*). The *SMA* is in essence an average value based on a window calculated with the arithmetic mean of subsequences of *n* terms. This average is calculated over an equal number of data points on either side of a central value. Consider the following example of a horizontal tune correction with 10 data points ($P_0, P_1 ... P_9$) and a 5 point averaging window. The points in the extremities are kept intact in the resulting function. The points P_1 and P_8 become the average of their value and of their adjacent points (P_0, P_2 and P_8, P_9 repectively). For all other points the formula is:

$$SMA = \frac{P_{m-2} + P_{m-1} + P_m + P_{m+1} + P_{m+2}}{5}$$

After smoothing, the correction function goes through a sampling process. As the power converters in the LHC cannot ”follow” setting functions for current with data point spacing inferior to 0.1s, caution is needed. Bad data point positioning typically causes a power converter to trip. In the present configuration the LHC Feedforward application will smooth the trim correction using an unweighted moving average of 5-point sliding window and sampling every 10 seconds. This has been proved to be more than enough to efficiently remove signal noise and provide enough data points for setting corrections.

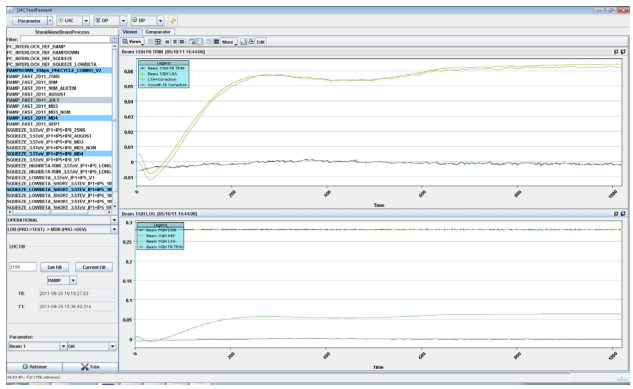

Figure 2: LHC Feedforward application.

LHC Software Architecture

The LHC Software Architecture (LSA) is a framework implemented in Java that covers all essential aspects of control of the LHC such as generation, modification and management of settings, measurements and hardware exploitation. This and other functionalities are made available through a set of clean and well defined APIs divided by domains (optics, parameters, contexts, etc). LSA revolves around three key concepts: *parameter*, *context* and setting. Parameters are organized in a hierarchical structure with each level being dependant on the level above. Thus, changes made on top level parameters are propagated down the hierarchy until the lowest level. The parameters on the top level typically represent physics-related concepts namely tune, chromaticity or orbit, while the lower are related to hardware i.e. power converters. Operators and experts commonly only manipulate top level parameters known as *knobs*. LSA automatically reflects those changes to the lower-level parameters using algorithms called *make rules*. Parameters can have different values depending on the time period considered. This relationship between a parameter value and the time period is called a *context*. There are three types of contexts, *supercycle*, *cycle* and *beam process*. For the LHC, a *context* is called *beam process* and several have been created for the different machine phases: injection, ramp, squeeze, etc.

LHC Feedforward Software

As aforementioned, the LHC Feedforward application has been developed to ease the computation of trim corrections from measurements and their merge with operational settings. It is a standalone application and it is presently available in the CERN control room. The application has been developed using the standard set of technologies for LHC related software: Java, Spring [4] and Swing. Figure 2 shows the interface of the LHC Feedforward application.

At the moment the application is able to perform feedforward corrections on tune, chromaticity and orbit for ramp and squeeze beam processes.

Feedforward corrections on a particular parameter con-

sist of a simple three step process enumerated:

- Logged feedback corrections for the said parameter are retrieved from the Logging Database through its Java API.
- Measurements undergo a smoothing process to eliminate possible noise. Only a subset of these data points are used for the feedforward correction.
- Corrections are applied to the operational settings of the selected parameter using the LSA API.

From the implementation perspective the application is divided into three logical components. The DAO layer is responsible for the communication with both Logging and LSA databases. Direct database access is not possible for security reasons and therefore queries must be done through the already mentioned Java APIs. The business layer contains the correctors and the smoothing algorithms. There are three *correctors*, each one responsible for the calculation of a correction function of a particular parameter, tune, chromaticity or orbit. From the Java implementation perspective these correctors are in separate classes implementing a common Java interface. Hence, *correctors* are homogeneous in functionality and the implementation of a new corrector for a new beam parameter simply requires the implementation of the corrector Java interface. The user interface was created in Swing reusing some of the available standard components from LSA. The interface is divided in three subpanels: a panel for the selection of the beam process to which corrections will be applied; a panel for the selection of the parameter to be corrected and the fill from which the feedback corrections will be taken; a visualization panel where current parameter settings, the proposed correction and the corrected settings are displayed. Additionally, a rudimentary mechanism for comparison of settings and measurements has been implemented. Although quite limited in functionality it allows some brief analysis of fill and settings data.

SIMULATION BASED FEEDFORWARD

In addition to the feedforward of corrections calculated from logged feedback correction data, a second path was used to reduce the stress on the feedback systems. For the optimization of the duration of the nominal squeeze [5] tools have been developed in the toolchain for online modeling [6] that allow to transfer the power converter (PC) *K* parameter settings to MAD-X and recalculate the optics functions. After the settings are generated in a beamprocess for the LHC the online model framework application, `Beamprocess Scanner` is used to calculate the optics functions from the settings extracted at a given time in the PC setting functions. Among other features, the evolution of the optics key parameters (tune, chromaticity,...) can be plotted and stored. The value functions are inverted and applied as correction trims to the available highlevel parameter knobs.

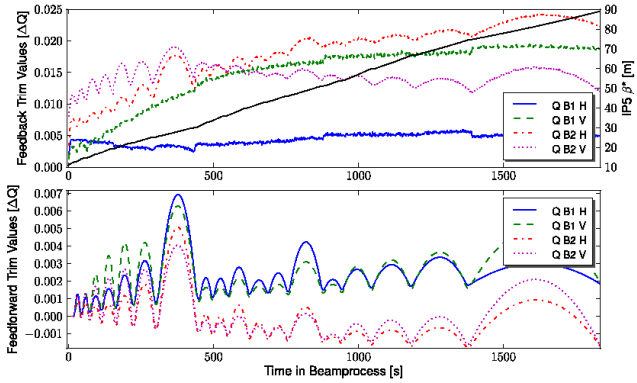

Figure 3: Evolution of the tune knob trims along the 90m un-squeeze. The upper plot shows the real time trims of the tune feedback applied during the un-squeeze, the lower the calculated feedforward corrections from simulation (only the beam 1 corrections were applied). The β* in IP5 from 11 to 90m is shown in the upper plot as well.

This procedure was successfully applied for the tune of beam 1 during the commisioning of the 90m Un-Squeeze [7]. Figure 3 shows the comparison of the tune correction trims required by the feedback system and the proposed corrections from the simulation run. The profit of the feedforward can be clearly observed by the nearly flat real-time trims for beam 1 in the horizontal plane. Real-time trims very similar to the proposed feedforward correction were required for beam 2 where no feedforward had been applied.

RESULTS

The first real test of feedforward corrections was during the commissioning of the first 1.18 TeV ramp. The first ramp trial had already failed due to major tune shifts and the tune feedback was not operational. These were the perfect testing conditions to prove the worth of feedforward corrections. Despite the software being immature and the algorithms not optimized, the accelerator successfully completed the ramp. Since then corrections for chromaticity and orbit have been commissioned for ramp and squeeze. The development focused first on the ramp process which was the more problematic. The next beam parameter to be corrected was chromaticity. Ever since the initial commissioning only one feedforward correction was needed until the present day. Finally, orbit trims have been performed both in ramp and squeeze. Support for orbit corrections was more complex due to the number of parameters involved. Corrections are introduced in LSA at the *K* level since no *knobs* have been defined. Corrections have been successful although very infrequent.

Figure 4 shows the reduction in tune feedback correction after feedforward corrections had been applied to ramp settings.

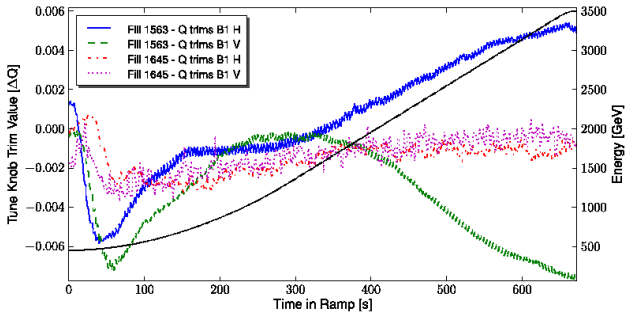

Figure 4: Comparison of the evolution of the tune feedback trims for two fills: 1563 before feedforward and 1645 after feedforward.

CONCLUSIONS & PROPOSED ENHANCEMENTS

The LHC Feedforward application can currently perform corrections during the ramp and squeeze for tune, chromaticity and orbit. The software has been successfully used during 2010 and 2011 achieving the expected results. In parallel, the real-time feedback system has been performing well and was used during every ramp and squeeze in the past year. Hence, feedforward corrections haven't been pursued rigorously and are only performed when new beam processes are created. In addition, due to the high reproducibility of the machine very few corrections were needed throughout 2010 and 2011. However, one should not underestimate the importance of feedforward corrections since they ensure that the beam is not lost in case of feedback malfunctions has occasionally occurred. The simplicity of the LHC Feedforward from an implementation standpoint should be credited not only to the remarkable reproducibility of the LHC but also on the exceptional capabilities of the LSA system. One of the major shortcomings of the application is its limited capability for comparison of parameter corrections and settings over the course of time. This feature would facilitate analysis the effect of feedforward corrections over several fills.

Morever, the application requires a manual selection of the beam process to be corrected, an action prone to mistakes. At the moment of this writing a new feature has been added to the LSA API which allows the retrieval of the name of the beam process used during a determined time period. The integration of this functionality in the LHC Feedforward application would automatize the selection of the beam process and lessen the possibility of mistakes.

ATLAS ONLINE DETERMINATION AND FEEDBACK OF THE LHC BEAM PARAMETERS

J. Cogan*, R. Bartoldus, E. Strauss SLAC, Menlo Park USA
D. Miller, University of Chicago, Chicago USA
On Behalf of the ATLAS Collaboration

Abstract

The High Level Trigger of the ATLAS experiment relies on the precise knowledge of the position, size and orientation of the luminous region produced by the LHC. Moreover, these parameters change significantly even during a single data taking run. We present the challenges, solutions and results for the online luminous region (beam spot) determination, and its monitoring and feedback system in ATLAS. The massively parallel calculation is performed on the trigger farm, where individual processors execute a dedicated algorithm that reconstructs event vertices from the proton-proton collision tracks seen in the silicon trackers. Monitoring histograms from all the cores are sampled and aggregated across the farm every 60 seconds. We describe the process by which a standalone application fetches and fits these distributions, extracting the parameters in real time. When the difference between the nominal and measured beam spot values satisfies threshold conditions, the parameters are published to close the feedback loop. To achieve sharp time boundaries across the event stream that is triggered at rates of several kHz, a special datagram is injected into the event path via the Central Trigger Processor that signals the pending update to the trigger nodes. Finally, we describe the efficient near-simultaneous database access through a proxy fan-out tree, which allows thousands of nodes to fetch the same set of values in a fraction of a second.

INTRODUCTION

ATLAS is one of several large experiments situated on the Large Hadron Collider (LHC) at CERN [1]. To cope with the LHC's extremely high bunch crossing rate, currently ≈ 20 MHz, ATLAS makes real time decisions to accept or reject event data using a trigger system [2]. Several algorithms in the software trigger, such as vertex finding and b-jet identification, rely on specific knowledge of the luminous region to maintain a high identification efficiency for interesting physics events.

However, the parameters of the luminous region–the beam spot–change significantly during the course of an LHC fill. The width typically grows $\approx 3\ \mu m$ while the position can drift by $5-10\ \mu m$. To operate at maximum trigger efficiency, we measure and communicate the beam spot parameters to the trigger farm in near real time. We require over 100,000 vertices to measure the 1,300 colliding bunches in the current LHC structure. Running a vertexing algorithm on the trigger farm itself provides access to the large statistics needed at a high rate. Since each trigger process operates independently of the others, our challenge becomes coordinating them to measure the beam spot and then feed it back to each of them for use in tracking algorithms. This measurement and feedback is accomplished without disrupting data taking.

* jcogan@cern.ch

EXPERIMENTAL SETUP

While ATLAS is comprised of several sub detectors, we will focus on the silicon trackers and the trigger system. We use these systems to observe and reconstruct charged particle track and vertices.

ATLAS Silicon Trackers

The Pixel detector, comprised of three concentric cylindrical layers and three end-cap discs on each side, has an excellent hit resolution of $\sigma_{r\phi} \approx 10\ \mu m$ in the plane transverse to the beam axis, and $\sigma_z \approx 115\,\mu m$ in the direction of the beams. The Semi-Conductor Tracker (SCT), surrounds the Pixel detector and has four concentric cylindrical layers in the central region, as well as nine disks on each side. The SCT's silicon is shaped in strips and provides $\sigma_{r\phi} \approx 17\mu m$ and $\sigma_z \approx 580\mu m$ resolutions. The trigger system uses data from both detectors for tracking and vertexing, however the final vertex resolution is dominated by the Pixel hits. They cover an acceptance range of $|\eta| < 2.5$ in pseudo-rapidity, or about 10 degrees from the beam axis.

ATLAS Trigger

ATLAS employs a three level trigger system, one in hardware (L1) and two in software called the High Level Trigger (HLT). A detailed description can be found elsewhere. Here we restrict ourselves to the points related to the beam parameter determination.

Central Trigger Processor For our purposes, the L1 Central Trigger Processor (CTP) performs two important roles. First, the CTP tells the ATLAS Data Acquisition System what is the current LumiBlock (LB). A LB is a period of data taking with nearly equivalent detector conditions, often lasting 60 seconds. It is important that all the events in the same LB use the same beam spot for consistency checking. Second, the CTP has a small data fragment it adds to the data stream as the events are read into the HLT. This fragment contains information about the L1

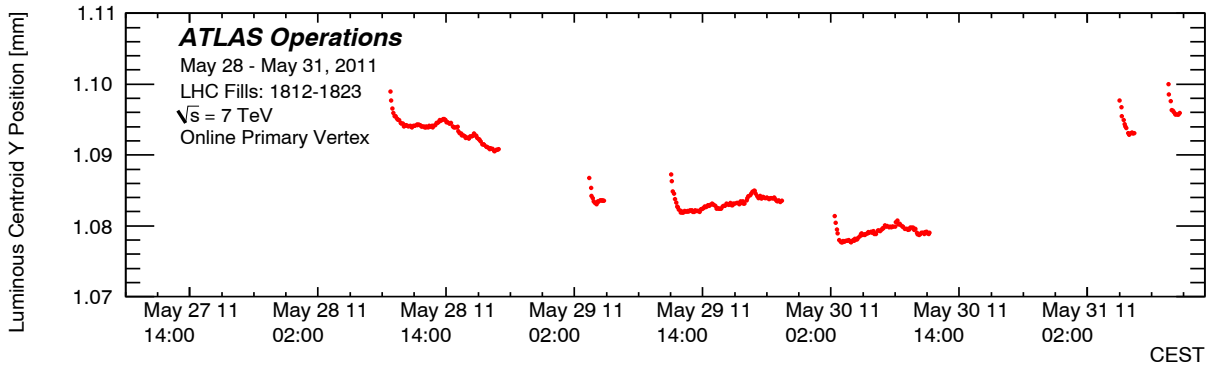

Figure 1: Time-variation of the luminous centroid position in y measured in the High Level Trigger every five minutes, for six separate LHC fills recorded over the span of four days.

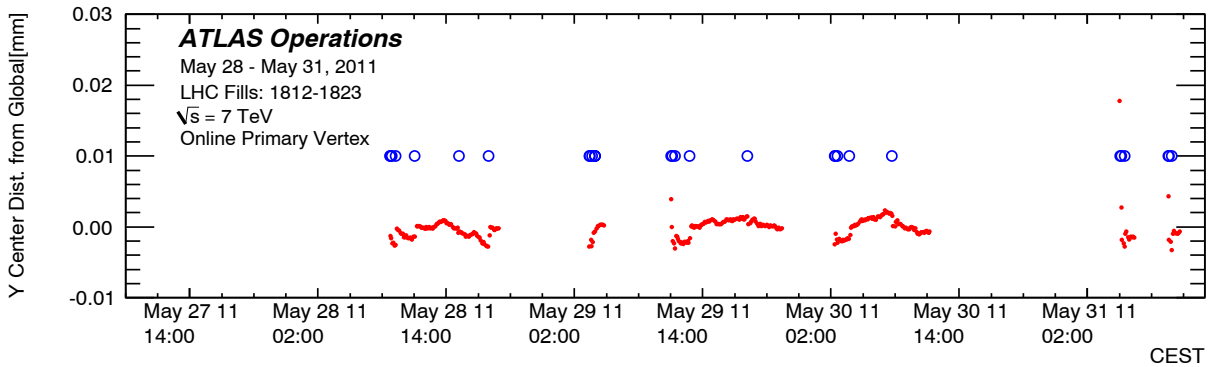

Figure 2: Time-evolution of the deviation of the luminous region position in y. The deviation represents the difference between the most up-to-date measurement and the value stored in the conditions database. The blue circles mark the time of the updates while the red dots show the deviation in millimeters as a function of time. Each red data point uses five minutes of data calculated on the High Level Trigger Farm, for six separate LHC fills recorded over the span of four days.

trigger decisions, the LB, and which set of beam spot parameters to use.

ATLAS High Level Trigger The ATLAS HLT comprises two software triggers: Level-2 (L2) and the Event Filter (EF). The L2 and EF sequentially decide to accept or reject events based on physics objects they have reconstructed. The HLT is run on commercially available server racks with more than 6,000 L2 and EF processors each.

The L2 trigger is the first level to access tracking information and is able to process approximately 75,000 events per second, only examining each event's respective Region of Interest. Due to the presence of tracking information and the high attainable rate of events, the beam spot algorithm runs on the L2 farm for all events that passed certain L1 multi-jet triggers.

The Beam Spot Algorithm

Events which pass the L1 trigger are considered by the beam spot algorithm if they contain sufficiently high quality vertices. When the algorithm processes an event, it calculates the position in x, y, z of the three vertices in the event with the highest number of tracks. Each of these positions is added to local histograms and is used to compute the center of the beam spot and its width (still convolved with the detector-resolution). To calculate the width of the beam spot we employ a split vertex method (described elsewhere [3]), whose primitives are also histogrammed.

METHODS

While building and maintaining this system presents many challenges in tracking and commissioning, we will focus on the hurdles related to the coordination and cooperation of the High Level Trigger Farm.

As we discuss the various components of the feedback system we will mention the latency each one introduces. We define latency to be the time between an event passing the L1 trigger and our first ability to execute an update based on that information. The total latency is approximately 5 minutes.

Gathering

As the beam spot algorithm runs, it accumulates statistics in the local histograms. First we must aggregate these histograms along with those from other applications running concurrently, across all 6,000 L2 processors. We accomplish this via a *Gatherer* tree, in which the leaf nodes

are the trigger processors. Every 40 seconds, the $\approx$ 240 trigger processors in the same server rack send their histograms to the rack level gatherers which sums and stores them locally. At the next 40 second interval the $\approx$ 30 rack level gatherer send their histograms to the top level gatherer where they are summed to produce farm level histograms. From here the farm level histograms are pushed to a historical archive, where asynchronous monitoring applications existing off the L2 or EF farms can query them. To mitigate possible out-of-phase problems between the gatherer and the beam spot monitoring tool, we wait another 60 seconds, bringing the total latency at this step to 140 seconds.

Calculation

Once the histograms are summed across the L2 farm, they are analyzed to extract the beam spot parameters. This requires fitting Gaussian functions to the vertex position histograms to find the distribution mean and width, which correspond to the beam spot center and raw width respectively. The split vertex method is used to calculate the ATLAS vertexing resolution which is then deconvolved to produce a corrected width. Here we calculate both the beam-average parameters as well as per bunch measurements.

We log the calculated parameters, regardless of whether an HLT beam spot update was executed. The parameters are published to the ATLAS online conditions database (COOL) and the LHC logging database (TIMBER). The complete calculation and logging adds 15 seconds to the update latency.

Update Criteria

We do not update the HLT with each new set of beam spot parameters. While the system could handle the continuous feedback, it complicates the following data analysis and adds little extra precision. Thus, there are four criteria, any of which can trigger an update. Each criteria is based on the *current* and *nominal* beams spot. The *current* beam spot refers to the set of parameters just calculated from the HLT histograms. The *nominal* beam spot, on the other hand, refers to the beam spot parameters in use by the HLT. These criteria are completely configurable and were selected to optimize the performance of the displaced vertex triggers. They are as follows:

- The position difference (current to nominal) is greater than 10% of the width in any direction.
- The width difference is greater than 10% the nominal width in any direction.
- The statistical error on a parameter drops by 50%.
- The current beam spot has a valid status flag, while the nominal has an invalid flag. This flag is used to invalidate the beam spot after a beam dump.

The Central Trigger Processor

To update the parameters used by the HLT, the monitoring tool must first indicate to the 13,000 trigger processes that their beam spot is out-of-date. Furthermore, it is imperative that at any given LB the entire trigger farm is using the same set of beam spot parameters.

To accomplish the update, the monitoring application publishes the new parameters to a temporary network location and informs the CTP of the new beam spot.

The CTP writes the beam spot parameters into the conditions database with an interval of validity starting at the next LB, N. At the same time it updates its data fragment with the LB number of the next beam spot update. When the first event in LB N arrives the HLT nodes discover there is a new beam spot available from the information in the CTP fragment. Each trigger process then reloads the parameters from the conditions database. In this way, over 13,000 nodes (L2 and EF) are told there is a new beam spot, with a clean LB transition.

Since the CTP waits for the next LB this step adds 60 seconds to the update latency.

Proxy Tree

There is a final problem: how can 13,000 processes query the conditions database simultaneously? We have two advantages in this situation. Firstly, each process is asking the same question, "what is the beam spot for LB N?". Secondly, each process receives the CTP fragment (and thus queries the database) with some random time offset, $\approx 50\ ms$ relative to the other processes. This offset comes from the average event processing time.

To exploit these advantages we employ a database proxy tree built on the CORAL abstraction layer. Instead of directly querying the conditions database, the trigger process asks a database proxy which may or may not already have the response cached locally. If a proxy does not have the response it passes the request further up the tree. If the top level proxy does not know, it asks the CORAL server which queries the Oracle conditions database. As the response goes back down through the tree, each proxy stores the query-response pair locally and thus prevents unnecessary database access in the future.

Thus, only a few trigger processes need to wait the full round trip time to query the database; most nodes wait only for their nearest proxy to retrieve the answer from local memory. On average, each process only waits $\approx 10\ \mu s$. As the waiting time is short compared to the average processing time at L2, this induces no dead time on the HLT. Finally, the top level servers, CORAL and Oracle, are saved from attempting to field 13,000 requests.

RESULTS

The automatic beam spot determination and feedback has been in place since early 2011. In the following section we summarize its feedback performance and some of the physics results produced from its logging output.

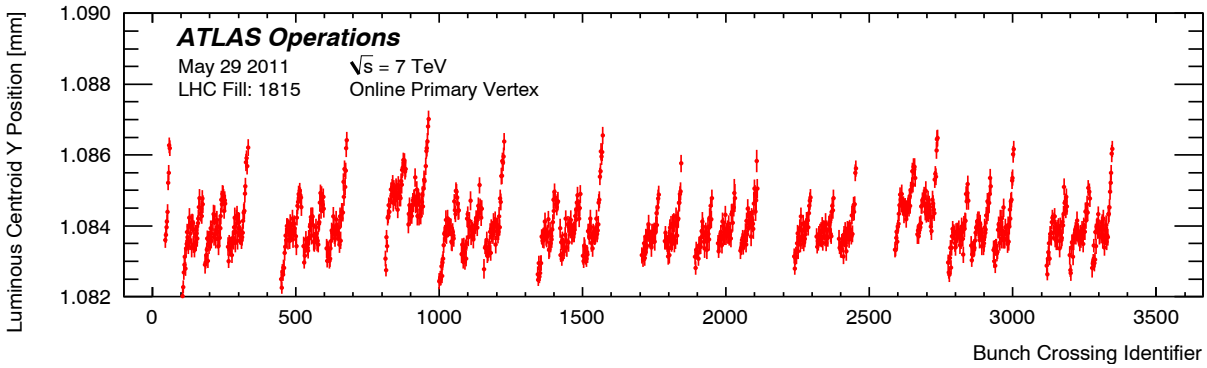

Figure 3: The luminous centroid position in y measured in the High Level Trigger for each of the 1024 colliding bunch pairs separately. Distinct structures are visible, with variations of up to 5 μm and repeating patterns across the injected bunch trains.

Feedback

Here we discuss four measures of the feedback mechanism: latency, frequency, system load, precision.

