Process communication: Process communication covers the communication of devices at the field and control level with supervisory controllers or computers. For lab equipment GPIB and proprietary RS232/RS485 connections are unavoidable. For industrial automation equipment PROFIBUS DP is the recommended choice. It is the dominating fieldbus in Europe and is naturally supported by S7 PLCs and many other devices. A major reason for its success is the technological and functional scalability based on a common core as well as the programming model, which easily maps to PLC operation.

Experiment Computer: For economical reasons, all experiment computers should be PCs. Linux, being well established in the scientific community, is the only supported operating system. There is no definition of a specific kernel version or distribution. Direct device access should not be implemented on conventional PCs but on CompactPCI systems. CompactPCI allows deploying a variety of existing software in a mechanically more robust platform that fits into 19" racks.

Middleware: Since the framework aims at an inherently distributed system, software support for the transparent distribution of services between systems is required. For this purpose TACO has been selected as the middleware system. TACO is a client-server framework developed for beam line control at the ESRF in Grenoble. In a TACO environment each device or hardware module is controlled by a TACO server. The server offers a set of device-specific functions, which can be accessed by TACO clients via a RPC-based mechanism over a TCP/IP network. To make its functions available to clients, the device server registers itself with the so called "manager" process. The manager operates as a name server, which is consulted by clients to get the actual location of a server. TACO includes a simple database for sharing of configuration data and operational variables between clients and servers.

Application level: On the client side, two variants of application programs are used: Where flexibility is desired and no GUI is needed, the scripting language Python is used. More static GUI applications are implemented in C++, using the "Qt" class library, with TACO access provided by device specific C++ wrapper classes. Recently, due to pressure from instrument scientists a macro language consisting of fixed command words and their corresponding arguments was defined. The idea was to have an extremely simple tool for standard scans without having to deal with the complexity or traps of a full programming language. As a consequence, the macro language has no control structures or variables and instead of loops it provides a "scan" command specific for each instrument. An interpreter for this command language was first implemented in python using the python "cmd" module on the neutron reflectometer MARIA [5].

THE BIODIFF CONTROL AND DATA ACQUISITION SYSTEM

Physical Architecture of the Control System

According to Fig. 2 the control and DAQ system is implemented as a distributed system with a hierarchical architecture. On top of the system resides the so-called control computer with all application software – GUI-based as well as script-based. Via the experiment network the control computer accesses the "server computers", to which all front end systems (detectors, monitors, position encoders, motor controllers, …) are attached. On the "server computers" TACO servers are running, which access the peripheral devices via dedicated device drivers. The only exception is the computer provided by Maatel for the NIP system, where a TANGO server is running.

The "slow control" peripherals are indirectly connected to the "server computers" via a PROFIBUS segment with the main S7-300 PLC. Stepper motor controllers and SSI modules as well as digital and analogue I/Os reside in ET200 decentral periphery systems, which are connected to the PLC via an additional subordinate PROFIBUS

segment. The safety PLC (ET200S F-CPU), the adapter modules for encoders with NDAT interface as well as a touch panel for local operation of the PLC are connected to the same subordinate PROFIBUS segment.

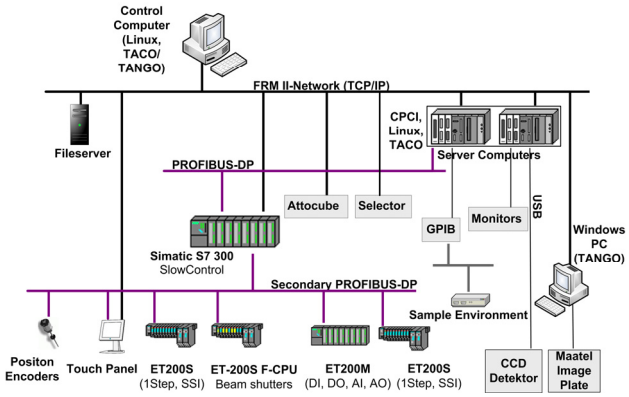

Figure 2: Physical architecture of the BIODIFF control and data acquisition system.

The CCD camera is connected to a server computer via USB. Selector and the controller for the attocube positioners are connected to a server computer via Ethernet.

Software Architecture

As shown in Fig. 3, the implemented software is distributed between three levels of the system hierarchy. All software below the lower dashed line runs on PLCs in the front end. The software modules shown between the dashed lines are running on the server computers. This comprises TACO servers and device drivers for dedicated HW modules, e.g. detector electronics, counter/timer board, PROFIBUS controller or GPIB controller. The TACO middleware is the glue that connects the server computers to the control computer, where the client application programs as well as the TACO manager and database (all above the upper dashed line) are running. Since TACO is location-transparent, the application programs could run on any Linux-based system.

A thin abstraction-layer implemented in Phython above the generic TACO-Python binding hides many details from the user, e.g. it allows the use of symbolic names and provides the conversion between device units and physical units. This abstraction layer provides a comfortable script access to all spectrometer features. On top of this abstraction layer the above-mentioned macro language has been implemented, which is the standard tool to do measurements with the Instrument. Measurement data are stored in the NeXus format. It is intended to implement a GUI-based measurement program in future, but its functionality has not been defined yet. Up to now only one GUI-based program has been implemented, which visualizes the mechanical setup of the instrument and allows interactive control of each axis, in order to support service by technical personnel.

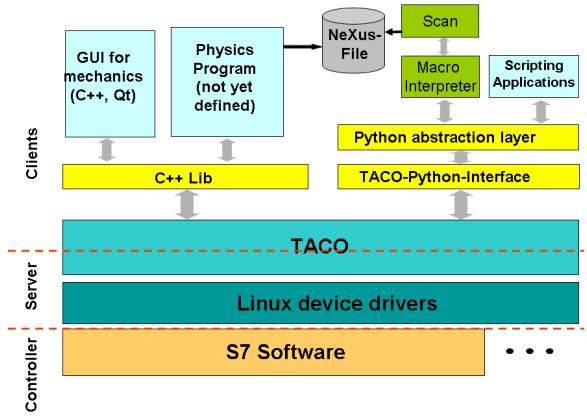

Figure 3: BIODIFF Software structure.

CONCLUSION AND OUTLOOK

Since the "Juelich-Munich Standard" is the common, powerful toolbox used in all JCNS instruments, the implementation of the control and data acquisition system was straight-forward. Especially the integration of the TANGO subsystem controlling the NIP was without any problems, due to the generic TANGO/python binding and because of the similarities between TACO and TANGO. The BIODIFF started commissioning in October 2010, when it saw first neutrons. Due to a one year shutdown of FRM-II the commissioning had to be interrupted and is expected to continue in October 2011.

Currently the introduction of TANGO for the neutron instruments at FRM-II is discussed, since TANGO is the natural successor of TACO. As a consequence, in future the BIODIFF control and data acquisition system may switch from TACO to TANGO

BINP SB RAS, Novosibirsk, Russia

Abstract

The control system for the magnetic system of the free electron laser (FEL) is described. The characteristics and structure of the power supply system are presented. The power supply control system based on embedded intelligent controllers with the CAN-BUS interface is considered in detail. The control software structure and capabilities are described. Besides, the software tools for power supply diagnostics are described.

INTRODUCTION

A high-power free electron laser based on the accelerator-recuperator [1] is under construction now at Budker Institute of Nuclear Physics. The first and second phases of the project were commissioned recently. As with other particle accelerator facilities, the magnetic system of the FEL is an important part of the installation. It consists of many magnetic elements of different types: bending magnets, quadrupole lenses, and correctors. In total, the first and second stages contain about 80 and about 120 magnetic elements, correspondingly. The windings of all elements are fed from DC current power supplies designed and manufactured at BINP. These power supplies are in turn controlled by analog-to-digital and digital-to-analog converters (DACs and ADCs), which are connected to the control computer with the CAN-BUS interface [2]. The control system of the power supplies of the magnetic elements is described in this article.

POWER SUPPLY SYSTEM

As mentioned before, the magnetic system of the FEL consists of several types of magnetic elements. The elements differ in their influence on the electron beam and the amount of consumed DC current, which results in the use of power supplies of various types. The main characteristics of the power supplies applied are shown in Table 1. This table also presents the quantity of power supplies of different types for the first and second stages of the FEL. All other characteristics of the power supplies are presented in detail in [3]. One can see from Table 1 that the amount of low-power (3A and 10A) supplies used is large, while the number of high-power (300A, 1000A, and 2500A) supplies is very small. In addition, the low-power supplies are very small and do not require water cooling. Therefore it is very convenient to combine those numerous low-power supplies in one rack, their control joined in one multi-channel control device. At the same time, high-power supplies require a larger space and more parameters to measure and control, and hence an individual control device.

Table 1: Main Parameters of the Power Supplies

Imax, A	U max, V	Qty		Magnetic elements
		1st stage	2nd stage	
±3.0	12	90	125	Correctors
±10.0	20	54	70	Bending magnets, Quadrupole lenses
300	12	0	5	Bending magnets, Quadrupole lenses
1000	12	2	2	Bending magnets
2500	48	1	1	Undulator

CONTROL HARDWARE

As mentioned above, all control devices used in this system have the CAN-BUS interface and are connected to one CAN-line. Using the CAN standard for this system allows integrating the control of different power supplies, sometimes of different volume and considerably spaced. Depending on the details of this system operation, required accuracies, dimensions and consumed power, all power supplies could be divided into groups according to the method of their connection to the control hardware:

1) low-power supplies operated by multi-channel control devices and
2) high-power power supplies operated by precision single-channel control devices

For the first group, a **CANDAC16-CANADC40** pair is used. **CANDAC16** is a 16-channel digital-to-analog converter, and **CANADC40** is a 40-channel analog-to-digital converter. This pair is used to control a set of 16 power supplies. **CDAC20** devices are used for control of power supplies of the second group, which have higher accuracy in comparison with those of the first group, but one device can control only one power supply.

Table 2: Parameters of the Control Devices.

Parameter	Candac16	Canadc40	Cdac20
DAC resolution	16 bits	-	21 bits
DAC accuracy	0.05%	-	0.005%
DAC channels	16	-	1
ADC resolution	-	23 bits	23 bits
ADC accuracy	-	0.03%	0.003%
ADC channels	-	40	5

Scale (input/output)	10 V	10 V	10 V
Qty of devices used in the 1st stage	10	10	3
Qty of devices used in the 2nd stage	24	24	7
Qty of devices used in the 3rd stage	24	24	12

All the above control devices are developed and manufactured at BINP [4]. Table 2 presents the main characteristics of all the devices as well as the quantity of devices applied in the 1st, 2nd and 3rd stages of the FEL.

Figure 1 shows the arrangement of the power supplies and control devices and their connection with the CAN-BUS.

The low-power supplies are grouped in sections, 16 power supplies in one section. Each rack contains up to 3 sections. Each section is controlled by a **CANDAC16-CANADC40** pair.

The way of connection of high-power supplies to their controllers depends on the size of the power supply and presence of additional electronics.

All above controllers are connected to a single CAN line, which is connected to the control IBM PC. It should also be noted that all control devices can operate both in the single-channel mode and the multi-channel one. This ability allows one to organize single-channel measurement of the output current of power supply "on demand", without interrupting the usual measurement cycle for the output currents of other power supplies.

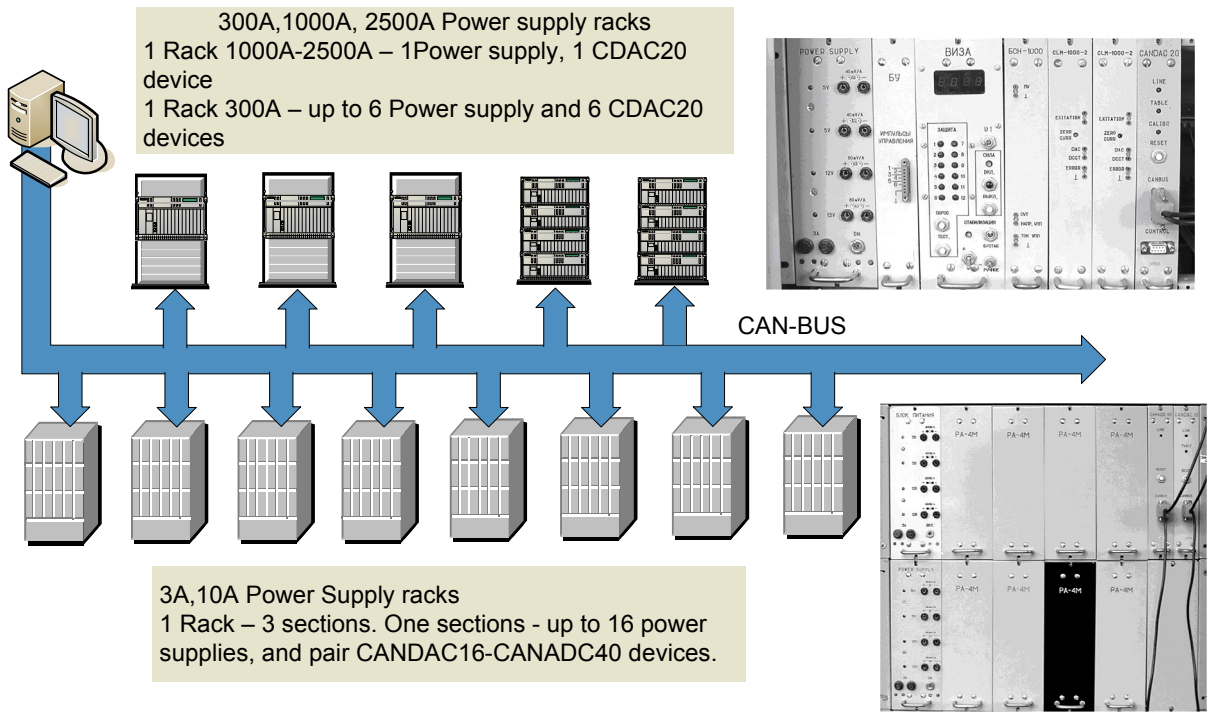

Figure 1: Arrangement of the power supplies and their connection to the CAN-BUS.

CONTROL SOFTWARE

The software controlling the operation of all the power supplies is implemented in one application. The main features of the program are as follows:

1) an advanced user interface, allowing full control of the power supply operation;

2) remote control of all the power supplies using the Epics Channel Access Server, i.e., one can set and check the currents of the magnetic elements from any other computer in this local network;

3) demagnetization of all magnetic elements of the system via applying current of an alternate polarity to an element and amplitude damping from the maximum source current to zero;

4) the possibility of saving/loading the currents of all or an arbitrary set of the power supplies;

5) a set of tools for diagnostics of the power supply operation: real-time verification of the output current and measurement of ripples in an automatic mode;

6) similar operation in all FEL configurations: the 1st, 2nd and 3rd stages.

The main window of the control software is presented in Fig.2. The power supplies and their states are shown in lines, containing the name of a magnetic element fed by this power supply and its current at this moment. The color of line and its content reflects the actual state of the power supply.

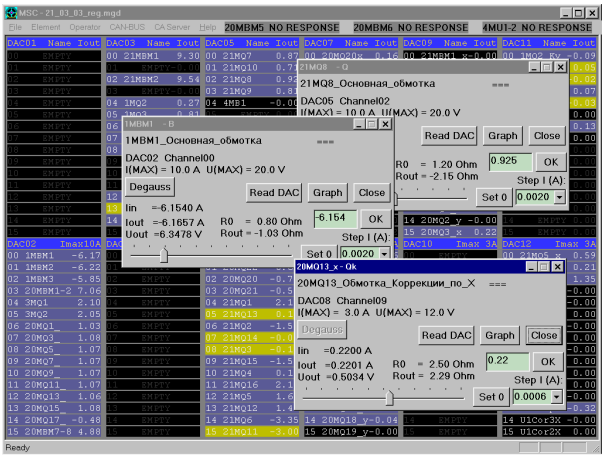

Figure 2: Main window of the control software.

Since the number of magnetic elements is very large, it is very difficult to find a particular element in this list. There is a mnemonic scheme of the entire FEL facility with magnetic elements that simplifies search for a required element. The scheme is shown in Fig.3.

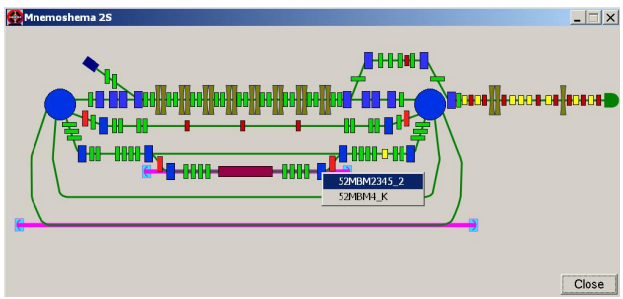

Figure 3: Mnemonic scheme of the FEL magnetic system.

To change current in a required element, the user has to open an individual dialog window, clicking on the corresponding element in the mnemonic scheme or the corresponding colored line in the main window.

As mentioned above, the control application also has some tools for diagnostics of the regularity of the power supply operation. One of them is the real-time comparison of current set for a power supply and a measured current value. If the difference exceeds a certain limit, the line in the main window that corresponds to this power supply is marked yellow (warning) or red (alarm). The program also watches the time stability of current set for a power supply. If the current changes in time by a value exceeding a certain limit, this power supply will be marked with color too.

Another diagnostic tool for the power supplies is a the control of ripples of output current with frequencies of up to 500 Hz. To implement this, the test program runs a cycle of single-channel measurements on all ADC channels, measuring the output currents of all the power supplies. Processing of one power supply includes construction of a measurement array of a required length and mathematical treatment of the data, i.e. finding the average current, maximum deviation and root-mean-square deviation of the current. Results are displayed in a separate window, shown in Fig. 4. The values of maximum deviation and root-mean-square deviation of current are presented graphically with vertical bars. The entire array of measurements is also displayed. The ripples, if any, can be detected by the magnitude of the color bars and analyzed in the graph of the array of measured values.

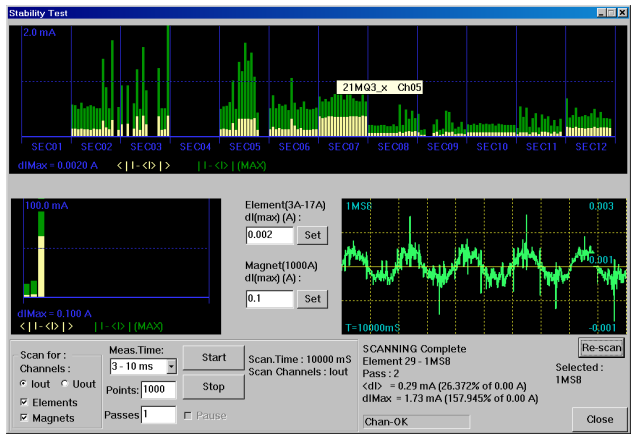

Figure 4: Window of the test of the power supply ripples.

In addition, for the purpose of remote control of the power supplies, the EPICS portable channel access server is built in the control application. Each power supply is presented with 3 process variables (PVs) on this server: a PV for the specified current, a PV for the measured current, and a PV for the measured voltage of the power supply.

CONCLUSION

The control system of the magnet power supplies has been operating for 8 years, demonstrating high stability and convenience of use. The diagnostic tools allow full control of the regularity of the power supply operation. The built-in EPICS channel access server allows integrating the control software to the EPICS-based control system.

THE MRF TIMING SYSTEM. THE COMPLETE CONTROL SOFTWARE INTEGRATION IN TANGO

J. Moldes, D. Beltrán, D. Fernández, J. Jamroz, J. Klora, O. Matilla, R. Suñé
CELLS, Cerdanyola del Vallès, Barcelona, Spain

Abstract

Alba [1] is a synchrotron light source under installation located nearby Barcelona. This 3 GeV third generation light source is planned to deliver the first X-rays beam to the users in 2012. The linac was commissioned in 2008, the booster in 2010/2011 and the Storage Ring in 2011. The seven beamlines included in the "Phase One" are being commissioned at the end of 2011.

The timing system is mainly used to synchronously distribute signals to all the equipments of the machine that need them. It is built on top of the MRF [2] timing solution. It is a fast digital, point to point, event based system. The system basically works by sending event codes from one event generation source (synchronized with RF/4 frequency) through a fast, tree structured, bidirectional fibre optics cabling network to many event receivers (about 100), which react to these event codes in different ways, amongst which the most commonly used is to generate a pulse (which characteristics are configurable) in one of its outputs. This pulse is connected to the hardware equipment that physically needs it. There are currently 418 output signals connected to different equipments. In other words, timing provides the "synch" in the synchrotron, keeping synchronized all the key systems (power supplies, RF and diagnostics).

The receivers are also capable of sending event codes up to the event generator when they detect activity in one of their two inputs. The generator can then redistribute this event again in downwards direction to all the receivers. This feature has been used to implement the Fast Interlock system [3]. There are currently 49 interlock signals connected to the system.

Logging of events with globally distributed timestamps is available in the receivers. This feature is specially useful (coordinated with Fast Interlock system) to easily and quickly determine the cause of a sudden beam loss.

The event generator is also capable of distributing up to 8 arbitrary digital signals using another feature called Distributed Bus (DBus).

In combination with other systems, timing will also be the key for getting the desired filling pattern of the machine and for implementing the top-up feature.

LAYOUT

The layout of the system is detailed in Fig. 1. As pointed above, it is basically a tree structured fibre optics network, starting from the event generator (EVG from now on) fanned out by the fanout/concentrators (fanouts from now on) and ending in the event receivers (EVR[s] from now on). This downwards path is the one mainly used. The EVG sends event codes to the EVRs, which react to them mainly by generating a pulse in any of its outputs.

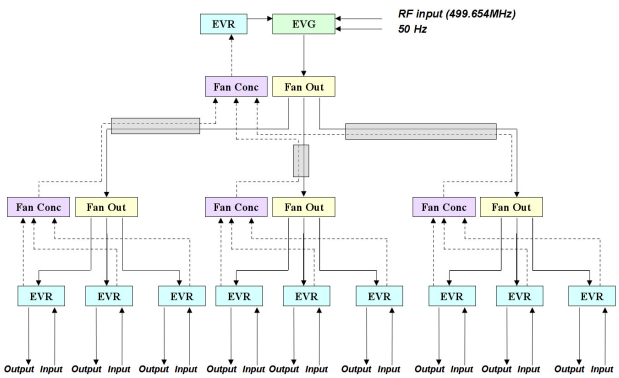

Figure 1: Layout of the Timing System.

However, the communication can also be done in upwards direction, starting from any of the EVRs sending an event up to the EVG. The later can then propagate downwards the event to all the EVRs. This is the core of the Fast Interlock system [3].

THE HARDWARE

Hardware was provided by different companies.

The core of the system, formed by the EVG, EVRs and fanouts, was supplied by MRF [2]. The EVG is the 230 model and almost all the EVRs are also 230 model. In addition to these, a few units of EVRTG300 have been acquired for special purposes, which we will see later.

It was decided to host the EVG and EVRs in cPCI machines, due to their robustness and reliability. Hence, the EVG and EVRs (model 230) were supplied in cPCI 3U form. The 3U cPCI chassis cPCIS-2632 and CPUs cPCI-3840 were supplied by Adlink [4].

The fanouts come in 6U cPCI form. Adlink chassis cPCIS-6418U and cPCIS-6130R were selected to host these cards. Fanouts control is much simpler than EVG and EVRs and hence it is not necessary to use a CPU to manage them. They provide an ethernet connection and an API based on UDP that is enough to control them.

The EVRTG300 units are also 6U cPCI form and were mounted in cPCI-6130R chassis with a cPCI-6965 CPU.

The fibre optics cables were supplied by R&M [5].

In the next section we will have a more detailed view of the main hardware components (EVG, EVRs and fanouts) and their main capabilities. Thought extensive, it is not a

complete description of these devices. See [2] for full information.

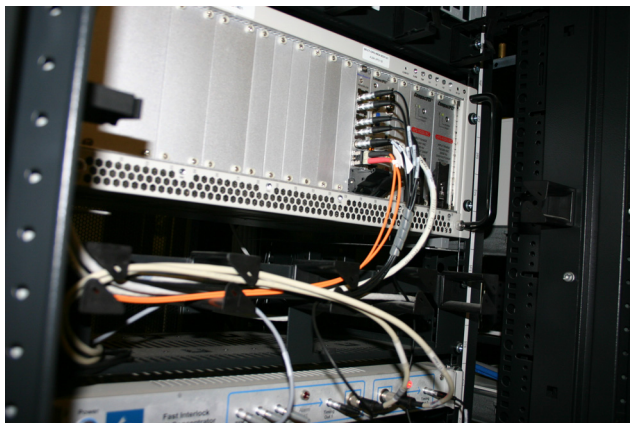

Figure 2: cPCI chassis with CPU and 1 EVR.

Figure 2 shows an example of use of the system. We can see a cPCI chassis with a CPU and an EVR. The four outputs of this EVR are used in this case to provide timing to 8 BPM units. We can also see two inputs coming from a Fast Interlock concentrator [3], in this case coming from any of the 8 BPM units in case the beam orbit gets out of limits. The two orange Rx/Tx fibre optics cables are also visible in the figure.

Event Generator

The EVG is responsible for creating and sending out the events to the EVRs.

Events are sent out by the EVG as event frames (words), which consist of an eight bit event code and an eight bit distributed bus data byte. The maximum event transfer rate is derived from the external RF/4 clock. The optical event stream transmitted by the EVG is phase locked to the clock reference.

There are several ways of generating the events:

- Trigger events. A single event is fired by an internal configurable counter.
- Sequence events. This is the feature used in our case. The sequence is a table like structure, with pairs timestamp - event, so the users can define exactly the time to wait until the next event is sent. The sequence itself is triggered by an internal configurable counter. Receivers can be grouped by subsystem to react only to some events. This way, users can fire different events that trigger only a given subsystem, without affecting the rest.
- software events: any event can manually be sent on user request.
- events received from the upstream EVRs (used for the Fast Interlock System).

In addition to events the EVG enables the distribution of eight simultaneous signals sampled with the event clock rate. This feature is called distributed bus. Distributed bus signals may be provided externally or generated on-board by programmable counters.

Event Receivers

EVRs decode timing events and signals from the optical event stream transmitted by the EVG.

The EVRs lock to the phase event clock of the EVG and are thus phase locked to the RF reference.

The EVRs basically convert the data got from the EVG to hardware outputs. Every info packet got from the EVG is 16 bits long, and is divided into two parts:

- Event code (8 bits).
- DBus bits (8 bits). Any output of the receiver can be configured to follow any of these bits. When the value of this bit is 1, the output is set to high, and it is set to low when the value is 0. This means that we can reproduce up to 8 arbitrary digital signals in any part of the machine at clock frequency resolution.

Two mapping RAMs (only one can be active at a time) are provided in order to configure how the EVR will react when receiving a given event. This RAM contains a table like structure in which event codes are associated to different actions, amongst which the most common ones are:

- Trigger a pulse in a given output. The delay since the event is got is configurable, as well as the width. Both width/delay can be set in 8 nano seconds steps.
- Set a given output to high. A delay is configurable.
- Reset a given output to low. A delay is configurable.
- Log the event. Events can be stored with globally distributed timestamps into a log memory.
- Forward the event downstream.

Two external hardware inputs are provided to be able to take an external pulse to generate an internal event. This event can also be transmitted in upwards direction to the the master EVR and from this to the EVG for distributing it downwards to all the EVRs. This is the core of the Fast Interlock system [3]: any interlock signal connected to any receiver can be distributed to the whole machine in 4.2 micro seconds.

EVRTG300 units add to the above a special feature. A fine grain delay of 10 pico seconds steps can be set in any of its outputs. This will be used for being able to inject any bucket of electrons in any position of the storage ring. It will also be used for the kicker magnets delay fine tuning and for providing timing to the streak camera.

Fanouts

These devices are mainly hardware devices and have few configurable settings. They have a dual function:

- The 8-way fan-out receives the optical event signal through a fibre connected to the uplink RX port. This signal is fanned out to all eight downstream ports.
- The concentrator receives signals from up to eight EVRs or downstream concentrators and forwards the signals upstream.

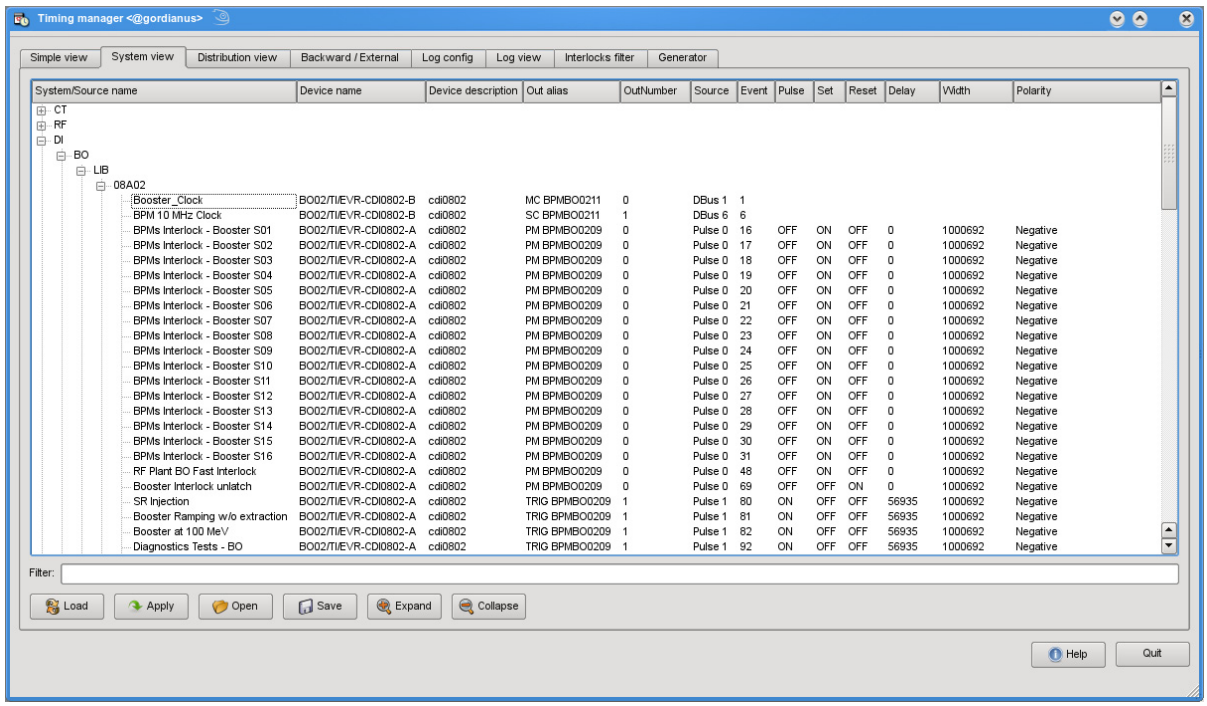

Figure 3: Timing manager GUI, the main users interface with timing system.

THE SOFTWARE

The software for controlling the system was developed from the lowest level up to the highest user GUIs level. In the middle we had to develop the core of the system: the tango device servers in order to integrate all the components into tango [6].

Drivers and API

Linux device drivers for the EVG and the EVRs had to be developed. Drivers for kernel 2.6 were developed by R. Suñé and J. Pietarinen from MRF [2].

In addition to this, a binding for python has been developed in order to use the manufacturer's API, which is written in C++. Swig [7] has been used for this purpose.

Tango Device Servers for EVG, EVR and Fanouts

Tango device servers have been developed to control all the features of the EVG, EVRs (both 230 and 300 models) and fanouts. These device servers have been written in python, using the above mentioned *pythonized* API and the python binding for Tango: PyTango [6]. They allow to control all the features of a single unit. In addition to this, the tango device server allows to permanently store in Tango database the configuration of a given unit and reload it when the device server is started. This permits the permanent storage of the configuration of the whole timing system.

Tango Device Servers for Configuring and Monitoring the System

In order to be able to control all the units in a centralized and convenient way, the TimingManager device server was developed. This device allows to set/retrieve the configuration of all the EVRs using a simple XML format and also configure/retrieve the logs.

A TimingMonitor device server was developed for monitoring the system health. This device is continuously monitoring the status of the EVG, EVRs and fanouts to find any problem that may occur.

THE GRAPHICAL USER INTERFACES

EVG and EVR Expert GUI

Expert GUIs for the EVG and EVRs (both models included) were developed. These GUIs communicate respectively with the EVG and EVR tango device servers in order to set/retrieve all the settings of the unit. These GUIs are meant to be used by expert users only.

Timing Manager GUI

This GUI is the users main interaction point with the system. Fig. 3 shows this application. This GUI runs of top the TimingManager device server.

Users provided the initial configuration of the system in a spreadsheet, basically specifying for each output of each receiver which event or events would trigger that output and also the configuration of the pulse/set/reset to be triggered. For each receiver they also provided a tag, which was used for splitting it and building the tree structure shown in Fig. 3, hence allowing users to group EVRs by subsystem and easily locate any output.

The first three tabs, show basically the same information but sorted in different ways. As shown in the figure, every line shows the output information, formed by

the tree node (including event name), the EVR tango device name, a user editable description for that EVR, a user editable alias of the output, the output number, the source for the output (DBus number or event code), pulse/set/reset (exclusive), pulse delay and width (the later no applicable for set/reset) and polarity. Delay, width and polarity are user editable.

The difference between "Simple view" and "System view" is that the former shows only one line per output (different events can trigger the same output), while the later displays the same line as many times as events trigger it. "Distribution view" show the same information as the "System view", but in this case the tree is built from the event code down to the EVRs, hence allowing users to know which outputs of which EVRs are triggered by a given event.

"Backward/External" allows the configuration of the backward events, used by the Fast Interlock system [3].

"Log config/Log view" allows the configuration of the logging of events in any EVR and retrieving/inspecting the contents of the logs of all the EVRs.

"Interlocks filter" allows to enable/disable forwarding of a given event in the main top EVR of the system (the one on the top in Fig. 1). This is useful for preventing a given interlock to be propagated downstream.

"Generator" tab allows users to enable/disable the EVG sequencer and editing it's contents.

The open/save buttons allow users to load/save the configuration of the whole timing system.

Timing Monitor GUI

This GUI is built on top of the TimingMonitor device server, which is continuously monitoring the system and warns about any problem it detects. A snapshot of the GUI can be seen in Fig. 4.

Figure 4: Timing monitor GUI.

The aspects that are monitored:

- EVR violation. All the EVRs can detect a problem in the fibre optics link it receives.
- Direct heartbeat. A heartbeat event is periodically sent by the EVG. A time out alarm is set by any EVR if it doesn't receive that event for a predefined time.
- Reverse heartbeat. Every EVR is instructed to send a heartbeat periodically up to the main EVR.
- EVR Alive. It checks the tango state of every EVR device server.
- Fanouts. It checks the status of the fanouts.

CONCLUSION

The development of the control of ALBA timing system has been quite a big effort. It has proved to be a very useful tool for commissioning, during which the fine tune of the timing of any of the key elements of the machine was possible with simply a two click operation. The save/open feature allowed the saving/restoring of any configuration of the whole timing system with a 3 click process. The permanent storage of all the settings in tango database allows a transparent recover after a system shutdown (i.e. for maintenance): all the settings are automatically restored on power up.

The timestamped logging feature also proved to be a valuable tool for commissioning, allowing to easily and quickly find the root of the problem when beam was suddenly lost.

The Fast Interlock system [3] has also proved to be the fastest system for interlocking the whole machine.

The control system has provided the users a very simple tool which abstract them from the big complexity of the underlying system.

As part of the tango project [6], all the code and its dependencies are free software and can be freely and easily reused by the community with relatively little effort.

CONTRIBUTIONS

Many people has contributed to this project. Specially remarkable is the outstanding effort in developing a big part of the software by R. Suñé before leaving Alba. Thanks to J. Pietarinen [2] for his excellent support for the devices he provided. Many thanks to O. Matilla and D. Beltrán, who were the main designers of the system itself. Thanks also to J. Jamroz for hardware support.

STATUS OF ALMA SOFTWARE

T.C. Shen, J. Ibsen, R. Olguin, R. Soto, ALMA, Santiago, Chile

Abstract

The Atacama Large Millimeter /submillimeter Array (ALMA) will be a unique research instrument composed of at least 66 reconfigurable high-precision antennas, located at the Chajnantor plain in the Chilean Andes at an elevation of 5000 m. Each antenna contains instruments capable of receiving radio signals from 31.3 GHz up to 950 GHz. These signals are correlated inside a Correlator and the spectral data are finally saved into the Archive system together with the observation metadata. This paper describes the progress in the deployment of the ALMA software, with emphasis on the control software, which is built on top of the ALMA Common Software (ACS), a CORBA based middleware framework. In order to support and maintain the installed software, it is essential to have a mechanism to align and distribute the same version of software packages across all systems. This is achieved rigorously with weekly based regression tests and strict configuration control. A build farm to provide continuous integration and testing in simulation has been established as well. Given the large amount of antennas, it is imperative to have also a monitoring system to allow trend analysis of each component in order to trigger preventive maintenance activities. A challenge for which we are preparing this year consists in testing the whole ALMA software performing complete end-to-end operation, from proposal submission to data distribution to the ALMA Regional Centers. The experience gained during deployment, testing and operation support will be presented.

OVERVIEW

ALMA software [1] is a very complex system, developed by distributed teams across three continents. Every six months a new release takes place and once it is deployed at the Operation Support Facility (OSF), it is responsibility of the ALMA Department of Computing (ADC) in Chile [2] to take care of its maintenance. ALMA has scheduled for Sep 30th of 2011 to start operating in the so called "Early Science" mode. In preparation for such a big challenge, ADC has designed and implemented an entire support system around the core ALMA software in order to successfully achieve this important milestone.

In the following sections a description of the software verification and maintenance processes, together with the required infrastructure will be described.

ALMA OPERATION SUPPORT PROCESSES

Array Element Configuration

ALMA is composed of 66 antennas, photonics references, Correlators and control computers which need to be configured according to the science verification purpose. Due to ALMA still being under the construction phase, reconfiguration of the system is an activity run on daily basis.

ALMA observation software saves the system configuration variables in the Telescope Monitor and Configuration Database (TMCDB), a relational database built on top of Oracle R11. Each array element has an average of 1500 variables, in addition to the deployment information. It is unviable to do it manually, (as the first antenna has been done) and a template based approach has been developed, allowing to configure a new element in matters of minutes.

As soon as the number of antennas increases, it is hard to keep track of their status and deployment configuration. Several web based applications were developed to depict live deployment information.

Regression Tests

A new version of ALMA software is released every six months. The new release is deployed and verified on site together by North American, European and local software staffs. After the acceptance, the local software group is responsible for supporting and maintaining this new production release, together with guarantying the system's stability. Modifications in this operational release are driven either by software patches for bugs fixing or by adding new functionalities. A new weekly iteration of this release is deployed at the control computers in order to consolidate these modifications and a battery of regression tests is executed to guarantee system reliability.

The regression tests suite aims to verify the software functionality through the execution of the same tasks performed during science operations. Additionally, tests focused on the validation of the ALMA software deployment and are also executed.

The pass criteria applied for every test is simple and atomic. The idea is to avoid misinterpretation about the test completeness. For example:

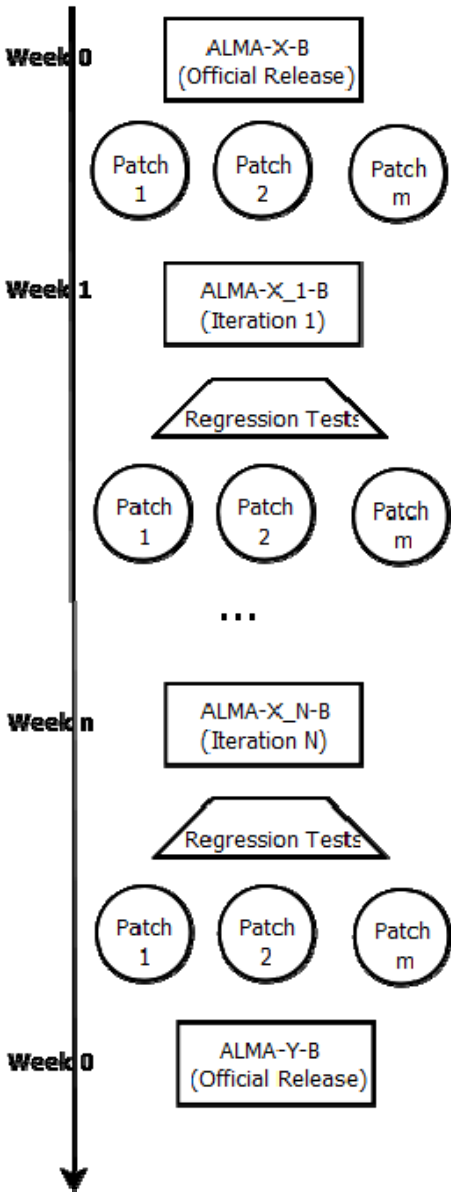

Figure 1: Regression Tests Workflow.

Description: *Create a manual array*
Test Execution: *Within the OMC, open the "Create Array" plugin. Create a manual array by selecting all available antennas, a Photonic Reference and a Correlator. (if another array was created, dispose of it previously)*
Pass Criteria: *A manual array has been created and all available antennas are assigned to it.*

Despite most of the tests being executed and the results verified manually, ADC has been working on the automation of the tests suite. A framework based on pyUnit has been implemented in order to allow the automatic execution of the tests and the verification of the passing criteria. The "Auto Regression Tests" framework takes the information from an XML configuration file, in which a test is defined. Every tests suit consists in: (1) cleanly initializing the system, (2) allocating the required resources, such as: the selection of available antennas, photonic references, and Correlators, (3) executing the specified tests, (4) releasing allocated resources and shutdown of the whole system, and (5) reporting the results. In cases, when the test suite collects scientific data, the data must be analyzed in order to verify the coherence of the observations. To cover this area, validation routines have been developed in collaboration with the science team, which in turn basically reduce the raw data by means of tools such as TPOINT, CASA, etc. Upon the event when a Boolean result is not easy to achieve visual inspections will be required.

In conclusion, regression tests provided an objective and reliable way to verify the system functionalities after the deployment of new software iteration. However, this process requires working continuously on the upgrade of test suites as scientific scripts evolve and new features being introduced in the system.

In the near future, the goal of this is to execute the same tests suite across all ALMA software development centres in order to verify and validate a fresh release.

End-To-End Tests

Aside from the weekly regression tests, which focus on the observation software, a complementary verification is done in parallel, which focuses on the end to end aspect. These tests start with (1) proposal submission phase, (2) proposal selection phase, (3) proposal scheduling and observation phase, (4) observation data replication from OSF to Santiago data centre and (5) data replication to ALMA regional centres.

Software Patch Workflow

The workflow starts with (1) bug detection and reporting, (2) debug and troubleshooting process, (3) patch preparation. (4) Control Board approval, (5) testing, (6) deployment in the operational environment, (7) and consolidation for the next software iteration.

ALMA uses JIRA as the main tickets reporting system. Together with JIRA, several custom data mining tools were developed to produce periodically statistics about downtime and the ticket associated. Other key process indicators are also generated in order to provide sufficient information to allocate efficiently the available resources.

Scalability Tests

These tests aim to validate in advance the capacity of ALMA software to deal with all the array elements when it is completed. Tests are focused on (1) diskless real-time machines booting process, (2) CORBA notification services, (3) TMCDB access during software start up, (4) monitoring system, and (6) dynamic resource allocation during observation.

Currently ALMA has 20 antennas integrated into the array. Scalability showed that the current software scales correctly up to 30 antennas, but problems start to occur

when the 40 antennas boundary is crossed, which is the number of antennas expected at the end of 2012.

ALMA SOFTWARE SUPPORT INFRASTRUCTURE

In order to successfully and efficiently perform the aforementioned processes, several computing infrastructures are required. In the following sections key infrastructures are depicted.

Virtualization

The virtualization technology has been the foundation to provide computing power in ALMA. Starting from 2009, several virtualization technologies have been tested, such as XEN, KVM. But the final choice was VMware ESX. The final decision was based on features of administration tools rather than a performance reason [3]. Virtualization is being used in several areas, not only in the testing and development environments but also in production environment, i.e: build farms, non real-time production servers (web, database, applications). Virtualization provides the flexibility and efficiency to deploy servers to accomplish dynamic ALMA operation needs.

After two years of production experience with virtualization, a new step has been taken: consolidate the hardware infrastructure in blade system. Two chassis with Dell M610 blade servers were procured and put into operation.

ALMA Software Build Farm

ALMA software is a four Gb. of source code which takes around ten hours to compile. Currently they are four different active versions being used. In order to support these four branches of software the concept of build farm had been introduced two years ago. Now there are six nodes configured to generate daily builds. Failures found during compilation are notified by email and remedy action is taken immediately.

Hudson has been chosen to be the main continuous integration tool. In addition of it, several custom scripts were created to generate change logs automatically from the code version control repository. These logs are useful for telling the nature of the modifications in the production branches and unsolicited modifications are investigated and reverted if there is no valid justification from the developers. Developers also benefit from the daily build in order to simplify the bug fixing and verification activities. Now having daily builds reduce the time to prepare a working environment to test patches.

Standard Test Environment

ALMA software was designed to run on top of a set of servers which are grouped as the minimum unit under the concept of Standard Test Environment (STE). [3]. In order to fulfil the requirement to commission and verify antennas in parallel, multiple STE were deployed at the OSF. Each STE has the same network subnets and addresses definition in order to guaranty the same environment to run ALMA software. To cope with the repetitive network addresses, virtual routing and forwarding (VRF) technology has been deployed and overlapping IP addresses can be used without conflicting with each other.

STE is also the platform being used to develop and test ALMA software under simulation. There is a total of 13 STEs across ALMA. Some of them are as simple as a set of three servers, and in the other hand, the one dedicated to control the array will eventually have up to 135 servers in it.

To administrate the configuration, installation and maintenance of such an amount of computers, an approach based on Puppet has been tested and validated. It is expected to be the official tool at the OSF soon. This tool will allow for an agile and efficient way to manage dynamic infrastructure.

Monitoring System

To operate the ALMA Observatory, aside from the previously mentioned array elements, it is likely important to make reference of the operation support infrastructure, such as, computer rooms, network devices, operation building facilities, power generators, etc. To guarantee a smooth and successful observation, both areas must work co-ordinately. By having two sites, the ALMA Operation Site (AOS) located at 5000 m., and the OSF located at 3000m over sea level, make the maintenance activities even more complex. In this context, the M&C (Monitor & Control) system plays a fundamental role on defining the live heath status of components of the entire Observatory. The design of the M&C must ensure a proper information distribution to users and specialists for decision making and must also provide alarms to trigger corrective actions, if required.

When ALMA reaches its full capacity with 66 elements in the array, there will be around 1 million monitor variables, which will generate information at a data rate of 40 GB/day. It's really a big challenge to maintain this M&C system, not only in the operational aspects but also solving the storage problem of such amount of data throughout time.

The ALMA Observatory M&C system is a three tiers software: (a) data acquisition layer, (b) data distribution and processing layer and (c) data display layer. Due to historical reason, the array M&C system was designed without considering the support infrastructure's M&C system and vice-versa. The first one is based on ACS BACI properties [1] and the second one is provided by an industrial solution provider. Both systems have components in the aforementioned three layers and works perfectly in the context where they were conceived. But unfortunately neither of both is flexible enough to interoperate with other. Therefore in order to integrate both systems, a third framework is introduced: Zenoss, this framework has several features which make it very suitable for this purpose: template oriented design for

quick devices configuration, vast range of monitoring protocols, powerful events engine, build-in notification services, Zope based core written in python and round robin database as main storage, etc.

By using Zenoss, as the interfaces which access both systems, it is possible to retrieve and consolidate information. A prototype implementation has demonstrated that is feasible to provide consolidated graphical users interfaces or dashboards according to user profiles, such as: array operators, facilities managers, instrumentations and software teams. Additionally, Zenoss provides a very convenient way to storage time series data by using round robin database (RRD). This automatically drops old data and eliminates additional maintenance work. Historical data saved in RRD allows providing trend analysis, characterize overall system behaviour and predict potential failures.

Currently array M&C and the implementation based on Zenoss are still under development. For infrastructure, the off the self system is currently installed and is being fine tuned.

CONCLUSION

ALMA has started to operate in "Early Science" mode since September 30th of 2011. And the preparation achieved in terms of software verification, has proven to be a key factor to achieve this huge milestone for the ALMA communities.

Testing infrastructure and simulation are important resources which are usually relegated to the least priority of astronomical projects. In our experience, these must be considered as part of the original design.

Regression tests, performed systematically, are essential to guaranty stable software and detect bugs introduced involuntarily by developers.

A prototype and semi-production monitoring system has been implemented and deployed. This tool produced relevant information for the maintenance department in order to schedule preventive and corrective activities.

Projects with a big number of elements must validate the scalability feature of its software design and implementation. We suggest that the earlier the better.

ALMA is the first astronomical project constructed and operated under industrial standards, therefore, it is important to include good practices from the industrial area.

ACKNOLEGMENT

The authors wish to acknowledge the contribution and cooperation of ALMA CIPT and especially to ALMA ADC Software Group, which works are reflected in this paper.

THE IMPLEMENTATION OF THE SPIRAL2 INJECTOR CONTROL SYSTEM

F. Gougnaud*, J.F. Denis, J.F. Gournay, Y. Lussignol, P. Mattei, R. Touzery, CEA-IRFU / Saclay, France

Abstract

The EPICS framework was chosen for the Spiral2 project control system [1] in 2007. Four institutes are involved in the command control: Ganil (Caen), IPHC (Strasbourg) and IRFU (Saclay) and LPSC (Grenoble), the IRFU institute being in charge of the Injector controls. This injector includes two ECR sources (one for deuterons and one for A/q=3 ions) with their associated low-energy beam transport lines (LEBTs). The deuteron source is developed at Saclay and the A/q=3 ion source at Grenoble. Both lines will merge before injecting beam in a RFQ cavity for pre acceleration. This paper presents the control system for both injector beam lines with their diagnostics (Faraday cups, ACCT/DCCT, profilers, emittance-meters) and slits. This control relies on COTS VME boards and an EPICS software platform. Modbus/TCP protocol is also used with industrial devices like power supplies and Siemens PLCs. The Injector graphical user interface is based on EDM while the port to CSS BOY is under evaluation; also high level applications are developed in Java. This paper also emphasizes the EPICS development for new industrial VME boards ADAS ICV108/178 with a sampling rate ranging from 100 K Samples/s to 1.2 M Samples/s. This new software is used for the beam intensity measurement by diagnostics and the acquisition of sources.

THE SPIRAL2 INJECTOR

The Spiral2 Injector Control System is globally managed by CEA-IRFU.

The Spiral2 Injector is composed of 2 beam lines, one (LEBT1) developed at LPSC Laboratory, Grenoble and the other (LEBT2) at the IRFU Institute, CEA Saclay. Both lines will merge at the end of 2012, before injecting the beam into an RFQ cavity.

The beam line in Grenoble was commissioned in 2009. It is controlled by Epics but the Ion source has been controlled by a Labview PC for a long time. The goal is to control all the equipment from Epics. So, a replacement by Epics is in progress. All Labview interfaced parameters are implemented in a soft Epics database that uses the Labview-CA gateway.

On the LEBT2 at Saclay, the control system is being finalized. On 15th September, 2011, a 7mA proton beam was conducted to the end of the line, with 85% transmission, i.e. 5.5 mA at the end of the line.

The Saclay proton/deuteron source control system has been done in Epics. It controls several pieces of equipment: a magnetron, a pulse generator, an impedance adaptor, an extracting beam High Voltage power supply, a gas injector controller and a repelling electrode power supply.

SPIRAL2 EPICS PLATFORM

Software Platform

The goal of this platform is to install all the PCs and VMEs of the Spiral2 accelerator in the same manner. This platform provides a software development model that each Epics developer has to use to build the different Spiral2 applications. In this way, we have got a homogeneous control system on the whole Injector. At present this platform uses Epics 3.14.12, VxWorks 6.8 and Linux RHEL5 on PCs. Modbus/TCP protocol is used to interface PLCs, power supplies and some beam diagnostics such as beam profilers.

A Subversion (SVN) repository is available at Ganil to manage the software development [2].

Hardware Platform

The Spiral2 Injector standard VME is composed of an Emerson Motorola MVME5500 and NEXEYA ADAS VME boards [3]:

- ICV150 with 32 ADCs, 16 bit resolution and 30K Samples/s
- ICV714 with 16 DACs, 12bit resolution
- ICV196 including 96 binary input/output channels
- ICV108, a controller board with a 4 M bytes RAM
- ICV178 with 8 ΣΔ ADCs, 16 bit resolution, 1.2 M Samples/s.

IRFU has developed the Epics drivers for these boards. Three VMEs control the LEBTs Epics control system and one specific VME is dedicated to controlling emittance-meters.

POWER SUPPLIES

This software was designed by Ganil [4]. All the power supplies are of Hazemayer type and are current power supplies. They are connected to the Ethernet field bus and are accessed via the Modbus/TCP protocol. The Epics driver, provided by Mark Rivers from the University of Chicago, is used to control these power supplies. At present on the line LEBT1, in Grenoble, there are 15 power supplies (1 Sextupole, 1 dipole, 1 solenoid, 2 triplets of quadrupoles, 6 steerers). On the LEBT2 line, at

Saclay, there are 20 power supplies (2 dipoles, 2 solenoids, 7 quadrupoles, 9 steerers).

"FAST ACQUISITION" AND FARADAY CUPS, ACCTS AND DCCTS

The beam intensity of the Spiral2 Injector is measured in 2 ways. One way is beam destructive measurements with five Faraday cups [5] in the Low Energy Beamline Transfer, and beam non-destructive measurements by one ACCT and two DCCTs in the Low and Middle Energy Beamline Transfers. The beam runs in pulsed or CW mode.

At the beginning of the project, we developed a beam current measurement based on the VME ICV150 board (30 K Samples/s) but this acquisition wasn't precise enough with pulsed beam and couldn't display the shape of the pulse.

The principle for this acquisition is to synchronize the acquisition at the pulse start [6], to buffer the digitalised data, to display the pulse shape and to calculate an average value for each pulse.

The solution relies on the VME ADAS ICV108 and ICV178. These boards are described more precisely in [7]. Both boards communicate via the VME I/O P2 lines. The ICV108 includes an external trigger and a RAM buffer of 4 M bytes. This acquisition uses the RAM in "Flip/Flop" mode.

At present the Epics driver permits the use of two boards ICV178, i.e. 16 channels. To optimize running with regard to the 4 M bytes RAM and the sampling frequency, only the channels, corresponding to the equipment used for the intensity measurement, are sampled. The operator chooses the configuration on the display and the driver changes the configuration "on-fly".

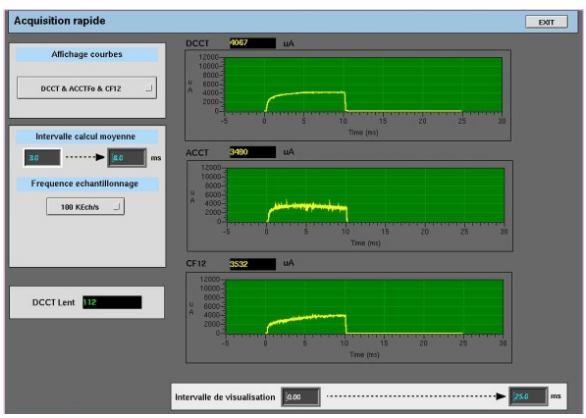

Figure 1: EDM display with one ACCT, one DCCT and one Faraday Cup.

This driver provides compressed (averaged) data, if necessary, to the applications, to speed up the visualization of graphs. The configuration "compressed" or "not compressed" is specified in the Epics database.

On the display (fig. 1), the operator has to give the interval of visualization and the interval dedicated to the average.

This fast acquisition is also used by Hall probes and emittance-meters.

BEAM PROFILERS

Profilers permit to measure and visualize the beam dynamics. In the LEBTs, these profilers are secondary emission profilers. This equipment and its control are completely managed by Ganil. The communication with the electronics is based on Modbus/TCP. An Epics IOC application is used to configure measurements and to calculate average and offset subtraction. A JAVA server task [8] provides supplementary calculations to those carried out by the IOC application to the client applications. These new calculations are supplied as Epics Process Variables that are surface, signals sum, gravity center, standard deviations and widths. They are done for an area of a horizontal or vertical profile according to the requested configuration.

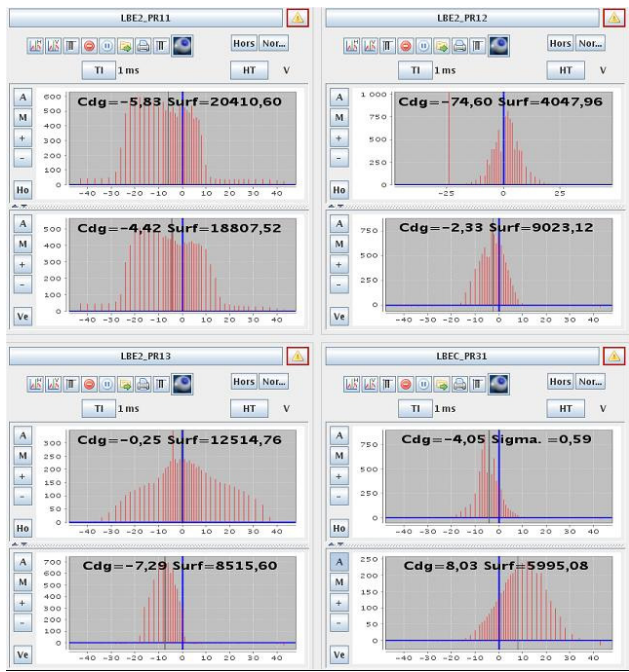

Figure 2: Beam profiles display, JAVA application using XAL framework.

EMITTANCE-METERS

The transversal emittance is the cartography of the transverse angles of the particules of the beam. It provides information on the divergent or convergent aspect of the beam and is used to measure the focal of the beam to study the propagation of the particles and to tune the beam.

At present a pair of emittance-meters is installed on each of the 2 beam lines. These emittance-meters and their control are carried out by IPHC Institute in Strasbourg.

A specific VME controls the 3 pairs of emittance-meters of the Injector. It is composed of the standard

VME boards: one ICV150 to acquire temperatures, a pair of ICV108/178 dedicated to faster acquisition, one ICV196 binary input /output board used for selection and configurations for hardware, one ICV714 to generate voltage ramps and besides an ISEG board to generate high voltage and a brushless motor board OMS MaxV to move the actuator of the measurement head.

When the emittance measurement is requested, the program gets the user parameters and waits for validation of the PLC process. Then, the program applies the maximum voltages requested to the plates of the measurement head and comes in a loop made up of 3 sequences: positioning, voltage ramp setting and current reading. For each position during the move, the voltages on the plates are decreased until an electrical field equal to zero is reached. Then, the field is inversed and the sequence position, voltage ramp, current reading is repeated. For every step of the voltage ramp, the current created in the Faraday cup is recorded.

For the human operator interface, there are 3 levels of EDM displays: data catching, configuration and debugging. A 3D visualisation is necessary. Therefore, a Java HMI was developed and recently a CSS BOY display has been created (fig. 3).

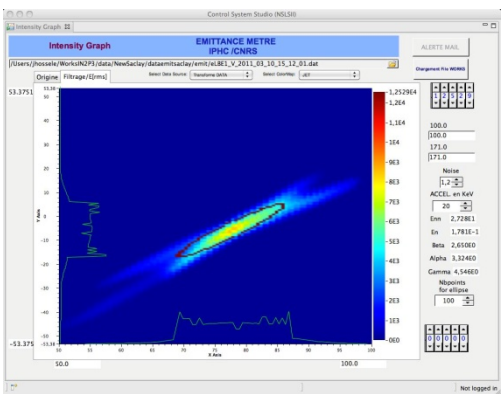

Figure 3: Emittance-meter HMI in BOY.

SLITS

The objective of the slits is to remove a part of the halo surrounding the heart of the beam. A pair of thermocouples is integrated into each slit to monitor the temperature that is controlled by an Epics IOC through the ICV150 ADC board. The control of the motor driver is based on Modbus /TCP in the same way as the power supplies.

PLCS FOR INTERLOCK AND VACUUM

Siemens S7 PLCs were chosen by the Spiral2 project. Interlock PLCs provide safety of the pieces of equipment on the beam line at Saclay and at Grenoble. When these 2 lines join at Ganil, only one PLC will ensure the two beam lines interlock. Vacuum is controlled by one PLC at Saclay and one PLC at Grenoble. The PLCs are connected to Ethernet and supervised by a Muscade station and with Epics EDM HMIs. Muscade is a proprietary CEA SCADA whose objectives are supervision, diagnostics and distant maintenance. It runs on Windows PCs.

Protocol Modbus/TCP is used for the communication between Epics IOCs and PLCs.

The PLC can run in “local” or “distant” mode. This mode is read by Epics. When the PLC is in local mode, it memorizes the commands for Epics.

HOST-BASED PERL APPLICATIONS

A set of applications running on the Linux OPIs have been developed based on Linux. They are written in Perl and they use the cap5 Channel Access library provided by Andrew Johnson from ANL. A wrapper above cap5 has been designed to hide the details of the implementation. The interest of this approach has several aspects compared to a similar development made in SNL on the VME target for example: intrinsic power of the Perl language, ease of developments of applications based on an interpreted language, availability of a simple debugger. The performance is not a real issue for the type of applications aimed (fast acquisition buffers of several hundred of bytes can be read at 10Hz, processed and stored on disk without any problem).

The following applications have been developed: correlation of parameters for beam tuning, ECR sources beam spectrum acquisition, a thumbwheel generic tool for parameters fine setting and several utilities functions.

ACKNOWLEDGEMENTS

Special thanks have to be addressed to Jean-Michel Joubert for the cabling and Arnaud Roger, Tom Joannem and Cedric Peron (IRFU/SIS) for their development on PLCs.

Abstract

CTA (Cherenkov Telescope Array) is an initiative to build the next generation ground-based γ-ray instrument. The CTA array will allow studies in the very-high-energy domain in the range from a few tens of GeV to more than a hundred TeV, extending the existing energy coverage and increasing by a factor 10 the sensitivity compared to current installations, while enhancing other aspects like angular and energy resolution. These goals require the use of at least three different sizes of telescopes. CTA will comprise two arrays (one in the Northern hemisphere and one in the Southern hemisphere) for full sky coverage and will be operated as an open observatory.

A prototype for the Medium Size Telescope (MST) type is under development and will be deployed in Berlin by the end of 2011. The MST prototype will consist of the mechanical structure, drive system and active mirror control. Four CCD cameras and a weather station will allow the measurement of the performance of the instrument. The ALMA Common Software (ACS) distributed control framework has been chosen for the implementation of the control system of the prototype. In the present approach, the interface to some of the hardware devices is achieved by using the OPC Unified Architecture (OPC UA). A code-generation framework (ACSCG) has been designed for ACS modeling. In this contribution the progress in the design and implementation of the control system for the CTA MST prototype is described.

THE CTA ARRAY

Very High Energy (VHE, energies > 100 GeV) γ-rays are produced in both galactic and extra-galactic objects like pulsars, pulsar wind nebulae, supernova remnants and active galactic nuclei. In recent years, thanks to the success of Imaging Atmospheric Cherenkov Telescope (IACT) instruments like H.E.S.S., MAGIC and VERITAS the field has experimented a major boost, with more than 100 sources already established as VHE emitters. The technique used by IACTs is based on the fact that VHE γ-rays interacting with the atmosphere produce electromagnetic showers, whose charged components generate Cherenkov light in a narrow cone. An IACT consists of a reflector that concentrates the Cherenkov light in a camera composed of sensitive photo-detectors, usually photomultiplier tubes (PMTs). The measured light distribution in the camera of each recorded event allows to reconstruct the arriving direction, energy and type of primary particle which caused the particle shower. In systems of telescopes the individual images can be combined to provide stereoscopic information, enhancing the resolution and background suppression.

The goals of CTA require the use of more than 50 telescopes of three different sizes. A few large size telescopes (LST), with dishes of 23 m diameter, are designed to achieve a good sensitivity in the energy domain from a few tens of GeV up to about a hundred GeV. In order to achieve a good sensitivity at energies above a few TeV a large number of small-size telescopes (SSTs) will be deployed. For the core energies a considerable number of MSTs, of 10-12 m diameter each, will be used.

CTA will comprise two arrays (one in the Northern hemisphere and one in the Southern hemisphere) for full sky coverage and will be operated as an open observatory. By extrapolating the distribution of known VHE objects, it is expected that CTA will detect around 1000 new objects. Details on the science motivation, design concepts and expected performance of CTA are provided in [1].

THE MEDIUM SIZE TELESCOPE PROTOTYPE

A prototype of one of the design concepts of the MST is under development [2] and will be deployed in Berlin (Adlershof Campus) by the end of 2011 or the beginning of 2012. The main goal of this prototype is to test a design of the mechanical structure and drive system, but other prototype instruments like the Active Mirror Control (AMC) units will also be tested. No PMT camera will be installed on this prototype.

The MST prototype has a Davies-Cotton type reflector with diameter of 12 m, and a focal length of 16 m. The design of the telescope structure can be seen in Fig 1. Besides the mechanical structure, the prototype will consist of a dummy camera of 2.5 tons (to resemble the effect of the real PMT camera that will be in the final MST units), the drive system, active mirror control, four Charged-Coupled Device (CCD) cameras and a Weather Station (WS), plus some additional sensors designed to test the behavior of the structure. Time stamps of events will be obtained either via the Network Time Protocol (NTP) or a Global Position System (GPS) receiver. Emulated data sources will be

* see http://www.cta-observatory.org/ for full author and affiliation list

employed to resemble a realistic operation scenario of the prototype. Details of individual devices are provided later in this document. A full size prototype of one-quarter section of the dish has been constructed. The purpose of this prototype is to test the fabrication methods, costs, and to provide a *test bench* for mounting the mirrors.

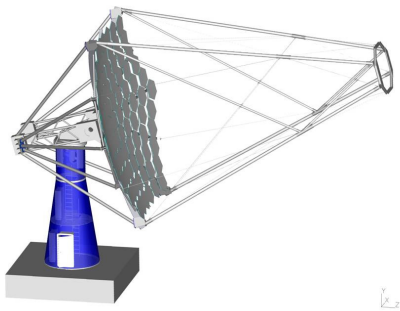

Figure 1: View of the design of the mechanical structure of the MST, composed by a quadrupod (camera support), a dish structure, a counterweight, the "head" (connecting the dish and the tower), and the tower with the foundation.

CONTROL SOFTWARE FOR THE MST PROTOTYPE

The MST prototype is the first opportunity inside the CTA consortium to integrate a considerable number of hardware devices and to exercise the control software. Each individual CTA telescope will be a complex system that has to operate in synchronization with the other telescopes and auxiliary devices. The CTA consortium will allow flexible observation scheduling by including the possibility of fragmenting the arrays in several sub-arrays.

Typically, a control software for an installation of the size of CTA should allow a flexible way of accessing the hardware. Engineers would require expert modes of accessing the devices for testing purposes, while astronomers will require a framework to operate an array composed of several dozens of telescopes, typically without being familiar with the complex details of the devices. The mentioned constrains fit naturally in the distributed computing paradigm, and in particular in the Object Management Group (OMG) CORBA specification, the most successful distributed object platform.

The ALMA Control Software [3] is a framework on top of the operating system that provides a complete environment and structures at the base of application software developments. ACS is meant to be a general system, based on CORBA and the C++, Java and Python languages. The core of ACS is based on a distributed component model, with ACS components implemented as CORBA objects in any of the supported programming languages. ACS Components are the base for high level control entities and for the implementation of devices such as a telescope drive system. ACS provides common CORBA-based services such as logging, error and alarm management, configuration database and lifecycle management, while hiding the complexities of CORBA programming. ACS is developed by the ALMA project and the main responsibility for the subsystem is at European Southern Observatory (ESO).

Due to the similar level of complexity and requirements of ALMA and CTA, ACS is currently being considered by the CTA consortium members to serve as the control middleware. It has been decided to use ACS for controlling the MST prototype because it will provide an excellent platform to test the behavior of ACS with CTA hardware, while serving as a learning platform.

CTA will be composed of a large number of devices that in principle might use very different hardware interfaces (serial lines, Ethernet, CAN-bus, etc.) Large experiments benefit by setting a standard way of accessing the hardware, either by defining a standard hardware interface like in ALMA (CAN-Bus) or by setting a lower level software layer like, for example, OPen Connectivity-Unified Architecture (OPC UA). For CTA it is in general preferred to select devices using Ethernet interfaces, and to set OPC UA servers for those devices requiring a different interface. Some preliminary studies and prototype developments have been taken place at LAPP[1] [4] in order to illustrate the implementation of the OPC UA standard. In particular these implementations concerned some electronic components and related functionalities devoted to the online security control of the H.E.S.S. 2 [5] camera. These studies have confirmed the homogeneous way of connecting electronic boards via the low software layer of the OPC UA and the standard way of integration in the ACS environment (by means of the DevIO mechanism in the ACS terminology). A similar approach has been adopted for the MST prototype: A standard way of deploying OPC UA servers has been investigated, and an ACS access method (a Java DevIO class) is under development with the support of the ACS development team from ESO, complementing the existing C++ DevIO for OPC UA [6].

The ACS components for the control of the MST prototype are being designed using an Unified Modeling Language (UML) based code generator. The UML models are created using MagicDraw UML Standard v.17.0 on Linux, which is used to create the input required by the ACS code generation framework (ACSCG) [7]. From the UML model, ACSCG generates the interface definition language (IDL), configuration database files and Java implementation skeleton. The Java skeleton can be extended to provide an OPC UA client functionality, in order to communicate with an OPC UA server. In order to model the OPC UA servers the OPC UA Java Software Development Kit (SDK) v. 1.1.0-975 is being used.

A software development, integration and test environment has been deployed in DESY, composed by two Dell PowerEdge R510 machines with 12 fast disks, 12 Nehalem

[1]Laboratoire d'Annecy-le-Vieux de Physique de Particules-http://lapp.in2p3.fr/

Cores, 36 GB RAM memory and 10 Gbit Ethernet interface using the same layer level 2 switch. A RPM based installation of 64 bit ACS releases has been developed. An archive for permanent storage of the prototype measurements is under development, which will also serve as a *test bench* for the CTA archive. The DESY data-center will be connected to the MST prototype site, ca. 15 km away, by a broadband connection.

PROTOTYPE INSTRUMENTATION

Drive System

The drive system of the MST prototype is designed to resemble the expected operation modes of the CTA telescopes, allowing pointing of the prototype to any position and to track any astronomical object. The telescope will operate with two motors, one for azimuth and one for elevation. As a first instance to test the drive concept, a test stand was build to evaluate the design (see Fig 2).

The drive system of the prototype is composed, at a lower level, of the control of 6 drives (2 for azimuth and 6 for elevation) communicating via a *Bosch-Rexrot* programmable logic controller (PLC). The PLC operates VxWorks and hosts an OPC server. Earlier versions of the PLC firmware provided an OPC Data Access (DA) specification server, with plans to be replaced with an OPC UA server. As OPC DA is only working for Microsoft Windows environments, and for CTA Linux based software will be used, a solution was developed to deal with the limitation imposed by OPC DA, consisting in the deployment of an OPC DA to OPC UA wrapper software as interface to Linux software (*MatrikonOPC UA Wrapper for COM OPC Servers*). At the time of writing this document, the *Bosch-Rexroth* PLC firmware was upgraded to provide an OPC UA server that was under evaluation. The next step will be to create an ACS component for the drive system which will use the OPC Java DevIO class mentioned before.

After the ACS component has been tested and deployed, the drive control software will be used to interface the drive test stand. When the prototype is deployed a first phase of commissioning will take place, when the control software will be used to tune the system by using fiducial marks. In a later phase, the control system will be used to track astronomical objects and to check the pointing with the CCD cameras.

The CCD Cameras

The most important tool to check different aspects of the MST prototype will be a set of four CCD cameras. One goal of these CCD cameras will be to test the structural design of the prototype, and, with the help of a WS, the effect of the temperature, wind and other environmental factors. Additionally, the CCDs will be used to perform mirror adjustments, and will allow for measurements of the optical point spread function. The output images will be stored in the standard astronomical FITS data format. Excluding the emulated data sources, the CCD cameras will be the source of the largest fraction of data volume of the prototype.