- Latency: As discussed in **Methods** section, the update mechanism has a minimum amount of time between an event being observed and an update it might trigger. The total latency is $\approx$ 4 minutes which is shorter than typical beam behavior and satisfies the trigger needs.
- Frequency: At the beginning of a fill the update mechanism first fires five minutes after collisions begin (because of latency) and then 4-5 times in the first 30 minutes due to the rapid decrease of statistical errors. After this early phase, beam orbit drift and emittance blow up are the most common causes of beam spot updates. These updates happen much less frequently, typically occurring only once every few hours.
- System Load: Once the HLT nodes receive the new CTP fragment, they must all fetch the new beam spot. However due to the proxy tree this causes only a 10 ms pause for each process on average. This load is so small that it induces no system dead time.
- Precision: As discussed in **Update Criteria** section the feedback mechanism maintains the difference between current and nominal beam spot parameters small by occasionally updating the HLT. In Figures 1 and 2, we see the current and nominal beam spots are kept within a few microns despite 30 micron variations in the current value over the course of a week.

Physics

The occasional updates of the beam spot used by the HLT keeps tracking-triggers operating at a high efficiency. In addition to the updates, the monitoring tools also record the parameters across time and for each colliding bunch separately. We provide time lines of the position and width in all three directions, and the tilt with respect to the beam axis of the luminous ellipsoid. Furthermore each value is available for offline analysis and stored with the statistical error from the fitting process.

The online system is uniquely positioned to perform the 1,300 per bunch calculations because of the high rate of good vertices available at L2. Capitalizing on the high rate of events, we calculate the center of the luminous region for each bunch to within $\approx 1\mu m$, which is better spatial resolution than the LHC dedicated hardware can obtain. Examining the bunch position variation within a train, shown in Fig. 3, we see unambiguous evidence for beam-beam kicks from long range collisions at the LHC. Long range collisions occur when a bunch in beam 1 passes near, but not through, a bunch in beam 2. Each bunch exerts an electromagnetic force on the other distorting its orbit and shape.

CONCLUSION

We have developed a system to calculate and monitor the LHC beam parameters using the ATLAS High Level Trigger Farm. Furthermore, if the nominal beam spot parameters used by the HLT tracking algorithms differ significantly from the current values an update is executed while the system continues to collect data.

We coordinate the communication to and from the 13,000 independent HLT processes by exploiting the gatherer and proxy systems already in place. Finally, the HLT's beam spot is maintained within microns of the current value while inducing no dead time on the data taking system.

BEAM BASED FEEDBACK FOR THE LINAC COHERENT LIGHT SOURCE*

D. Fairley, K.Kim, K. Luchini, P. Natampalli, L. Piccoli, D. Rogind, T. Straumann
SLAC National Accelerator Laboratory, Menlo Park, California, U.S.A.

Abstract

Beam-based feedback control loops are required by the Linac Coherent Light Source (LCLS) program in order to provide fast, single-pulse stabilization of beam parameters. Eight transverse feedback loops, a 6x6 longitudinal feedback loop, and a loop to maintain the electron bunch charge have been commissioned on the LCLS, and have been maintaining stability of the LCLS electron beam at beam rates up to 120Hz. This paper will discuss the design, configuration and commissioning of the beam-based Fast Feedback System for LCLS. Topics include algorithms for 120Hz feedback, multicast network performance, actuator and sensor performance for single-pulse control and sensor read back, and feedback configuration and runtime control.

INTRODUCTION

The Linac Coherent Light Source at SLAC requires several beam-based feedback systems to stabilize electron beam parameters. In April 2010 the LCLS began operating at a 120Hz beam rate. Several architectural changes were made to the LCLS control system in order to stabilize the beam at 120Hz. These changes were implemented in two phases over the last two years, and finalized this summer with the successful commissioning of the LCLS Fast Feedback system. This paper discusses the architectural changes required to achieve single-pulse stabilization at the 120Hz beam rate, the commissioning process and the performance of the feedback system.

FEEDBACK REQUIREMENTS OVERVIEW

The LCLS feedback systems stabilize several beam parameters through feedbacks of three basic types, transverse feedback loops, a longitudinal feedback loop, and a few simple single parameter general feedback loops. These feedback loops were prototyped in MATLAB and had been maintaining stability of the LCLS beam until the summer of 2011.

Transverse Trajectory Feedbacks

Transverse trajectory feedbacks have been commissioned at nine locations along the linac where the launch into the downstream section is important. They stabilize the X and Y position and angle of the beam. The majority of them run at 10Hz rep-rate. The Linac-to-Undulator (LTU) Feedback operates at beam rate, up to 120Hz, for single-pulse stabilization of the beam position and angle before entering the undulator region. See Figure 1.

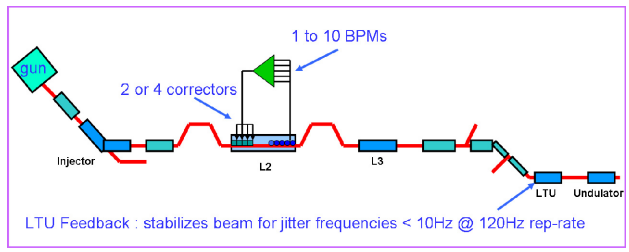

Figure 1: Transverse Feedbacks.

Longitudinal Energy and Bunchlength Feedback

The longitudinal feedback is responsible for single-pulse stabilization of the beam energy at four locations along the LCLS linac, and the bunch length at two locations along the linac. This feedback maintains all six parameters simultaneously using a 6x6 matrix of transfer coefficients [1]. Figure 2 is a schematic of the longitudinal energy (δ) and bunchlength (σ) feedback. The longitudinal feedback operates at beam rate, up to 120Hz.

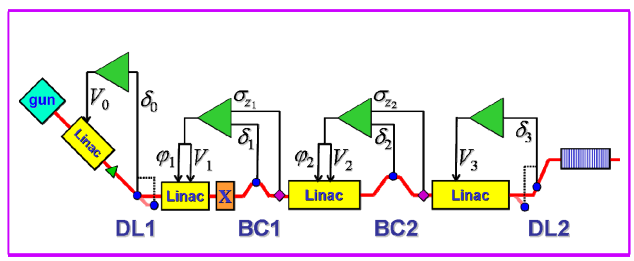

Figure 2: Longitudinal Feedback [2].

Other Simple Feedbacks

The Fast Feedback system allows for addition of feedbacks through its modular 'framework' design. The feedback engineer can define a feedback by entering a set of sensors, actuators, an algorithm, and identifying the parameters to maintain. Several simple single sensor, single actuator feedbacks were planned for the LCLS. The Bunch Charge feedback is an example; it maintains the charge by adjusting the laser intensity based on the charge reading of a beam position monitor.

120 Hz Feedback

In April 2010 the LCLS began operating at 120Hz beam rate. For 120Hz feedback the time-critical devices

*Work supported by U. S. DOE Contract DE-AC02-76SF00515

are the corrector magnets, which require 6ms to settle to within 85% of the reference point. Figure 3 is a diagram of the message timeline required to correct the 120Hz beam. This diagram shows that the feedback calculations must be completed within 2ms to successfully make corrections with the magnets. We further divided the 2ms, giving the sensors 1ms to produce measurements, and the feedback processors 1ms to calculate and send corrections to the actuators. [3]

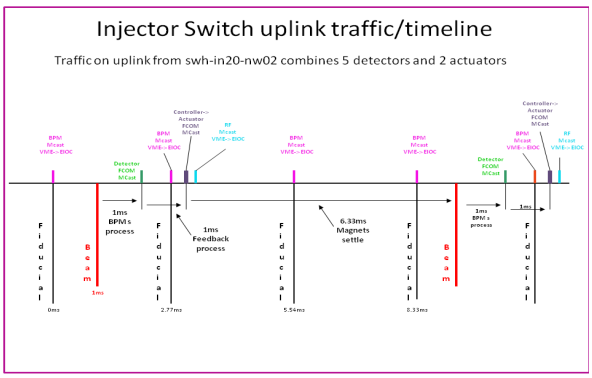

Figure 3: LCLS Fast Feedback message timing diagram.

120 Hz beam operation draws power from two interleaved 60 Hz power line phases which have differing noise characteristics that must be corrected independently by the feedback. The LCLS timing system assigns a 'pattern' for each pulse that indicates from which 60Hz "timeslot" the pulse is generated. This pattern-based timing is quite complex and can indicate other properties on each timeslot, such as whether there is a pulse, or the beam-rate.

The feedback processors must interface to the timing system in order to properly correct for each 60Hz timeslot variation. Since these differing noise characteristics include a large DC offset it was further required that the RF and magnet actuators interface to the timing system so that they can manage these power differences as 'offsets' even when the feedback is off.

Additional Requirements

The LCLS has additional features that prove challenging for continuously running feedback loops. Figure 4 shows where the final energy can be set automatically to a value anywhere between 4.3 GeV and 14GeV. The linac configuration can change using bend magnets to direct the beam into dumps at various locations along the linac, or to move the chicanes. A kicker magnet upstream of the undulator region can kick out pulses on a pulses-by-pulse basis, and is used to protect the undulator magnets. The beam charge can be changed from as low as 20pC up to 250pC

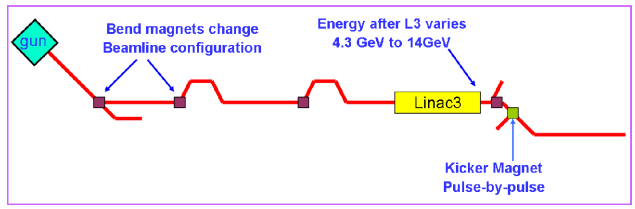

Figure 4: LCLS Changing beam line.

LCLS FEEDBACK COMMISSIONING

In order to meet the 120Hz single-pulse stabilization requirement, and correct for the 60Hz differences the final production feedback system required several architectural changes and additions to the LCLS. These upgrades are described in detail in [4]. The significant changes include:

- Faster network communications
- Timing pattern based processing
- Faster feedback processing

The system upgrades were first developed in a test environment that included a dedicated network with three switches and a router, a timing system processor, two sensor devices and their control processors, a magnet subsystem, an RF control subsystem, and a feedback processor. See Figure 5.

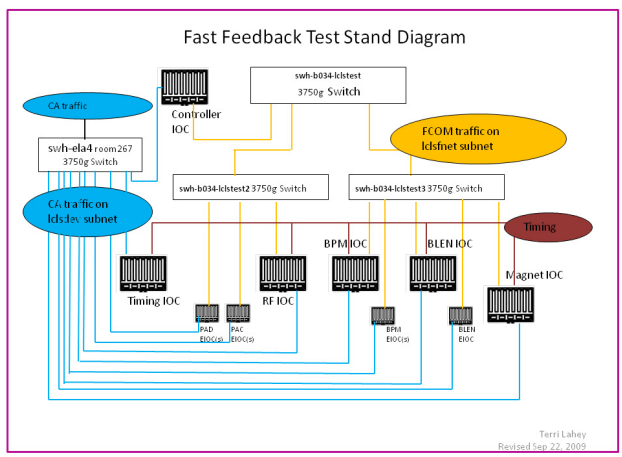

Figure 5: LCLS Fast Feedback test stand.

This full test setup was instrumental to developing these significant changes on schedule. The individual subsystems were debugged, the network was developed and characterized, the configuration tool and EDM displays were developed, and much of the feedback timing and control between subsystems could be worked out without requiring time on the production system. The following sections detail the architectural changes made to the LCLS and describes the performance improvements of the system.

120HZ PHASE I

The 120 Hz Fast Feedback system was installed and commissioned on the LCLS in two phases. Phase I included installing the dedicated feedback network, and

adding a new timing system interface to the actuator devices. During phase I we were allotted three 8 hour shifts with beam to commission the network, sensors and actuators.

Dedicated Network

A dedicated gigabit Ethernet network was added to the LCLS infrastructure, to isolate the feedback communications from all other network traffic. The feedback IOC applications communicate over this new network using an IP-Multicast/UDP based protocol called FCOM, developed at SLAC [5], which works similar to a reflective memory communication scheme. The network interface software provides a simple API and has been developed as a software module that can be added to any IOC that must become part of the LCLS Feedback system. Figure 6 shows the added network. Each IOC used in feedback communicates on this network via a second on-board NIC and the FCOM software module.

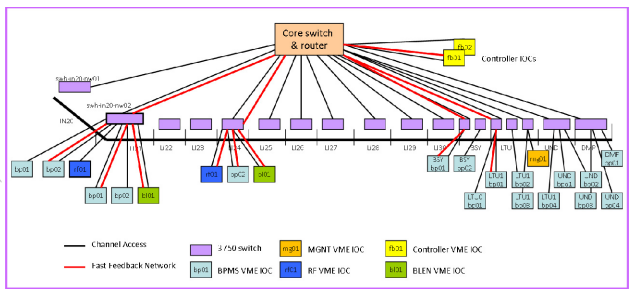

Figure 6: An isolated Feedback network added to the LCLS infrastructure, shown in red.

The Feedback Network is defined as a separate VLAN and includes its own uplinks from the LCLS sector switches to the main switch and router. Test-stand testing demonstrated the feedback communications capable of transporting round-trip messages from a sensor IOC to the feedback controller IOC and back in under 200us.

Timing System Interface

The timing system interface for actuators and feedback loops includes an Event Receiver and interface software module developed at SLAC called a Pattern-aware Unit (PAU) [6]. The PAU is a 'multiplexer' software module, which allows the actuator or feedback IOC to accept set point values per timing pattern. This software module registers with the timing system to receive a fiducial event. It queries the timing system for the current pattern pipeline and chooses the correct set point based on the current pattern. See the diagram in Figure 7.

The PAU allows any LCLS actuator device to discover the 'timeslot' pattern assigned to each pulse in order to synchronize its processing with the pulse.

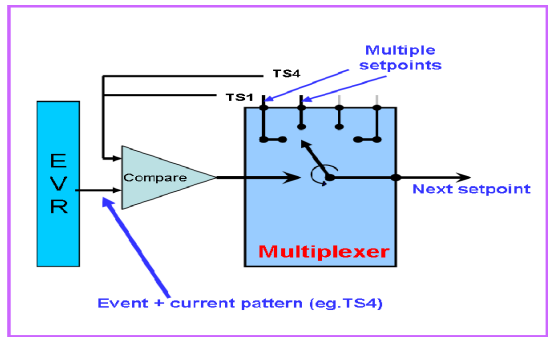

Figure 7: Each PAU input has an assigned timing pattern and actuator set point.

Sensor Devices

LCLS sensors already had an EVR and were interfaced to the timing system. The beam position monitors (BPMs) and bunch length monitors, (BLENs) were made available to the Fast Feedback by integrating the BPM and BLEN control processors with the FCOM software module. On the FCOM network the BPM measurements take less than one msec. to arrive at the feedback IOCs after a pulse, meeting the 1ms requirement.

The BLENs were not able to meet this requirement, but the flexible feedback configuration options allowed us to adjust the longitudinal feedback to delay processing and make up the difference by sending corrections to the RF actuators later in the timeline (the RF system does not require settling time as the magnets do).

Actuator Devices

LCLS RF stations and corrector magnets were integrated with the feedback network with the FCOM module, and the timing system using the PAU module. The new PAU software module proved very successful in aiding beam stability for users before the Fast Feedbacks were commissioned in 2011, and seamlessly handled the addition of the FACET program, which drew additional power on one of the 60Hz power line phases, creating a 30Hz disturbance. Thus the PAU allowed the magnets and RF to correct with an offset at 60Hz and two offsets at 30Hz.

120HZ PHASE II

The second phase of the Fast Feedback commissioning was accomplished in 2011. During this run the Fast Feedback controllers were installed and 11 feedbacks were commissioned using one to four hours of machine development time once per week over several months.

Feedback Controller and Software Framework

In order to gain processing speed, as well as interface to the timing system and the new network, the feedback loop calculations were implemented in EPICS IOCs. The LCLS IOCs consist of a VME6100 processor with two NICs, an EVR, and run the RTEMS real-time operating system.

The Feedback Loop Controller IOC application uses EPICS records for data and configuration storage, and is a multi-threaded application using the EPICS OSI library. This Feedback Controller application can run one or more feedback loops. The Controller IOC application is developed as a software 'framework' that handles common functions, such as managing operational limits on sensor readings, actuator set points, feedback calculated parameters, managing changing machine conditions, and error checking and reporting

Four Controller IOCs were installed and commissioned. The first transverse feedback loop was commissioned over two test days, and then five more were quickly added. The configuration tool described in [4] made it very simple to configure and install the remaining feedbacks, since the framework had already been commissioned. The 120Hz LTU feedback was the last transverse feedback commissioned. The transverse feedbacks average a processing time of less than 400us, meeting the overall 1ms requirement. Figure 8 shows the plots of the working 120 Hz LTU feedback.

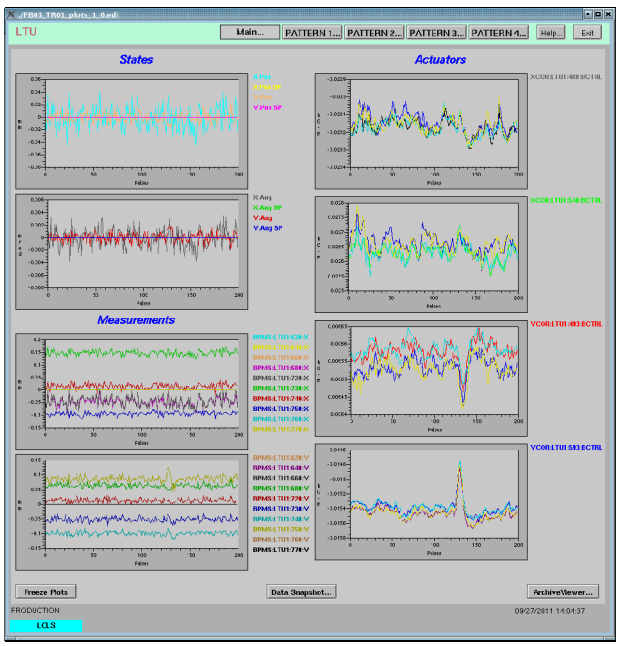

Figure 8: LTU Feedback plots.

The Longitudinal Feedback was the biggest commissioning challenge. As a global feedback, it must maintain energy stability of the beam through the many transitions of the LCLS machine, such as energy changes, charge changes and beam tune-up for each new user. This feedback had to be integrated and tested with many other machine tuning high-level applications and in many different machine configurations.

SUMMARY

Commissioning a feedback system on a production machine is a complex, difficult task. The demands on a working accelerator leave little time for global system commissioning. It is often useful to review the project as a whole and identify efficiencies in hindsight:

- Prototyping the feedbacks in MATLAB allowed machine operation with a fairly stable beam for users until Fast Feedbacks were fully commissioned.
- Investing in an extensive test stand for development allowed engineers to develop enhancements to a near-complete point.
- A 'virtual machine' in the test stand might have reduced even further our need for production test time.
- The network upgrade was inexpensive as it used mainly existing network infrastructure, but it cannot support 360Hz beam rate. A reflective memory solution might have been better for future growth.

Most importantly, commissioning in two phases gave us a fast network and timeslot aware actuators to use at 120Hz before full feedback installation. This allowed us to 'shake out' the bugs for half of this complex upgrade before moving on to the full feedback installation, and later allowed us to stabilize beam adequately during production shifts while commissioning feedbacks on development days.

COMMISSIONING OF THE FERMI@Elettra FAST TRAJECTORY FEEDBACK*

G. Gaio, M. Lonza, R. Passuello, L. Pivetta, G. Strangolino, Sincrotrone Trieste, Trieste, Italy

Abstract

FERMI@Elettra is a new 4th-generation light source based on a single pass Free Electron Laser (FEL). In order to ensure the feasibility of the free electron lasing and the quality of the produced photon beam, a high degree of stability is required for the main parameters of the electron beam. For this reason a flexible real-time feedback framework integrated in the control system has been developed. The first implemented bunch-by-bunch feedback loop controls the beam trajectory. The measurements of the beam position and the corrector magnet settings are synchronized to the 50 Hz linac repetition rate by means of the real-time framework. The feedback system implementation, the control algorithms and preliminary close loop results are presented.

INTRODUCTION

Since the beginning of the FERMI@Elettra commissioning [1], a framework based on Matlab allowed the flexible implementation of slow feedback loops by arbitrarily choosing sensors and actuators from a pool of devices [2]. Based on the response matrix concept and its inversion through the Singular Value Decomposition (SVD), the framework was used to implement a slow trajectory feedback whose main goal was to steer the beam and restore a given trajectory. Since the feedback was a loop written in Matlab running with a period of a few seconds, less importance was given to its dynamic response and ability to damp noise up to a certain bandwidth.

The tight specifications in terms of stability required by a new concept machine such as a seeded FEL together with the uncertainty about the tools necessary to support a challenging commissioning, led to the implementation of a fast feedback system joining the flexibility of the Matlab framework with the capability to interact with the beam shot by shot.

To achieve such results, beam diagnostics (electron and photon Beam Position Monitors – BPMs, charge monitors, bunch length monitors, fluorescent screens, etc.) and actuators (magnet power supplies, RF plants, etc.) communicate in real-time at the linac repetition rate. A distributed shared memory (Network Reflective Memory, NRM) based on a dedicated Gigabit Ethernet network allows deterministic data exchange through the control system [3].

IMPLEMENTATION

Although a feedback loop running at 50 Hz can be easily managed by an up-to-date computer, its components must be carefully evaluated to prevent weird behaviour due to unpredictable execution time. In fact, in order to optimize the feedback performance, the whole process of collecting BPM data, performing feedback calculation and setting correctors, must be carried out in one intra-shot period of 20 ms, thus reserving just a few milliseconds for each of these operations.

CPU

The trajectory feedback relies on the control system front-end computers which interface BPMs and corrector power supplies. An additional computer, called “real-time server”, is dedicated to the feedback processing. They all are VME systems with MVME7100 PowerPC CPU boards running Linux and the Adeos/Xenomai real-time extension. The availability of four Gigabit Ethernet ports onboard allows an easy and effective separation between real-time and non real-time traffic.

The adoption of the Adeos/Xenomai real-time extension reduces the latency and the jitter of critical tasks to the microsecond range. To take full advantage of the system real-time capabilities, all the software which implements data processing and communication with the hardware is executed in Adeos/Xenomai interrupt handlers or tasks. Shared memories and FIFOs allow communication between real-time tasks and Tango servers running in user space.

Sensors

55 stripline (linac) and 25 cavity (undulator region) BPMs provide beam position measurements with a measured resolution of 10 and 4 μm respectively.

The Libera Single-Pass detector, manifactured by Instrumentation Technologies, has been chosen to acquire the bunch by bunch analog signals from the stripline BPMs. The detector features two Ethernet links:

- One 100 Mbit/s port directly connected to the control system network mainly used by the Tango device server, running embedded, to configure the detector parameters (gain, offsets, …) and monitor the electronics status.
- One 1 Gbit/s port providing low latency data by transmitting, synchronously to the machine trigger,

* This work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3.

UDP packets containing horizontal and vertical beam positions and the four raw stripline waveforms.

The real-time acquisition is done by six VME based control system computers, each handling a group of up to 15 BPMs. A standard Gigabit switch serializes the Ethernet packets coming from a group of detectors and sends them to the CPU.

On the CPU side, a dedicated Ethernet port, which is in charge of collecting data in real-time, uses a customised driver to provide raw access to its interrupt routine. Once the packets are received, a kernel module application executed in the interrupt handler extracts and copies beam position information in the NRM and in a local circular buffer.

In the worst case, the whole trajectory is acquired by the front-end computers in about 140 μs.

The cavity BPM detector consists of two homemade MicroTCA cards, ADO and ADA [4]. ADO acquires analog signals directly from the cavity BPM front-end and transmits the data using a UDP packet. ADA drives the BPM calibration signal which is generated after each shot. Both boards provide a 100 Mbit/s Ethernet port that will soon be upgraded to 1 Gbit/s.

The cavity BPMs acquisition system is similar to that of the stripline BPM, except that the position calculation and the detector supervision are directly managed by the low level computers. Three control system computers are reserved for data collection through dedicated Ethernet switches.

Actuators

The trajectory correction is done by two types of magnets: air-cored, used in the low energy part of the linaca nd in the undulator region, and iron-cored, used in the rest of the machine. Two homemade magnet power supplies (model A2605 and A2620 respectively) provide 5 or 20 Amps. The external interface relies on a 100 Mbit/s Ethernet link and a simple UDP protocol allowing to drive the output current and get the status of the power supply at a maximum rate of 200Hz. Eleven low level computers, installed along the accelerator, interface the power supplies through dedicated Ethernet switches.

A kernel module application running in each computer receives synchronization and correction data from the NRM. A timer of the CPU working at 10 KHz, started every machine shot, sequentially set the power supplies connected to it. At each timer interrupt, the kernel module routine sends an UDP packet containing the current setting to one power supply; the timer is stopped immediately after the last power supply is set. The generated current is the sum of the setting provided by the Tango server and the one from the trajectory feedback. A single low level computer manage up to 40 power supplies.

Real-time Communication

The NRM plays a fundamental role interconnecting in a deterministic way all the 20 CPUs involved in the trajectory feedback. It also provides the "bunch number", a sort of "real-time timestamp" which univocally identifies each linac shot.

At present, the total amount of data exchanged on the NRM by the trajectory feedback is about 3 KB per shot. It mainly contains BPM data, corrector values and the related bunch number. The maximum propagation time across the NRM is 1 ms.

The feedback acts on the electron beam bunch by bunch, which means that the correction of a given bunch is calculated based on the measured position of the previous bunches. To maximize the dynamic performance of the feedback, the open loop total delay must be at most one shot period, thus 20 ms. The following is the time schedule of the whole feedback chain within one shot period starting from the generation of a given bunch number:

- **0 ms**: time zero, bunch number starts propagation on the NRM.
- **1 ms**: new bunch number available on the NRM.
- **1.2 ms**: linac shot, the BPMs acquire the beam position.
- **2.2 ms**: new beam positions available on the NRM.
- **3 ms**: feedback routine calculates corrector values.
- **7 ms**: new corrector values available on the NRM.
- **9 ms**: all the corrector power supplies are set with the new values.

The remaining time is sufficient for the magnet current to reach the final value and to provide the required magnetic field to the incoming bunch.

Feedback Processing

Although, for practical reasons, the trajectory feedback routines run on one dedicated CPU, the flexibility of the system allows running bunch by bunch feedbacks on every CPU which joins the NRM.

Similarly to the rest of the real-time software, the feedback code is written as a Xenomai kernel module. In particular, to take advantage of the floating point operations, which are not supported in the standard Linux kernel, the algorithm code runs in a Xenomai thread.

A Tango device server, interfaced to the kernel module by a shared memory, configures at runtime the list of sensors and actuators, sets the control parameters and loads or measures the response matrix for each of the feedback loops. Each Tango device server implements about 100 Tango commands/attributes.

The control algorithm is based on a standard PID controller which is preceded by either a configurable low pass or median filter; the latter has better performance in presence of spiky data. A series of notch filters could be configured to remove efficiently periodic noise sources. As the whole feedback chain is carried out in the time period within two shots, the closed loop dynamics is dominated by one period delay.

The response matrix is empirically calculated by measuring the trajectory perturbation produced by each corrector. The measurement procedure is integrated in

the feedback software and is carried out with a bunch by bunch measurement. The power supplies are driven sequentially with a programmable current ramp. In the meanwhile the BPMs are acquired synchronously to the corrector excitation. At the end of the process, an algorithm calculates the response matrix correlating ramped kicks and trajectory distortions. To halve the measurement time, the process can also be performed in parallel on both planes.

The SVD algorithm is employed to calculate the correction matrix. In the "inversion" process, correctors, singular values and BPMs can be individually weighted. The correction efficiency and robustness to mesurements errors can be optimized by means of singular value reduction with the algorithm known as Tikhonov regularization.

COMMISIONING

During the FERMI@Elettra commissioning no relevant periodic noise has been measured on the beam, except for a ripple introduced by a bending magnet power supply, which has been eventually replaced. Temporary malfunctions of the timing distribution and the low level RF systems have erratically affected the beam trajectory, but also these problems have been solved by fixing the source of the disturbance. Slow drifts, which are mainly related to temperature variations and slow changes in the characteristics of the accelerating cavities, are presently the main noise sources that the feedback is supposed to counteract (Fig. 1).

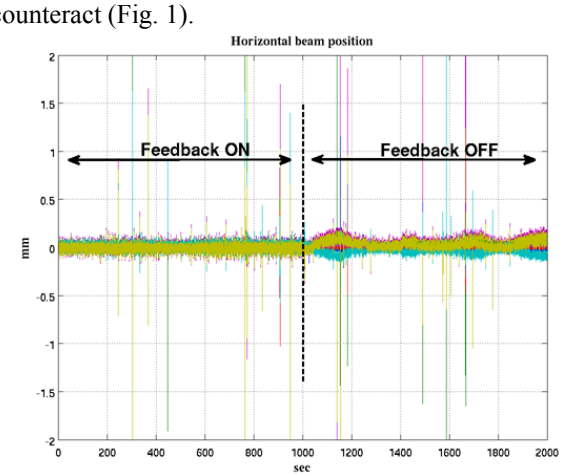

Figure 1: Feedback effect on the horizontal trajectory measured with 34 BPMs in the linac.

Micro interruptions of the electron beam due to quick trips of the RF plants and lasting a couple of linac shots, are automatically recognized by the software using simple heuristic rules and filtered out.

In order to study the closed loop behaviour, a Matlab simulation code has been developed. It allows the rapid tuning of the control parameters by manually optimizing the system response. The sensitivity function calculated with the simulation using a given set of PID parameters (kp=0.05, ki=0.2, kd=0) agrees quite well with the one measured on the real machine (Fig. 2).

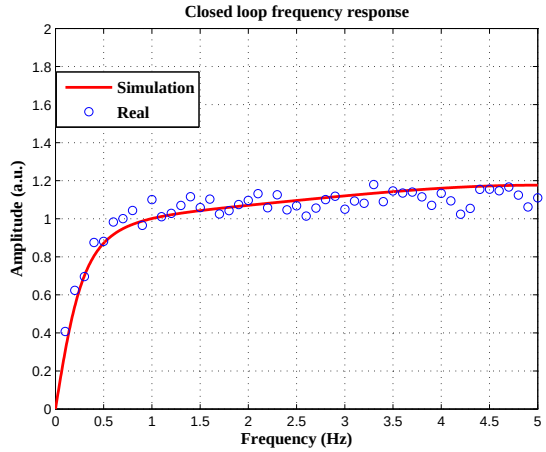

Figure 2: Simulated vs. real sensitivity functions with the linac working at 10 Hz repetition rate.

At present two fast trajectory feedback loops are used during commissioning shifts (Fig. 3). The first controls the trajectory in the linac by means of 34 BPMs and 34 correctors. The main goal is to keep stable the beam trajectory in the accelerating structures. The second makes use of 8 BPMs and 8 correctors, and act on the beam position in the undulators. With the present configuration of the control parameters no evidence of disruptive coupling between the two loops has been noticed. Nevertheless a global approach using all of the BPMs and correctors in a single loop will be pursued in the next future.

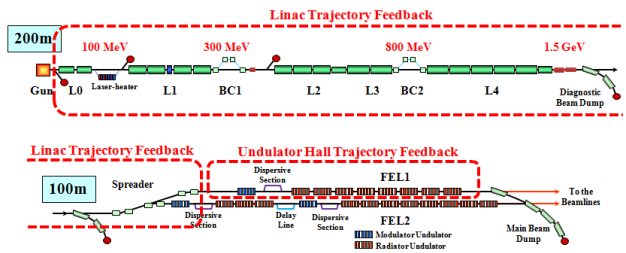

Figure 3: The machine sectors where the two feedback loops are currently operating.

The fast response matrix measurement procedure demonstrated to be very efficient. By using a four-shot ramp per corrector, the measurement of the linac response matrix in both planes takes less then 20 seconds (10 Hz repetition rate).

Small variations of the beam energy, changes of the beam transport optics, uncorrelated noise coming from the electronics and non linearity of the BPMs can lead to discrepancies between the response matrix and the real machine, and produce an increase of the beam position *rms* when the feedback is on. The amplification of the noise is concentrated in the higher part of the spectrum. In order to mitigate this problem, the Tikhonov regularization method has been adopted. It allows a good correction at the lower frequencies while the higher part of the spectrum is not amplified significantly. This method has the additional advantage of avoiding the

correction of unreal trajectories that often brings to useless high corrector strengths.

Although the fast feedbacks have been successfully used during the first experiments on the beamlines, the most frequent usage is during the machine commissioning with the following purposes:

- Perform trajectory scans inside the accelerator cavities to find a condition that minimizes the beam emittance.
- Restore a given golden trajectory.
- Keep stable the trajectory when changing the phases of the RF plants.

Each feedback loop can be easily operated and monitored from the control room using a QTango [5] graphical panel (Fig. 4).

The general configuration of the feedback including correction and control parameters can be changed also by non-expert people. In addition to the standard ON/STANDBY/OFF buttons and trajectory plots, a *SlowMode* checkbox reduces automatically the feedback gain by a factor of ten. When the feedback is run just once to restore or steer a trajectory, the *SteerMode* checkbox controlling the Tikhonov regularization factor is enabled, and the singular value reduction is not applied.

A useful graphical feature using slide bars allows selecting just a part of the machine and to close the loop on it. This is accomplished on the fly by setting to zero the weights of BPMs and correctors that must be excluded.

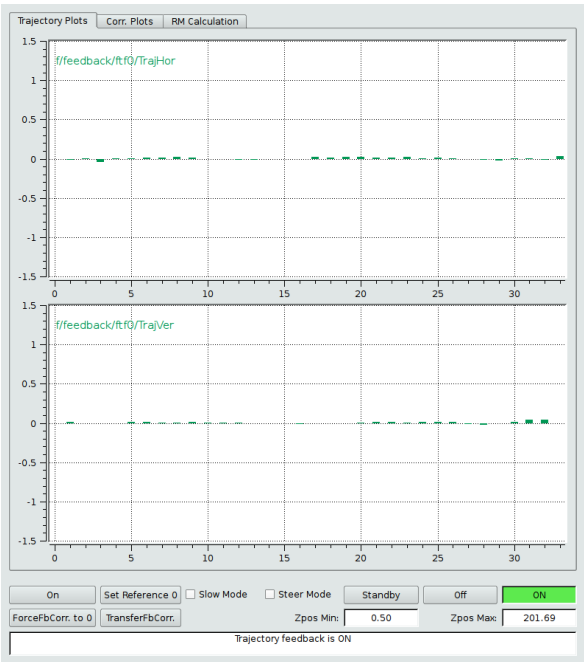

Figure 4: Fast trajectory feedback control panel.

CONCLUSION

The experience gained in developing fast feedback systems for the Elettra storage ring [6] together with the availability of a powerful and well integrated real-time framework, helped the development and commissioning of the fast trajectory feedback, which is now regularly used during machine operations.

Additional features are planned to facilitate its operation and increase the robustness in case of disruptive events such as unexpected changes of the beam energy due to trips of the linac accelerating sections.

THE DESIGN OF THE ALBA CONTROL SYSTEM: A COST-EFFECTIVE DISTRIBUTED HARDWARE AND SOFTWARE ARCHITECTURE

D. Fernández-Carreiras, D. Beltran*, T. Coutinho, G. Cuní, J. Klora, O. Matilla, R. Montaño, C. Pascual-Izarra, S. Pusó, R. Ranz*, A. Rubio, S. Rubio-Manrique, R. Suñé*,
CELLS, Cerdanyola del Vallès, Barcelona, Spain

Abstract

The control system of Alba [1,2] is highly distributed. The hardware infrastructure for the control system includes in the order of 350 racks, 17000 cables and 6300 equipments. More than 150 diskless industrial computers, distributed in the service area and 30 multicore servers in the data center, manage several thousands of process variables. In this environment, the software client server model, with fast and reliable communications, was imposed. Tango[3] plays an important role. It is a big success story of the Tango Collaboration, where a complete middleware schema is available "off the shelf". Moreover, Tango has been effectively complemented with Sardana SCADAs (Supervision Control And Data Acquisition) [4,5], a great development effort shared and used in several other institutes.

The whole installation has been coordinated from the beginning with a complete cabling and equipment database, where all the equipment, cables, connectors are described and inventoried [6,7]. The cabling database, or "ccdb" can be considered as the core of the installation.

This paper explains the design and the architecture of the control system, describes the tools and justifies the choices made. Finally, it presents and analyzes the figures regarding cost and performances.

INTRODUCTION

Alba is a third generation synchrotron located near Barcelona in Spain. The Installation of the Control System for the Accelerators finished at the end of 2010. The final functional tests took place during the first weeks of 2011, right before the commissioning of the Storage Ring (see Fig. 1), which started the 8th of March of 2011. Currently we are carrying out the final stages of the installation and commissioning of the seven Beamlines of the first phase.

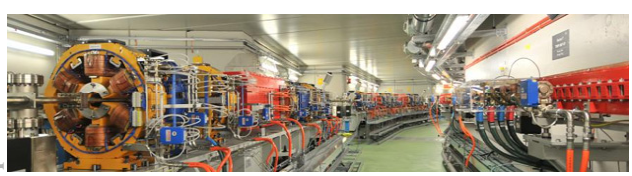

Figure 1: Picture of the Storage Ring (left) and Booster Accelerator (right) in the tunnel.

ARCHITECTURE AND PHILOSOPHY

Typically equipments are located in the tunnel and their controllers and electronics are installed in cabinets in the service area. This results in hardware being distributed all over the place. With this highly distributed installation, we needed as a general rule, distributed software, combined with a fast and robust fieldbus. On the other hand, although we have real time requirements, they are managed by the hardware avoiding the complexity and costs of managing a real time operating system such as RT Linux, VxWorks or RTEMS.

Ethernet as a Fieldbus

Ethernet is the standard for both control networks and fieldbuses. This makes the installation homogeneous, easy to maintain and guarantees a good longevity of the components. The network is physically configured as a star with two main switches having a backplane of 800Gbps each, and 20 Gbps links with the aggregators. It is logically organized in Virtual LANs (VLAN) for separating sectors and subsystems. There are independent VLANs for Safety, Diagnostics CCD cameras, Monitoring and Controls. In addition, every sector has a VLAN for Controls handling Beam Position Monitors, Power supplies, diagnostics, diskless computers, etc. The control room has workstations for running human machine interfaces all connected by Ethernet without any other application specific cable. The only exception is the Personnel Safety System (PSS), which has an independent Safety Bus, and an independent cabinet in the control Room.

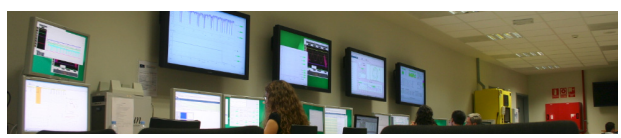

Figure 2: Picture of the Control room for the Accelerators.

The different pieces of software run on diskless compact PCI and industrial PCs, distributed in the service area with direct access to the hardware devices. The boot servers, archiving, Tango databases, CCD data acquisition and various other services, like electronic logbooks are centralized in the computing room (showed in the Fig. 2), where virtualization is broadly employed.

Tango as the Middleware

Tango was chosen among the three options we considered (Tango, EPICS [8], commercial SCADA). Although EPICS had clear advantages in several aspects, like a significantly wider catalogue of tools and a much wider community, Tango was preferred because of its

*On leave

newer technologies, object orientation, and definitely, because most members of the controls team at that time, having worked at the ESRF[9] before, were more familiar and in contact with the Tango community. Choosing Tango, we also disallowed having real-time and deterministic links in our middleware. We use a standard Linux distribution (currently openSUSE 11.1), as the main operating system for controls, with no real time extensions, which makes it cost-effective and easier to deploy and to maintain. Due to few very specific cards, a Windows installation is required in few computers (currently Windows XP), for which drivers were only available for this operating system. This is the case of the Low Level Regulation of the Radiofrequency cavities.

Human Machine Interfaces

Commercial SCADAs, have notoriously evolved over the last fifteen years. After the "crisis of the dot-com" at the beginning of the last decade, many companies were merged or absorbed in bigger ones. Nowadays, the number is still considerable, although, Wanderware and Siemens WinCC are the most popular. They used to be "monolithic" in the past, then they became distributed and today they turned out to be "Networked" in order to match recent requirements. They are integrating upwards with ERPs, and whereas in the past the challenge was to support a large variety of hardware, today the challenge is to ensure consistency of the information, atomic transactions and cyber security. Nevertheless, there are many examples of commercial SCADAs in particle accelerators, like "Global Screen" at Soleil [10] or PVSS (now absorbed by Siemens) at CERN [11] among others. However often in the industry, SCADAs cover the whole manufacturing process, whereas in scientific installations is often limited to human machine interfaces.

Commercial SCADAS did not fulfil our requirements. We needed an optimized access to hardware, a powerful and flexible environment for sequencing and macro execution, software synchronization, generic graphical interfaces, and access to save/restore facilities. For these reasons, we promoted a development of a scientific SCADA on top of Tango: Sardana [4]. Sardana also covers a complete framework for graphical interfaces: Taurus [12].

Real Time Hardware, non Deterministic Software

There are some cases, in which deterministic links are mandatory, such as synchronization or interlocks, where the system cannot afford having sporadic delays or loosing communications. We managed this determinism by suitable hardware, where dedicated systems handle the specific requirements.

The Equipment Protection System [EPS] [13] uses B&R hardware. It comprises about 50 PLCs and more than 100 distributed periphery supervising more than 7000 signals. Temperatures, water flows, valves, flow switches, compressed air, and vacuum valves, gauges and pumps are controlled by the EPS. Equipments inside the tunnel are integrated in shielded boxes with the remote periphery, guaranteeing a better modularity, shorter cables and facilitating the maintenance works.

All CPUs are intercommunicated by an independent deterministic network (Ethernet PowerLink), with a cycle time of 10 ms in most cases, ensuring a response time for interlocks of that order. Every experimental station has an independent EPS, communicating with the machine through hardwired digital inputs and outputs.

The Personnel Safety System is based on Pilz PLCs, SIL3 compatible following the norm IEC 61508. It is totally independent concerning hardware and software and relies on a dedicated safety bus with about 150 ms cycle time.

The timing system [14][15] is based on events and is built with hardware provided by MRF (MicroResearch Finland). It transmits the events using a clock of 125MHz synchronous with the RF frequency and a few picoseconds jitter. Each event receiver is configured to perform an action (i.e. activate pulse on an output) for a particular event code. There is one event generator and about 100 Event Receivers installed on the diskless compact PCI in the service area.

This infrastructure also handles the Fast Interlocks, redundant to the PLCs interlocks. This is an innovative system implemented by MRF upon Alba requirements. The system has a 8 nanosecond resolution providing time stamps and buffering of events, required for post-mortem analysis. In total 418 elements of the accelerator are synchronized and 49 fast interlocks are managed with a response time of about four microseconds.

AUTOMATIC CONFIGURATION AND CODE GENERATION

In order to facilitate the installation, and reduce maintenance time and costs, a central information repository has been setup: the equipment and cable database [6]. It is a relational database implemented on mysql, where types of equipments, cables and connectors are declared allowing later naming and managing instances of every item. This is the repository used for cabling installation, generating labels, cable check and validation. It has been extensively used during the preinstallation, and is constantly updated and kept up-to-date. Figure 3 shows a view of its web interface.

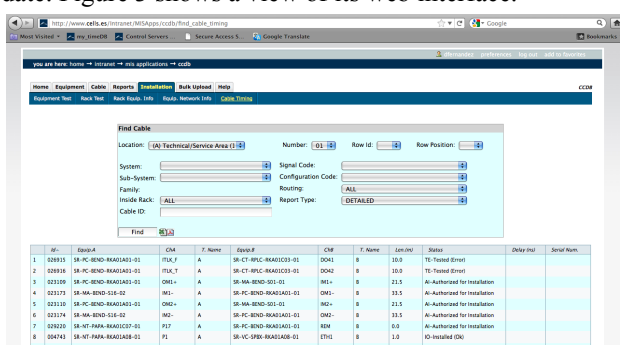

Figure 3: Snapshot of the web interface of the Equipment and Cabling database.

This is critical, since it is used for automatic software generation for PLCs, some Graphical interfaces and several files for configuration of network services, like DHCP, Radius and DNS.

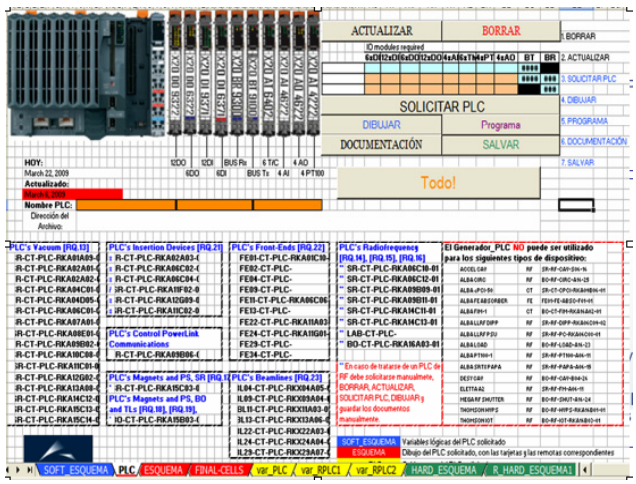

Figure 4: Excel application for EPS code generation.

Many components of programs running in the PLCs of the Equipment Protection System are generated automatically from the database. The huge effort done for keeping the database up-to-date and consistent pays back here, when software components are configured automatically, reducing the errors and increasing the efficiency. A Visual Basic Script running in excel generates another file containing the declaration of variables, data structures, software tasks, modbus mapping and documentation [16]. Figure 4 shows a view of the front page of the excel file. The Logic is still programmed manually due to the difficulty managing the large number of exceptions to the standard interlock rules. In addition, Tango attribute names and the expert GUIs are also generated from the controls equipment and cabling database.

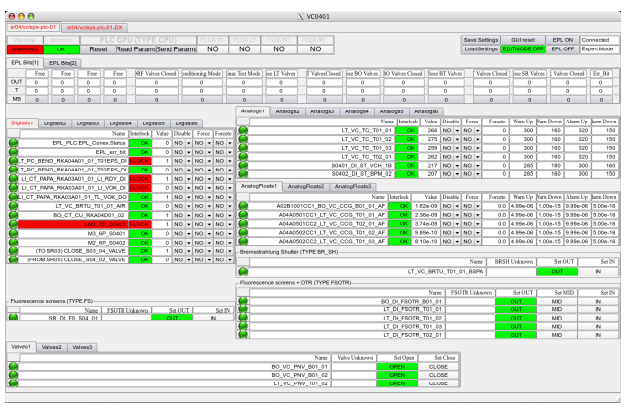

Figure 5: One of the expert GUIs of the EPS.

Important parts of the control system have also been configured from the cabling database. A python API [17] has been created for access to the ccdb, which provides functions for different purposes like extracting all information about equipments and connections between equipments. For example, for each vacuum device (gauge, pump or valve), all ports and the controller corresponding to that device, as well as the serial line and controls computer associated are extracted from the database. Other valuable pieces of information are also queried from the ccdb like the particular PLC which manages a given pressure interlock, the vacuum valves associated to that interlock, etc. Furthermore, the information available in the cabling database is used to extend the displays of the control system and allocate equipments in generic browsers. Figure 5 shows a view of a graphical user interface generated from the ccdb. The cabling API enables applications to sort and search by location of controllers or by location of the gauges connected to them. Also, graphical interfaces benefit from a centralized repository. For example a grid widget may query the cabling database to obtain the name of the instrument connected to a port, and show it as a label. Figure 6 shows the general user interface for vacuum controls, which uses few widgets automatically generated.

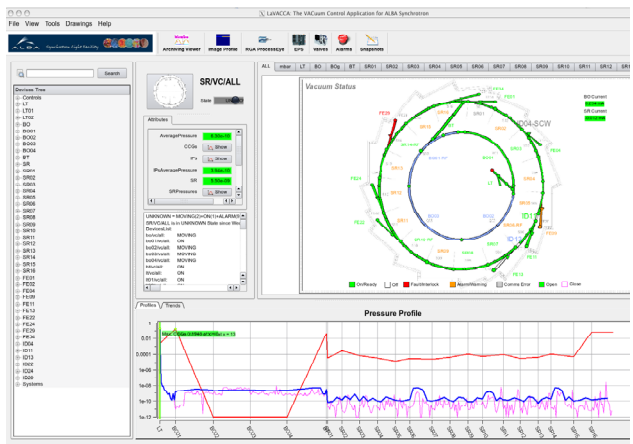

Figure 6: Snapshot of the vacuum control general graphical user interface (Vacca).

COSTS AND BENEFITS

We have considered price and functionality as important constraints for the design of the control systems Tango is cheap in terms of licences. It is distributed under the LGPL conditions and is free of charge. We have a similar case regarding the Operating Systems. Most distributions are free (openSUSE11.1). Windows workstations and servers cover less than 10% of the installation. Most programming is written in Python, for both control and data acquisition.

However, in several cases commercial packages like Matlab are needed. Packages for accelerator modeling like Matlab Middle Layer, need Matlab licences.

The choice of cPCI and Industrial PCs made the bill considerably cheaper compared to VME. We considered savings of at least 30%. ADLINK proved to be a cost-effective solution for cPCI crates, CPUs, data acquisition cards (DAQ) and Industrial PCs. ADCs are used in most places, whereas the use of voltage to frequency converters and counters cards is limited to few cases.

B&R PLCs proved to be a cost-effective solution. They are small powerful and above all, economical if we compare them with the market leaders such Siemens.