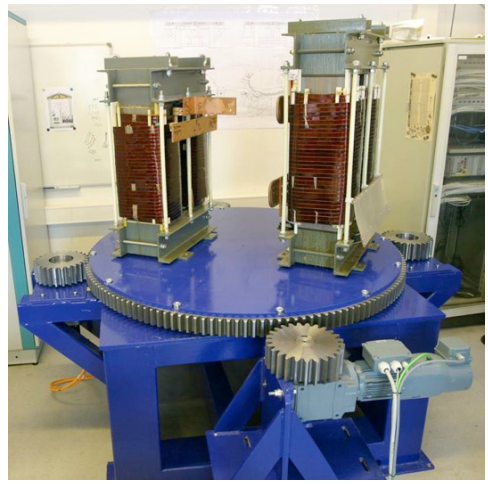

Figure 2: The MST prototype test stand.

The chosen CCD camera model is a Prosilica GC 1350 which has a resolution of 1.4 Mpix (1360 x 1024) and a pixel size of 4.65 μm. These CCD cameras are interfaced via GigE Vision interface (allowing up to 1000 Mbit/s on Gbit Ethernet). The Allied Vision Technologies (AVT) PvAPI SDK allows to control and capture images from GigE Vision CCD cameras in a Linux environment. It is accessible by most programming languages such as C++ and Java (via JNI). The evaluation of this software has been positive, working correctly in the test machines in both implementation languages. The next step involves the implementation of an ACS component to operate the CCDs.

The Active Mirror Control

The design of the CTA telescopes makes use of tessellated reflector composed of individual mirror facets (see [8] for details). Each individual mirror facet will be attached to an AMC unit which has the functionality of allowing a perfect mirror alignment. This will allow online re-alignments of the LSTs reflectors, where the deformation caused by the weigh of the telescope will cause misalignments depending on the telescope elevation. It will also allow, for larger timescales, to perform re-alignments in MSTs and SSTs. The dish of the MST prototype will be completely covered by a mixture of real and dummy mirrors. Several AMC units of two different AMC design concepts will be installed in the prototype (see [1] for details in the design concepts). One type of unit communicates via XBee radio modules, creating a Wireless Personal Area Network (WPAN) that is accessed via a XBee receiver connected to a PC via USB or RS-232 serial interface. The other type of unit is interfaced via CAN-Bus, accessed via a Ethernet-CAN-Bus gateway.

From the MST prototype control design point of view the idea is to unify the higher level interfacing to both unit types. This can be achieved with a higher lever ACS com-

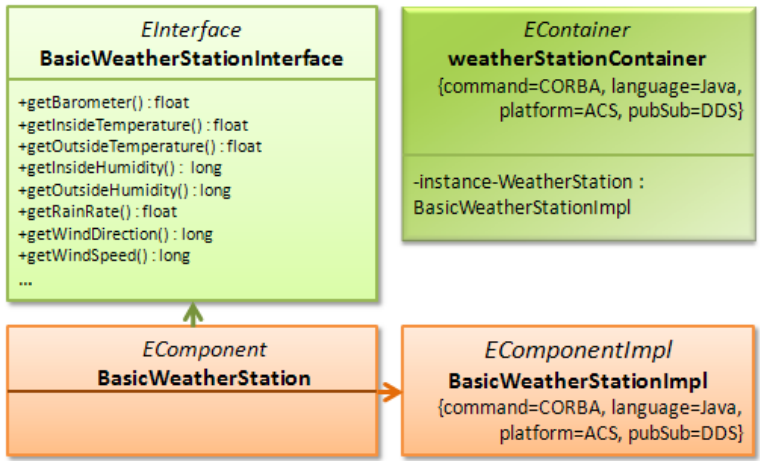

Figure 3: UML class diagram of an ACS component for the weather station for the prototype, modeled with MagicDraw.

ponent which sends the common instructions for the alignment procedures, acting as client for the lower level ACS components that will be different for each of the two AMC concepts.

For the AMC units using the XBee communication a preliminary version of a Python ACS component which uses the *Pyserial* library has been developed. Real movement of the AMC actuators was tested by using the ACS *Object Explorer* generic client. The movement of an AMC unit installed in the "quarter-dish" has also been recently tested.

The Weather Station

A WS has been acquired and will be installed nearby the MST prototype to continuously monitor the weather parameters, allowing correlation with the behavior of the structure of the MST with changes in the environmental status like, for example, the wind speed or temperature.

The chosen WS model is a *Davis Vantage VUE*. This WS is able to measure the wind speed and direction, as well as other quantities with the required accuracy and measurement rate. The instrument is composed of an outdoor unit communicating via a WPAN with an indoor unit, including a data-logger with some limited internal storage capacity and equipped with a RS-232 serial interface.

The WS is the least complex component of the MST prototype and for that reason has been the first device used to experiment with previously mentioned software development procedures. Starting from the lower level, an OPC UA server has been implemented with the OPC UA Java SDK which uses the RXTX library to communicate with the WS *datalogger* via the serial line. In a higher lever, a Java ACS component has been implemented using the UML-model based code generation framework (see Fig. 3), and tested with the ACS *object explorer*.

CONCLUSIONS

The MST prototype will act as the first realistic *test bench* for the control software for the CTA array. Equipped with complex systems like the drive system and AMC, the MST prototype will allow the evaluation of the ACS control middleware while the hardware design concepts are being tested, providing input and expertise to the software control developers of CTA. The use of tools like the UML code generation and the OPC UA servers, already tested the relatively easy system of the WS, will eventually allow the setting of a efficient framework for the CTA array control while optimize the productivity.

ACKNOWLEDGMENTS

We thank the excellent support of ACS experts from ESO Garching, in particular G. Chiozzi and H. Sommer. We want to acknowledge the help of A. Lopatin by teaching us ACS. We gratefully acknowledge support from the agencies and organisations listed in this page: http://www.ctaobservatory.org/?q=node/22

CONTROLS SYSTEM DEVELOPMENTS FOR THE ERL FACILITY*

James Jamilkowski#, Zeynep Altinbas, David Mark Gassner, Lawrence T. Hoff, Prerana Kankiya, Dmitry Kayran, Toby Allen Miller, Robert H. Olsen, Brian Sheehy, Wencan Xu,
BNL, Upton, Long Island, New York

Abstract

The BNL Energy Recovery LINAC (ERL) is a high beam current, superconducting RF electron accelerator that is being commissioned to serve as a research and development prototype for a RHIC facility upgrade for electron-ion collision (eRHIC). Key components of the machine include a laser, photocathode, and 5-cell superconducting RF cavity operating at a frequency of 703 MHz. Starting with a foundation based on existing ADO software running on Linux servers and on the VME/VxWorks platforms developed for RHIC, we are developing a controls system that incorporates a wide range of hardware I/O interfaces that are needed for machine R&D. Details of the system layout, specifications, and user interfaces are provided.

INTRODUCTION

Since the BNL ERL was conceived as an R&D testbed for a future electron-Relativistic Heavy Ion Collider (eRHIC) upgrade, many elements of the necessary Controls System have been designed and implemented. A 20 MeV superconducting 5-cell 703 MHz RF cavity that will accelerate and decelerate the electron beam passed its first milestone of the Cold Emission Test (CET) within the last two years [1]. Aside from further 5-cell RF measurements, Fundamental Power Coupler standing-wave RF conditioning was completed this summer for the superconducting gun FPCs at a power up to 125 kW (CW) and 250 kW (pulsed).

In 2012, the first ERL Gun-to-5-cell-cavity (G5) test where ~1 μA electron beam will be generated using the gun/laser assembly and accelerated in a simplified, linear version of the ERL layout is expected to begin. The ultimate goal for the completed facility will be to verify efficient energy recovery while running CW reaching electron beam average currents on the order of ~0.5 Amperes [2].

INFRASTRUCTURE

The ERL has benefited from a long legacy of hardware and software development at the Collider-Accelerator Department (C-AD). Where possible, we have leveraged existing interfaces that utilize our C++ Accelerator Device Object (ADO) based software running on both VME/VxWorks and LINUX Red Hat machines. Services such as archiving, logging, and storage are shared between ERL and the other parts of the C-AD complex, though they reside on a separate Ethernet subnet as shown in Fig. 1.

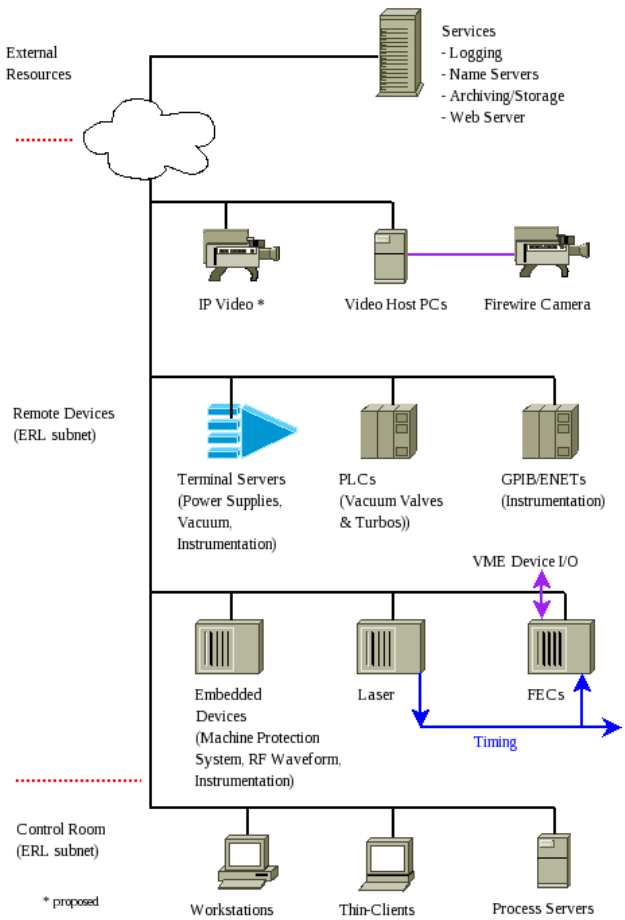

Figure 1: ERL Controls network-based architecture, including existing and proposed elements.

For legacy reasons, the Cryogenic System resides on an independent controls system and subnet of the Ethernet network. For the purposes of ERL, selected Cryogenic data is transferred to the Controls System at a rate of 0.2 Hz. Details of the Machine Protection System (MPS) can be found in ref. [3].

INSTRUMENTATION

Beam Position Monitors

ERL beam position monitor signals will be processed using Libera Brilliance Single Pass modules from Instrumentation Technologies. Five of these devices will be used during the first ERL beam tests scheduled for early 2012.

*Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the US Department of Energy.
#jpj@bnl.gov

The Libera device includes an ARM processor, on which an embedded configuration of LINUX runs, providing access to the functionality of the device via a vendor-supplied library and collection of kernel modules. The vendor also provides a cross-development environment, to allow software development on a conventional desktop LINUX system.

Using the cross-development environment and the library's programming interface, software was developed which runs on the Libera's processor, providing remote access to the device's functionality. The code base is identical to the code base used for VME or other embedded systems used in the facility. In this manner, each Libera device appears, from the control system perspective, to be just another network-attached embedded controller.

Each device will provide a TTL signal that will be used by the MPS to interlock when position readings stray from acceptable values.

Beam Loss Monitors

Four types of electron beam loss monitoring detectors are employed at the ERL: Photo-Multiplier Tubes (PMTs), Ion Chambers (IC), Heliax cables, and PIN Diodes.

The PMTs & ICs will provide current signals with respect to loss levels that will be processed by custom VME based amplifier/integrator/detector cards currently used in the RHIC beam loss system. These cards provide analog signals to standard VME ADC modules for monitoring and a TTL output for beam loss interlock level to the MPS. CAEN 24 channel HV VME controller modules will supply individually controllable references for the PMT high-voltage bias allowing each of the 14 PMTs to be "tuned" for a desired response. The 8 ICs are biased collectively by a manually adjusted supply.

The 16 Heliax cable detectors each have their own pair of bias supply and integrator module, identical to what is currently used for beam loss detection in the Alternating Gradient Synchrotron (AGS). Analog output loss data will be digitized using VME ADC modules, and control will be effected using a VME digital output module.

Eight Bergoz BLM PIN diode modules have been employed at the ERL using a SIS VME scaler module for data acquisition and a VME digital output module for calibration pulse control.

One TTL signal will be provided to the MPS that will indicate the status of the beam losses relative to a trip threshold.

Beam Profile Monitors and Cameras

A series of actuated profile monitors from Radiabeam Technologies will be used to gather information regarding the electron beam profile from light gathered from both YAG and Optical Transition Radiation (OTR) screens. Standard VME digital I/O modules will provide the insertion controls for each multi-position instrumentation package, and image capture will be performed using a setup that includes a LINUX host PC with a IEEE1394 Firewire interface to the attached camera. The image gathering and analysis software has been well-documented in ref. [4] using our custom ADO toolset.

To date, LINUX software Firewire support issues have prevented the active use of more than one camera per host PC through our standard software. As a potential alternative, we will evaluate a Gigabit Ethernet camera for use at the ERL. The feasibility of using low-cost, "lightweight", dedicated host PCs instead of the more expensive multi-role servers that have been previously used will be explored as well.

Multi-axis lens controller modules from Image Labs will be used to adjust the picture for each camera. LINUX ADO software provides remote access to the device through a serial terminal server for up to two cameras per unit.

A TTL insertion status signal from each profile monitor will provide an input with which to interlock the MPS under high average beam current conditions in order to prevent damage to the YAG flag screens.

Pepper Pot

Electron beam emittance measurements will be acquired and presented via a remote interface that is currently being designed. One possible implementation of the system would make use of existing PC-based data acquisition and would require further development of custom software that has been created to perform similar measurements for the Electron Beam Ion Source (EBIS) project. Actuator controls will make use of VME digital I/O modules.

Halo Scraper

Six scraper jaws will be used in the injection straight and zig-zag sections to remove the electron beam halo in support of measurements under limited average beam current conditions. Each jaw is actuated using stepper motor controllers interfaced with VME Front-End-Computers (FECs) that provide position control, position readings, and limit switch detection. The motion controller interface software was created for previous projects.

Signals derived from controller status relays are expected to provide the necessary MPS inputs in order to protect the scraper jaws from intercepting high average beam currents while running in a high intensity mode.

Faraday Cups

The halo scrapers will perform double-duty as Faraday Cup pick-ups. Three additional Faraday Cup beam dumps will be installed for the measurement of beam current during the initial G5 tests, progressing to six in the zig-zag portion of the G5 injection transport. VME analog modules will be used for the data acquisition to the Controls System through custom Faraday Cup amplifier cards installed in a Eurochassis. External triggering of the sampling will be performed using a VME delay module that was created for past projects.

Integrating Current Transformer

The Bergoz BCM-IHR ICT will monitor the performance of the accelerator and alert the MPS should the beam current exceed the maximum allowed for a given operational mode. Gain, calibration pulse parameters, and signal polarity control will be provided using VME digital output modules, and triggering of the integration will be executed using a VME trigger delay board.

Methods for transmitting the ICT statuses to the MPS are currently being reviewed.

Differential DC Current Transformer

A platform is in the planning stages that has the goal of providing beam current readings from matched Bergoz NPCT transformers in the injection and beam dump transport while comparing both signals with a reference generated by a current source. A loss of current between the two transformers over a desired threshold would trigger an input to the MPS as an indication of significant beam losses. The merits of two basic options are under review: PLC-based sampling with interlock outputs, or a Xilinx processor paired with ADC and digital output daughter cards. The latter platform has been used for an increasing number of RF [5] and Instrumentation projects at C-AD in recent years, each using the VxWorks OS. Additional VME trigger delay module channels are needed to gate the data acquisition.

LASER

The electron bunch is initiated at the photocathode in the superconducting gun by a 9.38 MHz laser. The laser is a mode-locked Nd:YVO_4 master-oscillator power amplifier of custom design (Lumera Laser GmbH), required to achieve the low repetition rate and phase-locking requirements. The frequency-doubled output will be further conditioned by transverse and longitudinal shaping techniques [6]. Basic controls provided by the manufacturer are accessed using an attached PC running the Windows XP operating system. Efforts to implement a remote interface for the laser on the Controls system have previously involved the creation of a C++ server process in Cygwin that allows for direct integration with our infrastructure over Ethernet. Increasing concerns over Cyber Security issues and the hardware limitations of the included PC may result in a change in control strategy. The primary alternative would be to create a remote ADO server running on a LINUX machine that would interact with the laser PC over a serial connection.

Laser beam transport steering and shaping is achieved using a series of Newport gimbal mirror assemblies that can be moved by piezo actuators interfaced with a Newport 8-axis motor controller module. LINUX software has been developed to remotely send commands and return readings from each device.

An autocorrelation measurement system is under development, which will utilize an externally triggered fast ADC VME module in order to sample light from a photodiode synchronously with the laser pulses. Software has been developed to control another Newport linear actuator, which will be adapted to gather the digitized beam signal in conjunction with the motion of the photodiode.

Since the laser clock will provide the master timing for other systems at the ERL, a method for synthesizing related timing signals is needed. To that end, a Stanford Research Systems DG645 Digital Delay Generator will be used. LINUX software has been created to provide remote I/O over Ethernet for the device.

RF

Low-Level RF control of the 5-cell cavity tuner was first achieved using an analog phase-locked loop (PLL). This included motion controller and ADC VME boards for the cavity tuning feedback control, and a digital I/O VME board for gain control. Such a system was used successfully in support of the CET, and for further cavity tests since then. This included microphonics measurements [1] gathered from a fast ADC VME module that samples the LLRF signals in addition to the RF incident, reflected, and transmitted power. Over the course of multiple cold tests of the cavity, it became apparent that we were experiencing frequent gaps in data gathering from the digitizer when the total number of clients using the data exceeded a relatively small number. This issue was eventually resolved by first lowering the sampling rate from 16384 Hz to 4096 Hz, and then by configuring a data reflection server that shifts the client load from the FEC to the server's host machine. Details of a digital replacement for the analog LLRF platform can be found in ref [5, 7].

Additional CW RF power measurements are performed by two meters from Boonton. Data is relayed to the Controls System over a GPIB interface and GPIB to Ethernet bridge to a LINUX server process. Since there is also a need for pulsed RF power measurements, there is a separate LINUX program that acquires pulsed measurements from another Boonton meter over Ethernet.

POWER SUPPLIES

ERL main and trim dipole, quad, and solenoid magnets will be operated using power supplies from four different manufacturers: IE Power, BiRa, Kepco, and Danfysik. The controls for the former two types will leverage existing hardware and software interfaces, including the BNL Power Supply Controller (PSC) and commercial analog I/O VME modules. The Kepco and Danfysik units make use of serial I/O, though they will be configured for RS232 and RS485 respectively. User interfaces are provided through separate LINUX processes that utilize the Ethernet network and a serial Terminal Server.

Software development has been completed for the Kepco power supplies, and efforts to configure the intermediate hardware for the Danfysik interface are underway.

USER INTERFACE

The foundation for ERL user interfaces is firmly rooted in the existing application paradigm at the BNL C-AD: basic device interaction is performed through the Parameter Editing Tool (PET), live data graphing is available through the General Purpose Monitor (GPM) application, and logged data can be plotted through the LogView application.

Being that the ERL is a much smaller facility than others at the C-AD, we chose not to implement an alarm system. Instead, facility users have expressed a desire for synoptic displays that would graphically highlight any abnormal conditions, and allow the user to quickly drill down to the necessary subsystem controls in order to address the cause. Limited testing has been performed using MEDM on LINUX. We are currently planning on creating control pages using MEDM for the G5 tests, though evaluations of alternative graphical process control systems will likely continue in parallel.

CONTROL SYSTEM FOR LINEAR INDUCTION ACCELERATOR LIA-2: THE STRUCTURE AND HARDWARE

G. Fatkin*, P.A. Bak, A.M. Batrakov, P.V. Logachev, A. Panov, A.V. Pavlenko, V.Ya. Sazansky
Budker Institute of Nuclear Physics, Novosibirsk

Abstract

Power Linear Induction Accelerator (LIA) for flash radiography is commissioned in Budker Institute of Nuclear Physics (BINP) in Novosibirsk. It is a facility producing pulsed electron beam with energy 2 MeV, current 1 kA and spot size less than 2 mm. Beam quality and reliability of facility are required for radiography experiments. Features and structure of distributed control system ensuring these demands are discussed. Control system hardware based on CompactPCI and PMC standards is embedded directly into power pulsed generators. CAN-BUS and Ethernet are used as interconnection protocols. Parameters and essential details for measuring equipment and control electronics produced in BINP and available COTS are presented. The first results of the control system commissioning, reliability and hardware vitality are discussed.

INTRODUCTION

Flash X-Ray radiography facilities are used for registration in hydrodynamic experiments. Linear Induction Accelerators (LIA's) are considered to be the most prominent source of electrons which are converted to gamma radiation [1]. The have because of their relatively low emittance, high currents(up to a few kA) and energy (up to tens MeV).

LIA-2 was originally designed as an injector for 20 MeV linear induction accelerator, but it can be used as an independent 2 MeV X-ray source for flash radiography with high space resolution. This machine has been built with the goal to keep the minimum possible emittace and therefore the minimum beam spot size on the target. The reliablity of the machine is of great importance. Basic parameters of LIA-2 are presented in Table 1.

Table 1: LIA-2 Basic Parameters

Parameter (Units)	Value
Maximum electron beam energy (MeV)	2.0
Maximum electron beam current (kA)	2.0
Number of pulses	2
Cathode heater DC power (kW)	2.5
Time interval between pulses (μ s)	2-10
Pulse duration, flat top $\pm 4\%$ (ns)	200
Maximum repetition rate (Hz)	0.1
Min. beam spot size FWHM on the target (mm)	1.5

* george.fatkin@gmail.com

Let us note, that there are only a few linear induction accelerators for flash radiography around the world. Well known facilities are: FXR (Livermore Laboratory, USA), AIRIX (PEM, France), DARHT (Los-Alamos, USA), DRAGON (China) [2], [3], [4], [5]. The control system of DARHT-2 is described in [6]. The approach that allows us to get the minimum possible emittance leads to a large amount of controlled devices (for comparison DARHT-2 has 74 induction cells for 20 MeV installation, we have 48 induction cells for 2 MeV).

INSTALLATION STRUCTURE

The accelerating stucture (see fig. 1) includes 1 MV, 2kA diode whith dispenser cathode and 1 MV accelerating section placed just after the diode exit. Both sections of high-voltage pulsed transformer include linear chain of 96 induction cells put on accelerating tube.

The voltage for supplying inductors is generated by 48 identical modulators: pulsed power devices composed of pulse forming network, high-voltage switch (thyratron), demagnetizing generator and control electronics. Output pulse voltage is 50 kV, duration – 300 ns, output current comes up to 5 kA. Each modulator feeds two induction cells.

Low-temperature dispenser thermo cathode is heated up by a special 70 A generator. Cathode heating current should be turned off at the moment of shot to ensure zero magnetic interferention. Four short focusing solenoids are powered by pulsed current generators which should be synchronized. Three dipole correctors are powered by direct current. Beam diagnostic system consists of two beam current transformers, capacitor-based pulsed voltage dividers, X-Y strip-line beam position monitor (BPM) and movable Faraday cup.

Normal operating cycle of LIA consists of two stages: slow and fast. During slow stage the elements of installation are prepared for fast operations: forming networks and demagnetizing generators are charged, thyratrons are preset, the states of various elements are checked. The duration of slow stage is 20-30 ms. If all elements of LIA are in normal condition, then the fast stage is initiated. This stage starts from the moment of inductor's demagnetizing and finishes with beam generation. Duration of this stage is about 150 μs. If any failures occur during this stage, interlock subsystem disables the experiment start.

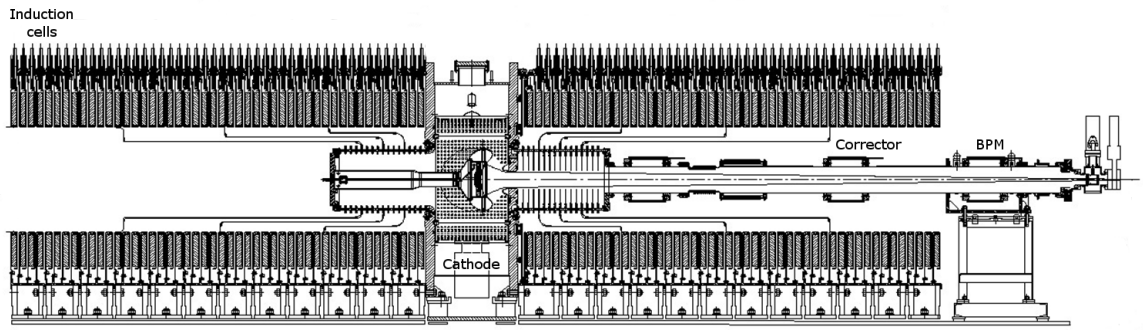

Figure 1: LIA accelerating structure.

CONTROL SYSTEM FEATURES

Let us formulate the features of control system of LIA. The hardware synchronization system is needed to provide trigger pulses to modulators during both stages of operation. The interlock system is an absolute necessity because of high experiment cost and preparation time. To ensure beam quality and to provide full information on installation performance more than 200 waveforms per shot should be recorded.

Planned time of operation of LIA is tens of years. Thus the control system must be based on modern widespread hardware standards and software.

Most of the controlled devices are high-voltage pulse generators. Special precautions should be taken to protect control electronics from high-voltage breakdowns. Electronics and transmission lines should also be protected against interference induced by high voltage pulses.

Control system must be scalable to allow adding induction cells. The most numerous control object is modulator. They are grouped in sections by 6 in each and linearly distributed along accelerator's length. It is convenient to have control elements structured accordingly.

Therefore we can formulate following features of the control system of LIA:

- Linearly structured
- Strict hardware synchronization
- Hardware interlock subsystem
- Adequate waveform recording subsystem
- High-power nature of the installation considered
- Based on modern widespread standards
- Scalable

STRUCTURE

The control system of LIA is functionally divided into four subsystems: pulsed power control subsystem, timing subsystem, waveform recording subsystem and interlock subsystem.

Pulsed power control subsystem is controlling all devices during slow phase of operation. This is mainly done by software using CAN-bus.

The timing subsystem generates and distributes trigger pulses to modulators and other devices. Each modulator needs 6 trigger pulses for proper operation. The delay of pulses initiating discharge should be individually adjusted for each thyratron with accuracy less than 10 ns. Other pulses may be set with accuracy about 100 ns. Altogether there are 288 timing channels.

The waveform recording subsystem provides information about installation state and beam quality. Flash radiography facilities are used to conduct very expensive experiments. To estimate the reliability of the installation, 96 "fast" signals (duration about 300-1000 ns) are recorded on each shot. Recorded data is stored and statistically analyzed. Overall accuracy around 1% for these signals is needed to ensure beam quality. In addition about one hundred technological signals are recorded and analyzed during the slow phase of operation.

The interlock subsystem prevents damage to the installation and prohibits experiment start if alarm signal from any of the devices is recieved. It has to be absolutely reliable.

The structure of the control system of injector is shown on fig. 2. High-voltage system for injector consists of 8 identical sections. Each section contains 6 modulators supplying 12 induction cells. Local controller performs all operations necessary for the functioning of section: modulator timing, waveform recording, interlock functionality, CAN-bus interaction. Local controller is 6U 8-slot CPCI crate installed directly at the modulators section rack. This is done to minimize cables length thus minimizing noise signals. Local controller is shown on fig. 3.

Six modulators are connected to common CAN bus, which is used for their setup and controls slow changing parameters. Trigger pulses for demagnetizing and thyratron preparation are received from central crate and split to all modulators using the F-16 splitter board. All other fast thyratron pulses are generated using digital delay line which is started by a trigger pulse from main controller.

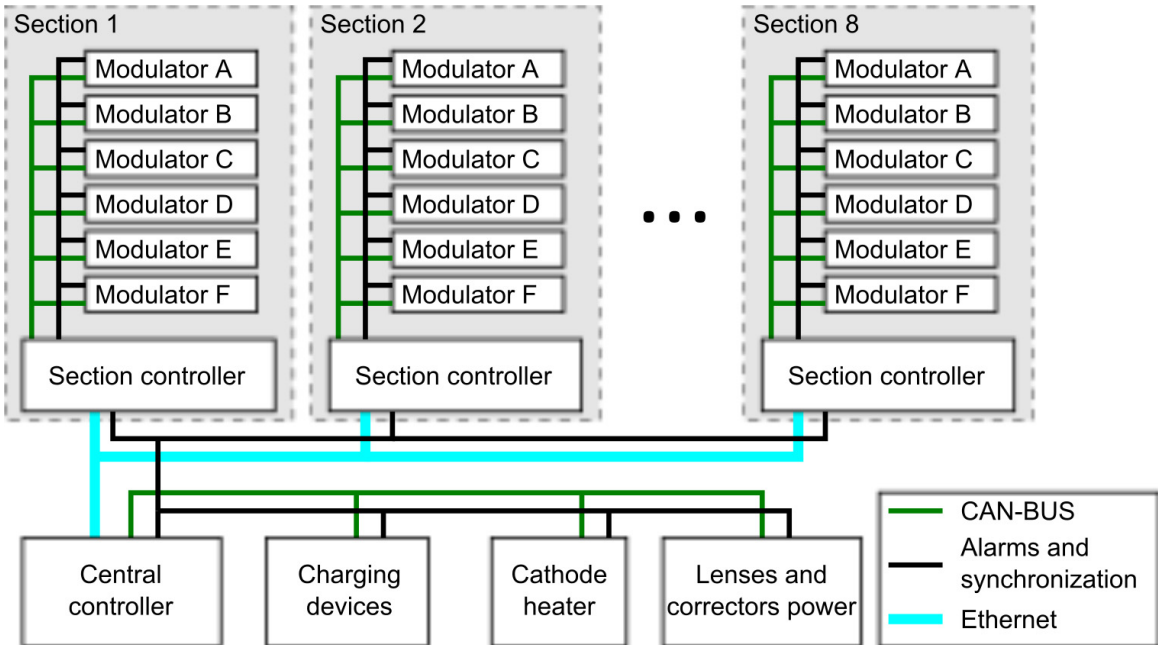

Figure 2: The structure of LIA control system.

Local controller also gathers alarms from all modulators and generates section alarm signal.

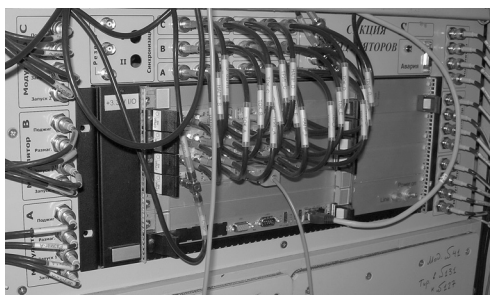

Figure 3: Local controller.

The central controller synchronizes and supervises local controllers operation. It controls charging devices, lenses, BPM and cathode heater via CAN-bus. It also gathers alarm signals from sections and raises general alarm in case of breakdown in any section. All controllers and operator's PC are interconnected using Ethernet.

The hardware synchronization of the installation is done using general following pulses: local controller starts, demagnetizing and thyrathron preparation signals, cathode heater turn off, lenses starts, experiment start. This pulses are transferred using coaxial lines.

Hardware

Common mezzanine card (PMC) and CompactPCI standards were chosen as a hardware basis for control system. CompactPCI was chosen as a widespread industrial standard compatible with x86 architecture. It allows to use widespread operating systems (Windows, Linux) and benefits from wide range of COTS automation equipment. PMC cards allow interchanging host system (CompactPCI, VME, PCI,...), thus electronics made for the LIA control system could be used for other tasks. CompactPCI rear input output (RIO) modules are used to effectively cope with huge amount of cables.

LIA is high current and high-voltage facility with operation cycle in nanosecond time region. Therefore survivability of electronics at the environment of periodic high-voltage discharges is an issue. We decided to develop hardware directly interfacing to high-voltage devices ourselves. Doing this we have the possibility to improve the survivability of hardware if needed. This approach proved to be useful to overcome false shots due to imperfect grounding in synchronization subsystem. We have unified hardware of all controllers to make maintenance easier.

Four modules were specially developed in BINP for use in LIA control system. Waveform recorders ADC200-ME and ADC812-ME were developed for waveform recording sub-system. Both of them are in PMC standard. Their specifications are given in table 2. ADC200-ME is used for the measurement of fast signals: inductor currents and voltages, BPM signal, signals form faraday cup and current transformers. ADC812-ME is used for slow waveforms recording. Inputs of two ADC812-ME's are placed on CPCI RIO module that is also used to route device alarms to F-16.

Two other modules were developed for interlock and synchronization sub-systems: DL200-ME (digital delay line with built-in interlocks) and F-16 driver/splitter. DL200-ME specifications are shown in table 3. Interlock channels are optically decoupled to protect the board from high-voltage breakdowns. FPGA is used to allow a pro-

Table 2: Waveform Recorders Specifications

	ADC200-ME	ADC812-ME
Channels	2 simultaneous	8 simultaneous
Conversion rate	200 MSPS	5 MSPS
Accuracy	12 bit	12 bit
Memory	1M×2×12 bit	1M ×2×12 bit

grammable interlock logic. There are two modifications of DL200-ME firmware, fast and slow. Fast modification (DL200-ME-F) is used in local controllers. Slow modification (DL200-ME-S) is used in main controller, provides 80 ns step and has specific interlock logic.

Table 3: DL200-ME Digital Delay Line Specifications

Output channels	16
Step	5ns (80 ns for S modification)
Jitter	<0.5 ns
Counter	15 bit (23 bit for S modification)
Interlock channels	16
Alarm channels	2

F-16 is a RIO CPCI module. It has two modifications: driver and splitter. F-16 driver is controlled by DL-200ME. It forms 16 decoupled synchronizing signals and gathers alarm signals. Another modification is F-16 splitter that splits two incoming signals on 8 outputs each. It is used to split slow synchronization pulses from main controller to all induction drivers in section.

Kontron [7] CP-6000 processor boards are used as central processing units in all crates. They have 2 Ethernet ports (4 with backplane) and PMC mezzanine slot. 4GB CompactFlash memory contains OS and control software.

Two boards are used as mezzanine carriers for PMC modules: Kontron CP-690HS and a module with built-in CAN controller constructed in BINP. TEWS [8] TPMC810-10 is used as a mezzannine CAN controller with two DB-9 connectors.

CONCLUSION

Features of LIA control system were formulated and the structure of the control system was designed. CompactPCI and PMC standards are used for control system hardware. Hardware for the control system has been developed, manufactured and tested in operation. Some of this hardware is used at other works in BINP.

LIA-2 was tested at single pulse regime of operation. Diamaeter of the electron beam diameter on the target (FWHM) less than 1.3 mm was achieved. Further experiments are continued on the customer site. High survivability of hardware was demonstrated in the environment of high-voltage discharges. The experience gained during creation and operation of LIA is usable for design of the control system of 20-MeV flash X-Ray radiography complex.

AN EPICS IOC BUILDER

M.G. Abbott, T. Cobb, Diamond Light Source, Oxfordshire, UK

Abstract

An EPICS IO Controller (IOC) is typically assembled from a number of standard components each with potentially quite complex hardware or software initialisation procedures intermixed with a good deal of repetitive boilerplate code. Assembling and maintaining a complex IOC can be a quite difficult and error prone process, particularly if the components are unfamiliar. The EPICS IOC builder is a Python library designed to automate the assembly of a complete IOC from a concise component level description. The dependencies and interactions between components as well as their detailed initialisation procedures are automatically managed by the IOC builder through component description files maintained with the individual components. At Diamond Light Source we have a large library of components that can be assembled into EPICS IOCs. The IOC Builder is further finding increasing use in helping non-expert users to assemble an IOC without specialist knowledge.

INTRODUCTION

The IOC builder is a Python framework designed to automate the process of assembling complex IOCs from existing components. It also provides facilities for generating databases, either as auxiliary records to link components in an IOC, or for the generation of standalone templates.

At Diamond the IOC builder has been used to generate Diagnostics and Power Supply controller IOCs, which show a combination of repetition and variation which is perfect for scripted generation, most area detector IOCs which need complex setting up, and a number of other photon beamline IOCs. The builder has also been used to generate the templates for the Libera EPICS driver [1, 2].

An IOC is normally assembled from existing EPICS support modules together with a small amount of IOC and module specific glue. Input to the IOC builder is either in the form of a structured Python script or a list of component instances specified in XML. The XML version of the IOC builder is designed for more routine IOC definitions where all that really needs to be specified is a list of components provided by EPICS modules and their parameters.

Each EPICS support module at Diamond can be found in a well defined location and has a clearly defined structure. As part of this structure IOC builder definitions are defined by each support module; these define the components such as templates or hardware drivers that go into an IOC.

```
import iocbuilder
iocbuilder.ConfigureIOC()
from iocbuilder import *

# Load support module definitions for needed modules
ModuleVersion('ipac',         '2-8dls4-5')
ModuleVersion('Hy8515',       '3-9')
ModuleVersion('asyn',         '4-10')
ModuleVersion('streamDevice', '2-4dls2-1')
ModuleVersion('newstep',      '1-4')

# Define the hardware resources used
card4 = modules.ipac.Hy8002(4)
serial = card4.Hy8515(0)

# Create two newstep controllers
for ch in range(2):
    asyn = modules.asyn.AsynSerial(serial.channel(ch))
    modules.newstep.NSC200(
        M = 'TS-TEST-DEV-01', P = '',
        PORT = asyn.DeviceName(), CH = ch)

WriteNamedIoc('ioc', 'TEST-IOC')
```

Figure 1: Complete script to assemble a simple IOC with serial hardware and stream device protocol definitions.

BUILDING AN EXAMPLE IOC

Figure 1 shows a complete IOC builder script for assembling a simple IOC, which in this case uses the streamDevice support module to communicate over a serial port provided by the Hytec 8515 IP card. Here we need five support modules with specific versions loaded by the calls to `ModuleVersion` and two items of hardware (the 8515 serial IP module and a carrier card in which to install it), and we create two instances of the newstep NSC200 component before writing out the entire IOC to the `ioc` subdirectory.

The IOC that is written out contains a top level make file in standard EPICS style together with a standard `configure` directory containing a file `RELEASE` with the relevant `ModuleVersion` definitions converted into EPICS version definitions. The rest of the IOC directory contains the necessary makefiles to link all the required libraries and EPICS dbd files together and template substitutions to complete the definitions.

Note that inter-module dependencies are automatically handled, the only thing the user needs to do here is to specify module versions in the correct order. The XML builder even automates this step by taking as input an existing `configure/RELEASE` file and walking the associated dependency tree.

USING THE IOC BUILDER

An IOC build script normally has a fairly stereotypical structure, consisting of four stages:

- Initialisation and configuration.
- Loading module definitions.
- Creation of IOC resources.
- Generation of output.

Initialisation and Configuration. The IOC builder can be used to generate IOCs to target a variety of architectures; at Diamond we support VxWorks, Linux and Windows. Alternatively the builder can be used to just generate a record template file. To choose between these options the builder must be configured before importing most of the iocbuilder symbols by calling one of the functions `ConfigureIOC` or `ConfigureTemplate`.

Loading Module Definitions. Each EPICS support module at Diamond contains IOC builder definitions specific to that module in the file `etc/builder.py`, and these definitions must be loaded into the builder by calling the builder `ModuleVersion` function before the support module can be used. Many support modules have dependencies on other support modules, so these dependencies must be loaded in the correct sequence.

Creation of IOC Resources. At its simplest an IOC can be defined as just a list of component instances where each component is a resource defined by a support module. The XML builder uses this approach where the input to the builder is essentially a table of component names and their arguments.

More generally it is sensible to structure an IOC definition script with a little bit of care. Hardware definitions can be placed first and it makes sense to separate them from the software resources that use them. Any required resource initialisation will automatically be created as required.

All the resources defined by individual support modules are loaded as Python submodules of the module `iocbuilder.modules` as can be seen in Figure 1.

Generation of Output. Typically the IOC builder can either write out a complete Diamond conformant IOC directory structure, or a single template file, using the functions `WriteNamedIoc` or `WriteRecords` as appropriate.

Creating EPICS Record Templates

The IOC builder was originally written to create complex databases, as gluing together hand-written templates with substitutions or macro processing rapidly becomes cumbersome. This functionality is available for normal IOC generation when some EPICS records are required to connect components together, but is more useful for building complex EPICS record templates.

The basic building block for doing this is the `iocbuilder.records` object which has record constructing methods for each record type. This object is automatically populated as DBD files are loaded, both from EPICS base on startup and from individual module definitions. Records are constructed in memory as Python objects with attributes for each possible record field, and assignments to these fields are automatically checked against the DBD definitions.

To simplify the naming of records when creating them a configurable record naming convention is established when initialising the IOC builder, both enforcing the Diamond record naming convention, and allowing the prefix of the name to be established separately.

Frequently records are generated in association with hardware with specific values written to the `DTYP` and `INP` or `OUT` fields. The builder supports this with record constructors tied to hardware instances which automatically populate these fields.

Figure 2 shows a fragment of a script using these mechanisms to generate a database with 22 record and 217 field definitions.

```
SetChannelName('SA')
power = Libera.ai('POWER',
    LOPR=-80, HOPR=10, ESLO=1e-6, EGU='dBm', PREC=3,
    DESC = 'Absolute input power')
current = Libera.ai('CURRENT',
    LOPR=0, HOPR=500, ESLO=1e-5, EGU='mA', PREC=3,
    DESC = 'SA input current')
Trigger(False, ABCD_() + ABCD_N() + XYQS_(4) +
    [power, current] + MaxAdc())
UnsetChannelName()
```

Figure 2: Fragment of script to generate an EPICS template. Here `Libera` is a device instance, `Trigger` creates a fanout record, and its arguments are functions for generating further records.

Using the IOC builder with an XML file

While the Python interface is useful for building many similar IOCs, many of our IOCs take the form of hundreds of similar objects with slightly different parameters, e.g. motors with different resolutions. This can be better presented in a tabular form, so the IOC builder contains a utility called the XML builder that can build an IOC from parameters stored in an XML file and an interactive graphical editor `xeb` ("XML Editor for the Builder", see Figure 3) that can read and write the correct format XML file. To support this, each argument of every builder object must be annotated with a description and a type as described in the `ArgInfo` section below. The editor can then do suitable error checking and type casting of the arguments, and present descriptive prompts to the user.

In fact, the XML builder and Python scripting are two equivalent approaches with similar power that suit different working styles.

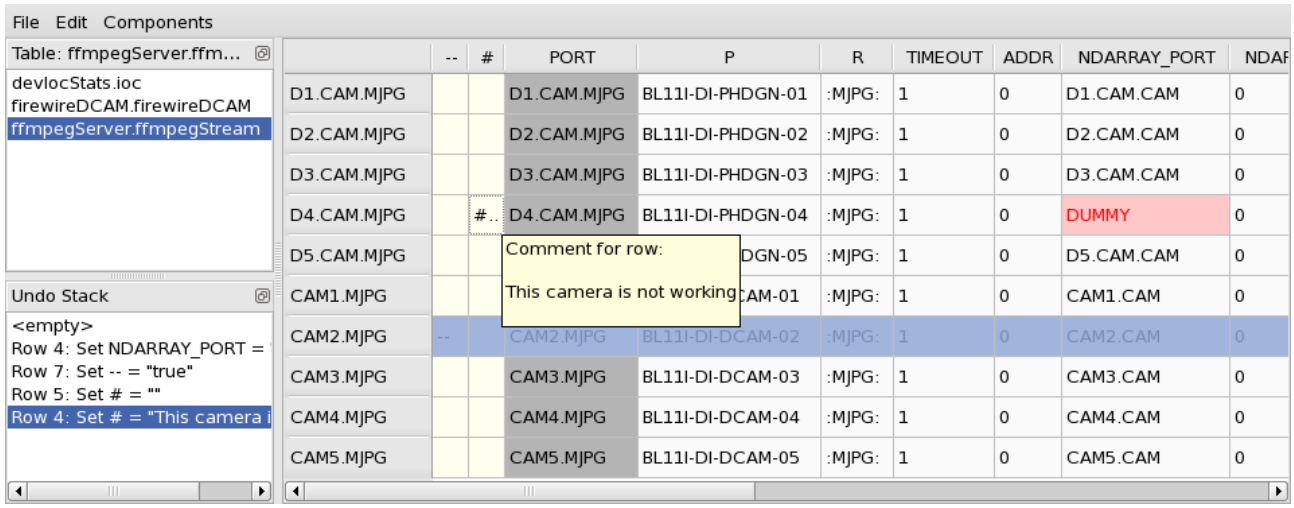

Figure 3: XEB: XML Builder Editor showing camera configuration for an area detector IOC.

MODULE DEFINITIONS

For an EPICS support module to be useful with the IOC builder it is necessary to create IOC builder class definitions for the resources defined by the module. These should encapsulate any module, linkage and DBD dependencies, and should also define any startup script commands needed by the support module. Ideally a good set of builder definitions should capture all the specific knowledge required to use the support module so that the developer of the IOC doesn't need to know.

The builder definitions for a support module are loaded from the file `etc/builder.py` in the base of the support module, which is loaded as a submodule of `iocbuilder.modules`. Builder resources are generally defined by creating subclasses of the `ModuleBase` class exported by the builder, largely as subclasses of `Substitution` to declare EPICS database templates, or of `Device` to declare resources with linkage or initialisation dependencies.

A support module builder definition file should open with imports from `iocbuilder.modules` of all support modules on which it depends to ensure that all dependencies have been loaded.

Module Base

Component resources are normally declared as subclasses of `ModuleBase`. This class performs a number of important functions:

- Ensures the module is included in the build.
- Ensures any module dependencies are resolved, this includes ensuring that dependent modules are linked and initialised in the correct order, and may involve automatically loading other modules.
- Defines path dependent access to files defined by the module. For example, this is used to locate the template file in a `Substitution` definition.

Any subclass of `ModuleBase` can define the value `Dependencies` to specify a list of other modules which must be instantiated before this class is used.

```
class NSC200a(Substitution):
    Arguments = ['P', 'M', 'CH', 'PORT']
    TemplateFile = 'NSC200.template'

    ArgInfo = makeArgInfo(
        P    = Simple('Device Prefix', str),
        M    = Simple('Device Suffix', str),
        CH   = Simple('Channel number', int),
        PORT = Simple('Asyn port string', str))

class NSC200b(AutoSubstitution):
    TemplateFile = 'NSC200.template'
```

Figure 4: Template definition examples showing both manual and automatic template definitions.

Template Definitions

Template definitions are the simplest to write, and are defined as subclasses of the `Substitution` builder class. The defined subclass must define the template file name, an enumeration of the arguments required by the template, and their descriptions. The definition of `NSC200a` in Figure 4 shows this.

The constructor for `NSC200a` will then expect to be called with exactly the listed keyword arguments and will fail otherwise. An alternative constructor can be defined for the class if appropriate.

The class `AutoSubstitution` is a subclass of `Substitution` which automatically searches the specified template file for template parameters to populate the `Arguments` and `ArgInfo` fields, and so allows a template definition to be just two lines as show in the definition of `NSC200b` in Figure 4; this is equivalent to `NSC200a`.

Every instance of a `Substitution` subclass results in the appropriate entries in the `Db/Makefile` and an associated `.substitutions` file.

Device Definitions

The `Device` class is used for component resources which need any of the following elements:

- Startup script initialisation.
- Loading of DBD files, either for new record definitions or for record device type definitions.
- Loading of libraries.
- Custom entries in Makefiles.

A component resource is created by defining a subclass of `Device` and setting values for a number of values, including:

LibFileList A list of libraries that must be linked when using this component.

DbdFileList A list of DBD files defining the EPICS resources provided by and making up this component.

Initialise() This method will be called during the generation of the IOC startup script to generate any device specific initialisation code.

Typically every support module should have a `Device` definition which defines `LibFileList` and `DbdFileList` to record the libraries and DBD files used to load the support module and which is marked as a dependency of the other components of the support module.

Component Argument Descriptions

The XML builder expects every builder component to be annotated with "metadata" documenting the parameters required to instantiate that component. This is done by creating an `ArgInfo` object, for example as shown in the definition of `NSC200a` in Figure 4.

`makeArgInfo` optionally takes the `__init__` method as the first argument, if a custom `__init__` method has been defined, followed by named arguments describing each argument that should be passed to `__init__`. Each of these arguments can be one of:

Simple A simple type

Ident An identifier, lets you specify that this argument should be something of a particular type

Choice One of a list

Enum As choice, but pass the index of the selection to the `__init__` method

It is also possible to add ArgInfo objects together, and filter them using the `filtered` method. This allows more complicated argument structures to be built up.

The `AutoSubstitution` simplifies this process for templates: as the template file is scanned for arguments, an `ArgInfo` object is automatically assembled at the same time. Specially formatted comments in the template file can be used to provide argument descriptions.

```
class Hy8002(IpCarrier):
    MaxIpSlots = 4      # 4 IP slots in this card

    def __init__(self, slot, intLevel=2):
        self.__super.__init__(slot)
        self.intLevel = intLevel

    ArgInfo = makeArgInfo(__init__,
        slot     = Simple('VME Slot number', int),
        intLevel = Simple('VME Interrupt Level', int))

    @classmethod
    def UseModule(cls):     # Assign shared interrupt
        super(Hy8002, cls).UseModule()
        cls.swapint = cls.AllocateIntVector()

    def Initialise(self):
        self.InitialiseCarrier(
            'EXTHy8002', self.slot, self.intLevel,
            self.swapint)
```

Figure 5: Module definition for Hy8002 IP carrier card.

An Example Device Definition

Figure 5 shows the complete module definition for the Hy8002 IP carrier device, part of the ipac support module. The `IpCarrier` class is a subclass of `Device` providing special support for IP carrier cards.

This device is fairly unusual in having only two arguments, but typical in the use of defaults. The `UseModule` method is called by `ModuleBase` immediately before creating the first instance of this class.

CONCLUSIONS

The IOC builder is being used for an increasing number of IOCs at Diamond and has been under continuous development for around five years by both authors.

There are some obstacles to using the IOC builder outside Diamond, the largest being the dependency on the Diamond directory structure. The builder code is reasonably well structured, though a transition to documentation using Doxygen seems to have been unhelpful.

Work on the builder continues in response to internal Diamond developments.

This work was first presented outside Diamond at the EPICS workshop at ICALEPCS 2009 [3].

CONTROLVIEW TO EPICS CONVERSION OF THE TRIUMF TR13 CYCLOTRON CONTROL SYSTEM

D.B. Morris, TRIUMF, Vancouver, Canada.

Abstract

The TRIUMF TR13 Cyclotron Control System was developed in 1993 using Allen Bradley PLCs and ControlView. A console replacement project using the EPICS toolkit was started in Fall 2009 with the strict requirement that the PLC code not be modified. Access to the operating machine would be limited due to production schedules. A complete mock-up of the PLC control system was built to allow parallel development and testing without interfering with the production system. The deployment allows both systems to operate simultaneously, easing verification of all functions. A major modification was required to the EPICS Allen Bradley PLC5 Device Support software to support the original PLC programming schema. EDM screens were manually built to create displays similar to the original ControlView screens, thus reducing operator re-training. A discussion is presented on some of the problems encountered and their solutions.

INTRODUCTION

The TRIUMF TR13 Cyclotron was designed by TRIUMF and built in collaboration with EBCO Technologies, now ACSI [1][2]. The control system was built by TRIUMF using two Allen Bradley PLC5 Programmable Logic Controllers (PLC) [3] and the ControlView OPI toolkit supported by the Chronos [4] multitasking system which runs on top of Microsoft DOS 6.22. The operator console computers running the ControlView displays are Intel 486 based PCs. They communicate with the PLCs using the Allen Bradley DataHighway Plus (DH+), a serial highway operating at 57.6 kbaud. Figure 1 shows a block diagram of the original system, which has been running essentially unmodified since 1993.

UPGRADE RATIONALE

The upgrade was driven by several factors:

- The ControlView toolkit is obsolete and the ageing hardware is difficult to support. Newer hardware is not supported by ControlView.
- The system performance degraded with a second installed console due to limitations of the DH+ serial highway.
- The dual console system was not supported by ControlView. Avoidance of conflicts between the two control masters was procedural and error-prone.
- The consoles are located in a harsh environment with high noise levels and wide temperature swings. Controlview does not allow remote consoles, so the operations area could not be relocated or duplicated, remotely.

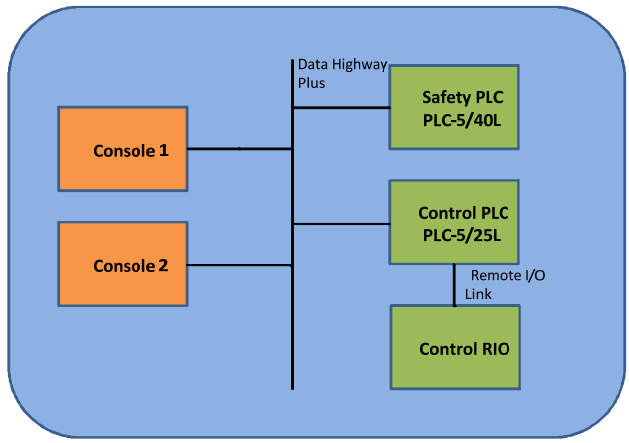

Figure 1: Original System.

UPGRADE LIMITATIONS

The principal limitation for the upgrade was that the PLC program must not be modified as this would trigger a re-licensing requirement of the entire cyclotron. In addition, the upgrade was not to affect the production runs which are scheduled every weekday, varying in length and frequency during the day. There is no regular pattern which would allow testing periods.

REPLACEMENT OPTIONS

On the software side, it was decided from the outset to use the EPICS control system tool-kit which is used for the ISAC control system. Alternative options, such as using the Allen Bradley RSView product or other commercial OPI products were not considered because of cost and in order to conserve the control group resources.

On the hardware side, several options were investigated for the replacement and finally rejected:

- Installing an Ethernet Coprocessor into the PLC chassis because it would have required PLC module re-addressing and PLC program changes.
- Use of a Serial to DH+ module because of speed limitations.
- Replacing the PLC CPU with a ControlLogix or other PLC because it would require rewriting the PLC program.
- Installing a Datalink translator between ModBus/TCP and DataHighway Plus because of speed limitations and possible size limits of the translation tables.

It was decided to replace the PLC CPUs with fully compatible PLC-5 Ethernet Processors. This would require no PLC program changes and allow deployment

of an EPICS OPI with fast communication between console and PLC. The new system could be deployed in parallel with the ControlView system greatly simplifying commissioning. Figure 2 shows a block diagram of the upgraded system.

This solution required replacement of the PLC program development software, Ladder Logistics from ICOM, as it did not support the Ethernet enableed PLC family. An available copy of ICOM's WinLogic 5 was initially used to monitor the PLC while the EPICS interface was developed. WinLogic 5 was eventually replaced with a current version of Rockwell Automation RSLogix.

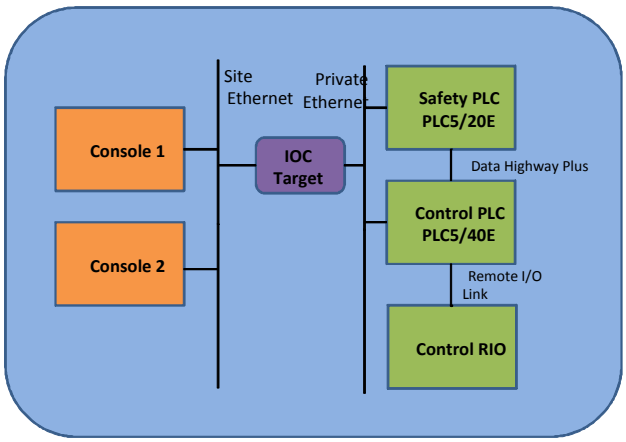

Figure 2: Replacement System.

FEASIBILITY TEST

A test system was set up to prove that the selected methodology was sound and that the underlying EPICS device support would work for the TR13. A mock-up was built of the Control and Safety PLC systems by scavenging parts and purchasing an assortment of modules from E-Bay vendors (see Fig. 3). The total investment in the mock-up was about $2500. With the hardware assembled, the existing PLC software was configured for the Ethernet PLCs and installed.

An EPICS IOC application running on a Linux based platform was built using the PLC5 Device Support library from SNS [5]. A rudimentary EPICS run-time database was created to access some of the PLC memory locations. The PLC status was monitored using WinLogic 5. Successful communication in both directions was observed between the IOC and PLC.

SYSTEM DEVELOPMENT

EPICS Run-time Databases

PLC addresses and device functionality were identified by examining the PLC ladder logic. Differences between the tag address layout in the TR13 PLC memory and ISAC conventions precluded the use of existing device and component schematics. Because of the small size and one-off nature of the system it was decided to instantiate the devices interactively into schematic diagrams for the different TR13 sections and not to upgrade available tools [6]. Following the methodology used for the ISAC control system, EPICS run-time databases were designed using the Capfast [7] schematic editor from which the run-time databases were generated.

OPI Screens

The TR13 operations group required that the EPICS display screens be as similar as possible to the existing ControlView displays in order to reduce operator re-training and improve acceptance of the new system. This required that all screens be manually created, since the auto-generation tools that were available [8] would have needed extensive modifications to handle the visual representation of control components and especially of the device interlocks. The effort to modify the ISAC tools was deemed too high given the one-off nature or the TR13 system.

Some 160 OPI screens were developed using edm, the standard graphical display tool for EPICS systems at TRIUMF.

The ControlView interface had been optimized to use keyboard input extensively, with Function keys, arrow keys and others triggering actions in the system. In contrast, edm is based on the X-Windows system, and provides less in the way of keyboard support. Although some edm widgets support arrow keys for increment and decrement, the standard coarse/fine adjustments available in the ControlView system could not be implemented with the same level convenience for the operators.

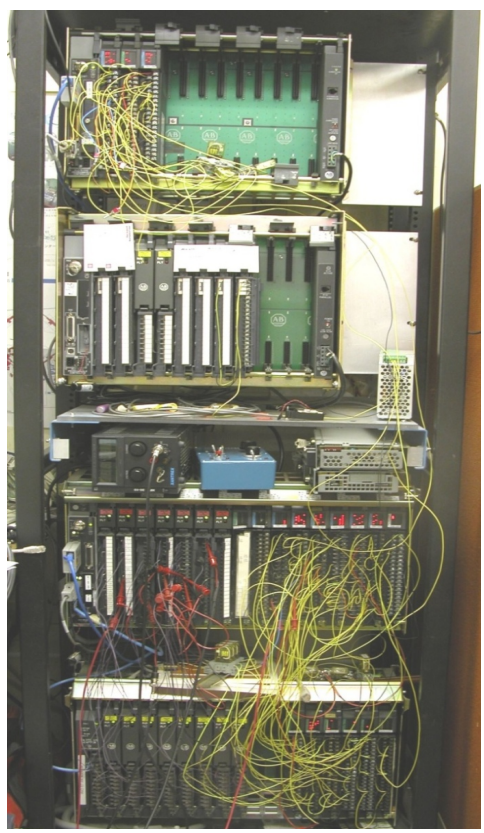

Figure 3: The mock-up system with wires simulating device feedback.

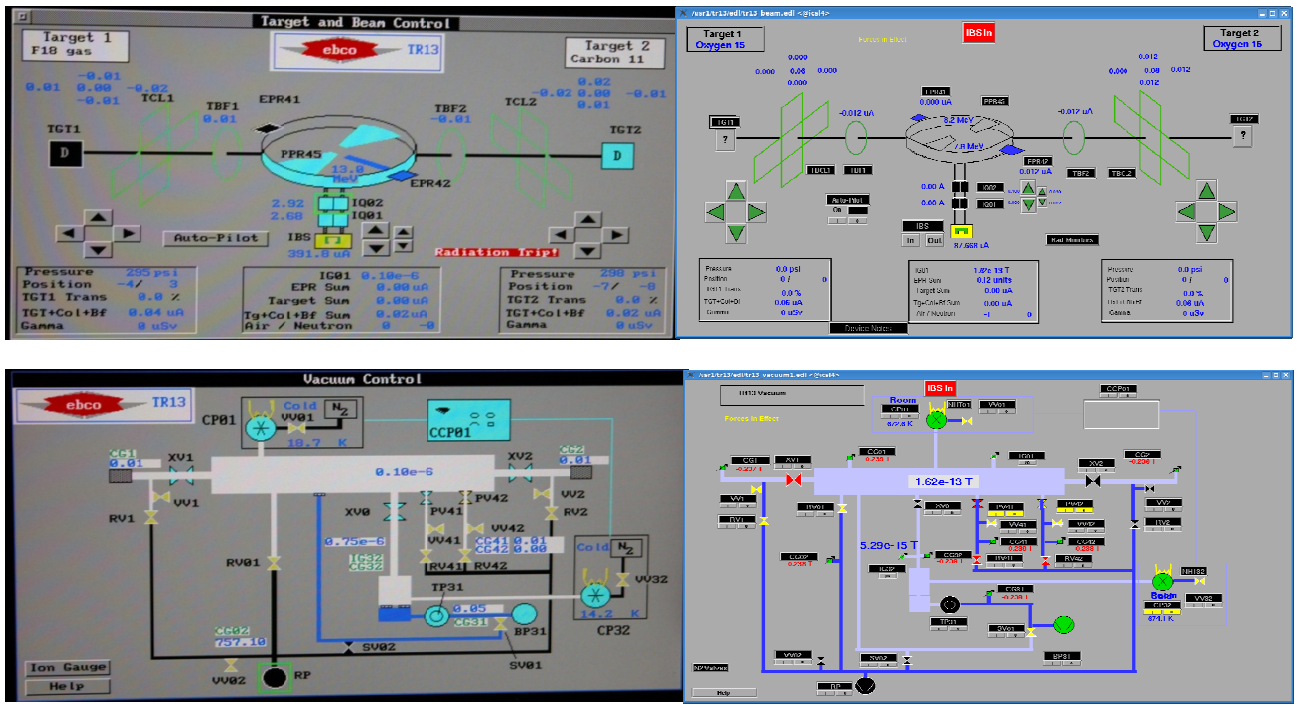

Figure 4: Examples of ControlView (left) and EDM (right) screens.

IMPLEMENTATION

In order to not affect the production schedule of the cyclotron, maintenance days were used to install and test the new system incrementally:

1. The Safety PLC was replaced with an Ethernet enabled unit, the Safety program was loaded and started, and the safety system was tested for proper operation.
2. The Control PLC was replaced and regular operation was tested.
3. The EPICS SoftIOC with a small database was started on the new console computer and operation of the ControlView system was monitored for anomalies.
4. Control was tested using the EPICS interface. During this phase some irregular system behaviour was observed, such as certain valves turning off unexpectedly.
   Investigation of the structure of the PLC5 Device Support code traced the fault to a design philosophy from SNS that was incompatible with the TR13. The SNS implementation uses a PLC memory block for efficient command writes to the PLC. The driver monitors this transfer block, and re-asserts any words that change in the block to ensure all commands are valid. In the TR13 PLC memory, there is no separation of command bits, status bits, internal bits and one-shot bits into different memory blocks. This led to unintended write operations with unexpected side effects by the SNS driver. These problems were resolved by the author with an extensive re-write of the PLC5 Device Support. Several new features were added, including direct bit and word write, optional scanning of bit and word changes, timer and counter accumulator reads and many new diagnostic tools at all levels of the driver. The driver was also modified to handle proper octal/decimal conversion, as the PLC programming tools use a mix of these for I/O bits and words versus internal memory. All the existing database addresses had to be modified to handle the new driver structure.
5. The new driver was installed in the IOC and further testing resulted in acceptance of the driver for operations.

IOC PLATFORM

As can be seen from Fig. 1 and Fig. 2, the EPICS implementation introduces an IOC between the operator consoles and the PLCs. This alleviates some of the problems encountered with console “competition” under ControlView. The IOC could – in principle – be implemented as a software process on one of the consoles. At TRIUMF this is never done because of the risks of user interference with the IOC application, not to mention the possibility of a user shutting the IOC application down.

Typical installations for the TRIUMF ISAC facility provide an IOC server that will run several SoftIOCs. In the case of the TR13, a dedicated target platform was required that could be placed in the cabinet with the PLC hardware.

An Intel based platform was preferred, as all our Linux development systems are Intel based, avoiding cross-

compiling with its associated infrastructure. To improve reliability there should be no moving parts.

An Intel Atom based Netbook was used as a test platform to test processor load and performance. Results showed sufficient power and resources to support the IOC processing approximately 2900 EPICS records. The final IOC was implemented on an Atom - Mini-ITX platform.

This solution proved efficient and cost-effective and was therefore adopted as a standard small IOC platform for EPICS at TRIUMF. It has the additional possibility of performing specialized hardware I/O via PCI cards.

ACCESS SECURITY

Several layers of security were implemented for this system to prevent unauthorized operation while still allowing operators to monitor the cyclotron remotely. The console computers limit access through host allow/deny rules and user identification. The IOC computer implements a firewall to restrict access to a select few site computers such as the consoles and the development computers. The firewall also blocks any access from external systems to the private network connection to the PLCs. In order to connect the RSLogix PLC programming tool to the PLCs, a cable must be deliberately connected between an MS WindowsXP computer and the private network switch.

OUTSTANDING ISSUES

The present PLC5 Device Support does not restore the PLC-IOC connection after a power interruption to the PLCs. This will be resolved by placing the PLCs on a UPS circuit so that brief interruptions do not affect the connection. In the near future a reconnect function will be implemented in the driver.

LESSONS LEARNED

The project was to take 6 months based on experience with typical new installations. It actually took about one man-year of work spread over 26 months.

The *EPICS Learning Curve* contributed to the long development time, as the author was new to the environment.

Much of the time was taken in building the databases and screens, and then fine tuning them to get proper operation. There was an extensive amount of infrastructure required, including network configuration, power distribution and IOC target platform research and configuration. New software tools included scripts to bring the project within the existing project control mechanisms, principally deployment of production files to the target system.

Unforeseen was the effort going into upgrading the PLC driver.

A final influence was due to resource conflicts with other high priority projects and the requirement to schedule work around the on-going isotope production schedule.

Abstract

The upgrade of JET to a new all-metal wall will pose a set of new challenges regarding machine operation and protection. One of the key problems is that the present way of terminating a pulse, upon the detection of a problem, is limited to a predefined set of global responses, tailored to maximise the likelihood of a safe plasma landing. With the new wall, these might conflict with the requirement of avoiding localised heat fluxes in the wall components. As a consequence, the new system will be capable of dynamically adapting its response behaviour, according to the experimental conditions at the time of the stop request and during the termination itself. Also in the context of the new ITER-like wall, two further upgrades were designed to be implemented in the shape controller architecture. The first will allow safer operation of the machine and consists of a power-supply current limit avoidance scheme, which provides a trade-off between the desired plasma shape and the current distribution between the relevant actuators. The second is aimed at an optimised operation of the machine, enabling an earlier formation of a special magnetic configuration where the last plasma closed flux surface is not defined by a physical limiter. The upgraded shape controller system, besides providing the new functionality, is expected to continue to provide the first line of defence against erroneous plasma position and current requests. This paper presents the required architectural changes to the JET plasma shape controller system.

INTRODUCTION

The JET [1] plasma position and current controller (PPCC) [2] is a real-time system responsible for the control of the currents in poloidal fields (PF) circuits, the plasma current and the plasma shape [3]. Its two main components are the shape controller (SC) and the vertical stabilisation (VS) systems. PPCC receives its input data from the magnetics systems, poloidal field (PF) circuits, central interlock and safety system (CISS), pulse termination network (PTN), radio-frequency (RF) and lower-hybrid (LH) systems, central timing and triggering system (CTTS) and Level-1, the high-level plant configuration interface. The latter is used for the configuration of the system, both with parameters from the session leader (SL) user-interface and from the PPCC expert settings. Magnetic signals arrive from the ATM real-time network systems [4] and are used to calculate the plasma current, radial and vertical moments, perform the reconstruction of the plasma boundary [5] and to provide flux measurements. Some of these are used later as control variables in the form of plasma current, gaps and flux. The PTN connection enables the shape controller system to change its execution configuration, as part of a global response to an external event.

The main output of SC is the voltage reference to all the PF amplifiers. It can also trigger the stop of a JET pulse through PTN, or CISS, in the case of internal problems, control errors and violation of amplifier limits. The boundary reconstruction coefficients and the circuit currents are sent to other JET plant using the ATM real-time network.

Each circuit can be controlled either in absolute current, proportional (to the plasma current) current or against a geometrical parameter, defined as a vector, named gap. Examples of gaps are the radial outer gap (ROG), which defines the distance between the outer limiter and the plasma, and the radial inner gap (RIG). The amplifier can also be set in a blocked state, where minimum negative voltage is applied, and no induced current is allowed to flow in the circuit (due to the presence of a diode); or in the free-wheeling state where 0 V are applied across the circuit.

The SC system is based on time windows, so that each circuit can change its control mode during the experiment. Indeed, most of the amplifiers start the experiment either blocked or in absolute current control, as no plasma exists at that time. As soon as a sustained plasma breakdown is achieved, most circuits are either set in proportional current or gap control. The shape controller hardware is based on

* See the Appendix of F. Romanelli et al., Proceedings of the 23rd IAEA Fusion Energy Conference 2010, Daejeon, Korea

VME®, PowerPC® and custom built I/O and data acquisition cards. The system control cycle is 2 ms.

eXtreme Shape Controller

A module named eXtreme Shape Controller (XSC) [6] allows a full boundary control. The main idea behind the XSC algorithm is to control the full plasma boundary, while minimising the error over a large set of geometrical shape descriptors, so that the system is no longer limited to the accurate control of only a few gaps, further constrained by the circuit control mode selections. When the XSC is used, all the circuits in shape controller are set to proportional current control, with the appropriate current references provided by the XSC algorithm.

The XSC operational scenarios are implemented around a given plasma shape and equilibrium (in terms of plasma current, internal inductance and the ratio of the poloidal kinetic to magnetic pressure). Using linearised plasma models, the predicted PF currents for a given plasma shape and configuration are evaluated. If these are within power supply saturation limits, the XSC is finally designed by carefully tuning the weighting matrices related to the minimisation function [7] and the system stability is assessed in closed-loop simulations. As the algorithm is valid only around a given equilibrium, the plasma must be driven into the reference conditions using shape controller, before enabling XSC.

P1 Logic

Plasma current is induced by changing the flux across a central solenoid. At JET this circuit is named P1E and is responsible for generating the current in the ten stacked central solenoid coils. The current is produced by a flywheel generator, named PFGC, capable of delivering a maximum of 400 MW of power. As shown in Fig. 1, at the same time, a second circuit, named PFX is also capable of driving current, in different windings, of the six central pancakes. The main role of this circuit is to reduce the stray fields, increasing the inboard vertical field and allowing for a more *D* shaped plasma.

The PFGC is a single quadrant amplifier, producing single direction current and voltage. A special circuit with hardware switches, named *s1* and *s4* in Fig. 1, allows for the current to flow in opposite directions during the same plasma pulse. When required, this scheme is used to provide a pre-magnetisation of the iron core, by forcing current through the solenoid in the opposite direction (*s1* closed and *s4* opened) in respect to the one using during the experiment (*s1* open and *s4* closed). The result is a larger amount of flux available to induce plasma current and consequently a greater pulse length.

Since having currents in opposite directions in the PFGC and PFX circuits will lead to high repulsion forces, up until recently, the current in the PFX circuit was only allowed to flow when the current in the PFGC circuit was greater than

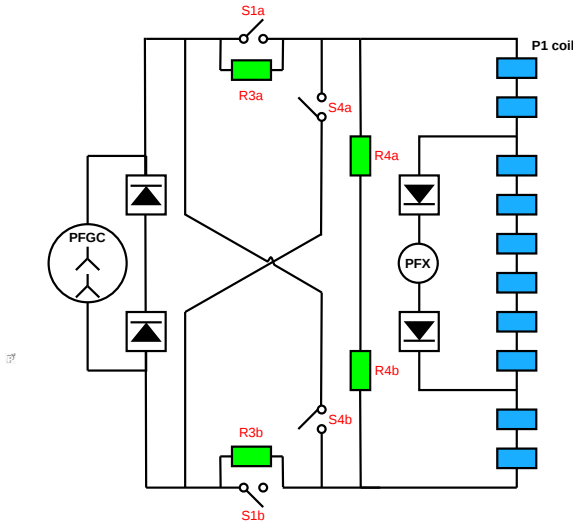

Figure 1: Simplified version of the JET ohmic circuit layout. By commutating the different switches, current from the flywheel generator will flow in opposite direction.

a positive value (with the convention that a positive PFGC current is the one to be used during the plasma pulse).