Concerning cabling, the fact of having a highly distributed architecture with electronics installed inside shielded boxes located in the tunnel, allowed shorter and cheaper cables. For a machine of 268m, we have an average length of 20 meters (36 if we consider only pure signal cables) with a final average cost of 120 Euros per cable. This is only a very rough estimation since for the price depends much on the type of cable. A high voltage cable for vacuum devices is much more expensive than a connection to a thermocouple, for example.

The having Ethernet as a fieldbus increased the cost of the network installation for the control system, but reduced significantly, the number of serial lines, which installation and commissioning is more time consuming, and we reduced significantly the number of cable types. CCD cameras, oscilloscopes, power supplies etc. are all controlled by Ethernet, reducing drastically the number and the length of coaxial cables.

CONCLUSION

The design of the control system had as main premises being functional and economic. From the beginning, a special attention was paid to cost and effectiveness. Choices such as Ethernet as a fieldbus proved to be correct since now (five years after the design of the control system of Alba) is the common choice. Currently during the commissioning, choices like a compact and economic PLC, or the absence of VME (extremely popular in this type of installations), are working very well. The tendency is to reduce the number of computers and rely even more on Ethernet.

Moreover, in order to make the installation and maintenance easier, a central repository (so called cabling database or "ccdb") was created. It soon turned out into a central repository for the whole installation, kept up-to-date and from where important pieces of software were automatically created. Some examples are the declaration of variables in PLCs, files for configuration of network services, dynamic attributes in device servers and components of graphical interfaces. This is a great tool for the maintenance since the information related to the installation is only in one place.

CONTRIBUTIONS

The whole controls, electronics, network system administration groups actively participated in the design, installation and tests of the control system. Among them, the person managing the installation of the Cabling Toni Camps and Beamline electronics engineering, Julio Lidón had a important role. Other persons which actively contributed are Zbigniew Reszela, Antonio Milán, Maciej Niegowski, Sergi Blanch, Jairo Moldes, Lothar Krause and Fulvio Becheri. Furthermore, the help of the Management Information System group, in particular, Oscar Sánchez, Isidre Costa, Alberto Nardella, Anne-Cecile Klora, Daniel Salvat and Valentí Prat, who developed and maintained the cabling database, the TimeDB and the Project Management system has been crucial. Furthermore we would like to thank the whole the ESRF in particular Emmanuel Taurel, Alejandro Homs, Vicente Rey and Laurent Claustre, who were involved in the early stages, and the other partners in the Tango Community, Nicolas Leclercq, Pascale Betinelli and Alain Buteau, from Soleil, Mark Heron from Diamond, and Timo Korhonen from SLS, who were always available to answer questions and give valuable advice.

TOWARDS HIGH PERFORMANCE PROCESSING IN MODERN JAVA BASED CONTROL SYSTEMS

M. Misiowiec, W. Buczak, M. Buttner, CERN, Geneva, Switzerland

Abstract

CERN controls software is often developed on Java foundation. Some systems carry out a combination of data, network and processor intensive tasks within strict time limits. Hence, there is a demand for high performing, quasi real time solutions. Extensive prototyping of the new CERN monitoring and alarm software required us to address such expectations. The system must handle dozens of thousands of data samples every second, along its three tiers, applying complex computations throughout. To accomplish the goal, a deep understanding of multithreading, memory management and interprocess communication was required. There are unexpected traps hidden behind an excessive use of 64 bit memory or severe impact on the processing flow of modern garbage collectors. Tuning JVM configuration significantly affects the execution of the code. Even more important is the amount of threads and the data structures used between them. Accurately dividing work into independent tasks might boost system performance. Thorough profiling with dedicated tools helped understand the bottlenecks and choose algorithmically optimal solutions. Different virtual machines were tested, in a variety of setups and garbage collection options. The overall work provided for discovering actual hard limits of the whole setup. We present this process of architecting a challenging system in view of the characteristics and limitations of the contemporary Java runtime environment.

OVERVIEW

Diagnostics and Monitoring at CERN

Device monitoring and alarm management systems have long been running separately as part of the CERN accelerator controls environment [1]. Both deal with a vast quantity of diverse devices scattered around CERN installations to acquire, process and redistribute their data. What makes a difference is the meaning of data. Monitoring system periodically collects the statuses of the supervised infrastructure. In principle, data shows no irregularities, as the underlying equipment is by and large healthy. The alarm system, however, carries the information already known to have indicated abnormal conditions. They must be swiftly delivered, through the Operators, to the experts capable of solving the problem. In one case both systems clearly intersect: when the monitoring data flags an erroneous situation and must be converted into an alarm.

Prototyping

Recently it has been decided to prepare and evaluate an architecture of the combined solution, a system that would coalesce all the types of data, devices and users, embracing both worlds. Significant effort has been put to model several possible outcomes based on well established CERN software packages [2][3]. To constitute a solid foundation for such analysis and discover genuine physical boundaries we would certainly face, an independent prototype was constructed [4].

For prototyping it was decided to only cover the most critical topics. The outcome was focused and tuned to maximal extent to satisfy the hardest requirements. From a technical viewpoint such effort helped us to:

- determine if the requirements can be realistically matched with available components,
- establish hard limits for performance & scalability,
- find optimal solutions for the most resource-consuming operations.

In this paper we discuss selected subjects - design choices, issues, best practices - that have become important in achieving expected quality.

ARCHITECTURE

Problem Description

CERN monitoring system works in a heterogeneous environment. It has to communicate with a variety of *devices*, through a set of different protocols. Many devices are regular CERN Linux servers. Majority, however, typically front-ends to the physical equipment, operate on less standard or legacy architectures, unknown to Java products. Devices provide monitoring or alarm data in form of *metrics*, sample values describing their state. Metrics are published either periodically (*monitoring agents*) or immediately after an erroneous condition is discovered (*alarm agents*). Devices and the network that connects them are *not fully reliable. No real-time* infrastructure is used to communicate with them. Once delivered to the monitoring server, metrics have to be verified, correlated, converted into alarms, etc. Such an individual *calculation* based on metric(s) is defined in a *rule*. Decisions are made which of them and in what form should be afterwards delivered to the clients - the GUI applications that present the state of the CERN infrastructure to the Operators. Information flow must be *preserved* for future inquiries too.

Requirements

The system is expected to fulfil a long list of requirements, of which a subset relevant to this paper is presented. For this paper we focus on the performance, scalability and reliability issues. The system must be at the time of writing able to:

- acquire alarm metrics from around 10000 devices,
- deliver alarms within bounded time frame,
- acquire 50 metrics/min from 2500 monitoring agents,

- in total, on average, handle 2000-5000 metrics/sec,
- in total, on average, perform around 5000-20000 rule calculations/sec,
- sustain traffic peaks in form of alarm avalanches with several times bigger throughput.

Considering constant expansion of the CERN infrastructure, the amount of equipment is bound to increase. Thus, our system would hopefully accommodate for double the numbers presented above.

Among the points omitted here are: two-way communication with devices, managing misbehaving devices, reconnections, filtering the input, failover mechanism or any configuration aspect.

Design

The overall design follows a classic multilayer architecture with clear separation of concerns. The bottom tier is represented by scattered devices - data providers. Above lies a data acquisition tier (DAQ), which caters for a variety of middleware protocols to communicate with the devices. Those include JMS, Yami4 [5], SNMP and CERN extension of CORBA called CMW [6]. DAQ is located on a separate machine due to the nature of its intensive self-contained computations. Another machine hosts the middle-tier whose main component is a rule engine (RE), a core calculation unit of the system. All the components above the device layer are built in Java.

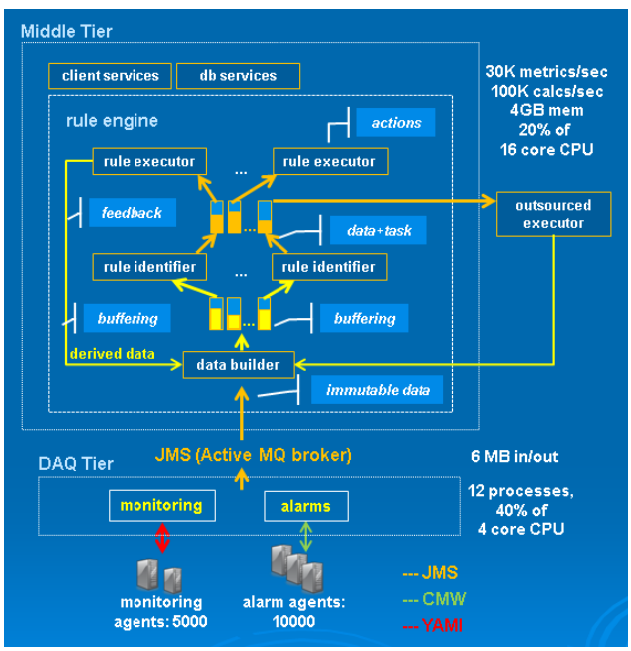

Figure 1: System architecture.

Figure 1 gives a system overview. The numbers associated show the final setup and the results of enduring tests performed with the ultimate architecture. Bottom tier consists of various classes of devices supervised by their DAQ counterparts using middleware protocols.

Now we decompose the presented architecture to look thoroughly at the issues solved throughout and major topics that had arisen.

TECHNICAL PATH

Uniformity

Our bottom tier is a heterogeneous environment. The messages holding data samples are of different shape, the middleware they flow through is divergent. What we pursue however is the opposite: a unification of resources.

CERN control systems largely rely on JAPC library [6]. JAPC operates with different middleware protocols while preserving a common high-level API. It adopts the concept of a *parameter,* which describes a device and a class of data it offers. For each parameter JAPC is able to establish an appropriate transmission channel to its underlying device. JAPC unifies data acquisition across the whole bottom tier. It seamlessly consolidates the access to over 10000 parameters.

The data itself is consistently shaped thanks to introducing a common *metric* structure. It encapsulates every type of input data. JAPC monitoring threads translate the incoming traffic into a stream of unified metrics, whereby acting as pipeline data converters. Such metrics are complete: they hold all the information required for further processing. From then on they are marked immutable, which is crucial to efficient data distribution and task parallelism of the middle-tier.

DAQ outgoing stream of metrics is again divided into new parameters. Such parameters represent logical domains rather than individual devices (alarms vs. monitoring data, computers vs. equipment, etc). It renders an amalgam of almost randomly acquired source data into a narrowly classified stream of metrics. Moreover, DAQ can decide on the pace those metrics are fed into the output JMS channel (recurrent vs. continuous flow) and the size of messages holding them. The latter prevents JMS environment from being flooded with miniscule pieces of data. It reduces the total overhead lied upon the messages too. In any case, the JMS infrastructure must be tuned accordingly to system needs, considering message persistency, lifetime, etc.

Data unification settles a foundation for effective parallelization in the middle-tier. It notably improves the testing capabilities of the whole system. Presented mechanism partly obliterates the need for distributed caching, an attractive yet highly problematic solution.

Decomposing for Concurrency

Rule engine is the core processing unit of the middle-tier server. A *rule* is a definition of calculation performed on the set of metric values, typically the most up-to-date ones. An example is a threshold rule that verifies if a metric value is within defined boundaries (e.g. temperature) or a mathematical formula where several disparate metric values need to be used to calculate the result. For sake of clarity, we skip all more advanced topics on rule calculations here. The output of the rule can be any action performed by the server, e.g. throwing an alarm, but also an *artificial* metric (created by the server, not monitored devices), which is in turn fed into another rule. Hence, rules form a tree structure which metrics

flow through. The same metric can be obviously used by many rules. As rules are laid out at the startup, it is always known where every original or artificial metric should be passed to.

Rule engine is a classic example of task, data and pipeline decomposition [7]. Each metric is an independent immutable piece of data. Rule is a task, which must be performed every time a set of arguments, metrics, is available. The input metric channel, along with the paths they flow between rules, constitutes a data-driven pipeline processor, a chain of responsibility. The overall structure vows for concurrent architecture.

There are three tiers of processing in that model. The first is an input channel, where immutable metrics are prepared and made available. The second tier is made up of rule *resolvers* (*identifiers*). They place each metric among the arguments of every rule they belong to. Once the argument list is complete, a self-contained *rule job* representing a single rule calculation is created. The last tier is comprised of rule *processors,* which take such jobs and perform associated calculations, likely producing artificial metrics (Fig. 1). As metrics and rule jobs are immutable and independent, numerous rule identifiers and rule processors can act autonomously. It gives the ground for parallelism.

The crucial is however what separates those three tiers. Java 6 Queue implementations (FIFO buffers) constitute the buffering layer [8]. The first layer holds metrics, the second keeps rule jobs, however they are both identically set up. Buffering layer implements the asynchronous Reader/Writer pattern. What has a decisive impact on the performance of the rule engine is the number of buffers, their sizes and the strategy for choosing one to read or write. Long tests proved the following to perform optimally in our setup. The layer is composed of a few buffers (2-4), each has a capacity of about half a million elements. Writers and readers are at least twice as numerous as the buffers. The strategy on reading the data is straightforward: pick the buffer holding the least elements. For writing, use the smallest buffer at the time for a period, e.g. 1000 writings, then repeat choosing. Both round-robin or random choosing strategies appeared to have fallen short of the selected policy. Its efficiency depends on many aspects, some being low level hardware properties (e.g., CPU cache hits).

Having a buffering layer configurable, including various R/W policies, is a precious feature. It greatly helps to find an optimal setup for a given architecture. During the tests it is essential to monitor the contents of the buffers and watch against any missed writings.

Because of the hierarchical composition of rules there is a natural tendency to break calculations into periodic stages, *rounds*. It partly roots in the fear that generating artificial metrics and passing them further may spark off an avalanche of computations. On the contrary, we have found no legitimate reason for staging the processing. The rule engine is left to run at its natural speed continuously. Artificial metrics are not directly handed to the following rules, but fed back into the input channel. It gives a perfectly consistent view on both processing and data. It also results in the highest throughput of all, reaching *100000* non-trivial calculations a second sustained for over a week without a single metric lost.

It is worth mentioning the thread scheduling discipline is typically OS-specific. Therefore a designer must guarantee that multicore CPU will be properly utilized for a given setup. It might need additional tweaking of the OS parameters.

Garbage Collection

Once the architecture is optimized at the level of data structures, algorithms and task parallelization, tuning the garbage collection remains as the pivotal job. Understanding how garbage collectors affect an application is crucial to laying out realistic boundaries on how performing the system can be.

The combination of extensive computing (non-trivial method calls) and frequent memory allocations contributes to numerous garbage collections within a time frame. Moreover, in such case garbage collectors require to operate on those heap structures (e.g. old generation) that inflict stop-the-world pauses - all the application threads get inhibited for a considerable period [9]. Unlike the Java Real Time System, none of four main garbage collectors available in Standard Edition guarantees non-interruptible work for the underlying application. They however differ in the lifecycle of such interruptions and the use of threads to perform on.

Although our system in general exhibits only soft real time requirements, in order to achieve massive continuous processing of metrics it is essential to impose almost hard real time requirements on the JVM. Testing various configurations of GC options for heightened number of calculations, we experienced a common pattern - failing scenario. Once the GC starts pausing the application on a regular basis, it will inevitably break down having less and less chance to make up for the lost time.

Having thoroughly tested our prototype with JRockit, Parallel-Compacting, Concurrent Mark-Sweep and GarbageFirst (G1) collectors in a variety of options, we found the last two establish the most sustainable environment. Due to the nature of processing and uniqueness of our setup such a statement cannot be generalized. It remains only as an incentive for every designer to never neglect the topic.

Table 1: Example Options Used with Tested GC's

GC	Selected options
PC	UseParallelOldGC, DisableExplicitGC, ParallelGCThread, CompileThreshold, MaxGCPauseMillis, NewSize
CMS	CMSIncrementalMode, CMSIncrementalPacing, CMSIncrementalDutyCycleMin, CMSIncrementalDutyCycle
G1	GCPauseIntervalMillis, G1ParallelRSetUpdatingEnabled, G1ParallelRSetScanningEnabled

GarbageFirst is a server-style collector, targeted for multi-processors with large memories. It also well utilizes the 64 bit architecture. G1 is considered the most efficient mechanism available in Java Standard Edition and has been decided a default solution shipped in JDK7.

Garbage collectors undergo constant development, changing their shape across JVM versions. Modern research concepts, as *split bytecode verification* or *lock coarsening,* enhance the overall process.

Memory Allocation

Organising memory allocation is a subject complementary to garbage collection. Java developer is offered to set up at least the boundaries of memory available to the application through a series of JVM options. Besides, the choice of the computer architecture and operating systems notably influences the outcome. As 64 bit multicore servers have become a prevailing standard, excessive use of the heap space emerged tempting. When the 4GB limit per JVM is surpassed (effectively much less depending on the operating system, see Table 2) an application can handle massive volumes of data in memory. The number of threads allowed to be created is also substantially larger. Nonetheless, experimenting with the settings shows it immediately brings a performance penalty in form of extended garbage collections, a hindrance we struggle to overcome at any cost. The other known effect of upgrading to 64 bit architecture comes with the need to operate on extended memory addresses. It is generally considered to moderately hamper the speed of processing.

Table 2: Memory Available in 32 bit Java SE [10]

OS	Heap Size
Linux	2.2-3 GB
Solaris	3.5-4 GB
Windows	1.4-1.8 GB
MacOS	<4GB

As for the garbage collection, choosing the right computer architecture and finally tuning the memory available affects the overall quality of our application. All those topics should be consciously scrutinized.

Profiling

Testing a complex Java system cannot be effectively carried out without the help of profiling tools. A rudimentary support for code orchestration comes with a JDK tool, VisualVM [11]. It allows to watch a lifecycle of the application with respect to its CPU, memory and thread consumption. Monitoring these characteristics is indispensable when tuning the garbage collection and memory allocation properties.

VisualVM and JConsole rely on the JMX support that JVM instance offers. We can easily profit from the feature by exposing some parts of our system as JMX calls. It lets manage the system during tests using a standard out of the box tool.

CONCLUSIONS

Java software design should always be considered with respect to the characteristics and shortcomings of the modern Java runtime environment. Conversely, garbage collection and memory allocation settings are often perceived superfluous, concise choice of data structures and concurrent routines considered secondary. Performance and scalability tests tend to be underestimated.

CERN monitoring and alarm system is a high throughput, semi real-time and most importantly reliable application based on the Java components. Architecting its prototype has brought tangible evidence how some often neglected issues determine the overall result of software development.

We have shortly discussed a selection of topics whose deep understanding may be vital to achieving a quality distributed software. They are more than likely to influence an outcome of designing any Java-based system that shares similar requirements.

THIRTY METER TELESCOPE OBSERVATORY SOFTWARE ARCHITECTURE

K. Gillies#, C. Boyer, TMT Observatory Corporation, Pasadena, CA 91105, USA

Abstract

The Thirty Meter Telescope (TMT) will be a ground-based, 30-m optical-IR telescope with a highly segmented primary mirror located on the summit of Mauna Kea in Hawaii. The TMT Observatory Software (OSW) system will deliver the software applications and infrastructure necessary to integrate all TMT software into a single system and implement a minimal end-to-end science operations system. At the telescope, OSW is focused on the task of integrating and efficiently controlling and coordinating the telescope, adaptive optics, science instruments, and their subsystems during observation execution. From the software architecture viewpoint, the software system is viewed as a set of software components distributed across many machines that are integrated using a shared software base and a set of services that provide communications and other needed functionality. This paper describes the current state of the TMT Observatory Software focusing on its unique requirements, architecture, and the use of middleware technologies and solutions that enable the OSW design.

TMT INTRODUCTION

The Thirty Meter Telescope (TMT) is an advanced, wide field (20 arcmin), altitude-azimuth telescope with a primary mirror consisting of 492, 1.44 meter segments. At first light, a facility multi-conjugate adaptive optics (MCAO) system will be available using a laser guide star (LGS) system. The facility's twin Nasmyth platforms will concurrently support multiple instruments, which are all available during the night for observations. Two science instruments will be delivered for use with the MCAO-LGS system: IRIS, a near-infrared instrument with parallel imaging and integral-field-spectroscopy support; and IRMS, an imaging, multi-slit near-infrared instrument. A seeing-limited, wide-field, multi-object optical imaging spectrograph (MOBIE) will also be available at first light. The operations model includes PI-directed observing from remote facilities and on-site service observing by staff. The telescope and facilities are currently in the advanced design phase. The telescope is planned for the summit of Mauna Kea on the island of Hawai'i in the United States.

TMT SOFTWARE ARCHITECTURE

Significant aspects of software systems for large observatories have converged around a few common ideas and solutions due to similarities in the facilities, their requirements for operation and use, and the issues related to development and maintenance [1]. The TMT software architecture takes advantage of these prior solutions when possible. It's then possible to focus attention on the problems unique to TMT and reuse common solutions for the parts of the software system that are known or of little risk. We can also improve upon the solutions used in the previous generation of systems when experience has shown that aspects of the known solutions have issues.

The complexity of some aspects of the TMT software control system scale with the telescope aperture size, and the software must also scale to handle this complexity. Segmented mirror control for TMT requires more moving parts behind the mirror and with it more sophisticated control software than existing segmented mirror systems.

It's also true that not every aspect of TMT software complexity scales with the size of the aperture. Many things that work for 8m class telescopes work just as well with TMT. An example is proposal submission and planning software.

A complete description of the architecture for a system the size of the TMT software system requires more than a few pages. Table 1 shows some of the broad range of challenges related to the software that executes at the telescope site. This paper will show one way the architecture addresses the challenges of Table 1.

Table 1: Architecture Challenges

Challenge	Description
Acquisition	There are demanding requirements on the system performance and coordination for target acquisition and observation setup.
Composition challenges	Some components must be used in a variety of situations or composed in different ways to support different applications. For instance, the MOBIE wavefront sensors must act as part of MOBIE but also work as part of the phasing system.
Wavefront measurement	Wavefront measurement functionality and hardware is potentially spread throughout telescope systems and instruments making it a challenge to cleanly decompose the system and software. This was a problem with 8m class telescopes as well.
Distributed development	Multiple, distributed, international partners provides a new level of software construction and management complexity.
Operations maintenance	The long lifetime of TMT requires an architecture that can be enhanced and modified without impacting the operations system.

#kgillies@tmt.org

Architecture Overview

TMT has adopted the idea of a technical architecture and functional architecture from other recent large telescope projects (e.g. ALMA [2], ATST[4]). The *technical architecture* is the software infrastructure that provides the foundation for the functional architecture. System features, such as logging and command support, are part of the technical architecture. The *functional architecture* consists of the decisions and software components that enable the activities of the observatory from the point of view of the users. For instance, how does the system collect header information for a science data frame?

A software system should be viewed in many ways. At the highest level in the functional architecture, TMT software is modeled as the 5 large *principal systems* shown in Figure 1. Each principal system is focused on specific, easily-identifiable functionality, and each is itself a collection of other software components or systems. Viewing the system at this level allows one to think more easily about flow of control and where software functionality exists within the system.

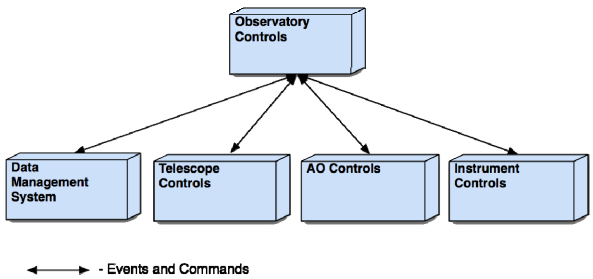

Figure 1: One view of the TMT software architecture splits the system into five large principal systems.

This view shows communication is hierarchical and flows down from Observatory Controls to the other principal systems. This command communication is low-bandwidth by design; any high-speed communication occurs within a single principal system.

Figure 2 drills down one more level to show sub-systems that represent major hardware and software components within the principal systems. At the top of the figure are the observing user interfaces and the software components within Observatory Controls that sequence and synchronize the activities of the other systems to generate the user's desired science data.

The integration of these software components requires software infrastructure that is outside the scope of the individual components themselves. The horizontal bar dividing Figure 2 in half represents this software infrastructure. The idea of shared software infrastructure based on a set of services and associated software focused on integration is a successful strategy in large observatory software architecture [1, 2, 4]. TMT calls this software Common Software (CSW). CSW is the implementation of the technical architecture.

Common Software is a collection of software and services. A *service* is a set of related software functionality together with behavior and the policies that control its usage. TMT CSW uses external packages (i.e., software not developed by TMT–COTS or open source middleware, etc.) to implement the CSW services. Abstractions and wrappers are present between the CSW services and the external packages to enable some isolation from specific product choices. For a component programmer integration of a component with TMT requires the use of a service-oriented API and library code that must be linked with the component.

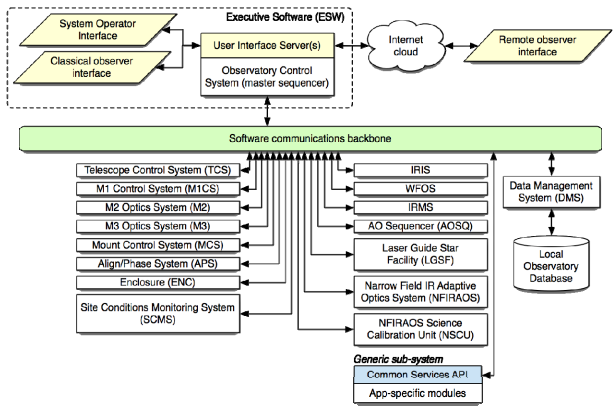

Figure 2: The major systems of the Telescope Controls, AO Controls and Instruments connected by the software infrastructure provided by the technical architecture.

Table 2 is a list of services provided by CSW that are needed to enable the functionality of the Functional Architecture.

Table 2: List of Planned CSW Services

Service	Task Description
User single sign on	Centrally manage user authentication and access control
Commands	Support for subscribing to, receiving, sending, and completing commands in the form of configurations
Location/Connection	Locate and connect to components within the distributed system
Events/Telemetry	Enable event-based functionality based on publish, subscribe paradigm
Alarm/Health	Support monitoring and publishing component alarm and health signals
Configuration	Manage initial values and system and component configurations history
Logging	Capture and store system logging information
Time	Standards-based, precision time access

One important example is the event services. These services allow one component to send a piece of information (i.e., an event) to one or more other

components. The Event Service provides a high-performance, publish-subscribe message system. Components can signal actions (events), publish status information (telemetry), or publish control information (event streams). One big advantage of this type of service is that the publishers and subscribers are decoupled; each requires no knowledge of the existence of the other.

OBSERVING MODE ORIENTED ARCHITECTURE

Operations experience has shown there are drawbacks to limiting the modeling and construction of the software structure to the principal system level, and this has driven architecture changes for TMT. For instance, principal systems are large systems that must handle all observing modes and operations scenarios. This results in broad, complex software interfaces that are difficult to verify and modify during operations. It continues to be valuable to view the system at the principal system level, but to address this and the challenges of Table 1 a more flexible approach is required. Flexibility is a key design concept that can result in a software system that can respond to the changing needs of science operations over the project lifetime.

The functional structuring approach planned for TMT that addresses these issues is called Observing Mode Oriented Architecture (OMOA) [3]. An observing mode is a well-defined instrument observing task and an associated set of owned resources, procedures, and capabilities that implement the mode. An example observing mode for TMT is: IRIS multi-filter integral field spectroscopy using the NFIRAOS adaptive optics unit with AO laser guide star correction. An instrument will generally have several associated observing modes for acquisition, science objects, and calibrations.

A goal of this architecture is to eliminate software waste and run as little software as is necessary to execute an observation using a specific observing mode. To accomplish this, the software within principal systems must consist of smaller components that are then assembled into a dynamic system configuration that is specific to the observing mode.

To explain this approach, the software components you might find in a principal system are shown as layers in Figure 3 with specific responsibilities described in the following sections.

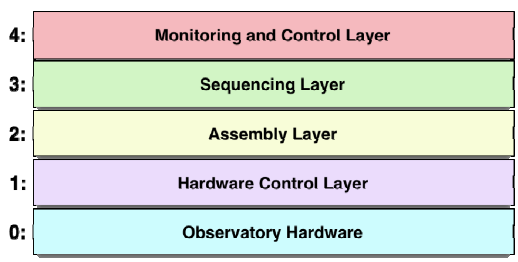

Figure 3: OMOA software structure layers.

Hardware Control Layer

In 2011 the trend is towards motor controllers and other hardware controllers and sensors that are network-resident devices capable of controlling multiple channels or to Programmable Application Controllers communicating via high-level commands over a standard TCP/IP-based network. It is generally no longer necessary to develop single use, low-level device drivers; a software investment that requires skilled programmers and significant effort that generates long-term technical debt and hinders change during operations.

The lowest layer in the OMOA software system, called the Hardware Control Layer, consists of all the controllable hardware that is available for use by higher levels of software. A sea of similar software components called Hardware Control Daemons (HCD) at layer 1 controls the TMT low-level hardware of the telescope, adaptive optics, and instruments.

Each HCD is associated with one or more networked motion controllers or other low-level hardware controllers (shown as layer 0 in Figure 3). The HCDs act as adapters and provide a uniform software interface and feature set focused on device control to the layers above. The HCDs are *always executing,* and each can be accessed at any time by the software layers above.

This layer is one place where external systems can be integrated. As an adapter, a HCD can isolate a proprietary connection to an external system making it look like a conforming system device. The HCD also provides a suitable location for device simulation allowing device end-to-end system testing without hardware presence.

Assembly Layer

The Assembly Layer exists just above the Hardware Layer at layer 2 in Figure 3. Software at this layer consists of components called *Assemblies* with two roles in the OMOA. The first role is to allow the grouping of HCDs into higher-level entities. This is required when individual hardware devices must be considered as a unit or requiring processing. The second role of components in the Assembly Layer is to provide more sophisticated hardware control functionality that integrates devices across different HCDs to produce higher-level devices or add uniformly useful capabilities.

Assemblies can be transient or long-lived. An example of a long-lived Assembly is one that provides telescope pointing, tracking, and offsetting. An Assembly can also be created dynamically to provide combinations of HCDs that need to be coupled for a specific observing mode during an observation. An example might be the coordination of wavefront sensor detector readout processing and the control of the probes for the wavefront sensors.

Sequencing Layer

The Sequencing Layer is layer 3 in Figure 3. Components at this level are called sequencers because they control and synchronize the actions of the HCDs and Assemblies. The sequencer components are dynamically

created and composed in order to execute a specific observing mode. This approach is possibly the most innovative part of this software architecture, because it is this layer that gives the software its compositional flexibility and other qualities. Individual sequencers can provide higher-level control of a set of distributed hardware. The ability to cut across the development hardware boundaries and compose and control hardware as needed is what allows this approach to eliminate many of the challenges mentioned in Table 2.

The components in this layer share software interfaces that allow them to be plugged together to form the sequencing engine for a specific observing mode. There can be one or many sequencing components in an observing mode sequencer. The goal is that the sequencing components for a mode be assembled into a single process. This minimizes complexity and performance issues related to distributed processes and communication of commands across process and machine boundaries. A large amount of software related to command input/output in systems is eliminated, and fewer tiers result in higher performance and simplicity.

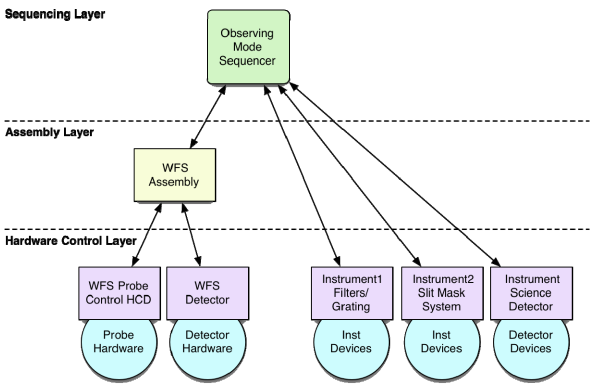

Figure 4: A simple example showing the lowest 4 layers of an OMOA observing mode configuration.

The sequencer for an observing mode is constructed during observation execution with a *Configuration Factory* that takes as input an observing mode and an observation description from another software tool such as a high-level planning GUI. The Configuration Factory has been programmed with instructions on how to construct the matching sequencing process for the observing mode.

Figure 4 shows a simplified, partial example of an instrument like TMT's MOBIE in a seeing-limited observing mode. At the lowest level are the HCDs for the wavefront sensor probes, instrument hardware, and detectors. An assembly exists to integrate and provide higher level functions for the wavefront sensor hardware and detector. All other sequencing for the observing mode is in the Observing Mode Sequencer that is created dynamically for the observation. The HCD components could be separate processes running on distributed hardware while the sequencing components exist in a single process within the Observatory Controls.

This example demonstrates the flexibility inherent in this approach. It allows the grouping of software and hardware in an optimal arrangement for a specific observing mode with only the functionality needed to support a specific mode. During operations this allows new observing modes to be rolled out more easily with minimal influence on current functionality.

Monitoring/Control Layer

The Monitoring/Control Layer (layer 4 in Figure 3) is the layer of software that contains the user interface programs that are used to observe with the telescope. At TMT there will be graphical user interfaces for use by observers during the night. These applications use the CSW services to control and monitor the system.

SUMMARY

The TMT software architecture is similar to the systems constructed for 8m telescopes, but it has been enhanced to take advantage of changes in software and hardware technology as well as 10 years of experience with the principal system architecture approach.

The TMT technical architecture is based on a set of shared software services, each of which is itself based on open-source or commercial software.

The functional architecture uses the structuring approach of the Observing Mode Oriented Architecture. The goal of OMOA during observation execution is to allow, for any given observing mode, the minimal amount of software needed to execute the mode. By taking this approach, many of the problems outlined in Table 1 are minimized or eliminated.

The innovation in OMOA is the implementation of the principal systems as more focused fine-grained components at the architectural level. This single change provides the opportunity to reduce the amount of software needed at the telescope, thereby reducing the complexity of the runtime system. This, coupled with the use of dynamic system configurations focused on executing individual observing modes, addresses the need to sequence systems with more flexibility and higher performance than currently possible.

TOWARDS A STATE BASED CONTROL ARCHITECTURE FOR LARGE TELESCOPES: LAYING A FOUNDATION AT THE VLT

R. Karban, N. Kornweibel, ESO, Garching, Germany
D. Dvorak, M. Ingham, D. Wagner, Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA.

Abstract

Large telescopes are characterized by a high level of distribution of control-related tasks and will feature diverse data flow patterns and large ranges of sampling frequencies; there will often be no single, fixed server-client relationship between the control tasks. The architecture is also challenged by the task of integrating heterogeneous subsystems which will be delivered by multiple different contractors. Due to the high number of distributed components, the control system needs to effectively detect errors and faults, impede their propagation, and accurately mitigate them in the shortest time possible, enabling the service to be restored. The presented Data-Driven Architecture is based on a decentralized approach with an end-to-end integration of disparate, independently-developed software components. These components employ a high-performance standards-based communication middle-ware infrastructure, based on the Data Distribution Service. A set of rules and principles, based on JPL's State Analysis method and architecture, are use to constrain component-to-component interactions, where the Control System and System Under Control are clearly separated. State Analysis provides a model-based process for capturing system and software requirements and design, greatly reducing the gap between the requirements on software specified by systems engineers and the implementation by software engineers. The method and architecture has been field tested at the Very Large Telescope, where it has been integrated into an operational system.

CONTEXT

The European Southern Observatory (ESO) carries out an ambitious programme focused on the design, construction and operation of powerful ground-based telescopes for astronomy. Worldwide, Extremely Large Telescopes are considered one of the highest priorities in ground-based astronomy.

The European Extremely Large Telescope (E-ELT), a revolutionary new 40-metre-class ground-based telescope, will be the world's biggest eye on the sky, when it begins operating early in the next decade [1].

The E-ELT is characterized by a high level of distribution of control-related tasks and will feature diverse sets of data flow patterns and large ranges of sampling frequencies.

Within the E-ELT, the Telescope Control System (TCS) will maintain wave front quality throughout the duration of the observation. Considering the multitude and inter-relation of E-ELT distributed control loops (covering about 1000 moveable mirrors, and actuator stroke management), maintaining the wave front during the observation is foreseen to be more demanding than acquiring the target. This is a fundamental difference from our past experience on the Very Large Telescope (VLT) project - the essential complexity (the complexity associated with the underlying problem) has increased, and thus it is imperative to avoid adding any more complexity than necessary.

The TCS includes all hardware, software, and communication infrastructure required to control the telescope (including the dome), and to interface to subsystems down to, but not including, actuators and sensors, as they are typically delivered together with the respective sub-system. The main functions provided by the TCS are related to Control and Interlock (an automatic and immediate stop of a unit in case of a safety critical situation) handling, and fault management.

The **main challenges** can be summarized as follows:

- Large number of control points (the primary mirror alone encompasses 15000 actuators)
- Number of interfaces (15 subsystems, 9 focal stations, site operation)
- Large data volume (700 Gflops/s, 17 Gbyte/s in real-time in adaptive optics) of engineering data
- Multitude of interacting, distributed control loops (from 0.01Hz up to kHz rates)
- Software intensive distributed control strategy
- Integration of heterogeneous distributed components, provided mainly by contractors, adds additional complexity.

ARCHITECTURE

Separating the concerns of astronomy from those of technical implementation is a key goal of the architecture. Astronomy domain-specific knowledge should be isolated from the (technical) subsystem domain, which is typically contracted to an expert in that domain. The implementers of the subsystem should not be required to have knowledge of the astronomy domain. Another major architectural driver is the need to query knowledge of the state (e.g., temperatures, position of actuators, and taking into account uncertainties of sensor readouts) of the physical system and to control this state. Due to its high distribution and tight coupling this knowledge is essential to be able to deliver a functioning system.

The architecture must satisfy certain (domain independent) quality goals. The most important are

related to the conceptual integrity. The conceptual integrity is the underlying vision that unifies the design of the system, at all levels. The architecture should do similar things in similar ways.

The **main goals** for the TCS **architecture** are:

- Define a framework and design rules to enable the software engineer to develop the domain specific applications which address and match the functional needs from the wave front control strategy.
- Contain system complexity.
- Promote modifiability and scalability (and long-term maintainability).
- Enable high availability and fault tolerance.

These strategic goals can be achieved by applying certain tactics:

- Carry out the system design according to a well defined set of design patterns.
- Have a uniform way of designing closed loop control on the subsystem actuators, i.e. how are the sensor data processed, the state of the hardware system estimated, and the actuators commanded?
- Represent the state of the hardware system and the control system in a uniform way.

The design of the control system architecture brings together engineers from different domains: system, software, control, and electronics. Close collaboration between those disciplines is essential to close the gap between systems engineering and the other technical disciplines.

The data-driven architecture (explicitly formalizing the data and meta-data produced and consumed by a system, transported with messaging [10], see Figure 1) consists of three tiers organized in a decentralized manner in order to separate domain knowledge (e.g., tracking a celestial object vs. mirror control), integrate heterogeneous control systems, and support the implementation of flexible wave front control strategies.

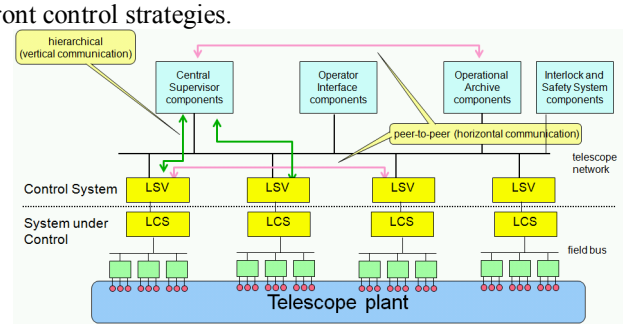

Figure 1: Conceptual Architecture.

The first tier provides robust and simple access to sensors and actuators of a subsystem and is called the Local Control System (LCS). The second tier adapts the LCS to the astronomy domain and is responsible for closed loop control of the sub-system's actuators and sensors. It is called the Local Supervisor (LSV). The third tier, the Central Supervisor, provides high level interaction with users and among subsystems.

STATE ANALYSIS AND MBSE

A Model Based Systems Engineering (MBSE) methodology is characterized as the collection of related processes, methods, and tools used to support the discipline of systems engineering in a "model-based" or "model-driven" context [7]. The State Analysis (SA) method [3] [8] is targeted to the control related domain, and focuses on behaviour, which is an often underestimated aspect in Systems Engineering. The SA method, which is founded on a state-based architecture and goal-based operation, defines a process for identifying and modelling the states of the physical system and their relationships. The methodology enables effective coordination, robust execution, and flexible response mechanisms in the system by defining goals (e.g., keep tracking error within a certain RMS error) for the states of the physical system instead of defining precise execution procedures up front.

State Analysis provides a uniform, methodical, and rigorous approach for developing control system architecture by:

- Discovering, characterizing, representing, and documenting the state variables of a system;
- Modelling the behaviour of state variables and relationships among them, including information about hardware;
- Identifying interfaces and operation; and
- Capturing the mission objectives in detailed scenarios motivated by operator intent.

In State Analysis, nominal and off-nominal states are given equal stature in the model. State Analysis provides the opportunity for (but does not obligate) earlier consideration of faults and off-nominal behaviour. Fault Detection, Isolation, and Recovery (FDIR, also known as Fault Management) becomes an integral part of the control system design. A strict boundary is drawn between the **Control System** being designed and the target **System Under Control**, as shown in Figure 2.

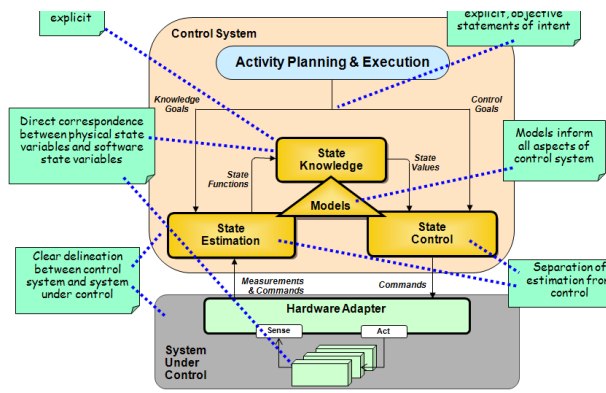

Figure 2: State Analysis Architectural Concepts.

State Analysis provides sound architectural principles and rules which help to achieve the requirements and goals of the E-ELT TCS. Thus, many concepts of the method have been baselined by the project, and adapted to the specific needs of the project (like where to draw the line between

control system and system under control for contractual reasons).

VLT FIELD TESTING

As part of validating the technology decisions for the E-ELT, control systems at the VLT (Figure 3) [4] are being refurbished using technologies intended for use in the E-ELT control systems. The upgrades serve several purposes: field test technologies and methods in an operational environment (outside the lab), provide input into the E-ELT technology decisions, address obsolescence in the UT telescope control systems, and ready observatory technical staff for the construction of the E-ELT.

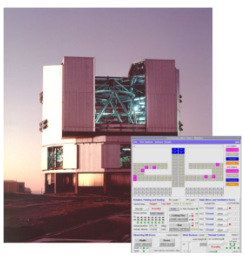

Figure 3: VLT UT.

As the first step in the upgrade and field test program, the enclosure (dome) control system (ECS) of one Unit Telescope (UT) was refurbished in 2010, using the SA method and architecture. It is now successfully operating at the Paranal observatory.

The Enclosure Control System Upgrade comprised:

- Dome and Windscreen;
- Seal, louvers, Observing Doors;
- Telemetry
- Thermal input/output (I/O);
- Approximately 1500 I/O points.

The refurbished control system interfaces to existing sensors and actuators in the field, and integrates transparently with the existing dome control interface at the supervisory level. The application of SA was therefore limited to the LCS and LSV.

The SA control pattern drove the development of the data model, which consisted of building a façade to the System Under Control, identifying and defining State Variables (SVs) and specifying Goals).

Though only a limited and introductory application of SA was made, the architectural rules of SA aided in improving the design of the control system software. Estimators (which generate state knowledge based on available evidence) read blocks of field data and publish data to State Variables. The Estimators were largely implemented with LabView.

During 2011 and 2012, the project will be working to upgrade the control system of the main axes. The goal of the project is to achieve the same or improved scientific performance while tackling obsolescence in the system by upgrading with specific technologies and architectures targeted for use in the E-ELT.

The main axes control system provides the means for telescope positioning (moving the telescope in either Altitude or Azimuth axis in order to point the telescope) and telescope tracking (coordinating the movements in both axes in order to track celestial objects given their position, motion and the current time).

The main axes upgrade applies more rigorously the SA method than the enclosure upgrade, together with other MBSE concepts. In particular, a SysML [5] profile for SA is being developed, allowing integrating the SA artifacts into an overall system model. The overall system model is built according to principles of the Object Oriented Systems Engineering Method (OOSEM [5]), which distinguishes a logical and physical model of the system, and also provides means to describe the system "as-is" and "to-be" and the relations between the two– particularly useful for an upgrade project. JPL has already defined an initial UML profile for SA [6], which serves as a starting point for the SysML profile.

Figure 4 shows a snippet of a State Effects Diagram (SED), which is a SA artifact used to identify SVs, Measurements, Commands, and the causal effects between them. The main focus in this diagram is the set of effects on and of the physical state variable "Azimuth Position And Velocity". Every box on the diagram corresponds to a physical SV which has to be estimated and possibly controlled.

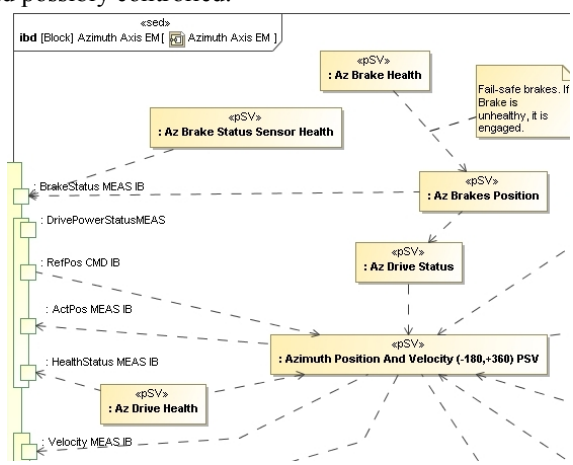

Figure 4: State Effects Diagram of Main Axes.

The abstract <<affects>> relationships are later on modelled in a more rigorous way using SysML State Charts, Parametric models or Activities, if and only if a more accurate description is needed.

The corresponding conceptual architecture (Figure 5) can be derived from the SA artifacts, including the SEDs. It shows two SVs "EncHeadHealth SWSV IB" and "AzPosVel SWSV IB" with their respective estimators and controller, interacting with the Azimuth Axis Local Control System. Since everything is contained in the same model, referring to the same model elements, the information on the system is all consistent.

Many artifacts created using SA can be re-used across projects and systems because they express domain concepts in an implementation-independent way. For example, SA artifacts from a previous design of an Antenna array [2] can be leveraged for the E-ELT.

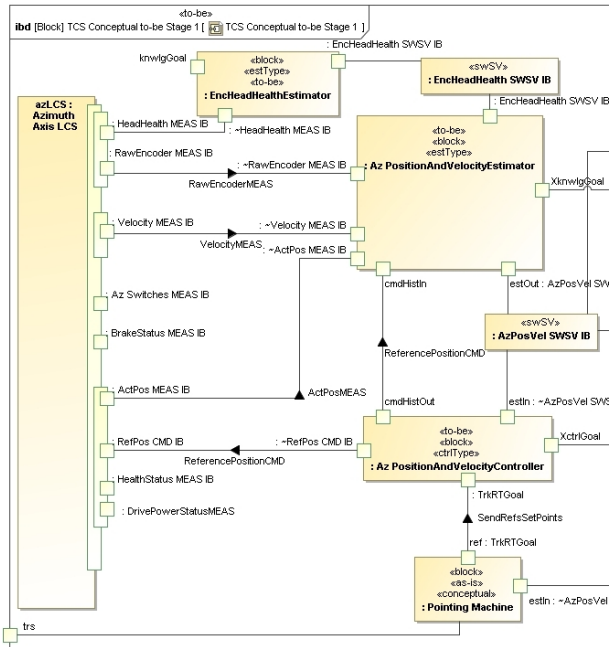

Figure 5: Conceptual State Based Architecture.

IMPLEMENTATION

JPL implemented the State Analysis method with its Mission Data System (MDS) architecture [9], which provides software libraries, classes, and behaviour reflecting the SA concepts (e.g., state variables, goals, etc). The current MDS implementation is based on method invocation: for example, a state variable is queried if its current constraint (its goal) can still be satisfied.

The current ESO prototype implementation is based on messaging, using the Data Distribution System (DDS) as its middleware. State Variables are realized by DDS topics. Consequently, controllers and estimators can simply publish and subscribe to a SV, making combination of multiple SVs in a control algorithm simple and without requiring knowledge of where the SV resides or what estimates it.

In this way, the full SA control pattern is implemented with the publish/subscribe mechanism, which allows runtime attaching and detaching of clients, for example to trace measurements and verify the behaviour of the control system.

SUMMARY AND FUTURE WORK

State Analysis is built on a sound theory which enables building an architecture for a distributed system, like the E-ELT, following well defined principles and rules. Although the scalability for very large systems needs still to be verified, the first practical experiences on the VLT give us confidence to pursue the path of applying SA for the VLT upgrade and eventually for the E-ELT control system.

Integration with other MBSE practices is fundamental to address all relevant system aspects, and requires, in particular, a SysML profile. The definition of the mapping between SA and SysML, and the formalization of SA concepts and relations in an ontology is part of the ongoing collaboration between ESO and JPL.