Justification for the Upgrades

The upgrade of JET to a new all-metal wall poses a set of new challenges regarding machine operation and protection. These will be handled by a major project named Protection of the ITER-like Wall (PIW), responsible for the coordination amongst all the infrastructure that provides the diagnostic data (e.g. infra-red cameras and pyrometers) and the systems required to take control actions (e.g. PPCC and additional heating systems). The major problem is that the current strategy to stop a plasma pulse might conflict with the requirement of avoiding localised heat fluxes in the inner wall components. The greatest limitation in PPCC was that the stop strategies are global during the pulse and could not be adapted for the pulse phase and plant conditions.

A second improvement, aimed at an optimised operation of the machine, was designed in order to enable a limited amount of PFX current to flow before a positive value of P1E current is achieved, without putting the machine integrity and safety in jeopardy. The enlarged operational space will allow the earlier formation and exploitation of the X-point configuration.

Finally, a current limit avoidance (CLA) [8] system was designed in order to avoid PF current saturations when the XSC is used to control the plasma shape. It uses the redundancy of the PF coil system to automatically obtain almost the same plasma reference shape with a different combination of currents in the PF coils. In particular, in the presence of severe disturbances, it tries to avoid the current saturations by *relaxing* the plasma shape constraints. Its feedback scheme asymptotically guarantees an optimal trade-off between shape error and distance of the coil currents from their limits.

PIW STOPS

As illustrated in Fig. 3 the PPCC code was updated to react to ten different stop sources for each available time window. Examples of stop sources are localised hot spots in the main chamber, magnetohydrodynamic modes and unavailability of a crucial resource for the experiment (e.g. additional neutral beam power heating). A stop response is configured with a control mode and a control value for each of the 9 PF circuits. The only exceptions are the P1 circuit, for plasma current control, and the P4 circuit, for radial wall distance control, which are programmed using an hold-and-ramp waveform. These waveforms consist of four distinct segments where an hold value time is specified, together with a ramp-rate to the following value. Moreover, the values and times of an hold-and-ramp waveform can be synchronised to the plasma current waveform values, being dynamically adjusted to its values at the time of the stop.

A special type of stop, named jump to termination, enables the system to react to a stop request by fast forwarding the execution to the time window corresponding to the pre-programmed termination time, ignoring any time windows in between.

The request for a stop is driven by the real-time protection sequencer (RTPS) [9], connected to PPCC using the real-time network. RTPS is responsible for the central coordination of all the JET actuators and reacts to alarm requests from the vessel thermal map (VTM) [10] system.

An alternative sequence facility is also available in the PIW PPCC version. The idea is to switch to a different experimental program if a given resource is not available during the execution of the experiment, allowing to maximise the optimisation of resources and machine time.

It should be noticed that the old, pre-PIW, stops are still available to be used when required and can be programmed together with the PIW stops.

POET

In order to study the implications of enabling current on the PFX circuit, while there is still current from P1E flowing in the opposite direction, a project named PFX-on-early-task (POET) was started. The major problems addressed concerned the modelling of the maximum forces in the P1 stack, taking into account the machine mechanical structure, and the effects of external faults in the machine integrity if these were to happen while taking advantage of the new operational space.

At the same time a study regarding the implementation of a new control logic for PPCC was also performed, mostly based on the value of the current across the central pancakes, given by: $P1C = P1E + PFX$. As depicted in Fig. 2, it was decided to set three operational regions: one where no PFX is allowed to flow, so that $P1C = P1E$; a second where the value of PFX is limited; and finally a region where the PFX value is only limited by the amplifier. Even if the control system is not used as a protection system, it makes every effort to avoid triggering the interlock protection systems, and consequently a state machine with the previously described logic was implemented in PPCC. All the possible current combinations, simulation of possible faults, and the performance of the controller itself were asserted using a simulator of the controller, connected to linearised plasma models provided by the CREATE [11] tools. The results of these simulations have also allowed to select the first set of values for the limits, even if these are then expected to be tuned during the experimental campaigns.

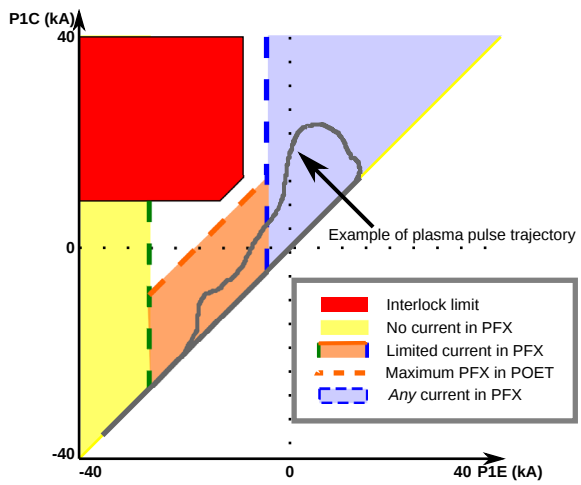

Figure 2: The new POET region will enable the use of PFX early in the plasma discharge. A possible plasma pulse trajectory is represented in grey. PPCC ensure that none of the limits are violated due to an erroneous request.

CURRENT LIMIT AVOIDANCE

The previously introduced current limit avoidance (CLA) was implemented as an additional feature of the eXtreme Shape Controller, being completely transparent to the existing SC code. As depicted in Fig. 4, the CLA modifies the PF current requests computed by the XSC before sending them to the SC, which is set in proportional current control mode with the only exception of the P1E circuit, as this is usually controlling the plasma current. Even when away from the saturation limits the CLA can be used to automatically equalise the best distribution of currents for a given shape, a process that is usually manually performed while developing the XSC controller settings for a given experiment.

Any changes performed by the CLA to the actual plasma shape are hidden from the XSC controller in order to inhibit its reaction. More details regarding the actual algorithm can be found in [8].

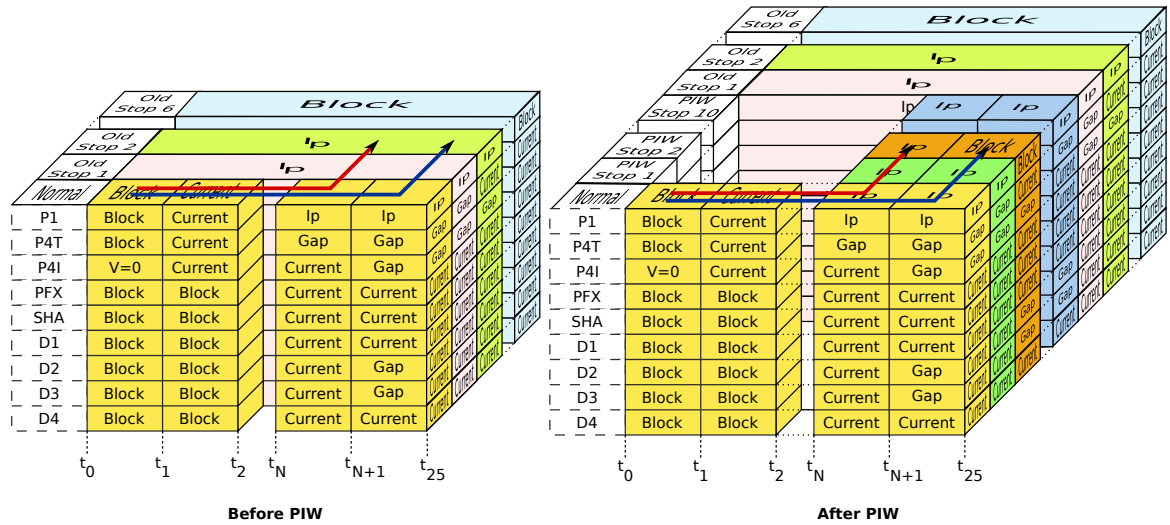

Figure 3: The previous version of shape controller had the same reaction to the same stop trigger, independently of the pulse phase and plant conditions. With the new all metal wall this could lead to highly localised hot spots and it was decided to allow for up to ten different stop responses for each experimental time window. The first column labels the 9 PF circuits controller by SC. In this example, for the same stop trigger (PIW stop 2), depending on the stop time, different control modes will be set.

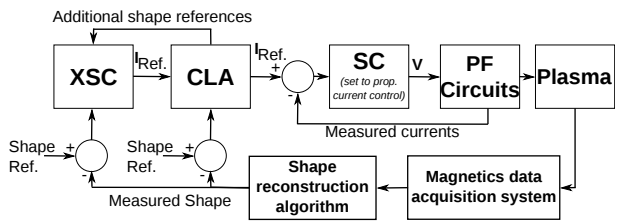

Figure 4: The XSC and CLA are implemented as additional modules of shape controller. XSC provides the current references to be controlled by SC which then sends voltage commands to the PF amplifiers. The additional shape references have the purpose of hiding from the XSC controller any changes to the plasma shape due to the CLA algorithm.

CONCLUSIONS

The JET shape controller was upgraded in order to cope with the operational requirement of the new ITER-like-wall. A new stopping architecture enables a greater control over the experiment and enhances the first line of defence for the machine protection. A new operational mode, named POET, enables an earlier exploitation of the X-point configuration, optimising experimental resources and time. Finally, it is expected that with the introduction of a current limit avoidance module it will be possible to demonstrate a safer operation of the machine, while using XSC, even in the presence of disturbances and when working near the power supply limits.

UPGRADE OF THE CLS ACCELERATOR CONTROL AND INSTRUMENTATION SYSTEMS*

E. Matias #, L. Baribeau, S. Hu, C.G. Payne, H. Zhang
Canadian Light Source, University of Saskatchewan, Saskatoon, Canada

Abstract

The Canadian Light Source is undertaking a major upgrade to its accelerator system in preparation for the eventual migration to top-up and to meet the increasing demanding needs of its synchrotron user community. These upgrades on the Linac include the development of software for new modulators, RF sections, power supplies and current monitors. On the booster ring the upgrades include the development of new improved BPM instrumentation and improved diagnostics on the extracted beam. For the storage ring these upgrades include fast orbit correct, instrumentation for use by the safety systems and a new transverse feedback system.

CLS ACCELERATOR

The CLS linear accelerator was originally constructed in 1964, with major upgrades and enhancements in the 1980s and again in 1999 when the machine was repurposed as an injector for the new synchrotron. The booster ring, storage ring and first round of synchrotron beamlines were constructed and commissioned between 1999 and 2003. The 1999 upgrade included replacing all of pre-existing CAMAC equipment with VME and the adoption of EPICS. The only legacy control equipment after 1999 was hard-wired electronics and Modicon Micro84 PLC.

In order to effectively offer top-up operation a series of upgrades focused on machine reliability, availability and reproducibility are currently under way.

Currently under construction at the CLS is a second linear accelerator designed to demonstrate the feasibility of producing Molybdenum^{99} using a particle accelerator. This accelerator is a standalone machine not integrated into the main accelerator control system.

COMMON ELEMENTS

Architecture

As shown in Figure 1, CLS utilises an EPICS based control system using EPICS Channel Access as the primary enterprise data-bus.

EPICS is utilised at the lower layer. High level accelerator control screens have been developed using EDM. The Matlab - Accelerator Tool Box is used for high-level on-line physics applications.

*Research described in this paper was performed at the Canadian Light Source, which is supported by the National Sciences and Engineering Research Council of Canada, the National Research Council of Canada, the Canadian Institute for Health Research, the Province of Saskatchewan, Western Economic Diversification Canada, and the University of Saskatchewan.
elder.matias@lightsource.ca

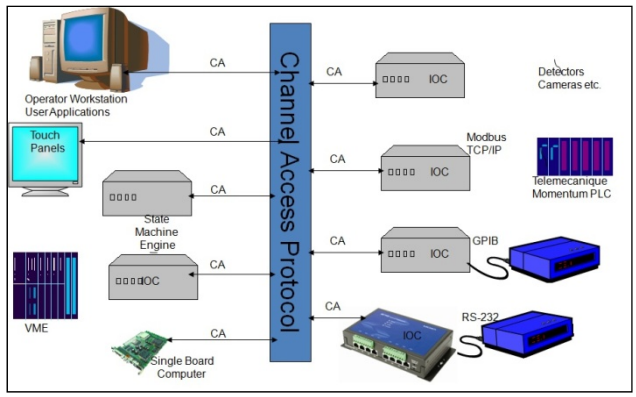

Figure 1: Architecture.

We find the use of the Moxa MIPS based controllers (Model UC-7408-LX and DA-662-16-LX) compelling [3]. Over the past four years CLS has deployed 120 Moxa computers in the facility and has yet to experience any significant hardware failure. The Moxas are used as full fledged EPICS IOCs primarily interfacing Ethernet, USB and Serial devices into the control system.

Increasing we are seeing a series of network aware Ethernet based devices being integrated into the control system.

Modicon Momentum PLCs continue to be used primarily for machine protection. These are interfaced into the CLS control system through Modbus over TCP/IP. Siemens S7/300 and S7/400 are used in the cryogenics plant, Booster Ring RF and Storage Ring RF Systems.

VME64x is primarily used for motion control and data acquisition applications. The Prodex MaxV is used with a combination of drivers [1]. Data acquisition is primarily accomplished with the use of SIS3820 scalar boards.

Some preliminary development work is occurring on the use of microTCA equipment, primarily focused on beamline data acquisition.

Alarm Handler

CLS has completed the transition from a locally developed legacy alarm handler to using the SNS BEAST[2] alarm handler. BEAST is built on top of the Control System Studio Toolkit [3]. The CLS deployment uses mySQL as the relational database for alarm storage.

Working closely with accelerator operations staff a strategy was adopted to limit alarms to those process variables that require action to be taken by operational staff.

CNSC regulatory requirements dictated that a proper human factors engineering review be performed using

relevant sections of NREG-0700. Based on careful review we were able to demonstrate compliance [4].

Currently under development is a second deployment of BEST targeting mechanical maintenance staff. These alarms would be restricted to process variable alarms that would indicate the need for preventative maintenance to occur.

The alarm handler is supplemented with a series of auto-diallers that are triggered based on certain critical process variables.

Electronic Logbook

After many years of relying on paper based log-books, CLS in the past year has started to introduce an electronic logbook based on the TRIUMF electronic log book system.

The electronic logbook system is currently operated in parallel and redundantly with the paper based logbook.

Save and Restore

CLS utilises a locally developed Save-Restore application. Originally driven by the need to support diskless IOCs, the CLS Save and Restore is a server based application that also permits accelerator operations staff to take and restore machine snap-shots of the accelerator configuration.

Radiation Monitoring

CLS has used the Canberra ADM606M radiation monitors for nearly eight years. The local indicators (horns and lights) were found to be inadequate given background noise in close proximity to the monitors. As a result of a human factors assessment of the monitors it was determined that the following two upgrades were required: (1) local annunciation needed to be augmented with the use of additional strobes and horns and (2) the control room interface needed to be upgraded based on human factors engineering standards [5].

An improved local annunciation system was developed and deployed. Data from the ADM monitors is obtained by EPICS running on Moxa UC7408 computers.

LINAC

The Linac is the oldest accelerator at CLS, originally constructed for nuclear physics experiment the Linac was repurposed in 1999 as an injector for the synchrotron facility. The machine has performed well over the past ten years, however given its age and the transition to top-up it is now necessary to upgrade the accelerator.

Linac ACIS System

CLS has used the Siemens S7/400 F PLC platform in the design of lockup systems for many years. However the Linac hall was the last remaining hall/tunnel to still make use of an older Modicon Micro84 based system. In October of 2009 CLS replaced the last remaining Modicon Micro84 system with a Siemens S7/400 system [6]. The system design is based on the requirements of IEC 61508.

The As-Low-As-Reasonably-Practical (ALARP) hazard and risk analysis technique was applied to the design of this system.

Linac Modulators

Work is ongoing in the replacement of end of life components on the linac, including linac sections, the gun, and modulators. New modulators were installed in April of 2011 with the installation of new sections expected in 2012.In the modulator upgrade, 6 old PFN type modulators were replaced with 6 solid state modulators from ScandiNova. Each modulator has 30 solid state IGBT's which discharge at 1170V and fire directly to a "split core" pulse transformer. The klystron pulse voltage is 250 KV, pulse current 250A, pulse width is 4 μs, and the pulse power is 62.5 MW.

Two MOXA DA662 computers are used for modulator monitor and control. Each computer communicates with 3 modulators using ScandiNova TCP/IP protocol, which is a variant of TCP/IP. StreamDevice is used for EPICS device support. The driver is based on an EPICS driver developed by PSI/Swiss Light Source.

A Modicon Momentum PLC is used to monitor vacuum and water status to provide external machine protection interlocks.

BOOSTER RING (BR1) ENHANCEMENT

Tbe booster is a relatively new machine that was installed in 2002.

Upgraded BPM Electronics

The CLS booster ring was commissioned using Bergoz BPM electronics. Once commissioned the need for BPMs diminished and they were not regularly used. As part of a plan to better characterise the injection system we decided to upgrade the booster to Libera Brilliance BPMs.

Eight Libera Brilliance BPMs have been installed in the booster ring to better understand the operation of the booster. The first measurement carried out with these Libera BPMs was to monitor the booster tunes. Figure 2 shows the booster tune measurement results at the beginning of the ramp, which were obtained by simple fast Fourier transform of the turn-by-turn beam position in each plane. To evaluate the performance of the booster during the whole ramp (600 ms), further attempts were made to monitor the tunes later in the ramp. Unfortunately, oscillations were not big enough to get a tune measurement at later times of the ramp. Therefore, the booster extraction kicker was used to excite the beam to introduce an oscillation at different stages of the ramp. In the past, the tunes at the extraction time were assumed to be the same as the tunes at injection, i.e., ν_x=0.806 and ν_y=0.77. The measurement results show a tune shift at the extraction time, ν_x=0.81 and ν_y=0.704. Recently, the booster response matrix was measured with stored beam in the booster at 150 MeV. Further efforts will be made to invert the response matrix with singular value decomposition and apply correction to improve the injection efficiency.

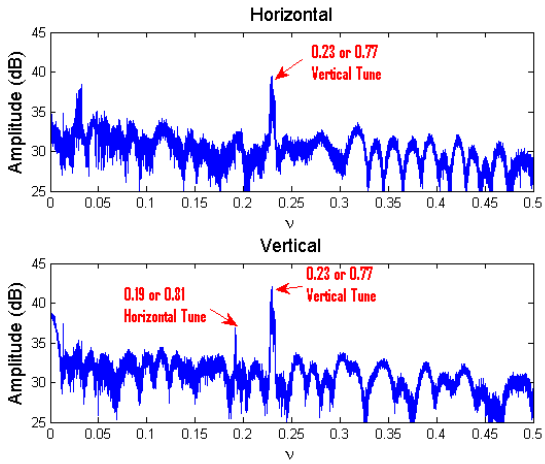

Figure 2: Booster Tune at the beginning of a ramp.

TRANSFER LINES

Power Supply Upgrade

Many of the original power supplies used in the CLS transfer lines were nearly 20 years old and dated back to the original EROS ring. CLS has recently completed a major replacement program to upgrade thelegacy power supplies with new power supplies from IE Power. The motivation for this upgrade was to reduce unplanned down-time and gain increased machine reproducibility, something critical as we move towards top-up operation.

Booster to Transfer Line BPM Monitor

CLS is currently testing a Libera Brilliance Single Pass BPM connected to strip-lines in the transfer line.

Current Transformers

CLS is currently installing additional Bergoz Fast Current Transformers (FCT) along the LTB transfer line connected to oscilloscopes. This augments a series of pre-existing Bergoz Integrated Current Transformers (ICT) that are connected to charge integrating ADC boards.

STORAGE RING (SR1) ENHANCEMENT

Transverse Feedback Systems

Due to the inherit stability of the storage ring, CLS was able to operate without the use of a transverse feedback system for many years. As the need for higher current operation became evident and user needs advanced, it became necessary to develop a transverse feedback system.

A transverse feedback system has been deployed to the CLS storage ring. It has three main functions:

1) Since high purity single bunch injection cannot be achieved at the CLS, any unwanted bunches have to be kicked out after injection. The transverse feedback system can work as a bunch cleaning system to establish an arbitrary fill pattern after injection. An enhanced feature, periodic bunch cleaning mode, has also been introduced to maintain high bunch purity, i.e., 10^{-5} at any time during a single bunch run.
2) The CLS transverse feedback system can be used to damp the transverse betatron oscillation associated with coupled-bunch instabilities. With the transverse feedback system, it is now possible to completely fill the storage ring, resulting in fewer electrons per bunch and consequently an increase in the beam lifetime. Figure 3 shows the comparison of the beam profile without/with the transverse feedback system.
3) Previously, the beam had to be excited by the injection kicker to determine the storage ring transverse tunes. With the transverse feedback system, it is now possible to excite only one bunch with limited amplitude for tune measurement. This feature has been extensively used for beam optics studies by CLS accelerator physicists.

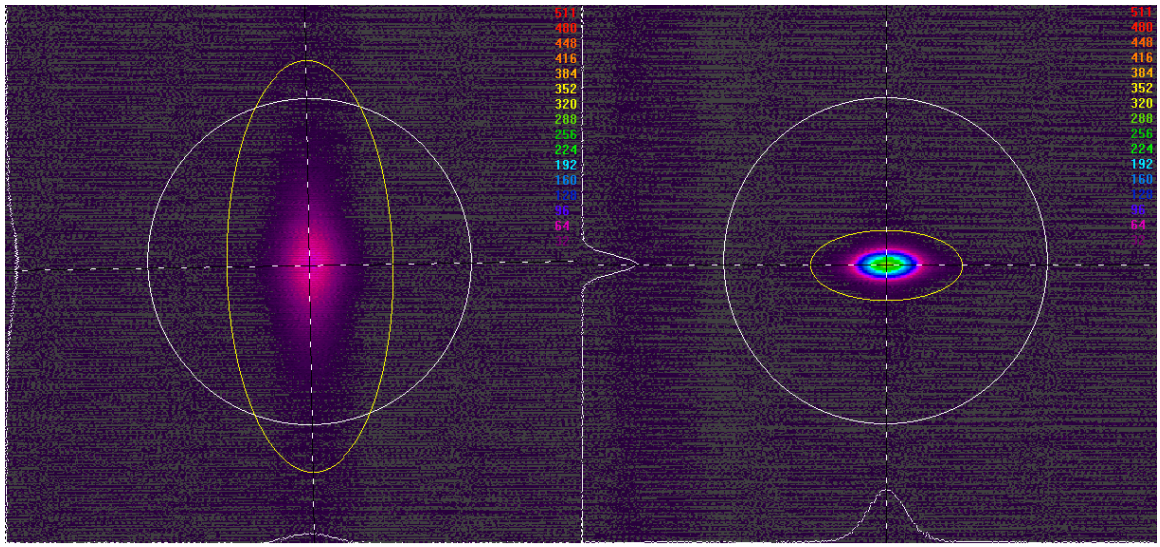

Figure 3: Transverse beam profile without/with TFB.

Orbit Correction

Due to the inherit stability of the machine CLS a fairly slow Matlab orbit correction scheme meet our initial needs. CLS is now in the process of commissioning a faster orbit correction system based on RTEMS.

CONCLUSION

Driven by the need to meet evolving requirements for increased machine reliability, availability and reproducibility we are undertaking a series of upgrades to the CLS accelerator control system.

Abstract

The Accelerator Control System at Fermilab has evolved to enable this relatively large control system to be encapsulated into a "box" such as a laptop. The goal was to provide a platform isolated from the "online" control system. This platform can be used internally for making major upgrades and modifications without impacting operations. It also provides a standalone environment for research and development including a turnkey control system for collaborators. Over time, the code base running on Scientific Linux has enabled all the salient features of the Fermilab's control system to be captured in an off-the-shelf laptop. The anticipated additional benefits of packaging the system include improved maintenance, reliability, documentation, and future enhancements.

INTRODUCTION

The Fermilab control system [1] [2] has never been packaged for utilization by other institutions. When it was needed at remote sites, a special effort was made to provide an autonomous system with an umbilical cord to Fermilab to ease maintenance and operation. Until recently, there was never a need for a stand-alone implementation at an isolated site. New facilities [3] for accelerator R&D, collaboration with other institutions, remote experimental sites, and the desire to test new functionality in an isolated environment suggested the demand for packaging the Fermilab control system. The package with evolving enhancements is known as ACSys (Accelerator Control System) and has been demonstrated to run on a laptop.

REQUIREMENTS

This implementation is not intended to run on all operating systems and processors. The approach is to build for a rich environment while keeping the configurations manageable. Thus, a laptop running Scientific Linux is the foundation for a "single-box" solution. Additional "boxes" can be added as needed to interface hardware, increase the capability or isolate systems utilizing Scientific Linux or a vxWorks framework. Currently, Sybase is the supported database architecture.

PROCESS

The original goal was to provide a minimal control system implementing only the bare essentials. This reduced system was built on a Fermilab "standard-issue" laptop utilizing a scripting language, a device-only database, and a local front-end for data acquisition. While this version brought in much of the infrastructure, it left many desirable features out of the implementation.

The gradual extension of the goals evolved into a full-featured control system analogous to the existing Fermilab control system. The work to minimize the system proved to be more time-consuming in the long run and was not capable of maximizing the potential of the system. A full implementation enabled a platform for testing enhancements and provided an autonomous control system at remote locations.

ACSys is effectively the Fermilab control system with the ability to redirect the resources to coincide in a single instance. For protection of the existing control system, a unique IP port was used for communication. Also, distinct multicast addresses were used for various services such as state transitions and event notification.

COMPONENTS

ACSys is a tiered implementation (refer to Fig. 1.) It consists of a console tier for applications and displays; a central services tier for database, logging, save/restore, data consolidation and alarms; and a front-end tier for data access and control. These tiers are logical and can be associated with one or more physical pieces of hardware.

ACSys is a layered protocol (refer to Fig. 1.) Their is a peer-to-peer messaging protocol tunnelled on UDP/IP. This protocol is then used by several data acquisition protocols for reading and setting data, plotting data in real-time, and triggered data snapshots. Alarm handling involves another protocol providing unsolicited event and exception notifications.

Implementing layered protocols enables many implementations to coexist. For instance, data acquisition can be accomplished with multiple protocols in the same architecture. This enables the adiabatic evolution of enhancements without imposing change to stable or critical systems.

Console Tier

The console is a X-based server/client of displays and a client for data manipulation. These displays can be implemented in C++, Java, a drag-and-drop graphical display manager (Synoptic [4]), Web-based, or with a scripting language (ACL). The console optimizes data acquisition with a data pool manager for several console instances.

†Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.

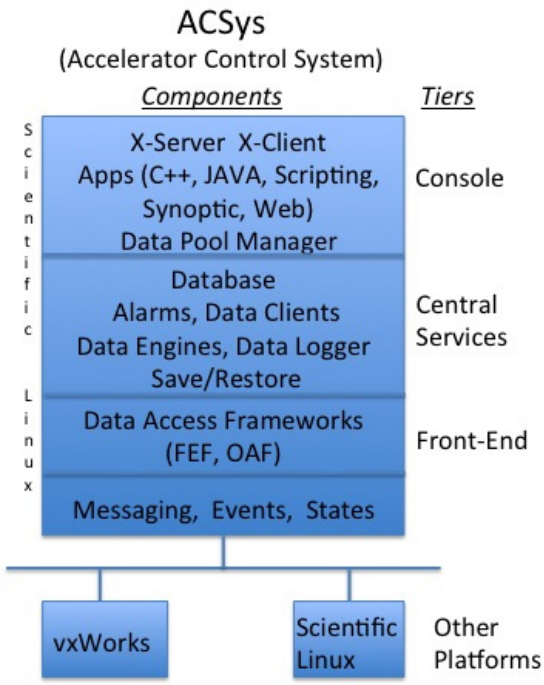

Figure 1: ACSys Configuration.

Central Services Tier

The database is a key component of the central tier. Sybase has been utilized for many years and the system capitalizes on several Sybase features. These features have been enumerated and ACSys provides an excellent development platform for an alternative database in the future.

The alarms server is a central repository for all announced alarms. These alarms are then distributed to consoles for individually configured displays. The monitoring of alarm limits is performed by a front-end. An unsolicited message is sent to the server when the condition becomes either bad or good.

The central tier provides a data engine to efficiently acquire and distribute data to clients such as save/restore. These engines also provide the equivalent data pool manager for Java applications.

Data loggers also use the engines to acquire a list of devices based on time or event. The data logger provides an archival circular repository. The duration of the repository is based on frequency and size of the data.

Front-end Tier

Prior to this effort, a new front-end framework (FEF) was being developed. This framework is designed for Scientific Linux. The framework is written in Erlang with C++ interfaces and is functional. A more mature framework called OAF (Open Access Frontend) is written in Java and has been used primarily for software devices or calculations.

The FEF [5] and OAF architectures complement other frameworks operating in vxWorks. These environments can be added to the configuration with additional platforms (outside the box).

Global Services

Other pieces of the infrastructure exist in ACSys. A peer-to-peer messaging system provides protocol payloads between cooperating connected tasks. Also, by setting a registered device, a global state transition is announced over a multicast frame. Normally, a hardware clock synchronizes data and its collection by asserting events in a serial protocol. A software solution can provide similar functionality generating periodic, sequenced and one-shot events. Global event notification occurs via a multicast frame for either hardware or software generated events.

The components listed above are not an exhaustive list of all available implementations, but are distinguished as core components. These components are readily available at this time to the implementer.

RESULTS

This effort has resulted in a fully capable stand-alone control system. ACSys provides a collaboration infrastructure consistent with the global control system at Fermilab. ACSys provides a testing environment for control system and accelerator system development. ACSys can also provide an isolated control system for remote operation.

A potential candidate for adopting the control system is an evolving experiment at Fermilab. In this case, the experiment has an on-site and remote detector. ACSys has positioned itself as a viable system to support this experiment. The control system offers common support and development with Fermilab personnel at a time of dwindling resources.

Current R&D efforts at Fermilab are using the Fermilab control system. A successful collaboration should ensure future instrumentation and analysis can be accomplished with Fermilab supported tools. ACSys makes remote R&D for collaborators a reality. This reality will aid in integration into the on-site control system providing a more maintainable system.

There are other benefits. Developing a generic system forces an understanding of dependencies that are sometimes taken for granted. These dependencies evolve since our target is not to commercialize the system, but to build a system for our users at Fermilab. Targeting other uses forces a reflection on implementation choices.

There are future benefits. The ACSys meetings and discussions are useful to discuss new directions and development. The direction of the group is providing input to new requirements of the control system. Hopefully, this direction will evolve into an active global development for the control system. The packaging of a system implies the documentation must be enhanced. This additional requirement is always a desirable bonus.

REVOLUTION AT SOLEIL: REVIEW AND PROSPECT FOR MOTION CONTROL

D. Corruble, P. Betinelli-Deck, F. Blache, J. Coquet, N. Leclercq, R. Millet, A. Tournieux,
Synchrotron SOLEIL, Saint Aubin, France

Abstract

At any synchrotron facility, motors are numerous: they are the significant actuators of accelerators and the main actuators of beamlines. Since 2003, the Electronic Control and data Acquisition group at SOLEIL has defined a modular and reliable motion architecture integrating industrial products (Galil [1] controller, Midi-Ingenierie [2] and Phytron [3] power boards). Simultaneously, the software control group has developed a set of dedicated Tango [4] devices. At present, more than 1000 motors and 200 motion controller crates are in operation at SOLEIL.
Aware that motion control is important in improving performance, given that the positioning of optical systems and samples is a key element of any beamline, SOLEIL wants to upgrade its motion controller in order to maintain the facility at a high performance level and be able to respond to new requirements: better accuracy, complex trajectory and coupling multiaxis devices such as hexapods. This project is called REVOLUTION (REconsider Various contrOLlers for yoUr moTION).

CONTEXT AND HISTORY

Since 2003, the Electronic Control and data Acquisition group at SOLEIL has defined some standards (products and technologies) for motion control in order to provide high level support and maintenance while reducing costs.
One guideline is to prefer integration of industrial products rather than in-house development.

The challenge is to convince our internal customers that SOLEIL's motion control system can meet their specific needs with a ready solution.

The first implementation of this motion control system was done on LUCIA [5]; the first beamline of Soleil that was temporarily located in SLS [6] in late 2003. The first hardware and software prototypes were tested and debugged very early.

HARDWARE ARCHITECTURE AND PRODUCTS

To be modular and flexible, the hardware architecture of the motion control system is based on the following two principles. First the separation of control unit and power units, and then the use of standard signal exchanged between units, like a nerve impulse exchanged between the brain (control unit) and muscles (power unit). The motion units are packaged in a 19" rack that integrates industrial products. These racks specified by SOLEIL have the objectives of being easy to use, easy to maintain and cost-effective.

CONTROLBOX (the brain) integrates the Galil DMC-2182 8-axis industrial motion controller and provides easy to use connectors.

DRIVERBOX (muscles) integrates up to 8 Midi-Ingénierie boards dedicated to stepper motors.

VACUUMBOX (muscles) integrates Phytron power and control temperature boards, and is dedicated to stepper motors running in a vacuum.

SERVOBOX (muscles with a bit of mind) integrates a power board developed by SOLEIL and based on an Elmo [7] component: a numeric amplifier which manages a current loop. ServoBox is dedicated to servo motors (brushless and direct current). The prototype was validated in 2011

Today SOLEIL has standard hardware boxes able to control several kinds of motor: bipolar 4 phase stepper, brushless and DC. Theses boxes are also able to read several type of encoder: incremental (RS422/TTL signals), resolver, absolute SSI, and absolute analog.

Furthermore the flexible architecture could be connected to other technologies like 3 or 5 phase stepper motors, ceramic (piezo) actuators or sin/cos encoders via an interpolator.

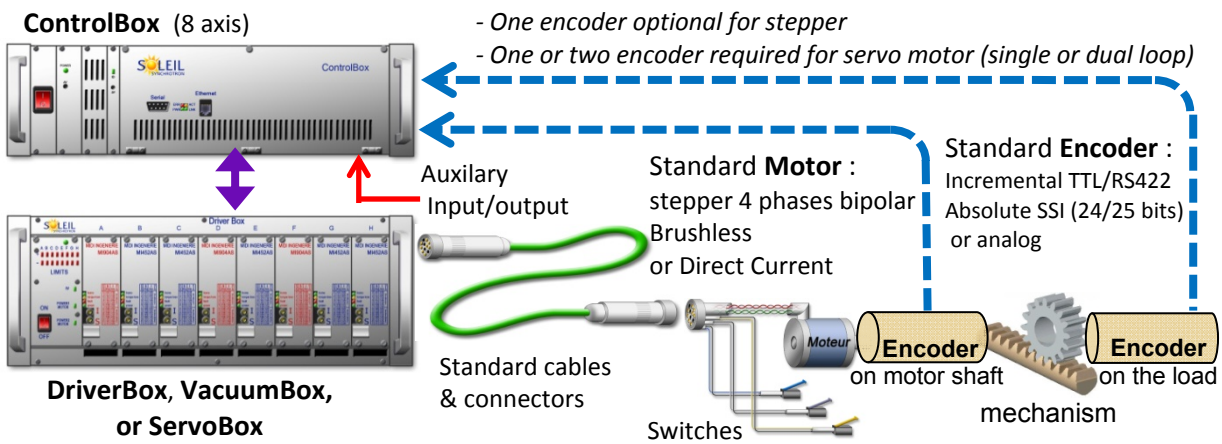

Figure 1 : Hardware architecture, standardized technologies and products.

To extend the range of supported technologies and add new features, a few years ago SOLEIL developed a flexible encoder tool in a SOLEIL proprietary format board [8]. The processing of encoder signals by a FPGA is used by example for encoder protocol transfer, encoder signals adder, complex trigger, etc.

SOFTWARE ARCHITECTURE: MULTI-LAYER PROCESSING

Motion control features are shared between embedded software in motion controllers and Tango [4] devices distributed on many servers.

Embedded Software in Motion Controllers

The firmware is provided by the controller manufacturer: Galil. It includes options for SSI encoders and for specific control loops dedicated to ceramic motors.

The microcode is developed by SOLEIL in a Galil proprietary language. Its first feature is to manage data exchanged with Tango device servers, including concentration of data and filtering all access by the device to the hardware functions. The second feature is to embed low-level motion processes as a discontinuous closed loop for stepper motors with backlash and progressive approach, static and dynamic error compensation, a multi-sensor homing process, and so on.

Theses functionalities can be completed by specific processes dedicated to specific applications especially for security of equipment. For example:

- Speed loop for phase control of RF cavities.
- Limitation of the range of 3-axis tripods according to the signals of inclinometers.
- Management of the ratio between powered and rest time of ceramic motor under vacuum.
- Limitation of the difference in position between 2 axes of a mirror bender.
- Collision avoidance according to security equations of multi-axis positioners.
- Etc.

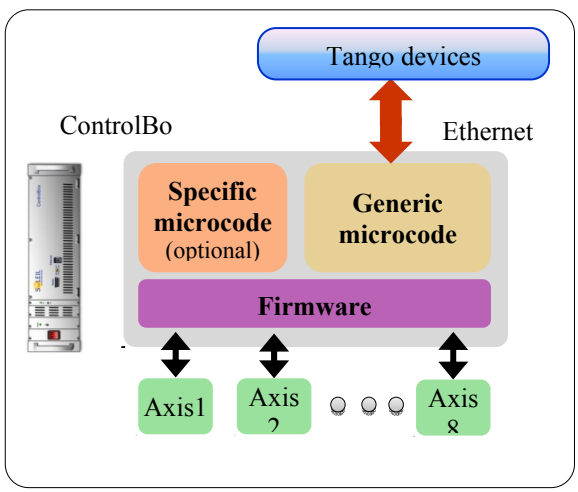

Figure 2: Embedded software architecture.

SOLEIL Motion Control Tango Devices Server

A set of motion control Tango device servers dedicated to our motion controllers has been developed in C++ by SOLEIL's Software Control and data Acquisition group. Binaries can run on Windows or Linux server.

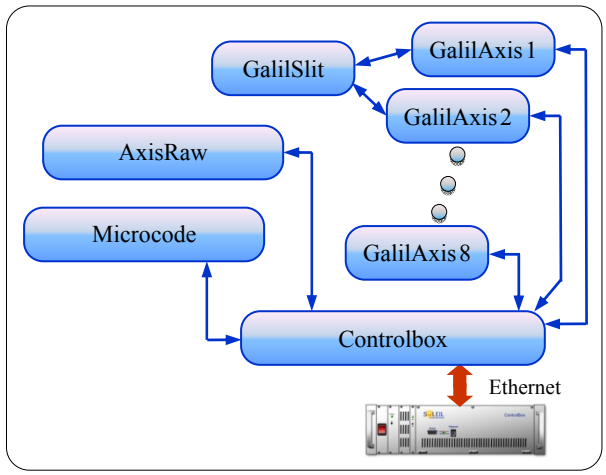

Figure 3: Tango devices servers architecture.

The lowest level and most essential device server is called ControlBox. It manages communication with hardware by TCP/IP protocol and provides data used for other devices. The GalilAxis device is a software object which represents a real motor. The device interface (properties, attributes and commands) is limited to simplify use. Multiple configurations and complex settings are hidden and not directly accessible to this software level. The GalilSlit device manages a pair of axes and supervises the master/slave relationship managed by hardware. It offers Gap and Offset attributes. The AxisRawDataReader device is a specialist device. It provides expert data from hardware, such as Tango attributes (read/only). Finally the MicrocodeDataViewer device provides access to variables of specific microcodes. It is used for supervision.

CURRENT RESULTS

Quantitative Results

Today the installed base of standard motion control equipment is wide and quite homogenous. It is broken down to around 15% for the machine and 85% for beamlines. As of May 2011, 1183 stepper motors controlled by 220 ControlBox and roughly as many DriverBox or VacuumBox units are operational at Soleil.

Furthermore 107 non-standard axes, like stepper 5 phases, ceramic and brushless motor (installed before ServoBox was in operation) are driven by 35 non-standard power racks, but they are controlled by ControlBox.

However, this is not the case for all motors. 37 mechanical devices with 244 axes are fully non-standard. They are mainly distributed in motorized magnetic insertion devices, diffractometers and hexapods. The reasons for this non-standard hardware, are firstly because

the control group did not have an effective solution when the equipment was chosen and also that manufacturers refuse to guarantee the performance of equipment if their own motion control system is not used.

Qualitative Results

Currently the initial objectives have been achieved and the motion systems work. Costs are controlled. There is no delay in providing working systems. The hardware components are reliable. Very little equipment is returned to the supplier. Software is efficient and reliable. Interventions relating to motion control during operation are very few. Performances are sufficient today for almost all applications.

Standardization has been largely successful. However, do not fall asleep and remember that future results get ready today: the revolution is coming…

MOTION CONTROL PROSPECTS: A REVOLUTION

Need to Upgrade: Birth of a Revolution

Firstly Galil released a new generation of motion controller (Accelera products) in 2009, so our standard controller belongs to the previous generation and has been produced for 8 years. It will be discontinued in a few years, but when?

Secondly, new motion control applications become more complex and demand more performance. Some examples:

- Hexapod platforms are more and more used in radiation facilities. They require control of complex multi-axis trajectories and calculation for kinematic equations.

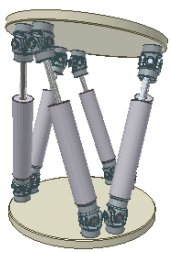

Figure 4: View of Stewart Hexapod platform.

- Nanopositioning: be able to position an axis to within few nanometers and keep this position by compensating for external disturbances, by using external sensor (e.g. interferometer). This requires fast and powerful calculations and openness to new technologies.
- Synchronization: be able to synchronize several axes and sensors to perform a continuous scan over complex trajectories. This requires fast signal processing calculations

So in the future, to preserve the use of standardized products, these products need to be improved. That means the next standard controller must be faster and more powerful in calculation and provide new features. SOLEIL must consider the next standard controller today.

A Technical Collaboration and a Founding Event

MAX IV [9] is the next Swedish radiation facility. The construction has just begun, the first beam is planned in 2015. MAX IV needs to define an up-to-date motion system architecture and select a controller quickly and efficiently.

SOLEIL and MAX IV have similar motion controller requirements: reliable, high performance and flexible, and they have similar guidelines too: minimal or no in-house development, standardization of hardware, modular solution, ready to use and complete solution

Consequently SOLEIL and MAX IV started a new technical collaboration to work together on this. This collaboration is called REVOLUTION, an acronym of REconsider Various contrOLlers for yoUr moTION.

In mid May 2011 SOLEIL and MAX IV organized a workshop "Exchange around motion control in radiation facilities". It was the founding event of the REVOLUTION project. 20 participants from 7 European facilities discussed an overview of motion systems in synchrotron facilities: status, main issues and plans

Figure 5: Map of radiation facilities participating in the motion control Workshop in May 2011.

The main results of the workshop are a written summary of thoughts [10], a creation of a dedicated mailing list "MOtion control Community in RAdiation Facilities" [11] and a principle of organizing a workshop every second year. The next motion control workshop will be hosted by the DIAMOND [12] facility, in the UK.

Some Guidelines of the REVOLUTION

The REVOLUTION's objective is to provide a complete ready-to-use solution for motion control. The main steps and deliveries of the project are clearly defined. The first and essential step is the selection of an industrial motion controller as a new standard. This controller will be integrated into a crate. After the design of the crate, an industrial company will be selected to manufacture it.

Another significant part relates to software developments: embedded software in the controller and Tango devices. The last step is about technical training for staff and writing technical documentation

The scoping of the project defines Rebox as the name of the next motion controller together with its crate. The capacity to replace any ControlBox by Rebox, and therefore backward compatibility of technical specifications (e.g. connectors) is a major principle. Finally the new features expected of the Rebox are set in the short, medium and long term (e.g. support of sin/cos encoder signals, extended auxiliary internal or remote I/O, etc.).

CONCLUSION AND PERSPERCTIVES

Although based on positive results in quality and quantity, the need for improvement of motion control systems is essential to maintain the SOLEIL facility at the highest level of performance. This need to obtain an efficient, complete and ready to use system is shared with the MAX IV facility under construction. REVOLUTION, the technical collaboration born from the common need will share costs and good ideas.

REVOLUTION is already underway. Starting from the motion control workshop, through the loan of equipment and skills with Swedish partners and continuing with a study of available controllers and detailed evaluation of some, the road is still long but major steps are defined to achieve the goal.

GDA AND EPICS: WORKING IN UNISON FOR SCIENCE DRIVEN DATA ACQUISITION AND CONTROL AT DIAMOND LIGHT SOURCE

E. P. Gibbons, M. T. Heron, N. P. Rees
Diamond Light Source, Oxfordshire, United Kingdom

Abstract

Diamond Light Source has recently received funding for an additional 10 photon beamlines, bringing the total to 32 beamlines and around 40 end-stations. These all use EPICS for the control of the underlying instrumentation associated with photon delivery, the experiment and most of the data acquisition hardware. For the scientific users Diamond has developed the Generic Data Acquisition (GDA) application framework to provide a consistent science interface across all beamlines. While each application is customised to the science of its beamline, all applications are built from the framework and predominantly interface to the underlying instrumentation through the EPICS abstraction. We will describe the complete system, illustrate how it can be configured for a specific beamline application, and how other synchrotrons are, and can, adapt these tools for their needs.

INTRODUCTION

Diamond Light Source has developed a beamline automation system that combines the low-level control system EPICS with the high-level data acquisition system GDA. This combination is used on the majority of beamlines at Diamond and has proven to be very successful at enabling scientists to maximize the quality and quantity of the wide range of science being performed. Use of the system results in a seamless experience for visiting scientists; from applying for beam time to having easily available data, be it raw, reduced, or partially analysed. The system design is such that changes in requirements can be accommodated in a timely and efficient manner. Both EPICS and GDA are open source projects allowing Diamond to benefit from development in both by third parties.

SYSTEM CONTEXT

The detailed description of the system begins with the generalised context diagram, shown in Fig. 1.

Scientist

Scientists interact with the system by reference to scientific properties of the experiment, such as the energy of the photons of the beamline. Scientists define experiments, run scripts and analyse data recorded. They do not have access to all low level details of the beamline.

Engineer

Engineers need access to all low level details of the beamline for commissioning and trouble shooting. The interaction is real-time in nature.

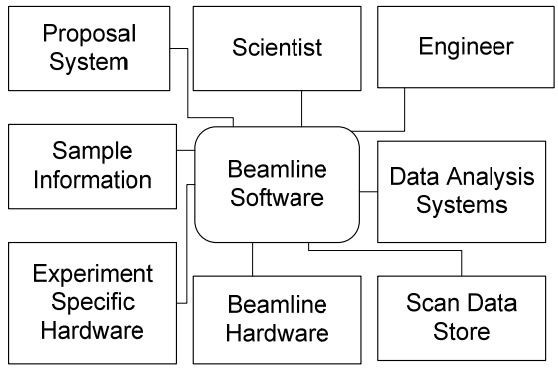

Figure 1: Context Diagram.

Data Analysis Systems

In order to aid scientists to make best use of time at Diamond great emphasis is given to providing on-site analysis of data. The aim is for this to be done automatically and the results fed back to the scientist as soon as possible.

Scan Data Store

The output of all scans is stored in a centrally available store. The store may also contain the results of any analysis performed on the data during the visit.

Beamline Hardware

This item encompasses all Diamond hardware on the beamline, as opposed to hardware brought by scientists for particular experiments. Hardware that is normally scanned or monitored during an experiment includes intelligent motor controllers, high speed 2d detectors and sample mounting robots.

It is important to note that for performance reasons some high speed detectors write directly to the Scan Data Store.

Experiment Specific Hardware

For some experiments scientists will make use of specialised equipment that is not normally on the beamline. Such equipment acts under control of the scanning mechanism of the beamline software. The beamline software has to be able to accommodate such additions in a timely and efficiently manner.

Sample Information

High level automation requires use of Sample Information systems containing details of samples and their locations in sample mounting robots. This information is presented to the scientist to aid automatic data collection, and linked to data to aid analysis.

Proposal System

This is Web based system used by potential users to request time on a beamline. The automation system uses this to check that a user is to be granted access to the beamline.

SOFTWARE DESCRIPTION

Figure 2 is a first level breakdown of the Beamline Software.

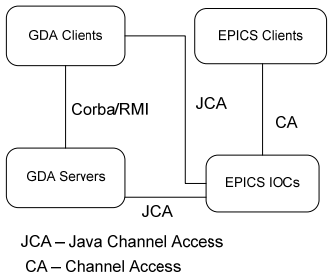

Figure 2: First level breakdown of the Beamline Software.

GDA Clients

Scientists interact with the beamline using the GDA Client program. This GUI is a Java application built using the Eclipse Rich Client Platform. It contains panels allowing the user to:

- Issue individual commands to perform actions. The command set is extremely diverse. A simple command would be to request the value of a variable, such as temperature readout. A complex command would be to execute a multi-dimensional scan of physical properties of the beamline resulting in measurements of multiple detectors and creation of a Scan Data file.
- Issue commands to execute a script file containing multiple commands. The script file can contain a simple list of commands or Jython programming language statements allowing the scientist to create complex sequences.
- Edit script files.
- Define scans using technique or even beamline specific GUI panels.
- View the results of scans and perform rudimentary analysis.
- Initiate science specific analysis of data.
- View results of automatic analysis of data.
- Perform technique specific actions using specific GUI elements, e.g. sample alignment.
- View the state of currently running measurements.

EPICS Clients

Engineers interact with the beamline using the EPICS clients, such as graphical user interfaces, which at Diamond are predominately EDM screens. EDM allows the beamline scientist or engineer to set and monitor values in the IOCs. EPICS archival and alarm handling systems are also used.

GDA Servers

The GDA Servers have several important features. Firstly the conversion between the engineering and scientific aspects of the beamline; this conversion is being represented by a set of Scannables and Detectors. Secondly a comprehensive and extensible scan mechanism for scanning such Scannables and Detectors and creating scan data files. Thirdly scriptable control of server objects via a Jython interpreter. The server can contain any additional Java objects one may want for a particular beamline; such as interfaces to hardware not supported by EPICS.

EPICS IOC

The EPICS IOC provide the majority of the hardware abstraction layer in the system, and specialised modules that are used by the GDA to provide important data acquisition tasks.

GDA AND EPICS IN UNISON

Given the very generic nature of GDA and EPICS there are many ways in which the two can be combined to create powerful, flexible and user friendly data acquisition systems. In the following sections we will describe two such systems in use at Diamond.

RECIPROCAL SPACE TRAJECTORY SCANNING

Beamline I16 at Diamond Light Source contains a six circle diffractometer which allows the orientation of a sample and detector relative to the incident x-ray beam to be set with few constraints. Such an arrangement permits measurements to be made over a wide range of reciprocal space.

GDA currently allows for three types of scans; a simple step scan, a constant velocity scan or a trajectory scan. In a simple step scan a measurement of a detector is made at different fixed motor, or pseudo-motor, positions. In a constant velocity scan the motors move at a constant velocity and the measurements are triggered by an additional time frame generator. In a trajectory scan the motors move along a series of points and the measurements are triggered to coincide with when each point is reached.

As well as performing scans of the six independent axes of the diffractometer, scientists need to scan in other space coordinates such as reciprocal space. A simple step scan through a number of points in reciprocal space is performed by the general purpose GDA scan command given in Fig. 3.

```
scan hkl [0 0 1] [0 0 1.1] [0 0 0.01] det1 0.1 peak2d
```

Figure 3: GDA command to perform a simple step scan through reciprocal space.

In the command the term ‘scan’ is the name of the command; ’hkl’ is the name of the object that represents a position in 3 dimensional reciprocal space; the 3 variables following ‘hkl’ represent the start, end and step size values of ‘hkl’ in the scan. The step size variable is followed by the name of the detector to be measured at each point in the scan and the exposure time per point. In this example the detector generates a 2d image; the final argument in this example is a pseudo-detector that analyses the reading from the 2d image and reports back the parameters of the analysis.

The system that relates hkl to diffractometer angle is called DiffCalc. Although built to work with the GDA scanning system DiffCalc can be used independently of GDA [10].

At each point in the scan the hkl object is asked to move to a new position represented by the tuple [h, k, l]. From these values the hkl object calculates the positions needed for the six axes and sends them as a single move command to the individual EPICS motor records in the appropriate IOC. Once all motors have moved the scan command then instructs the detector to read for the given exposure. After the exposure the value of hkl and the data from the detector are written to a scan file.

Trajectory scans are preferred to step scans as the former involve less time starting and stopping of motors. However trajectory scans need to be performed using low level motor controllers and involve hardware triggering of detectors and some form of data storage system. On the face of it, making a system for scientists to perform either scan from very similar generic commands would seem a daunting task; but given the design of the GDA scan mechanism this has been relatively straightforward.

To perform the same measurement as a trajectory scan the user simply replaces the term ‘scan’ in the command shown in Fig. 3 with ‘trajscan’.

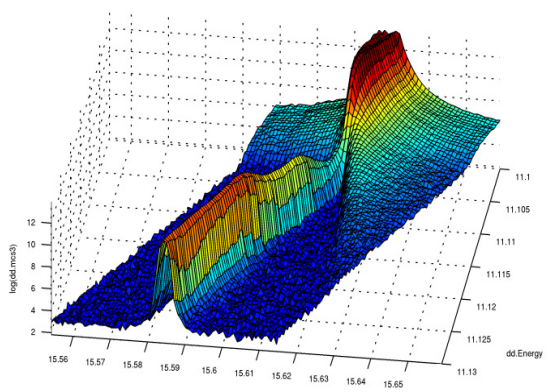

Figure 4: Detector readings from a trajectory scan of angle eta repeated for different incident photon energies.

In this case, rather than sending move commands to the six Epics motor records during the scan, the whole trajectory is calculated and sent to the related Epics TrajectoryScan [11] interface at the start. The Epics Trajectory Scan interface relays the trajectory to a program in the underlying intelligent motor controller. Once the scan is started the motor controller is responsible for sending the trigger pulses to the detector; GDA simply monitors the state of the detector as the scan proceeds. Whenever a new reading from the detector has been made the pseudo-detector peak2d fits a 2d Gaussian to the image and reports the size, position and sum over a region of interest. All of this data for each point is written to the scan file. Certain parts of the data are displayed on an XY plot in the GDA client.

Figure 4 displays actual results from using a trajectory scan of angle eta repeated for different photon energies. In this case the single channel detector was connected to a multichannel scaler with the motor controller’s at position signal connected to the channel advance source. GDA scanning is multi-dimensional which allows for the whole dataset to be taken by a single trajscan command.

Note that the trajscan command works with any scannables and detectors that implement particular Java interfaces. Also the list of detectors that can be read at each point is only limited by the particular hardware configuration. In addition the format of the data and how that is written is not limited. On I16 the Pilatus detector writes its image directly to the Scan Data Store and GDA simply records the filename in the scan data file along with the hkl values and the values from the analysis pseudo-detectors. On other detectors the whole image could be read by GDA and written directly into the scan data files. The scan data file format at Diamond is currently either a GDA specific ASCII format or, more commonly, Hierarchical Data Format (HDF5) compatible with the Nexus standard.

TIME RESOLVED 2D SCAN

Beamline I22 is a non-crystalline diffraction beamline at Diamond Light Source. A typical experiment on I22 involves recording a sequence of scattering patterns from a collection of detectors. The timing of the individual detector exposures is controlled by a time frame generator (TFG). For further complexity the whole sequence is repeated over a grid of positions of a sample.

Most of these detectors on I22 are connected to GDA directly. However a recent addition is a Pilatus detector that is interfaced to GDA using the EPICS AreaDetector system [12].

Once the TFG has been programmed via the GDA GUI the whole time resolved grid scan is performed by the single command shown in Fig 5.

```
scan px 0. 10. 1. py 0 10. 1. ncd
```

Figure 5: GDA command to perform a 2d scan of two motors, px and py, taking data from the detector system, ncd, at each point.

In the command in Fig. 5 px and py are ScannableMotors that control the x and y position of the sample and ncd is the detector system. Note that the ncd object starts the TFG for each value of px and py, and reads all the frames that are triggered by it.

The output of this command is a combination of 2 files. The first file, the so called master, is created by GDA, is compatible to the Nexus standard and is in HDF5 format. It contains the metadata for the scan, the positions of all scanned motors and the data from the directly connected detectors. The second file contains the Pilatus image data written by the HDF5 writer AreaDetector plugin; it too is in HDF5 format. The HDF5 writer plugin writes the data with a dimensionality that matches that of the data in the master file. By putting an external link to the second file in place of the Pilatus data in the first, Nexus compatible readers read the data in the second as if it were within the first.

HDF5 AREA DETECTOR PLUGIN

The use of the EPICS HDF5 AreaDetector plugin is proving very useful at Diamond, not only can much higher frame rates be achieved when writing to a single HDF5 file than the traditional approach of a single file per image, but the read rate is also improved.

CONCLUSION

The combination of GDA and EPICS has proven to be highly successful at providing flexible, powerful and user friendly data acquisition systems for beamlines at Diamond Light Source.

GDA is an open source project that is under continual development and welcomes collaborators. The www.opengda.org website provides downloads and documentation to aid evaluation by those considering its adoption.

ACKNOWLEDGEMENTS

GDA is primarily developed and supported by the Diamond Light Source Data Acquisition and Scientific Computing group. The EPICS system at Diamond is developed and supported by the Diamond Light Source Controls group. The following members of the two groups are acknowledged particularly: Mr R Walton and Dr M Pearson for the I16 trajectory scan; Dr T Richter for the I22 time resolved 2d scan; and Mr U Pedersen for the HDF5 AreaDetector plugin.

TANGO COLLABORATION AND KERNEL STATUS

E. Taurel, ESRF, Grenoble, France on behalf of the Tango community
ALBA, DESY, ELETTRA, ESRF, FRM-II, MAX-LAB, SOLEIL

Abstract

This paper is divided in two parts. The first part summarizes the main changes done within the Tango[1] collaboration since the last Icalepcs conference. This will cover technical evolutions but also the new way our collaboration is managed. The second part will focus on the evolution of the so-called Tango event system (asynchronous communication between client and server). Since its beginning, within Tango, this type of communication is implemented using a CORBA notification service implementation called omniNotify. This system is being re-written using zeromq as transport layer. The reasons for the zeromq choice as well as a first feedback of the implementation will be given.

WHAT IS TANGO?

Tango is a control system tool kit developed by a community of several institutes. It is object oriented with the notion of devices (objects) for each piece of hardware or software to be controlled. Each device is an instance of a Tango class. Each Tango class is hardware or software specific. Tango classes are merged within an operating system process called a Device Server. Device configuration parameters and network addresses are kept in a database or in a file. Three types of communication between clients and servers are supported: synchronous, asynchronous and event driven.

KERNEL LIBRARIES

Since the Kobe conference, Tango has had 3 kernel library updates. The first release (Tango 7.1.1 in November 2009) was a minor changes and bug fixes release.

The second one was the release 7.2 in October 2010. The main change in this release is the thread safety of the client part of the Tango API. This means that you can share a C/C++ pointer to DeviceProxy instances between different threads. DeviceProxy is the name of the main Tango API client part class. Much faster algorithm when a device server process is shutdown was implemented. Another change is that an application (client) is now able to subscribe to the same event several times.

Then in March 2011, we had release 7.2.6 which was again a minor changes and bug fixes release.

PACKAGING, GUIS AND OTHER

Since several releases, Tango kernel libraries and basic tools are available for Linux via a source code distribution. It is based on classical GNU Autotools and allows a user to build and install the Tango control system with the standard configure / make / make install commands. For Windows, we provide a binary and ready to install distribution. Since several months, we have a binary distribution available for Linux as well. It is based on the Debian packaging system. The classical source distribution has been split into two source packages (for licensing issue related to our Java CORBA Object Request Broker) and 19 binary packages including documentation and debug packages. All these packages are available for Debian and Ubuntu linux flavours. For Ubuntu, a launchpad Personal Package Archive (PPA)[3] has been created making the Tango installation process a matter of a few clicks. The next Ubuntu release available end of October 2011 will natively incorporate these Tango binary packages in the Ubuntu Software Center.

Tango support three languages to write clients and servers. These languages are C++, Java and Python. We also have Graphical layers for these three languages. Since the very beginning of Tango, we have a Java layer called ATK (Application Tool Kit). This layer allows Java Swing application development with widgets (Java beans) interfaced to Tango objects (device, command or attribute). ATK is continuously developed by adding new widgets adapted to requests regarding graphical application development. We now have another Java GUI layer named Comète. It is developed by our Soleil colleagues. This layer opens the data source to something else than Tango objects. Using Comete, it is possible within the same application to get data coming from live Tango devices, but also from the Tango history database (Hdb) or from data files. See mini oral WEMAU012 for more informations on this subject. A C++ graphical layer named Qtango[3] and based on Qt[4] is also available. It is actively developed by Elettra and a online GUI development tool has been added recently. See poster WEPKS022. Finally, a Python layer named Taurus[5] is in active development at the Cells-Alba synchrotron. It is based on PyQt and is fully integrated in the Qt designer tool.

Our code generator named Pogo is since its major release 7 based on a Domain Specific Language (DSL) using the Xtext[6] and Xpand[7] technologies. It is now routinely used to create / update C++ Tango classes. Nevertheless, this tool in its release 7 does not support Python or Java Tango classes. You still have to use the previous Pogo release 6 in these cases.

Since the very beginning of 2011, the Tango security system is routinely used to protect the ESRF machine control system. This allows safer routine operations of the accelerator complex.

The Tango archiving service is actively developed and is now used in several institutes. See poster MOPKN016 for more information on this subject.

COLLABORATION MANAGEMENT

With the increasing number of collaborators using and/or developing Tango, it was becoming difficult to take decisions regarding its evolution. This could become a major problem in the near feature if nothing was done. Therefore, the rules governing our collaboration have been re-discussed and refined. We now have a new release of our Memorandum Of Understanding (MoU)[8]. Three types of collaborators are now defined. The first type are collaborators who do not sign this MoU. Not signing the MoU means that the institute (or individual) is not part of the Tango management board and does not have a right to vote on Tango issues. They are Tango users. The two other types of collaborators are the so-called contributors and committers. The committers contribute resources to the collaboration. The contributors can propose code modifications to the committers for Tango core issues and /or submits Tango device classes to the public repositories. Today (October 2011), we have 4 committers and 3 contributors.

All the strategic decisions about Tango development are now taken by an executive committee. This committee has one member for each institute who has signed the MoU (committers or contributors) plus a "collaboration coordinator". If there is no common agreement between all the committee members on a particular subject, decisions are made by voting. To take a decision, a 2/3 majority is required. Each committee member has at least a weight of 1. An extra vote is acquired for members representing committers institute.

The collaboration manager does not have voting right. His rule is to chair the executive committee meeting, to inform the collaboration of the strategic decisions made during the meetings and to discuss with Tango related project leaders matters like schedule and resources. A Tango executive committee meeting is organized at each classical Tango collaboration meeting. Examples of decision taken by this committee are:

- Tango is no more supported on Solaris platform
- The Source Code Management system used in public repositories related to Tango has to be SVN.
- The new Tango event system will be implemented using the zeromq software
- A list of 9 kernel improvements (extracted from a list of 27) has been selected as having the highest priority.

ON-GOING PROJECTS

On top of the classical evolution of the software already developed around Tango, we have several new projects in their development phase.

On the Java side, our colleagues from Soleil decided to take over the rewriting of the kernel part used when writing Java Tango class. Before this Soleil decision, we did not have the necessary resources within our collaboration to develop and maintain the Tango framework for our three languages at the same level. New features are implemented first in C++. Tango in Python is a layer above the C++ implementation and therefore benefits from the new C++ features with little effort. Java is an independent development and Tango kernel used in Java Tango classes were several major releases late compared to C++ and Python. The new development uses new features added in Java 1.5 like annotations which we hope will made the maintenance of this project less time consuming.

As already explained, the new major release of our code generator is not able to generate Java or Python code. Once the development concerning Java Tango classes will be finished, the code generator will be updated. For Python, more thinking has to be done about the best way to integrate this language in the code generator.

With the always increasing number of features incorporated within Tango, it was more and more difficult to achieve a good level of stability when a new release is introduced. To address this problem, we are now doing Continuous Integration using Jenkins[9]. The tool is configured in a way that as soon as we commit some changes in the repository of Tango C++ kernel code, it generates 20 different flavours of the libraries on 5 Operating Systems (mainly Linux and Windows). Then it compiles 10 Tango classes and finally run our test suite on the 5 operating systems.

Our test suite were composed of two different parts:

- Several test cases developed using a home made test system
- Other test cases using shell script and small C++ software with classical assertions.

A new project is now well on its way to merge these two blocks of test cases in a single one using CxxTest. CxxTest[10] is a xUnit like testing framework for C/C++. By adding new test cases, we will also try to increase our test coverage of the Tango kernel libraries to something close to 75%.

The work needed to implement the 9 kernel improvements selected by the Tango executive committee has also started. Here are some examples of these nine tasks:

- The new Tango event system (detailed below)
- The test suite improvements (shortly explained above)
- The need to have Tango device attribute with enumerated data type
- Implement structures as possible data type for Tango device attributes. This is a limited definition of structure: Only one level (no structure as data member of a structure) and all data members have to be simple Tango data type.

RE-THINKING THE EVENT SYSTEM

The Tango event system is based on the CORBA notification service. When an event is detected (or thrown by the user code), it is sent to the notification service. Then, it is the job of the notification service to forward

the event to all the processes which have subscribed to this event. We are using the CORBA notification service implementation called omniNotify. We now have some experience with this architecture and the following drawbacks have been detected:

- In the case of several clients (event consumers) interested by the same event, the notification service forwards the event to each client using unicast network transfer. This can be a bottleneck in case of a large number of consumers and in case of events carrying large amounts of data (eg images)
- The event data are transferred using CORBA Any objects. This means that in term of performance, it suffers from the unavoidable memory copy due to CORBA Any usage
- In case of event supplier sending events at a high rate with events carrying large amount of data and several subscribed consumers, the notifd has to buffer the event data. This could easily leads to a large memory consumption in the notification service process.
- The omniNotify implementation we have selected is an open source software but it is a "dead" project.

ZEROMQ

After miscellaneous studies, decision has been taken by the Tango executive committee to do a re-factoring of the Tango event system based on zeromq[11] software. The main point leading to this choice are:

- The high level of performance given by zeromq
- Its simplicity in term of infrastructure required (no additional process, no shared memory usage)
- Its availability in many different languages
- The support of a multicast protocol

But what is zeromq? This definition is taken from the zeromq guide available from their web site: *0MQ (ZeroMQ, OMQ, zmq) looks like an embeddable networking library but acts like a concurrency framework. It gives you sockets that carry whole messages across various transports like in-process, inter-process, TCP and multicast. You can connect sockets N-to-N with pattern like fanout, pub-sub, task distribution and request-reply. Its asynchronous I/O model gives you scalable multicore applications, built as asynchronous message-processing tasks. It has a score of language APIs and runs on most operating systems. 0MQ is from iMatix and is LGPL open source*.

During the pre-choice studies, the Data Distribution Service (DDS)[12] was also a candidate. Tango is definitively Open Source and this limits the number of DDS implementations available. Even if the level of performance given by DDS is also attractive (but less than 0MQ), it has been judged as less simple for the end-user. The tested implementation requires several additional processes to run on each host where it is used which make the system heavy. It also uses shared memory which could be damaged in case of process using DDS crashes.

THE TANGO USAGE OF ZEROMQ

0MQ provides a way to transport your data but it does not address the problem of data formatting for communication between computers built on different architecture. For synchronous and classical asynchronous communications (not event driven), Tango uses CORBA which has a well defined Common Data Representation (CDR). If the data you want to transport are defined in a CORBA IDL file, all the Object Request Broker (ORB) compilers will generate methods to encode or decode your data to/from this CDR definition. Therefore, the CORBA CDR is the data encoding selected for the new Tango event system while the transport is done using 0MQ.

We also need to define which data has to be transferred between the event supplier and the event consumer(s) to implement a full features event system. These data have been grouped in four parts:

- A string describing the event type: This string is built from the fully qualified Tango device name, the device attribute name and the event type (eg: tango://host:port/the/dev/name/attribute_name.change)
- A single byte encoding the event sender host endianess
- Some call informations allowing the Tango software layer to retrieve which object / method has to be called on the event consumer side. These informations are mainly the receiving object identifier (global information for a whole Tango system) and the method name. As explained previously, these data are encoded using the CORBA CDR
- The event data themselves. These data are already defined in the Tango IDL file for the synchronous communication. These event data are sent on the wire using the CORBA CDR.

Due to this splitting, we are able to use 0MQ multipart messages with one message part for each data group. A 0MQ multipart message is an entity which is fully transferred or not at all. Either you receive all message parts or none of them. Each part of the multipart message is itself managed like a simple 0MQ message.

The event propagation between the event supplier and one or several event consumer(s) is implemented using the 0MQ pub/sub pattern. The event supplier (the Tango device server process) is the publisher while event consumers (the Tango clients) are the subscribers. When you have several subscribers connected to one publisher, it is the 0MQ layer which takes the responsibility to propagate the data to all subscribers. By default this is done using TCP unicast communication. 0MQ also supports a multicast transport using OpenPGM[13] which is an implementation of the Pragmatic General Multicast (PGM) protocol. PGM is a reliable multicast transport protocol. Using multicast to transport Tango event seems a natural way. Nevertheless, it needs to solve the multicast address problem. Every host belonging to a multicast group will receive all the events sent to this group. For

instance, if you have only one multicast address, all the hosts with publishers/subscribers processes will see all the events flying in the system. If some of the events carry large amount of data, it will rapidly become a performance bottleneck. Ideally, one multicast group (address) should be assigned to each event but this will lead to a very high number of addresses. In a more realistic world, the number of multicast addresses available is limited and you have to find an algorithm to spread your events in these multicast group. It's not at all an easy task and depends a lot on which kind of data are generated by the controlled equipments. The decision has been taken to, by default still uses TCP unicast transport for the event propagation. Nevertheless, a Tango control system administrator will have the choice to use multicast transport when tuning the control system. A Tango control system property (configuration data) is defined to specify multicasting usage. This configuration parameter contains the multicast address, the port number and the list of event (device name/attribute name and event type) which should be propagated using this multicast group.

With 0MQ pub/sub pattern, subscriber(s) must set a subscription. This subscription is used by 0MQ as a message filter. Subscription are length-specified blobs. By default, a subscriber filters out all incoming messages. When the subscription is defined, the subscriber receives only messages beginning with the specified subscription buffer. We are using the first part (fully qualified event name) of the multipart message sent by the publisher as the subscription buffer. Thus, a client will receive only the events it is interested in even if on the device server side, the same publisher is used to publish several types of events for several devices.

IMPLEMENTATION

On the server side, the implementation uses two publisher sockets. The first one is used to propagate the heartbeat event. This event regularly sent allows client(s) to know that the device server process is alive, The second socket is used for the real events publishing and is used for all event types for all devices hosted by the device server process.

On the client side, the implementation uses 3 sockets. The first one is a subscriber socket connected to the publisher(s) sending heartbeat events. The second one is the subscriber connected to the real event publisher(s). During Tango event subscription, this socket is connected to the publisher supplying this event and a new subscription blob is associated to this socket. The third socket is a 0MQ Request/Reply socket pair using in-process communication. The 0MQ Request/Reply pattern covers the classical case of one requester asking a service to do something and to send a reply to the requester. 0MQ sockets are not really thread safe. You can use them within different threads only if a full memory fence has been executed before its usage in another thread. The Tango API is thread safe. Therefore, we have to cover cases where several threads required Tango events subscription. As explained above, this requires some actions on the event subscriber socket. Therefore, the Tango event subscription is done via a Request/Reply socket couple with in-process transport.

We have selected release 3 of 0MQ because it implements subscription forwarding. This means that the subscription requests are forwarded to the publisher and the associated filtering is done on the its side. This leads to less network bandwidth usage and less CPU consumption on the subscriber side (client side).

0MQ is written in C/C++ but it's API is C. Nevertheless, a C++ binding is provided and used in the C++ Tango implementation. (thus also covering the Tango Python case). On Java side, 0MQ also provides a binding based on the Java Native Interface (JNI).

Some very preliminary performance tests have been done. The result are summarized in table 1. This is the number of event/sec for events carrying 1 32 bits integer and 1024 integers (32 bits as well) forwarded to 1 and 10 subscribers. Tests have been done using unicast transport. The publisher runs on a Intel core 2 duo at 2.6 Ghz. The subscribers run on a Intel P4 at 2.3 Ghz. The network bandwidth is 100 Mbit/sec.

Table 1: New Event System Preliminary Tests

	1 Long (32 bits)	1 K Long (32 bits)
1 Subscriber	25500	2150
10 Subscribers	2700	270

CONCLUSION

From the first part of this paper, it is clear that Tango is still evolving. The community still wants to improve it and the problem is not a lack of ideas on how it could be improved but rather a lack of resources to improve it. Concerning Tango event re-factoring, it is still too early to draw conclusions on 0MQ usage in a long term. Nevertheless, we now have in labs a Tango event system based on 0MQ. It gives a significant improvement in term of performances and allow Tango to be more user friendly by removing the need of one extra process (notifd) .

BLED: A TOP-DOWN APPROACH TO ACCELERATOR CONTROL SYSTEM DESIGN

J. Bobnar, K. Žagar, COBIK, Solkan, Slovenia

Abstract

In many existing controls projects the central database/inventory was introduced late in the project, usually to support installation or maintenance activities. Thus construction of this database was done in a bottom-up fashion by reverse engineering the installation. However, there are several benefits if the central database is introduced early in the machine design, such as the ability to simulate the system as a whole without having all the IOCs in place, it can be used as an input to the installation/commissioning plan, or act as an enforcer of certain conventions and quality processes. Based on our experience with the control systems, we have designed a central database BLED, which is used for storage of machine configuration and parameters as well as control system configuration, inventory, and cabling. The first implementation of BLED supports EPICS, meaning it is capable of storage and generation of EPICS templates and substitution files as well as archive, alarm and other configurations. With a goal in mind to provide functionality of several existing central databases (IRMIS [1], SNS db, DBSF etc.) a lot of effort has been made to design the database in a way to handle extremely large set-ups, consisting of millions of control system points. Furthermore, BLED also stores the lattice data, thus providing additional information (e.g. survey data) required by different engineering groups. The lattice import/export tools among others support MAD and TraceWin tools formats which are widely used in the machine design community.

INTRODUCTION

With the complexity of new machines growing, the complexity and size of the control systems also grows rapidly. Big machine control systems are normally distributed across several hundred I/O controllers, and each of them might run several different applications. In addition, the controllers are interconnected with numerous cables and to various kinds of equipment.

In such a large system it is recommended that an inventory of all the equipment and control points is maintained in a well organized structure, so that information is conveniently available. A good equipment and data management system can help during the design of the machine as well as developers and engineers during the development cycles. On the other hand the physicists and operators can benefit significantly from such a system during commissioning and operations.

BOTTOM-UP VS. TOP-DOWN APPROACH

Until today, several different systems have been set up in various laboratories around the world. Most of these systems are specific to each individual machine. They have usually been introduced late in the project, thus being created in a bottom-up approach: gathering all the information in the system and then the database was populated by reverse engineering the installation. Furthermore, the majority of the systems covers only one specific domain, such as for example inventory or lattice, depending on who initiated the use of the database and what stage the project was in at that time.

Having this in mind we wanted to create a general system, which would allow one to create the machine in a top-down approach, starting already in the design phase of the project and later being used during day-to-day operations.

This approach brings several benefits. Besides having a good overview of what has already been completed, it also allows simulating the system as a whole even before having all the parts in place. In addition, it can also serve as a data exchange system between developers and different types of development and design tools.

The database can serve as an input to the installation and commissioning plan. Well designed structure and tools can use the information about the machine and output it in a way required during each project phase. For example, at the very beginning it can be a powerful tool to enforce the naming convention for the whole facility, while later it can provide relevant data for engineers etc.

During the operational phase of the machine, the database serves as an image of the complete system and allows for an easy system-wide modification and change tracking of the installation.

MAIN OBJECTIVES

The first version of BLED was initiated by the European Spallation Source (ESS) [2]. ESS, currently in the design update phase, uses several different lattice design tools. Therefore, it was very inconvenient to share the data among the designers, since some use TraceWin [3] while others use MAD [4] as their lattice design tool. Having proper import/export tools for the database, the exchange of data can become much easier, because all users have access to all parts of the lattice design.

Beside the aforementioned benefits of top-down approach and data exchange, BLED shall also be used during construction to generate the survey data for engineers. Using the information that is provided by the lattice design tools, most of the required data is already

available and only needs to be exported in the appropriate way.

During control system development and operation the database stores the data for all the control points in the system and it is possible to generate configuration files for control system, such as EPICS db files or BEAST and BEAUtY XML configurations [5]. In addition to pure control system configuration, other system description files could also be obtained from the database (e.g. XAL XML configuration [6]).

The database can also be a valuable tool to non-engineering departments (e.g. purchasing department), which could use it to track the list of components that remain to be purchased as well as to keep track of the purchases (i.e. delivery dates).

Another important aspect of the database is the naming convention, which is advised to be introduced early in the project. Selecting and enforcing consistent convention presents a high organizational risk, because all teams must conform to the convention. With introduction of BLED, it is the database and the tools that will take care of properly named items and verify every entry.

DATABASE STRUCTURE

Database has been designed as a Java object model equipped with Java Hibernate [7] annotations. Once the model is created, Hibernate takes care of the construction of the complete database (and later communication), thus making the model completely independent of the underlying database technology. Initially ESS will use MySQL, but if at any later time a decision is made to switch to a different database, only the database driver needs to be replaced and Hibernate will generate a new database.

The database is designed to provide functionality to store the history of the entities, which are expected to evolve during development and operation. Every change in any of these entities is recorded in order to be able to at any time revert to a previous version.

Since no database can satisfy the needs of every user, special custom tables have also been defined, which can be used to create virtual tables and store additional data, which may not belong to any of the existing tables.

Current version of the database consists of approximately 60 tables divided into 6 packages.

The Main Package

The main object of the model is the *Subsystem*, which represents every single part of the machine, either be it a logical system such as the *Target* or a real system such as an *RF Cavity* or a *Beam Position Monitor*. The subsystems are organized hierarchically, where each subsystem can have none or several child elements. Within each single subsystem all children are sequentially ordered, considering their physical position in the machine. This allows for organizing all the accelerator components according to their location and/or functionality (e.g. *spoke* subsystem can have several *spoke cavities* subsystems as its children).

The Devices Package

Subsystem represents the base class for all components of the machine. Several other classes (e.g. *Magnets*, *Power Supplies*, and *Cavities*) that describe physical components are derived from this base class. These components form the actual machine. In case of the accelerator the devices within each parent subsystem are ordered either into the lattice (if applicable) or bound to a specific device, which they are related to (e.g. *Power Supply* is related to a *Magnet*, but is not a part of the lattice). Beside the machine related parameters, the database also contains information about the precise location and orientation of the components, allowing for generation of survey data or for simulating the particle beam.

The hierarchy of the components is such that one can easily add another type of device and create appropriate tables for it.

The Control System Package

Control system package defines all controls software related items. On one hand it provides the list of all control points, associated with appropriate subsystems, and on the other hand it provides information about installed configurations for archiving and alarm systems.

The initial version of BLED is primarily focused on the EPICS framework. Therefore, it contains the collections of all process variables, EPICS applications and templates, substitution values etc. as well as provides links to the versioning system (Mercurial), where the source code of the related software (i.e. device support) is located.

The Infrastructure & Deployment Package

All *IOControllers*, *Racks*, *Servers,* and *Computers* are also parts of BLED. Together with the infrastructure parts (*Room* and *Building*) they present the deployment view of the machine. The deployment view describes on which location and on which equipment the particular control system software is deployed.

The Wiring Package

Wiring is another important part of the installation. The database provides facilities to record each cable that connects any two ports in the machine. It is possible to define the type of the cable (including physical characteristics such as diameter) as well as the type of connector on all free ends of the cable. Not only linear (2-end cables) are supported, but also storage of Y or even more complicated cables is allowed.

The Parameters Package

Every machine or individual parts of it have certain characteristics, which are not physical descriptions of particular equipment, but represent higher-level information such as energy or minimum spot size on the target. BLED provides necessary tables to store such parameters and associate them with subsystems, responsible personnel, references etc. [8].

DATABASE INTERFACE TOOLS

In order to effectively manage and make the most use of the database, certain graphical tools will be developed. These tools will verify that each new entry in the database corresponds with the rules set forth by the designers. Using only such designated tools it will be assured that the database integrity is not broken during updates.

Besides the management tools, the system will also provide a set of tools necessary to generate particular configuration used either in the control system or any other part of the machine operation. Such tools represent the main interface to top-down development approach.

All management and configuration tools will be based on the web technologies (*Google Web Toolkit*). This will eliminate problems with running the software on different platforms as well as make it available to all registered users. Additional tools or updates to existing ones will not require users to do individual updates, since all the deployment will reside on the server.

Naming Convention Tools

Naming convention is an important issue, which has to be introduced early in the design of the machine in order to enforce it on every possible step. The naming convention tool will help the developers construct names for their control points so they will be in coherence with the facility-wide convention. The tool will allow the user to specify which subsystem a particular control point belongs to and suggest the appropriate name for it, based on the hierarchy of the subsystem.

Lattice Generators

During the design development of the machine several lattice design tools might be used. The interoperability of those tools is limited, because each of them works on special set of configuration files that are valid only for each particular design tool. In order to ease the process several parsers and data exporters will be created, which will parse these configuration files and import data into the database. Other users may then export the data into format understood by their preferred design tool.

Control System Configuration Management

ESS is estimated to have an order of one million control points. Construction and maintenance of such a large system can introduce significant problems if it is not managed and overseen properly. BLED tools will minimize these problems by verifying the completed work and help generating the missing parts of the system. Once the control points are defined, BLED will take care of generating configuration files for services (archive, alarm etc.), eliminating the risk of mistyping names or skipping a particular part of the system. Also, the effort required to do the task will be minimized.

At some time certain control points may change, effecting numerous configurations across the whole system. By having a well organized database, such cases can be easily spotted and all the necessary configurations would be regenerated.

Equipment Inventory

As mentioned before, BLED will also serve as the equipment inventory database. Therefore, tools will be created to allow editing as well as browsing and searching through the list of available equipment. It will display the details of each selected piece of equipment including its connections to other pieces of equipment and also allow tracking the location of the component.

Machine Parameters Management

Parameters management tools will assure that the parameters list is alive and that people responsible for each section will have access to the lists and be able to inspect and modify them [8]. Several criteria for searching the parameters will be established, such as for example subsystem or team criteria. In addition, facilities to export the data in various formats (Excel, PDF) will be provided.

CONCLUSION

Maintaining accurate information on several ten thousands of devices and a million control points can be a challenging work and cannot be done without proper tools. Therefore, a good management system needs to be installed and supported by extensive set of graphical and utility tools, which can save a lot of time and reduce risks.

ACKNOWLEDGEMENTS

We would like to express our gratitude to all the people involved on the BLED project, especially controls group at ESS, which was the main initiator of the project and funded the first developments.

WEB-BASED EXECUTION OF GRAPHICAL WORKFLOWS: A MODULAR PLATFORM FOR MULTIFUNTIONAL SCIENTIFIC PROCESS AUTOMATION

E. De Ley, D. Jacobs, iSencia Belgium, Ghent, Belgium
M.Ounsy, Synchrotron Soleil, France

Abstract

The Passerelle process automation suite offers a fundamentally modular solution platform, based on a layered integration of several best-of-breed technologies. It has been successfully applied by Synchrotron Soleil as the sequencer for data acquisition and control processes on its beamlines, integrated with TANGO as a control bus and GlobalScreen™ as the SCADA package. Since last year it is being used as the graphical workflow component for the development of an eclipse-based Data Analysis Work Bench, at ESRF.

The top layer of Passerelle exposes an actor-based development paradigm, based on the Ptolemy framework (UC Berkeley). Actors provide explicit reusability and strong decoupling, combined with an inherently concurrent execution model. Actor libraries exist for TANGO integration, web-services, database operations, flow control, rules-based analysis, mathematical calculations, launching external scripts etc.

Passerelle's internal architecture is based on OSGi, the major Java framework for modular service-based applications. A large set of modules exist that can be recombined as desired to obtain different features and deployment models. Besides desktop versions of the Passerelle workflow workbench, there is also the Passerelle Manager. It is a secured web application including a graphical editor, for centralized design, execution, management and monitoring of process flows, integrating standard Java Enterprise services with OSGi.

We will present the internal technical architecture, some interesting application cases and the lessons learnt.

INTRODUCING PASSERELLE

Passerelle[1] is a component-based solution assembly suite, developed and distributed by iSencia Belgium since 2002. It is based on an integration and on extensions of Ptolemy II[2] (Univ. Berkeley), OSGi/Equinox & other OS libraries. Passerelle comes with an execution engine, enhanced actor development API, reusable actor libraries and several graphical model editors.

Passerelle is already used for several years in "production-mode" at different sites. Two important reference sites are :

- Belgacom, the main Belgian telecommunication provider, where it is used to automate diagnosis and repair processes for the customer help-desk operators, and for field technicians.
- Synchrotron Soleil in France, where Passerelle is used as sequencing engine for beamline experiments.

Since last year, the core Passerelle modules are provided in open source, together with an eclipse-based graphical editor, at the eclipse labs hosted by Google.

ACTOR-BASED DEVELOPMENT

Passerelle inherits many core concepts from Ptolemy II, the main ones being :

- actor-based development
- using graphical hierarchical models for defining executable solution assemblies
- separation between the "topology" of the actor assemblies and their runtime semantics by picking alternative *Director* components

Passerelle/Ptolemy actors and sequences are a direct implementation of the well-documented *pipes-and-filters* architecture pattern, see for example [3]. Such an architecture promotes component-based solution designs with strong decoupling. Each actor in a complete process has a single responsibility that must be fulfilled based on data in messages received on the actor's input port(s). Results must be sent via the actor's output port(s).

Runtime semantics, or "models of computation", are determined through the usage of one of the "domains" provided by Ptolemy II. Passerelle is based on the *Process Networks* domain, which is a good basis for data-flow and process engines that internally require asynchronous behaviour and transparent actor-based concurrency.

Both actors and directors are implemented as Java classes, building on a rich API with base classes and utilities.

All of this results in a system that promotes designing and developing with reusability in mind. Actors are the basic level of reusable components and can be picked from actor libraries. There are actors for all basic flow control elements (branching, filtering, routing, loops, error handlers,...), but also libraries of domain-specific actors like Tango device control, database querying and updating etc.

Sub-processes can be easily stored in the library by end-users and can be reused between models.

Additionally, the clear split between actor development, solution assembly and execution environments supports different roles in solution delivery and maintenance for designers, developers, users and administrators.

ADVANCED CONCURRENCY FEATURES

Automation of non-trivial processes quickly confronts a solution developer with complex technical requirements. How can we control many simultaneous activities? How to assign system resources for a combination of long-running tasks and fast tasks? How to cater for peak loads in an optimal way?

The combination of asynchronous, event-driven internal processing, with the transparent concurrency that comes for free with the actor model means that neither the actor developer, nor the model designer, need to care too much about such technical complexities. Passerelle processes are automatically concurrent. Each actor can perform its work in an own thread that is managed internally by the engine. Each interaction between actors is buffered, so temporary overloads of an actor do not impact the others.

The philosophy behind the Passerelle engine, which is made possible thanks to the core Ptolemy design concepts, is that both an actor developer and a model designer should just focus on the desired functionalities. The complexities to ensure an optimal execution are hidden, and can be maintained and improved independently.

APPLICATION DOMAINS FOR SYNCHROTRONS

Passerelle actors and sequences can be used to automate all kinds of processes. By combining the right execution model with the right set of actors, the same process automation platform can handle e.g. :

- sequences for data acquisition and control
- workflows for data analysis
- autonomous monitoring and alarming
- scheduling batch processes
- …

A COMPLETELY MODULAR AND DYNAMIC PLATFORM

The Passerelle engine has been integrated in a complete platform for Java enterprise solutions with rich browser-based user interfaces. This has been designed from the ground up as a fundamentally modular system, through the usage of OSGi. This helps in several respects :

- strict control of intermodular dependencies with versioning
- OSGi bundles provide active modules with well-defined life-cycles
- support for dynamically updating/extending operational systems without downtime
- a very clean and performant service-based architecture

Just as for actors, OSGi promotes a model where each module has a limited responsibility, with a clean public interface and low coupling.

The Sherpabeans Java web framework integrates the following core technologies within an OSGi architecture :

- Apache Wicket for the web view layer
- JPA, Hibernate, eclipse link for persistence
- many smaller libraries

SherpaBeans itself is a collection of OSGi bundles that can be recombined at will. Some important modules are :

- scheduler for background jobs
- role-based security
- asset repository
- publish/subscribe notifications
- OSGi bundle upload and lifecycle management
- ...

This architecture makes it possible to deliver a basic Passerelle Manager platform with all core services, including a *web-based graphical model editor* (see Figure 1 below), an execution engine, some standard actor libraries and a complete web-based administration interface.

This system can then be extended in different ways by uploading extra modules as OSGi bundles (e.g. with new actors or new management features), designing and running new sequences etc.

ACTOR DEVELOPMENT WITH OSGI

In cases where the automated processes must be operational 24x7, even a short interruption to stop a sequence, and start a modified version, is problematic. Thanks to the dynamism offered by OSGi, many types of adaptations can be done without downtime.

A typical example is upgrading the logic of an actor implementation, e.g. for a bug fix or adapting to upgraded backend APIs etc.

To prepare for easy and dynamic maintainability, it is good practice to design actors in 2 layers :

- a service layer, containing the real logic behind a standardized task-based API that can be used by an actor
- a simplified actor, that basically feeds received data to the right service, collects its results and generates output messages from them

This results in actors that act as “binding” between a control layer (defined by the process model) and the service layer.

In an OSGi-based environment, each service can be offered by a dedicated bundle. When the bundle becomes active, the service is registered and is available for usage. When the bundle is deactivated or uninstalled, the service disappears. On the “client”-side, the actor can lookup the available service implementation(s), is notified about any changes in the status of the service, and can even pick the best one when multiple implementation versions would be available.

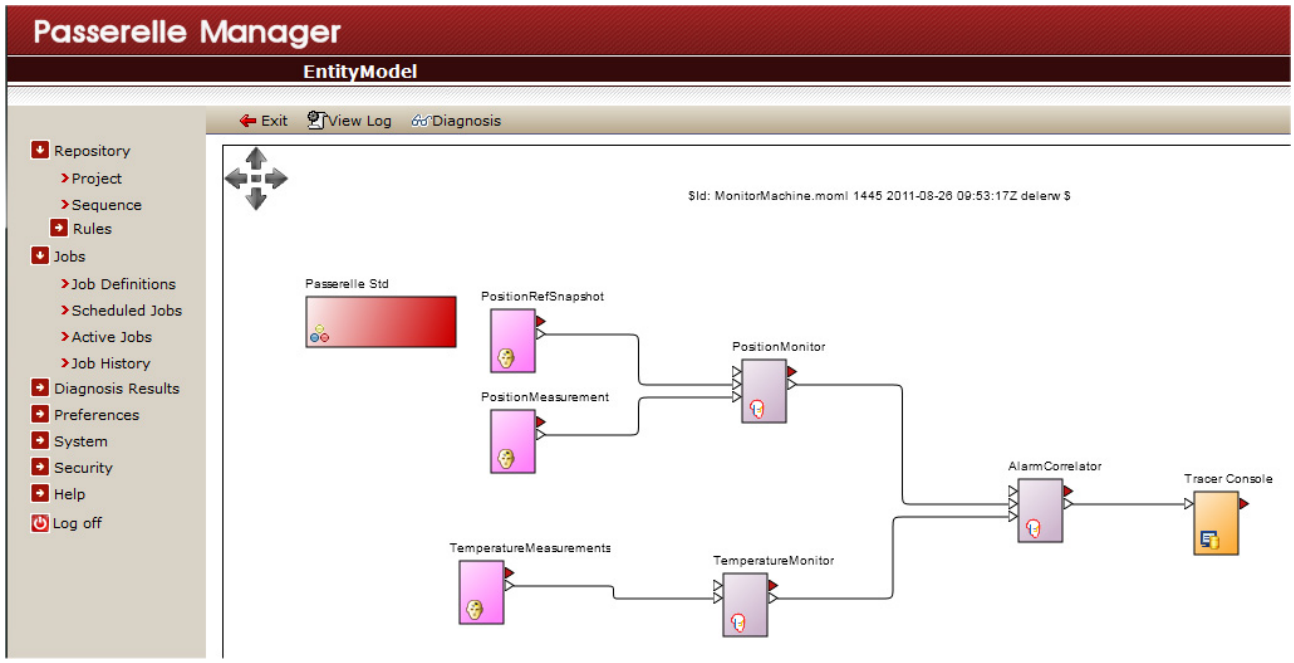

Figure 1: Screenshot from the web-based model editor in Passerelle Manager.

THE RESULT : EXTREME FLEXIBILITY FOR PROCESS AUTOMATION, WITHOUT DOWNTIME

Via the Passerelle Manager's web UI, it is possible to manage the lifecycle of each service bundle, to upload new versions etc.

The end result is a fully secured and dynamic platform to design new or updated processes via the browser, to upload new or updated actor and service implementations, to schedule process execution, consult execution traces etc.

COMBINING MODULES IN DIFFERENT PACKAGING OPTIONS

Through picking and recombining subsets of the available OSGi bundles, several solution packages can be obtained, with almost complete reuse of the core Passerelle bundles.

By using OSGi's service-based architecture, with a clear split between interface bundles and implementation bundles, it is also possible to provide several replaceable implementations of core service interfaces. For example, the asset repository has two implementations :

- the "enterprise" version, with persistence in a relational database, to be used inside the Passerelle Manager
- a simple file-based version, to be used with desktop workbench/IDE

Besides the Passerelle Manager, the following packages are possible :

- a standalone eclipse based Passerelle workbench
- the Passerelle eclipse workbench as plugins in larger workbench undertakings, like ESRF's Data Analysis WorkBench (DAWB) [4].
- an OSGi version with a Swing HMI (Figure 2 below)
- a plain Java-main Swing HMI, as OSGi bundles are finally also useable as plain jars...

EXAMPLE : ACTORS FOR DATA ACQUISITION VIA WEB SERVICES

In many enterprise environments, both scientific or non-scientific, the usage of web services is common, e.g. via SOAP or REST. Automated processes often include steps to obtain data from other software systems (often denoted as "backend systems") via such web services.

The preparation of a web-service request, and the interpretation of the received response typically involves tedious XML generation/parsing work. In many cases it's preferred to use frameworks like Apache Axis, JAXB etc to generate a Java binding.

In such a context, it is good practice to create an OSGi bundle for each required backend service. This bundle encapsulates the following responsibilities :

- accept request data from the client/actor
- prepare the outgoing request to the backend
- send the request, potentially with some safety measures to prevent overloading the backend
- collect the response or errors
- store the results and timing information etc in a database
- return the results to the client/actor

The actor layer becomes quite simple does not need to care about web service protocols, data persistence etc.

Such a design improves testability and maintainability.

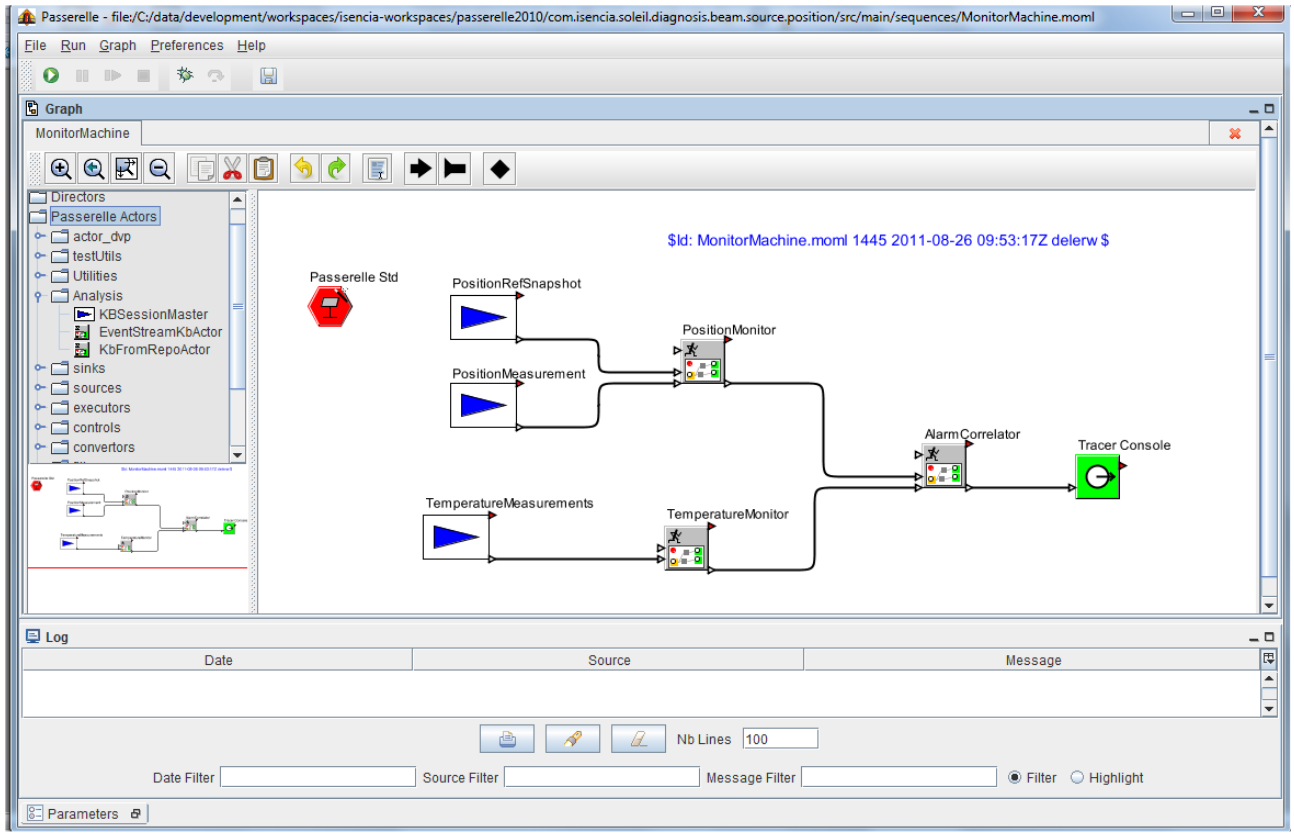

Figure 2: Screenshot from the Swing-based HMI/editor.

When the backend needs to change its web service, or the protocol changes for any other reason, or extra technical features like timeout management etc need to be added, this can all be done via an upgrade of the service bundle(s), without requiring a downtime.

CONCLUSIONS

Through a fundamental modular and componentized approach, it is possible to obtain advanced platforms for process automation.

By rigorously following good service-based design approaches in the context of an OSGi-based platform, a generic platform providing a complete tools set for designing, running and maintaining process models, consulting execution traces etc, becomes the starting point for a robust system that can be extended and updated without requiring downtime.

FPGA-BASED HARDWARE INSTRUMENTATION DEVELOPMENT ON MAST*

B.K. Huang, Dept. of Physics, Durham University, Durham and CCFE, Abingdon, Oxfordshire, UK
G. Naylor, N. Ben Ayed, G. Cunningham, A. Field, S. Khilar, CCFE, Abingdon, Oxfordshire, UK

Abstract

On MAST (the Mega Amp Spherical Tokamak) at Culham Centre for Fusion Energy some key control systems and diagnostics are being developed and upgraded with FPGA hardware: real-time data acquisition, vertical stabilisation, resonance mode driving, laser triggering, fast timer prototype, neutral beam monitoring and the bolometer upgrade. FPGAs provide many benefits including low latency and real-time digital signal processing. We accomplish lower costs by using industry standards such as the FMC (FPGA Mezzanine Card) Vita 57 standard [1] and by using COTS (Commercial Off The Shelf) components. Abstracting of the design and by using a flexible FPGA architecture gives resistance to obsolescence of modules and the ability to upgrade easily to add functionality by changing individual modules (connected by standard interfaces), avoiding the need to change the whole system.

FPGA DEVELOPMENT ON MAST

FPGAs are becoming more widely used in fusion research. In conjunction with appropriate hardware (DACs, ADCs, communication interfaces, etc) they offer a large number of capabilities including timing synchronisation, triggering, analogue/digital processing, I/O control, real-time feedback, embedded processors and more. As such this paper discusses this technology presented as a "standard architecture" where some systems (Resonance Mode Driving and Detection, Vertical Stabilisation, Real-Time Fast Acquisition, Fast Timer Prototype, NBI) use this architecture.

STANDARD ARCHITECTURE

MAST like other experimental facilities is a place where researchers are continually interested in investigating newly discovered phenomena. In order for researchers to be effective in this aim, it is necessary to have flexible hardware which allows researchers to adapt the system to the needs of their experiments. In many cases purchasing "turn-key" solutions to a cutting edge research experiment is either not possible or very expensive. We accomplish lower cost and flexibility instead by using a standard architecture that has the aim of being cost effective, flexible and reliable. By using open standards (Gigabit ethernet, FMC, SPI/IIC, AXI, ST Optical Fiber) it makes it easier to use different components of a system (such an FMC ADC board) in a variety of systems. This makes it easier to develop new systems, maintain and upgrade existing systems.

RESONANCE MODE DRIVING AND DETECTION

Toroidal Alfvén Eigenmodes (TAE) are global plasma modes at frequencies of 80 to 120 kHz. These eigenmodes can be considered analogous to orbit beam eigenmodes in synchrotrons and accelerators [2]. In MAST these modes can be driven by Neutral Beam Injection (NBI) or a time varying magnetic field generated by external coils.

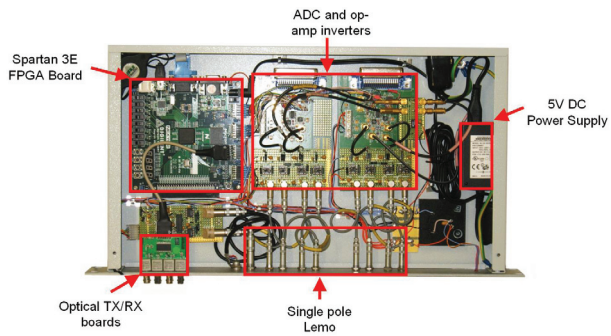

Figure 1: A resonance mode driving and detection system. Toroidal Alfvén Eigenmodes appear at ~80-120 kHz. An FPGA used system is used to create a time varying edge magnetic field perturbation by driving ~10 A sine wave in coils around the edge of the plasma.

The FPGA system (see Figure 1) is designed to drive these external coils. The FPGA creates an analogue sine wave via 16-bit DACs which are swept in frequency from 80 to 120 kHz. The sine wave is modified to have a fast zero crossing which reduces the reflected amplifier power. A ~10 A current is driven in the TAE coils using a matched resonant circuit. Parameters are loaded onto the FPGA using a serial UART connection which is connected to a rack-mounted serial over ethernet device. The benefit of UART is that it provides a low level communication (with a cost of only two wires) which can be used to debug the device. A future upgrade will likely switch this to gigabit ethernet. Additionally a 1 MHz 12-bit ADC can be used to digitise an arbitrary input signal for closed-loop real-time feedback, such as for tracking the resonant TAE frequency in real-time.

LASER TRIGGERING

A laser triggering system developed on MAST [3] is used to trigger 8 Nd:Yag Lasers 1.6 J 33 Hz (peak power 10 MW). The system incorporates a Spartan 3E FPGA with UART communication, fast rise-time triggers, and optical amplitude digitisation. This system is currently being enhanced for physics experiments in closed loop triggering applications to study plasma disruptions and instabilities.

VERTICAL STABILISATION

The Vertical Stabilisation system controls the vertical plasma position by adjusting the voltage in the P6 coils (see Figure 2).

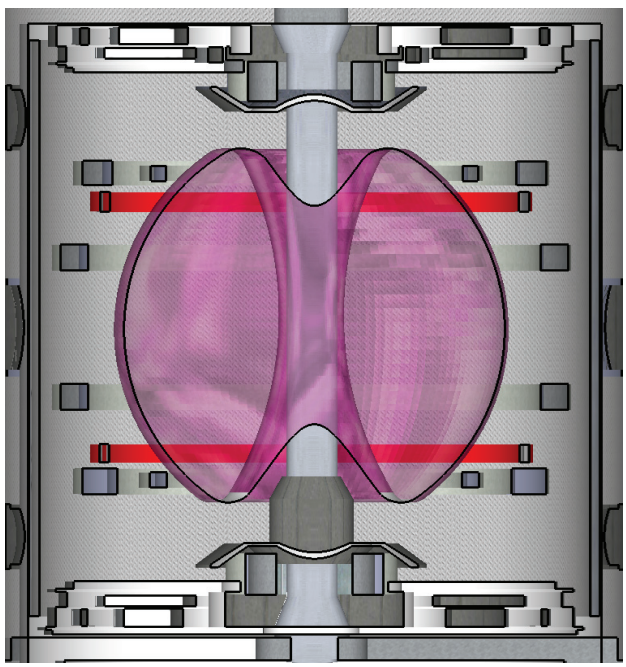

Figure 2: A cutaway view of the MAST vessel. The P6 magnetic coils which control the vertical position of the plasma are highlighted red. The coils are wired anti-parallel and driven by the vertical control system.

Currently an analogue vertical position control system is used to minimise the loop delay. However, there is little headroom between the optimal loop gains and those at which fast plasma events, such as 'Edge Localised Modes', will cause the amplifiers to trip. It is hoped that the use of an FPGA system (see Figure 3) will retain the benefit of low delay while allowing use of dynamic gain control and optimal filtering to make best use of the available dynamic range in the closed loop system.

The system comprises of: SP601 Spartan 6 FPGA, FMC12PEXP LPC Digital I/O, ADS1672 24-bit 625 ksps, remote management board, custom fibre optic boards for trigger/clocking, ATX power supply, 16-bit DAC for waveform generation.

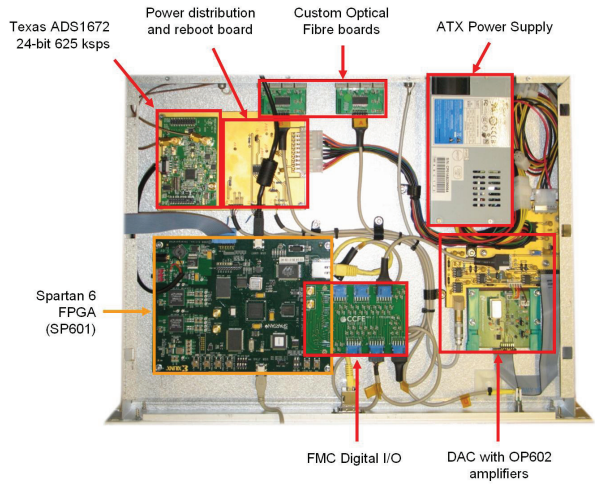

Figure 3: The new digital vertical stabilisation system contains a SP601 Spartan 6 FPGA. Gain coefficients and vertical position waveform are loadable over the Gigabit ethernet.

FAST REAL-TIME DATA ACQUISITION

The Microwave Imaging Diagnostic on MAST requires a fast real-time data acquisition system. Using the AXI bus it is possible to achieve a high continual streaming rate of 8 GB/s. This speed is based on 16 channels acquiring at 14-bits at 250 Msps: $16 * 2\,\text{Bytes} * 0.25\,\text{Gsps} = 8\,\text{GB/s}$. The system has been proved to be capable of achieving acquisition speed of >10 GB/s. This is compared to the theoretical rate of 12.8 GB/s for two DDR3 RAM chips 64-bits wide driven at 400 MHz DDR.

The hardware consists of 2xML605 FPGA Virtex6 boards, with on board 2 GB DDR3 RAM (4 GB Total), 2xFMC108 4DSP 14-bit 250 Msps ADC, FMC12PEXP LPC Digitial I/O, Gigabit Ethernet, Compact Flash, ATX Power Supply and Optical Reboot Board. The SSMC connectors on the FMC108 boards are internally wired to SMA front panel connectors. This is due to the fragility of SSMC (rated only for ~10 on/off connections) compared to the ~500 for SMA.

FAST TIMER PROTOTYPE

On experimental physics devices it is necessary to distribute a common clock to synchronise all instruments. A fast timer prototype (see Figure 4) has been developed to allow synchronisation using a distributed 10 MHz clock and generation of variable delay/length triggers. The system is a 1U system with ATX power supply, remote management board, LPC FMC12PEXP digital I/O, optical clock and trigger boards. The system uses an SP601 Spartan 6 board with Gigabit ethernet for communications. The generated pulse has a 37 ns precision with ~4 ns jitter. On board parallel (BPI) flash to store the firmware to makes this system fully standalone (the network is not needed for booting).

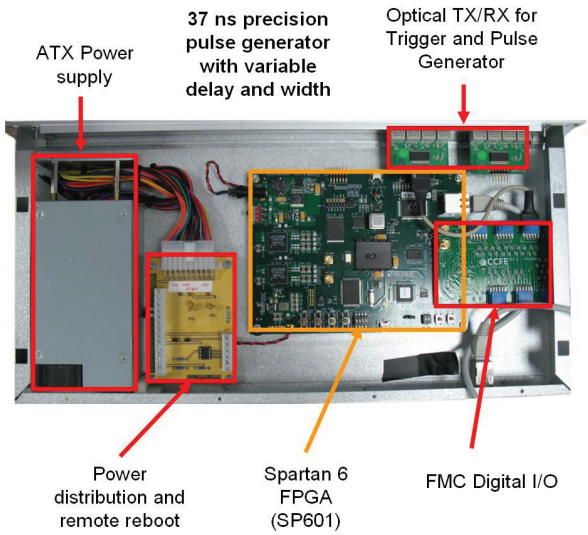

Figure 4: The Fast Timer Prototype. A simple system that contains many aspects of the FPGA standard architecture showing the ease with which new diagnostics and control systems can be developed. It is a completely remote managed system that communicates over ModBus.

NBI FPGA DIAGNOSTIC

The Neutral Beam Injection (NBI) system on MAST injects over 3.2 MW of power into the tokamak. As part of the running operations there are occasionally arcing currents. Currently these are monitored at 20 kHz sampling rates but since arcs can happen over smaller timescales than 50µs. This new system (see Figure 5) will include: 4 Channel 1 Msps 12-bit ADC, ATLYS Spartan 6 FPGA, ATX power supply, remote reboot board.

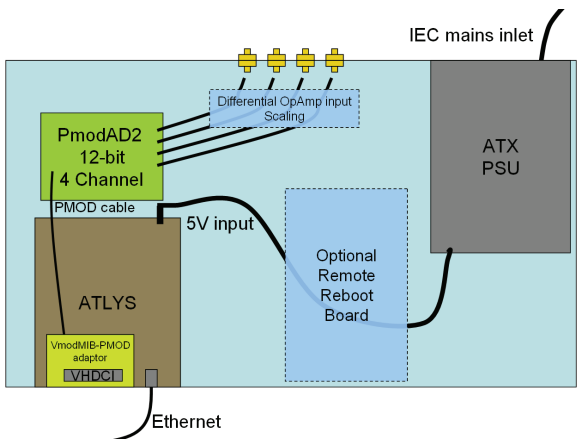

Figure 5: The NBI arc detection acquisition system. This system increases the sampling rate from 20 kHz to 1 MHz in order to better resolve the voltage waveform during an NBI arc event. This system utilises an ATLYS Spartan 6 board and follows the FPGA standard architecture.

BOLOMETER UPGRADE

The bolometer array is a 32 channel system on MAST which measures plasma irradiation from visible to soft X-ray. The detection system is based on gold foil configured as a wheatstone bridge whereby incident radiation causes a voltage difference across the bridge.

The challenge with this system is that in any given time interval a very small amount of power falls onto the gold foil thus making the diagnostic sensitive to noise. An additional requirement is low temperature drift. In order to increase the sensitivity of the system and help prevent problems with low DC offsets and 1/f noise a chopping sine wave at 20 kHz is used. The hardware will be FPGA based to control the calibration of the wheatstone bridge, digital filtering, control waveform and other control operations.

CONCLUSIONS

Significant FPGA development is occurring on MAST in key control systems using a standard FPGA architecture. The adoption of a standard architecture has enabled the development of a number of different diagnostics performing a variety of different functions.

FPGA COMMUNICATIONS BASED ON GIGABIT ETHERNET

L.R. Doolittle, C. Serrano, LBNL, Berkeley, CA 94720, USA

Abstract

The use of Field Programmable Gate Arrays (FPGAs) in accelerators is widespread due to their flexibility, performance, and affordability. Whether they are used for fast feedback systems, data acquisition, fast communications using custom protocols, or any other application, there is a need for the end-user and the global control software to access FPGA features using a commodity computer. The choice of communication standards that can be used to interface to a FPGA board is wide, however there is one that stands out for its maturity, basis in standards, performance, and hardware support: Gigabit Ethernet. In the context of accelerators it is desirable to have highly reliable, portable, and flexible solutions. We have therefore developed a chip- and board-independent FPGA design which implements the Gigabit Ethernet (GbE) standard. Our design has been configured for use with multiple projects, supports full line-rate traffic, and communicates with any other device implementing the same well-established protocol, easily supported by any modern workstation or controls computer.

INTRODUCTION

The FPGA communication system based in GbE is the result of two success stories. First FPGAs, whose capabilities have improved dramatically in the last few years in terms of size, performance, and flexibility. This tremendous improvement has enabled the range of applications of FPGA solutions to explode, increasing the volume of production, and therefore reducing the price of every new generation of FPGA family appearing on the market. The second success story corresponds to Ethernet (and GbE as the highest performance flavor to see adoption in today's commodity hardware). The key to the success of Ethernet resides in its simplicity and its associated side effects [1]. Implementation is simple in hardware and provides larger data rates than most computers can process these days. The evolution of the Ethernet protocol since its creation has accompanied that of computers since its creation in 1970s, and has been the Local Area Network (LAN) protocol by excellence ever since (with the market of Ethernet switches alone amounting to $16 billion in 2010).

In accelerators, FPGAs have introduced a great deal of flexibility and performance into machine fast controls and operations. They are extensively used to implement highly specialized tasks where simplicity, low production cost, and reliability are big assets. Even if simple and reliable, these systems need means for communications with commodity computers for configuration, data acquisition and diagnostics via Global Controls such as EPICS and TANGO. The nature of highly specialized hardware, combined with the simplicity of the GbE protocol make the implementation of GbE in FPGAs our preferred way of communication with the Global Controls.

STANDARD SELECTION

Once computers are taken away from highly specialized hardware in accelerators, a number of hardware standards other than GbE are available to enable communication between FPGAs and Global Controls, such as: PCI, USB, CAN, VME, VXI, cPCI, PCIe, IEEE-488 (HP-IB), IEEE-1392 (Firewire), SATA (or eSATA), etc. Longevity is a usual requirement for hardware installed in accelerators, and the chosen communication standard should last at least as long as the actual hardware. While CAN, VME, IEEE-488 and cPCI are indeed standards, they do not achieve as much performance/simplicity ratio as that provided by GbE. PCI hardware will undoubtedly be present for a long time, however active development seems to have shifted from the original parallel standards to the high-speed serial PCIe version.

USB can be amazingly attractive for small projects. Throughput is high, as is the availability for hardware components for both sides of the link. On the other hand, both software and hardware models are very much desktop-based. Cable distance is limited, and the standard is young and unstable enough that software support can be quirky. The LBNL experience running USB-based instrumentation affirms that it should be avoided for production accelerator installations. Ethernet on the other hand accounts for maturity, stability, high availability of hardware, high performance and ease of integration with highly specialized hardware in accelerators.

OVERVIEW

In addition to GbE, our implementation includes IP, UDP and ARP at full line speed. UDP seems a better match to real-time communications than TCP since point-to-point dedicated networks are normally available in accelerator deployments, and is much better suited to the finite resources of an FPGA. The additional complexity added by supporting UDP over raw Ethernet is largely rewarded by the extensive UDP support on the host side (BSD sockets API, and its descendants). Raw Ethernet support is not as usual, and programs manipulating raw Ethernet packets typically require elevated levels of privileges, removing one layer of security.

Fig. 1 shows a block diagram of an implementation example using the FPGA Ethernet module. The core func-

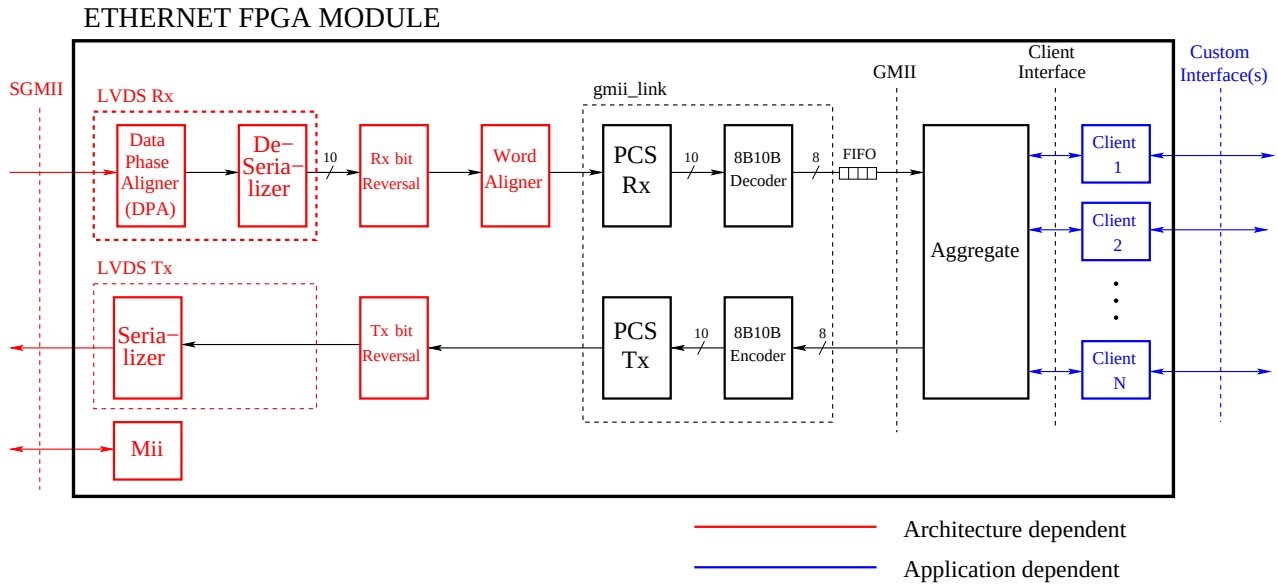

Figure 1: Top level block diagram. Example where the architecture dependent modules correspond to the implementation on an Altera Stratix-IV EP4SGX230KF40C2ES FPGA.

tionality is implemented in the Aggregate module, which has been custom-designed using Verilog HDL. A clean separation between this module and rest of the design allows for flexibility and portability, benefiting from a well defined medium-independent interface in the GbE side (GMII in the example shown in Fig. 1, which is defined as part of the GbE standard), and another well defined client interface for data exchange with the FPGA fabric. Details on the core design and interfaces are given next.

CORE DESIGN

The core design described here includes the architecture/implementation independent modules, shown in black in Fig. 1. This logic is independent of the targeted FPGA (as well as any peripherals), the particular application of the communication, and implements layers 2, 3, and 4 of the OSI model.

The FPGA Ethernet module has compile-time configurable IP and MAC addresses, and the current implementation assumes that the host side uses a single UDP port number for communication. Aggregate implements the upper level logic to (de)encapsulate UDP packets. It extracts the UDP packet length in the length field and uses it to generate the necessary control signals needed to interact with the client modules in the FPGA fabric. The host has the possibility of communicating with any of the n clients (in blue in Fig. 1), where each client is assigned a UDP port number. More details on the clients are given later.

The PCS Rx/Tx modules implement the 802.1x PCS standard, building a block which interfaces the Ethernet framer to Tx PMA (Physical Medium Attachment). It performs preamble generation, inserting idle patterns, 802.1x link negotiation and all the low-level signaling (excluding 8B10B coding, which is implemented in the 8B10B Encoder/Decoder). The 32-bit CRC of the Ethernet frame, and the length of the IP and UDP packets are checked for correctness. If any errors are detected, the whole Ethernet frame is dropped and the clients stay idle. Details on the clients are given next.

INTERFACES

Client Interface (FPGA side)

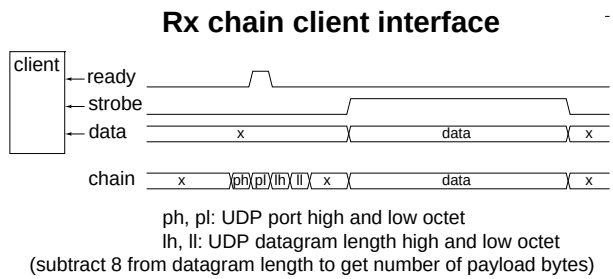

Figure 2: Rx chain in the client interface shown in Fig. 1.

The Aggregate module provides the data contained in the UDP packet payload to the client modules (application dependent modules shown in blue in Fig. 1), where the distinction of each client is done using the UDP port number. These clients exist to provide the flexibility of implementing different custom protocols adapted to the application needs. This level of communication relies on data transaction from levels 1 through 4 in the OSI model, and custom interfaces to interact with the rest of the fabric in the FPGA. The different client instantiations share a common interface with the Aggregate module (labeled “client interface” in Fig. 1), and each implement a custom interface

with the rest of the fabric in the FPGA (labeled "Custom Interface(s)" in Fig. 1).

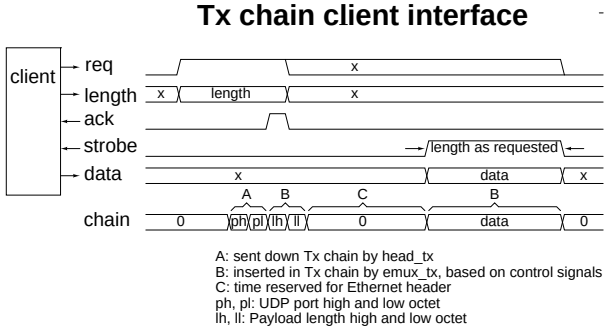

Figure 3: Tx chain in the client interface shown in Fig. 1.

Figs. 2 and 3 show the Rx and Tx flow chain for the client interface, respectively (seen from the clients' perspective). The Rx chain follows a simple strobe and data transmission, where the strobe is high if the data is valid, and the UDP packet it was sent into contained the UDP port associated with the client. A ready signal is provided a fixed number of clock cycles before the strobe, which can be used by the client module to anticipate when it will receive valid data.

The Tx chain follows a similar transmission scheme (strobe and data), preceded by a transmission request for a scheduler to assign when each client transmits the data onto the Ethernet link. When the client is ready to send data, it sets the request signal along with the length of the data to be transmitted. Once the scheduler has established the turn of the client to send the data, it sends an acknowledge to the client, that will then receive a strobe for as many clock cycles as previously specified in the length field.

The design is modular, and each UDP clients is handled by a different Verilog module. In addition to that, the project package includes means to automatically generate Verilog code for the Aggregate module, including automatic replication of client handling logic, and the proper module prototype to connect to as many clients as needed.

On-board Local Bus to UDP Gateway

Local bus encoded 64−bit frame

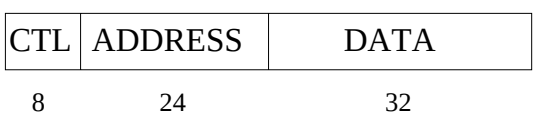

Figure 4: Local bus 64-bit frame.

In the general case, the Ethernet module provides a link between UDP/IP, and a series of customized interfaces, There are as many clients as protocols are encoded in the UDP packet payloads, and each client is assigned a UDP port number to be accessed from the host side. One example of client is what we call the Local Bus to UDP Gateway, where the access to FPGA registers is provided by a very simplified on-board data, address, strobe type local bus.

The master of the transaction is the software side, which can send series of register read and write commands to the FPGA by concatenating the 64-bit frame pattern (shown in Fig. 4) into the UDP payload. One of the 8 control bits is used to indicate the read/write command. If a read command is found, the FPGA ignores the data field and responds using the same 64-bit pattern, where the control and address field remain unchanged, and the data field is filled with the corresponding register value. On the other hand, if a write command is found, the data field is written onto the corresponding register, and the same frame is sent back to the host (which can use it as an acknowledgement). This scheme described above has an intrinsic bandwidth limit for the FPGA, since it only sends data upon request.

Host Interface (GbE link side)

The Ethernet protocol has increasingly added support for different data rates and physical media, and different FPGAs implement the physical layer (including serializer and deserializer mechanisms) differently. It was therefore indicated to provide a medium-independent interface to the core of the design in order to preserve generality and portability. A GMII interface (defined as part of the Ethernet standard) is provided to connect the FPGA core logic and the architecture specific modules (in red in Fig. 1).

The package described here also includes means to attach a live simulation of the synthesizable Verilog to a Linux tun/tap interface, where the GbE link can be abstracted and third party software can be used to exchange UDP packages with the FPGA logic, which has been extremely helpful in the debug process and can be used for early development of software without the need of actual hardware.

CONCLUSIONS

The Ethernet module has been used in various projects under different inter-lab collaborations. The package contains (not counting various instantiation of hardware primitives) purely synthesizable Verilog. There is no need for off-chip memory and synthesizes using 930 logic cells, and 3 block RAMs on a Xilinx Spartan-6 XC6SLX45T (which accounts for 1.7% and 2.6% of the available resources respectively). The physical layer has been demonstrated functional using GMII, Xilinx Virtex-5 MGT, and Altera Stratix-IV LVDS. The project is continuously evolving as new needs arise, and physical layer support plans or currently ongoing testing include RGMII (double-date-rate GMII), Spartan-6, and Virtex-6.

THE UPGRADE PATH FROM LEGACY VME TO VXS DUAL STAR CONNECTIVITY FOR LARGE SCALE DATA ACQUISITION AND TRIGGER SYSTEMS

Chris Cuevas, David Abbott, Fernando Barbosa, Hai Dong, William Gu, Edward Jastrzembski, Scott Kaneta, B. Moffit, Nick Nganga, Ben Raydo, Alexander Somov, William Mark Taylor, Jeff Wilson, Thomas Jefferson National Accelerator Facility, Newport News, Virginia, U.S.A

Abstract

New instrumentation modules have been designed by Jefferson Lab that take advantage of the higher performance and elegant backplane connectivity of the VITA 41 standard of VXS. These new modules are required to meet the 200 KHz trigger rates envisioned for the 12GeV experimental program. Upgrading legacy VME designs to the high speed gigabit serial extensions that VXS offers, comes with significant challenges, including electronic engineering design, plus firmware and software development issues. This paper will detail our system design approach including the critical system requirement stages, and explain the pipeline design techniques and selection criteria for the FPGA that require embedded Gigabit serial transceivers. The entire trigger system operates synchronously at 250MHz, utilizing global clock and synchronization signals distributed to each front-end readout crate where finally the VXS switch slot distributes these signals to all front-end modules. The readout of the buffered detector signals relies on 2eSST over the standard VME64x path at >200MB/s. We have achieved an aggregate of 64Gb/s rate of trigger information from payload to switch slots within one VXS crate and will present results using production modules in a two crate test configuration with both VXS crates fully populated. The VXS trigger modules that reside in the front end crates, will be ready for production orders by the end of the fiscal year. VXS Global trigger modules are in the design stage now, and will be complete to meet the installation schedule for the 12GeV Physics program.

VXS SELECTION CRITERIA

VME with serial extensions or VXS was selected as the 12GeV data acquisition backplane foundation for the front end detector readout and trigger hardware interface. The 6GeV experimental program relied on FastBus ADC and TDC with VME single board computers providing the configuration and readout of Physics data, along with custom electronics developed for the trigger system. [1] The new requirements for 12GeV experiments demand higher trigger and data readout rates as shown in Table 1.

We have a successful record with VME and VME64x custom data acquisition and trigger modules that were developed during the 6GeV program to replace aging and obsolete hardware. When VITA41 (VXS) [2] was initially emerging we decided that the specifications for the new serial extensions would meet and exceed our requirements for creating digital energy summation for hundreds of ADC channels within a VXS card enclosure. The VXS backplane also is an elegant solution to distribute critical and essential global clock and synchronization signals to each front end module without cumbersome cabling or additional rear transition hardware. The VXS selection offered low risk and allowed a logical upgrade path for our legacy hardware. The VME consortium was promoting the addition of gigabit connectivity to a very large customer base, and the new VXS standard remains a viable choice for the future. [3]

Table 1: Experiment Rates and L1 Trigger Channel Count.

	Hall B CLAS12	Hall D GlueX
L1 Trigger Channels	4,000	4,500
#VXS Crates (Total Crates)	38 (43)	25 (52)
#Single Board CPU	43	52
L1 Trigger Rate	<20KHz	<200KHz
L1 Data Rate(MB/s)	60MB/s	3GB/s
L3 Farm Data Rate (Disk MB/s)	10KHz (60MB/s)	20KHz (300MB/s)

SYSTEM TOPOLOGY OVERVIEW

VXS offers dual star switch capability with 18 payload slots connected to two central switch slots. The VITA 41.0 specification lists 4 full duplex gigabit connections or "lanes" from each payload slot, to the each switch slot and a line rate of 10 Gb/s, so 80 Gb/s bandwidth is offered with dual star connectivity. At the start of our R&D hardware design phase in 2005, we were using the Xilinx Virtex-IV series with gigabit transceivers capable of 3.125Gb/s. Our production payload modules will use Xilinx Virtex-V transceivers capable of 6.25Gb/s line speeds. All four full duplex lanes are routed on the circuit board, but presently only two lanes are used to one switch slot. The front end payload modules are sixteen channel, 250MHz flash ADC boards [4] that use these gigabit lanes to transmit digital sum information to one of the VXS switch slots.[5] This switch slot module is a Crate Trigger Processor (CTP) which collects 64Gb/s from the 16 payload modules and processes a crate summation that is optically transmitted over a parallel fibre optic cable[6] to a Sub-System Processors (SSP) and finally to a Global Trigger Processor (GTP)[7] that determines if a Physics trigger condition was satisfied.

HARDWARE DESIGN CHALLENGES

High Speed Gigabit Serial Transmission

The design challenges for reliable and successful transmission of gigabit serial data over the VXS backplane requires the investment of high speed circuit board layout and routing tools. The FPGA selection requirements include at least four full duplex Gigabit Transceivers, user I/O pin count >500, and fast integrated block memory with multi-rate FIFO logic. We use circuit board routing simulation tools such as Mentor Graphics HyperLynx [8] which are invaluable for critical simulation and verification of circuit board signal integrity for the gigabit transmission paths before the manufacturing process. The FPGA devices that we use are capable of 6.25Gb/s serial transfer, and we have designed our circuit boards with signal integrity techniques using standard FR4 circuit board material to achieve >2.5Gb/s which meets the data transfer bandwidth requirements.

Another significant investment required for the hardware verification of the gigabit transceivers was a digital signal analyzer with 8GHz bandwidth to measure and record the backplane and fibre optic gigabit transceiver performance and to perform jitter analysis on the critical system clock and synchronization signals with at least 1ps resolution. We have purchased the Tektronix jitter analysis software which is a critical tool for the verification of our system clock, and for measurements of the phase controlled jitter attenuated clock provided by the Signal Distribution (SD) switch card in every crate [9].

The investment of firmware development tools from FPGA industry leaders, Xilinx and Altera were also taken into consideration for the upgrade path to VXS, and costs for firmware simulation and verification tools from industry leading vendors must be considered because the license and maintenance fees are not trivial.

We use the Xilinx Aurora protocol for serial transmission which is robust, simple and is included with the FPGA development tools. Considerations for forward error correcting algorithms have been planned, but not implemented at this time.

Fiber Optic Distribution Network

As shown in Figure 1, the digital sum value from each CTP in the front-end crate, and the distribution of the global clock, synchronization and trigger commands from the global trigger hardware, use a separate fibre optic cable. The crate sum fibre link is shown in orange, and the critical timing signals distributed to each front-end crate are blue. Each fibre optic link makes use of the Avago POP4 fibre optic transceivers and parallel OM3 rated glass fibre cable with MTP connections. These fibre optic transceivers operate at 3.125 Gb/s for an aggregate bandwidth of 10 Gb/s which is ample enough for the summing information that is sent forward to the global trigger processing hardware. The fibre link used for the distribution of the global clock, critical timing signals and trigger commands run at 1.25 Gb/s.

Global Trigger Essentials

The global trigger SSP modules collect the 10Gb/s trigger information streams from each of the front end crates via the parallel fibre optic connections. These trigger data streams represent energy sums from calorimeter detector apparatus and hit patterns from Time-Of-Flight (TOF) detectors. The SSP are VXS payload modules, so after the SSP has performed the required sub-system alignment, the trigger data is passed forward to the GTP on the VXS backplane. The final trigger word is cabled to the Trigger Supervisor (TS) [10] and is distributed to the front-end crates and modules to initiate data readout.

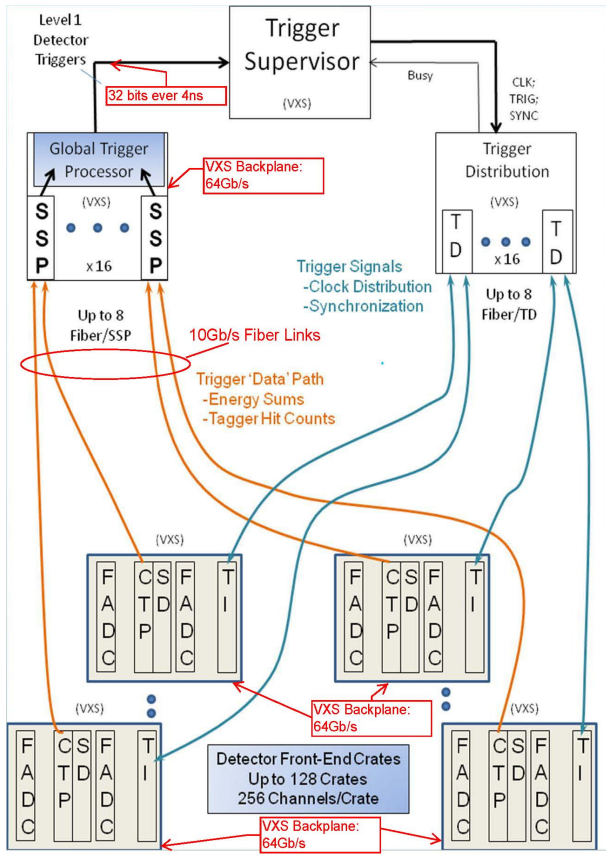

Figure 1: Gigabit Serial Links.

System Latency and Transport Protocol

The Level 1 trigger is formed from the detector signals that have been selected for a given Physics event. The energy sums from a calorimeter, for instance, are created in firmware and transported on the VXS backplane using Xilinx's Aurora™ [11] protocol. Aurora™ is the low latency communication protocol between FPGAs on payload and switch boards. Other serial gigabit protocols such as Ethernet or PCIe cannot be used because the latency is too large to meet the 3.2μS requirement. This requirement comes from our choice of a commercial

Time-Digital-Converter ASIC [12]. These protocols include other properties that are not required for the transfer of the digital sum information and will add significant overhead compared to Aurora™. The Aurora™ protocol is also used on the fibre optic communication interface, and Aurora provides full duplex lane bonding to achieve aggregate bandwidth sufficient to transfer information from each crate to the global trigger crate modules.

Data Rates with Linux Single Board Computers

The VXS crates use single board computers (SBC) and the Data Acquisition Group at Jefferson Lab has evaluated the performance offered by various companies.

In our present two crate test station, one SBC is a GE-7875 (Intel Core 2 Duo) and the other VXS crate uses a Concurrent v717 (Intel mobile core i7). These SBC have similar interrupt response times of ~5μs and maximum network throughput of 116MB/s using only 5% of the CPU resource. These SBC support 2eSST VME transfer mode and with a 200 KHz trigger rate, we achieve a nominal VME backplane transfer of >40MB/s. Each crate can accept 256 coaxial detector signals, and typical occupancy for a fully populated crate will be <10%.

LATEST PERFORMANCE RESULTS

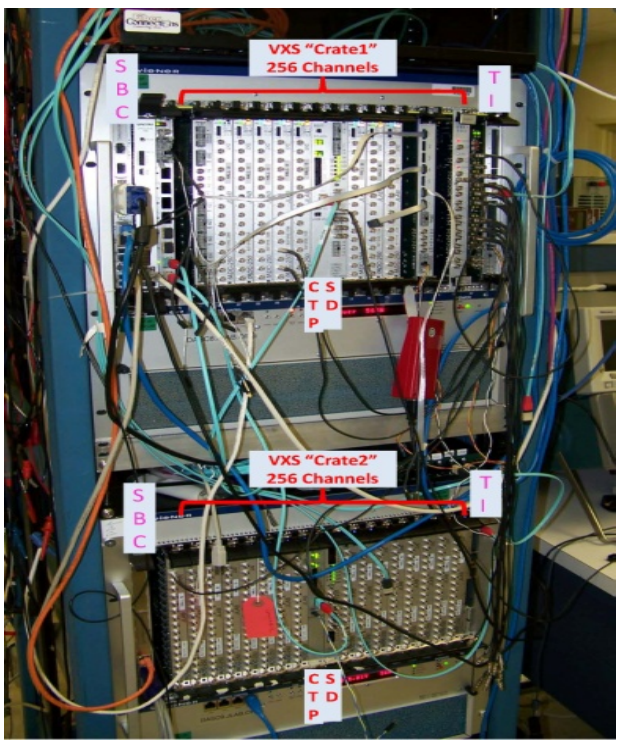

Figure 2: Two VXS crate test station.

A photo of two VXS crates, which are almost fully populated with payload boards, is shown in Figure 2.

Each payload module has 16 coaxial inputs, and these inputs are captured with a 12-bit flash ADC. A fully populated crate can accept 256 coaxial detector signals and all channels participate in creating an energy sum value which is transferred every 4ns. Depending on the location of the detector apparatus, the typical number of channels for a Physics trigger that will have relevant signal occupancy is <10%. For our two crate testing, we inject pulse signals to at least 12% of the channels to simulate a typical occupancy from a detector apparatus.

Figure 3 shows data transfer rate versus a Level 1 Trigger rate with channel occupancy at 12.5%. The aggregate data transfer rate of >40MB/s is from both VXS crate SBC. Selected input channels produce pulses at trigger rates set with a programmable generator, and several trigger rates points are shown. The Trigger Interface has the capability to store up to 256 trigger events (block) before signalling the SBC for VME 2eSST block readout. This block-event capability allows the fully pipelined system to accept a 200 KHz trigger rate and transfer the Physics event data from the SBC to the software trigger storage server. Figure 3 also shows the advantage of event blocking and larger events per block reduce CPU response time and data overhead per event.

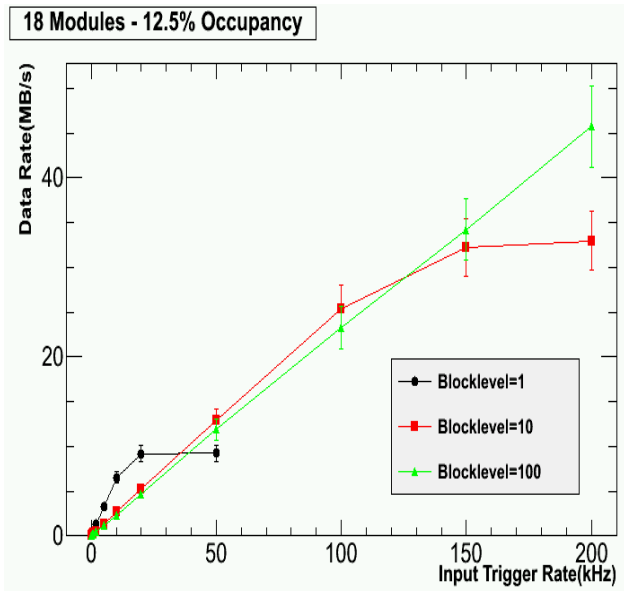

Figure 3: Trigger rate vs. Data rate and Block-level affects.

CONCLUSION

We have met the requirements and milestones established for the new front-end data acquisition hardware and trigger system functions defined at the conceptual design phase for the 12GeV experimental upgrade project.

The upgrade path the VITA 41 or 'VXS' presented many significant engineering design challenges for both circuit board and firmware development. Careful planning including the cost of essential circuit board design and simulation tools, plus the required test equipment is critical for success. We now have the essential experience with high speed gigabit serial backplanes, FPGA transceiver technology, and firmware development.

In the next two years we will be challenged with production testing of the new front-end and trigger

hardware, and will be required to meet the implementation goals for pre-commissioning the detector readout and trigger systems in the 12GeV experimental areas. The two crate VXS test station has been an excellent foundation for the development of data acquisition and trigger commissioning 'tools' that will be essential for full qualification of the VXS hardware systems needed when the 12GeV Physics programs begin.

Abstract

The accelerator control systems at CERN will be renovated and many electronics modules will be redesigned as the modules they will replace cannot be bought anymore or use obsolete components. The modules used in the control systems are diverse: analog and digital I/O, level converters and repeaters, serial links and timing modules. Overall around 120 modules are supported that are used in systems such as beam instrumentation, cryogenics and power converters. Only a small percentage of the currently used modules are commercially available, while most of them had been specifically designed at CERN.

The new developments are based on VITA and PCI-SIG standards such as FMC (FPGA Mezzanine Card), PCI Express and VME64x using transition modules. As system-on-chip interconnect, the public domain Wishbone specification is used.

For the renovation, it is considered imperative to have for each board access to the full hardware design and its firmware so that problems could quickly be resolved by CERN engineers or its collaborators.

To attract other partners, that are not necessarily part of the existing networks of particle physics, the new projects are developed in a fully 'Open' fashion. This allows for strong collaborations that will result in better and reusable designs.

Within this Open Hardware project new ways of working with industry are being tested with the aim to prove that there is no contradiction between commercial off-the-shelf products and openness and that industry can be involved at all stages, from design to production and support.

OVERVIEW OF CONTROLS HARDWARE

The Controls Group of the Beams Department (BE-CO) at CERN is responsible for the specification, design, procurement, integration, installation, commissioning and operation of the controls infrastructure for all CERN accelerators, their transfer lines and the experimental areas. The group provides services like general machine and beam synchronous timing generation and distribution (see Figure 1) and signal observation systems, as well as support for drivers and higher-level software.

As basis the group uses a set of standardized hardware and software controls components. The hardware used in the control systems is diverse: analog and digital I/O, level converters and repeaters, serial links and a range of timing modules. Overall around 120 modules are supported that are used in systems such as beam instrumentation, cryogenics and power converters.

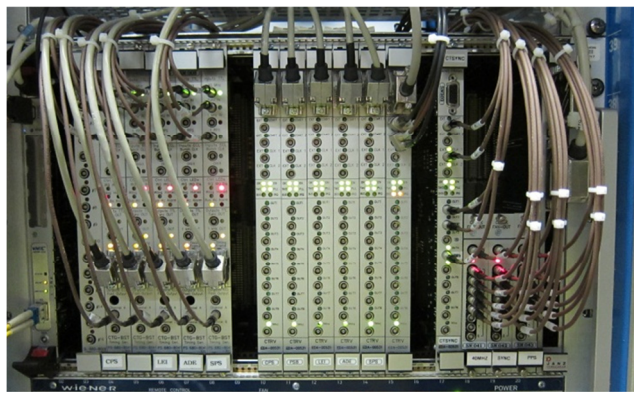

Figure 1: Timing crate controlling LHC.

Only one in four of the currently used module types are commercially available, while the others have been purposely designed at CERN. Furthermore, one in four of the module types are considered obsolete, meaning that existing modules can be maintained, but they cannot be used for new installations. These modules may have been designed up to twenty years ago and are still stocked in limited quantities. In most cases they can be repaired, but cannot be ordered or be re-produced in-house as the electronics components are no longer available.

STANDARDS FOR NEW DESIGNS

To replace the obsolete modules and to progress with new control and timing technologies, there is a continuous flow of new designs to be made.

To ease maintenance it has been decided in 2009 to base new designs on two platforms: VME64x [1] and PICMG 1.3 [2]. The latter defines an industrial type of PC that uses the PCI Express bus for its plug-in cards.

Most of the functionality that is required by the equipment groups is needed for both platforms and therefore every new device, such as a Time-to-Digital Converter (TDC) or an Analog-to-Digital Converter (ADC), would need to be designed twice. Potentially for *n* bus types and *m* functions required, *n* times *m* designs are needed.

If it were possible to put the specific required functionality on a mezzanine card, then with a single design of a carrier card for each platform, the number of designs would be reduced to n + m. The carrier card will contain basic functionality that is needed for every design,

#Erik.van.der.Bij@cern.ch

such as the bus interface, an FPGA, memory and other support functions while the mezzanine would only contain the specific functionality required.