This research was carried out at the European Southern Observatory and at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

MIDDLEWARE TRENDS AND MARKET LEADERS 2011

A. Dworak, P. Charrue, F. Ehm, W. Sliwinski, M. Sobczak, CERN, Geneva, Switzerland

Abstract

The Controls Middleware (CMW) project was launched over ten years ago. Its main goal was to unify middleware solutions used to operate CERN accelerators. An important part of the project, the equipment access library RDA, was based on CORBA, an unquestionable standard at the time. RDA became an operational and critical part of the infrastructure, yet the demanding run-time environment revealed some shortcomings of the system. Accumulation of fixes and workarounds led to unnecessary complexity. RDA became difficult to maintain and to extend. CORBA proved to be rather a cumbersome product than a panacea. Fortunately, many new transport frameworks appeared since then. They boasted a better design and supported concepts that made them easy to use. Willing to profit from the new libraries, the CMW team updated user requirements and in their terms investigated eventual CORBA substitutes. The process consisted of several phases: a review of middleware solutions belonging to different categories (e.g. data-centric, object-, and message-oriented) and their applicability to a communication model in RDA; evaluation of several market recognized products and promising start-ups; prototyping of typical communication scenarios; testing the libraries against exceptional situations and errors; verifying that mandatory performance constraints were met. Thanks to the investigation performed the team have selected a few libraries that suit their needs better than CORBA. Further prototyping will select the best candidate.

CERN MIDDLEWARE

The Controls Middleware (CMW) project was launched at CERN over ten years ago. Its main goal was to unify middleware solutions used to operate CERN accelerators. Many software components were developed, among them the Remote Device Access (RDA) [1] library. The main responsibility of the library was to allow communication with servers that operate hardware sensors and actuators. The RDA design corresponds to the Accelerator Device Model [1] in which devices, named entities in the control system, can be controlled via properties. RDA implements this model in a distributed environment with devices residing in front-end servers that can run anywhere in the controls network. It provides a location-independent and reliable access to devices from control programs. By invoking the device access methods, clients can read, write, and subscribe to device property values. Currently over 4000 servers (processes) are deployed, which contain altogether almost 80,000 devices. In total the system gives access to more than 2,000,000 properties/IO points, on which clients may perform read/write operations or monitor their values. [2]

Present Implementation

From the beginning there were certain requirements [3] imposed on RDA that drove its implementation: relying only on standards; interoperability with the already existing communication infrastructure at CERN; portable on LynxOS with an old gcc v.2.95 compiler, Linux, Windows, HP-UX and AIX (only the first three are still supported; LynxOS is being eradicated); C/C++ and Java bindings for client/server libraries; request-reply and publish-subscribe operations on device data. Each call type should provide timeout settings and handling of communication errors. Moreover, complementary, centrally managed services like naming service, reservation service and access control should be supplied.

To facilitate development of the new library it was decided to base it on an already existing, mature product. CORBA [4] was a very popular middleware at that time and fulfilled all the requirements. Thus it was chosen as the communication layer. The C++ implementation was based on omniORB (currently 4.1.2,) and the Java implementation on JacORB (currently 2.2.4.) RDA library wrapped CORBA, hiding all its complexities and providing a simple to use API. The proposed solution was widely accepted and became an operational and critical part of the infrastructure.

Shortcomings of the System

Unfortunately, the demanding run-time environment revealed a few shortcomings of RDA. Accumulation of fixes and workarounds led to unnecessary complexity. Desire to deliver a better, more user-friendly solution led to a general review of the system. Discussions with library clients helped to identify several major issues, of which the most troublesome are the ones directly correlated with CORBA [5]. First, the CORBA standard is inherently huge and complex. Libraries that try to fully implement it have a major memory footprint. This is an issue especially for older front-end computers. It is well understood that RDA as a communication framework uses only a small fraction of the CORBA platform, but users still have to pay the full run-time price. On the other hand, libraries such as JacORB do not implement the full functionality. This leads to mismatches in behaviour of Java and C++ bindings. The struggle to support "asynchronous" operations on top of the synchronous calls leads to unnecessary complexity in the library code and design. Second, the way CORBA is used in RDA leads to multiple data conversions between different representations. This is both time consuming and leads to higher memory usage. Third, CORBA is based on the static Interface Definition Language (IDL), which is difficult to manage and evolve in large, complex environments such as CERN. Finally, the community supporting open-source implementations is shrinking.

There is a significant lack of new releases from the major implementations like JacORB, even if the major bugs have been identified and fixed a long time ago.

MIDDLEWARE EVALUATION

In view of a 1-year accelerator shutdown at CERN, starting end of 2012, there is a unique opportunity for introducing a major new version of RDA, which should solve all the limitations experienced with CORBA. Therefore, the CMW team launched the middleware review process, aiming at choosing a new, modern middleware library, to be used for the future version of RDA.

In addition to previously specified general requirements we expect that the new transport library provides:

- Consistent implementation for C++ and Java.
- Easy to trace peer-to-peer communication with reliable request/reply and publish/subscribe messaging patterns.
- Synchronous and asynchronous communication
- Quality of Service (QoS): timeout management, message queues and priorities, various thread management policies.
- Small library size, low memory and resource usage.
- Certain performance characteristics (described later)
- No, or only a few, external dependencies that can be linked with an application, preferably no need for additional services (e.g. brokers, global servers, daemons).
- Open source, with a license allowing to redistribute our product further; good documentation, and support from a large active community.
- Simple, easy to learn and use API.

The CMW team evaluated several market recognized middleware products. A short description of each product is provided below, including a general assessment and results of tests. Detailed performance results and other quantitative measurements are gathered and presented in the next paragraph. All opinions and criticism are based only on our knowledge and products evaluation.

In line with the requirements the following middleware standards and protocols were of no interest: XML-based protocols (e.g. SOAP, XMPP), Stomp, P2P (FastTrack, BitTorrent), MPI, MQTT (rsmb, Mosquitto) nor WebSphere MQ.

The Current Solution: omniORB/JacORB

CORBA is an object-oriented communication platform created by OMG. The standard defines the wire protocol and the IDL, which is used to specify object interfaces. It describes also mappings from IDL to several languages. The complexity of the communication process is hidden from the user, who cannot differentiate between a local and a remote call. The standard and chosen implementations are well documented. Unfortunately there are many shortcomings described in the previous paragraph. Also, the CORBA API is old-fashioned and heavy, thus it has a very steep learning curve and its community shrinks.

Evaluation of Ice

Ice [6] belongs to the object-oriented middleware category. It is conceptually very similar to CORBA, which is an advantage for those who already know it.

The product supports C++ and Java, and runs on Linux and Windows. Compilation on LynxOS fails due to the use of modern C++. It has a static type system and relies on separate specification files to describe interfaces and data structures. Apart from a request-reply model, Ice provides a publish-subscribe event distribution service called IceStorm. Full control over QoS and many tuning options are available. Performance wise Ice satisfies our needs. It uses a compact binary encoding that conserves bandwidth and is very efficient to marshal and unmarshal. Additionally protocol compression can be enabled. Sizes of statically compiled libraries and of binaries of a simple ping-pong server and client indicate a heavy use of global state that brings in the majority of Ice, no matter how much of it is actually used. On the other hand, the well designed API, modern and flexible IDL, easy to use language mappings, up-to-date documentation and a detailed tutorial are a big plus. The library is distributed with GPL license; sources are available for download.

Ice seems to be a very strong candidate due to its industrial presence and number of existing deployments. It also fulfils majority of our requirements.

Evaluation of Thrift

Thrift [7] belongs to the service-oriented middleware category, which means that the central notion in this system is that of remote services being accessed over the network.

The library supports C++/Java and runs on Linux/Windows. Compilation for LynxOS is problematic due to the use of modern C++ features. Thrift has a static type system and relies on separate specification files to describe the service interface and data structures. It supports simple request-reply communication in synchronous and asynchronous mode. It has a small memory footprint and fulfils the performance needs, but it is still an immature product with an incomplete implementation. Tutorial on the product webpage is empty and there is no documentation.

We decided to exclude Thrift from further investigation.

Evaluation of ZeroMQ

ZeroMQ [8] is a message-oriented middleware library, which resembles the standard Berkeley sockets. Because of supported communication patterns and various transports like in-process, inter-process, TCP and multicast it may be easily used as a concurrency framework.

The core of the library is written in C. Bindings for C++, Java (through JNI) and many more languages are supported. The library runs on most modern platforms.

With minor changes it is possible to run it on LynxOS. ZeroMQ has no type specification and does not know anything about the data a user sends. For this reason it has to be used with an external serializer. Because of similarities to the BSD sockets the API is familiar and easy to learn and use. In contrast to the BSD, the ZeroMQ API is more intuitive and user-friendly. Moreover, apart from simple socket send/recv calls, many complex communication patterns are implemented and ready to be used (e.g. request-reply, publish-subscribe, workload distribution). Users have full control over communication policies and QoS (synchronous or asynchronous communication, timeouts, high water marks). The library has a small memory footprint. To achieve the best possible performance it uses different protocols depending on the peers location (TCP, PGM multicast, IPC, inproc shared memory). Parallel protocols may be easily changed so an eventual upgrade from unicast to multicast is easy. The direct connection between the system parts results also in reduced maintenance costs as there is no need for brokers or daemons. A detailed documentation and broad, easy to follow tutorial are available on the product website. The project is under the LGPL license, with a large and active open source community. If needed, full commercial support may be obtained from iMatix, the authors of the product.

We consider ZeroMQ as one of the major candidates to replace CORBA.

Evaluation of YAMI4

YAMI4 [9] belongs to the message-oriented middleware category, in which communicating peers exchange messages between each other. The distribution is therefore explicit and seen in the user code.

The library supports C++/Java and runs on Linux/Windows. With small changes it is possible to compile it for LynxOS. YAMI4 has a dynamic type specification. Data structures (messages) are created dynamically without describing them with IDL. It is an inherently asynchronous communication system with support for request-reply and publish-subscribe over TCP. QoS may be configured through message priorities and timeouts. The library has a small memory footprint and, as our tests show, even if considerably slower than the statically typed products, it fulfils the performance needs. It is an open-source project under GPL, with a thorough documentation and a modern, intuitive API.

YAMI4 is already successfully used at CERN. Unfortunately, community behind the product is small.

Evaluation of the DDS Products

DDS [10] (Data Distribution Service) is an OMG standard, targeting real-time distributed systems. It belongs to the data-oriented middleware category, where the communicating parties declare their interest in a topic and the system takes care of delivery of only relevant data.

There are five wire-interoperable implementations of DDS. We evaluated the three most mature ones. All three products support C++ and Java languages, however due to use of modern C++ they do not support LynxOS out of the box. DDS has a static type system and relies on separate specification files to describe data structures. Compatibility of the generated code with the code generated from the CORBA IDL may be accomplished. Single-direction data flow is the most frequent use-case. It is possible to set up request-reply communication but this requires two symmetric channels. Because of the nature of the channels, this approach is not applicable for CMW, thus additional request-reply middleware would have to be used in parallel. DDS is an asynchronous system that supports many QoS settings, including message priorities. A nice additional feature is Dynamic Discovery, which allows a DDS application an automatic discovery and connection with another DDS application. This feature does not work for us as our network do not support multicast. The products are well documented, but the DDS API is neither easy to use nor compact. In fact, the multitude of settings and concepts provided by the standard is overwhelming and renders the products to be cumbersome and difficult to use.

Evaluation of OpenSplice DDS

OpenSpliceDDS [11] is the only DDS implementation that needs a separate daemon process on each node as individual user processes do not use the network services directly. The daemon is used for service discovery and for data transfer between nodes. Such a solution creates additional complexity, which should be avoided in CMW.

Evaluation of CoreDX DDS

CoreDX [12] is a small-footprint DDS implementation. Unfortunately, due to the licensing policy, further redistribution to third parties would be problematic.

Evaluation of RTI DDS

RTI [13] provides the most mature and widely adopted implementation of DDS. It is distributed with a number of useful tools for system monitoring and administration. As a research organization, CERN is eligible for a free of charge IRAD license and even access to the source code is available. On the other hand, the library size and simple binary programs are significant.

Evaluation of AMQP family

AMQP [14] is a wire-level protocol used for messaging. An AMQP system consists of a broker responsible for message routing between the communicating parties and a client library implementing the protocol. It does not provide any data model - only binary messages are supported. As AMQP is a broker system, implementation of request-response is cumbersome and almost two times slower than in a direct mode. Only recently, the first stable version of the protocol was released, but there is still no product that supports it. On the other hand, there are a few products using the previous, noncompliant versions of the protocol: Qpid v 0.10, OpenAMQ and RabbitMQ v 0.9, and

SwiftMQ v 0.8. The AMQP standard is still evolving and every new protocol version is not backward compatible. Moreover, the specification is still a work in progress and there is no clear indication on its future direction and support from industry [15]. Two products were evaluated, Qpid and OpenAMQ, however taking into account all the outstanding issues around AMQP, we decided to withdraw them from further investigations.

PERFORMANCE TESTS

The communication within CMW should be reliable and fast. Analysing the current usage statistics, it was estimated that the new transport over a GbE network, between a server on a new front-end (Inter Core 2 Duo, 1.5GHz, 1GB RAM, GbE) and a client running on a similar machine should handle approximately:

1) 4000msg/sec req-rep calls, payload = 4Bytes
2) 5msg/sec req-rep calls, payload = 10MBytes
3) publish 400 x 8B to 10 clients, in less than 100 msec
4) publish 30 x 8B to 10 clients, in less than 20 msec

For each candidate library all four scenarios were tested. The most interesting results were obtained from test 1 (see Figure 1), where the price for the YAMI4 dynamic model and additional hop through Qpid broker can be seen. A similar problem with IceStorm is revealed by test 3 (see Figure 2). That test also unveiled the brilliant, automatic message batching implemented in ZeroMQ.

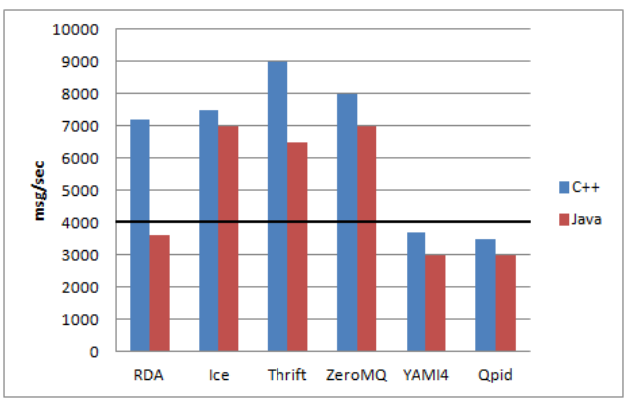

Figure 1: Test 1, a client talking to a C++ server.

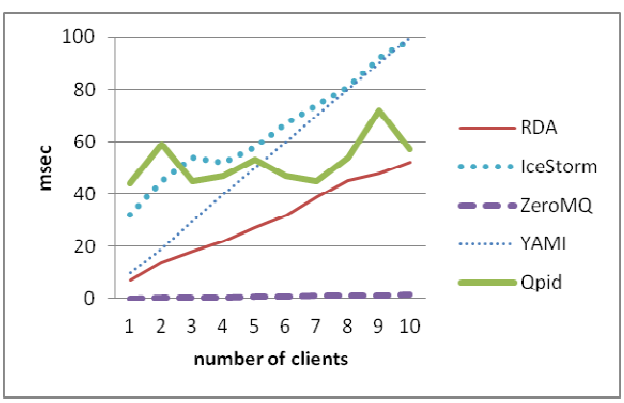

Figure 2: Test 3, pub-sub to a C++ server.

CONCLUSIONS

The paper presented several market recognized middleware products, evaluated according to the requirements of the CERN accelerator control system, as well as considering the product maturity and ease of use.

	patterns	QoS	resources	performance	user friendly	community	score
CORBA	✗	✓	✗	✓	✗	✗	2
Ice	✓	✓	✗	✓	✓	✓	5
Thrift	✗	✗	✓	✓	✗	✗	2
ZeroMQ	✓	✓	✓	✓	✓	✓	6
YAMI4	✓	✓	✓	✗	✓	✗	4
RTI	✗	✓	✗	✓	✗	✓	3
Qpid	✗	✓	✗	✗	✓	✓	3

Figure 3: Summary of evaluated middleware products.

The results are gathered in Figure 3. Three libraries were qualified for further prototyping: Ice, ZeroMQ and YAMI4. Based on prototyping the CMW team will select and adopt one of them for the future version of RDA.

Abstract

EPICS version 4 extends the functionality of version 3 by providing the ability to define, transport, and introspect composite data types. Version 3 provided a set of process variables and a data protocol that adequately defined scalar data along with an atomic set of attributes. While remaining backward compatible, Version 4 is able to easily expand this set with a data protocol capable of exchanging complex data types and parameterized data requests. Additionally, a group of engineers defined reference types for some applications in this environment. The goal of this work is to define a narrow interface with the minimal set of data types needed to support a distributed architecture for physics applications, data acquisition, and data analysis.

INTRODUCTION

Version 3 of EPICS [1] consisted of three key components: the narrow client interface that presented channels of various scalar data types with metadata for display and control, a robust and high performance network protocol for these data types, and a process database that allowed the definition of control logic to achieve steady state control. Many clients were developed to provide batch, SCADA, and DCS capabilities to physics research facilities. Version 3 offered little to help develop application for data acquisition, model based control, or experiment control. Many facilities developed monolithic programs with some general libraries to build toolsets to accomplish these functions. Version 4 of EPICS, features an extended data type definition and a protocol that can serialize and de-serialize these data types to extend the narrow interface to develop services above the instrumentation level to support these functions. This paper will explore the extended interface that is being presented to the services and clients to support this functionality and the middle layer services that are planned to work in this protocol to support a modular architecture to support data acquisition, experiment control, and model based control.

VERSION 3 CHANNEL TYPES

The version 3 channel types included the basic scalar data types along with metadata to make the value useful in a process control system. These meta data included a time stamp, information that allowed the channel to be displayed, alarmed, or controlled. The time stamp is the primary mechanism for identifying when the value was read. This enables us to look for correlations between various system parameters. It also included an alarm severity that identified a channel that was not valid, or in an alarm condition. The metadata also included information to inform a client how to display a value with either display limits, display ranges and engineering units for analog type values, state labels for discreet signals, and dimensions for strings or array [2]. It also included information to understand the limit of control for analog settings and discreet outputs. These types provided reasonable functionality for device integration. They provided little to no support for data acquisition, model based control, and experiment control where the channels needed to be more complex and dense. Version 4 core allows the definition of any data structure to be serialized and transported [3]. This version defines a set of general and specific normative types to support these functions. This paper will discuss this set of normative types and their application in the middle layer services that are being developed to support this new scope.

VERSION 4 MIDDLE LAYER USE CASES

When we study the physics toolkits that have been developed such as SDDS [4], Matlab Middle Layer Toolkit [5], and XAL [6], it becomes clear that several utilities are always available. There is always a description of sets of EPICS Process Variable that are predefined for lists of channels that need to be operated on or displayed. This is specified as two services in version 4: Directory Service and Gather Service. These tools also have need to acquire information from a static data store for alignment data, magnet mapping data, and other static data that is in a relational database. These sets of data fall into several categories: named value pairs, or sets of values such as coefficients. In addition, data acquisition and model based control required large vectors of data or multidimensional arrays, or images. Data over large periods of time are also useful in this environment. It is these use cases, that drive the creation of the extended set of data types that will be exposed through the version 4 PVAccess API In addition to the extension of the data types to support these functions, The version 4 PVAccess server has been connected to the

EPCIS version 3 database to serve this data on the version 4 protocol as the first set of General Normative Types: NTFloat, NTDouble, NTEnum, NT String, etc. See Figure 1.

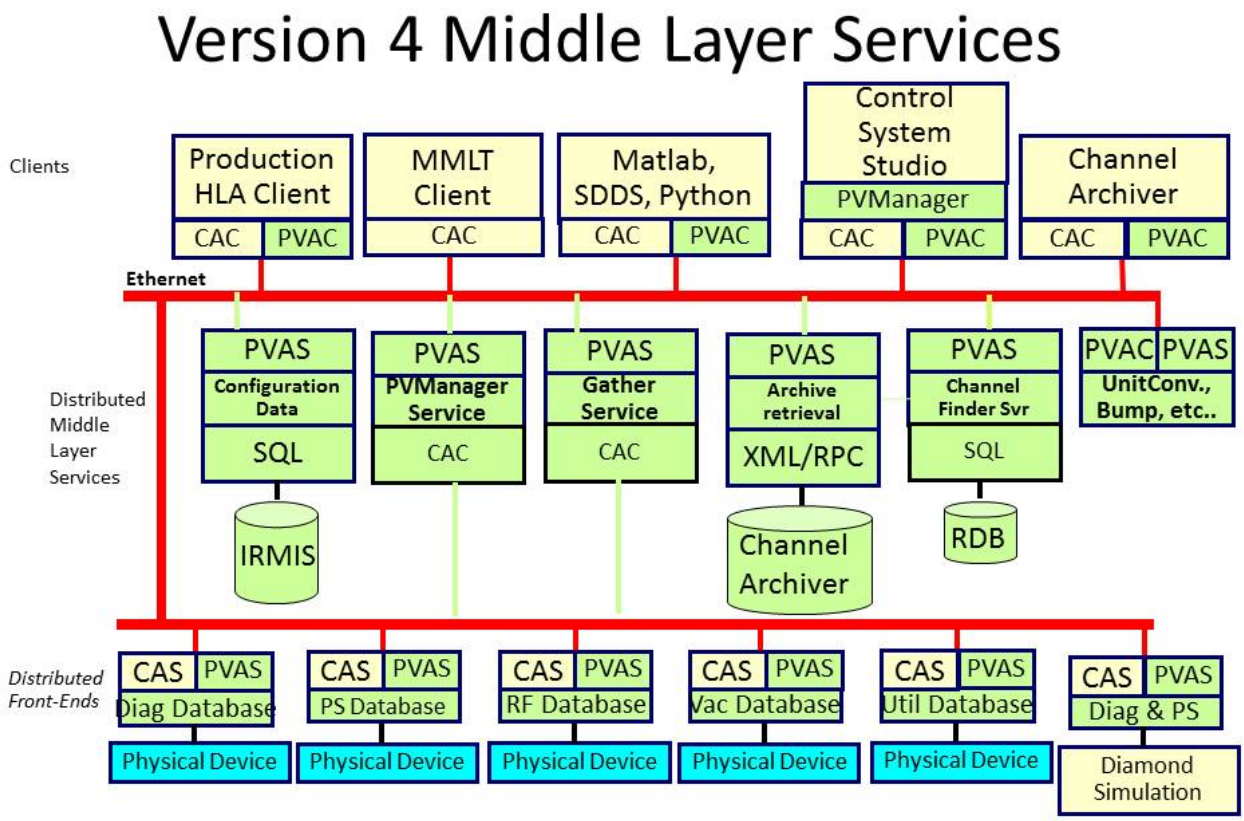

Figure 1: An EPICS Version 4 architecture drawing showing the new middle layers services that can be done with this extended set of data types. Many of these tools are being presented in this conference.

VERSION 4 NORMATIVE TYPES

Several normative data types have been defined to extend the set supported under EPICS version 3. All of the following normative types include a definition for time stamp called: NTTimeStamp , and alarm information called: NTAlarm. The general normative types are:

NTPVList, NTTimeArray, NTFreqArray, NTHistogramArray, NTMultiChannelArray, NTNDArray. NTStatisticalSamples, NTImage, and NTTable,

NTPVList

The PVList is a data structure that contains a list of process variables. In addition to the list of process variable names, this channel contains information needed to connect to this channel and provide the group as an order list. The fields may include connection information such as IP Address, port, priority, and an indication if it is currently available on the network. The field to create an ordered list could be the physical position along a beam line or storage ring.

NTTimeArray, NTFreqArray, NTHistogram

The arrays types need to be different as they represent very different data. The type informs the clients what types of information they present and the operations that can be done on them. NTTimeArray is from a digitizer and must have the time between samples to understand how it relates to other waveforms taken relative to it. NTFreqArray is an FFT of a NTFreqArray that requires the delta frequency between samples. The NTHistogram is an array of counts for different ranges of a scalar. This array can count values on either a linear distribution or log distribution..

NTMultiChannelArray

The multichannel array is a container for aggregating a set of scalar values into a single vector that is typically from the same time such as an orbit, or vacuum profile.

NTNDArray

An N dimensional array is used to transport a vector of data taken over time or a two dimensional array taken over time. This extends to an N dimensions.

NTStatisticalSample

A statistical sample is used to compress the data being sampled at a higher time frequency, into a lower frequency into a statistical sample that includes: high value, low value, mean, time of first sample, first sample, time of last sample, last sample, standard deviation,:number of samples and the or'd alarm severity of all of the samples. This data type is useful for reducing data from a longer period to a shorter period such as: raw bpm data samples at 10 KHz and reported at 1 Hz or record data being sampled at 10 Hz and being archived once every minute. It can also be used to compress a very long range of data coming back from the data archiver where the browser only has 500 pixels for displaying the data. Compression on the server side would greatly reduce the amount of network traffic and data transfer time.

NTImage

An image is a multi-dimensional array that needs additional information to know how to display it or do math operations on it. The NTImage must know the encoding and compression to be able to integrate, perform background subtraction, or display the image.