Fortunately in 2009, the FPGA Mezzanine Card (FMC) standard ANSI/VITA 57.1 [3] was just published by the same organization that is responsible for the VME specifications. This standard defines a mezzanine card of around 84 mm by 69 mm in size and uses one of two connector types that have either 160 or 400 pins. There is no protocol defined for the signals on the connector as they should connect directly to an FPGA on the carrier board. As an example, Figure 2 shows such a carrier board for FMC mezzanines and uses a Xilinx Spartan 6 as FPGA. The mezzanine cards are supposed to contain only I/O logic such as buffers or an ADC, while a small front-panel space is available for external connectivity.

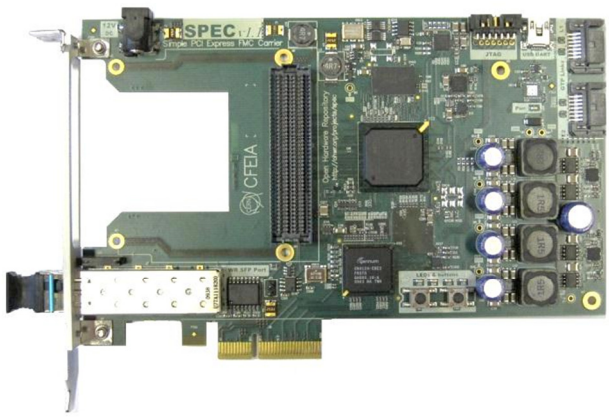

Figure 2: PCI Express carrier for FMC mezzanines developed as Open Hardware.

As many mezzanines and carriers use the same functions, the logic blocks inside the FPGA should be re-usable. To interconnect these blocks we decided to standardize on an internal bus called Wishbone [4]. Wishbone is a simple address/data bus meant to be used for system-on-chip designs and is an open standard. We collaborated in the update of the Wishbone B4 Specification to include a pipelined mode that enhances communication with high-latency high-throughput devices, such as DDR RAM controllers. Many ready-made building blocks are already available, such as Wishbone to I2C or to one-wire bus protocols.

Of course not all new designs for the control system use the FMC standard. E.g. level converters needing a large front-panel space for connectors are designed in the VME64x format.

NEED FOR OPEN HARDWARE

When new hardware is needed, in a few cases it could be bought directly from industry. This would be a resource gain as it is designed, built and tested already. At the same time it likely has proven its worth by many users in different applications. However, ready-made modules don't always have the exact functions we need. E.g., even for simple ADC modules CERN needs specific trigger modes or input capabilities that are not usual. Furthermore, when a bug is found, it may be hard to get a correction from the company as CERN's applications are very complex and the reported bugs may be difficult to reproduce. Ultimately, as there is normally no access to design documentation, it is impossible to help in solving problems.

It would be valuable if the advantages of both commercial and custom hardware could be combined. We believe we have found a way to do this by using the concept of "Open Hardware", similar to the concept of "Open Software" that has proven its worth.

The main ideas behind the Open Hardware paradigm are:

- All specifications and design files are published to benefit from peer review and to enable remote collaboration.
- All detailed production files for the hardware, including PCB production files, precise bill-of-material and assembly instructions are published so that anyone can reproduce the hardware.
- Peer reviews are actively sought for to improve the designs and make them better re-usable.

OPEN HARDWARE REPOSITORY

To allow sharing of design information, a simple web site or mailing list is not enough. Therefore, in 2008 a custom development of a collaborative tool was made and the first Open Hardware Repository (OHR) site went public in February 2009. One year later, the site was moved to the Open Source program called Redmine while in February 2011 the data was moved to a 'fork' of Redmine called ChiliProject [6]. The OHR website ohwr.org [7] now contains for each project modules such as a Wiki, a file repository, a news page and notably an issues list to keep track of found problems and required changes (see Figure 3). It is truly open as anyone can access all information.

One thing is to have the final design information available; another thing is to understand the reasoning behind certain design choices. Actually we try to have this information in the form of dedicated documents and by keeping an archive of the mail exchanges between the collaborating engineers.

At the end of August 2011, the OHR site hosted 45 active projects of which 37 are initiated by different CERN groups, while 8 are from other institutes or companies. On average each project mentions 3.6 persons as developer. About thirty projects describe hardware designs, often with associated software. Another twenty projects document re-usable IP core designs that will speed up many hardware projects. Also general software tools such as a production test environment and utilities to test the performance of ADCs are hosted.

On the OHR site there are around twenty projects related to FMC developments. E.g., one can find the complete designs of carrier boards in VME64x and PCIe format. As FMC mezzanines one can find projects of

Figure 3: Open Hardware repository project page of the Simple PCI Express FMC carrier.

ADCs using different sampling speeds (100 kSPS, 100 MSPS) and TDC and Fine delay modules with a resolution of 1 ns or better. These projects are initiated by CERN while a reconfigurable hardware interface for computing and radio (RHINO) is initiated by the University of Cape Town in South Africa. Bristol University in the UK started a Trigger/Timing Logic Unit in FMC format for use in a beam-telescope.

Examples of designs that do not use FMC are a small footprint single board ARM-based computer running Linux and a TTL to NIM level converter board in VME format. Also full designs of a network switch for the White Rabbit timing network can be found.

As many projects can re-use much of the functionality that is implemented inside the FPGAs, there is also a wide range of so-called IP-cores many of which interface to the Wishbone bus: examples are a DDR3 controller, Gennum GN4124 core, VME64x core, Wishbone serialiser and Wishbone slave register generator. Also an LM32 RISC processor core and a TDC that can be implemented inside an FPGA are fully documented in the OHR.

To the users the advantages of using the OHR are clear: not only does the collaboration tool allow one to easily work with known colleagues, but it also allows to find in a single place similar designs, examples of well documented projects and of course other engineers that have the same attitude of sharing and helping.

CERN OPEN HARDWARE LICENCE

Even for Open Hardware it is necessary to have a licence that defines the conditions under which a licensee will be able to use or modify the licenced material. Although many licences exist for developing Open Software (GNU, GPL, etc.), it appeared that there was none usable to cover hardware developments. For this reason the Knowledge Transfer Group developed the CERN Open Hardware Licence (CERN OHL) [8] that is compliant with the Open Source Hardware (OSHW) definition criteria [9]. In the spirit of knowledge sharing and dissemination, the CERN OHL governs the use, copying, modification and distribution of hardware design documentation, and the manufacture and distribution of products.

It shares the same principles as open-source software: anyone should be able to see the source (the design documentation in case of hardware), study it, modify it and share it. In addition, if modifications are made and distributed, it must be under the same licence conditions – this is the 'persistent' nature of the licence – which ensure that the whole community will continue benefiting from improvements, in the sense that everyone will in turn be able to make modifications to these improvements.

Although the CERN Open Hardware Licence was originally written for CERN designs hosted in the Open Hardware Repository, it is also used by other designers wishing to share design information.

EXPERIENCE WITH INDUSTRY

It was expected that the Open Hardware paradigm would change the model of how to work with industry. When commercial hardware was needed for CERN's accelerator control systems, it was usually obtained from companies with thirty or more staff. Now as the design information is open, there is no risk that a design will be unmaintainable when a company closes or an engineer leaves. This allows CERN to work with companies that are often much smaller in size. In the past two years, to speed up the development of specialised hardware and notably for the development of firmware of interfaces to Wishbone or VME64x, we have used the services of over twelve companies in eight different countries.

We have also seen that a large company is interested in developing hardware based on the White Rabbit timing protocol specification for which several Open Hardware projects are on-going. The company would not reveal its own independent design, but is willing to support the project in other ways such as standardisation of the protocol and reviewing the different designs. Another company will likely adapt the PCI Express FMC carrier to

use the PXIe bus and republish this design under the CERN OHL. This new card will be able to profit from all FMC mezzanine cards and the associated firmware and software developments too.

Finally, for the first tender process for CERN of the production and support of 70 PCIe FMC carrier cards, out of the seven companies requested, five did reply. These companies, all having already PCIe products in their catalogue, indicated that they would like to produce extra and sell them as a product of their own, exactly as was intended by the Open Hardware paradigm and licence. Actually any company, even if it did not win the contract, may produce the designs, stimulating a competitive environment. As it is likely that the FMC mezzanine cards will be produced by different companies than those producing the carriers, the Open Hardware concept may promote cooperation between companies.

One of the first designs in the Open Hardware repository is the nanoFIP, an interface chip for the WorldFIP industrial fieldbus. It is likely that this FPGA, that replaces an obsolete commercial device, will be used by a company to renovate a WorldFIP installation inside a train. Also for this company the full availability of the design information is crucial.

FUTURE WORK

As more and more projects are using the OHR, it will be important for engineers to be able to easily find designs for re-use. Currently a simple text based search is possible, but this may not be enough once hundreds of designs are available. The quality of the projects in the OHR will also be important. Already now some projects are very complete and active while other projects have only little information available. Currently this is covered by a status field that shows if a project is in planning state, mature, in alpha, beta or released. This may not be enough.

To allow sharing of design information such as schematics and the PCB layout, it should be possible for everyone to use the same tools that were used to generate this information. We believe that there are currently no free, open tools that are usable enough to make very complex designs and therefore we are looking into possibilities to raise one of the existing free tools to the required level, or to develop another one. Similarly we are helping to add VHDL support to the Icarus Verilog simulation and synthesis tool. Of course these developments will be made with the Open Software paradigm and we hope to attract other interested engineers to help in doing these developments.

CONCLUSIONS

The BE-CO Group at CERN is responsible for electronics that needs to be supported for tens of years. In some cases commercial hardware can be used but has the disadvantage of being black boxes that can only be supported by a single company.

By developing Open Hardware the designs function exactly how we need and in principle anyone can make improvements. Outside specialists may help and the peer review gives the potential for having really good designs. Also one is not tied to a single company for the production and support.

The CERN Open Hardware Licence paved the way for a solid legal ground, while the developed ohwr.org site allows engineers from different sites to easily collaborate on designs and to make the information public.

Having started with designs based on well-established standards such as VME64x, PCIe, FMC and the FPGA-internal Wishbone bus has helped to attract users and to make modules that are easily re-usable.

Finally, it has been shown that small engineering businesses find good opportunities to participate in the design efforts, while companies of various sizes have shown interest in producing and supporting Open Hardware designs in the same way as their own products.

Almost three years of experience show that the OHR environment and the ideas of Open Hardware are stimulating to engineers as it allows the sharing of their knowledge and results in better quality and better documented designs. For companies it gives new opportunities that may need to change their way of operating.

Designed using the Open Hardware concept, the PCIe carrier and 100 MSPS ADC mezzanine are being produced by industry, ready to be installed in CERN's control systems in early 2012. The nanoFIP fieldbus interface chip is also finished and is being designed into control systems. The public nature of this design attracted a European company to re-use it. Other modules, such as the VME64x carrier and 100 kSPS ADC, fine delay and TDC mezzanines are available as working prototypes and will be produced and supported by industry. This base set of modules, together with the supporting IP modules and drivers that have been made will allow rapid development of other modules that will be required by CERN's control systems and those of other installations.

CHALLENGES FOR EMERGING NEW ELECTRONICS STANDARDS FOR PHYSICS*

Raymond S. Larsen, SLAC, Menlo Park, CA 94028, U.S.A.

Abstract

A unique effort is underway between industry and the international physics community to extend the Telecom industry's Advanced Telecommunications Computing Architecture (ATCA and MicroTCA) to meet future needs of the physics machine controls, instrumentation and detector communities. New standard extensions for physics are described which have been designed to deliver unprecedented performance and high subsystem availability for accelerator controls, instrumentation and data acquisition. Key technical features include an out-of-band imbedded standard Intelligent Platform Management Interface (IPMI) system to manage hot-swap module replacement and hardware-software failover. New software standards or guidelines are in development which will extend the reach of platform independent software standards to simplify design of low level drivers. Efforts to make the new standards broadly available in the marketplace through lab-industry collaboration are discussed.

INTRODUCTION

Several hurdles face the development and market acceptance of any new standard. In the case of earlier distinctly lab standards like NIM, CAMAC and FASTBUS the physics market itself banded together a priori to express a need and then develop an in-house standard. Success was guaranteed mainly by a simultaneous high rate of growth of both new labs and new front end and computing chip technologies. These standards were not universally adopted but had a reasonably high acceptance rate over several decades. As time went on the VME standard took over in the labs, supported by a strong military market focus. In 1994 ATCA and MicroTCA telecom standards were released and several labs working on next-generation machines became convinced that it was time for extension of this high availability high performance platform into physics controls, instruments and data acquisition. In early 2008 DESY made a decision to explore the platform for the recently approved X-Ray Free Electron Laser (XFEL). At the same time the International Linear Collider (ILC) R&D team chose ATCA as its technical and cost model. In early 2009 several labs joined the PCI Industrial Computer Manufacturer's Group (PICMG), an open-source standards organization of 250 companies, to develop formal standard extensions for physics. Goals included increased I/O channels and board size for analogue functions; rear transition modules with managed interfaces to enable hot-swap operation; and precision machine time synchronization and event triggering architectures. At the same time a software working group was launched to work on standardizing application interfaces, architectures and protocols and generic low level drivers for common modules such as ADCs; and to explore industrial high availability auto-failover software techniques for N+1 redundant systems in which a computer node has a backup processor and hub switch for example, or a backup timing network and generator-receiver at the node level.

The two major hardware standards have passed PICMG approval and are in publication, while software efforts continue with a dedicated core group. Exploration for controls is growing at several laboratories led by DESY, SLAC, IHEP and ITER. Several detector groups are exploring xTCA for LHC upgrades and several non-high energy physics machines including XFEL at DESY, LCLS at SLAC and others.

The major challenge today is to mature the new standard sufficiently quickly to meet needs of emerging new machine opportunities, particularly programs such as LCLSII at SLAC, the European Spallation Source in Europe and a number of smaller machines. The remainder of this paper will review progress to date and show examples of lab-industry collaboration to provide core infrastructure and common applications support.

TECHNICAL JUSTIFICATION FOR XTCA FOR PHYSICS

The initial attraction of xTCA for the 20-mile linear collider was based on bandwidth and throughput to cover machine and detector applications for the next 1-2 decades; and on its dual redundant Gbps serial backplane to achieve 0.99999 availability at the crate (shelf) level. The large ATCA card was seen to be most suited to special high throughput processor engines for fast RF feedback and detectors, while smaller more economical MicroTCA platform seemed best suited to Control systems supporting a variety of low and high speed applications in the same crate, e.g. medium speed RF feedback and slow DC magnet or vacuum controls and monitoring. A serially-networked xTCA architecture also easily accommodates so-called *network-attached devices* such as beam monitoring instruments distributed along a large machine at low density communicating only by serial link. A third attraction is the ability to extend IPMI management functions into non-xTCA devices, such as pulsed modulators and magnet power supplies, to bring unprecedented diagnostic information into control rooms and maintenance service centers.

*Work supported by US Department of Energy Contract DE-AC03-76SF00515

In summary, xTCA offers the following features:

- ATCA large card platform ideally matched to high bandwidth and throughput DAQ applications
- ATCA accommodates up to eight AMC mezzanine cards
- AMC mezzanine cards adapt easily to MicroTCA platform with similar bandwidth performance if desired
- MicroTCA real estate is cost effective for both very high speed applications as well as a high density of slow speed applications typical of industrial control
- Standards maintained and advanced by large industry consortium
- Consortium now includes laboratory members to advance features for both physics and non-physics applications
- Applications in non-physics areas including telecom potentially increases volume, improves market stability and decreases unit cost

NEW INFRASTRUCTURE STANDARDS FOR PHYSICS

Technical Features

The first standard extension, PICMG3.8, provides a standard hardware IO and management interface to the large ATCA card, which was left unspecified by PICMG. PICMG since has added an IPMI interface but no standard connectors. A new power and management connector was developed by the physics group for the standard. The interface is expected to cover a range of perhaps 80% of all applications. Where justified, the company or physics designer is permitted to choose a different connector which however compromises the physics goal of *interoperability* of designs made by different labs and companies.

The first test application at SLAC of PICMG3.8 is shown in Fig. 1.

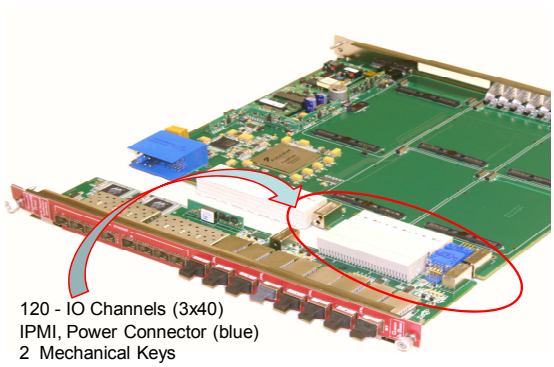

Figure 1: New ATCA RTM Interface PICMG3.8.

The second standard extension on MicroTCA specifies an entirely new 12-slot double-wide crate (shelf) and RTM with power and management controlled from the host AMC. The RTM card is identical in size to the AMC card but flipped vertically to properly align the rear panel with the in-line rear card guides. The IO interface is two 3-row 10 column channels (shielded 100Ω pairs) of which ten pairs are used for power, IPMI and JTAG connections. The concept is shown in Fig. 2 and industry hardware in Figs. 3-5.

Only the AMC connects to the backplane containing all the standard dual star interconnections plus a new layer for triggering and interlock sums. In addition a group of *extended options area* standard lines are specified for point-to-point precision clocks or triggers. The dual star redundant backplane is shown in Fig. 6.

The RTM connects to the host AMC only through its IO connector. Both the AMC and RTM are hot swappable although to swap the RTM all cables must first be disconnected. The RTM is expected to need replacement much less often than the more complex AMC.

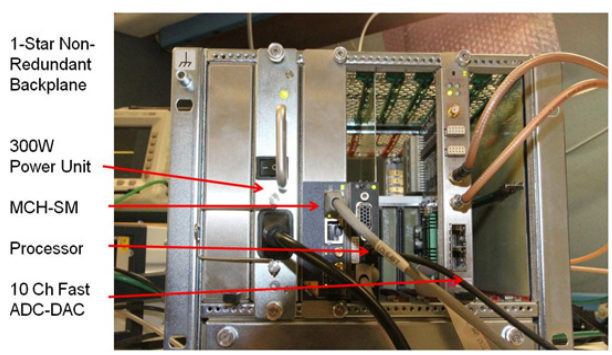

Figure 4: 6-Slot Development Platform MTCA.4.

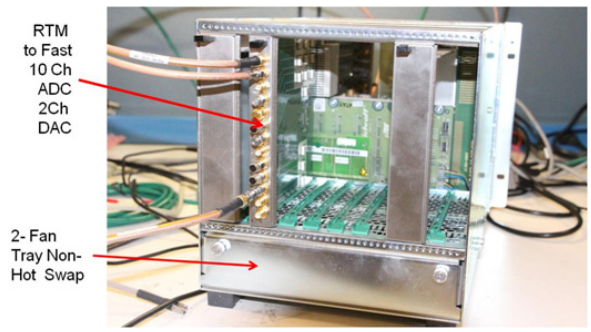

Figure 5: Rear of 6-Slot Shelf with Fast Digitizer RTM.

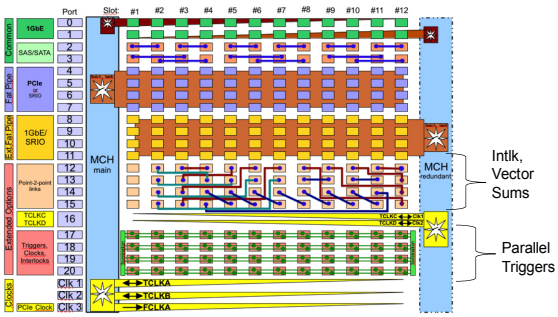

Figure 6: 12 Slot Redundant Backplane MTCA.4.

Progress Toward Infrastructure COTS Availability

One of the important metrics for the viability of any standard unless wholly developed and supported internally is availability of Commercial Off The Shelf products and servicing. Table 1 summarizes progress in the number of vendors supporting key components of the new standard, which officially is just being made public for the first time. Clearly the numbers are small but although no names are mentioned a significant number of major ATCA vendors contributed to the development and are fully engaged in product development.

Table 1: COTS Infrastructure Progress MCTA.4

Infrastructure	Description	COTS Availability
Development Shelf non-redundant	6-payload shelf with PU, integral cooling fans	2 vendors
Station Node Shelf dual star redundant	12-payload slot shelf , hot-swappable fan tray(s)	3 vendors
Modular Power Supplies	12V Power Units (PUs) 300/600/900W	2-4 vendors
Hub Controller (MCH) – full featured for timing needed	MCH Controller w/ integral IPMI shelf manager, hot-swap, access to radial timing option	2 vendors Switches for radial timing lines need development
IO Controller Processor (IOC)	Generic AMC processor running Linux, EPICS	2+ vendors
Timing Module	1 or 2-wide AMC (SLAC needs EVR compatible, needs adaptation)	1st units available (U. Stockholm), need COTS sources (2)

Note that the last item on the list is a timing module for MCTA.4, which has been developed in a collaboration of DESY with University of Stockholm but only recently is completed to where commercialization can be considered. Two versions are in progress, a single wide Tx-Rx unit suitable also for use on an ATCA Carrier board, and a double-wide for MTCA.4 that will allow additional channels to be distributed outside the shelf via the RTM. Small quantities of the first have been delivered and are operational, while the design of the second is in progress for completion in late 2011. Commercial sources are interested and working toward solutions also. The single wide unit and double-wide concept are shown in Figure 5.

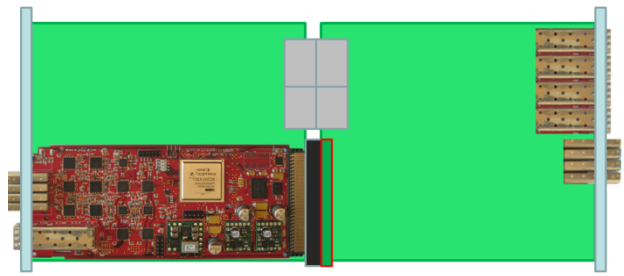

Figure 7: MTCA.4 Tx-Rx Timing Module Prototype (Stockholm University & DESY) and Double Wide Concept (in design, Stockholm).

LAB-INDUSTRY APPLICATIONS DEVELOPMENTS ON MTCA.4

The next important metric is the commercial availability of key generic AMC modules:

- High performance fast digitizers for DAQ and LLRF applications
- FPGA modules to process instrumentation tasks such as interlocks, beam position, beam charge etc.
- AMC Adapter modules for common industry standards e.g. PMC, Industry Pack, FMC etc,

With these three generic modules and customized RTMs developed by either labs or by industry, the bulk of controls and monitoring requirements for an accelerator can be instrumented. Some AMC adapter applications include stepping motor drivers, temperature, beam loss, wire scanners, fast frame grabbers, etc. Examples are shown in Figures 6-13.

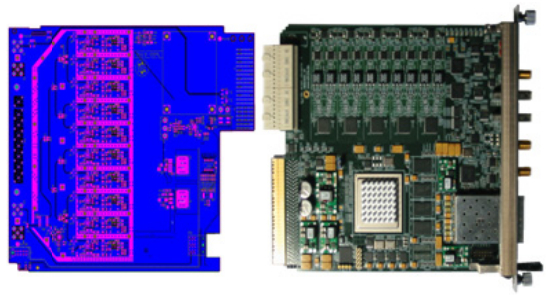

Figure 12: IF Down-Converter RTM to Struck ADC-DAC (DESY).

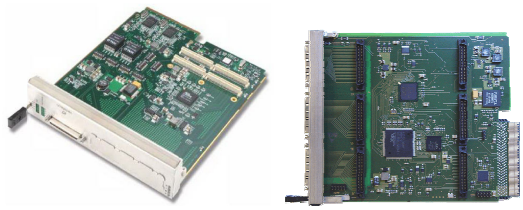

Figure 13: PMC Double Wide AMC Adapter (Vadatech) and 3-IP AMC Adapter (TEWS)*
*Now available on MTCA.4 version with RTM.

Progress Toward Generic Applications COS Availability

Table 2 summarizes progress toward development of COTS suppliers for generic AMC modules. There are 1-2 vendors in existence or in development for the items shown. It is the goal of the PICMG program to develop at least two commercial suppliers for critical products so the Physics Technical Committee has chosen to apply this to both basic infrastructure and basic generic products.

The right hand column is a partial list of the instrumentation applications that can be served by this limited list of generic products. In other words, a small number of complex AMC products is highly leveraged to a number of applications which significantly reduces development costs and speeds time to project-readiness (or to market for vendors).

RISK FACTORS AND RISK REDUCTION

General Observations

Most if not all new accelerator projects, by the time they have spent years in development and battling for approvals, are highly averse to potential time and cost risks associated with a new standard. The decision by a single large project or a number of projects to adopt a new controls and instrumentation platform, an event that occurs approximately every two Sun-Spot Cycles in physics and industry, must be solidly based on enough prior work to demonstrate the technology, especially the

Table 2: COTS Generic Applications Progress

Generic AMC	COTS Availability	RTM Adapters
10/2 Ch ADC/DAC 16 bit 125 MSPS	1 vendor available 2nd vendor due end FY11	• RF-IF down-mixers • BPM adapter • Photodiodes
4 Ch ADC AMC 14-16 Bit 125 -500 MSPS	1-2 vendors in development	• BPM single bunch • BPM multi-bunch • Beam intensity Toroid • Beam Length
FPGA Virtex/Spartan, FMC optional	1 vendor in development	• Interlocks ADCs12 bits, 8 ch @60 MSps, 16ch@2KSps • Wire scanner interface
AMC Industry Pack Adapter (2-3 IPs)	2 vendors in development	• Stepping motor control • Vacuum control-monitoring • Temp control-monitoring
AMC PMC Adapters	2 vendors	• Timing Rx adapter • Frame grabber adapter

software, and the hardware-software costs by achieving basic COTS availability.

ATCA is actually a decade old and it is in mid-ramp in Telecom which now is claiming in excess of $1B per year of product in a $10B per year market. A small part of this is in MicroTCA which developed as a standalone in a second phase of development so is much less mature. Therefore one has to admit that establishing any new platform takes time and investment and involves risk.

On the other hand, technologies advance rapidly, obsolescence is inevitable, and at some point all platforms have to be replaced. Laboratories must plan the inevitable changes to minimize risks to ongoing and emerging products when they do occur. Otherwise, as many laboratories have learned, a failure to modernize adiabatically during the long life of huge accelerators can cause insurmountable barriers of time and cost when they become truly unavoidable.

Lab Industry Collaborations a Tool for Risk Reduction

New platform development is a large costly undertaking and requires a dedicated community of champions to achieve. The PIMCG consortium is such a community which has had large success for many years. The xTCA for Physics standards efforts are only two years old but have already saved large development time and cost by the collaboration. Coordinated joint development of basic industry support for both infrastructure and generic applications is already paying dividends. There is major work ahead for any lab adopting the standards, but a great deal is already done and being made available to the entire community.

NEXT STEPS: SOFTWARE EXTENSIONS

The xTCA for Physics collaboration has achieved its initial goals and now must bring the same enthusiasm to developing streamlined software modules, tools and supports. The major goal is to standardize modules to address imbedded FPGA based systems and to simplify development of new applications by such standards or best practices guidelines. The objective as in hardware is to make products built in both labs and industry more compatible and *interoperable* as has been achieved through the IPMI management system for the hardware platforms.

CONCLUSION

The xTCA for Physics Lab-Industry collaboration has achieved the launching of a new hardware and software architecture for physics. Its ultimate success depends on many factors and will vary across many applications, but it is now available as new system that is already being explored and adopted at several labs. The next major effort must be to extend software compatibility at low levels of hardware, which has never been achieved satisfactorily in any present standard.

The same approaches that underlie the xTCA architectures are also extendable to non-xTCA devices such as Megawatt class power supplies and pulsed modulators for RF systems, AC and DC high availability systems etc. A judicious use of extra dual or N+1 redundancy can enable us to visualize in future "machines that never break." Of course they will break, but the high availability architectures of xTCA applied broadly (which linacs have inherently) can make render breakages of little or no impact in keeping the machine running.

Similarly Intelligent Platform Management diagnostic extensions beyond basic control and instrument modules into all major power systems and remote instruments will have a major impact on machine uptime and reduce the time, effort and number of people required for servicing.

ACKNOWLEDGMENTS

This paper represents the work of an entire community far too many to name.

The PICMG xTCA for Physics collaboration was sponsored by DESY, IHEP, FNAL, SLAC and now has added lab members CERN, IPFN Lisbon, ITER, KEK, LBNL and Sincrotrone Trieste. Cypress Point Research and TripleRing Technologies were industry sponsors.

Enormous credit is due to key contributors from both labs and industry, including Schroff, ELMA, Positronix, TE Systems, Pentair-Schroff, Performance Technologies and others from among over 40 industry members

The DESY XFEL teams headed by Kay Rehlich and Stefan Simrock (now with ITER) made ground-breaking technical contributions in ATCA and MTCA.4 early applications and design.

Special thanks to Robert W. Downing, the driving force with Dick Somes who constructed and edited both specifications; to Stefan Simrock and A.P. Gus Lowell who lead the Software team; and to Joe Pavlat, PICMG President and Doug Sandy, PICMG Technical Officer for unwavering support. Sincere thanks to the xTCA pioneers at SLAC: Z.Geng, A. Young, D. Brown, C. Yee, C. Xu, D. van Winkle and E. Williams.

UPGRADING THE FERMILAB FIRE AND SECURITY REPORTING SYSTEM

C. King, R. Neswold
FNAL†, Batavia, IL 60510, U.S.A.

Abstract

Fermilab's homegrown fire and security system (known as FIRUS) is highly reliable and has been used nearly thirty years. The system has gone through some minor upgrades, however, none of those changes made significant, visible changes. In this paper, we present a major overhaul to the system that is halfway complete. We discuss the use of Apple's OS X for the new GUI, upgrading the servers to use the Erlang programming language and allowing limited access for iOS and Android-based mobile devices.

INTRODUCTION

FIRUS is an acronym for **F**ire **I**ncident **R**eporting and **U**tility **S**ystem. It was developed at Fermilab in the early eighties using the technology available at the time resulting in consoles that run on MS-DOS based PCs using Digital Research's GEM graphical user interface and servers running Motorola's VersaDOS. Consoles communicate with servers via ARCNET and are segregated from Fermilab's main network for security reasons. This has resulted in a reliable, high-availability system that is still in use today.

OVERVIEW

FIRUS is comprised of front-ends, minis and consoles which all communicate via a private ARCNET network. The network is divided into eight trunks as shown in Figure 1. The front-ends are connected to all eight trunks, while the minis and consoles are only connected to one.

Front-Ends

At the heart of FIRUS are the two front-ends, "blue" and "red". The blue front-end is considered the primary and the red front-end is the backup. Under normal conditions, both blue and red divide the load of scanning minis and communicating with consoles equally. They each hold a full copy of the device database, which contains hardware addresses and alarm limits. Edits to the database go to blue, which then forwards the changes to red's copy.

FIRUS is designed to be fault-tolerant against a single front-end failure. The two systems monitor each other and, if one determines the other is unresponsive, it will assume responsibilities for all minis and consoles until the other front-end returns to service. This feature also allows us to take one system down for maintenance without impacting Fermilab's security and fire departments.

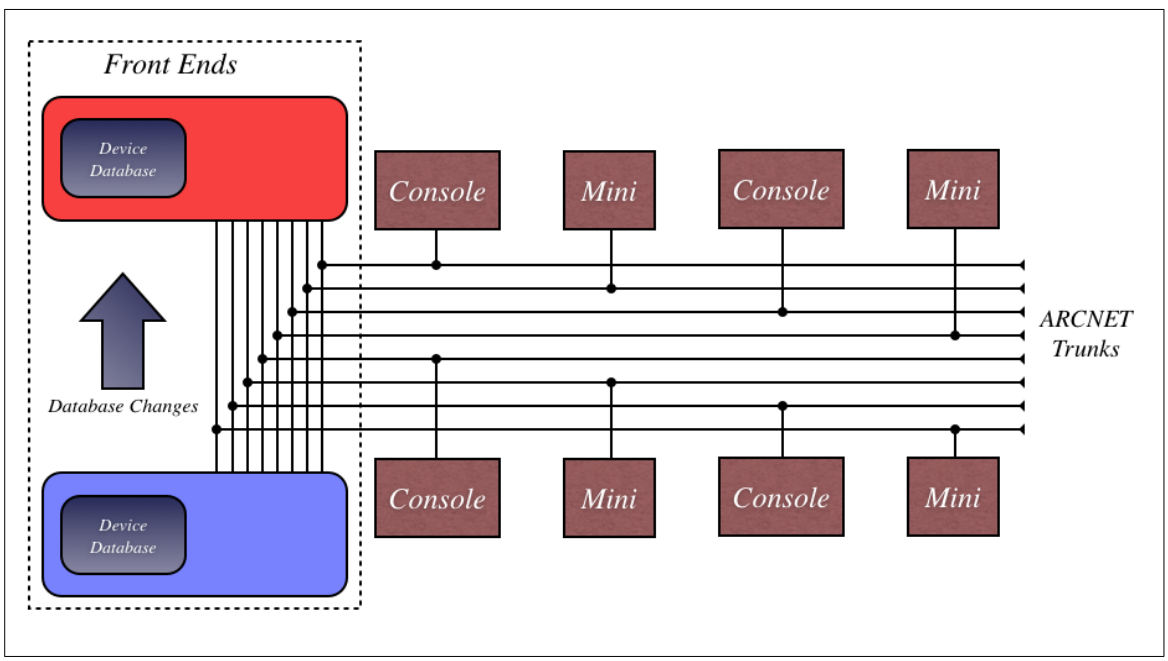

Figure 1: FIRUS Topology.

†Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.

Minis

"Minis" are small, embedded systems distributed site-wide. There are 150 minis currently active in FIRUS. Each mini is controlled by an 80186 embedded processor which uses an ARCNET interface to communicate with the front-end systems. A system can contain up to seven daughter cards each of which provides analog or digital inputs. The analog cards provide 16 channels of 16-bit A/D conversion while the digital cards supply 16 bits of input. Each digital input is instrumented to detect shorts, open circuits and grounded signals. Minis are embedded software modules that connect to device hardware.

Consoles

All user interaction with FIRUS happens on the console. The important features of a FIRUS console are as follows:

- Alarm acknowledge and display
- Alarm logging
- Device database management
- Real-time parameter page display
- Data logging at multiple rates
- Real-time and logger plotting
- Synoptic picture displays
- Fully configurable
- Password protection for sensitive items

UPGRADING THE CONSOLE

The FIRUS console hardware hasn't had a refresh since it's original inception in the mid eighties. We are now reaching the point of obsolescence, thus creating a nightmare maintenance scenario. GEM compatible PC hardware was becoming increasingly hard to come by. GEM requires EGA which is fairly low resolution by today's standards and only supports a limited sixteen colours. Contrast that with the ultra high resolution, million colour displays of today and it's not hard to see that change is needed.

The combined memory issues with MS-DOS and GEM was also a source of frustration. Adding features and making changes were almost impossible. Eventually the FIRUS application had to be split into two separate executables because of GEM's 64K maximum resource data segment size, resulting in a stripped down FIRUS application and a utility FIRUS application known as UFIRUS. Because MS-DOS is not a multitasking environment, this split basically removed some features from FIRUS as a whole since most users would never run UFIRUS.

Mac OS X

As it became more of a challenge to obtain replacement PC hardware, more time was invested in determining a new platform for the FIRUS console. Windows XP, Linux with QT, Java and OS X were all possible, but OS X won out because of it's modern graphical interface, it's Unix core and it's powerful set of **free** development tools[1].

OS X has the benefit of being a direct descendant of NeXT Inc.'s OPENSTEP operating system[2]. It inherited from OPENSTEP the feature-rich, object-oriented interface as well as the beginnings of a build environment that Apple has masterfully crafted into what is now known as Xcode. Xcode presented a learning curve but proved to be well worth the effort. It was clear that not only was Apple catering to the end user, they were also making OS X attractive to the developer.

Design Goals

FIRUS has been in use by Fermilab since the early eighties, hence our most important design goal was to minimize the user's learning curve. User acceptance was very integral to the success of the upgrade. Most people are annoyed and/or frightened by change, especially with changes without fundamental improvement to the workflow. Obviously changing the graphical user interface poses some changes that may require the users some time to adjust, but overall we strove to minimize most changes unless deemed value added.

Other design goals included:

- No changes to front-end code so both GEM and new consoles could run side by side for verification purposes
- FIRUS will be one cohesive application (GEM was two separate applications)
- Add a kiosk mode to keep unprivileged users from switching away or quitting the FIRUS application
- Automatic software update distribution with versioning

ARCNET Challenge

After deciding on Mac OS X, iMacs and Mac minis were chosen as the hardware we would use to replace the current consoles. Both the iMac and Mac mini are the least expensive of the Macintosh line, yet were powerful enough for our needs. They also both have a very small footprint and are able to physically fit where any GEM console currently resides.

One of the more challenging aspects of the FIRUS console upgrade was how to get the desired Macintosh computers connected to ARCNET. Since iMacs and Mac minis were the chosen hardware, ARCNET cards were not an option. The search was on for a device that would bridge the gap. Our search turned up such a device. The USB22-CXB from Contemporary CONTROLS is an external USB to ARCNET bridge that is powered by the USB port thus eliminating the need for separate power, and it connected to directly to our coaxial-based ARCNET topology.

Alas, our excitement was short lived when we discovered that the USB22 was virtually unsupported on OS X. Contemporary CONTROLS had no plans to add support, so if we wanted to use the device we would have

to do it ourselves. Our first thought was to make the USB22 a true network device in order take advantage of built in network configuration in OS X. While this approach worked well (we were able to copy large files, stream video and browse web pages over ARCNET), it was not compatible with the FIRUS minis. The minis were unable to ignore the multicasted TCP/IP traffic and would become unresponsive. Since updating the software in the FIRUS minis was out of the scope of the upgrade, we had to abandon the network driver for a more FIRUS-specific solution. The final decision was made to use OS X's application level USB driver interface. Code for supporting the USB22 is built in to the FIRUS consoles, and as a result, the application can notify the user of network or device problems in a more timely manner.

Development Notes

Overall, the development of the new FIRUS console was an exciting project to work on. The Xcode integrated environment make easy work of designing the user interface elements. The source code editor aided code production by providing context sensitive help and autocompletion. The debugger worked flawlessly, and the instrument tools for memory issues assured that the high -availability goal for the console could be attained.

Xcode, however, wasn't our only learning curve. We also received lessons on usability. Just because certain standard features of OS X are indispensable in some applications, doesn't mean they will automatically be well received in the FIRUS console. One specific incident pertained to the basic alarm screen. We assumed that giving the users ad-hoc sorting by any displayed column would be a feature they couldn't live without. As it turned out, that was one feature they couldn't live with. FIRUS operators were so used to alarms lists that are sorted by decreasing time that they didn't want to even have the ability to change it and possibly misread the alarm screen. From that point on, we became more FIRUS user- centric in our user interface design.

FUTURE DEVELOPMENT

Now that the FIRUS console upgrade is complete and in the process of certification, we look toward future development for FIRUS. During development of the FIRUS console upgrade we discovered a number of front-end deficiencies as well as inaccurate behaviour.

Front-End Upgrades

In the lifetime of the FIRUS system, the front-ends went through one major upgrade. Right before Y2K, we upgraded the hardware from a 68K-based VME board to a multi-gigahertz Intel-based PC. The FIRUS software was ported -- not rewritten -- from Motorola Unix to a BSD Unix. The upgrade gave us a lot of CPU horsepower and much more memory to use than the original system. None of these extra resources have been exploited, yet. Now that the consoles have been updated, we look to modernize the front-ends again.

The software in the front-end was written in a time of limited CPU resources and memory constraints. The operating systems didn't support threads and the FIRUS processes weren't written to fork parallel processes to handle multiple requests. We feel that, with the resources available on the new consoles, a greater number of requests will be placed on the front-ends. They need to scale gracefully with the extra load, which the single threaded design won't be able to do.

Another shortcoming is that the tasks on the front-end don't communicate with each other when some global, system state has changed. The database task, for instance, doesn't inform the alarm task that an entry has changed. Instead, a console will see the change when the alarm task eventually rereads the database. It would be nice if state changes, like this, are synchronized better within the front-end.

Our decision is to rewrite the front-end software using the soft real-time, functional programming language, Erlang. Erlang was developed by Ericsson to use in their telephony equipment[3]. The language features concurrency primitives as part of the language and uses very light-weight processes to break a problem into simple pieces. Processes communicate with each other using message queues. The Erlang runtime is very rich and includes an ACID-compliant, distributed database (which will get leveraged in the upgrade.) There is also a web server module so the front-ends could generate and deliver web pages displaying status.

Remote Access/Mobile Devices

In today's well-connected world, WIFI and cellular data access are the norm. People have come to expect universal access to their data. Now the question arises. How do we securely deliver remote access to FIRUS.

We are currently testing a web-based remote alarm display that gives users access both on and off site. This is done securely by routing all traffic though a proxy server using a secure socket layer (SSL). All on-site access is automatically allowed. Off-site access is allowed only after password verification. This is currently in use by our on-site fire technicians. When testing contact circuitry, they are able to view alarm status on the web browser running on their portable scanning device. This has been very successful by reducing the testing time in the field.

We believe the future of the FIRUS console could include application development on mobile devices. Today's mobile devices are essentially ultra portable computers capable of running complex applications. With proper security considerations, we feel that many of the console features could be incorporated into applications for the iPhone and iPad and possibly some Android-based devices.

CONCLUSION

FIRUS has been a reliable, high-availability system that has been in use since the mid eighties at Fermilab. But

over the last few years, FIRUS started showing signs of it ageing architecture. In this paper, we presented the highlights of the FIRUS console upgrade as well as detailed what remains to be done to take FIRUS into the future.

SARAF CONTROL SYSTEM REBUILD

E. Reinfeld, I. Gertz, I. Eliyahu, Soreq NRC, Yavne ANL ISRAEL

Abstract

The Soreq Applied Research Accelerator Facility (SARAF) is a proton/deuteron RF superconducting linear accelerator, which was commissioned at Soreq NRC. SARAF will be a multi-user facility, whose main activities will be neutron physics and applications, radio-pharmaceuticals development and production, and basic nuclear physics research. The SARAF Accelerator Control System (ACS) was delivered while still in development phase. Various issues limit our capability to use it as a basis for future phases of the accelerator operation and need to be addressed. Recently two projects have been launched in order to streamline the system and prepare it for the future development of the accelerator. This article will describe the plans and goals of these projects, the preparations undertaken by the SARAF team, the design principles on which the control methodology will be based and the architecture which is planned to be implemented. The rebuilding process will take place in two consecutive projects. The first will revamp the network architecture and the second will involve the actual rebuilding of the control system applications, features and procedures.

INTRODUCTION

SARAF is currently under construction at Soreq NRC [1]. It will consist of a medium energy (up to 40 Mev) high current (up to 2mA, CW, upgradable to 4mA) RF superconducting LINAC of protons and deuterons. The main accelerator assembly was built and delivered to the SARAF facility in 2007 and two beam lines were constructed by the SARAF team and completed in 2010. The project phase I is planned to be completed during the next couple of months and phase II is planned to start soon after (figures 1 and 2).

The accelerator control system was delivered while in development state and consisted of a number of semi-independent control systems, each designed to control a specific component of the accelerator [3]. Development ceased after delivering the system to SARAF team and was held in breakdown maintenance mode until the first two beam lines were constructed.

This article will describe the accelerator control system rebuilding project which is planned to transfer the control system from development mode into operational mode, and prepare it for phase II of the SARAF project.

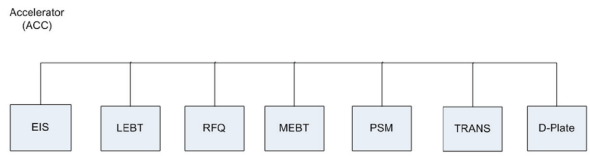

Figure 1: Accelerator overview.

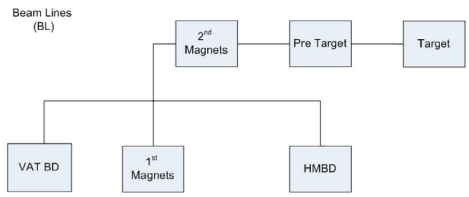

Figure 2: Beam lines overview.

PROBLEM DEFINITION

While preparations took place to the beam lines construction, the accelerator control system (ACS) was not developed further and was kept running with minimal effort and with no dedicated engineering staff.

As the beam lines construction advanced, it became apparent that the control system as a whole needs to be reviewed and assigned with control engineer team in order to "fix" the problems which were encountered by operators on a daily basis.

A review was conducted and as the system was further analyzed it became apparent that in order to prepare the facility for phase II of the project, the current control system which may have been fine for the development and commissioning stages must be overhauled and rebuilt.

The main issues which have to be solved can be summarized by the following list.

1. Lack of knowledge and documentation of the current control system. As the control system delivery was not completed there is close to no documentation at all on the various control components and mechanisms.
2. Fragile infrastructure. Key elements are missing from the control network infrastructure, which potentially can lead to severe consequences.
3. No methodology or strategy. Development of the control system was conducted "on the fly" and with no broad picture overview on how an accelerator control system should be built.
4. Waste of time and resources on keeping the system running. The operators have to deal with a control system which does not fully answer their needs and requirements.

In short, the system required a rebuilding effort that will stream line it into a solid operational control system that will provide a solid basis for further operation and development.

SOLUTION DEFINITION

To rebuild the system a methodical approach is planned, in order to address the issues described above systematically. Planning a strict method and following it in the implementation stages is important for standardization. An effort is made to complete each phase of the project as planned.

Revamping the infrastructure could be done in parallel, and was launched as a secondary project. This project is planned to upgrade the SARAF network capabilities in term of bandwidth, introduce network elements which were missing or not up to date, introduce cyber security protection suite tailored according to current standards for national infrastructure and should provide a solid foundation to the control system rebuilding project. The network revamp was defined as a necessary goal that is part of the control system base.

The control system rebuilding road map is described in figure 3.

Several constraints have to be taken into account when implementing the solution. The main constraint is that the rebuilding process will be done while the accelerator is still operational and a long period of shut down time is not planned. This means that the rebuilding process will be done on a living system and calls for careful planning and structuring of the rebuilding process, especially when migrating the software and tools, and when replacing specific applications.

IMPLEMENTATION

The project was divided into several consecutive phases. Each one consists of several action blocks which can be done in parallel to prevent bottle necks and to allow progress in various subjects by different teams.

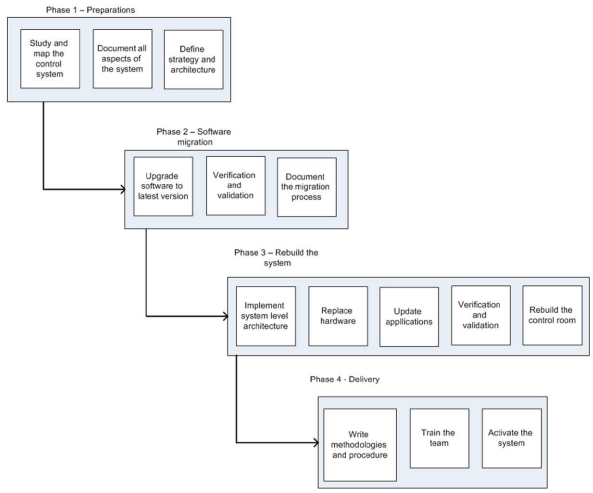

Figure 3: Project phases.

Phase A - Preparations

This phase creates a concrete control system knowledge base in the facility and defines the structure of the rebuilding project. This phase involves a thorough mapping and documentation of the entire control system. It involves reverse engineering efforts of the facility team members including the operators and engineers. At this point every major issue or bug found while reviewing the system will be cleaned and the applications will be updated wherever possible.

Mapping the system includes mapping I/O points, hardware, software and tools and reorganization of the system data.

Phase B – Software Migration

The SARAF control system is based on Labview 8.2.1 software. Some of the new control hardware is not compatible with this version as well as tool kits needed for new instalments. In this phase the software will be migrated to the latest stable version of Labview, and the entire application suite and control system will be migrated as well.

This will be a challenging step as the accelerator will be operational when the migration process takes place, and so both versions will coexist in the control system until all the applications are replaced.

Phase C – Rebuild the System

This phase will introduce new capabilities to the system, starting with a higher level of hierarchy to support flow control and implement the architecture designed in phase I of the project. This phase will see replacement of obsolete hardware, major update to all relevant application and should result in a stream lined and robust control system.

The last step of this phase will be the rebuilding of the control room according to modern design principals which will allow higher flexibility for operators and designers to work in.

Phase D – Delivery

The last phase will see the delivery of the control system to the SARAF team. After writing down operation methodologies, the team will be trained to use the system and the new tools introduced to it.

The following period will be to activate the control system and to monitor it for bugs and fine tune it according to operators needs.

SUMMARY

The SARAF facility has reached a maturity level to transfer it from the development state it was delivered, into an operational state. Two projects were launched to address the transfer, one to address infrastructure issues, and create a work environment which is stable and robust. The second is to rebuild the control system and create a basis for the future phases of the SARAF project, and to assimilate the engineering methodologies needed to operate and support a system of this kind.

THE UPGRADE PROGRAMME FOR THE ESRF ACCELERATOR CONTROL SYSTEM

J. Meyer, JM. Chaize, F. Epaud, F. Poncet, JL. Pons, B. Regad, E. Taurel, B. Vedder, P. Verdier,
ESRF, Grenoble, France

Abstract

To reach the goals specified in the ESRF Upgrade Programme [1], for the new experiments to be built, the storage ring needs to be modified. The optics must be changed to allow up to seven meter long straight sections and canted undulator set-ups. Better beam stabilization and feedback systems are necessary for the nano-focus experiments planned. Also we are undergoing a renovation and modernization phase to increase the lifetime of the accelerator and its control system.

This paper resumes the major upgrade projects, such as the new beam position monitoring (BPM) system, the fast orbit feedback, the ultra-small vertical emittance and their implications on the control system. Ongoing modernization projects such as the solid state radio frequency amplifier or the high-order mode (HOM) damped cavities are described. Software upgrades of several sub-systems e.g. vacuum and insertion devices, which are planned either for this year or for the long shutdown period, beginning of 2012, are covered as well. The final goal is to move to a Tango [2] only control system.

THE ESRF UPGRADE PROGRAMME

In 2008, the Council of the ESRF launched the ESRF Upgrade Programme 2009-2018, an ambitious ten-year project. Funding for a first phase of the Upgrade (from 2009 to 2015) has been secured to deliver:

- Eight new beamlines, mainly with nano-focus, with capabilities unique in the world
- Refurbishment of many existing beamlines to maintain them at world-class level
- Continued world leadership for X-ray beam availability, stability and brilliance
- Major new developments in synchrotron radiation instrumentation

Producing nano-sized beams needs long beamlines, which at the ESRF will reach 120 metres. An extension of the experimental hall will be built to house the new beamlines.

Nano-focusing also requires a high reliability, stability and brilliance of the x-ray source. To reach the goals of the update program, the x-ray source also needs to be modified.

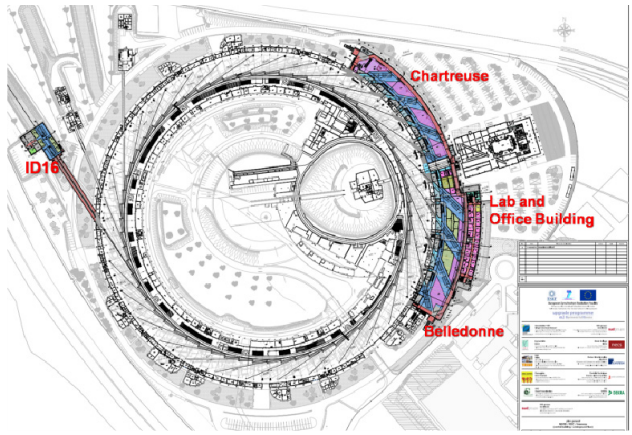

Figure 1: Experimental Hall Extension.

X-RAY SOURCE IMPROVEMENTS

Several improvements are already in preparation since 2009 in the framework of the ESRF Upgrade Programme.

BPMs and Fast Orbit Feedback

The old beam position monitoring system was already replaced at the end of 2009 with 224 Libera [3] measurement systems. With these high precision e-beam position measurements, the exchange of all 96 steerer power supplies and the installation of a fast, redundant communication network, we are now able to prepare a new fast orbit feedback system with a correction rate of 10 kHz. The result should be a better correction of e-beam movements.

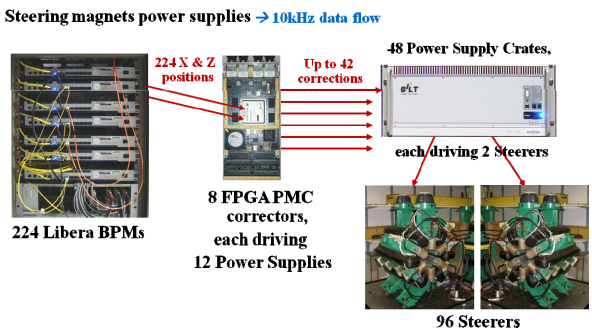

Figure 2: Fast Orbit Feedback System.

The feedback system is actually under test and should be operational at the end of 2011. The challenge for the control system was the progressive exchange of the steerer power supplies, during several months, without perturbing the operation.

Ultra-Small Vertical Emittance

A new algorithm for coupling correction was developed and implemented for the storage ring. Using this, together with the high precision Libera beam position monitors a vertical emittance of $\varepsilon_z = 4.4 \pm 0.7$ pm could be reached.

Two procedures to preserve the small vertical emittance during beam delivery were successfully tested: stable ε_z = 6-7 pm for a 7/8 +1 filling mode and 10 pm for a uniform filling.

During the last winter shutdown, 32 new skew quadrupole magnets have been installed on the storage ring to correct the coupling induced by insertion device movements. The goal is an ultra small vertical emittance of ε_z = 2 pm. The first already carried out tests are promising, and the new fast orbit feedback system will help this goal to be reached.

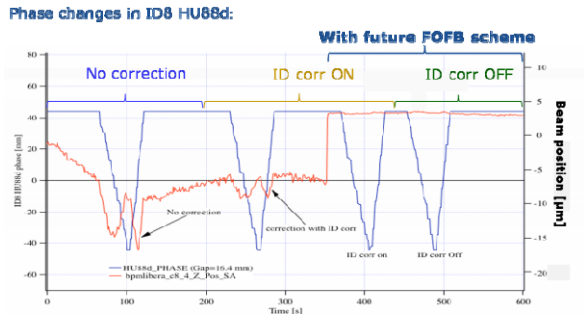

Figure 3: Correction of ID beam perturbation.

6m Straight Sections

The lattice of the ESRF storage ring was designed with 32 long straight sections of alternating high and low horizontal beta values. This currently provides 5 m of available space for insertion devices. The ESRF Upgrade Programme proposes to increase the length of selected insertion device straight sections from 5 to 6 or even 7 meters. This will provide a higher level of brilliance and increased insertion device flexibility. For example, longer insertion devices for a single beamline, sharing of the straight sections between two experimental stations using the canted undulator approach, reshuffling the RF cavities layout and freeing straight section space for new beamlines are possible uses of the increased straight section length.

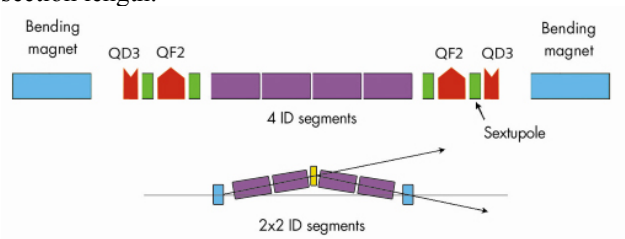

Figure 4: Uses of long straight sections.

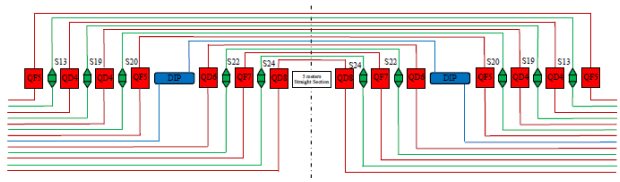

Figure 5: Initial, family-wise, power supply steering.

To allow such long straight sections, a lot of power supplies need to be changed from a family-wise control to individual control. The beam steering algorithmns had to be revised.

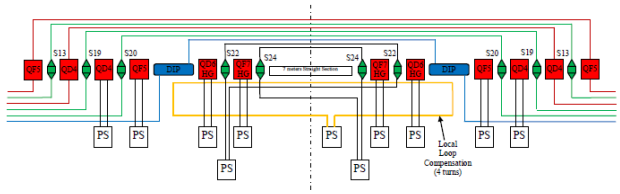

Figure 6: Power supply control for a 7m straight section.

High Power Solid State Radio Frequency Amplifiers and HOM Damped Cavities

The sub-system with the highest failure rate on the ESRF storage ring during the last years was the radio frequency system. To increase the long term reliability, two projects are in progress in the frame work of the Update Programme.

The replacement of the klystron based radio frequency transmitters with solid state radio frequency amplifiers and the development of new HOM-damped accelerating cavities.

Solid state amplifiers consume less power, have a high redundancy and need much less tuning effort compared to a klystron.

The first amplifier tower has been tested at the ESRF. Delivery and installation of the first full transmitter is planned for the end of 2011.

A careful software design is important, because the control system needs to combine the new and the old radio frequency controls in a coherent way.

Figure 7: Solid state RF amplifier at Soleil.

High order mode tuning of the accelerating cavities, especially at higher e-beam currents, is complicated to achieve. To overcome the limitation, a new design of a HOM-damped cavity [4] was made. The prototypes have been delivered to the ESRF and are currently under test.

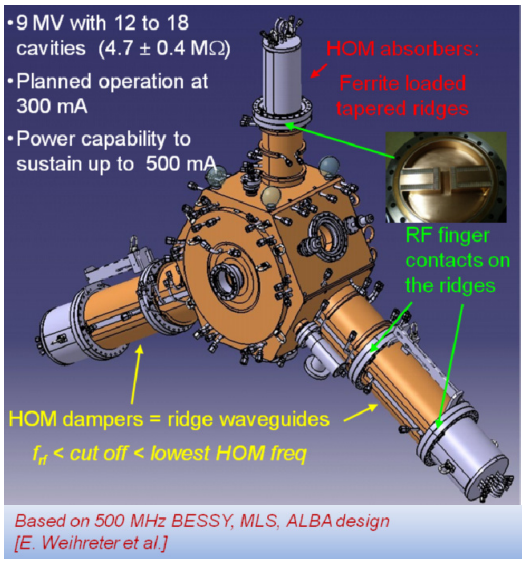

Figure 8: HOM-damped cavity design.

CONTROL SYSTEM UPGRADE

The first goal for the control system is the smooth integration of all X-ray source improvements without losing the reliability achieved over the last years.

In addition, specific long term goals have been defined for the control system.

Move to a Tango-only Control System

The ESRF accelerator complex is controlled with a mix of our legacy control system Taco, developed in the 1990's and our new Tango control system. Tango is a collaborative development which offers much more features, development and survey tools. For several years already we have been working on the replacement of Taco by Tango.

The Upgrade Programme and the long shutdown period from the end of 2011 until May 2012 offer a good opportunity to progress on the goal to replace Taco completely by Tango. The software redesign of several sub-systems is in progress to be ready for a long testing period. The exchange of the vacuum control software will be finished, by the end of 2011 and the new software for frontend and insertion device control is progressing.

A software redesign means a complete review of all features from the hardware interface to the graphical user interface.

In 2010 we still had 45% Taco devices. In 2012 we would like to have less than 25%.

Increase the Reliability

Several measures have been taken to increase the reliability of the control system.

A survey of all control computers was set up with NAGIOS [5] so that any CPU, memory or disk problem, for example, can be detected automatically.

The usage of the Tango administration system allows an immediate overview of all device servers running on control system hosts. With the new failure statistics, we can even identify infrequently occurring software crashes and schedule the necessary action.

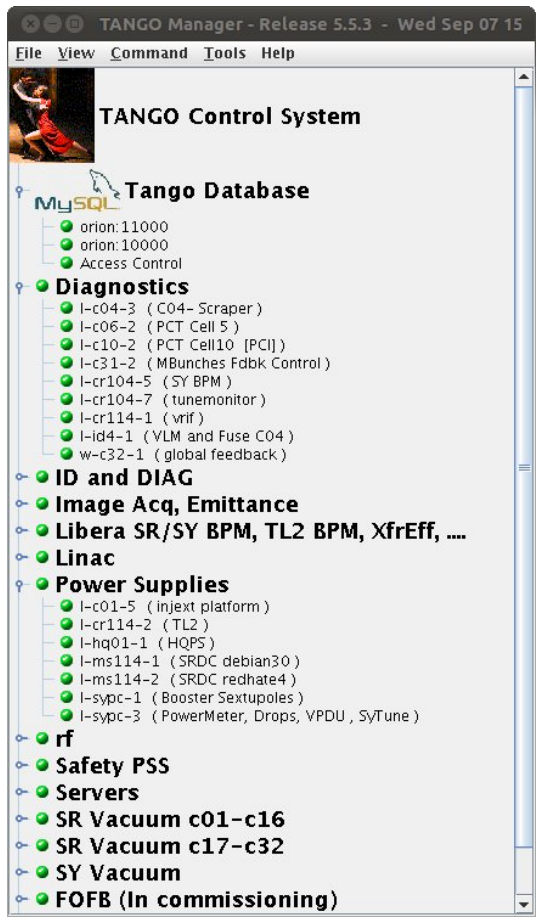

Figure 9: Tango administration GUI.

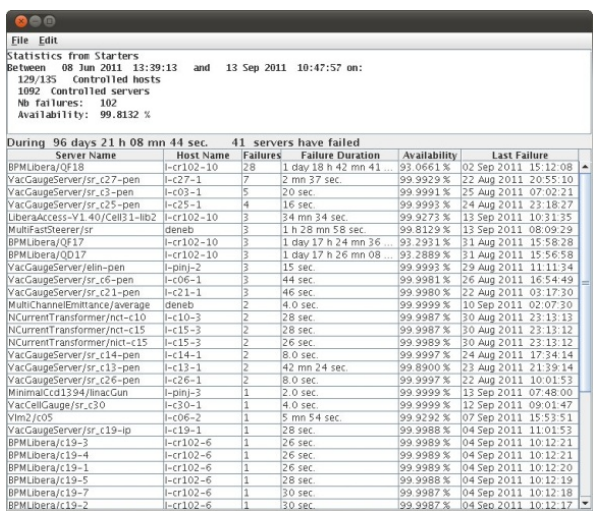

Figure 10: Failure statistics.

More High-level Analysis Tools

To allow better diagnostics or prediction of problems on the accelerator complex, a lot of effort goes into high-level data analysis tools. These analysis features can be implemented in the different device server layers, but must be regrouped into specific graphical user interfaces (GUI).

One example of such a high-level data analysis tool is the vacuum leak detection system, based on the residual gas analysers (RGA) [6], installed on the storage ring. The goal is to detect air leaks, water leaks and any abnormal out-gazing.

For example, the relative partial pressure survey is a 3-dimensional representation of selected partial pressures. Each relative pressure corresponds to a pressure change against its own reference. There is one reference pressure for each mass for every residual gas analyser and for every storage ring filling mode. This is particularly useful for a first and quick analysis of vacuum events. Figure 11 shows a typical partial pressure change signature in the case of an air leak event. Air leaks are clearly linked to strong relative changes of partial pressures corresponding mainly to masses 14, 28 and 40 (N, N2, and Ar).

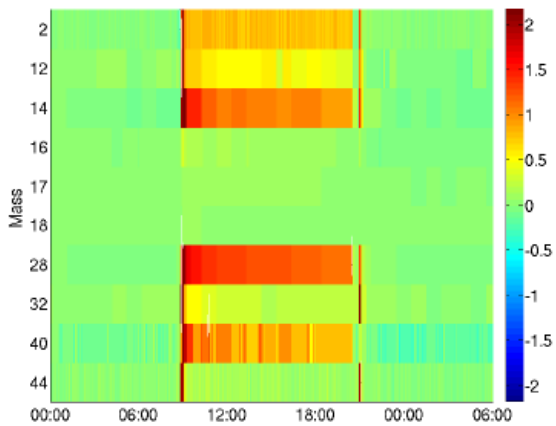

Figure 11: Real-time relative partial pressure survey.

The specific graphical user interface enables the handling of all RGAs around the storage ring and provides a complex alarm configuration as well as online and post-mortem data analysis.

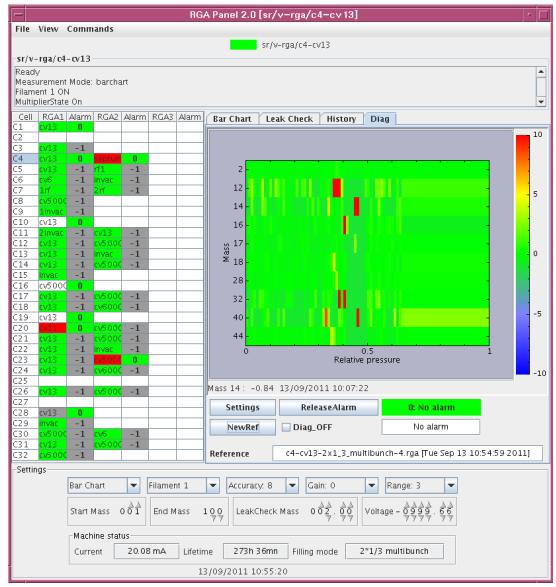

Figure 12: RGA monitoring GUI.

CONCLUSION

Conducting the upgrade in parallel to full user operation and maintaining the high stability and reliability of the X-ray source is very demanding.

As a consequence of the construction work of the experimental hall extension, a long shutdown period of 5 months is scheduled, at the beginning of 2012. During this period a lot of modifications of hardware and software will be prepared and installed. The challenge is to restart the accelerator complex with the same reliability in May 2012 to continue user operation.

We hope that all the different modifications and improvements on the X-ray source as well as on the control system will lead to a successful implementation of the new nano-focus beamlines.

CHANGING HORSES MID-STREAM: UPGRADING THE LCLS CONTROL SYSTEM DURING PRODUCTION OPERATIONS*

Sonya Hoobler, Ron Chestnut, Sergei Chevtsov, Thomas Himel, Karen Dayle Kotturi, Kristi Luchini, Jeff Olsen, Sheng Peng, Judith Rock, Robert Sass, Till Straumann, Robert Traller, Greg White, Michael Zelazny, Jingchen Zhou, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, U.S.A.

Abstract

The control system for the Linac Coherent Light Source (LCLS) began as a combination of new and legacy systems. When the LCLS started operating, the bulk of the facility was newly constructed, including a new control system based on the Experimental Physics and Industrial Control System (EPICS) framework. The Linear Accelerator (Linac) portion of the LCLS was repurposed for use by the LCLS and remained controlled by a legacy system, built 25 years ago. This legacy control system is being upgraded to EPICS during LCLS production operations while maintaining the 95% uptime required by the LCLS users. The successful transition is made possible by thorough testing in sections of the Linac that were not in use by the LCLS. Additionally, a system was implemented to switch control of a Linac section between new and legacy control systems within 10 minutes. Rapid switching enables testing during maintenance periods and accelerator development days. If any problems are encountered after a section has been switched to the new control system, it can be quickly switched back. At this time, 50% of the Linac sections are operating under control of the new EPICS system. This paper describes the system upgrade with emphasis on the deployment scheme.

BACKGROUND

Hybrid Control System

The LCLS has a combination of control systems: a newly built EPICS control system and a legacy control system. The legacy system was built for the SLAC Linear Collider (SLC) 25 years ago and has been continuously improved since. The system uses distributed RMX microcomputers ("micros"), each supporting up to 15 CAMAC crates, to monitor and control accelerator components. There is a centralized host, an Alpha 6600 running the VMS operating system, which coordinates the micros, maintains a centralized database, and handles all operator interface functions [1]. Two years into LCLS user operations, this system is still used to control some functions in the Linear Accelerator (Linac) area of the LCLS. Specifically, it supports the accelerating RF system and its timing, various diagnostic signals, and the operator interface to the safety systems. The LCLS Linac is split into 11 areas, called sectors. Each sector contains a micro and four or more CAMAC crates that interface to accelerator components. Most sectors are very similar to one another and contain identical signals and devices.

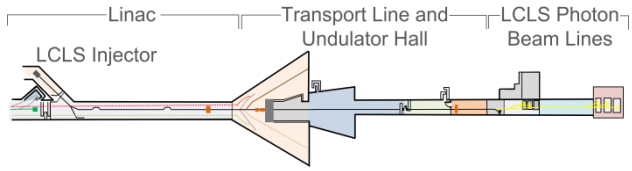

Figure 1: Overview of LCLS. [2]

Legacy System Data Access

The primary means for operators and physicists to interact with the legacy control system is a graphical user interface called the SLC Control Program (SCP). In more recent years, two additional interfaces have been developed that provide access to legacy system variables from the EPICS control system. The first is the SLC Channel Access Server (SLCCAS) [3], which provides read access to many variables over Channel Access (CA). The second is Accelerator Integrated Data Access (AIDA) [4], which provides read and write access to many variables from Matlab, Java programs, and scripts.

Upgrade Project

In order to improve LCLS uptime and reliability, dependencies on the legacy control system are being removed. In the LCLS Linac this effort has two phases. The first phase replaces the SLC micros with EPICS IOCs, fully integrating the CAMAC-controlled devices into the LCLS EPICS control system. The second phase will upgrade the CAMAC to new hardware. This paper discusses the first phase.

Challenges

The legacy control system has benefited from decades of refinement and is feature-rich. Additionally, thousands of signals in the LCLS Linac must be ported to EPICS. Reproducing features and accurately copying all signals are two main challenges of this project. Another challenge is to perform the upgrade during a production LCLS run, while meeting strict uptime requirements for LCLS users.

*Work supported by U. S. DOE Contract DE-AC02-76SF00515

DESIGN

System Architecture

Each Linac micro is being replaced by a standard LCLS EPICS IOC, which consists of an MVME6100 processor running the RTEMS operating system installed in a VME crate. A serial CAMAC driver board was developed to enable an IOC to communicate with CAMAC hardware. EPICS CAMAC drivers, EPICS databases, and higher-level IOC software were also created to replace the legacy software.

A switching interface chassis was built for each sector. Each chassis determines whether that sector is controlled by a legacy micro or a new IOC. Control can be switched locally or remotely. Thus some sectors can be controlled by the legacy system while others are controlled by EPICS, and sectors can be tested or upgraded independently. The switching chassis also greatly aided testing, allowing developers to compare live data between the IOC and micro by switching back and forth.

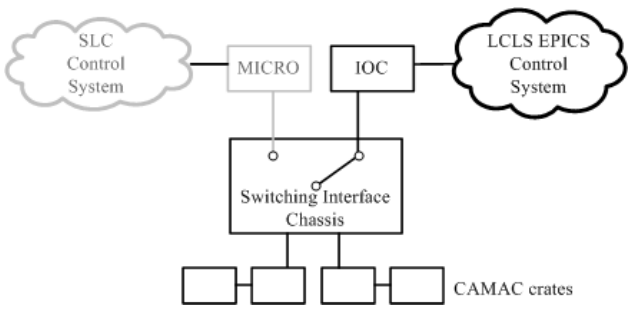

Figure 2: Hardware to enable switch between micro and IOC control.

Automated Data Transfer

Thousands of signals were ported to EPICS. To reduce errors, scripts were written to transfer and update data. For example, scripts were used to:

- Generate EPICS databases from the SLC database.
- Copy variable values to the new system when switching a sector to EPICS control. Variable values were not automatically copied from EPICS to the legacy system when switching back. This provided a known good configuration to return to in case of problems, with the disadvantage that when switching back to the legacy system, some variable values had to be copied manually.
- Modify existing user displays, replacing old PV names with new names.

Application Programming Interface

Before the upgrade, many high-level software applications used AIDA to read and control RF system variables. These applications did not need to be modified. This is because AIDA was updated to read and control these variables through EPICS as well. Additionally, the AIDA directory service is updated when a sector is switched over and thus AIDA accesses the data from the appropriate control system. Applications that used Channel Access to access SLCCAS data had to be updated with the new PV names.

When converting SLC database variable names to EPICS Process Variables (PVs), some names were changed to comply with the LCLS naming conventions.

UPGRADE TO EPICS

Development Testing

Initial testing was performed in a lab test stand with two CAMAC crates. Fortunately, two unused Linac sectors were available for several months of the initial testing, on which much of the software could be tested. These sectors' RF systems were not all available, however, so not all software could be thoroughly tested there.

Transition Infrastructure

In parallel with the development testing, some infrastructure was released to production to support and ease the transition, and to facilitate the switching of individual sectors. These were done months before the upgrade:

- PV gateway: A PV gateway was installed to translate the old SLCCAS PV names to the future EPICS PV names [5]. Scripts were written to reconfigure the gateway, based on which system was controlling each sector. This gateway allowed clients to begin using the new names early for read-only purposes.
- Data archiving: PVs were added to the Channel Archiver early in the project so that control system users would have access to months of data history when sectors were switched over. The users agreed that this provided sufficient archived history in the new system and that they would use the old system if they needed older data.
- User interfaces: New and existing EDM screens, using the new PV names, were released to production. The original displays remained available for comparison or as a backup—in case users suspected problems with the new displays.
- Alarms: Signals were added to the alarm handler. On a per-signal basis, these alarms were automatically disabled if the associated sector was not under EPICS control.
- Data sources: Scripts were written to update the AIDA directory service when a sector was switched.

Switchover Tool

Scripts were created to perform most of the tasks associated with switching a sector. Using these scripts, switching a sector took less than 10 minutes. These scripts were made available on operator displays, so operators could switch a sector back to the legacy system if needed. This happened on several occasions, when operators needed to use a feature that had not yet been implemented in the new system or to compare data in the new system with the familiar legacy system. This made the control system users more comfortable with leaving a sector under EPICS control, knowing they could easily back out if needed. This also made it convenient to test for a relatively short period. These scripts did the following:

- Reconfigure and restart the PV gateway
- Update AIDA directory service
- Boot IOCs
- Copy settings over (one way)
- Restart some Channel Access clients

Production Testing

In production, testing was done on the LCLS Linac during scheduled maintenance periods and accelerator development days. As individual sectors could be switched, it was sometimes possible to test a sector that was not needed for that day's accelerator program. Most of the tests lasted a few hours. The sector was switched to EPICS control before testing and back to the legacy system afterward. These short tests provided opportunities to find problems and then fix them without using valuable beam time. Adding all the time up, testing required about 25 hours during maintenance periods and for about 60 hours during physics studies. Further testing took place during a 2-month scheduled downtime when all sectors were switched to EPICS control. This allowed maintenance groups to become familiar with the new system, although it did not allow extensive testing as most systems were off.

PRESENT STATUS

At the present time, about half of the sectors are under EPICS control. Small bugs are being fixed and remaining features are being completed. The remaining sectors will be switched to EPICS in the next month or two. This design is expected to be used when upgrading other (non-LCLS) areas of the SLAC Linac.

CONCLUSIONS

Extensive testing in a lab and in unused Linac sectors greatly aided development. The ability to switch between control systems and compare data was found to be invaluable during testing.

Great effort was taken to create an implementation scheme with minimal disruption to the user program. This was found to be worthwhile. To date, interruption to the user program has been less than 30 minutes.

NEW DEVELOPMENT OF EPICS-BASED DATA ACQUISITION SYSTEM FOR MILLIMETER-WAVE INTERFEROMETER IN KSTAR TOKAMAK

Taegu Lee, Mikyung Park, and Y. U. Nam
National Fusion Research Institute (NFRI), Daejeon, Korea

Abstract

After successful achievement of the first plasma in 2008, Korea Superconducting Tokamak Advanced Research (KSTAR) has performed the 4nd campaign in 2011. During the campaigns, many diagnostic devices have been installed for measuring the various plasma properties in the KSTAR tokamak. From the first campaign, a data acquisition (DAQ) system of Millimeter-wave interferometer (MMWI) has been operated to measure the plasma electron density. The DAQ system at the beginning was developed for three different diagnostics having similar channel characteristics with a VME-form factor housing three digitizers in Linux OS platform; millimeter-wave interferometer, H-alpha monitor and ECE radiometer. However, this configuration made some limitations in operation although it had an advantage in hardware utilization. It caused unnecessarily increasing data acquired from the diagnostics when one of them operated at higher frequency. Moreover, faults in a digitizer led to failure in data acquisition of the other diagnostics. In order to overcome these weak points, a new MMWI DAQ system has been developed with a PXI-form factor in Linux OS platform and a control application has been developed on EPICS framework like other control systems installed in KSTAR. It also includes MDSplus interface for the pulse-based archiving of experimental data. Main advantages of the new MMWI DAQ system besides solving the described problems are capabilities of calculating plasma electron density during plasma shot and displaying it in run-time. To this end, the data can be provided to users immediately after archiving in MDSplus DB.

INTRODUCTION

In the first campaign of KSTAR, only a few diagnostics including the millimeter-wave interferometer were involved in experiments, but the number of diagnostics continuously increased according to the diagnostics upgrade plan and finally almost 30 different diagnostics were operated in the 4th campaign. Among many plasma physics parameters, electron density is a primary parameter and an interferometry is a widely used diagnostic tool for a measurement of the electron density [1][2]. The first DAQ system for the interferometer was developed with a VME-form factor housing three digitizers in Linux OS platform which was shared by three different diagnostics having similar channel characteristics; millimeter-wave interferometer, H-alpha monitor and ECE radiometer. Also, the DAQ system was developed on EPICS [3] middleware like other plant control systems and diagnostic DAQ systems installed in KSTAR, and performed as a standard input output controller (IOC). However, it turned out in the operation of last campaigns that the interferometer DAQ system made some limitations although it had an advantage in hardware utilization and in terms of maintenance. It caused unnecessary increase in the amount of acquired data when one of three diagnostics operated at higher frequency and resulted in a longer waiting time to read data stored in MDSplus [4] DB [5] Moreover, faults in a digitizer led to failure in data acquisition of the other diagnostics. In order to overcome these weak points and to increase the number of diagnostic channels, a dedicated DAQ system for the ECE radiometer was first developed before the 3rd campaign in 2010. Next, a Millimeter-wave interferometer (MMWI) DAQ system has been newly developed to measure electron density for the experiment of the 4th campaign in 2011 (see Table 1).

The MMWI DAQ system has been developed with a different H/W form-factor, PXI, and achieved more accurate timing and operation availability by adopting a new timing board and a standard software framework. Particularly, it can display raw data and calculated electron density data at once during plasma shot in real-time, and this feature is useful for longer pulse plasma operation. Same as the previous system, all the interferometer data are archived using MDSplus, while some of data is shared via EPICS Channel Access (CA) and displayed by using EPICS strip. The OPerator Interface (OPI) for the MMWI was developed using KWT, which stands for KSTAR Widget Toolkit and is a set of libraries developed in house using Qt [6].

Table 1: Channel Configuration in DDS#2 [5] (Old DAQ System)

Diagnostics	2008	2009	2010	2011
MMWI	4 ch	4 ch	4 ch	New DAQ (2 ch)
H-Alpha	30 ch	30 ch	30 ch	30 ch
ECE	8 ch	40 ch	New DAQ (48 ch)	76 ch

UPGRADE OF MMWI DATA ACQUISITION SYSTEM

The new MMWI DAQ system has been developed with PXI form-factor digitizers in 32-bit Linux OS platform to solve the described problems and improve performance.

The PXI system should use the NI-DAQmx library to interface EPICS device/driver in Linux OS. NI-DAQmx library supports only x86 32-bit architecture for Linux and support only some of NI devices.

H/W Upgrade

The MMWI data acquisition system consists of a 2.53Ghz dual-core PXIe embedded controller running on Linux,a home-made Local Timing Unit (LTU) and a Analog-to-Digital Convertor module[7]. The NI (National Instrument) PXI-6123 ADC module has 8 analog input channels, 16bit resolution, 4 configurable input ranges from ±1.25 to ±10V, and 64MB onboard memory. Although the input signal from a phase comparator to the ADC module varies from 0 to 5V, the operating input range is ±10V in order to avoid input saturation. The sampling rate in normal operation is 100kS/s per-channel. The bit-resolution of the new MMWI DAQ system was downgraded from 24bit to 16bit but the sampling rate was upgraded from 216kS/s to 500kS/s.

The MMWI data acquisition sequence is synchronized with KSTAR experimental cycle using the LTU and a dedicated timing network like other installed diagnostic DAQ systems. The LTU is configured with a pre-programmed scenario before plasma shot, and generates triggers and clock signals according to the scenario as soon as it receives a shot start signal from a Central Timing Unit (CTU) thru the optical timing network [8].

Specifications of the new MMWI DAQ system are as followings:

- NI PXIe-8108: 2.53Ghz dual-Core PXI Express, 4GB DDR2 RAM, up to 1GB/s system bandwidth and 250 MB/s slot bandwidth.
- NI PXI-6123: 8 simultaneously sampled analog inputs, 16-bit resolution, max 500 kS/s per channel, input ranges from ±1.25 to ±10 V.
- NI BNC-2011: BNC connectors for analog I/O, Shielded enclosure.
- LTU: accuracy < 5ns, resolution 5ns, output clock (1Hz ~ 200MHz), max 8 configurable multi triggering sections 2Gbps Optical communication speed, max 8 Trigger/Clock outputs

Figure 1 shows the configuration of the new MMWI DAQ System and network connections to the infrastructure of the KSTAR control system.

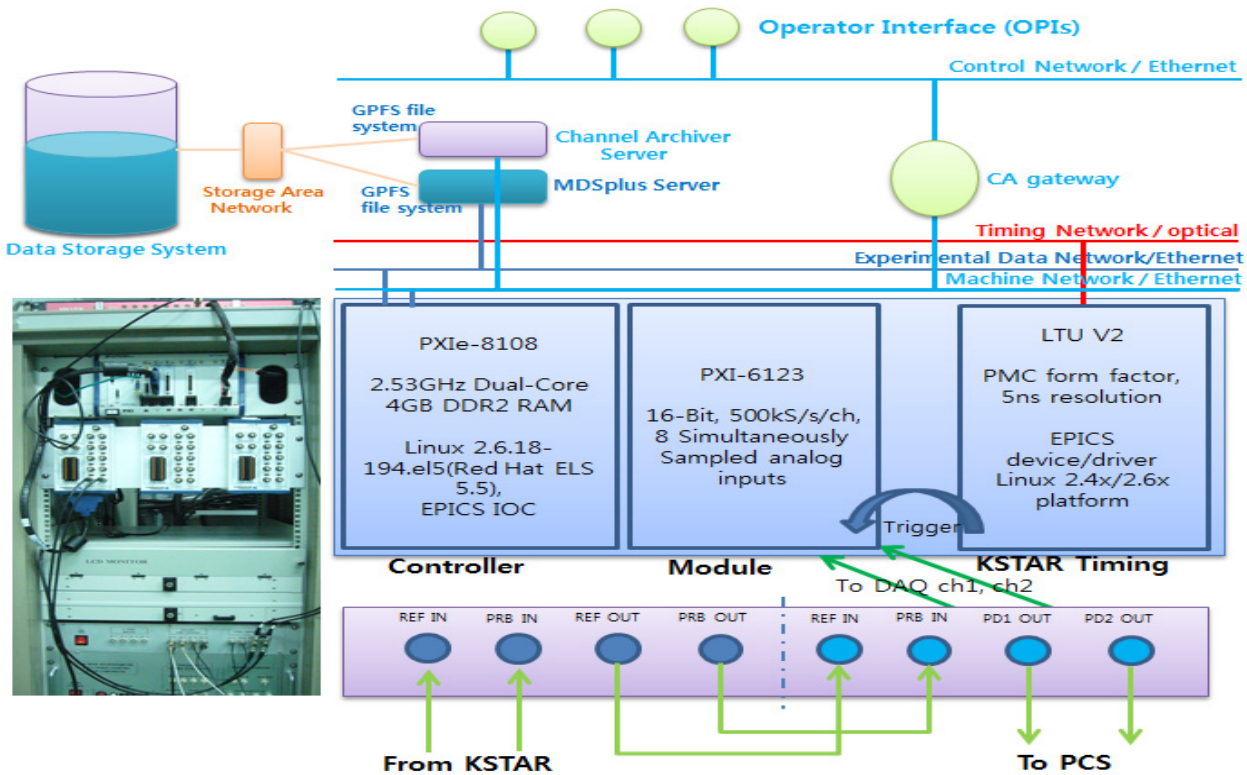

Figure 1: Configuration of MMWI DAQ System and network connections to the infrastructure of the KSTAR control system.

S/W Development

As mentioned above, the MMWI DAQ system is running in Linux OS platform, RedHat ES 5.5 (kernel – 2.6.18-194.e15). In general, all the data acquisition systems in KSTAR adopt a standard Software Frame-Work (SFW) that is developed and continuously improved in-house to reduce development time and improve system reliability. The SFW utilizes the IOC core software provided by EPICS and includes driver and device support software in common used with many other data acquisition systems in KSTAR [9]. The EPICS device/driver of the MMWI DAQ system is based on NI-DAQmx library to control National Instruments devices in Linux OS.

The SFW provides essential functions to support common records (shot number, blip time, seven states of system condition, etc), provide commonly used MDSplus interface to save acquisition data sampled at a high rate, and synchronize with a KSTAR plasma operation mechanism [9]. The OPI panels are developed by a particular set of Qt libraries named as KSTAR Widget Toolkit (KWT). They comprise of several sub-panels to configure and operate data acquisition, and to display the two types of density data in run-time; density data at 1 sec rate in AI record and full density data in a buffer in Waveform record. Additionally, the MMWI DAQ system uses common libraries of the KSTAR control system; the timestampLib to provide system time information and the sysMonLib to provide system health status of the system. Figure 2 shows the function blocks of MMWI DAQ IOC.

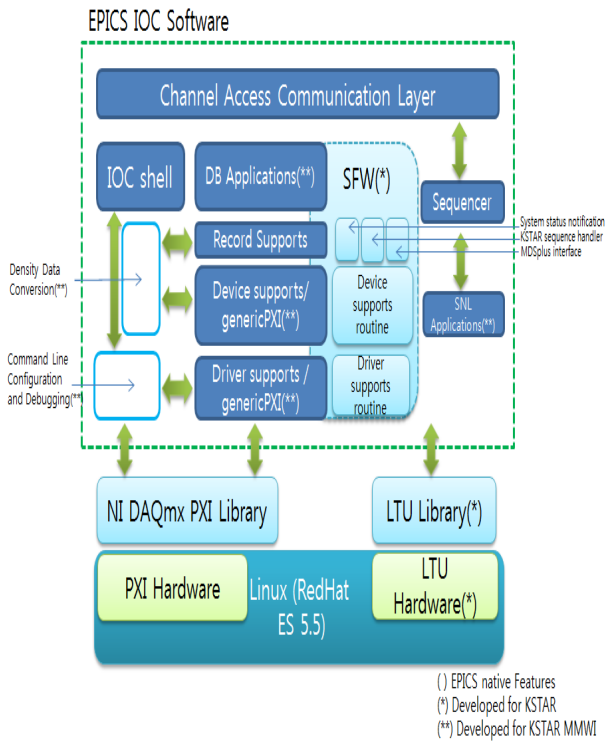

Figure 2: Function blocks for MMWI IOC.

All the programs to operate the MMWI DAQ system and archive diagnostic data are summarized as hardware driver for PXI devices (NI-DAQmx8.0.2), EPICS middleware interface program, MDSplus interface program, and Graphical User Interface (GUI) program (see Table 2).

Calculation of Plasma Density for Real-Time Service

The millimeter-wave interferometer is a diagnostic tool to measure plasma density by using the phase changes according to density in the propagation through plasma. When millimeter-wave travels through plasma, its phase varies depending on plasma density, and the phase difference from phase through vacuum is detected and converted to voltage signal to be proportional to the measured phase by a phase comparator. If the measured phase exceeds 2π, the fringe jump phenomenon occurs and the output voltage goes back to zero. In order to provide the density value to users in real-time, the MMWI DAQ system writes the density data in AI record and Waveform record after correcting fringe jump with two raw data having the phase difference of π.

When "DMA done interrupt" from the NI device is received at every one second, the IOC first performs a fitting algorithm to compensate for a slight curvature of the phase comparator circuit. Next, the IOC averages 1000 raw data from each of two input channels and then judges which signal is closer to the center of maximum detected voltage to select better channel for calculation of density. The averaging is executed once at the start of a DMA done event.

Even though the input channel is selected, it is changed to the other to avoid the fringe jump if it's voltage gap from the center voltage is larger than the other channel. When DMA data processing is complete, the IOC saves one calculated density data and two raw data from two input channels (without fitting) to files in the local HDD. It updates the measured density value in the waveform record and the final data in the AI record. This sequence is repeated at every DMA interrupt. After the completion of plasma shot sequence, the IOC moves two raw data and density data saved in the local HDD to MDSplus DB in the KSTAR central storage. Figure 3 shows the entire sequence of density calculation with the fringe-jump correction algorithm in IOC.

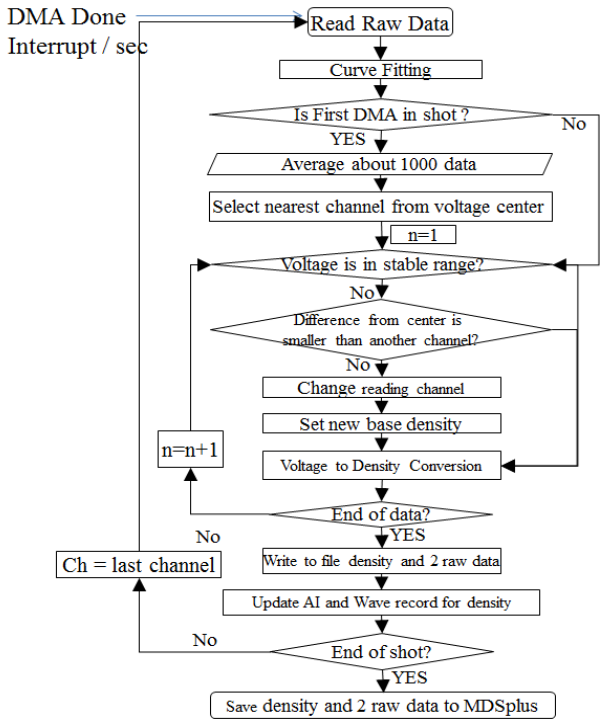

Figure 3: Sequence of density calculation with fringe jump correction algorithm.

OPERATION RESULT IN THE 4TH CAMPAIGN

After upgrading the MMWI DAQ system, both the stability and the usability of the system has increased considerably, and the amount of unnecessary data has also reduced. As shown in Table 3, just one fault occurred during the 4th campaign and even it was cause by the problem of NI-DAQmx on Linux in the case of long time operation. This problem is a big obstacle for a long time operation without system reset. Moreover, the same problem has occurred in all NI DAQ systems in KSTAR since 2008, and become the most significant fault source in the operation of data acquisition systems. We have now focused on solving it in cooperation with the manufacturer.

Table 3: Fault Counts in the Operation of the MMWI DAQ System

Campaign	DAQ fault counts	Lost shot	Total shot
1st 2008	23	23	1283
2nd 2009	4	2	1059
3rd 2010	14	17	2126
4th 2011	1	2	2002

Another deficiency is a small number of data points displayed in run-time during a shot. It displayed only 10 points data during a plasma pulse which was max 10sec in length in 2011. In the plasma experiments period, the new DAQ system operated successfully in data acquisition and density calculation only except for the case that the density changed momentarily and rapidly at the high density plasma. In addition, the heavy noise induced in the DAQ system has not been settled down.

SUMMARY AND FUTURE PLAN

In the fourth operation of KSTAR in 2011, the newly developed MMWI DAQ system was built and operated as an independent system. Add to the features of the previous system, the new DAQ system has many advantages in the views of hardware and software; the improved performance in data acquisition by adopting the standardization, more accurate synchronized operation with a new timing board, the run-time calculation and displaying density data. Also, there was a progress in the efficient data management. In the next campaign, the MMWI DAQ system will be modified to meet requirements arising in operation such as increasing the sampling counts to 10 for the effective run-time displaying and adding the function to archive the calculated data into MDSplus in real time to reduce the waiting time. Also, we will solve the problem of NI-DAQmx in the cooperation with the manufacturer.

Abstract

We have developed a data acquisition, control, and storage system for user experiments at the X-ray Free Electron Laser facility, SACLA, at the SPring-8 site. The system is designed to handle up to 5.8 Gbps data rate of shot-by-shot data in synchronization with the 60-Hz of beam operation cycle. A partial system for the light source commissioning was released in March 2011. The full system will be released to public users in March 2012.

INTRODUCTION

SPring-8 Angstrom Compact Free Electron Laser (SACLA) has been constructed at the SPring-8 site. SACLA is designed to generate X-ray laser with a wavelength as short as 0.062 nm by using a thermionic electron gun, an 8-GeV linear accelerator, and in-vacuum undulators [1]. The accelerator commissioning began in February 2011. The first lasing at a wavelength of 0.08 nm was achieved in June 2011.

The characteristics of XFEL such as the high-peak brilliance, perfect spacial coherence, and the ultra-fast X-ray pulse shorter than 30 fs are believed to open new opportunity in a variety of scientific fields. SACLA will deliver beam time to public users from March 2012.

DATA ACQUISITION SYSTEM FOR USER EXPERIMENT

Requirements and System Overview

Because the SACLA accelerator is driven with the pulsed operation, the X-ray laser is generated accordingly as the pulsed beam. The X-ray laser is generated by Self-Amplification of Spontaneous Emission (SASE) resulting in the fluctuation of the X-ray laser characteristics such as in the pulse intensity, spectrum, etc. In order to analyze the experimental results taking these fluctuation into account, the data acquisition (DAQ) in the experiment at XFEL must be done shot-by-shot in synchronization with the beam operation cycle. Furthermore, in many of the anticipated experiments, a single shot of the X-ray pulse will damage the sample specimen, the synchronized DAQ is indispensable to correlate the recorded data with the specimen characteristics such as orientation, size etc.

* email: myamaga@spring8.or.jp
† email: hatsui@spring8.or.jp

The most experiments will produce data with one-dimensional (1D) data such as waveform from digitizers, two-dimensional (2D) data from optical camera or multi-port charge-coupled device (MPCCD) for X-ray imaging. The devices installed at SACLA produce the data with a size ranging from 0.5 to 10 MB for each X-ray pulse. With 12 MPCCD sensors operating simultaneously at the 60-Hz operation cycle, which is the maximum number of sensors for the first user-experiment runs, data rate reaches 5.8 Gbps. The beam lime optical components consist of mirrors, a monochromator, attenuators, and beam monitors for intensity, position and arrival time. The control system should be designed so that users can correlate component status as well as monitor data with other detector data.

In order to meet these requirements, we have developed a data acquisition (DAQ) system for SACLA. The DAQ system has dedicated networks to transmit the data from all the instruments, monitors, and detectors. The system is also indirectly connected to the user network via a firewall system so that user can attach their own instruments to operate in a coordinated manner. This will lower the cost in building new experimental setup, and add flexibility to the DAQ system.

The DAQ system has on-line monitoring capability for the prompt examination of the experimental conditions. Raw and preprocessed data can be visualized by LiveView service operating in data-handling servers. In the case of the experiments that demand data preprocessing or data mining by high-performance computer for on-line data evaluation, the DAQ system can transfer the data to a PC cluster with 10 Tflops with high I/O performance (8 GB/s), or to the off-site 10 Pflops supercomputer "K computer".

The on-the-fly data compression relaxes the requirements of the bandwidth of data transfer as well as the final storage size to accumulate the experimental data. Embedded data compression for 2D data is available at the front-end Camera Link boards.

Control Framework

For control of the facility equipments, we have selected the MADOCA software framework [2], which has been developed and operated at the SPring-8 accelerator complex. The network-distributed computers are controlled via an RPC call by message-passing system. The system consists of the trigger distributors/counters, data-filling computers, parallel-writing high-speed data storage, and relational databases. Figure 1 shows the schematic of the data-

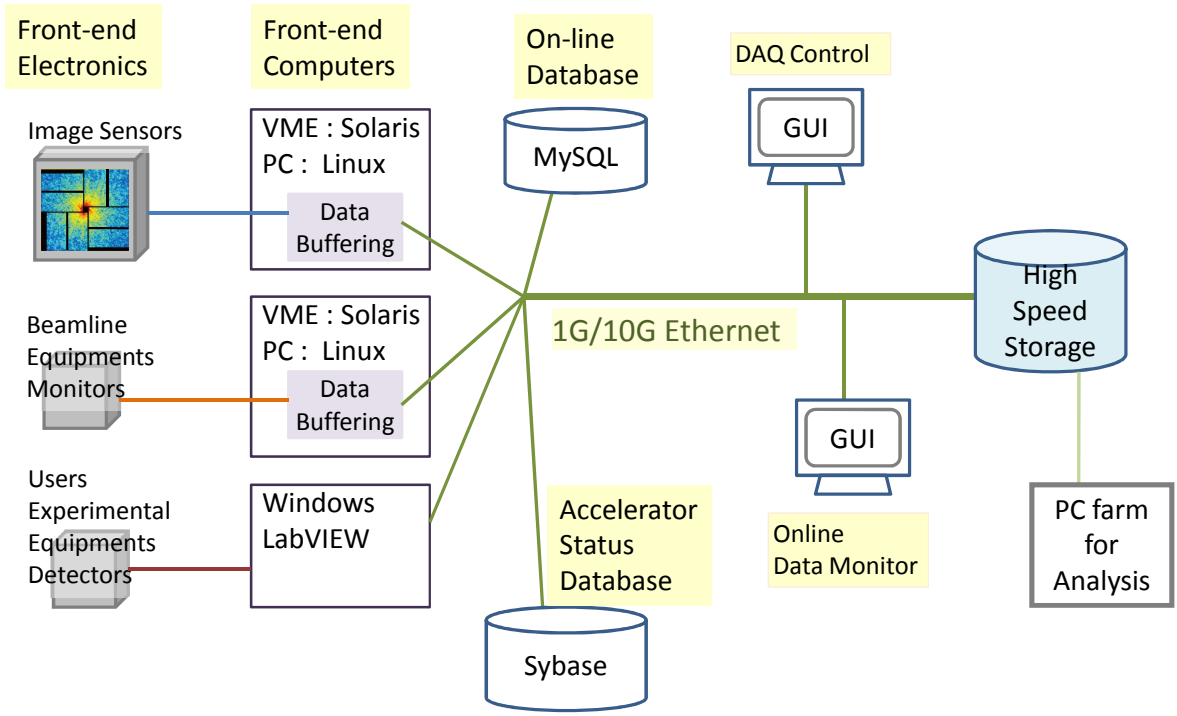

Figure 1: Schematic of the data-acquisition system for SACLA user experiment.

acquisition system for SACLA user experiment.

The original MADOCA has a limitation in the data transfer size. In order to enable a large data transfer for SACLA experiments, a client-server system with TCP socket is implemented to the framework. The large data set is transferred directly via TCP socket system, while the client and server process are controlled by the MADOCA messages. We have demonstrated that 80 % bandwidth of 1 Gbps Ethernet is available for the peer-to-peer data transfer with this system within the modified MADOCA framework.

We introduced the Qt software as the graphical user interface (GUI) for the control tools and data monitoring tools of the facility equipment. The Qt designer software allow us the prompt prototyping of the design of the GUI. The C++ program code of GUI is convenient to call the C API function of MADOCA directly from the GUI itself. So far more than 10 GUIs have been created for our DAQ.

Connectivity to the other software development environment became possible by using the TCP socket data transfer function added in this work. To date, these new functionalities yielded in successful operation of the real-time detector-performance-analysis software implemented on commercial software Igor Pro on Windows platform[3], and of an apparatus to measure the focused X-ray beam running on LabVIEW software on Windows platform.

Front-End System

The most critical part of our DAQ is to collect data from large 1D and 2D data without data loss in synchronization with 60-Hz beam operation cycle.

In the first experimental runs starting from March 2012, we plan simultaneous use of maximum two arrayed MPCCD detectors comprising totally 12 sensors. Each sensor has 0.5 M pixels in size with 16-bit quantized depth. A total throughput of 5.8 Gbps will be required for this sensor. We have chosen Camera Link, which has a transfer rate of more than 2 Gbps, for the interface of the image sensor. The required throughput is achieved by a configuration where each sensor has one Camera Link base-configuration interface. We use Camera Link connections independently for 12 sensors for the convenience of the later data handling. By utilizing an industrial-standard Camera Link interface, quick launch of the data acquisition system was achieved by simply applying a commercial image grabber board on the PC Linux system.

We have also developed a custom Camera Link interface board as a VME module as an upgrade of image acquisition. The module converts the Camera Link protocol to the Ethernet protocol so that the data are directly sent via the network from the front-end VME module to the back-end computers. An on-the-fly data-compression algorithm is implemented in the FPGA on the board so that the data size could be reduced at a very early stage of data acquisition. In the SACLA experiments, decompression speed on CPUs is one of the important performance of compression algorithm. We have developed and implemented a modified Range-Coder compression algorithm on FPGAs, which has superior performance in decompression speed than other standard lossless compression algorithm such as

JPEG 2000. The data size is reduced down to 40-50 % of its original size.

The waveform of the detector, such as in the time-of-flight experiment, is collected by a digitizer at the sampling rate of 4-GHz. The data size of waveform is to be up to 1 MB per X-ray pulse per detector channel before pedestal subtraction, and would be up to 100 kB after pedestal subtraction. A total throughput of up to 1 Gbps will be required. The PCI-express extension board on the PC Linux system is adopted for the digitizer to handle this data rate.

The intensity and the transverse location of the X-ray pulse are measured by monitors equipped with PIN photodiodes. The voltage waveform outputs from preamplifiers are digitized and fitted to Slater function on VME digitizers (MVD-ADC03) to deduce the charge detected by PIN photodiodes. A Solaris 10 operating system runs on the Sanritz SVA041 VME CPU board to control the ADC and other modules in the same VME chassis.

The profile of X-ray beam is observed by the YAG-Ce scintillator screen with a 0.3M pixels CCD camera system. The Camera Link interface board identical to MPCCD sensors is applied for the image acquisition of this CCD camera.

Timing System and Tag Number

The timing signal of the master-trigger system to drive the SACLA accelerator equipment at 60-Hz cycle is also delivered to the DAQ system for user experiment so that the detector could be operated exactly in synchronization with the timing of the X-ray pulse.

In the distributed DAQ system, shot-by-shot data is recorded independently at each front-end computer per X-ray pulse. Each datum must be uniquely identified so that one can collect all the data recorded in the same X-ray pulse to reconstruct the event. We assign a tag number, which is actually a sequential number of the master-trigger signal, to every datum to identify which one is related to which X-ray pulse. Because our master-trigger system does not distribute the encoded trigger number itself, the tag number is counted at each front-end computer node independently by the trigger counter module. All counters are set to the identical number at lease once at a certain point of beam operation to assign the identical tag number for the same X-ray pulse at every node.

Database

Most of the detectors for the facility equipment, such as the beam intensity monitors and beam position monitors, are always in operation when the DAQ system is ready. These data are taken shot-by-shot and are written to the fast relational database MySQL, with a tag number and the timestamp record. These data are shown as the present status of the XFEL beam on the monitoring system at the experimental station. The user can ascertain whether the beam condition satisfies the experimental requirement by this monitoring system. Users can acquire the data such as the beam condition from the database by specifying the tag number or the timestamp. For example, the correlation between the experimental data and the beam condition could be easily analyzed by fetching the data from this database. Access to the database by user programs is also possible via an interface server.

Network and Pipeline Scheme

The most important issue in the network for our DAQ is to guarantee the data transfer without loss. Therefore, in our system, all the data are transmitted via TCP/IP protocol over the standard 1- and 10- Gbps Ethernets to achieve the reliable data transfer by the features of TCP, e.g. ordered data transfer, retransmission of lost packets and error detection, with a reasonable cost.

Because the Ethernet is not capable of the critical real-time operations, we implemented a pipeline FIFO buffering system in the software framework of client-server system of TCP socket connection so that the data would not be lost at the application level even when data transfer is delayed. The FIFO buffer is implemented as a ring-buffer with shared-memory on a Solaris and Linux operating system. Owing to recent progress of information technology, a large memory size of over a gigabyte is available on the computer. We could make the pipeline depth large enough to hold more than 10 seconds of data, which would be sufficient even when the large latency of TCP/IP protocol occurs.

Storage

The 1D and 2D data from the front-ends are finally accumulated to the storage system. It must be able to handle up to 5.8 Gbps of throughput. The total size of data set will reach over 50 TB per day at this maximum rate. For ease of use, a single file system is preferred even for such a large storage.

We have chosen the StorNext single file system on the Data Direct Network (DDN) S2A9900 Storage system to satisfy these requirements. A total of 180 TB of storage is provided by the SAN cluster of the RAID system at over 1 GB/s of total throughput. Five Linux PCs are prepared as the parallel-writing file servers in this SAN system. By distributing the data from the front-end computers into these five file servers in parallel, we have demonstrated that the image and waveform data of up to 5.8 Gbps can be recorded to storage without any data loss.

PRESENT STATUS

Beam tuning of XFEL began in March 2011. During tuning, our DAQ system is intensively used to provide beam intensity data and beam profile data at the beam line components. Stable operation of our DAQ system contributed significantly to efficient and prompt beam tuning.

Several preliminary experiments are planned by internal users of our facility until March 2012. The 8-plates

MPCCD sensor will be used in these experiments. The beam repetition rate until March 2012 will be 10 Hz at maximum as a preliminary operation of SACLA. We will check the performance of the each component of our DAQ system during these preliminary experiments.

FUTURE PROSPECTS

We anticipate that a larger size image sensor will be required for the future experiments using the XFEL. In order to achieve smaller pixel size with higher peak signal and dynamic range, we are developing Multi-Via (MVIA) sensor by using SOI sensor technology [4] as the next-generation X-ray imaging sensor for SACLA. The detector size will be 1.9 M pixels per sensor with 16-bit quantized depth. By assembling 40 MVIA sensors, the total data rate will be 13 times larger than that for the first experimental runs.

An increase of the beam repetition rate from 60 to 120 Hz at SACLA is expected to be rather promising in near future with the present technique. At 120-Hz beam repetition rate, the 40 MVIA sensors will produce 146 Gbps data rate, which is 26 times higher than the present system. To meet these requirements, upgrades of the data transfer networks, front-ends, parallel implementation of the storage system are now under investigation.

SUMMARY

A data acquisition, control, and storage system has been developed for user experiments at the XFEL facility, SACLA, in the SPring-8 site. The shot-by-shot data acquisition in synchronization with the beam operation cycle of up to 60-Hz has been performed in the beam tuning of XFEL laser. The data transfer scheme with the ordinary 1- and 10- Gbps Ethernets has been proved to be reliable enough by introducing the pipeline buffering in the client-server system of TCP socket connection. We have demonstrated that image and waveform data of up to 5.8 Gbps could be recorded in parallel-writing high-speed data storage without any data loss.

Abstract

The construction of the X-ray free electron laser facility (SACLA) in SPring-8 has started in 2006. After 5 years of construction, the facility has completed to accelerate electron beams in February 2011. The C-band linac accelerates beams up to 8GeV. The beam size is compressed to a length of 30fs, and the beams are introduced to the insertion devices to generate 0.06nm X-ray laser. The first SASE X-ray laser was observed at the beginning of June 2011. The first scientific experiment will start at the end of October this year. The control system for SACLA adopts the 3-tier standard model by using MADOCA framework developed in SPring-8. The upper control layer consists of Linux PCs for operator consoles, Sybase RDBMS for data logging and FC-based NAS for NFS. The lower consists of Solaris-operated VME systems and the PLC is used for slow control. The Device-net is adopted for the frontend devices to reduce signal cables. The beam-synchronized data-taking link is installed to meet 60Hz beam operation. The accelerator control has gateways to the facility utility system not only to monitor devices but also control the tuning points of the cooling water.

FACILITY STATUS

The X-ray Free Electron Laser (XFEL) is generated by a combination of a high-energy linear accelerator and a set of insertion devices (ID). The XFEL project in SPring-8, now called SACLA, has started in 2006 with the success of SCSS prototype accelerator [1]. The SACLA facility is designed to be compact to fit within 700m available spaces in the SPring-8 site with lower construction cost.

Figure 1: A bird eyes view of the SACLA facility. The electron beams are generated and accelerated from the right hand side to the left inside the linac yard. A picture of SPring-8 site is imposed.

The main component of the SACLA accelerator consists of 64 C-band RF units of 5.7GHz operation frequency to accelerate electron beams up to 8GeV. The initial beam length is compressed to produce the laser peak power generated by a length of 30fs electron beams. The 8GeV-electron beams are introduced to the 18 units of ID to generate less than 0.1nm X-ray laser. A total length of the accelerator is 400m, and that of ID is 230m. The SACLA has a unique experimental hall for co-operative experiments that uses both X-rays from SACLA and SPring-8 for example pump-up and probe experiments. The SACLA facility is shown in Figure 1.

The facility construction has completed in February 2011. The accelerator structure conditioning with RF high-power started from several months before the facility completion. The electron beam commissioning has started right after the completion. The electron beams were successfully accelerated up to 8GeV and the first light from an alignment ID was observed shortly after. After three months beam tuning, high brilliant SASE X-ray was observed at the beginning of June as can be seen in Figure 2. The SASE laser signal has homogeneous round shape, and the maximum laser power is ~4GW. The laser beam intensity is quite stable (~18%) to be ready for coherent X-ray experiments.

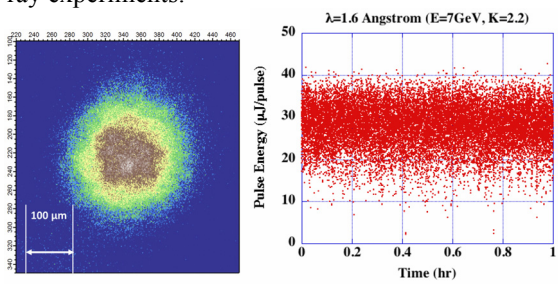

Figure 2: The observed profile of the SASE laser signal at 110m downstream of the last ID with 10keV (left). And the measured laser intensity stability (~18% fluctuation) during one-hour operation (right).

The laser wavelength has been improved from 0.16nm in June to 0.08nm at the end of July along with the progress of the beam tuning, as can be seen in Figure 3. Now, the laser beams are reproducible [2]. The electron beam tuning continues to achieve the laser coherency saturation and the first scientific experiment will start at the end of October this year.

The SACLA control system started smoothly at the early stage of the electron beam commissioning. The established MADOCA control framework helped smooth rise up of the SACLA control system and reduced time-consuming debugging work for the operation software.

Because of a large number of control points, however the control system had to be tuned suitably to meet high load, and system reliability was achieved along with the progress of the beam commissioning.

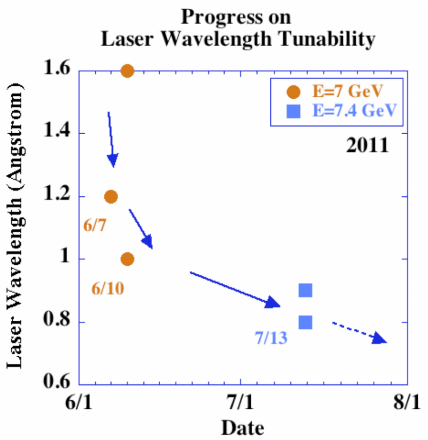

Figure 3: Improvement of laser wavelength of SACLA. The wavelength improved from 0.16nm to 0.06nm after two months beam tuning.

DESIGN CONCEPT

The design of the control system for SACLA is based on that of for SCSS test accelerator [3]. SCSS was constructed for the principle study of the free electron laser mechanism by using a linac and technology assurance towards the coming 8GeV XFEL machine, SACLA. We used common control devices for each subsystem of SACLA as much as possible [3]. This comes from the short construction period for the fast start up and less human resources coming from the joint project management sharing with SPring-8 operation.

Methodology Toward X-ray Laser

The basic elements for the SACLA control system shares commonly with those of SCSS, except for the difference coming from energy difference. The electron beam energy of SCSS is 250MeV on the other hand SACLA is 8GeV. This difference results the difference of the number of elements of the control system to build and equipment precision coming from the short wavelength. The wavelength of SCSS laser is around 50nm, on the other hand SACLA generates very short X-ray less than 0.1nm. The short wavelength also requires fine alignment of accelerator components and a series of ID, precise LLRF phase control, stable temperature both for high frequency timing signals and cooling water for accelerating structure [4]. Hence, we realized the facility utility control from the accelerator control [5].

Standard Control Structure with 3-tire Model

The SCALA control system follows the standard control structure with the established 3-tire model. The upper control layer consists of PCs running with SuSE Linux for operator consoles, Sybase RDBMS for data logging and FC-based NAS for NFS file server. The RDB data schema and the file server configurations are copied from existing SPring-8 control system with minimum modification. The lower layer consists of Solaris-operated VME systems for the faster control. The programmable logic controller (PLC) is used for slow control for example vacuum systems. The Device-net connected to the PLC module, is adopted for the frontend device control to reduce the number of signal cables. The VMEbus systems have a beam-synchronized data-taking link of a shared memory network to meet 60Hz beam operation for the beam tuning diagnostics [5]. The upper and lower layers are interconnected via many Gigabit Ethernet switches on which the MADOCA middleware runs. The 10GbE is introduced as a backbone data transfer line for user experiment. The out going 10GbE line is connected to the 10PFlops K-supercomputer in Kobe for the on-line analysis of experimental data that will be generated from two-dimensional X-ray detector. The schematic view of the control system is shown in Figure 4.

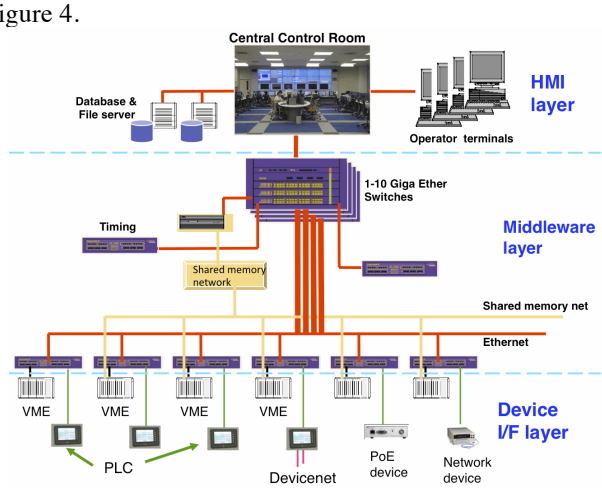

Figure 4: A 3-tier schematic structure of the SACLA control system. Beam commissioning is performed at the local control room nearby SACLA facility.

SACLA has an electron beam transport line to inject the electron beams to the SPring-8 storage ring as shown in Figure 1. At present, the injection is not scheduled yet, but SACLA works independently by using its own beamlines for X-ray FEL experiments. In order to avoid unexpected interference to the SPring-8 duty operation and guarantees independent operation between two facilities, the control network zone between SACLA and SPring-8 is loosely coupled. Also, the server computers such as a database machine and a NAS-based NFS file server are installed separately. On the other hand, the program development environment for SACLA shares with SPring-8 for the common software development. This configuration is good for the cooperative software development and timely program installation to the SACLA server without interference to the SPring-8 user-mode operation.

The number of equipment used for SACLA control is listed in the Table 1.

Table 1: The Number of Equipment for Controls

Equipment	SACLA	SACLA+SPring-8
Consoles	27	332
VME systems	175	450
Interlock stations	122	812
Network switches	181	758

EQUIPMENT CONTROL

The VMEbus systems and PLC stations are main base components of the SACLA accelerator control [4]. The C-band linear accelerator consists of mainly accelerating structures with 5.7GHz RF systems. We made one RF control unit and repeated the same configuration as much as needed. Additionally, fine timing system and beam monitoring system is necessary for the beam tune. Interlock systems are installed for the machine protection system (MPS) and personnel protection system (PPS), as shown in Figure 5.

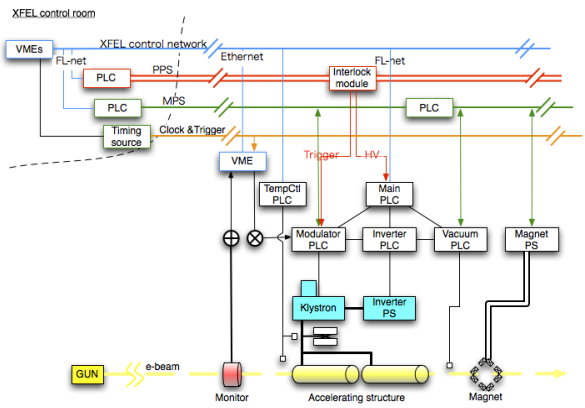

Figure 5: A schematic view of the SACLA control system. A typical control unit using PLC module for one C-band accelerating unit is shown in the figure.

The PLC system is used for RF high power (A, V) device control and the interlock systems. The PLC system is simple and suitable for the slow control with high robustness and reliability. On the other hand, the VMEbus system is suitable for the fast device control such as beam steering magnets and so on. To satisfy the stability requirements of the phase and amplitude of the cavity voltage, newly developed boards, such as DAC and ADC are equipped for LLRF VMEbus systems. A feedback control process (EMA on MADOCA) that runs on the VME CPU plays essential role to stabilize the phase and amplitude, which contributes the laser stability.

Implementation

The single-core CPU board, SVA041 already used in SPring-8, was selected for the SACLA control even though single core processor. The well-established CPU is good for smooth start-up of the control system. At the beam commissioning stage, the accelerator repetition rate is 1~ 10Hz, but it will go up to 60Hz and finally 120Hz (maybe 300Hz later). So far, signal process power of the Intel VMEbus CPU is enough but it is approaching to the marginal level, especially for the large data processing such as waveform data monitoring in on-line. A faster multi-core CPU with low power consumption is now available. The multi-core CPU (Core i7) will replace the current CPU if computing power is tight. The DMA and block transfer scheme was introduced to meet the waveform data handling from the 16bits ADC boards..

The FL-net is a FA-link that interconnects VMEbus systems and PLC stations. The FL-net link is divided into several links to keep independency of the device groups. The multiple links on the single VMEbus system is handled by using the virtual machine technology, Solaris10 Container. The I/O board configuration of the VMEbus had to adjust such that the I/O boards do not share one bus together with the large-data handling boards and also the slow control FL-net links. We prepare the monitoring and notify mechanism for FL-net unexpected link-down.

Database and Servers

The SPring-8 database system can process many data as we expected, however SACLA database system used almost full CPU power. The heavy load sometimes caused unexpected delayed responses to the accelerator operation GUI. Actually, the number of data was about factor two more than we estimated at the beginning of the database design phase. We adjusted the Sybase RDBMS configuration such as the procedure cache size, data cache size, the size of data log area and table lock mechanism. And we, also, optimized the periodic machine data-taking cycle to ease the database load. The alarm surveillance and monitoring programs handle many watching points as well. Especially at the alarm process start-up time, the heavy accesses from the alarm programs to the database deteriorated operation response.

We will add a 3GHz 12core FT-server with 48GB memory together with the current database machine of a 2GHz 8core CPU with 16GB (now 48GB) memory. We don't change NAS-based disk system because it has no problem. We, also, will tune the alarm software algorithm for much efficient surveillance and lighter database access.

Signals of Equipment

The number of equipment signals of SACLA is much larger than that of the SPring-8 accelerator complex, on the contrary to the initial estimation. The comparison of the data size is listed in Table 2.

Table 2: The Number of Equipment Signals

Accelerator	Analogue points	Digital points
SACLA	19,500	225,000
SPring-8 (Li,Sy,SR)	22,000	90,500

The estimation is the base to select the database computer specification because the CPU load depends on the size of the database schema, hence the size of the data,

however the NAS storage provides enough data transaction performance. The difference originates in the number of the units of RF acceleration structures in SACLA.

FACILITY CONTROL

The facility utility control of SACLA has unique features [5]. The accelerator beam tuning to achieve the stable laser imposes sever stability to the RF cooling water and electric power for example. The facility control has a gateway to the accelerator control to receive "put" command from the accelerator side. If the observed temperature deviated from the monitoring point, the water set point would be actively adjusted from the accelerator side. The precision of the monitoring sensors for the cooling water temperature was 0.01C, however the precision has to be improved to 0.001C resolution because the RF phase of the C-band shifted according to the water temperature drift.

The room temperature of the accelerator house and the spaces for the control racks of the LLRF systems have been monitored and kept into the database right after the completion of the facility building. The long accumulated temperature data about one year is useful to understand the stability and drift of the room temperature before the beam commissioning.

BEAMLINE CONTROL

Finally, SACLA will have five beamlines for the experiments. Now, one beamline (BL3) is ready for the scientific experiment. The application layer of the SACLA beamline control uses MADOCA identical to that of SPring-8 in order to achieve smooth migration of the current software developers from SPring-8 to SACLA. The beamline control uses the VMEbus system as well. The beamline components consist of slits, screen monitors, beam position monitors, a monochromator and so on, those have equipment interfaces similar to the SPring-8 beamlines. Additionally, the synchronized data-taking scheme is introduced to the beamline control [6]. In SACLA, this scheme takes the set value of optical devices and pulse motor positions, and sends these data to the beam-synchronized data-taking system for the accelerator. The data will be used for the experimental analysis together with the accelerator status. The beamline control ramped up smoothly and has been working with good stability.

DETECTOR DATA ACQUISITION

A linac-based FEL facility with the small number of beamlines has a feature such that a linear accelerator, insertion devices, an X-ray detector and data acquisition system (DAQ) for experiments have to work with required performance as a whole in order to generate the scientific results. In SACLA, the accelerator control framework, MADOCA, was introduced to the DAQ for the experimental data taking [7]. MADOCA interfaces between the accelerator control and the detector DAQ system to provide electron beam information to the laser experiment system, for example beam tag numbers as shown in Figure 6.

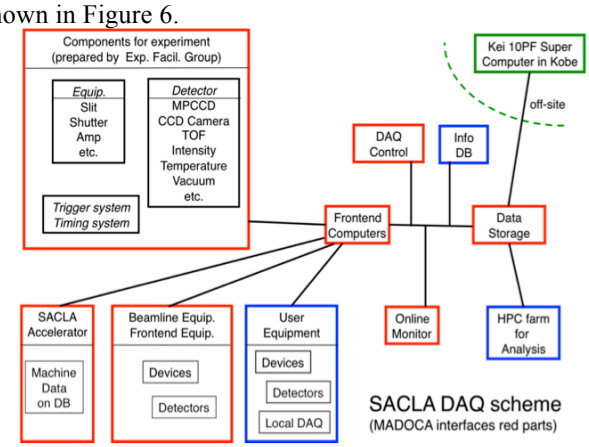

Figure 6: A schematic view of the SACLA DAQ for the X-ray detector. MADOCA plays as the middleware.

The multi-port CCD (MPCCD) sensor developed for SACLA experiments as workhorse detector has 0.5M pixels of 16bits data/pixel. Largest detector arrays consist of twelve MPCCD sensors. The DAQ system has to handle the data rate up to 720MB/s/system for 60Hz beam operation. The FPGA-based VME boards take the MPCCD image data via CameraLink interfaces. The data is compressed at the VME board then sent to the 240TB Infini-band storage system via data-handling PC servers. Whole the are pre-processed by a PC cluster, and transferred to the 10PFlops supercomputer "K computer" via 10Gbps Ethernet for on-line data mining and post analysis. The DAQ system is ready now and waiting for scientific experiments scheduled at the end of October this year.

Abstract

FERMI@Elettra is a new 4th-generation light source based on a seeded Free Electron Laser (FEL) presently under commissioning in Trieste, Italy. It is the first seeded FEL ever designed to produce fundamental output wavelength down to 4 nm with High Gain Harmonic Generation (HGHG). Unlike storage ring based synchrotron light sources that are well known machines, the commissioning of a new-concept FEL is a complex and time-consuming process consisting in thorough testing, understanding and optimization, in which a reliable and powerful control system is mandatory. In particular, integrated shot-by-shot beam manipulation capabilities and easy-to-use high level applications are crucial to allow an effective and smooth machine commissioning. This paper reports the status of the control system and the experience gained in two years of alternating construction and commissioning phases.

INTRODUCTION

FERMI@Elettra is a linac-based Free Electron Laser designed to supply photons in the soft X-ray spectral range. The 200 m long accelerator consists of a high brightness photo-cathode gun working at up to 50 Hz repetition rate, a 1.5 GeV normal conducting linac and two bunch compressors. The accelerated electron bunches, together with a tunable UV seed laser beam, are sent into a chain of undulators where they generate ultra short (<100 fs) and high peak power (~GW) coherent photon pulses with variable polarization. Two distinct undulator chains will be available, FEL-1 and FEL-2, covering the entire spectral range from 100 to 4 nm in the first harmonic.

Three beamlines have been designed so far, dedicated to different scientific areas: Low Density Matter (LDM), Elastic and Inelastic Scattering (EIS), and DIffraction and PROjection Imaging (DIPROI). The particular characteristics of the FEL photon beam enable time resolved experiments to study ultrafast dynamics and transient phenomena of matter under extreme irradiation conditions.

The FERMI@Elettra project has developed through several installation and commissioning periods and the achievement of intermediate milestones: first electrons from the photo-cathode gun in August 2009, linac energy at 1.2 GeV in September 2010, beam transported in the undulator hall in October 2010 and first free electron lasing in December 2010 [1].

Figure 1: Aerial view of the Elettra 2.4 GeV storage ring and the FERMI@Elettra Free Electron Laser.

OVERVIEW OF THE CONTROL SYSTEM

A complete description of the FERMI@Elettra control system is given in [2].

Fig. 2 shows the control system architecture. The low level computers are VME crates with PowerPC CPU boards or rack-mount Intel-based servers both running the GNU/Linux operating system with the Adeos/Xenomai real-time extension. Siemens S7 PLCs have been extensively employed in protection and safety systems, as well as for the low level control of undulators. In the control room, Linux PCs equipped with two or four monitors are used as operator workstations, while Intel-Xeon servers with a number of Xen virtual machines provide general common services such as network file system, remote boot, network services, database facilities, archiving system, etc.

The control system backbone is a pervasive Gigabit Ethernet network serving all of the machine tunnels and service areas of the facility. In addition, several isolated segments of data network are used to locally access Ethernet-enabled devices. The use of Ethernet as a fieldbus allowed us to reduce the number of low level computers (~70) necessary to interface a high number of devices.

A distributed real-time framework based on an in-house developed protocol called Network Reflective Memory (NRM) and a dedicated Ethernet network connecting all the low level computers, allows developing distributed

*This work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3.

real-time applications exchanging shot-by-shot data at the linac repetition frequency (10-50 Hz) [3].

The Tango toolkit has been adopted as control system software. Tango device servers are mostly written in C++ and Python, while graphical interfaces and control room applications are developed with QTango and Matlab. A high level software framework has been created to provide machine physicists with tools and methods to develop software applications for controlling the machine through its model.

The software development and deployment process relies on CVS. Bug reports and new requests are collected and managed using a ticketing system based on Bugzilla. Programmers develop the software using dedicated reference computers. The source code is then tagged on the repository, checked out and compiled on a clone of the field systems before being deployed in production. The system administrator hence performs the final installation keeping track of the details on an internal wiki page.

TWO YEARS OF MACHINE COMMISSIONING AND OPERATIONS: KEYS TO SUCCESS

The particular approach adopted in the project schedule, with alternating periods of installations and commissioning operations lasting in average five and nine weeks respectively, and the difficulties inherent in the commissioning of a novel machine, have set new challenges in the design and implementation of the control system. Since the beginning of each commissioning phase, physicists need to smoothly operate via the control system the machine components that have just been installed. Moreover, while performing the complex and time-consuming commissioning operations, the control system must effectively support them without inconvenience to their activities. For these reasons the control system must be flexible, high-performing and reliable: a service rather than a concern.

The experience gained in two years of installations and machine commissioning records several difficulties but emphasizes the importance of a few strategic factors that made it possible to meet the requirements mentioned above. They are in particular the standardization of hardware and software, the choice of Tango, the real-time framework and the use of Matlab.

Standardization

Special care has been taken from the beginning of the project in order to possibly adopt the same hardware/software technologies as well as the same control system architecture throughout the whole facility, from the photo injector to the experimental stations. Standardization involves several aspects of the control system: hardware interfaces (mostly Ethernet and serial), low level computers (VME/PPC or Intel servers, depending on the required performance and hardware interfaces), system software (Linux and Tango) and graphical interfaces (QTango and Matlab). Forcing standardization has been sometimes hard and slightly more expensive, but the benefits in reducing the development and maintenance costs are evident. A particular case is the adoption of the YAMS motor controller, an in-house design using commercial components, utilized for most of the stepper motors of the facility [4]. Being a flexible system it fits to any motion application while maintaining a common interface to the control system. More than 400 axes will be eventually controlled by YAMS.

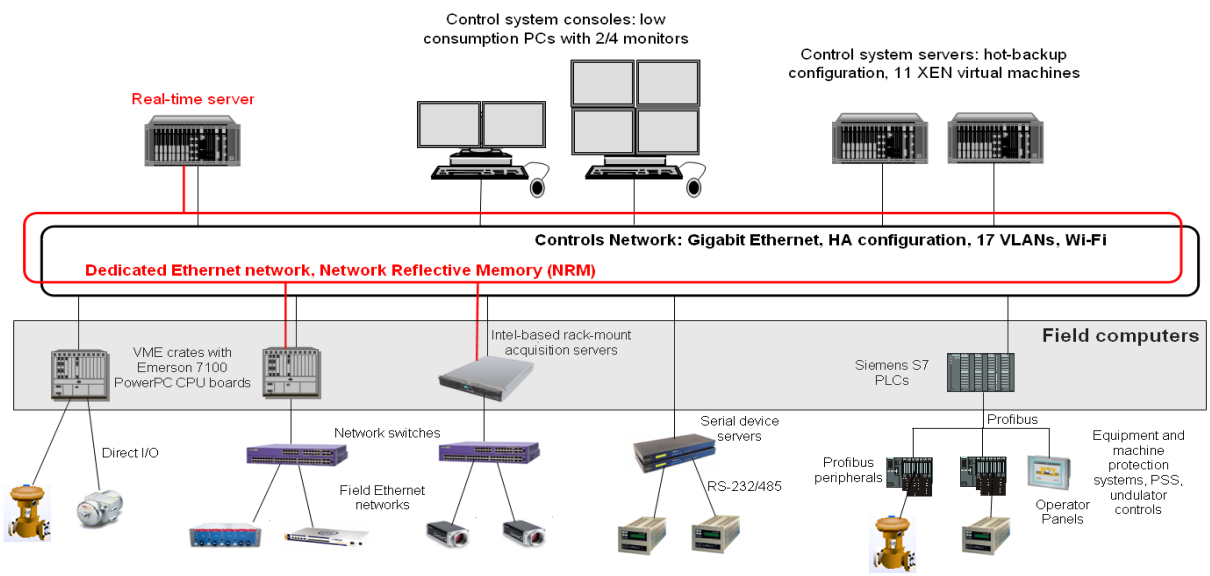

Figure 2: Architecture of the FERMI@Elettra control system.

Tango

The Tango toolkit is the real "glue" of the control system providing an effective integration of the controlled technical systems and the software controlling them. From the client point of view the machine components are seen through a uniform API interface regardless of the way they are connected to the control system.

The device model, which is the fundament of Tango, offers an object oriented approach to controls issues, with important benefits for the software development and maintenance. Each equipment or physical device connected to the control system is assigned a Tango device which exports an API with attributes and commands. Further hierarchical levels of Tango devices with a higher level of abstraction can then be developed to aggregate several devices, add more sophisticated functionalities or offer different views of the same device to the client level. This possibility has been widely utilized in FERMI@Elettra; following a general rule that we adopted, all of the coordination, processing and automation functionalities have been implemented in the device server level, leaving to the GUIs only display duties.

Tango is behaving as required in terms of reliability and performance, and confirmed to be mature and stable.

Real-time ramework

FERMI@Elettra is a pulsed machine with repetition rate up to 50 Hz. A distributed real-time framework well integrated into the control system provides the capability to measure and manipulate the laser, electron and photon beams, as well as to close synchronized feedback loops on a pulse-to-pulse basis.

All the relevant monitor points (e.g. electron and photon diagnostics) and control points (e.g. power supplies) are synchronized with the bunch trigger. Moreover, a real-time time-stamp called "bunch number" is distributed to all of the low level computers via the NRM.

The diagnostic electronics provide shot-to-shot data to the low level computers through real-time interfaces; data are tagged with the bunch number and stored in local circular buffers that can be easily read by high-level applications through specific Tango servers. The same data can also be placed in the NRM and shared in real-time with the other control system computers (see Fig. 3).

Most of the power supplies allow synchronized current settings. The values can be generated, sent to the low level computers through the NRM and set on the power supply shot by shot in real-time. Alternatively, an arbitrary waveform can be loaded into a local buffer through a Tango server and then used to set the power supply shot by shot after a trigger command.

The above described capabilities have been widely used during the machine commissioning. Relevant examples are FEL jitter studies carried out by correlating shot-to-shot data provided by photon and electron diagnostics, and fast emittance measurements using synchronized quadrupole power supplies and fluorescent screen CCDs.

A centralized real-time server can run synchronized feedback loops by reading sensors and setting actuators through the NRM at the linac repetition frequency. For now a fast trajectory feedback has been developed to correct the electron beam position in various locations of the machine [5].

Matlab

Thanks to the availability of effective Tango bindings, Matlab has been chosen to easily develop scripting procedures and GUIs interacting with the machine through the control system. Matlab has also been interfaced to simulation codes like Elegant [6], thus opening the way to the physicists for the development of their own machine physics applications and measurement procedures employed during the accelerator commissioning.

Matlab GUIs are also useful for graphical panels prototyping carried out by non-professional programmers such as physicists or specialists of technical systems. The GUIs are developed, used and modified several times, and eventually translated to QTango by controls people once they are stable.

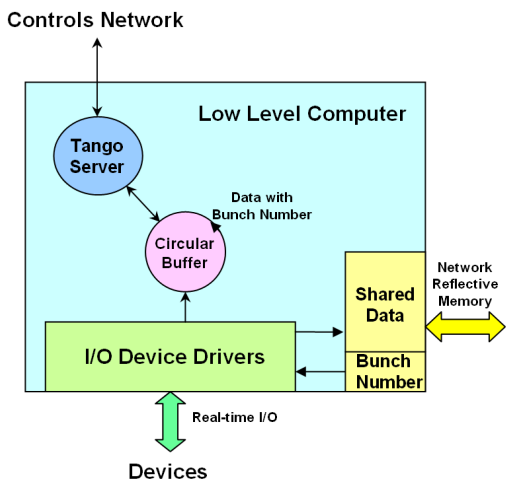

Figure 3: Software architecture of a low level computer acquiring real-time data.

EXPERIMENTAL STATIONS CONTROL AND DATA ACQUISITION SYSTEMS

Experiment controls are an extension of the machine control system and employ the same technology and architecture [7]. For practical reasons the control system of the experimental stations is logically separated from the machine: each of the stations has its own Tango database running on a dedicated virtual machine and separated VLANs in the controls data network. Access to the machine control system from the experimental stations is realized by providing a restricted view of the

machine devices through special Tango servers acting as bridges.

Data acquisition and online processing applications are developed using Tango on Linux machines. High-level applications can be developed both on Linux and Windows platforms using C/C++, Python, LabView, IDL or Matlab.

The NRM provides the experimental stations with the bunch number and pulse-to-pulse data from the upstream electron and photon diagnostics. This allows associating to the data acquired in each shot from the experiment detectors the characteristics of the corresponding FEL photon pulse, such as position, intensity, wavelength and bandwidth.

A scientific data storage system featuring a capacity of several hundreds of terabytes is being designed to accommodate the considerable amount of data that will be generated by the detectors with sustained data rate up to 400 MB/s. Dedicated acquisition servers will receive data from the detectors through high-speed real-time interfaces and will directly send them via dedicated 10 Gb/s Ethernet links to an online processing server, which will reduce data and eventually transfer them to a centralized storage system.

CONCLUSION AND OUTLOOK

After the commissioning of the machine and optimization of the FEL process in the first line of undulators (FEL-1), in July 2011 a coherent photon beam having the expected intensity and stability in a tunable wavelength range from 52 to 20 nm has been obtained, allowing the first rudimental experiments in the beamlines. In the next months, further optimizations will be carried out after the commissioning of the second bunch compressor and of the X-band RF cavity devoted to the linearization of the longitudinal phase space. In 2012 FEL-2 will be commissioned and more time will be gradually dedicated to the experiments, accomplishing the transition of the facility from commissioning to users operation.

The control system will evolve according to the new requirements. In particular, a number of additional feedback loops will be provided to stabilize the main beam parameters, such as charge, energy, bunch length and time of arrival. Moreover, further high-level applications will be developed to let the operators run the machine effectively and autonomously during users shifts.

CONTROL SYSTEM IN SWISSFEL INJECTOR TEST FACILITY

M. Dach, D. Anicic, D. Armstrong, K. Bitterli, H. Brands, P. Chevtsov, F. Haemmerli, M. Heiniger, C. E. Higgs, W. Hugentobler, G. Janser, G. Jud, B. Kalantari, R. Kapeller, T. Korhonen, R. A. Krempaska, M. Laznovsky, T. Pal, W. Portmann, D. Vermeulen, E. Zimoch,
Paul Scherrer Institut, 5232 Villigen PSI, Switzerland

Abstract

The Free Electron Laser (SwissFEL) Injector Test Facility is an important milestone for realization of a new SwissFEL facility at Paul Scherrer Institute (PSI) in Villigen, Switzerland. The first beam in the Test Facility was produced on the 24th of August 2010 which inaugurated the Injector operation. Since then, the beam quality in various aspects has been greatly improved.

The primary goal of the Injector Test Facility is to demonstrate a high-brightness electron beam which will be required to drive the SwissFEL main linac. The Injector further serves as a platform for the development and validation of accelerator components needed for the SwissFEL project.

This paper presents the current status of the Test Facility and is focused on the control system related issues which led to the successful commissioning. In addition, the technical challenges and opportunities in view of the future SwissFEL facility are discussed.

INTRODUCTION

The SwissFEL project at the Paul Scherrer Institute (PSI) foresees the realization of a SASE X-ray Free Electron Laser (FEL) operating at 0.1–7 nm photon wavelength by 2016 [1]. To minimize the facility length, and thus cost, the concept aims at relatively low electron beam energy. For the extensive study of the generation, transport and compression of high brightness electron beams and for developing the necessary components, PSI is commissioning the SwissFEL Injector Test Facility, a highly flexible 250 MeV linear electron accelerator [2].

The Injector Test Facility consists of a laser driven RF gun followed by an S-band booster section, a bunch compression section and a diagnostics section featuring an RF deflector and a series of FODO cells for emittance measurements [1].

The commissioning of the test facility proceeds in three phases: in a first step (phase 1), the gun section with some dedicated diagnostics was put into operation [3].

The second phase, lasting from August 2010 to May 2011 referred to the assembly of the full accelerator, with the exception of the bunch compression chicane, which was installed in July 2011.

The bunch compressor chicane will be put into operation during the third commissioning phase, starting later in 2011.

CONTROL SYSTEM OVERVIEW

The control and data acquisition system in the Injector Test Facility is based on a concept derived from the Swiss Light Source (SLS), in order to reduce the implementation effort due to limited man-power resources. Nevertheless, far more effort than originally foreseen was required to develop new applications and to elaborate on an infrastructure that fits well to the different characteristics of the FEL (i.e. linear pulsed machine) as opposed to the SLS (i.e. storage ring). Ultimately, an integrated system based on the EPICS toolkit was provided for both injector control and experimental data-acquisition.

EQUIPMENT INTERFACE

Equipment to be controlled and monitored connects to the control system mainly via VME crates (which fulfil VME64x standard). This concept was directly derived from the SLS [4]. An approximate total of 40 VME crates have been installed in the Injector Test Facility. In addition, non-VME solutions were elaborated upon to meet FEL requirements and to make use of new technologies.

An image capturing and acquisition system based on the Firewrire camera has been provided. Around 40 cameras were installed mainly for diagnostic screen monitor systems. Such cameras are interfaced to EPICS via the PC/Linux servers. The serial devices are controlled by means of the custom made embedded controllers based on the Virtex-4 FPGA. Such systems run EPICS on top of Linux.

Another embedded solution based on Virtex-4 FPGA is the “data concentrator” controller which is used to control magnet power supplies via fibre-optical links.

Temperature and humidity are measured by means of dedicated sensors interfaced to EPICS via the MSCB bus with embedded controllers.

NETWORK

The network of the Injector Test Facility was designed in view of the requirements for SwissFEL. We assumed that the number of network ports needed will be too high to fit into one class C subnet. Figure 1 schematically shows the layout of the network. Every circle in the diagram represents a class C network with 254 addresses. The connections of the different subnets of the EPICS network are controlled by the so called Channel Access Gateways, computers running software to minimize network traffic. The control room is the central location from where programs, mostly for commissioning, are run.

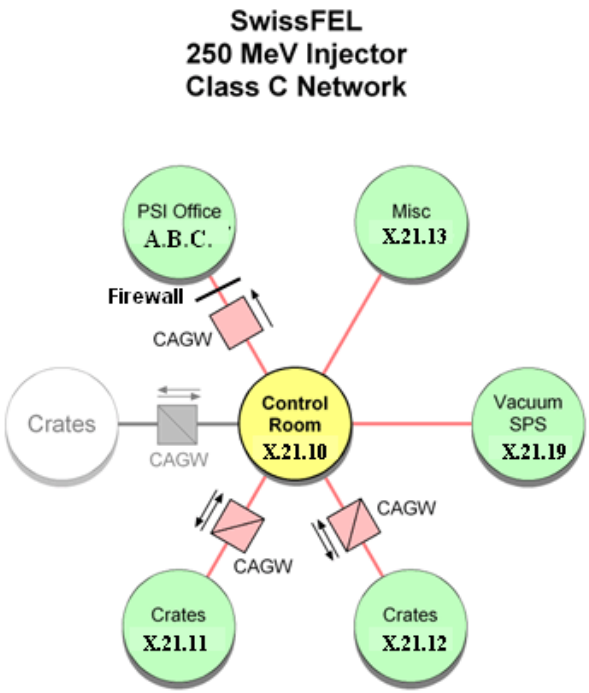

Figure 1: A schematic layout of the Injector Test Facility network consisting of several class C subnets.

SOFTWARE INSTALLATION

The control system software and configuration data is installed in a separate directory residing in a dedicated NFS file server. All files required to run VME and Linux IOCs and all client application configurations are located here. The 'swit' standard tool is used to install all control system applications at PSI.

PHYSICS APPLICATION

The Injector Test Facility is the first pulsed electron linac at PSI, and as such, the controls group had no previous experience in writing the necessary high level physics applications. These were mainly supplied by the physicists and engineers responsible for the commissioning. The controls group provides support by maintaining the MATLAB Channel Access (mca) interface to EPICS. Certain applications requiring primitive data types not supported by mca have made the transition to the more robust mocha (MATLAB Objects for Channel Access) package, which uses an in-house, C++ channel access library (CAFE) [5].

A number of physics process variables (PVs) have been implemented as soft EPICS channels (i.e. channels not connected to any hardware device) that hold information relevant for physics studies. One example is the emittance measured at a certain position along the beam axis. The measurement is time-consuming and invasive, but its value remains of interest for some time afterwards. It is therefore made available to other applications and status displays through a dedicated EPICS PV..

OPERATOR APPLICATIONS

As a backbone for operator applications we use programs from the EPICS toolbox like medm, alarm handler, and archiver. They are mainly chosen for compatibility to SLS as all accelerators are operated from the same control room and by the same operators.

Using a style guide for the application developers supports a consistent behaviour of all applications and a common integration of control room applications into EPICS. It provides rules for the application developer and simplifies the usage of the applications for the accelerator operators.