NTTable

A table is a fine way to collect a set of named parameters that are of a different type. This is a way to catch any arbitrary set of named elements that have a fixed number of values. If there is only 1 value (or row), it is a set of named value pairs. If there is more than 1 row, it is a set of named vectors. This can be used to capture a set of configuration parameters such as: experimenter name, company name, camera used, shutter speed, focus, etc… It can also be used to return the Twiss parameters for a set of magnets, where each column is one of the elements of the TWISS parameters and each row is a magnet.

CONCLUSION

PVData in Version 4 presents a set of normative types that can be aggregated, displayed, and archived. This include the version 3 normative types along with a server connected to version 3 databases. This set can be used to create general purpose servicers such as a directory service or a time synchronous vector from a distributed set of scalar values. PVAccess supports the serialization and de-serialization of PVData so that no changes are needed in this code to extend the set normative data types. More complicated services can collect the data needed from middle layer services as collections of these types and serve the results to high level applications or other middle layer services that will use them to create other results that may be served in turn to other clients or middle layer services.

This infrastructure along with this set of normative types are being used to develop the high level physics application environment for NSLS II in collaboration with the NSLS II control group, the NSLS II physics group, the SLS Control Application group and the Diamond Beam line Control Group. Early results show good performance. However, it remains to be demonstrated that this approach works and improves the overall development and maintenance of high level applications.

STATUS OF THE CSNS CONTROL SYSTEM

C.H.Wang, IHEP, 100049, Beijing, China

Abstract

The China Spallation Neutron Source (CSNS) is a high current proton accelerator which will officially start construction in September of 2011 in China. The CSNS control system has finished the preliminary design including devices interface determined and high level application.

This paper introduces control system design and 他和 progress of some prototypes as well as schedule and personnel plan.

INTRODUCTION

The CSNS[1] will be a 100KW accelerator based facility which is comprised of five major sections as shown in Fig. 1: a front end consisting of a 50 Kev H⁻ ion source followed by a 3MeV RFQ; a 80 MeV linac; a 1.6 GeV RCS; a 100 kw spallation neutron target which can be expanded to 500kw.

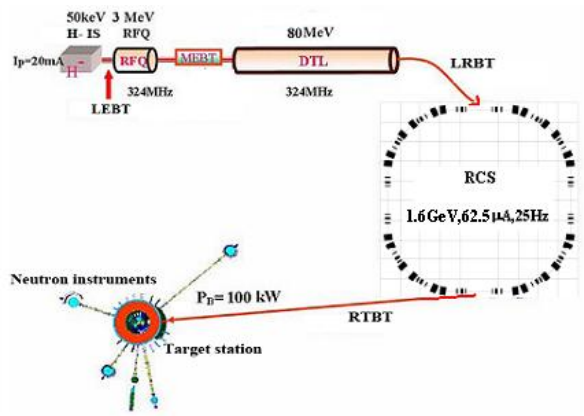

Figure 1: The Schematic Layout of the CSNS Facility.

The beam loss must be strictly controlled due to high current proton. On one hand, the radiation produced by the beam must be minimized for hands-on maintenance, on another hand, the damage to the equipments/devices due to radiation and thermal effect should be avoided since this facility has a strong radiation. So, the machine protection is very important.

CONTROL SYSTEM DESIGN

The defined scope for the control system is: that it will be a site wide monitoring and control system for the accelerator, target and conventional facilities. It will include all hardware and software of the following aspects as shown in the Fig. 2: computer system, networking, front-end controllers and hardware interface, machine protection system, as well as timing system.

The control system will not include any control or data acquisition for the target and the experimental stations. It further will not include the personnel protection system, which is a separate system that will be monitored by the control system. The control system will exchange data to conventional utility through the Ethernet. The overall task of the control system is to control and monitor thousand of the equipments/devices covering linac, LRBT, RCS and RTBT. In another word, the control system mainly provides the connections between operators/programs and accelerator equipments. Besides, it provides synchronization operation and equipments protection from the linac, RCS and the target.

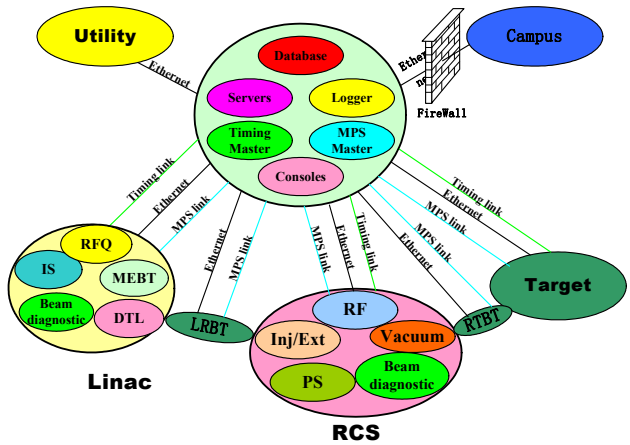

Figure 2: The Layout of the Control System Distribution.

Architecture of HW/SW

The control system will adopt the standard two layer architecture[2] with PC/Linux workstation as the Client. The EPICS IOCs are VME IOCs, one CPCI IOC, Embedded IPC IOCs and Embedded PLC IOCs for subsystem as shown in the Fig. 3. There will be no field bus to a third layer, but extensive use will be made of serial interfaces from layer two to the equipments. EPICS 3.14.10 and VxWorks 5.5/Linux 2.6 will be used for EPICS development environment. The interface from the control system to the equipment will be through different IOCs. The equipments interface has been determined.

Front End Interface

The Front-end include an ion source, LEBT,RFQ and MEBT. The ion source control system is typically a single component of the control system. It includes 5 parts: power supplies, vacuum, temperature measurement, water cooling and timing. All are required to be controlled locally in the tunnel and remotely at the central control room. The power supplies will work in the high voltage environment. So, they require high reliability and availability of the control system.

The prototype of the ion source control system was finished in 2009. All the devices had been controlled using YOKOGAWA FA-M3 PLC. One PC/Linux as EPICS IOC exchange data with the PLC CUP via Ethernet. The PLC CPU communicates with PLC I/O

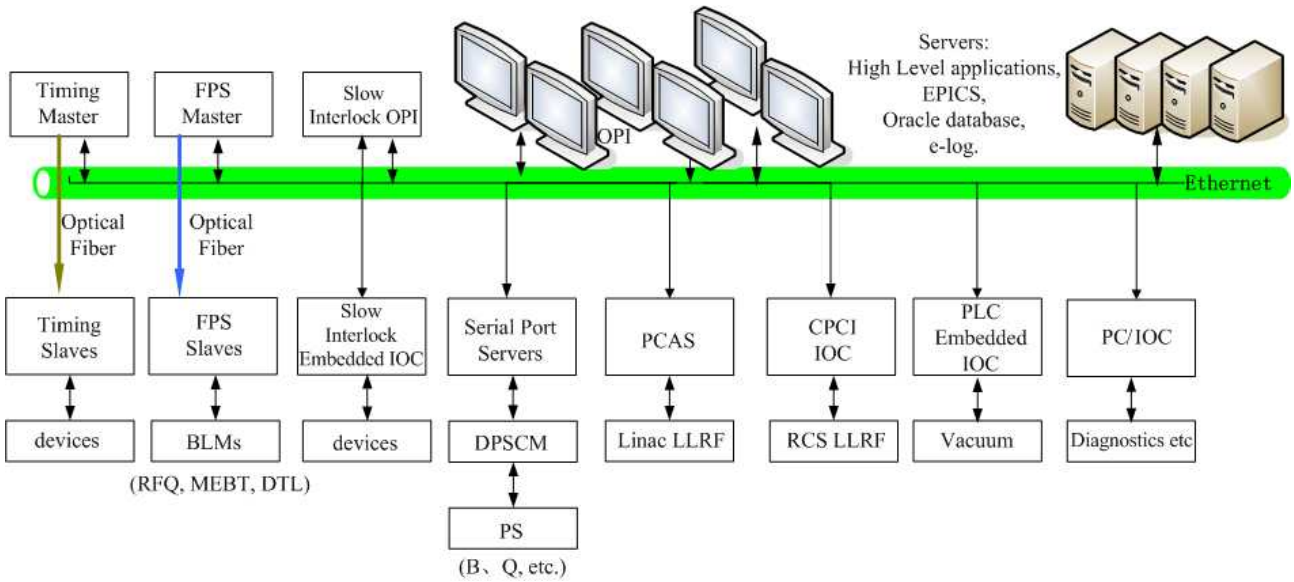

Figure 3: The Control System Architecture.

modules through the FA-Bus optical fiber. There is no extra electrical isolation between the ground and the high voltage platform. Some lessons are learn by the prototype like ground isolation, temperature modulation from relay switching on/off to PID control, more detailed specifications of the devices interface, processing of high voltage ramping and so on. In next step, the embedded IOC will be used to replace combination of the SoftIOC and the PLC/CPU as shown in the Fig. 4.

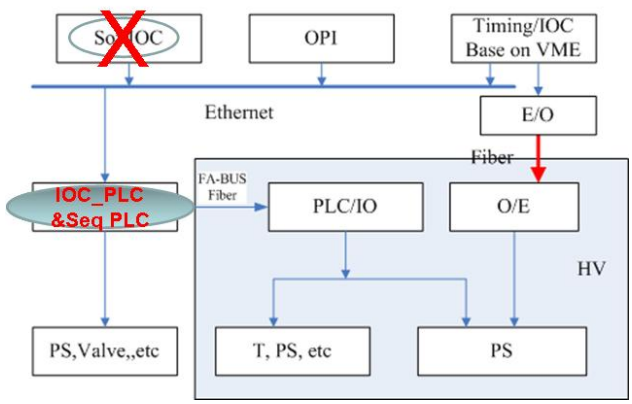

Figure 4: Ion Source Control System.

Power Supply Interface

There will be about 300 various magnet power supplies that are distributed in the linac, LRBT, RCS and RTBT. All the power supplies will be digital power supplies using a digital power supply module (DPSCM) developed by the power supply group. The DPSCM is an intelligent power supply controller with only serial port supporting Modbus RTU/RS232 and can implement logic control to the digital power supplies. Most work will be done within the DPSCM and power supplies. Since the ring is a rapid cycling synchrotron (RCS), the dipole and quadrupole power supplies with white circuit will provide 25 Hz sine waveform output to the magnets. Most magnet PS are DC power supplies, the RCS power supplies are DC plus AC power supplies with 25Hz sine waveform. Although these PS are different, the control interface to the different PS will be standardized. The requirements from the physics are very simple, for e.g. DC setpoint setting and reaback, AC amplitude/phase setting and readback. The DPSCM works fine for the RCS dipole/quadrupole power supply now.

After many times discussion between the control group and power supply control, the interface to the DPSCM has been determined using the serial port with Modbus RTU/RS232. The control group used a MOXA serial device DA682/Linux to connect the serial port of the DPSCM as shown in the Fig. 5. The communication between DA682 and the DPSCM is using Modbus RTU/RS232. We have developed Modbus RTU/RS232 driver and device support as well as database on DA682. In one word, this device is used as IOC to communicate with the DPSCM through the serial port with Modbus RTU/RS232 protocol. The prototype has been tested with the DPSCM with one power supply on site. The testing result showed that the software communication is ok and the speed can meet the requirement.

Vacuum Control Interface

The vacuum control system needs to monitor and control 128 ion pump power supply controllers, 45 vacuum gauge controllers and 27 gate valves in linac, LRBT and RCS,RTBT. The YOKOGAWA PLCs has been chosen for Ion pump and gate valve ON/OFF control and status monitoring. The MOXA serial device has been chosen for monitoring the gauges and pump power supply controllers via RS232/RS485.

#wangch@ihep.ac.cn

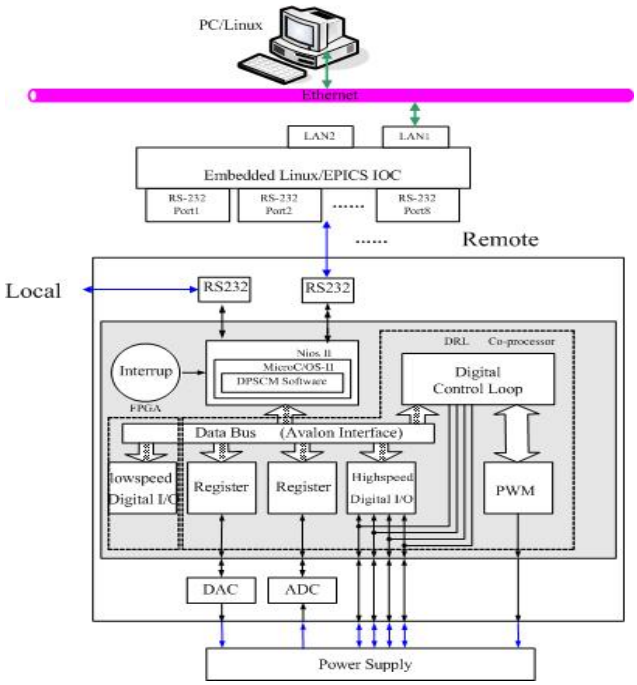

Figure 5: Power Supply Control System.

Injection and Extraction PS Interface

There are 8 injection power supplies and 8 kick pulse power supplies. YOKOGAWA WE7000 measurement has been used for the injection power supply prototype. The prototype test has been done in 12/2009. The control system is requested to monitor the PFN charge voltage and the kicker pulse current. The ZTEC oscilloscope (1GS/S, 300MHz, 12 bits, 2 Ch) with a built-in EPICS system is selected to get the charge voltage and pulse current. The ON/OFF control of the high voltage charge power supply will be implemented by YOKOGAWA PLC.

LLRF Interface

The Linac LLRF consists of a VXI crate and customized I/O module and a PC through RS422. It has been done by Linac RF group. The control system uses PCAS to communicate the API of the LLRF for changing local variable into EPICS PVs. The RCS LLRF will be implemented using customized CPCI I/O modules by RCS RF group. The control system needs to develop EPICS driver and database to interface with VxWorks driver supported by the company.

Machine Protection System

The machine protection system (MPS) has been redesigned during the preliminary stage referring to the MPS of the SNS[3] and J-Parc[4]. The design philosophy of the MPS is as follows:

- The devices local interlock done within the devices and send interlock signals to the MPS
- Hardware interlock,software recording as assitant
- Physical I/O redundancy for fatal faults in the key region/system
- Yokogawa PLC for equipment protection
- Customized Master and Slave for fast protection
- With a failsafe and rich self-diagnostic
- When a fault occur, MPS can shut down ionsource extraction high voltage and RFQ high voltage as well as perform post mortem analysis automatically

The MPS consists of two parts:

- Equipment protection for collecting signals and detecting internal faults from the equipments in Linac,RCS,Target and PPS. When any equipment fault occurs, it performs alarm handler and stop beam to avoid damage due to thermal effects
- Fast protection for interfacing BLM, once beam loss exceeds loss limit, shut down ion source and drop RFQ voltage to zero to avoid damage due to radiation and thermal effects

Besides, the MPS is also responsible for displaying status of the equipments and allowing automatic recovery from beam faults.

The equipment interlock consists of one central PLC and several PLC stations to collect signals and propagate the state signals of Linac,RCS and Target through the FL_Net to the central PLC. The FL_Net can accomplish data scanning within 200μs. The response time from a fault signal of the equipment to action can be within 20ms. How the FPS work is shown in the Fig. 6. Once the beam loss exceeds the loss limit, FPS will shut down ion source and drop RFQ voltage to zero within 20 μs to avoid damage due to radiation and thermal effects. The FPS consists of one Master and several slaves Fast responses are handled in FPGA (Xilinx Spartan 6) either locally or over bi-directional FPS optical communication. FPS unit monitors digital signals from BLMs. The ion source and RFQ are interfaced to MPS Master digital outputs. When any inputs on MPS unit changes, the output on MPS Master is triggered. The response time from MPS unit to MPS Master at 1 km distance is below 20 μs.

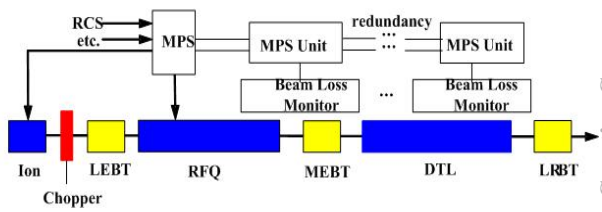

Figure 6: FPS working principle.

Timing System

Timing system is designed to provide triggers and clocks to the following systems: Front end, linac RF, injection, beam instrumentation, magnet power supply, RCS RF, extraction, spectrameter and target. The timing system consists of one EVG and several EVR stations. Detailed discussions with the above systems have been done, while there are still some points need to be studied further. Prototype using EVG/EVR has been setup. The specification of the EVG/EVR has been tested. The interface with the MPS has been studied and preliminary simulation has been done. Timing details about extraction have been studied and discussed with corresponding

systems. A dedicated hardware for the extraction timing has been designed.

Consoles

The consoles will be workstations and for cost reasons these are likely to be PCs running Linux. There are also some requirements to provide some PCs running windows for Win32 based applications. The accelerator, target and conventional facilities will be operated and monitored from the central control room, although there will be local control rooms available for device commissioning and troubleshooting.

Central Servers

There will be several central servers at the central control room. They are likely to be PC servers running Linux. They will provide development, applications, relational database, network, data archiver and viewer, alarm management, error logging, logging services and IOC booting.

Applications

The device application requirements can be met through the standard EPICS tools, control panels through EDM, alarm management through Alarm Handler, archiving through Channel Archiver together with Oracle database. Since web browsers have become an easy way to view and manipulate the control data, the CSNS control group is also planning to developed web-based control panel. Because the similarities between the CSNS and the U.S.SNS, the high level application framework will adopt XAL[5], used at SNS. XAL has been used for SNS commissioning and operation for over five years. Some XAL work in CSNS has been done including database framework of the CSNS accelerator by using standardized rules and interfaces. We have imported most of the equipments data of the CSNS Linac accelerator and two beam transfer lines. A virtual accelerator has been successfully setup. The control system will be responsible for providing high level application platform.

Network

A preliminary control system network design is based on 100Mbit switched Ethernet with a Gigabit switched Ethernet backbone. The network infrastructure will connect the control system computer to each of the local control and instrumentation areas with single and multi mode fibre. There will be a firewall between the control network and campus network. The control network will use a central core switch in the central control room and edge switches at each local control and instrumentation areas. The control network will be separate into several subnets. EPICS CA gateway will be used for the different IOC PV access and effective management of traffic and security.

CONSTRUCTION

The detailed program of work for construction phase of the project is currently being planned. The control system development will take 2 years. Some subsystem installation with the equipment installation will start in the end of 2012. The whole control system installation will be complete in 2/2016. The whole control system online commissioning will take 3 months. We are expecting to put it into operation in 5/2016. The CSNS control group is not only responsible for the CSNS control system construction, but also for the BEPCII control system maintenance. The CSNS control system would have a minimum resource requirement to get a basic system up and running.

ACKNOWLEDGEMENT

During the preliminary design stage of the control system, Prof. Songqiang Liu at SSRF in Shanghai gave many suggestion and help on some equipment interface definition. Dr. Dave Gurd at SNS who is a member of the ATAC gave me crucial advices and comments. Dr. Bob Dalesio at BNL , Mr. Ernest L. Williams Jr. at SLAC and Prof. Paul Chu at FRIB gave crucial suggestions on the control prototype and high level application. Dr. Gasper Pajor at Cosylab gave valuable suggestion on the FPS solution. The people in the control group made many contributions to the work of the control system. The author would like to thank all of them for their help and contributions.

STATUS OF THE ESS CONTROL SYSTEM

Garry Trahern, European Spallation Source (ESS), Lund, Sweden

Abstract

The European Spallation Source (ESS) is a high current proton LINAC to be built in Lund, Sweden. The LINAC delivers 5 MW of power to the target at 2500 MeV, with a nominal current of 50 mA. It is designed to include the ability to upgrade the LINAC to a higher power of 7.5 MW at a fixed energy of 2500 MeV. The Accelerator Design Update (ADU) collaboration of mainly European institutions will deliver a Technical Design Report at the end of 2012. First protons are expected in 2018, and first neutrons in 2019.

The ESS will be constructed by a number of geographically dispersed institutions, which means that a considerable part of control system integration will potentially be performed off-site. To mitigate this organizational risk, significant effort will be put into standardization of hardware, software, and development procedures early in the project. We have named the main result of this standardization the Control Box concept. The ESS will use EPICS, and will build on the positive distributed development experiences of SNS and ITER.

Current state of control system design and key decisions are presented in the paper as well as immediate challenges and proposed solutions.

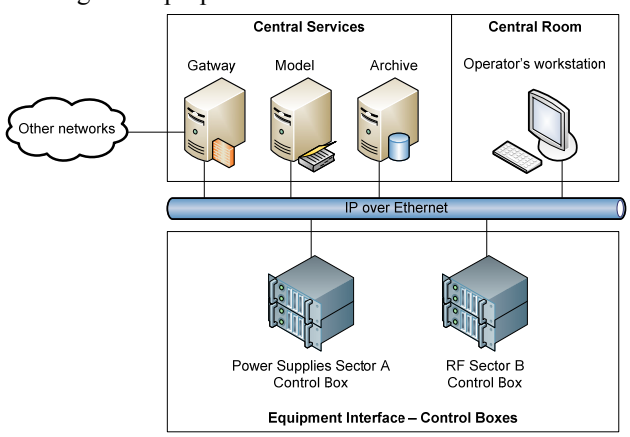

Figure 1: Three-tier architecture of the ESS control system.

CONTROL SYSTEM DESIGN

For the ESS control system, a slightly modified three-tier architecture is suitable. The three tiers [1] depicted in Fig. 1 are:

- **User interface** (upper right in the figure). These are graphical and non-graphical user interfaces. Most of them will be in the control room, but some will be elsewhere, e.g., for site-wide monitoring of the ESS status, and for remote access.
- **Central services** (upper left in the figure). Computer services that need to run continuously irrespective of user's activities, e.g., archiving of process variables' values, monitoring of alarm states, slow feedback loops, model of the machine as a whole, and management of activities that require coordination of several subsystems.
- **Equipment interfaces** (bottom in the figure). This tier is responsible for interaction with equipment and devices. It serves two purposes: to provide an abstract representation of equipment to higher layers through which the equipment can be monitored and controlled, and to implement real-time control loops.

THE CONTROL BOX

The Control Box metaphor is based on the philosophy adopted by ITER [2]. In ITER terminology the Control Box philosophy is realized with the concepts Plant System Host, CODAC, mini-CODAC and plant system I&C. It provides a standardized solution for all collaborating teams and is a cornerstone in the 3-year design update phase. An example structure of a control box is shown in Fig. 2.

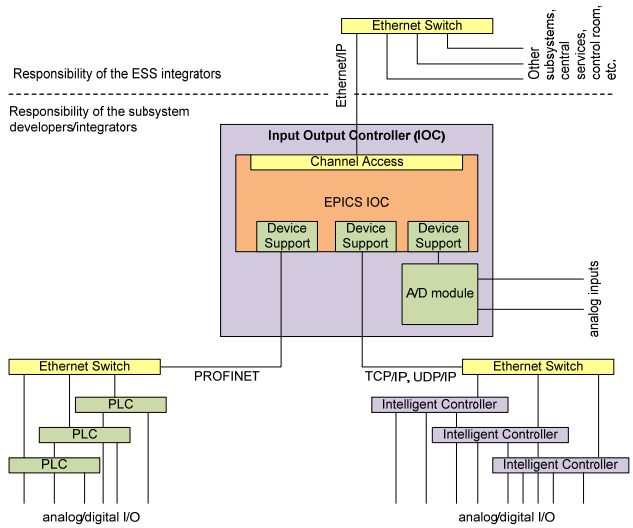

Figure 2: Schematic of Control Box components for a representative Control Box example.

Benefits

The main benefits of the Control Box are:

- To allow independent and yet standardized subsystem controls development,
- To encourage and enforce consistency between sub-systems (including target and experiments station),
- To facilitate testing of new equipment, e.g. EPICS drivers,
- To reduce risks early to prevent unexpected surprises at project integration time and
- To minimize throwaway hardware and software development.

Development

The Control Box should not be completely defined and developed too early in the project as the technology landscape to support it is rapidly evolving. We therefore expect to have iterative Control Box development.

It is necessary to develop Control Box software and hardware in (e.g., yearly) cycles. The main strategy is to start with software-only aspects (which are easiest to develop, test and distribute), and as soon as possible deliver a Control Box with a simple standardized hardware interface such as infrastructure PLC control.

In future versions functionality will be added (e.g. hardware support, including timing and feed-forward), and tools and support will evolve with available technology.

Hardware Platform

The Control Box concept enforces the usage of a common hardware platform for all teams and sub-systems to shorten the development time, support costs, etc. Therefore, the discussion on the selection of the hardware platform has been initiated early in the design stage and an iterative selection process has been agreed upon.