TIMING

Timing has a crucial role in the injector facility. It not only provides the triggering mechanism but also supports synchronous and reliable transmission of machine critical data. The timing system is based on the global event distribution by Micro Research Finland. We use the latest generation of the event system which supports real-time data transfer parallel to the event distribution. Non-VME systems e.g. Linux-based PCs which require timing, e.g. Firewire camera servers, receive timing information by PCI Event Receiver cards. The timing system is well integrated into the control system through which all its function are accessible. Sequencer of the event generator requires programming at high rate because some subsystems of the machine require trigger rates different than the machine nominal rate (i.e. 10 Hz). The sequencer is therefore programmed at the highest required rate which is 100 Hz in our case. Timing system capabilities has enabled us to realize a beam-synchronous data acquisition system for on-demand pulse-to-pulse correlated studies of the machine behaviour

DIAGNOSTICS

In order to support the extremely challenging SwissFEL Injector beam parameters, electron beam diagnostics components need to provide high performance with excellent reliability. At the same time, they have to be flexible enough to incorporate any improvements, which may be necessary to validate the final accelerator performance. Most of the beam diagnostics elements are based on the designs successfully implemented at the SLS as well as at other FEL facilities.

The major SwissFEL injector beam diagnostics tools include: integrated current transformer, wall current monitor, Transverse Deflecting Structures (TDS), beam profile monitors [6], beam position monitors (BPM), Electro Optical bunch length Monitors (EOM), and Bunch Arrival time Monitors (BAM).

Electronics of BPM systems (button, stripline, and cavity) is implemented in VME64x, which is the PSI standard for real time applications [7]. The digitized signals from BPM pickups are processed by dedicated FPGA modules. Calculated beam positions, at different averaging rates, are pushed into the EPICS database and immediately become available for the PSI control system.

The BPMs provide a high resolution (up to 10 μm) for a large range of electron bunch charges (10-200 pC).

Optical screen monitors together with direct (synchrotron and diffraction) radiation monitors are used to visualize the transverse electron beam profiles. The main controls components of these monitors are video cameras and VME based stepper-motor driving hardware.

Non-invasive monitoring of the longitudinal charge distribution in electron bunches is provided by EOM systems. Such systems for the SwissFEL are designed and built at the PSI [8]. Their resolution (~100 fs) is adequate for the expected bunch lengths. Core EOM elements are an advanced fiber laser system with pulse generating, phase locking, and synchronization electronics talking to the external world via serial (RS232) and GPIB communication lines. All EOM components are fully integrated into the PSI controls, which significantly simplifies their operations.

BAM systems will allow one to determine the beam arrival time with the resolution of ~10 fs. BAM signals can be used, for example, in feedback loops preventing beam energy drifts and stabilizing RF amplitudes of the injector linac structures. Key BAM elements are remotely handled by VME stepper-motor drivers as well as standing alone high precision motor controllers and signal synchronization devices talking via serial (RS232) communication lines. The work on the BAM developments and their integration into EPICS is in progress.

LASER

Two laser systems are used during the commissioning of the injector test facility: a compact, turn-key Nd:YLF amplifier suitable for basic commissioning tasks and a more sophisticated Ti:Sapphire amplifier allowing longitudinal pulse shaping and wavelength tuning for detailed emittance studies [1]. Both of the lasers require many devises to be interfaced to the control system.

More than 50 stepper motors are used to control mirrors on the optical path from the laser to the RF gun. The end user is able to monitor the beam shape at various locations by means of several firewire cameras. The beam laser energy measurement is based on the photodiode readouts. The photodiode signals are first pre-amplified, integrated in the boxcar integrator and digitised by ADC. For the proper operation the laser based system requires stable conditions in terms of the temperature, humidity and air pressure. There are several sensors installed to monitor such parameters in the air-conditioned laser hutch. They are interfaced to the control system by means of the MSCB distributed monitors/controller nodes. One of the challenges from the controls point of view was to improve the beam pointing stability at run-time. This was achieved by a dedicated application which performs a beam spot analysis, and through the PID loop, controls the motor mirror along both the X and Y axis [9].

RF

There are in total 7 RF systems foreseen: an RF gun, four accelerating structures, one x-band cavity and a deflecting cavity. Each of these systems consists of three parts.

A modulator supplied with an integrated control system that has been interfaced to EPICS with a serial TCP/IP connection.

An interlock system and low level RF (LLRF) were developed at PSI, based on VME, and are fully integrated into EPICS.

ALIGNMENTS

Computer monitoring and movement control of several parts of the Injector Test Facility system are required.

A Gun Solenoid magnet mover system with five degrees of freedom (DOF), which is based on the SLS HEXGIR systems, has been installed.

A second system is currently under construction to allow controlled movement of the RF XBand diagnostic equipment at the end stage. The HEXGIR girder mover system is flexible and can be adapted to different mechanical girder layouts. It is highly configurable with all physical parameters defined in one file. The system was designed to allow six degrees of freedom movement if needed [10]. The bunch compressor dipole magnet system has a simpler alignment system for horizontal movement only. All of these systems use EPICS in a single VME crate.

CONCLUSIONS

The SwissFEL Injector Test Facility provided us with an opportunity to develop and evaluate new ideas in light of the future SwissFEL project. The successful commissioning (phase 1 and 2) revealed some points for future improvement. The stability and performance of the Channel Access Gateways is questionable. The choice of firewire camera standard seems to be far from optimal for highly distributed SwissFEL environment. The GigE standard was chosen to improve the stability and reliability of the existing video system in the future. The fast feedback system is under investigation.

STATUS OF THE CONTROL SYSTEM FOR THE EUROPEAN XFEL

K. Rehlich, DESY , Hamburg, Germany

Abstract

DESY is currently building a new 3.4 km-long X-ray free electron laser facility. Commissioning is planned for 2014. The facility will deliver ultra short light pulses with a peak power up to 100 GW and a wavelength down to 0.1 nm. About 200 distributed electronic crates will be used to control the facility. A major fraction of the controls will be installed inside the accelerator tunnel. MicroTCA was chosen as an adequate standard with state-of-the-art connectivity and performance including remote management. The XFEL [1] will produce up to 27000 bunches per second. Data acquisition and controls have to provide bunch-synchronous operation within the whole distributed system. Feedbacks implemented in FPGAs and as service tier processes will provide the required stability and automation of the FEL. This paper describes the progress in the development of the new hardware as well as the software architecture. Parts of the control system are currently implemented in the much smaller FLASH FEL facility.

INTRODUCTION

The front-end electronics will be distributed along the 3 km long machine. Since a major part of the XFEL is running below populated public areas, the electronics has to be placed inside the tunnel close to the accelerator components. This requires appropriate shielding against radiation and remote management capability of the hardware. Furthermore, shots will have repetition rate of 10 Hz and a length of a ms. The bunches are spaced with 1/4.5 MHz and 27000 bunches per second have to be recorded and processed. A timing system is planned to synchronize all front-end systems. Data of all subsystems will be transmitted to central services and have to be sorted to sync all bunches. A fast DAQ system, designed and operated for FLASH [2], will provide a common solution for multiple services. As common hardware platform MicroTCA has been defined as the standard for XFEL fast controls.

MICROTCA STANDARD

Hundreds of megabytes per second have to be transferred within a crate and to the central services. MicroTCA provides these fast transfer rates and offers GigaLinks as point-to-point connections between modules for e.g. fast feedbacks. And MicroTCA has a very well defined interface to manage crates and individual modules. This is described in the next chapter.

But, the original specification was driven by telco applications. Analog IO and the distribution of timing information were not foreseen. Therefore a group of laboratories together with industrial partners initiated a working group within the PICMG ® [3] to specify rear transition modules, clock and trigger distribution. One result of this committee is the MTCA.4 specification, which is available since October 2011. It is fully compatible to the older MicroTCA specification. All existing modules can run in this new extended standard. During the specification period institutes and industry have designed first prototypes.

The driving idea of this MTCA.4 standard is to build only a few complex front modules as AMCs (Advanced Mezzanine Cards) and many simple RTMs (Rear Transition Modules) to adapt the AMCs to different applications. AMC and RTM are connected by two shielded 30 pair ADF connectors. They support fast GigaLinks as well as sensitive analog signal transmission. Six pairs of one plug are defined as management and power interface of the rear module. RTMs are fully integrated in the crate management. Hot-swap as well as a protection against wrong inserted modules are defined.

In September 2011 DESY has successfully demonstrated a MicroTCA system controlling one super-conducting RF module, with 8 cavities, driven by one 5 MW klystron. The Low Level RF system (LLRF) was completely installed in a MicroTCA crate according to the MTCA.4 standard.

The setup was (Figure 2):

- Three 125 MSPS, 16 bit ADCs with 1.3 GHz down-converters as RTMs.
- One controller with a vector modulator to drive the klystron.
- One timing module to synchronize the LLRF with the linac.
- A CPU and disk.
- An MCH as a switch for Ethernet and PCIe and to manage the crate.

It was shown that MTCA.4 can operate sensitive analog

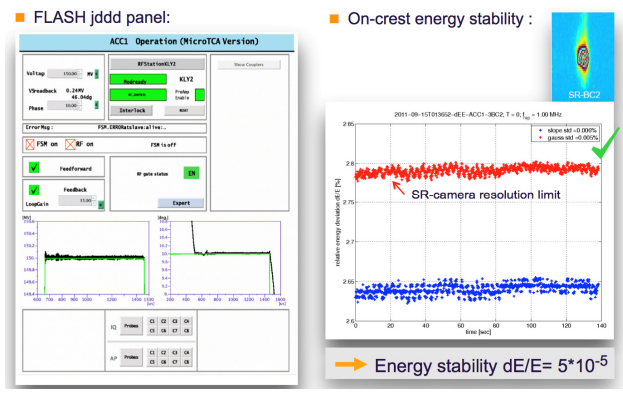

Figure 1: 800µs flat-top operation of FLASH with the new µTCA system.

electronics together with high frequency switched digital CPUs and FPGAs without degradation of signals quality.

The measured energy stability of the FLASH electron beam during 800 µs was better than $5*10^{-5}$ (Figure 1). This fulfills the XFEL requirements.

This demonstration included the full chain of new developed firmware, Linux drivers, DOOCS device servers and hardware management. In other words, the MicroTCA crate was completely integrated into the control system of FLASH. The device servers were written in a way that existing client programs find many names of the old VME system and required only minor modification to address new features.

Figure 2: The rack with the blue MicroTCA crate controls 8 superconducting cavities of one cryo module in FLASH.

HARDWARE MANAGEMENT

The hardware management operates on two levels. IPMI commands are available on the MCH Ethernet port for remote access. And within a crate PCIe is used to handle hardware events.

MicroTCA specifies IMPI functions for all hardware modules in a crate. It includes all AMC modules, fans, and power supplies. A DOOCS server, as a middle layer service, talks to all crates and dynamically detects inserted modules and monitors them. If a user inserts an AMC module the server creates a device instance for the module. It allocates data archives for the voltage and temperature readings and creates the corresponding addresses to be accessible for clients (Figure 4). During configuration of the server it is just required to specify the crate IP address, the other information is read from the hardware via well-defined IPMI commands. Furthermore, rebooting of a CPU with a frozen operating system can be initiated by power cycling an AMC via the IPMI DOOCS server.

Within a crate the PCIe signaling allows to handle removal and insertion of modules. In a running system one can remove e.g. one ADC board. The DOOCS server continues with the other ADCs and marks the removed one as faulty. After reinsertion of the ADC the server restores the registers and continues readout. This hot-swap does not require any operator actions. Linux drivers and DOOCS server processes automatically handle it.

MIDDLE LAYER SERVICES

As mentioned, XFEL will produce up to 27000 bunches per second. A data acquisition system (DAQ) has been implemented at FLASH to cope with the high data rates and to synchronize the data from a distributed system in one or more middle layer servers. The system is used for online processing of bunch related data, to archive all bunches of all monitors, and to store data of user experiments of the photon beam lines.

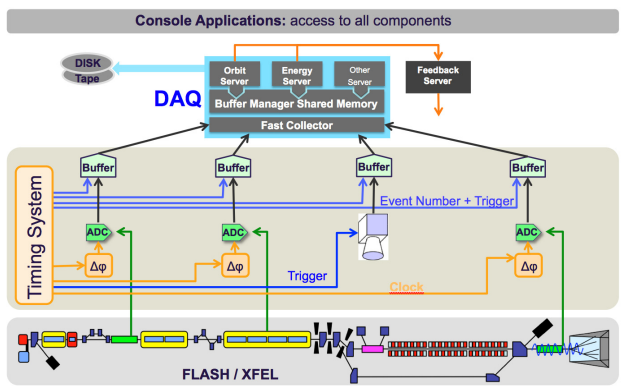

Figure 3: The timing system synchronizes the distributed controls. Data is collected in the central DAQ system.

The DAQ provides data of all BPMs for instance to calculate an orbit. This service was recently used to attach a slow orbit feedback to stabilize the beam in all sections of the accelerator (Figure 3). As a display and configuration tool jddd was used.

These three software packages, the DAQ, the feedback process and the jddd panel editor [4] are components to be used for XFEL commissioning. FLASH is used to test

the new hardware and software. Both, FLASH and XFEL will profit from this parallel development.

CONSOLE APPLICATIONS

The graphical operator panel design tool jddd is a further development for both machines. The goal of the design is to create a tool that is simple and can be used without knowledge of programming languages. Operators and subsystem experts are able to create themselves panels and can run them on multiple platforms. Jddd is Java based and the panels are stored in a Subversion repository. The panel can run on Mac OS, Windows and Linux operating systems.

Although jddd is usable without writing code, it has many complex widgets to construct highly dynamic panels. For example displays showing all running processes of the control system were created. During run-time these panels are dynamically updated by reading from a name server and device servers. See [4] for more information.

CONCLUSIONS

MicroTCA has been chosen as the standard platform for the XFEL. A first implementation of the LLRF controls based on this new standard has demonstrated that the most complex subsystem could be realized with excellent performance. This is a proof of principle for the new MTCA.4 standard. All required hardware and software components could be implemented and successfully tested. It includes hardware design, firmware, module management, Linux drivers, control system device servers and high level management server and display.

ACKNOWLEDGEMENTS

This work was only possible with the excellent contributions of many members of collaboration partners from Poland and Sweden, industrial partners, and the DESY groups MSK and MCS4 – many thanks to all of them.

THE LASER MEGAJOULE FACILITY: CONTROL SYSTEM STATUS REPORT

J.P. Arnoul, F. Signol CEA/CESTA, Le Barp, 33114, France
J. Nicoloso, CEA/DIF, Bruyères le Châtel, 91297, Arpajon, France

Abstract

The French Commissariat à l'Énergie Atomique (CEA) is currently building the Laser MegaJoule (LMJ)[1], an up to 240-beam laser facility, at the CEA Laboratory CESTA near Bordeaux. It is a Megajoule class facility, designed to deliver a high energy to targets for high energy density physics experiments, including fusion experiments. LMJ technological choices were validated with the LIL, a scale 1 prototype of one LMJ bundle. The construction of the LMJ building itself is now achieved and the assembly of laser components is on-going.

The presentation gives an overview of the general control system architecture, and focuses on the hardware platform being installed on the LMJ, in the aim of hosting the different software applications for system supervisory and subsystem controls[2] (Fig. 4).

This platform is based on the use of virtualization techniques that were used to develop a high availability optimized hardware platform, with a high operating flexibility, including power consumption and cooling considerations. This platform is spread over 2 sites, the LMJ itself of course, but also on the software integration platform built outside the LMJ to provide system integration of various software control system components of the LMJ.

LMJ FACILITY

The Laser Megajoule facility (LMJ) is presently under construction at the CEA/CESTA site near Bordeaux (France). LMJ is an up to 240-beam laser system designed to study inertial confinement fusion (ICF) and the physics of extreme energy densities and pressures. LMJ will be capable of focusing its energy of ultraviolet light on to an extremely small micro-target in an extremely short space of time. The characteristics of this facility were defined to obtain the temperature and pressure conditions required to reach thermonuclear ignition. Experiments will involve tenths of a milligram of matter in which nuclear fusion reactions will be produced. LMJ is an element of the Simulation Program that aims the guarantee of the safety and reliability of French nuclear weapons. It is comparable to the US NIF facility. LMJ will welcome national and international scientific collaborations, in order to become a privileged place of scientific exchanges.

The LMJ building covers a total area of 40,000 m2 (300 m long x 150 m wide). The four laser bays, 128 m long, are situated in pairs on each side of the target chamber. The experiment building (target bay) is a cylinder of 60 m in diameter and 38 m in height. The target chamber consists of an aluminium sphere, 10 m in diameter, fitted with several hundred ports for the injection of the laser beams and introduction of diagnostics. The 240 beams are grouped in 30 bundles of 8 beams in the laser bays and in 60 quads in the target bay. Numerous diagnostic instruments will be placed in the target chamber around the target to record essential measurements. They will make it possible to observe the behaviour of the target during its implosion and at the time of ignition. These diagnostics are the prime tools for the physicists to determine the characteristics of the plasmas they are studying.

LMJ PROJECT STATUS

The building itself is now complete; the mechanical assembly of the bundles in the two first laser bays is achieved and the assembly of the two others is in progress. The LMJ commissioning strategy is to have several steps towards full energy by successively providing each bundle with its optical components and control system, and at the same time using the already commissioned bundles for shots experiments.

A petawatt beam called PETAL is also under construction and will be coupled to LMJ's quad in the next few years.

The first experiments are scheduled on the LMJ facility for the end of 2014.

LMJ CONTROL SYSTEM ARCHITECTURE

General Architecture

The LMJ control system has to manage over 500 000 control points, 150 000 alarms, and several gigabytes of data per shot, with a 2 years on line storage.

It is composed of a dozen of central servers supporting about two hundreds of virtual machines at the central controls level and about 450 PLC's or rack mount PC's at low levels.

All these equipments are distributed on a pyramid of 4 layers: equipment microcontrollers and PLC's on the N0 layer, subsystem supervisory controls on the N1 layer, central controls on the N2 layer and facility management on the N3 layer.

From an industrial point of view, LMJ is divided into a dozen of major contractors, one for each LMJ subsystem. Each of these contractors supplies the N0 and N1 control system levels corresponding to the function he is responsible for. CEA itself defines the common technology and standards and is responsible of doing the integration of the different subsystems.

Software Architecture

All the command control software developed for the N1 and N2 layers by the different contractors uses a common framework based on the industrial PANORAMA E2 SCADA from Codra.

In this framework the facility is represented as a hierarchy of objects called "Resources". Resources represent equipments (motors, instruments, diagnostics…) or high level functions (alignment, laser diagnostics). Resources are linked together through different kinds of relationships (composition, dependency, incompatibility) and the resources life-cycle is described through states-charts. Control-Points, alarms, states and functions can be attached to any resource. Dedicated mechanisms manage the resource reservation and propagate properties and states changes into the tree of resources through relationships. There are about 200 000 resources in order to describe the entire LMJ.

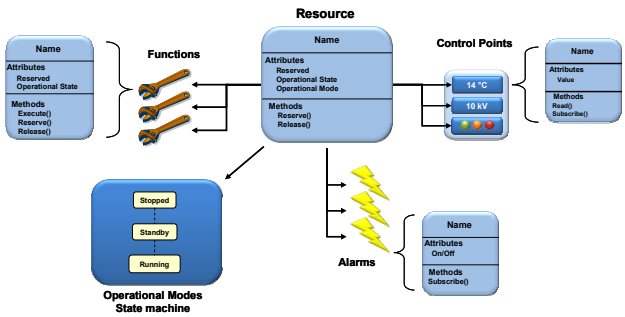

Figure 1: Data model.

The framework implements the data model described above as .net components inside the PANORAMA E2 SCADA and adds some common services to the standard features of PANORAMA E2:

- resources management,
- alarms management,
- lifecycle states management,
- sequencing,
- configuration management,
- event logging

Hardware Architecture

From the hardware point of view the LMJ control system is constituted of two platforms located in two different buildings:

- one for system integration (PFI), which is in operation at the present time in a dedicated building and consists of a clone of the operational control system at the N1, N2 and N3 layers and a mixture of simulators and microcontrollers for representing the N0 layer and real equipments.
- The operational platform (PCI), that will be integrated in the LMJ building at the beginning of next year and which consists of two sub-platforms: a small one for integrating the laser bundles and one for nominal operations.

For each platform, the network architecture (Fig. 2, 3) is composed of two redundant Alcatel-Lucent OmniSwitch 9702E chassis which provide redundant Gigabit attachments to the twelve subsystems backbones and 10 Gigabits attachments to the central controls servers.

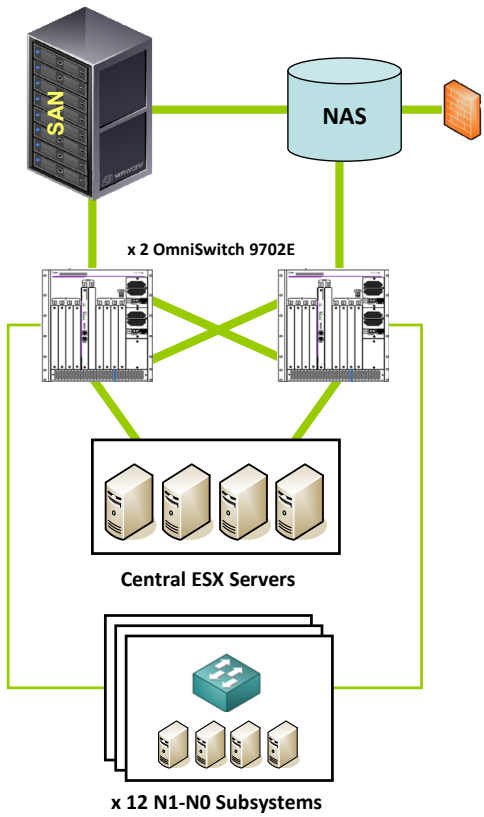

Figure 2: Network architecture.

On each platform, virtual independent contexts are configured using Virtual Routing and Forwarding technologies (VRF): on the PFI this allows to simulate different test contexts at the same time with identical IP address spaces, and on the PCI this allows simultaneous operation from the operational control room and the integration one.

All the N1, N2 and N3 layers are virtualized using VMware and DataCore solutions. Each PFI & PCI platform consists of one virtualization infrastructures composed of:

- 2 DataCore servers, each one managing 12 To of disks,
- 6 to 8 ESX Dell PowerEdge R815 servers, with 4x12 cores and 128 Go of RAM,
- 1 VCenter Server to manage the VMware infrastructure.

Each of these virtualization infrastructures is dimensioned to execute several hundreds of virtual machines.

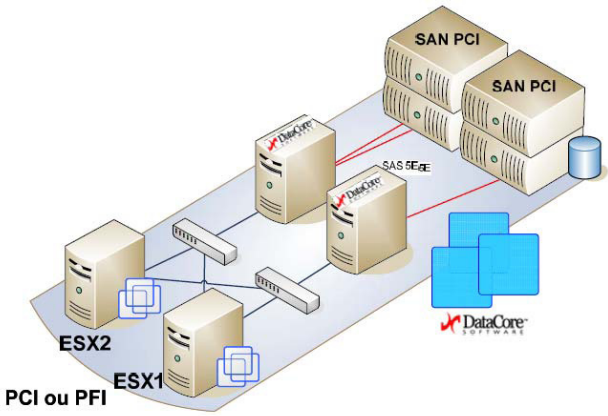

Figure 3: Network architecture.

From the configuration management point of view, application software is generated on the integration platform and stored on a 30 To Network Area Storage (NAS). Images stored on this NAS are made available to the operational platform across a 1 Gigabit dedicated link.

In conclusion the integration and operational platforms of the LMJ control system represent about 500 virtual machines hosted by around fifteen 48 cores / 128 Mo servers.

LMJ CONTROL SYSTEM ROAD MAP

The software framework was commissioned during summer and is now available to contractors to allow them realizing their supervisory systems. The N2-N3 software is currently integrated on a dedicated platform and his commissioning will be accomplished before the end of this year.

The next milestone is to integrate the N2-N3 software with the hardware of the integration platform that will be installed in the PFI building at the end of this year. The integration platform will then be ready to receive control subsystems of the N0-N1 layers from the middle of 2012.

All the N0-N1 subsystems will be integrated to the N2-N3 subsystem on this platform in 2012-2013, before being installed on the operational platform and integrated with laser equipments of the LMJ.

SUMMARY OF THE 3RD CONTROL SYSTEM CYBER-SECURITY (CS)2/HEP WORKSHOP

S. Lüders*, CERN, Geneva, Switzerland

Abstract

Over the last decade modern accelerator and experiment control systems have increasingly been based on commercial-off-the-shelf products (VME crates, programmable logic controllers (PLCs), supervisory control and data acquisition (SCADA) systems, etc.), on Windows or Linux PCs, and on communication infrastructures using Ethernet and TCP/IP. Despite the benefits coming with this (r)evolution, new vulnerabilities are inherited, too: Worms and viruses spread within seconds via the Ethernet cable, and attackers are becoming interested in control systems. The Stuxnet worm of 2010 against a particular Siemens PLC is a unique example for a sophisticated attack against control systems [1].

Unfortunately, control PCs cannot be patched as fast as office PCs. Even worse, vulnerability scans at CERN using standard IT tools have shown that commercial automation systems lack fundamental security precautions: Some systems crashed during the scan, others could easily be stopped or their process data being altered [2].

The 3rd (CS)2/HEP workshop [3] held the weekend before the ICALEPCS2011 conference was intended to raise awareness; exchange good practices, ideas, and implementations; discuss what works & what not as well as their pros & cons; report on security events, lessons learned & successes; and update on progresses made at HEP laboratories around the world in order to secure control systems. This presentation will give a summary of the solutions planned, deployed and the experience gained.

THE FACT OF ATTACK

2010 has seen wide news coverage of a new kind of computer attack, named "Stuxnet", targeting control systems. Due to its level of sophistication, it is widely acknowledged that this attack marks the very first case of a cyber-war of one country against the industrial infrastructure of another, although there is still much speculation about the details. Worse yet, experts recognize that Stuxnet might just be the beginning and that similar attacks, eventually with much less sophistication, but with much more collateral damage, can be expected in the years to come. Stuxnet targeted a special model of the Siemens 400 PLC series. Similar modules are also deployed throughout the world for accelerator controls like cryogenics or vacuum systems as well as the detector control systems in high energy physics (HEP) experiments.

As with Stuxnet's infection vector, several HEP laboratories reported virus attacks through USB sticks. In one case, the insertion of an infected stick bypassed all firewall protection and network segregation measures put in place to secure the corresponding control system network. As those measures were perceived being sufficient, the affected PC did not run any anti-virus software, which would elsewise have easily quarantined that more than 5-year old virus. However, when trying to establish an IRC connection "home", the virus was quickly identified in the control system firewall logs. Nevertheless, it managed to infect two more control PCs before being fully contained.

In September 2009, one site reported the successful attack against a web server used to display controls information to members of the corresponding experiment's collaboration. For that purpose, all control data was replicated onto a publicly visible web server. However, due to negligence, that web server was neither properly updated nor was the web application properly secured: In a first step, the attacker managed to discover a file injection vulnerability which has subsequently been misused to create a remote shell. A vulnerability in the unpatched kernel subsequently gave the attacker full root access. Its prompt detection avoided further damage.

A similar event was detected at an other U.S. site in spring 2011. After having compromised two Internet facing webservers one month earlier, the attacker escalated privileges right in time for the July 4th holiday week-end. Also here, timely attack detection prevented further misuse.

In April 2011, an email phishing attack hit Oak Ridge National Laboratory (ORNL) in the U.S. Of the approximately 500 recipients of the email about 10% clicked on an embedded link designed to install malware. In one case the user had sufficient privilege that was leveraged to install malware on a large number of additional systems at the laboratory. ORNL chose to sever its connection to the Internet, including blocking web access and external email, to prevent data exfiltration. The clean-up and recovery took two weeks before normal functionality was restored.

The ORNL SNS accelerator controls network was designed to be well isolated from the rest of the ORNL network. Consequently the SNS accelerator was able to remain fully operational during this incident.

The European Organization for Nuclear Research (CERN) was luckier in July 2011 where a researcher on SCADA security found a password of one of CERN's control system. This password was listed in a document made unintentionally public. Before the researcher

* With contributions from E. Bonaccorsi (LHCb), P. Charrue (CERN), P. Chochula (ALICE), S. Hartman (ORNL), T. Hakulinen (CERN), T. McGuckin (JLab), T. Sugimoto (Spring8), F. Tilaro (CERN), V. Vuppala (NSCL/MSU).

published his findings on his personal blog later in August 2011, he informed the U.S. Department of Homeland Security who subsequently informed CERN. Even though this password just provided read access to limited information, it was immediately changed and the compromising document removed from that web-server (as well as from the cache of the Google search engine).

These few security events dismiss the illusion to believe HEP laboratories are not of interest for adversaries and not under attack. Even when all aforementioned security events have been promptly detected, properly analysed, and finally mitigated, acting in retrospect is a bad strategy. While probably not being a high-level target, security officers of HEPs should prepare counter-measures in order to prevent and protect security events from happing.

CHALLENGES IN CONTROL SYSTEM CYBER-SECURITY

However, control system cyber-security is not easy.

CERN's "Access, Safety and Engineering tools" (ASE) group, widely responsible for personnel access and safety systems at CERN, and the ALICE experiment at CERN have both reported about their challenges when implementing standard control system cyber-security measures.

CERN has set up a working group on the protection of control system [4]. Since then, all control systems at CERN must adhere to the "Computer and Network Infrastructure for Controls (CNIC) Security Policy for Controls" [5] following a "Defense-In-Depth" approach. However, over time, some of the access and safety systems have suffered from problems due to the CERN security policies. The most problematic and hardest to debug in the past have been due to the non-robustness of various off-the-shelf systems to periodic security scans. There have also been other problems due to incompatible security patches as well as expiration of service passwords. In the best case, these problems have been an annoyance to the access and safety team. In the worst case, they have prevented the accelerators from starting and personnel from accessing the controlled zones during the very tight maintenance windows.

The ALICE experiment at CERN is experiencing similar problems: Technical requirements and operational constraints [6][7] often directly collide with security measures. ALICE reported that the regular LHC technical stops (2-4 days) are insufficiently short to properly apply all pending security patches. In addition, the CPU consumption of anti-virus software is still one of the top-5 most resource demanding programs.

OVERCOMING THE CHALLENGE

In order to mitigate their problems, CERN ASE has suggested publishing security scan data, i.e., scan schedules, history, and results. This shall allow to correlate scans with the system monitoring data, system failures, and to help prepare for interventions and maintenance. In order to validate the robustness of network-connected devices, CERN's ASE group is considering the TRoIE test-bench, where equipment can be stress-tested and qualified in a controlled environment (see below). The TRoIE test procedure might also be used defining a conformity specification of CERN security measures. The associated requirements could be given to equipment and system vendors during the project definition phase. This document should be sufficiently authoritative and contractual to truly deliver the message to the vendors of the importance of hardening their equipment to the risks of today's computing environments.

Network Segregation, Compartmentalization and Border Control are Essential

The safe and stable operation of the ALICE experiment at CERN is assured by the Detector Control System (DCS), based on a commercial SCADA system PVSS II. The DCS is running on an isolated network, fully compliant with the CERN CNIC standards and rules. The interoperability with external systems is based on the network "exposure and trust" mechanism. DCS hosts can be made visible to external networks by exposing them; remote hosts can be trusted and become accessible from the DCS network. Using these mechanisms, the DCS can largely profit from CERN central computing infrastructure such as name resolution or domain services and reduce the local administrative overhead.

Data produced in ALICE DCS is exchanged with external systems in a secured way. A limited number of data publishers are trusted by the DCS network and central DCS clients can subscribe to the published data using CERN's DIM and DIP data exchange protocols. The DCS then distributes this information to its subsystems using the PVSS II. In the same way, DCS feedback is published to the trusted subscribers. All systems can in addition produce files, which are stored on internal fileservers and automatically mirrored to publicly accessible fileserver located on the CERN general purpose network. Upload of data to the network is subject to strict security policies and is performed by admins upon user's request.

A set of dedicated processes periodically collect condition parameters tagged by detectors for web display and converts them to images which are transferred to a public webserver. The image transfer is based on the concept of private and public fileservers, which assures a complete decoupling of the web services from the DCS infrastructure.

Individual detector control systems are made accessible to remote experts via application gateways, based on Windows Terminal Services. These servers are the only entry point to the system and are accessible only by using user's personal accounts. The use of shared accounts required for the operation is restricted only to the consoles installed in the control room.

The LHCb experiment at CERN pursues as similar road in protecting their control network from malicious remote

access. Operational independence and strong isolation from the Internet as well as from central CERN resources have been important design criteria. Depending on a strong perimeter protection, LHCb has deployed a three-tier redundant firewall providing screened subnets and demilitarized zones. A default deny policy has been implemented together with a set of rules based on the needs of the internal devices to be protected as well as statistical analysis of the boundary and internal network traffic. Each bastion host is hardened at the operating system level, reducing the number of installed applications to minimum. Each web server and reverse proxy has been configured to run as a different domain user and is serving pages from a read only shared network file system whose access is filtered both at OS and network layer. X.509 certificates have been issued by a recognized and "trusted" certification authority and have been installed on all web servers in order to protect the confidentially of sensible data such as usernames and passwords. The entire network traffic is also mirrored and analyzed in real time by an open source intrusion detection system based on Snort.

The Japanese SPring-8 facility serves 55 different beam-lines used by more than 10'000 users per year. The corresponding experimental user networks allow for controlling experimental instruments and data acquisition systems attached to these beam-lines. While SPring-8 has already compartmentalized their experimental user network into 55 segments, it is mandatory to have access to the Internet for data transfer as well as providing users with access to mail and web pages. However, this access is often misused by non-essential applications or inappropriate usage like bandwidth exhaustion by media streaming (YouTube, P2P file sharing), unauthorized instrumental control from outside via VPN, and so on. In particular the latter is prohibited as it collides with SPring-8's radiation safety regulations [8]. Moreover, due to web-browsing, several virus infections had already occurred on the experimental user network.

In order to prevent these threats from spreading to other control systems, SPring-8 had deployed the CheckPoint InterSpect610 intrusion protection system (IPS). While this IPS was suitable in the past, it lacked application signature coverage and was not able to block traffic tunneling via the HTTP web protocol. Hence, in 2010 it has been replaced by the so-called "Next Generation Firewall" from PaloAlto (PA-500 and PA-2050). This firewall can detect and block many (file sharing) applications and viruses including tunnelling protocols. Indeed, until today, this next generation firewall has successfully contained the spreading of 287 different P2P applications as well as 140 different types of viruses. Furthermore, their new firewall provides fundamental statistics for future service upgrades.

The earlier mentioned security event at one particular laboratory forced a full re-examination of their network structure and security. Priorities included isolating and firewalling critical subnets, a thorough segregation of the existing network infrastructure into functional domains, the deployment of application gateways between domains as well as stronger use of administrative and network monitoring tools. Remote access is now based on Virtual Private Networks requiring multifactor authentication (Crypto Cards or USB smart cards). All of these actions are being implemented as part of a more active model of accelerator controls network and system security.

A strong model of Defense-in-Depth is now pursued to produce a long-term solution that meets new requirements while minimizing the impact on-going work at the laboratory and allowing for a continuing cycle of monitoring, assessing and updating security.

DEFENSE-IN-DEPTH

The "Defense-In-Depth" approach requires that security measures have to be deployed on every level of the hardware and software stack, and not only at the network layer. Therefore, a more holistic view is necessary.

Top-Down vs. Bottom-Up

At CERN, the accelerator controls group has started creating a security inventory and risk assessment of the control system computers, devices, accounts and applications, with the goal

- to improve security and reliability of the accelerator control infrastructure;
- to identify the most critical security risks in its control systems; and
- to identify solutions to improve their security, including funding and implementation measures.

This inventory is supposed to summarize all risks using a list of security and reliability attributes like patching status, network configuration, installation base for applications, account usage, etc. While taking advantage of already existing data [9] (and their subsequent clean-up), a web-based "Questionnaire" enables system experts to quickly enter data for the remaining attributes.

The first version has been released to CERN's system experts, and the Questionnaire is currently being populated. In a second step, risk factors will be assigned to each of the attributes in order to determine the overall risk. As a side effect, some experts use this information now for accelerator failure-response and maintenance planning.

Compared to CERN's bottom-up approach, the U.S. National Superconducting Cyclotron Laboratory (NSCL) follows a top-down solution aiming for full compliance with the ISO 27000 standard [10] and final certification [11]. Essential for a successful compliance with ISO 27000 is the full support by management as well as support from all stakeholders involved.

Following this standard, NSCL implemented an Information Security Management System called "ARGUS", a framework of policies, procedures, guidelines and associated resources to achieve the security objectives of the organization. OCTAVE Allegro [12] has been chosen as the risk assessment methodology.

With those tools, the critical information assets, including controls and PLC software & configuration, system documentation, software licenses, etc. have been identified and assigned a relative risk score. This score is combined, categorized and prioritised. The resulting risk is finally mitigated following the controls from ISO 27002 or in-house developed controls. However, acceptance of low or residual risks is possible, too, if properly documented and approved by the management.

Robustness of Controls Devices

Particularly challenging for NSCL have been the hardening of control system platforms such as PLC devices where it was difficult to implement secure software development processes. Focus on such devices has been put on the robustness of industrial control system components by CERN's TRoIE test-bench. Unfortunately, there are no complete and comprehensive security standards yet, which can be followed to secure embedded devices; but several initiatives have been started with the objective of improving the security level and the robustness of industrial systems [13][14].

Therefore, CERN has developed a methodology for automated testing which evaluates the devices' ability to handle erroneous and malicious network traffic. This approach is based on the injection of malformed packets in order to corrupt the normal behaviour of the device and detect possible anomalies. As it is important to enumerate all possible faulty packets for each protocol, TRoIE uses fuzzing and syntax techniques, and lets the tester generating packet sequences in a systematic manner according to the definition of specific protocol syntactic and semantic rules. This technique is generic enough to be applied to any communication protocol, even to industrial ones that exhibit very specific properties and features.

TRoIE is currently under development and a wider publication is under discussion.

CONCLUSIONS

Stuxnet should have been the wake-up call for all those who never believed that control systems could and would be attacked. Indeed, HEP laboratories around the world have seen computer attacks against their facilities, even if these were not dedicated attacks against control systems, yet. However, this should not serve as an argument not to take any action. Continuing to ignore control system cyber-security is grossly negligent.

On the contrary, several HEP labs have started to or do repeatedly review the security protections put in place. Although sometimes cumbersome and difficult to achieve, deploying a "Defense-in-Depth" approach is mandatory and corresponds to good practise. NSCL even goes so far as to aim for full ISO 27000 compliance even on the control system level, a feat which is definitely both an ultimate goal, and a very difficult challenge.

In addition, there was broad consensus that control system cyber-security is more a people problem than a technical one. Establishing a "Security Culture" is needed where system experts, administrators, vendors, and operators cease perceiving "security" as burden but consider it to be an integral part of the system requirements on a par with functional, safety, and maintenance requirements. With such a change of mind-set, a big first step is taken for a better cyber-security of control systems. Subsequent technical steps would then be more easily understood and eventually accepted.

With Stuxnet, a new era has begun. Stay tuned.

SARDANA, THE SOFTWARE FOR BUILDING SCADAS IN SCIENTIFIC ENVIRONMENTS

T. Coutinho, G. Cuní, D. Fernández-Carreiras, J. Klora, C. Pascual-Izarra, Z. Reszela, R. Suñé,
CELLS, Bellaterra, Barcelona, Spain
A. Homs, E. Taurel, V. Rey, E.S.R.F, Grenoble, France

Abstract

Sardana is a software package for Supervision, Control and Data Acquisition in scientific installations. It delivers important cost and time reductions associated with the design, development and support of the control and data acquisition systems. It enhances TANGO [1] with the capabilities for building graphical interfaces without writing code, a powerful python-based macro environment for building sequences and complex macros, and a comprehensive access to the hardware. Just as Tango, Sardana is Open Source and its development model is open to collaboration, which provides a free platform that scales well to small laboratories as well as to large scientific institutions. The first beta version has been commissioned for the control system of Accelerators and Beamlines at the Alba Synchrotron [2]. Furthermore, there is a collaboration in place, comprising Desy [3], MaxIV [4] and Solaris [5], and several other potential users are evaluating it.

THE DESIGN CHOICES IN THE SOFTWARE OF THE CONTROL SYSTEM

Alba is a third generation synchrotron located near Barcelona in Spain. The Installation of the Control System for the Accelerators finished at the end of 2010. The final functional tests took place during the first weeks of 2011. Currently we are carrying out the final stages of the installation and commissioning of the seven Beamlines included in the first phase.

The infrastructure implicated in controls includes more than 350 racks, 6300 equipments and 17000 cables. The controls architecture is highly distributed, comprising about 2500 network devices.

Tango as the Control System Middleware

Tango was chosen among the three options considered: EPICS [6], commercial SCADA (Supervisory, Control And Data Acquisition) and Tango. At that time, the commercial SCADAs were not adapted to the requirements, and although they presented some interesting features off the shelf (like the archiving, trending, etc), many applications needed to be developed anyway, and a non negligible effort needed to be dedicated to integrate motion, synchronization, sequencers, etc. In other words, they were not a solution per se, but to be combined with EPICS, Tango or other toolkits.

Sardana: the Scientific SCADA Suit

The other way around, both Tango and EPICS have various choices as graphical toolkits. However, they both lack in some way an integrated development and runtime environment as commercial SCADAs offer. But on the other hand, commercial SCADAs did not fulfil the requirements either. In several installations, like synchrotrons, we find a large control system for the particle accelerators with different subsystems such as vacuum, radio frequency, power supplies, diagnostics and protection systems, and many "smaller" control systems, one per experimental station. They usually have significantly different requirements.

We needed a flexible graphical interface, allowing multiple clients, with many specific capabilities such as diffractometers control, and above all, a powerful sequencer. Many of these characteristics are implemented in SPEC [7]. However, SPEC has some limitations in the Graphical interfaces and in the capability for managing multi-clients. Therefore at that point we decided to start a development of a SCADA for scientific institutions: *Sardana* [8]. In order to facilitate its adoption, Sardana is built on widely available Open Source technologies and it is itself distributed under the Lesser General Public License [9]. Nowadays it has already been exported outside Alba, and other institutes like Desy or MaxLab are participating in the effort.

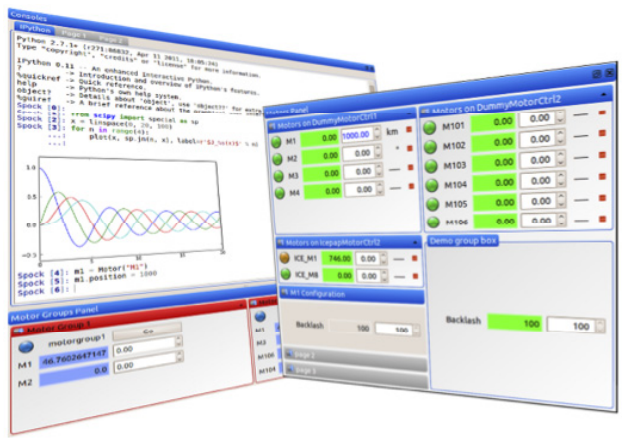

Figure 1: Few views and widgets of the Sardana´s Human-Machine interfaces.

Sardana provides optimized access to hardware, macro execution, software synchronization, generic graphical interfaces, and access to save/restore facilities (Fig. 1). It is mostly developed in Python. It has a Core in charge of managing the hardware: the "*Device Pool*". It has also a powerful sequencer which handles macros, scans, series, loops, etc: the "*Macroserver*" (Fig. 5). This is imperative in any experimental station in a synchrotron, and extremely useful in all cases.

HUMAN MACHINE INTERFACES

The Graphical User Interfaces (GUIs) are developed in a framework called Taurus [10]. It is written in python and built on top of PyTango [11] and PyQt4 [12]. The Command Line Interface (CLI) is based on IPython and makes extensive use of Taurus as well. It is known as "*spock"*(Fig.4), and it was highly inspired on SPEC. The appearance, standard macro names, and the syntax of SPEC command line have been adopted. This is an important point, because many Synchrotron users are familiar with SPEC, considered already a *de facto* standard.

Developers can create Taurus applications from the standard Qt designer benefiting from a catalogue of Taurus widgets which makes the task easier (Figs. 2 and 3).

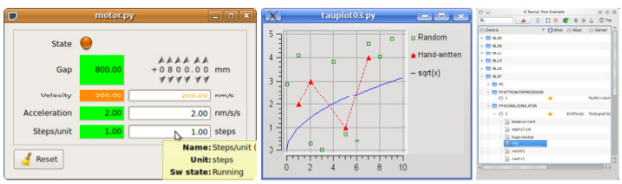

Figure 2: Taurus provides a complete catalogue of widgets.

But the aim is skipping the programming part if it is not needed. Sardana can be setup by "only configuring" the different components. Taurus provides an utility called TaurusGUI which produces standard GUIs from simple configuration files. This utility is typically used to generate standard interfaces for Beamlines. By just configuring a few parameters, a GUI is created for a given Beamline, including widgets for managing and launching macros and sequences, a synoptic view of the system,

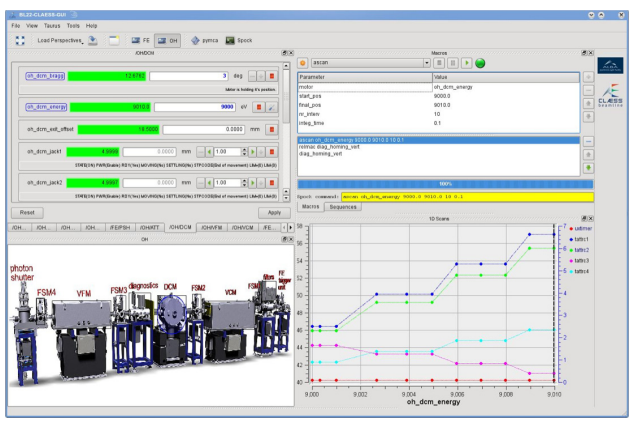

Figure 3: Taurus a highly configurable and customizable standard GUI for Sardana.

panels for controlling the instruments of the Beamline, graphical elements for monitoring values, etc. All these elements are presented in a highly customizable interface which allows the user to create different "perspectives" for different tasks. The elements of the GUI can be re-arranged by drag&drop, and new elements can be added just as easily without leaving the running GUI.

SEQUENCER, MACROS, MOTORS AND SCANS

Sardana provides a standard catalogue of reusable procedures (macros) and sequences for performing specific tasks such as scanning, acquiring data, controlling motors, etc. Besides, it offers the templates and tools for creating and maintaining a user repository of macros.

Although the names of the macros and the syntax might look compatible with SPEC, unfortunately, the differences in the technologies, parsing, grammars and hardware interfaces, made impossible to keep the compatibility with the existing SPEC macros. Hence, SPEC and Sardana are not compatible and macros can not be interchanged between them.

Macros are executed in a central process, called Macroserver. Typically there is a Macroserver in a Sardana installation, although there can be more than one if the application requires it.

Macros are python classes. They are executed and sequenced in the Macroserver, and can also be edited and debugged under its supervision.

Both Taurus based GUIs and CLIs (like spock) connect to the Macroserver through a TANGO object called the "Door". It is through this access point that macro execution can be controlled from outside the Macroserver. A Macroserver can have multiple doors but each door can only run a single macro at a time.

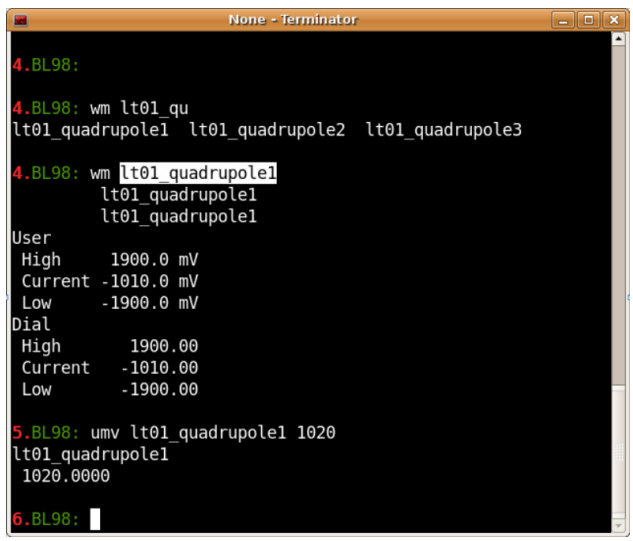

Figure 4: spock: The Command Line Interface of Sardana

When connected to a Macroserver, spock is fed with meta-information about the known macros and elements that are part of Sardana. This way, it can provide features like context sensitive word completion, command history, macro error handling and debugging. Graphical interfaces also receive this information enabling powerful widgets to be constructed .

Macros can be executed from the spock command line, which provides tab completion, history, etc. or from a graphical interface, having, favourites, recently used, etc.

Sequences are batches of macros. They can be easily created from the graphical user interface and also managed as favourites. One does not need to have notions of programming to create a sequence.

THE CORE

The core of Sardana is the so called "Device Pool". It is not only responsible to abstract specific hardware access but also to make sure this access is done as efficiently and as synchronized as possible. Hardware abstraction is possible by providing a set of interfaces to the outside world: Motors (discrete, continuous or pseudo), experimental channels (scalar, 1D and 2D or pseudo) and communication channels. Communication with specific hardware is achieved through the implementation of plug-ins known as "controllers". They can be written in Python or C++. A controller type exist for each interface supported by the Device Pool. When writing a controller, one must obey a specific interface in order for the controller to be considered valid. Controllers can be as simple as a mapping to another tango device server or as complex as a 4C diffractometer.

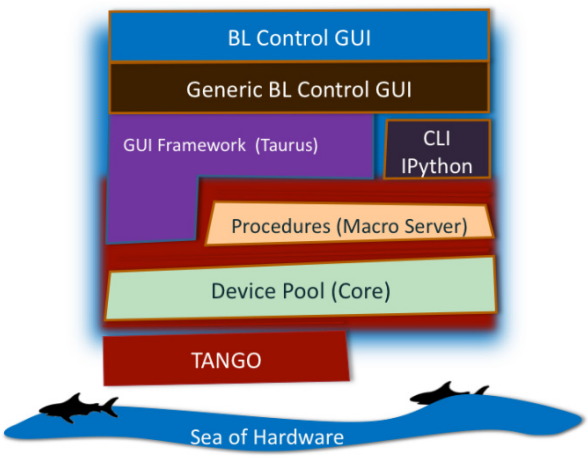

Figure 5: Conceptual design of Sardana.

NEXT STEPS AND STRATEGIC PLAN

In terms of strategy, we could publish the following mission statement: "*Produce a modular, high performance, robust, and generic user environment for control applications in large and small installations",* and the vision: *"Make Sardana the generic user environment distributed in the TANGO project and the standard basis of collaborations in control".*

Although Sardana has been used for the commissioning at Alba, and is installed and running in all Beamlines, is still in an early stage. There is a new release foreseen by the end of 2011, which will improve the experiment configuration, plotting, access to data files and overheads. Looking ahead to the version of 2012, our efforts will be focused among others in the configuration tool, full integration of 2D detectors, and continuous scans frameworks.

CONCLUSION

SCADAs are extensively used in industrial applications. They are optimized for access to Programmable Logic Controllers (PLCs), and popular field buses like Siemens Profibus, etc. Today there is no such a thing for scientific applications for which requirements are drastically different. Labview from National Instruments is a closer example, but it still lacks many important features, like complex "procedures". For example, Beamlines have devices such as diffractometers, combined with detectors, which needed to be scanned with monochromators, which are not well managed by Labview. SPEC manages all these cases, but it has poor Graphical Interfaces, and it does not allow concurrency and arbitration. There is place for improvement in this domain, and Sardana has included all these features in the requirements. There are still a considerable number of features pending and a great effort is still needed in this field. But Sardana is following the correct way, and several other labs (mostly synchrotron) have already expressed their interest.

CONTRIBUTIONS

Many people have worked in this project. In particular J. Ribas, who had a great contribution to the original "pytauico" and "pytauiwi", which was the seed for the current Taurus package. T. Nuñez and T. Kracht at Desy, D. Spruce and K. Larssen at MaxLab for the early tests and contributions to the Sardana device pool and Macroserver.

MODEL ORIENTED APPLICATION GENERATION FOR INDUSTRIAL CONTROL SYSTEMS

B. Copy, R. Barillere, E. Blanco, B. Fernandez Adiego, R. Nogueira Fernandes, I. Prieto Barreiro
CERN, Geneva, Switzerland

Abstract

The CERN Unified Industrial Control Systems framework (UNICOS) is a software generation methodology and a collection of development tools that standardizes the design of industrial control applications [1]. A Software Factory, named the UNICOS Application Builder (UAB) [2], was introduced to ease extensibility and maintenance of the framework, introducing a stable meta-model, a set of platform-independent models and platform-specific configurations against which code generation plugins and configuration generation plugins can be written. Such plugins currently target PLC programming environments (Schneider and SIEMENS PLCs) as well as SIEMENS WinCC Open Architecture SCADA (previously known as ETM PVSS) but are being expanded to cover more and more aspects of process control systems. We present what constitutes the UNICOS meta-model and the models in use, how these models can be used to capture knowledge about industrial control systems and how this knowledge can be leveraged to generate both code and configuration for a variety of target usages.

INTRODUCTION

Models are an abstraction of real-world phenomena that represent them for the purpose of problem solving. Model usage is gaining wide acceptance in the domain of industrial control software engineering as it allows to produce implementations that are closer to human understanding of a system than low-level coding.

A meta-model is the "model of a model", describing the properties of the model in a way that makes it applicable to wider range of related problem domains. For instance, a programming language grammar can be considered a meta-model of the programming language it describes. Such a grammar can be used to automatically determine whether programming statements are indeed valid and can therefore result into functional problem resolutions.

Another example of meta-models can be an XML Schema Description (XSD) – which is a meta-model for XML documents, themselves acting as models for the data they contain [3].

THE UNICOS META-MODEL

The UNICOS framework [1], designed to deal with heterogeneous COTS equipment, provides equipment abstractions of one of the following categories :

- I/O Devices – interfaces, which act as data transfer objects.
- Field Devices (pumps, valves etc..) – which act as domain objects.
- Process Control Object (PCO) Devices – which act as controllers, coordinating I/O and field devices.

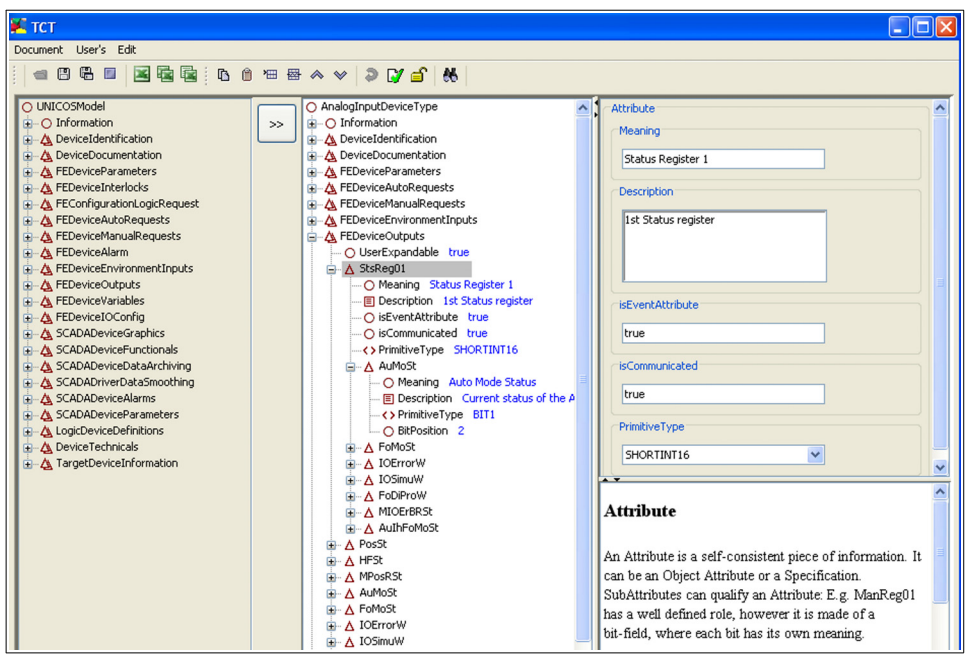

Figure 1 : Screenshot of the FESA General Editor for UNICOS device type creation.

Devices (in effect, object instances) that compose a UNICOS control system all therefore correspond to a Device Type (equivalent to an object class).

The UNICOS meta-model describes the properties and constraints that could be used to specify device types, thereby allowing to provide assistance and formal validation during the specification and implementation of device types.

An XSD Based Meta-Model

The UNICOS meta-model, being expressed in standard XSD, leverages off-the-shelf validation and binding technologies. Being a meta-model for XML documents, it also guarantees that UNICOS device types and device instances (both expressed as XML data) be exploited by any XML aware technology.

In particular, the reliance on XSD to express its meta-model allows UAB to reuse the FESA General Editor [4], a lightweight and general purpose graphical XML editor that provides input completion and validation using an XSD document. The FESA General Editor is used in particular to produce device types that comply with the UNICOS meta-model.

Figure 1 presents a screen capture of the FESA General Editor (also referred to as the "UAB Type Creation Tool" in the UAB context). The UNICOS meta-model is featured on the left hand-side column, where type creators can pick and mix Attributes belonging to different Attribute Families in order to compose their type. The middle column is a user-friendly XML document editor that allows to prepare a UNICOS device type. The right hand-side column provides a meta-data-based property sheet, complete with data validation, inline documentation hints and data entry assistance (such as support for drop-down lists of supported values).

Characteristics of the UNICOS Meta-Model

The UNICOS meta-model supports the definition of Device Types, *i.e.* a generalization of devices such as the ones found at CERN in industrial continuous processes.

Device types exhibit Attributes, which are the definition of device type properties. *For example*, attributes typically have properties such as :

- **Description**: used to document an attribute. , its purpose.
- **PrimitiveType** : specifies the property's data type (FLOAT, TIME, STRING, etc.).
- **isCommunicated**: defines whether the property is remotely accessible (from the SCADA layer for instance).
- **isSpecificationAttribute**: this property is used when the attribute value can be modified by the end-user.

To take an analogy with traditional object-oriented programming, Device Types can be thought of as an Object Class, while Attributes are the class' field members.

For better readability, Attributes of a Device Type are grouped in attribute families, such as *for example* :

- **FEDeviceOutputs**, which identifies a front-end device's outgoing signals.
- **SCADADeviceDataArchiving**, which specifies that SCADA-relevant configuration parameters to log data held in device properties to persistent storage.
- **TargetDeviceInformation**, which holds target platform-specific information (*e.g.* information that varies whether we are targetting a SIEMENS or a Schneider PLC device).

Once a Device Type is defined through the UNICOS meta-model (with the usage of the FESA General Editor [4]), and its peer SCADA and device level implementations are made available, the device type is ready to be handed over to UAB application experts, who will establish lists of devices present in their applications.

If we take back our OO programming analogy, application experts simply provide object instances composing their application, and benefit immediately from all the validation and tooling that the UNICOS meta-model grants them usage of.

MODELLING USAGES IN UAB

First and foremost, the UAB model's most prominent application is the UNICOS-CPC framework [5]. UNICOS-CPC provides a library of device types and associated code generation templates suitable for the implementation of continuous control processes, relying on PLC automata and the SIEMENS WinCC Open Architecture SCADA software package.

Building upon the UNICOS meta-model, a significant number of tools have been added to the UAB tool suite, in order to improve the quality of generated applications or better integrate UAB generated applications with the rest of the CERN infrastructure. These tools take full advantage of the standards compliance of the UNICOS meta-model but provide a stark example of how models can be applied to a variety of contexts and be leveraged with diverse levels of software expertise.

Automated Device Type Documentation

UNICOS Device Types, especially those defined in the UNICOS-CPC device types library typically exhibit a large number of properties that grant the UNICOS framework its support for fine-grained operation (any single property of a device instance can for instance be overridden, insuring that process experts can take over in order to deal correctly with unexpected or abnormal situations without experiencing hindrance).

It is therefore paramount to be able to automatically document device types in a human readable format, in order to assist control system developers in preparing device instances. Since the UAB model relies on XML, it can be transformed by means of XML Stylesheets (XSL), an XML dialect specialized in performing structured

template based transformations. Usage of XSL against UAB XML device type definitions makes generating web-based documentation a natural fit.

Figure 2 below presents an example of a manual Digital Input description diagram, mixed with auto-generated documentation of the device environment inputs

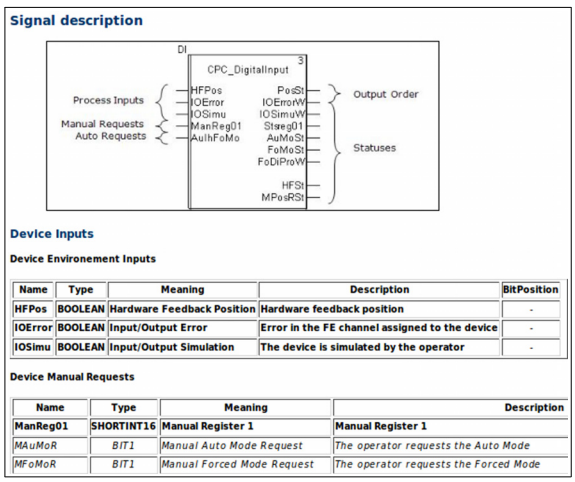

Figure 2 : Screenshot of UNICOS-CPC manual.

Integrating the UNICOS-CPC device type definitions with a content management system such as Atlassian Confluence and its support for inline XSL transformations provides a very simple way to assemble documentation mixing formal technical definitions (such as a list of device pins and their usage) with informal textual descriptions or comments. Other target documentation formats could be DocBook or OASIS DITA, both XML dialects suitable for authoring (and therefore potential targets for XSL transformations), providing results suitable for professional publishing.

Semantic Verification for System Specifications

While the choice of XML schema as a meta-model provides UAB with a large choice of supporting technologies, XSD (intentionally and inherently) lacks the flexibility and richness of other meta-models, such as the OMG Meta Object Facility (MOF) [6]. As a result, certain constraints cannot be easily expressed in XML-friendly form.

Furthermore, UNICOS device types are meant to be preparable by individuals unfamiliar with programming languages or constraint languages such as OCL [6], but still require the possibility to check in details that control system device instance lists comply with formal rules.

To avoid introducing too much complexity in the UNICOS meta-model, the Jython scripting language was chosen to perform these kind of validations, increasing the flexibility of the semantic rules mechanism and allowing the creation of platform specific rules. Most of these rules are applied over the specifications file (this file contains all the devices of a UNICOS application and its parameters).

Examples of existing rules are :

- Check the maximum length of a device's platform dependent name alias.
- Check the relevance of all inter-device relationships referenced in the specifications file.
- Verify that platform dependent input data does not contain illegal characters.

Such rules cannot be easily specified in XML schema.

Extended Configuration Generation

Another example of the application of the UNICOS meta-model lies with the support for extended configurations. UAB generated applications typically need to be integrated with the rest of CERN's infrastructure, such as :

- the LHC Alarm Service (LASER), to inform CCC operators of abnormal conditions across the entire accelerator and technical infrastructure
- other LHC devices communicating through protocols such as CMW (CERN Common Middleware) or DIP (CERN distributed information protocol)

Such integration relies on simple, well-known integration bridges that do not need any advanced code generation, but rather well-known and structure configuration parameters. Using code generation templates for such use cases would therefore introduce unwanted complexity and unnecessarily increase the UAB codebase.

For the purpose of the generation of such configurations, UAB employs a Python-based transformation tool called FlexExtractor [8].

FlexExtractor employs a pluggable strategy to obtain input data (for instance, from XML or a binary Excel file) and produce output data (for instance CSV, or binary Excel file), providing a language independent transformation processor in the middle.

Such a tool is ideal for non-programmers, who benefit from complex transformations without the burden of a programming environment and limitations of XSLT, and allows a decoupling that considerably eases maintenance of configuration generators.

EVOLUTION PERSPECTIVES

While we have seen that an XML Schema-based meta-model and XML data formats open the door to a variety of supporting technologies and target environments, its lack of expressiveness and flexibility also imposes unwanted limitations. Such limitations are the main reason for the creation of tools such as the Semantic Verifier mentioned ealier in this document, delivering the type of validation that XML based ones cannot support at all.

Another important point is that disconnected XML files typically lead to fragmentation of the knowledge and encourage the usage of these XML files in isolated processes.

Since the advent of the UAB project, new technologies have emerged, delivering the same affinities with XML while offering better data management capabilities and superior tooling.

Content Repositories

Content Repositories (also referred to as Java Content Repositories) are an emerging type of object-oriented databases that provide services such as :

- meta-data support – which, as we have seen, is the keystone of any generation or validation process.
- Navigation and query – either based on relational syntax (*i.e.* SQL), XML oriented (*i.e.* Xpath), Object oriented or even free text indexing (*e.g.* fuzzy search engines).
- Serialization support – allowing to import or export tree fragments so that they can be exploited or transformed offline – for instance to an XML representation, or to an in-memory object graph.
- Transaction and versioning support.
- Eventing support – allowing a decoupling between data providers and data consumers.

Some of these services, such as meta-data support, navigation and serialization are already present in the UAB architecture – others such as query, transaction and eventing support are essential in order to let the UNICOS meta-model scale up (for instance, to deal with redundant or hierarchical SCADA architectures, or to handle inter-PLC communication).

Xtext and the Meta Object Facility (MOF)

MOF [6] is a standard for model-driven engineering introduced by the Object Management Group (OMG). It was primarily used to act as a much-needed meta-model for the Unified Modeling Language (UML). MOF can be compared in some respect to XML Schema, but offers much higher flexibility, in its status of a closed meta-model, in effect, a model that can represent itself.

The Eclipse Foundation provides a generation tooling called “Xtext” which accepts models, defined using a closed-meta-model subset of MOF called ECore, but also more traditional inputs such as grammar normal forms or XML schema definitions, and can produce automatically tooling supporting :

- First off, the essential facilities enumerated earlier - meta-data support, navigation, queries, serialization, events.
- Advanced model data entry assistance such as autocompletion, on-the-fly validation and property sheets support, thereby replacing and enhancing the FESA General Editor (written manually) with auto-generated editors.
- Meta-programming APIs that can be used to manipulate data and call methods against the model programmatically at the meta-model level.

CONCLUSION

The UAB technology stack has already demonstrated the importance of a meta-model foundation in its support of the development of code generation tools.

Our experience with tooling development also showed that, even with a meta-model, flexibility and scalability are essential to ensure that the models can evolve and avoid knowledge fragmentation (for instance, rules defined by the Semantic Rule Verifier UAB tool have no place in the UNICOS meta-model today, and the effort of adding them there today would outweigh the benefits).

A PLATFORM INDEPENDENT FRAMEWORK FOR STATECHARTS CODE GENERATION

L. Andolfato, G. Chiozzi, ESO, Munich, Germany
N. Migliorini, ENDIF, Ferrara, Italy
C. Morales, UTFSM, Valparaiso, Chile.

Abstract

Control systems for telescopes and their instruments are reactive systems very well suited to be modelled using Statecharts formalism. The World Wide Web Consortium is working on a new standard called SCXML that specifies XML notation to describe Statecharts and provides a well defined operational semantic for run-time interpretation of the SCXML models. This paper presents a generic application framework for reactive non real-time systems based on interpreted Statecharts. The framework consists of a model to text transformation tool and an SCXML interpreter. The tool generates from UML state machine models the SCXML representation of the state machines as well as the application skeletons for the supported software platforms. An abstraction layer propagates the events from the middleware to the SCXML interpreter facilitating the support for different software platforms. This project benefits from the positive experience gained in several years of development of coordination and monitoring applications for the telescope control software domain using Model Driven Development technologies.

INTRODUCTION

Statecharts [1] have been successfully applied at the European Southern Observatory (ESO) for modelling reactive systems [2] such as telescopes and their instruments. Currently all ESO software platforms (the Very Large Telescope (VLT) [10], the Alma Common Software (ACS) [11], and the Standard Platform for Adaptive optics Real Time Applications (SPARTA) [12]), provide different application frameworks based on Statecharts to build monitoring and control applications. For the VLT platform a code generation framework integrated with Rational ROSE and MagicDraw has been developed and successfully employed to create more than 30 C++ control applications for different VLT/VLTI projects [6]. The SPARTA platform offers a C++ library to build Statecharts based applications. The ACS platform provides a tool to transform Statecharts into Java applications using Xpand template language [8].

Table 1: ESO Platforms (for non real-time applications)

Platform	OS	Languages	Middleware
VLT	Linux	C++, TCL/TK	CCS
ACS	Linux	C++, Java, Python	CORBA
SPARTA	Linux	C++	CORBA, DDS

These tools, although implementing the same formalism, support different sets of Statecharts features and, even for the commonly supported features, their operational semantics is often different due to lack of standard semantics for Statecharts [4]. In addition the UML models are not exchangeable between different generators because they are built using different UML profiles. Finally, for all three tools the generated/created source code depends directly on the state machine model and any change in the state machine logic requires a recompilation of the code.

In order to solve the above mentioned problems, reduce maintenance costs, and promote model reusability on different platforms (Table 1), the Generic State Machine Engine (GSME) project started at ESO with the objective of building a platform independent code generation tool from Statecharts called COMODO.

REQUIREMENTS

The requirements for COMODO were derived from the existing tools and can be summarized in:

- Support for the main Statecharts features
- Support for Statecharts inheritance
- Support for graphical and textual representation of Statecharts
- Support for multiple software platforms
- Support for Statecharts interpretation

Looking at the existing telescope control applications based on state machines, the most used Statecharts features are: composite and orthogonal states, shallow and deep history state, guards, entry/exit/on-transition actions, do-activities, and initial/final pseudo-states.

In addition to these standard features a requirement on model inheritance has been introduced to have the possibility of creating models that extend existing Statecharts (for example by adding states and/or transitions). Note that only “extension inheritance” is required, while “refinement inheritance” is not considered [3].

Statecharts is a graphical formalism and since it is part of the UML standard, any UML tool provides the possibility to create, edit, and visualize Statecharts models graphically. However, textual representation is useful for model comparison as well as for scenarios where UML modelling tools are not available. Therefore both graphical and textual Statecharts notations are mandatory for this project.

At last, the ability to change at run-time the behaviour of control applications becomes an important feature for:

- Reducing the model complexity by splitting a large model into several smaller ones. Consider for example the case where a control software application has to support different type of HW components that can be modified at run-time. One possible implementation is to include all HW configurations in one large Statecharts model. A second solution is to have one model per HW configuration and load the correct model at run-time. The latter is usually a better choice in terms of maintainability since smaller Statecharts models are easier to understand.
- Reducing the time needed to apply changes to the state machine logic. For example, during testing/deployment of an instrument, a large amount of time is dedicated to tuning the calibration procedures (i.e. to define in which order to move the hardware and acquire the data). Changing the behaviour of the calibration procedure without the need of recompiling speeds up considerably the testing/deployment phases.

Of course, interpreted Statecharts do not provide the same performances of compiled Statecharts and often require more memory. However, our target applications are monitoring and control applications running on workstations that do not require real-time reaction time.

STATECHART XML

COMODO is based on a StateChart XML (SCXML) engine and a model to text (M2T) transformation tool. Depending on the given software platform configuration, it transforms UML State Machine models into SCXML models and platform specific artefacts such as the application code needed to integrate the SCXML engine and the manually developed code (Figure 1).

SCXML [5] is a standard introduced by the World Wide Web Consortium (W3C) to describe Statecharts. The syntax is based on XML textual notation, and the operational semantics is well defined via pseudo-code. Furthermore, the SCXML language has been designed to be interpreted so that the dynamic behaviour of an SCXML application can be modified at run-time.

SCXML supports all standard Statecharts features required by the project. Moreover, it offers a possible implementation of the Statecharts inheritance via the XML inclusion mechanism.

The support for different ESO platforms is achieved by providing C++ and Java SCXML engine libraries that can be compiled on each of these platforms.

COMODO PROFILE FOR UML

A COMODO application is modelled with a subset of UML which consists of the state machine to specify its behaviour and some elements to describe the interface and its deployment. Applying domain specific stereotypes to the model elements, allows to customize and re-use the model for the different supported software platforms. Stereotypes were collected using the UML profile mechanism in the COMODO profile [13].