To further optimize the selection process a hardware selection table has been proposed where various important aspects of proposed platforms (VME, ATCA, PCI and all flavours) are leveraged against individual team requirements and scaled to the whole project size. Selection criteria for the platform includes:

- **Vendor support**: how many commercial vendors of crates and modules exist? A larger number implies that the probability of finding an off-the-shelf module for a particular task is higher.
- **Maturity**: how long has the platform been available, and how frequently is it used? Greater maturity implies lower risk and lower probability of backward-incompatible changes in the future.
- **Longevity**: how long is the platform expected to be available? Assessment should be given with the ESS's lifetime (several decades) in mind.
- **High availability**: how suitable is the platform for high-availability applications? (e.g., support for redundancy).
- **Software support**: how likely will software support (Linux driver, EPICS device support) be available for a device?
- **Prototyping vs. Production:** what is the cost of prototype development vs. production development, integration and support?
- **Risks and risk cost:** what are the risks connected to a specific platform selection and more importantly, what are the costs associated with these risks?

BEAM LINE ELEMENTS DATABASE (BLED)

ESS Control system will be built around a central configuration database (codename: BLED) where all accelerator parts and the relationships between the parts are modelled, as shown in Fig. 3.

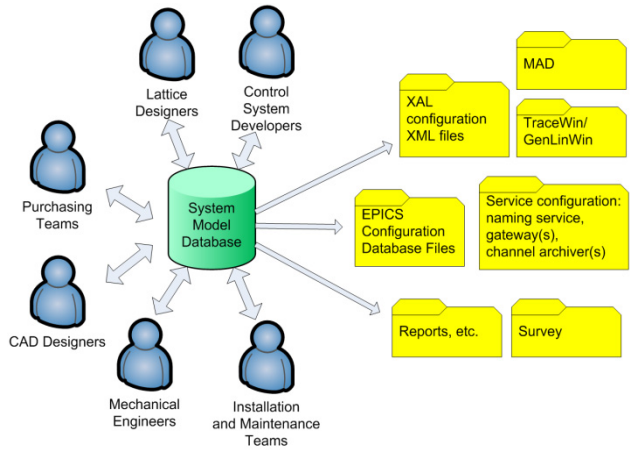

Figure 3: Users and main output of BLED.

This all-encompassing approach starts with the premise of where the equipment is located and includes data about the lattice as well as the equipment and devices. In addition, cabling information is stored in the database. The database also contains various high-level configuration parameters of the facility, all process variables, alarm definitions and alarm configurations and process variable archiving configurations. Basic information about the personnel who are making changes to the database is also included. Database entities are versioned. This makes it possible to recreate an older version of the facility model or some parts of the model, enables auditing and change tracking of the configuration and supports approval procedures for changes. The database should be constructed and operated so that it will provide a consistent model of the entire facility configuration.

Accelerator Parameters

To ensure consistency of the information being used amongst all subgroups throughout the period of accelerator design and construction, a parameter list database and web interface have been proposed in reference [3]. The main objective is to provide tools to identify inconsistencies among parameters and to enforce an ethos for groups as well as individuals to work towards a common solution. Another goal is to make the Parameter Lists a live and credible endeavour so that the data and supporting information shall be useful to a wider audience such as external reviewers as well as being easily accessible.

Control System Perspective

The use of the ESS Naming Convention in the configuration database for equipment and devices already provides the necessary information to identify all process variables in EPICS. However, in order to generate all EPICS database configuration files from BLED, a further extension of the BLED schema is needed. Therefore EPICS process variable fields, alarm server configurations and channel archiving configurations will be added to the schema to enable the generation of the EPICS database files, alarm configuration and channel archiving configuration files from the BLED configuration database. In the event that graphical database editing tools will leverage the configuration database, the schema will be extended with diagrams showing the positions of process variables on the diagrams.

DEVELOPMENT ENVIRONMENT

The Control System of the ESS will be complex (i.e., it will consist of a multitude of subsystems that will need to be integrated) and its development will require the cooperation of many developers and controls experts.

To allow proper development procedures, artefact sharing, code storage, etc., vital central services need to be set-up. Figure 4 shows a graphical overview of the environment. These services must provide the ability to:

- Share artefacts (code, documents) between engineers (Mercurial, DocDB, Plone),
- Perform version control (Mercurial),
- Continuously integrate SW development (Hudson),
- Perform complex and time consuming operations (DMSC),
- Offer a standard development environment regardless of the platform (Virtual Machine),
- Build and package software (Maven),
- Deploy artefacts to user machines or IOCs (yum, rpm),
- Perform automated testing (JUnit) and
- Report bugs and issues (Bugzilla).

Therefore, standards and guidelines must be put in place for development. Development tools and platforms should also be standardized.

ONLINE MACHINE MODEL AND SIMULATION

The user interface of the control system will most likely be based on XAL [4]. This software framework developed at SNS is a suite of Java/Python libraries and programs designed to interact with the EPICS services while providing human readable information to operate the machine. Through XAL it will be possible to change the state of the Linac by acting on all knobs and variables available to the EPICS system.

During the running of the machine, especially in the beam commissioning period, the operator has to decide which changes are needed to optimize the machine, for example to reduce losses, to steer the trajectory, etc. In this operation the user will be assisted by the Online Model: it will be a simulator of the Linac that interacts via XAL as a real machine and allows testing the parameter changes before applying to the real accelerator. Moreover the Online Model will be able to do automatic routine tasks such as loading the parameters from the running machine to find the optimal configuration for a specific problem, for example, to find the optimal configuration for correctors to steer the beam.

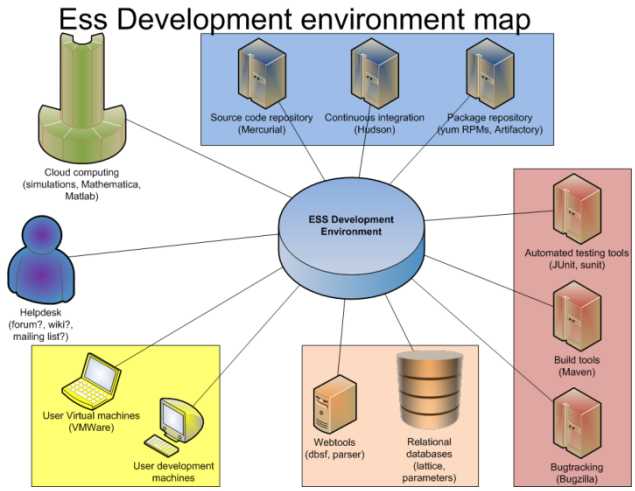

Figure 4: ESS Development environment map.

To have such instrumentality an optimal knowledge of the Linac is required, and this task can be achieved through a full campaign of simulations. Simulations are necessary to understand the dynamics of protons and the possible instabilities generated by errors in the productions of the Linac components during assembly or simply by random errors. The simulation code will be flexible enough to include unexpected phenomena arising during beam commissioning, and it will provide single and multi particle capabilities in order to predict the widest range of situations that the user can experience running the accelerator. The data to construct the simulation, e.g., systematic errors associated with component fabrication and alignment errors during installation will be maintained in the configuration database BLED.

STATUS

Design

There are three major advances in ESS controls design development that set stepping stones for further development:

- The **Conceptual Design Report** document has been drafted and describes the unified approach of controls covering the three main project segments: accelerator, target and instruments. All the development tools and services have been scaled accordingly to cover the additional segments such as

cryogenics and conventional facility infrastructure controls.

- The **Naming Convention** has been defined and approved. By learning as much as possible from ITER and SNS experiences, the naming convention was put in place early to allow proper enforcement and avoid pitfalls as the project advances.
- The initial **Costing Exercise** has been performed and provided the first estimation on the price of ESS controls. It is estimated to be less than 5% of total project cost.

Control Box

There have been several advances regarding the Control Box as well.

- The discussion on **HW platform** has been initiated with the individual teams, e.g. beam diagnostics and RF.
- It has been accepted that **early prototyping** and as-common-as-possible hardware platform is the required approach to allow the learning process to start early. This should reduce complications in sub-system integration during the construction phase of the project.
- The Control Box development cycle has been fully integrated into the **Development Environment**, see Fig. 5.

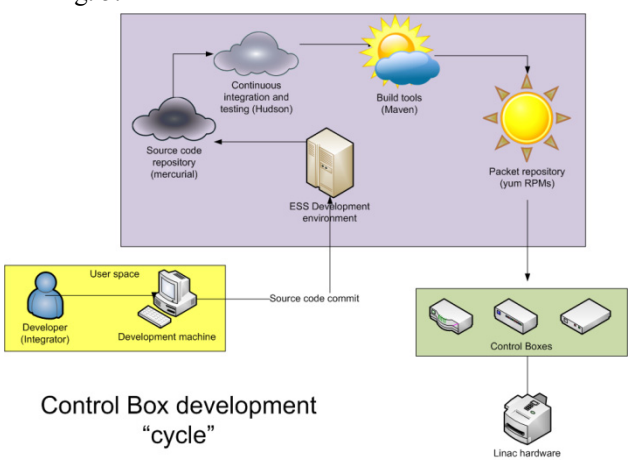

Figure 5: Control Box development cycle.

BLED

Since the Beam Line Elements Database is a vital component of the control system the development has started as well.

- The main database schema has been finalized and agreed upon.
- The Accelerator Parameters and Naming Convention tools are currently both under development.
- Various parsers and lattice tools (DBSF) have also been modified and developed to be consistent with BLED requirements.

Development Environment

The development environment as one of the key tools in the development process has been deployed in the DMSC, the Danish supercomputing cloud.

- Currently, the development environment is hosted on 8 CentOS service machines (3 designated for user's development) in the supercomputing cloud.
- It already provides an almost complete set of development tools: Mercurial, Hudson, MySQL database servers, Maven, Bugzilla, etc.
- It also provides a standalone virtual machine (based on Scientific Linux) that provides the required services for development across various platforms (Linux, Windows, Mac OS)

Timing and Machine Protection

Because of the significance of Timing and MPS to all parties (accelerator, target, instruments, safety), gathering of requirements for both have started. The possible designs and approaches have been described in the CDR documents and regular iterative meetings with different teams are underway to enforce regular collaboration and convergence for these two project-wide system.

SUMMARY

The control system is a sophisticated network connecting all the various parts of the accelerator and is essential for the synchronization and day to day running of all the equipment. Its organization will inevitably also determine its efficiency and usability. A certain degree of flexibility is expected.

Therefore, the development of the ESS control system has been from day one focused on the following key issues:

- Collaboration and communication,
- Unified development, integration and support,
- Learning from existing projects, and
- Interaction and iterative decision-making.

STATUS OF THE ASKAP MONITORING AND CONTROL SYSTEM

J.C. Guzman, CSIRO Astronomy and Space Science, Sydney, Australia

Abstract

The Australian Square Kilometre Array Pathfinder, or ASKAP, is CSIRO's new radio telescope currently under construction at the Murchison Radio astronomy Observatory (MRO) in Mid West region of Western Australia. As well as being a world-leading telescope in its own right, ASKAP will be an important testbed for the Square Kilometre Array. This paper gives a status update of the ASKAP project and provides a detailed look at the initial deployment of the monitoring and control system as well as major issues to be addressed in future software releases before the start of system commissioning later this year.

PROJECT UPDATE

ASKAP is located in the Shire of Murchison, a remote outback mid-west region of Western Australia, approximately 400 km northeast of Geraldton and 800 km north of Perth. The location also corresponds to the Australian SKA candidate core site. This region has been identified as ideal for radio-astronomy due to its very low population density and hence a lack of man-made radio signals that would otherwise interfere with weak astronomical signals. The site is now named the Murchison Radio-astronomy Observatory (MRO).

Approximately 75% of ASKAP time will be used as a survey telescope carrying out systematic observations of the entire southern sky. The rest of the time will be allocated to targeted observations either guest projects or target of opportunity observations. For more information about ASKAP project visit [1].

At the time of writing this paper there are 9 antennas installed, 6 of them have successfully completed their Site Acceptance Test. One of them (Antenna 29) has a Single Pixel Feed (SPF) L-band receiver and is being used as a part of the Australian Very Long Baseline Interferometry (VLBI) instrument.

All Integrated Product Teams (IPT) have passed their Critical Design Review and the project is well into production mode. The first full Phase Array Feed (PAF) front-end package, back-end electronics and control software has been installed on the Parkes 12m test-bed antenna in May 2011 and has been used in interferometry mode with the Parkes 64-m antenna to measure the PAF performance as well and to be a testdbed for the monitoring and control software system of ASKAP.

The next big milestone is the installation and first light of the Boolardy Engineering Test Array (BETA) system comprising of 6 ASKAP antennas at the MRO fully equipped with PAFs, front-end and back-end electronics, and monitoring and control software. Subsequent major project milestones are described in Table 1

Table 1: ASKAP Project Milestones

Milestone	Date
MRO infrastructure completed (including central site building and power for BETA)	Jan 2012
BETA "first light" and start of commissioning	Feb 2012
Construction of all 36 antennas complete	May 2012
Pawsey centre building (host of the ASKAP supercomputer) in Perth complete	Sep 2012
MRO power plant (ASKAP)	Dec 2012
ASKAP (with PAF) complete	Dec 2013

EVOLUTION OF THE ASKAP MONITORING AND CONTROL SOFTWARE

Software Architecture Update

After the Computing Preliminary Design Review (PDR) meeting in 2009, where we presented the first design of the ASKAP Software Architecture, and subsequent discussions with System Engineering and other IPTs, we agreed to extend the definition of the TOS (as defined in [2]). The new TOS contains all the software components related to monitoring and control of the facility and provides both raw data (visibilities) and telescope meta-data for the data processing stages.

The Central Processor (CP) group contains all components related to data reduction pipelines such as calibration and imaging, including services necessary to perform those tasks such as access to sky models and RFI data. This functional decomposition allowed us also to align to the overall ASKAP Architecture, on which TOS and CP subsystems were identified. Figure 1 presents a logical view of the current overall ASKAP software architecture.

Figure 1 also shows were EPICS lives within the software architecture. The actual implementation followed a more conventional tiered design, similar to other telescopes and particle accelerators, on which there is a middle layer providing local control and interfaces to the hardware sub-

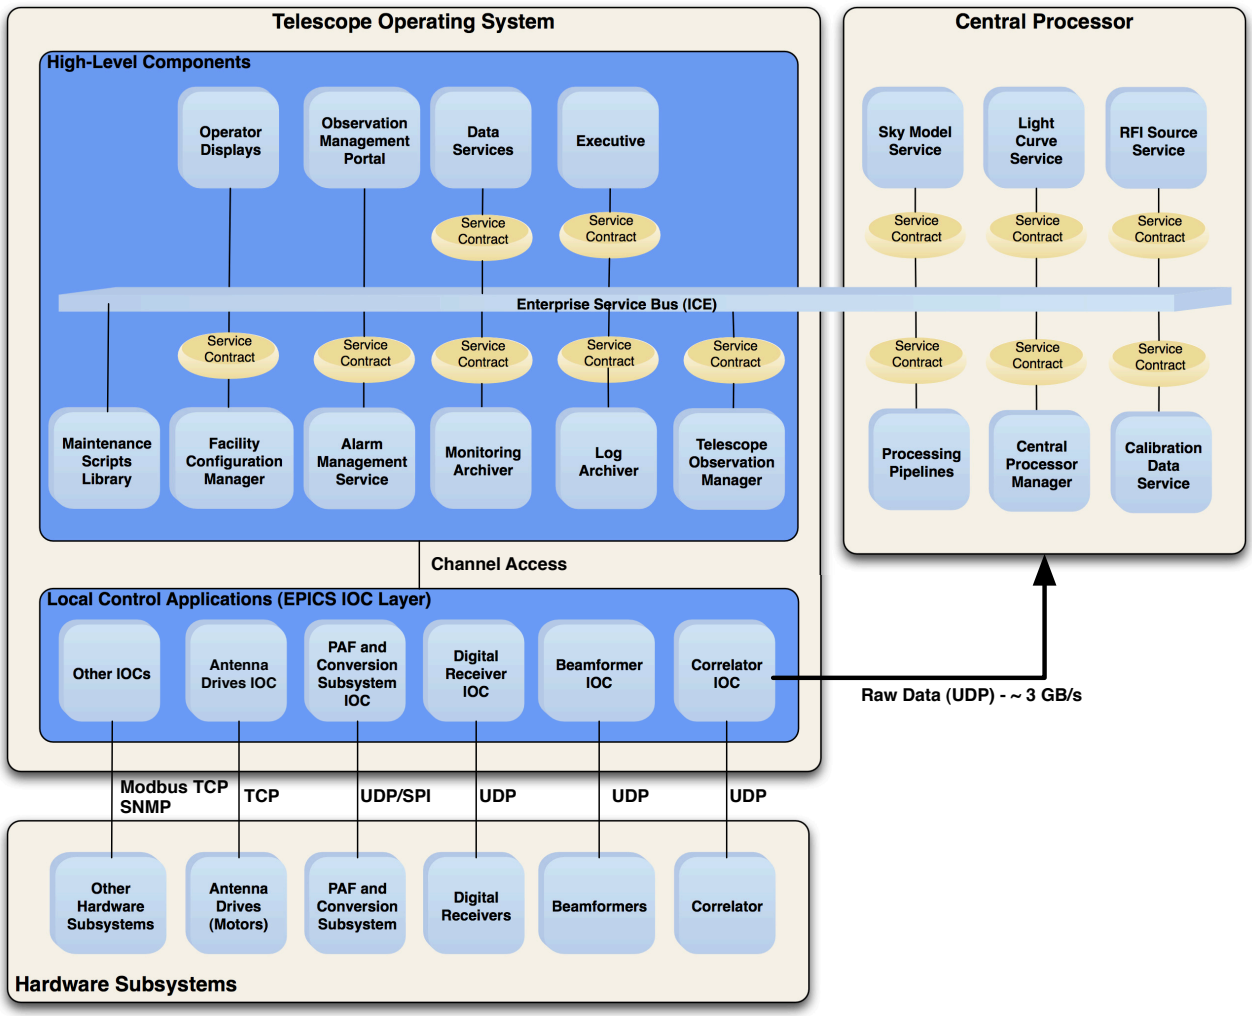

Figure 1: Logical view of the ASKAP software as implemented in latest version of TOS.

systems. This layer is implemented using EPICS IOC core. High-level components such as Monitoring Archiver, Telescope Observation Manager and Alarm Management Service use Channel Access to monitor and control the hardware subsystems. EPICS has several drivers already available for most common hardware field-bus such as SNMP and Modbus TCP. In case of our in-house UDP-based protocol (used in all our custom hardware) we have developed drivers using the EPICS C/C++ driver framework called ASYN [3].

A summary of the current control system specification is described in Table 2.

One of our requirements is to provide a flexible tool to perform maintenance operations on one or more hardware subsystems. We have developed a Python library for maintenance operations and system verification called Maintenance Script Library (MSL). This library is currently in used by engineers and instrument specialists to build specialised scripts that verifies one or more subsystems. This scripts can also be run by maintenance engineers after a piece of hardware has been replaced. The library supports concurrency and reporting. The Python library is built on top of PyEpics3 EPICS Python library developed by Matthew Neville [4].

TOS SOFTWARE RELEASES

The Build System

Since we rely heavily on several third-party software packages such as EPICS and ICE source code, we developed a powerful build system that ”wraps” several language-specific builders: scons (for C++ packages), EPICS make (for EPICS base, tools and applications), ant (for Java packages and applications), setuptools (for Python packages and applications) and autotools (for third-party packages that use autoconf). In addition, the build system supports recursive compilation, documentation generation (doxygen, Sphynx and javadocs), execution of unit and functional testing, release process via debian packages and Linux and OSX development environments.

The build system is implemented in Python and integrates also with Subversion (version control system) and

Table 2: ASKAP Monitoring and Control System Specifications

	BETA (6 Ant)	ASKAP (36 Ant)
Total Number of I/O Points	100,000	600,000
Total Number of Archived I/O Points	40,000	240,000
Monitoring data archival rate	130 GB/year	1 TB/year
Monitoring data archival rate max	1 kHz	1 kHz
Highest ”soft” control loop rate	1 Hz	1 Hz
Estimated number soft-IOC Linux computers	10	30
Science ”raw” data output rate	400 MB/s	3 GB/s

Hudson [7] (continuous integration tool).

The Development and Release Process

We have adopted an iterative and light-weight approach to our software development process, incorporating some best practices from agile methodologies. We do not use complicated Gantt Charts for our day-to-day software development planning, instead we have software release-based milestones. Every month, usually at the beginning of the month we produce a fully tested release of TOS software. Each release it is then installed and verified in the Parkes system. This monthly cycle follows the principle ”integrate early, integrate often”. This approach has been proven very useful, especially to adapt to requirement changes and external factors (hardware delay) on which we can arrange the amount of features that goes into one release or another.

Two tools has allowed us to put this methodology in practice and worth mention:

- Redmine [6], an open source project management tool that features issue tracking, milestone support, subversion integration and wiki. This tool is also being used by other ASKAP IPT and it has been a good way to do work exchange and tracking between IPTs.
- Hudson [7], an open source continuous integration tool, very easy to install, use and maintain. This tool allow us to perform continouous checking of build software as well as unit test coverage and some functional testing. Developers gets notified if they break the build.

KEY TECHNOLOGIES

EPICS

We have been using EPICS framework for the past 2 years and recently in production code in Parkes since July 2011. Overall we are very happy with the EPICS software and related tools, and more important with the openness and friendliness of the EPICS community.

Some of the EPICS tools we are currently using besides EPICS IOC core software are listed here:

- ASYN [3] for low-level EPICS driver development.
- Existing EPICS third-party drivers: devSNMP and modbus.
- PyEpics3 [4] as our Python Channel Access Client library.
- Alarm Handler (ALH). Offers a quick implementation (but limited) of the Alarm Management Service but soon to be replaced by most likely Control System Studio (CSS) BEAST.
- Sequencer and State Notation Language for state programming in the IOC applications.
- EDM for our Engineering GUIs, but starting to migrate engineering GUI development to CSS BOY.
- Control System Studio (CSS) [5]. We have just started to use CSS BOY for some of the engineering GUI and we are looking now to integrate CSS into our repository as well as some other CSS tools like BEAST, PV table, Data Browser.

ICE

We now have under our belt a good years worth of experience using ICE, and recently we have been discussing some of its short-comings (version 3.4.1). None of the short-comings are major issues and we decided that even though it may not be the most ”elegant” solution, our ICE implementation delivers do what we require in the area of high-level component communications.

Here we present some of the major issues, mainly related to ICE publish/subscribe implementation called IceStorm:

- Difficulty in debugging applications deployed in IceStorm. This is primarily due to the fact there are no observability tools which operate at the message or topic level.
- Lack of reliability features in IceStorm, particularly the inability for a subscriber to identify the fact that the broker/channel (IceStorm server) has gone away. There is no auto-reconnect feature as is present in other pub/sub middleware.
- No support for queues (only topics) so temporal decoupling is not possible.
- There is no guarantee of delivery of message. When a message is sent/published, if the subscriber is not running then the message is lost. IceStorm does not hold (or even persist) the messages and redeliver when the subscriber comes back up.

Despite these shortcomings, we have found the core functionality (Interface definition, RPC, Locator service) to be very good. Since the high-level component communication is not dominated by publish/subscribe communication these ICE issues are not critical, but we are looking into ways to improve them.

CURRENT AND FUTURE CHALLENGES

Over the past year and as we ramp up our software development one of the major challenges we encountered was how to deal with the creation of Interface Control Documentation (ICD). Since control software in our domain tends to cut across many subsystems and it is at the end of the data change, successfully delivery of fully tested software closely dependent on two things: ICD or something equivalent and the hardware to play.

An ICD is vital for developing the local control software or IOC, since it tells us with some degree how the hardware communicates and functions. We can also build emulator to assist the IOC development, integrate the IOC into the overall system for early testing and system debugging while we wait for the deliver of the full hardware.

ASKAP hardware/firmware developers responsible for production of hardware subsystems were not used (or did not have much experience) in producing ICDs. Their normal way of writing ICD and any formal documentation is to design the hardware, implement the firmware, implement some C-code software to verify the hardware and then write the ICD, by then it was too late for us and operators were forced to use the C-code program to operate the hardware while we debug and test IOC software. It took a lot of time and effort to come up with some mutual arrangement on which some form of ICD is written, even if not complete (it actually seldom is) so we can start developing, integrating and testing early into the overall system while they continue implement more functionality in the firmware.

Having an iterative approach with monthly releases have helped us greatly to adapt to changes in ICDs and late delivery of hardware.

Since we have to concentrate in the core software for start of BETA commissioning, we postponed some TOS feature to be developed over the next year or so, in particular:

- Integration of Control System Studio (CSS) into our software repository and the use of BEAST as our Alarm Management Service, with extension to capture alarms from High-level components via ICE.
- Implementation of the Facility Configuration Management.
- Implementation of the Observation Management Portal using web technologies.
- Optimisation and Refactoring of our code

We are very excited and looking forward for the upcoming months. We are hoping to get the first fringes by the end of 2011 and shortly after the first images from BETA.