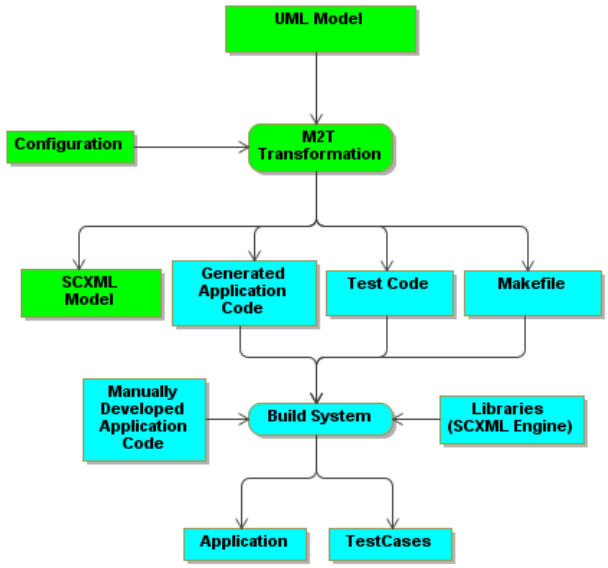

Figure 1: COMODO data flow: in green platform independent activities and artefacts, in blue the platform dependent ones.

MODEL TO TEXT TRANSFORMATIONS

The process to transform a UML model into the target application for a given platform consists of two parts:

- Transformation from UML model to SCXML
- Transformation from UML model to platform specific artefacts

The transformations are based on the mapping between the source model element and the generated artefact.

UML to SCXML Mapping

In order to transform UML Statecharts to SCXML, a mapping between UML model elements and SCXML syntax notation has been defined (Table 2).

The SCXML model is platform independent and even the implementation of entry/exit/on-transition actions and do-activities can be embedded in the model using SCXML scripting action language (or another scripting language supported by the target platform). However our target applications are normally developed in C++ or Java and therefore the interpretation has been limited to the state machine logic while actions and activities are compiled. This approach allows changing the state machine logic at run-time while leaving the advantages of compiled languages for the implementation of actions and activities.

Table 2: UML to SCXML Mapping

UML	SCXML
State Machine	<scxml>
State	<state>
Composite state	<state> (the initial sub-state must be defined)
Region	<parallel> (the initial sub-state must be defined)
Initial pseudo-state	<initial> or initial attribute of <state>
Final pseudo-state	<final>
Entry / Exit action	<onentry> / <onexit>
Transition (trigger [guardExpression] / action)	<transition event="trigger" guard="guardExpression">
Internal transition	<transition> with no target specified
Deep History	<history type="deep">
Shallow History	<history type="shallow">
Activities	<invoke>
Actions	Custom actions
Event (signal)	String
Timer Event	Send command with timeout

UML to Platform Specific Artefacts Mapping

The platform specific artefacts generated from the UML model are:

- Action and Activities stubs (generated only once the very first time)
- The code to handle the platform specific events and propagate them to the SCXML engine
- All artefacts to build the generated application
- Some basic test code used by the automatic test infrastructure provided by the software platforms

Each action and activity defined in the Statecharts model is mapped to a C++/Java class. Activities are started in separate threads while actions are executed via method invocation. It is foreseen to have also an action-to-method mapping (i.e. mapping of a group of actions to methods of a class) to avoid proliferation of classes, facilitate data sharing among actions, and reduce compilation time.

SCXML defines events as simple strings therefore a translation of platform specific events to the SCXML events has to be specified. For example a CORBA call has to be mapped to the corresponding SCXML event string and injected in the SCXML engine. Table 3 shows different types of events supported by the software platforms and their representation in UML.

Table 3: Events Mapping

UML	VLT	ACS	SPARTA
Signal	Command/Reply callback	CORBA method	CORBA method
Time event	VLT Timer callback	ACS Timer	Timer
Signal <<attribute>>	Database change notification callback	CORBA attribute change	CORBA attribute change
Signal <<fileio>>	UNIX file I/O event.	UNIX file I/O event.	UNIX file I/O event.
Signal <<internal>>	Internal event	Internal event	Internal event

IMPLEMENTATION

The UML to SCXML and UML to platform specific artefacts mappings are implemented using EMF [7] and Xpand tool set [8] which include a workflow executor (MWE), the Check constraint language, the Xpand template language, and the Xtend language. The code generator structure is shown in Figure 2.

The MWE workflow is used to drive different steps of the model to text transformations. Four workflows have been created: one per platform and one for the SCXML transformation. The steps of the workflow are:

- Load the UML Profile
- Load the model
- Validate the model by applying Check rules
- Run Xpand templates to generate artefacts

The step validating the model is important since normally UML tools do not impose any rule in the specification of Statecharts while SCXML, being an operational specification, requires well formed models. For this reason a set of Check rules have been written to verify that the model complies with SCXML specifications (for example that the initial state in composite states is always specified or that a transition from the history state is provided).

After the model has been validated, Xpand templates are executed to generate the artefacts defined in the mapping. A set of functions have been developed in Xtend language to help navigating the model to retrieve the model elements properties.

Note that veto strategy or round-trip code generation is not supported by the tool. Customization of the generated code is done via subclassing. Implementation of actions and activities is therefore performed by inheritance from abstract classes generated by the tool.

GENERATED APPLICATION

The applications generated by COMODO use an SCXML engine to process incoming events and trigger transitions.

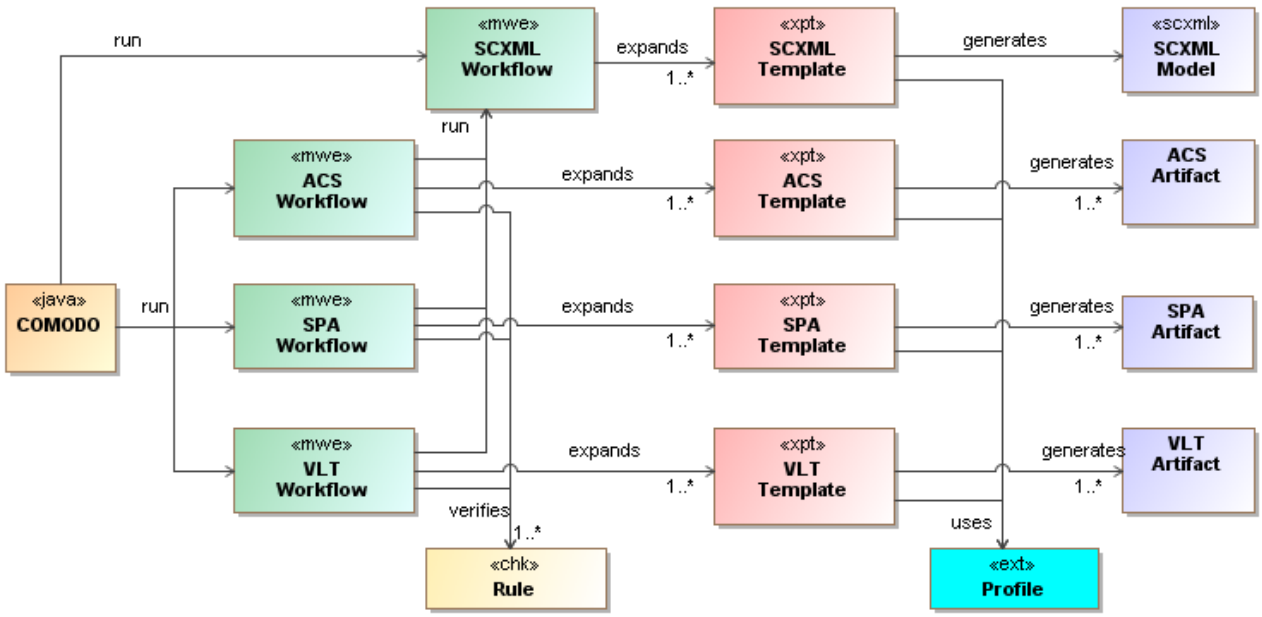

Figure 2: Code generator structure.

Apache Commons SCXML engine [9] has been selected to be the SCXML engine for Java applications. A C++ simplified prototype of the Apache Commons SCXML engine is being developed in house for the C++ applications.

Events are propagated to the SCXML engine via platform specific adapter classes generated by the tool. Actions and activities are executed by the SCXML engine using invoker classes, also provided by the tool. Access to platform services such as logging is provided to actions and activities via injection at creation time.

CONCLUSIONS

In this paper a cross-platform code generator tool from Statecharts was presented. The tool relies on the SCXML notation which provides a standard syntax and semantic specification to describe and execute Statecharts. Since SCXML models are interpreted, generated applications can change behaviour by modifying the state machine logic at run-time without the need for recompilation, reducing therefore the development time.

A UML to SCXML mapping is proposed to benefit from the graphical nature of Statecharts models.

The project is still at prototype level but it provides a complete UML to SCXML transformation and the generation of Java applications for the ACS platform. The next important step is to develop a C++ SCXML engine that is needed to support the other two software platforms.

LHCb ONLINE INFRASTRUCTURE MONITORING TOOLS

L. Granado Cardoso, C. Gaspar, C. Haen, N. Neufeld, F. Varela, CERN, Geneva, Switzerland
D. Galli, Università di Bologna-INFN, Bologna, Italy

Abstract

The Online System of the LHCb experiment at CERN is composed of a very large number of PCs: around 1500 in a CPU farm for performing the High Level Trigger; around 170 for the control system, running the SCADA system - PVSS; and several others for performing data monitoring, reconstruction, storage, and infrastructure tasks, like databases, etc. Some PCs run Linux, some run Windows but all of them need to be remotely controlled and monitored to make sure they are correctly running and to be able, for example, to reboot them whenever necessary. A set of tools was developed in order to centrally monitor the status of all PCs and PVSS Projects needed to run the experiment: a Farm Monitoring and Control (FMC) tool, which provides the lower level access to the PCs, and a System Overview Tool (developed within the Joint Controls Project – JCOP), which provides a centralized interface to the FMC tool and adds PVSS project monitoring and control. The implementation of these tools has provided a reliable and efficient way to manage the system, both during normal operations as well as during shutdowns, upgrades or maintenance operations. This paper will present the particular implementation of this tool in the LHCb experiment and the benefits of its usage in a large scale heterogeneous system.

INTRODUCTION

Due to the large nature of the LHCb experiment, a high number of PCs is needed to reliably and efficiently operate it. At this scale it is fairly unreliable to monitor and maintain the needed operation parameters without the help of a centralized tool that provides a global overview of the current computer infrastructure status. Furthermore, the heterogeneous nature of the underlying computer infrastructure is an added difficulty for monitoring and control of the experiment computer infrastructure.

The System Overview set of tools, is, therefore, based on a layered approach for monitoring different sets of parameters of the PC infrastructure:

- Hardware Layer – The hardware infrastructure (PCs) where the applications run
- Operating System Layer – The software infrastructure/environment where the applications run
- PVSS Infrastructure Layer – The supervisory control software running the experiment infrastructure/environment
- Application Layer – Specific software needed for system control and operation (PVSS Managers, OPC Servers, etc.)

SYSTEM OVERVIEW SET OF TOOLS

To monitor the parameters for the different monitoring layers, a set of tools were developed, which are able, for each of the existing environments, to gather the relevant parameters:

- Monitoring and Control Servers (FMC Tools)
  - FMC Linux tools [1] – to gather and publish Linux computers data and control processes and IPMI status;
  - FMC Windows Server – to gather and publish Windows computers data;
- GUI (Graphical User Interface) and "aggregation" Tools – to provide a centralized interface for monitoring and control;

Monitoring and Control Servers

The Monitoring and Control Servers gather data from the monitored nodes and publish the monitored parameters via DIM (Distributed Information Management) [2]. These servers are implemented differently for each of the operating system in use in LHCb and can be divided according to the layer they monitor:

Hardware Layer

OS independent:

- ipmiSrv – IPMI Server, which runs in only one LHCb node; This server polls the IPMI status of the PCs in the LHCb network, via ipmitool and publishes this in a DIM Service, which are available for subscription from other tools. The information obtained for each PC is the power status of the PC, and information pertaining the PC sensors which are available via IPMI (temperatures, fan info, currents and voltages)
- vmSrv – which runs on one LHCb node which can act on the hypervisor for the LHCb Virtualization Infrastructure; This server publishes power information for the VMs (Virtual Machines) on the LHCb system and is also able to control the power status via the hypervisor.

OS dependent:
For Linux:

- memSrv – Memory Server, runs on each of the nodes; gathers current memory usage information on the PCs
- cpuinfoSrv – CPU Info Server, runs on each of the nodes; gathers cpu information for the PC (number of cores, speed and type of CPU)

- cpustatSrv – CPU Statistics Server, runs on each of the monitored nodes; gathers CPU usage statistics for the PC
- fsSrv – File System Monitor Server, runs on each of the monitored nodes; gathers info the mounted filesystems and its usage
- nifSrv – Network Interface Monitor Service; monitors network traffic, uptime and statistics for each of the PC Network Interface Cards

For Windows:

- FMC Windows Server - Memory Usage, CPU information, CPU Statistics, File System information, Network Interfaces

Operating System Layer

For Linux:

- osSrv – Operating System Server, runs on each of the nodes; This server gathers operating system and kernel information

For Windows:

- FMC Windows Server - monitors Operating System information, Memory Usage, CPU information, CPU Statistics, File System information, Network Interface information and Processes and Services information.

PVSS Infrastructure Layer

- PVSS pmon process - A process monitor agent linked to each PVSS Project that runs independently from it. This agent monitors and publishes the state of PVSS processes. It can also act on these processes (start/stop/reset)

Application Layer

For Linux:

- tmSrv – Task Manager Server, which runs on each of the nodes; gathers the data for the running processes on each node and is also able to start processes on these nodes.
- psSrv – Process Monitor Server, runs on each of the monitored nodes; gathers info on the running processes on each PC
- pcSrv – Process Controller Server; this server keeps a dynamically manageable list of applications up and running on the farm nodes, stopping and/or restarting them as defined
- logSrv – Log Server, which runs on each of the nodes; collects the logs from the several FMC Linux tools running on the PCs

For Windows:

- FMC Windows Server – monitors processes and services information.

All these servers publish their data via DIM services which are then available for subscriptions from other tools. The services published follow a naming convention, independent of the system where the servers are running.

Note that while the Linux Servers have to run on each of the nodes being monitored, the Windows FMC Server runs on only one machine which has network access to all the windows machines which need to be monitored and the list of machines to be monitored must be defined on start time.

GUI and "Aggregation" Tools

FwFMC

The JCOP Framework [3] FMC component is a PVSS component which subscribes to the DIM services and commands published by the FMC servers and provides a GUI for easy interaction, monitoring as well as an archiving infrastructure for this data.

This tool can be configured from a database which holds the nodes and PVSS projects information as well as from a configuration file. It can also be configured manually adding the nodes and PVSS projects to be monitored.

FwSystemOverview Tool

The FwSystemOverview Tool reutilizes the data subscribed from the FwFMC tool and presents the status of the monitored computers in synoptic panels, with easy control and monitoring possibilities. It is also possible with this tool to monitor single processes and assign alarms for the unexpected dying of these processes. Alarms can also be configured for usage levels of CPU and memory.

The FwSystemOverview tool also has support for monitoring and controlling of PVSS Projects and is able to monitor individual managers via calls to the respective PVSS project Process monitor manager. This allows for PVSS project control for all the running projects from a single place. It is also possible to search for particular managers on all the running projects and act upon them simultaneously.

The monitoring level for each device can be defined and it is possible to monitor only relevant information for each device

FSM (Finite State Machine) [4] objects are also available from this tool, in order to create FSM hierarchies that enable the possibility of grouping the nodes and projects according to desired logical groups. This enables the possibility of grouping and controlling globally nodes and PVSS projects with similar functions or characteristics

LHCb ARCHITECTURE

The LHCb Online System is composed of 1747 PCs, of which 55 machines have Windows and 1692 have Linux installed. Also, of all these machines 34 are virtual machines.

1470 of these machines belong to a CPU Farm to perform the High Level Trigger, 167 are controls machines running the PVSS SCADA system and 110 are for infrastructure support (DBs, storage), webservers, reconstruction or data monitoring

These machines are all connected in the same network and are all accessible to each other within the network.

One machine houses the PVSS part of the System Overview Tool (FwFMC, FwSystemOverview) and provides a DIM DNS Node to where all the running Monitoring and Control Servers publish their data. This machine also serves as IPMI Master.

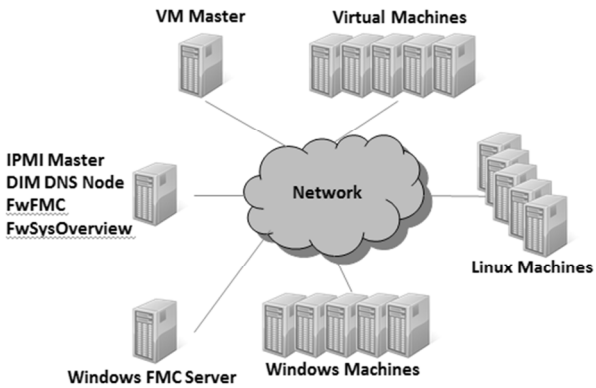

Figure 1: LHCb System Overview Architecture.

For the Hardware Layer monitoring, there are two machines that monitor the power status, fan status, temperatures and voltages:

- 1 IPMI Master – Runs the IPMI Server and polls the IPMI status from each of the nodes present on a configuration file; Controls the power of the configured nodes via IPMI commands
- 1 VM Master – Monitors and controls the power status of the Virtual Machines present on a configuration file.

Currently all of the available machines in the LHCb Online System are configured so as to be possible to monitor and control its power status.

Other parameters from the Hardware Layer (Memory and CPU usage monitoring) are configured on the nodes which are more prone to suffer more of high usage, either by running the respective servers if a Linux Machine or adding the node to a list of monitored nodes on the Windows FMC Server. Alarms are configured on these parameters so that eventual problematic situations are identified as soon as possible.

On the PVSS Infrastructure Layer, all PVSS projects have their status continuously monitored and all the individual managers of the projects are also monitored.

For the Application Layer, all the controls PCs and a few Linux PCs whose processes need to be monitored and controlled more attentively have also the task manager server running. Also the windows PCs which are configured in the Windows FMC server have the processes and services monitoring capability enabled.

LHCb USAGE

LHCb opted to develop the interface based on 2 hierarchies: one for monitoring and control of the hosts and one for monitoring and control of the PVSS projects. These hierarchies are divided according to sub-detector and function. This division allows for, at a quick glance of a synoptic panel, have an overview of the global system as well as the individual sub-detector or any particular function computer infrastructure.

This particular division also allows for the individual sub-detector to access only their specific monitored infrastructure and thus simplifies their particular needs for management.

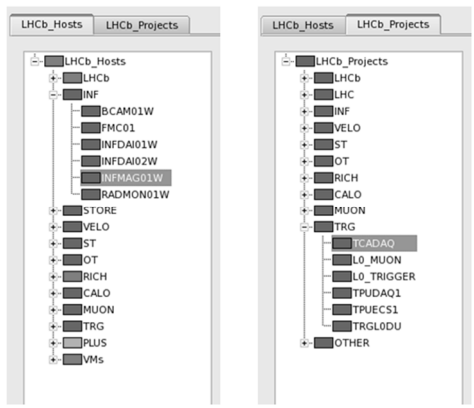

Figure 2: LHCb Hosts and Projects Hierarchies.

Using this division, it is easily identifiable on the "LHCb Hosts" hierarchy if there is any problem with the hardware of a particular system and its diagnose simplified - It is easy to identify the power status and memory usage of the machines as well as a list of running processes on it. It is common to send actions to the hosts (switch ON/OFF, reboot, kill processes) in order to fix the identified abnormalities.

Likewise looking at the "LHCb Projects" hierarchy gives you a global overview of the status of the PVSS SCADA control system and allows you the easy detection of any problem related with the PVSS projects which need to be running to ensure smooth and coherent operation of the experiment. It is commonly used to see if all the required PVSS projects are running and if any particular manager on any of the projects is functioning abnormally (process blocked) or not running (abnormally stopped, killed).

Another advantage of using the System Overview Tool is the possibility to search and globally manage the PVSS managers for all the configured PVSS projects (Fig.3). This allows an easier upgrade of the control software

available on the repositories as all the managers that would need to be stopped and restarted can now be managed from a single access place and in parallel.

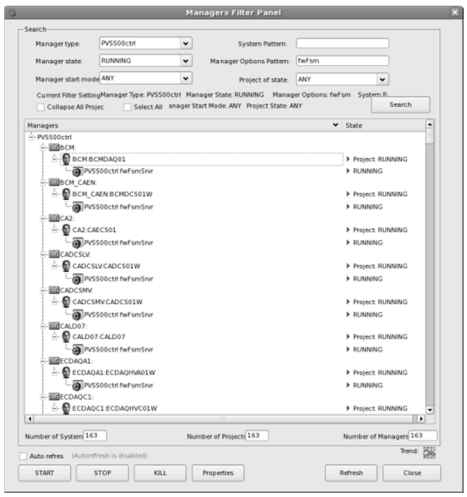

Figure 3: System Overview PVSS manager filtering.

CONCLUSION

The System Overview set of tools provide for a very elegant and user friendly central management tool, with many benefits to the administration of the LHCb online system. It enables an easy and complete monitoring system from a centralized place, permitting a global overview of the system status as well as a fine control over the several nodes, PVSS projects and processes of the system.

The system Overview tool is able to monitor an heterogeneous system with the same interface, detaching the monitoring and control interface from the monitoring and control servers which gather the data and are able to act on the nodes.

The system overview tool is also expandable to TCP enabled devices other than PCs, as soon as there is an available tool for these devices to publish their info into system overview.

OPTIMIZING INFRASTRUCTURE FOR SOFTWARE TESTING USING VIRTUALIZATION

O. Khalid, A. Shaikh, B. Copy
CERN, Geneva, Switzerland

Abstract

Virtualization technology and cloud computing have brought a paradigm shift in the way we utilize, deploy and manage computer resources. They allow fast deployment of multiple operating system as containers on physical machines which can be either discarded after use or checkpointed for later re-deployment. At European Organization for Nuclear Research (CERN), we have been using virtualization technology to quickly setup virtual machines for our developers with pre-configured software to enable them to quickly test/deploy a new version of a software patch for a given application. This paper reports both on the techniques that have been used to setup a private cloud on a commodity hardware and also presents the optimization techniques we used to remove deployment specific performance bottlenecks.

INTRODUCTION AND BACKGROUND

This paper reports our work to evaluate emerging software technologies such as virtualization and cloud computing for control system applications especially for small teams to quickly setup test environments for development and testing. Virtualization is a software layer that runs on the underlying hardware, and enables system administrators to run multiple operating systems as isolated applications or precisely speaking as virtual machines (VM). The technology have been around since 60's when IBM first developed it to enable users to share mainframe for their applications in an isolated way.

In recent years, virtualization technology have matured to provide bare-metal performance for virtual machines and have been increasingly deployed at large scale (from clusters to data centers) using cloud computing technology to optimize the utilization of the physical infrastructure in an elastic and flexible manner. According to National Institute of Standards and Technology (NIST), Cloud Computing is " a model for enabling ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider's interaction" [1].

NIST identifies two key characteristics of cloud computing that differentiates it from other ways of organizing and accessing computing infrastructures. First is *on-demand self service* that enables a consumer/user to unilaterally provision computing capabilities on demand without requiring human interaction with the service provider. Second feature of cloud computing is *resource pooling* of computing capabilities by the provider to serve multiple user-communities from the same physical infrastructure creating location independence where the user has no knowledge or control over the provided resources. The service model we have opted to deploy is *Infrastructure as a Service* (IaaS) to provide our user community with a capability to provision computing, storage and networking to run any operating system or application.

The key motivation to opt for a private cloud has been the way we use the infrastructure. Our user community includes developers, testers and application deployers who need to provision machines very quickly on-demand to test, patch and validate a given configuration for CERN's control system applications. Virtualized infrastructure along side with cloud management software enabled our users to request new machines on-demand and release them after their testing was complete.

IMPLEMENTATION

The hardware we use for our experimentation is HP Proliant 380 G4 machines with 8GB of memory, 500 GByte of disk and connected with gigabit ethernet. Five servers were running VMWare ESXi bare-metal hypervisor to provide virtualization capabilities [2]. We also evaluated Xen hypervisor [3] with Eucalyptus [4] cloud but given our requirements for Windows VMs, we opted for VMWare ESXi. OpenNebula Professional (Pro) was used as cloud front-end to manage ESXi nodes and to provide users with an access portal [5]. Number of deployment configurations were tested and their performance was benchmarked. The configuration we tested for our experimentation are the following as show in Fig. 1:

- Central storage without front end ($arch_1$): a shared storage and OpenNebula Pro runs on two different servers. All VM's images reside on shared storage all the time.
- Central storage with front end ($arch_2$): a shared storage, using network filesystem (NFS), shares the same server with OpenNebula front end . All VM images reside on shared storage all the time.
- Distributed storage remote copy ($arch_3$): VM images are deployed to each ESXi node at deployment time, and copied using Secure Shell (SSH) protocol by front end's VMWare transfer driver.
- Distributed storage local copy ($arch_4$): VM images are managed by an image manager service which downloads images pre-emptively on all ESXi nodes.

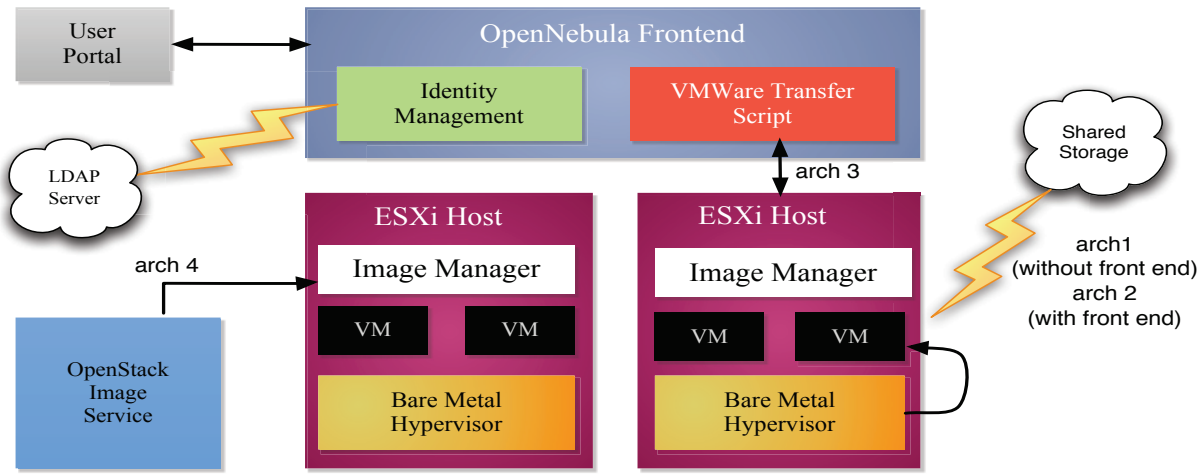

Figure 1: The cloud deployment architecture based on OpenNebula, OpenStack and VMWare ESXi software.

- Front end runs on a separate server and setup VM using locally cached images.

Each of the deployment configuration has its advantages and disadvantages. $arch_1$ and $arch_2$ are using a shared storage model where all VM's are setup on a central storage. When a VM request is sent to the front end, it clones an existing template image and sets it up on the central storage. Then it communicates the memory/networking configuration to the ESXi server, and pointing the location of the VM image. The advantage of these two architectural configuration is that it simplifies the management of template images as all of the virtual machine data is stored on the central server. The disadvantage of this approach is that incase of a disk failure on the central storage; all the VM's will loose data. And secondly, the system performance can be seriously degraded if shared storage is not high performance and doesn't has high-bandwidth connectivity with ESXi nodes. Central storage becomes the performance bottleneck for these approaches.

$arch_3$ and $arch_4$ tries to overcome this shortcoming by using all available diskspace on the ESXi servers. The challenge here is how to clone and maintain VM images at run time and to refresh them when they get updated. $arch_3$ resolves both of these challenges by copying the VM images at request time to the target node (using VMWare transfer script add-on from OpenNebula Pro software), and when the VM is shut then the image is removed from the node. For each new request, a new copy of the template image is sent over the network to the target node. Despite its advantages, network bandwidth and ability of the ESXi nodes to make copies of the template images becomes the bottleneck. $arch_4$ is our optimization strategy where we implement an external image manager service that maintains and synchronize a local copy of each template image on each ESXi node using OpenStack's Image and Registry service called Glance [6]. This approach resolves both storage and network bandwidth issues.

Finally, we empirically tested all architectures to answer the following questions:

- How quickly the system can deploy a given number of virtual machines?
- Which storage architecture (shared or distributed) will deliver optimal performance?
- What will be average wait-time for deploying a virtual machine?

Contextualization

One of the major challenge of deploying windows virtual machines is contextualizing them for a specific environment at deployment time e.g. a windows virtual machine getting a public IP address in CERN network and joining the domain to allow CERN applications to be deployed on it. This requires the VM to part of the public network at the deployment time, and be able to join the domain.

At CERN, network access is controlled by pre-registered list of authorized network interfaces. A list of virtual Machine Access Card (MAC) addresses are pre-registered in the network database. A new VM is deployed with one of the available MAC address. Once its get into a running stage, it gets connected to the network.

Next stage is to configure the machine to acquire the new machine name corresponding to the virtual MAC address. It's simpler to configure for Linux VM's as compared to Microsoft Windows XP VMs. For both we have adopted similar approaches to automate the contextualization process. Each VM is configured to launch a script at boot time that gets its MAC address and compare against a list of registered names (either using a local file or remotely access file). The matching name is updated in the VM and it's rebooted.

For Windows VM, as shown in Fig. 2, before the reboot there is an additional stage of reseting virtual machine's security ID as required by the domain controller and is linked

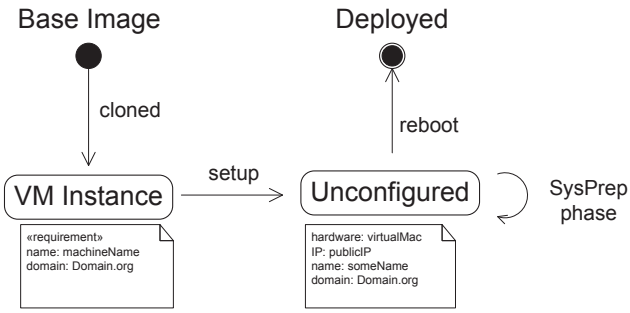

Figure 2: State diagram of a VM starting with the base image, and the stages it goes through to get to running state.

to the active directory entry. If the same security ID is used for all windows VM's, then they can't join the domain. This process is delegated to Microsoft's System Preparation (SysPrep) tool which configures the VM using a local configuration file. Once this configuration is completed; the machine is rebooted and then is available to end-user via the remote desktop connection.

RESULTS

All four different architectures were evaluated for four different deployment scenarios. Each scenario was run three times and the results were averaged and are presented in this section. Any computing infrastructure when used by multiple users goes under different cycles of demand which results in reduced supply of available resources on the infrastructure to deliver optimal service quality.

We were particularly interested in following deployment scenarios where 10 virtual machines were deployed:

- Single Burst (SB): All virtual machines are sent in a burst mode but restricted to one server only. This is the most resource-intensive request.
- Multi Burst (MB): All virtual machines were sent in a burst mode to multiple servers.
- Single Interval (SI): All virtual machines were sent after an interval of 3 mins to one server only.
- Multi Interval (MI): All virtual machines were sent after an interval of 3 mins to multiple servers. This is the least resource-intensive request.

The overall deployment times, as shown in Fig. 3, for $arch_1$ and $arch_2$ are very close to each other for all four test configuration. Both of these architectures were using a NFS based shared storage where all VM images were cloned on a storage server, and only VM setup commands were sent to the ESXi nodes with image pointers. All ten VM's got deployed within 75 mins of request initialization. This is the lower bound of the system. Where as $arch_3$ is using distributed storage but every time a VM request is made, a new image is transferred over SSH which is a very slow process and can take up more then 200 mins for some configurations. $arch_4$ is most interesting that clearly shows the optimization we implemented for auto-deployment of VM images prior to requests in the background which results in VM being deployed within 10mins.

Figure 4 shows that cumulative wait time for VM deployment is fairly stable for $arch_1$ and $arch_2$. $arch_3$ is taking the highest amount of time and $arch_4$ least. Similar pattern of wait time is observable in Fig. 5 and 6 as well. For MI configuration which is least resource intensive, $arch_2$ and $arch_3$ have a similar wait time which shows that both architectures are suitable for small-scale cloud deployments that a VM gets deployed within 30 mins. The only issue is central storage being a single-point of failure incase a hardware fault occurs. $arch_4$ keeps on out perfoming all other configuration, and hence was selected as the target deployment on our private cloud.

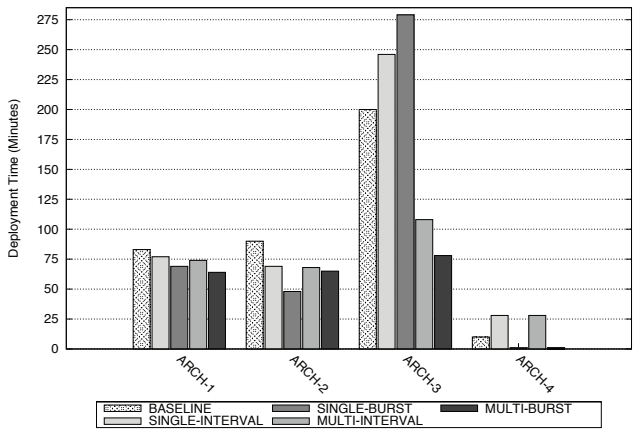

Figure 3: Aggregated total time taken to deploy all VM's in each test configuration for all architectures.

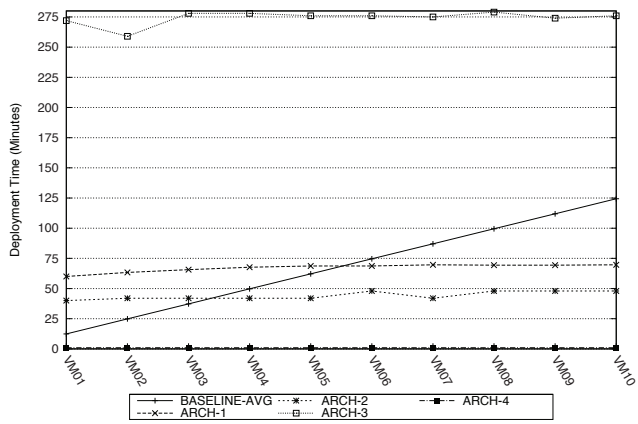

Figure 4: Evolution of deployment time for single-burst (SB) configuration.

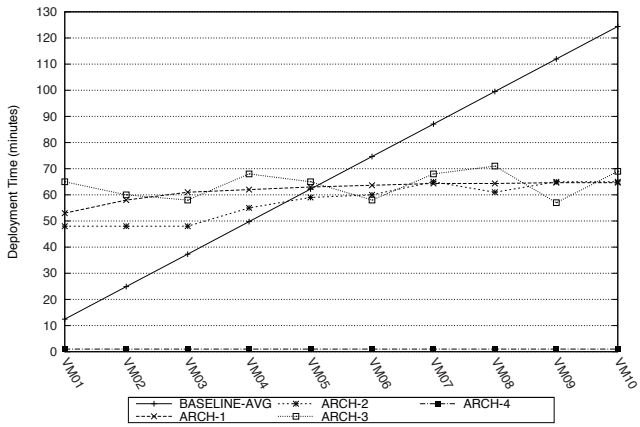

Figure 5: Evolution of deployment time for multi-burst (MB) configuration.

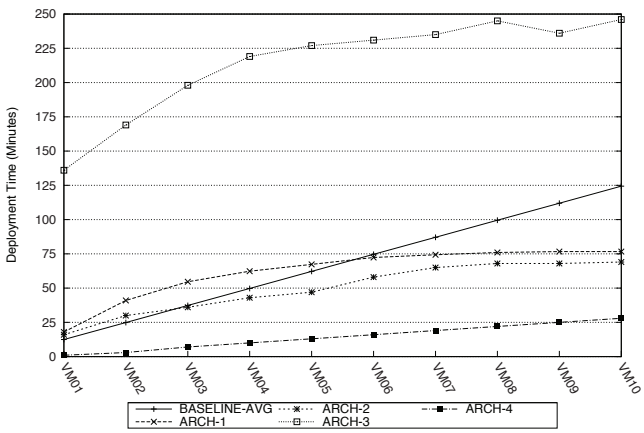

Figure 6: Evolution of deployment time for single-interval (SI) configuration.

CONCLUSION

Virtualization technology and the emerging cloud computing platform provides innovative way to utilize physical infrastructure in an elastic and flexible manner. It enables system administrators to meet various cycles of infrastructure demand when multiple user communities access the same hardware. Without cloud computing, it requires automated system administration tools to provide uniform access to storage, CPU, network and memory of a cluster of machines. Whereas, present day cloud computing management systems allows system administrators to not only virtualize their infrastructure which enables to deploy more applications/machines (virtual) on the shared physical hardware but also reduces the application deployment lifecycle.

In this paper, we have attempted to evaluate small scale private cloud infrastructure (up to 10 hardware servers) for software development teams so that they could quickly and on-demand request machine resources using available virtual machine technology. Our study have highlighted that

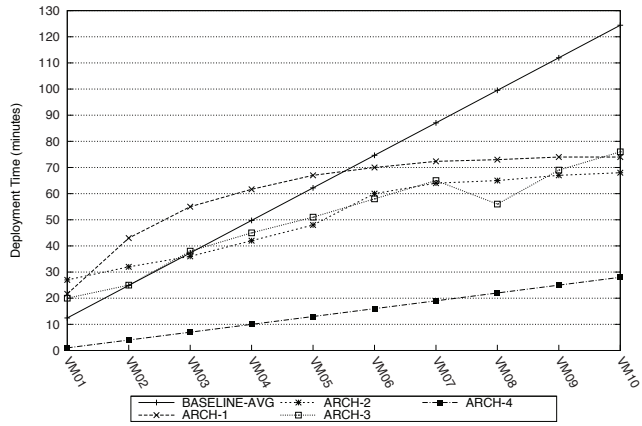

Figure 7: Evolution of deployment time for multi-interval (MI) configuration.

for optimal performance; a high-performance shared storage SAN and high-network bandwidth is preferable but this is often not possible for small scale deployments due to financial constraints. The experiments conducted in this study have indicated that a small scale private cloud is a feasible option without costly SAN or high-speed networking gear.

The results have also shown that distributed storage using locally cached images when managed using a centralized cloud platform (in our study we used OpenNebula Pro) is a practical option to setup local clouds where users can setup their virtual machines on demand within 15mins (from request to machine boot up) while keeping the cost of the underlying infrastructure low.

LARGE-BANDWIDTH DATA ACQUISITION NETWORK FOR XFEL FACILITY, SACLA

T. Sugimoto, Y. Joti, T. Ohata, R. Tanaka, M. Yamaga, JASRI/SPring-8, Hyogo, Japan
T. Hatsui, RIKEN/SPring-8, Hyogo, Japan

Abstract

X-ray Free-Electron Laser (XFEL) experiments demands large bandwidth network for data acquisition (DAQ). At the SPring-8 Angstrom Compact Free Electron Laser (SACLA) facility, the experimental data rate is to be up to 5.8 Giga bit per second (Gbps). Some of the experiments demands preprocessing and on-line analysis by high-performance computers. In order to fulfill these requirements, a dedicated network system for DAQ and data analysis has been developed. A DAQ network consists of a dedicated 10 Gbps Ethernet (10GbE) physical layer to secure the data bandwidth and a 1GbE layer for instrument controls. The DAQ network is connected to a primary storage and indirectly to a PC cluster for data preprocessing. A firewall system with virtual private network (VPN) features is also implemented in order to secure remote access from off-site institutes. The preprocessed data plan to be transferred to the off-site supercomputer "K computer" with high efficiency.

OVERVIEW OF SACLA

SACLA is a X-ray free electron laser facility (XFEL) in Japan. The SACLA is located at SPring-8 site, in the west region of Japan. Characteristic specification of the SACLA is electron energy at 8 GeV, peak bunch length of 30 fsec, 18-unit undulator with 18-mm magnetic period. The SACLA is designed to produce X ray with a wavelength as short as 0.06 nm at the repetition rate of 60 Hz. The SACLA consists of accelerator building, undulator building, and experimental facility. To utilize both the SACLA and existence facility "SPring-8", SACLA-SPring-8 experimental facility will be in service in 2012. In the SACLA-SPring-8 experimental facility, X rays from SACLA and SPring-8 can be used simultaneously.

The SACLA facility has successfully established. First X-ray lasing with a wavelength of 0.12 nm was observed on June 7, 2011.[1] By continuing beam commissioning, the wavelength 0.08 nm was achieved on July 13. First test experiment is planned from the October, 2011, and public experimental use will be open on March, 2012.

Experimental Requirement and Data Acquisition Network Design

In March 2012, the SACLA facility will deliver beam time to public users. Multi-Port CCD (MPCCD) detector [2] and its data acquisition (DAQ) system will be used in most of the anticipated experiments. Characteristic requirements are flexibility to change experimental setup within an approximately one-week cycle, robustness to minimize down time, and guaranteed network bandwidth to store all the data. Experimental users also need to use a PC-Cluster system for both on-line and off-line analysis. In order to meet these requirements, we have developed a DAQ system for the SACLA experiments. One MPCCD sensor has 512×1024 pixels with 16-bit data depth. With additional meta data, single-frame data size is about 1 Mega Bytes (MB). At the maximum acquisition rate of 60 Hz, a single sensor produces 480 Mega bit per second (Mbps). Using 12 MPCCD sensors, the data rate reaches 5.8 Gbps. To satisfy the required data rate, we divided the DAQ network (DAQ-LAN) into two physical layers, one is a dedicated 10GbE for large-bandwidth data transfer, and another is a low-latency 1GbE for instrument controls. We applied high-availability techniques to the network trunk lines to reduce down time. The target value of the down time is less than one day per year.

Some of the important SACLA applications, such as three-dimensional (3-D) coherent diffraction imaging at near-atomic resolution and protein nano-crystallography, demand high performance computing (HPC) infrastructures. At the SACLA facility, we plan to connect the DAQ system to the off-site 10-Peta-flops (Pflops) supercomputer "K computer"[3] to make HPC infrastructure available to users. In the foreseen analysis procedure, experimental data are first transferred to an on-site 10-Tera-flops PC cluster with high I/O capability for preprocessing, and then transferred to the K computer via a dedicated network or academic network SINET4.[4] The DAQ-LAN should be connected to the PC cluster and internet, which demands careful network design. This was achieved by the implementation of firewall systems with virtual private network (VPN) features.

THE DAQ NETWORK SYSTEM AT SACLA

The SACLA accelerator facility is controlled by many control-system components. All control-system components are connected to machine control network (CNTL-LAN). Considering how to use the DAQ system and how to ensure the security and the performance, we have developed additional three networks; 1. large-bandwidth data transfer network (DAQ-LAN), 2. experimental user network (DAQ-USER-LAN), and 3. network for data analysis (PC-Cluster-LAN). Policies of these three networks are described in this section.

Since the accelerator is a radiation generator, we must apply strict network security to the CNTL-LAN. Control-system components are fixed during the SACLA operating cycle (typically a few month). On the other hand, experimental machine time is one-week cycle, which is shorter than the operating cycle. The DAQ-LAN should be segregated from the CNTL-LAN for the DAQ-system flexibility. The DAQ system needs accelerator status data, such as wave form, beam intensity, and beam position acquired by non-destructive detectors. To satisfy the requirement and our network security, the CNTL-LAN and the DAQ-LAN are connected each other by a firewall system.

The DAQ-USER-LAN is another network for user experiments. Experimental users can use their own PCs and experimental instruments connected to the DAQ-USER-LAN. The differences between the DAQ-LAN and the DAQ-USER-LAN are 1. all instruments at the DAQ-LAN are managed by the SACLA staff to ensure the DAQ performance (large-bandwidth data transfer and low-latency DAQ control), 2. users' instruments can be connected to the DAQ-USER-LAN by themselves, and the network performance is best-effort 1GbE. The DAQ-USER-LAN is also connected to the CNTL-LAN and the DAQ-LAN by the firewall to acquire accelerator status and to control beamline components.

The PC-Cluster-LAN is another network for the PC-Cluster system. Experimental users can login from the DAQ-USER-LAN, and the users can perform on-line data evaluation using the PC-Cluster system. Off-line users can login from General-LAN in the SPring-8 site. The off-line users can analyze experimental data in the high-speed storage system. To read out the data from storage system, large-bandwidth network is required for the PC-Cluster-LAN. The PC-Cluster-LAN is also used to transfer experimental data from the SACLA to off-site supercomputer "K computer". To meet these requirements, we made policies on the PC-Cluster-LAN; 1. people who have permission can login the PC-Cluster system, 2. login path from the Internet must be protected using VPN system, 3. data-transfer path between the high-speed storage system and the PC-Cluster system should be more than 5.8 Gbps bandwidth, and the bandwidth is upgradable, 4. data-transfer path between the SACLA and the K computer should have more than the DAQ data rate (5.8 Gbps). We have two plans for the data-transfer path to the K computer, one is a best-effort 10 Gbps wide area network (WAN) SINET4, to be connected with in the autumn of 2012. Another plan is data-transfer path using a dedicated line between the SACLA and the K computer to guarantee the bandwidth.

To develop the real network systems, we isolated logical-network layer and physical-network layer. By isolating network layers, the network systems can have upgradability and redundancy. In the next subsections, we show network planning and implementations from each logical and physical view.

Logical Network Planning and Implementations

We made logical network plan of SACLA. We decided IP-address assignment based on same idea of the existence SPring-8 network system.[5] The reasons to adopt the same idea are 1. interconnection method between LANs match each other, 2. to reduce problem such as broadcast traffic[6], 3. to reduce administration cost using same assignment rules. From the IP-address-assignment rule, we applied class-B private addresses to the CNTL-LAN, the DAQ-LAN, and the DAQ-USER-LAN. We also applied class-A private addresses to the PC-Cluster-LAN, because class-A private address indicate open network in the SPring-8.

Each LAN has one (or two with high-availability configuration) layer-three network switch (L3SW). To isolate logical-network layer from physical-network layer, we applied virtual LAN (VLAN) technology. We assigned different VLAN IDs to the large-bandwidth network (10GbE) and the low-latency instrumental-control networks (1GbE). Using VLAN technology, we have flexibility to fold some VLANs on one physical layer or only one VLAN occupies one physical layer such as 10GbE line.

To satisfy requirements on data acquisition and beamline instrumental control on the DAQ-LAN, we assigned twelve VLANs. A segment named "DAQ Data" is a exclusive 10GbE network for data transfer. Other eleven segments are 1GbE networks for experimental instrument control. "DAQ Control" is a 1GbE network to control DAQ components. "Live View" is a best-effort 1GbE network for on-line monitoring. "BL1" (beamline 1), "BL3", and "LH1" (laser hutch 1) are networks to control beamline components such as monochromators and optical mirrors. For future beamline expansion, "BL2", "BL4", "BL5", and "LH2" segments are reserved. Other two VLANs are used for network managements. Near future, network segments for the SACLA-SPring-8 experimental facility will be added to the DAQ-LAN.

Physical Network Implementations for the DAQ System

From the experimental requirements, the physical network should have the following functions; 1. the DAQ-LAN have a bandwidth of 10 Gbps, 2. the DAQ-LAN should be upgraded to 40GbE/100GbE (IEEE802.3ba), 3. the DAQ-LAN can be used several spot in the experimental hall, and 4. the DAQ-LAN and the DAQ-USER-LAN should have robustness to minimize down time less than one day per year. From these requirements, we have developed the physical network in the SACLA experimental facility.

From the requirement of bandwidth and upgradeability, we applied $9/125$ μm single-mode fiber (SMF) as physical trunk lines. For example, the 10GBASE-LR needs two core of SMF, and we can upgrade to 40GBASE-LR4 or 100GBASE-LR4 with existent two-core SMF in the future. If we apply multi-mode fiber (MMF), it is diffi-

cult to upgrade the network, because 40GBASE-SR4 and 100GBASE-SR10 need 8 and 20 core of MMF, respectively.

Figure 1 shows network-wiring diagram at the SACLA experimental facility. The DAQ-LAN consists of two kind of trunk line: one is a exclusive 10GbE for large-bandwidth data transfer (red) and another is versatile 1GbE for instrumental control (blue). We also use same physical trunk line for the DAQ-USER-LAN (purple) and the PC-Cluster-LAN (green). All of wiring lines are distributed from the computer room. Each trunk lines have redundant configuration using link aggregation (LAG, IEEE802.3ad/802.1AX) technology to meet the requirements on robustness of the DAQ-LAN.

The DAQ-LAN with 10GbE is available at several DAQ stations; in the experimental hutch 1–4 (EH1–EH4), 19-inch racks beside EH2 and EH3, and 19-inch rack at experiment preparation room (EP) 1. The DAQ-LAN with 1GbE is available at the LH1, EP5, and the optical hutch 1 (OH1) in addition to the DAQ stations.

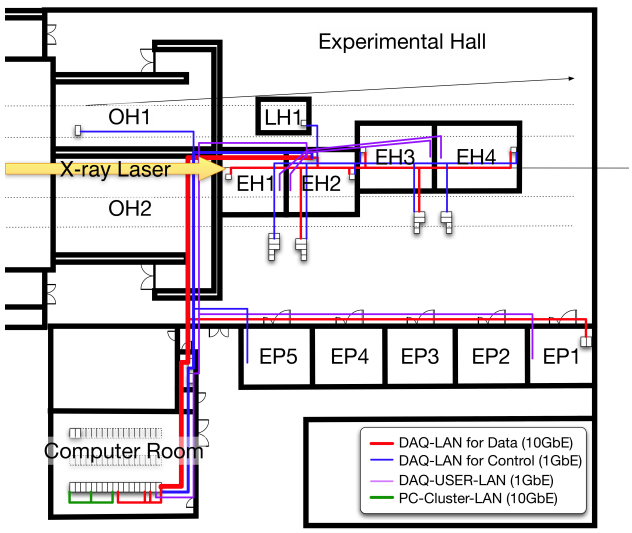

Figure 1: Overview of the SACLA experimental facility. X-ray laser comes from left side of this figure. The X-ray laser is focused in the optical hutches (OHs), and the X-ray laser is used for experiments at the experimental hutches (EHs). Experimental preparation rooms (EPs) are used for instrumental test. Red line is the DAQ-LAN data-transport line (10GbE). Blue line is the DAQ-LAN control line (1GbE). Purple line is the DAQ-USER-LAN (best-effort 1GbE). Green line is the PC-Cluster-LAN (10GbE).

Using the DAQ-LAN, the experimental data flow is described as below. Each detector outputs scattering image at 500 Mbps data rate via the Camera Link interface. MPCCD consists of 12 sensors, total data throughput is to be 5.8 Gbps. VME Camera-Link systems[7] receive data via the Camera Link interfaces. The VME Camera-Link systems send data to data file servers via the DAQ-LAN. Since the trunk line of data-transfer Ethernet is based on 10GbE, the network has enough capacity to transfer experimental data with 5.8 Gbps rate. Digital data from two VME systems are received by one data file server. The data file servers write data on the high-speed storage system via the FibreChannel. Each data file server has three GbE interfaces. Two GbE interfaces are used to receive experimental data at the rate of 500 Mbps from 10GbE line. Another GbE interface is used to control the DAQ system. Thus, we achieved 5.8 Gbps data rate from the MPCCD detectors to the high-speed storage system. Details of the DAQ framework is shown by M. Yamaga et al.[8]

Physical Network Implementation for the PC-Cluster System

We installed a PC-Cluster system at the SACLA experimental facility. The PC-Cluster system is aimed at 1. on-line data preprocessing, and 2. preprocessed data transfer to the K computer. Off-line data analysis will be carried out using off-site 10 Pflops K computer. Generally, network bandwidth over hundreds-kilometer distance is narrow. To make effective use of the K computer, we perform data reduction using the SACLA PC-Cluster system.

The PC-Cluster-LAN requires; 1. large-bandwidth data transfer between the high-speed storage system and the PC-Cluster system, 2. large-bandwidth data transfer from the SACLA to the K computer, 3. robustness to perform on-line analysis, down time should be equal to or less than that of the DAQ-LAN, and 4. versatile use of the PC-Cluster system, and users can login from the DAQ-USER-LAN, the General-LAN, and the Internet. It should be noted that users cannot login the DAQ-LAN from the General-LAN nor the PC-Cluster LAN.

From the requirement of large-bandwidth transfer (1), we have developed the PC-Cluster-LAN between the PC-Cluster system and the high-speed storage as 10GbE network. We also developed the PC-Cluster-LAN between the SINET4 and the PC-Cluster system for the requirement (2). The SINET4 is used for data transfer from the SACLA to users' institutes and the K computer. We also plan to connect the PC-Cluster-LAN with a dedicated network between the SACLA and the K computer to guarantee the data rate to the K computer. From the requirement of robustness (3), we choose ring-topology protocol as a high-availability mechanism for the PC-Cluster-LAN. The ring-topology protocol have much redundancy than that of LAG. From the requirement of versatile use of the PC-Cluster system (4), we installed firewalls between the PC-Cluster-LAN and other LANs to satisfy security policy of the SPring-8 site.

DATA TRANSFER PLAN FROM SACLA

To make effective use of data-transfer network, we have studied large-bandwidth data transfer technique from the SACLA to the off-site supercomputers. We have planed on-line analysis using the K computer. From the result of

on-line analysis at the K computer, we can judge the quality of experimental conditions. We set a present goal to finish the quality-judgement during the beam time. Thus, we can optimize experimental conditions during the experiment.

In order to determine data-transfer bandwidth requirement, we plan to use other two supercomputers. One is "FOCUS" supercomputer located at Kobe, just beside the K computer.[9] The Internet access line of the FOCUS is commercial WAN at 100 Mbps. Another is "e-Science" supercomputer located in the K computer site.[10] The e-Science is connected to the SINET4 at 4 Gbps. The SINET4 between the SACLA and the e-Science can be configured as a 4-Gbps dedicated line. In early of 2012, we plan to evaluate data-transfer throughput of the WAN and a dedicated academic network using the FOCUS and the e-Science.

SUMMARY

We have developed large-bandwidth networks for high-speed DAQ and the PC-Cluster systems at the SACLA. Experimental requirements are 5.8 Gbps bandwidth, flexibility, low down time, accessibility to CNTL-LAN, accessibility to the PC-Cluster system, and network security. We satisfied these requirements, and the DAQ system has no bottle neck from the detectors to the high-speed storage system. In March 2012, the SACLA facility will deliver beam time to public users. MPCCD detector and the DAQ system will be used. In the autumn of 2012, the PC-Cluster system will be connected with the K computer. Using the K computer, we plan to perform XFEL data analysis of 3-D coherent diffraction imaging at near-atomic resolution and protein nano-crystallography.

Abstract

Novosibirsk Scientific Center (NSC), also known worldwide as Akademgorodok, is one of the largest Russian scientific centers hosting Novosibirsk State University (NSU) and more than 35 research organizations of the Siberian Branch of Russian Academy of Sciences including Budker Institute of Nuclear Physics (BINP), Institute of Computational Technologies, and Institute of Computational Mathematics and Mathematical Geophysics (ICM&MG). Since each institute has specific requirements on the architecture of computing farms involved in its research field, currently we've got several computing facilities hosted by NSC institutes, each optimized for the particular set of tasks, of which the largest are the NSU Supercomputer Center, Siberian Supercomputer Center (ICM&MG), and a Grid Computing Facility of BINP.

A dedicated optical network with the initial bandwidth of 10 Gbps connecting these three facilities was built in order to make it possible to share the computing resources among the research communities, thus increasing the efficiency of operating the existing computing facilities and offering a common platform for building the computing infrastructure for future scientific projects. Unification of the computing infrastructure is achieved by extensive use of virtualization technology based on XEN and KVM platforms. The solution implemented was tested thoroughly within the computing environment of KEDR detector experiment which is being carried out at BINP, and foreseen to be applied to the use cases of other HEP experiments in the future.

INTRODUCTION

Over the last few years the computing infrastructure of Novosibirsk Scientific Center (NSC) located in Novosibirsk Akademgorodok [1] has improved dramatically as the new high performance computing facilities in Novosibirsk State University (NSU) [2] and various institutes of Siberian Branch of the Russian Academy of Sciences (SB RAS) [3] were established in order to be used as shared resources for scientific and educational purposes. The need for providing these facilities with the robust and reliable network infrastructure which would make it possible to share the storage and computing resources across the sites emerged instantly once the facilities have entered production. In 2008 a consortium of the following organizations:

- Institute of Computational Technologies (ICT) [4] hosting all the centralized scientific network infrastructure of SB RAS and Akademgorodok in particular,
- Novosibirsk State University (NSU) hosting NSU Supercomputer Center (NUSC) [5],
- Institute of Computational Mathematics and Mathematical Geophysics (ICM&MG) [6] hosting Siberian Supercomputer Center (SSCC) [7],
- Budker Institute of Nuclear Physics (BINP) [8] hosting a GRID computing facility (BINP/GCF) optimized for massive parallel data processing of HEP experiments (which is supposed to be used as a BINP RDIG [9] and WLCG [10] site in the near future)

was formed with the primary goal to build such a network (named later on as the NSC supercomputer network, or simply NSC/SCN) and provide it with the long term technical support. The first stage of the NSC/SCN infrastructure was deployed by ICT specialists in 2009 and it is being maintained ever since on 24x7 basis.

This contribution is focused on how the existing NSC/SCN infrastructure was used in order to build a virtualized computing environment on top of the NUSC and BINP/GCF facilities which is now exploited for running massive parallel data processing jobs related to KEDR detector experiment [11] being carried out at BINP. The prospected ways of using this environment for serving the needs of other BINP detector experiments and locally maintained GRID sites are also discussed.

NSC SUPERCOMPUTER NETWORK DESIGN AND IMPLEMENTATION

The supercomputer network as it is implemented now, has a star topology and based on 10 Gigabit Ethernet technology. As it is shown in Fig. 1, the central switch of the network is located in ICT and connected to each of the remote participating sites by means of two pairs of SMF G.652 fibers, two of which are equipped with the pair of long range (LR) 10 GbE optical transceivers and the remaining ones are used for two independent 1 Gbps wavelength-division multiplexing (WDM) technology based auxiliary control and monitoring links. The only exception is the link between the ICT and SSCC facilities which is less than 200 meters long and currently deployed over the MMF fiber equipped with the short range (SR) 10 GbE transceivers.

NSC/SCN is by design a well isolated private network which is not supposed to be directly exposed to the general purpose networks of the organizations involved.

#A.S.Zaytsev@inp.nsk.su

Each of the sites connected to the NSC/SCN infrastructure is equipped with the edge switch, used for the centralized access management and control, though the client side connections of the 10 Gbps uplinks are implemented individually on each site, reflecting the architectural differences between them. All the network links are continuously monitored by means of MRTG [12] instances deployed on sites.

The following approaches and protocols are now exploited for exposing computing and storage resources of the interconnected facilities to each other across the NSC supercomputer network:

- OSI Layer 3 (static) routing between the private IPv4 subnets,
- IEEE 802.1Q VLANs spanned across all the NSC/SCN switches,
- Higher level protocols for storage interconnect and also InfiniBand and RDMA interconnect across the sites over the Ethernet links (experimental).

RTT value observed between the sites in the network is less than 0.2 ms. The maximum data transfer rate between the sites for unidirectional TCP bulk transfer over the NSC/SCN network measured with Iperf [13] is equal to 9.4 Gbps. No redundancy implemented yet for the 10 Gbps links and the routing core of the network, but these features are planned to be added during the future upgrades of the infrastructure, along with increasing the maximum bandwidth of each link up to 20 Gbps, while preserving the low value of RTT for all of them. The prospects for extending the NSC/SCN network beyond Akademgorodok are also being considered.

NSC/SCN COMMON VIRTUALIZED COMPUTING ENVIRONMENT

Generic Design Overview

Since the early stages of deployment the NSC supercomputer network is interconnecting three facilities which are quite different from the point of view of their primary field of application and amount of resources available:

- NUSC at NSU: high performance computing (HPC) oriented facility (HP BladeSystem c7000 based solution running SLES 11 x86_64 [14] under control of PBS Pro [15] batch system) provided with 29 TFlops of combined computing power, 108 TB of total storage system capacity, and KVM [16] based virtualization solution,
- SSCC at ICM&MG: HPC oriented facility (30 TFlops of combined computing power plus 90 TB of total storage system capacity),
- GCF at BINP: parallel data processing and storage oriented facility (0.2 TFlops of computing power running SL5 x86_64 [17] plus 32 TB of centralized storage system capacity) provided with both XEN [18] and KVM based virtualization solutions.

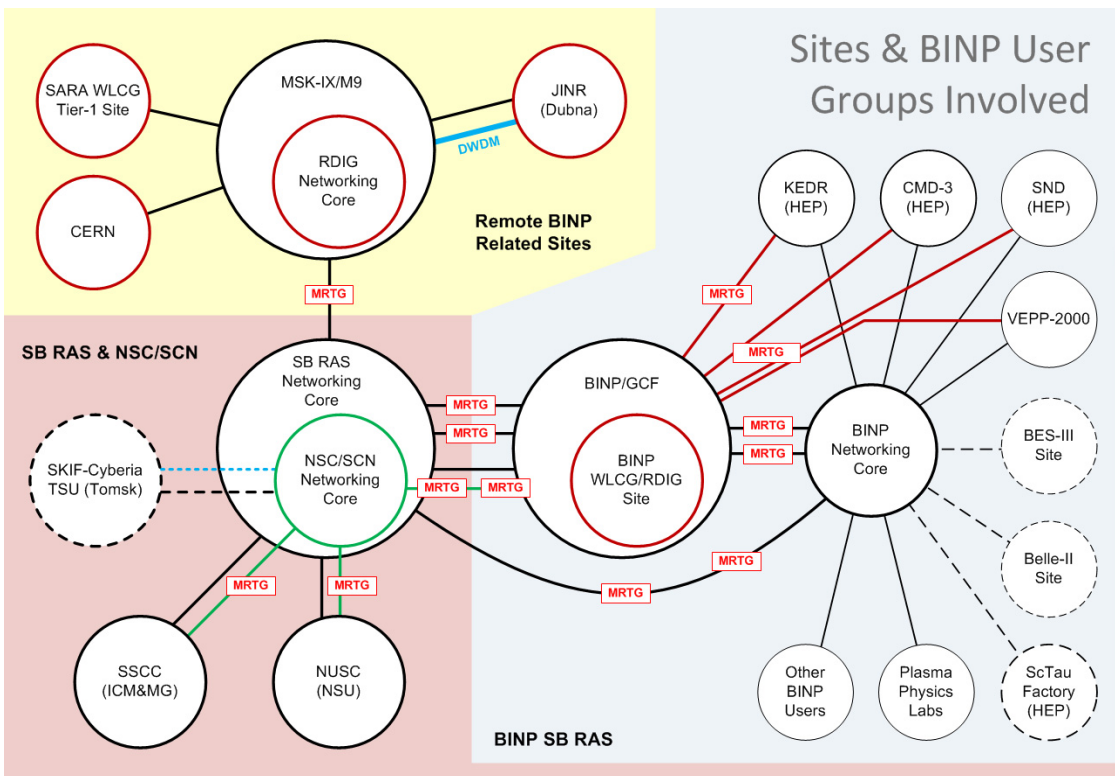

Figure 1: Networking layout of the NSC supercomputer network. Links to the user groups which are still to be established are represented by the dashed lines/circles, and the primary 10 GbE links – by the green lines. MRTG network statistics gathering points are also shown.

Considering the obvious imbalance of computing resources among the listed sites an initiative has emerged to use the NSC/SCN capabilities for sharing the storage resources of BINP/GCF with NUSC and SSCC facilities, and at the same time allow BINP user groups to access the computing resources of these facilities, thus creating a common virtualized computing environment on top of them. The computing environment of the largest user group supported by BINP/GCF (described in the next section) was selected for prototyping, early debugging and implementation of such an environment.

Computing Environment of KEDR Experiment

KEDR [11, 19] is a large scale particle detector experiment being carried out at VEPP-4M electron-positron collider [20] at BINP. The offline software of the experiment was being developing since late 90's. After several migrations the standard computing environment was frozen on Scientific Linux CERN 3 i386 [21] and no further migrations are expected in the future. The amount of software developed for KEDR experiment is about 350 kSLOC as estimated by the SLOCCount [22] tool with the default settings. The code is written mostly in Fortran (44%) and C/C++ (53%). The combined development effort invested into it is estimated to be more than 100 man-years. An overall size of experimental data recorded by KEDR detector since 2000 is 3.6 TB which are stored in a private format. Sun Grid Engine (SGE) [23] is utilized as a standard batch system of the experiment.

All the specific features of the computing environment mentioned here are making it extremely difficult to run KEDR event simulation and reconstruction jobs within the modern HPC environment of the NUSC and SSCC facilities, thus making it an ideal candidate for testing the common virtualized environment infrastructure deployed on top of the BINP/GCF and NUSC resources.

Implementation and Validation Procedures

The following candidates for a solution of the problem stated above were carefully evaluated at NUSC facility while trying to find an optimal configuration of the virtualized environment capable of providing both high efficiency of using the host system CPU power and the long term virtual machine stability at the same time:

- VMware server [24] based solution requiring minimal changes in the native OS of NUSC cluster – *ruled out due to the low performance and poor long term stability*,
- XEN based solution identical to the one deployed on BINP/GCF resources – *ruled out as it required running a modified version of Linux kernel which was not officially supported by the hardware vendor of the NUSC cluster,*
- KVM based solution which have shown the best performance and long term stability while running SLC3 based VMs among all the evaluated candidates and therefore *picked up for the final validation and running the KEDR detector production jobs*.

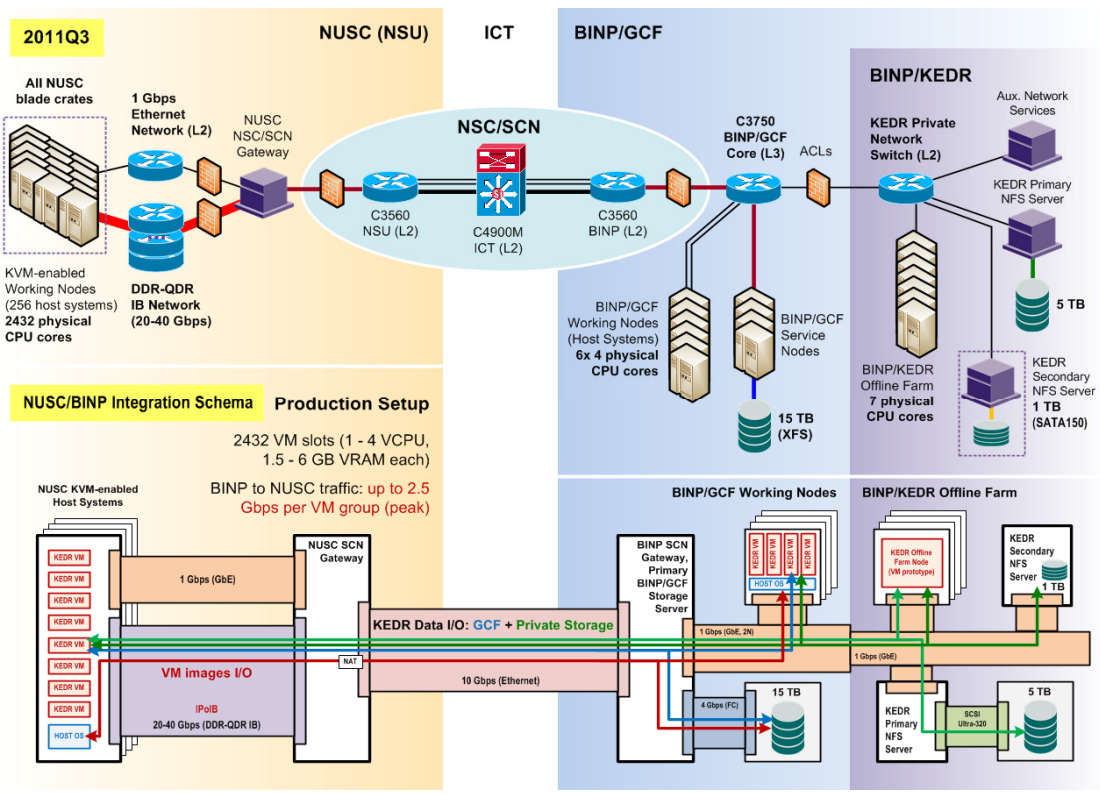

Figure 2: Networking and storage interconnect schema of the common virtualized computing environment spanning across the NUSC and BINP/GCF clusters as it is being used now for running the KEDR detector production jobs.

In addition the KVM based solution was validated during the large scale tests involving up to 512 dual VCPU virtual machines of KEDR experiment running up to 1024 experimental data processing and full detector simulation jobs in parallel controlled by the KEDR experiment private batch system.

All the stages of deployment of the KVM based virtualization environment on the computing nodes of NUSC cluster were automated and now handled via the standard PBS Pro batch system user interface. Furthermore, a generic integration mechanism has been deployed on top of the virtualization system which handles all the message exchange between the batch systems of KEDR experiment and NUSC cluster thus delivering a completely automated solution for the management of the NSC/SCN virtualized infrastructure.

The final layout of networking and storage interconnect schema developed for the KVM based virtualization environment deployed on the NUSC resources is shown in Fig. 2. Note that all the virtual machine images and input/output data samples are exported to the nodes of the NUSC cluster directly from BINP/GCF and KEDR experiment storage systems through the NSC/SCN infrastructure. It is foreseen that the similar solution is proposed to be deployed on SSCC side in 2011Q4 which would result in an increase of the amount of computing resources accessible via the NSC/SCN up to approximately 150 TFlops of computing power and 300 TB of shared storage capacity by the end of 2011 (taking into account the upgrades which are yet to be completed).

CONCLUSION

The supercomputer network of the Novosibirsk Scientific Center based on 10 Gigabit Ethernet technology which was built by the consortium of institutes located in Novosibirsk Akademgorodok, and currently provides a robust and high bandwidth interconnect for the largest local computer centres devoted to scientific and educational purposes. Although nowadays the NSC/SCN infrastructure is geographically localized within a circle of 1.5 km in diameter, it may be extended to the regional level in the future in order to reach the next nearest Siberian supercomputing sites.

The NSC supercomputer network once constructed made it possible to build various computing environments spanned across the resources of multiple participating computing sites, and in particular to implement a virtualization technology based environment for running typical HEP-specific massive parallel data processing jobs serving the needs of detector experiments being carried out at BINP. The solution implemented was tested thoroughly on a large scale within the computing environment of KEDR experiment in 2011Q1 and have been used for running production jobs ever since, delivering up to 75% of computing resources required by KEDR experiment over the last 9 months of continuous operation, resulting in a significant speed-up of the process of physical analysis, e.g. [25, 26].

Recently in 2011Q3 the other two local detector experiments (CMD-3 and SND detector at VEPP-2000 collider [27]) being carried out at BINP have successfully adopted the virtualization solution previously built for KEDR detector in order to satisfy their own needs for HPC resources. The solution obtained is foreseen to be used as a template solution for making a fraction of NUSC computing resources available for deployment of the gLite [28] worker nodes of BINP RDIG/WLCG resource site, Russian National Nanotechnology Network (NNN) resource site of SB RAS maintained by ICT, and also for prototyping the future TDAQ and offline data processing farms for the detector experiment at Super c-Tau Factory electron-positron collider proposed to be constructed at BINP over the upcoming 10 years. An experience obtained while building the virtualization based solution for running production jobs of BINP detector experiments which is compatible with modern high density HPC solutions, such as those deployed at NUSC and SSCC facilities might be of interest for other HEP experiments and WLCG sites across the globe.

THE MICROTCA ACQUISITION AND PROCESSING BACK-END FOR FERMI@ELETTRA DIAGNOSTICS*

A. O. Borga#, R. De Monte, L. Pavlovic, M. Predonzani, F. Rossi, G. Gaio, M. Ferianis,
ELETTRA, Trieste, Italy

Abstract

During the construction and commissioning of the FERMI@Elettra Free Electron Laser (FEL) facility, tight requirements for diagnostics readout, processing, and control electronics had been specified; together with a complete integration in the main machine control system. Among the diagnostics devices to be controlled, the Bunch Arrival Monitors (BAM) [1] and the Cavity Beam Position Monitors (C-BPM) [2]. The back-end platform, based on the MicroTCA (or uTCA) standard [3], provides a robust environment for accommodating such electronics, including reliable infrastructure features for slow control and monitoring of the electronics inside the crates. Two types of Advanced Mezzanine Cards (AMC) had been conceived, developed and manufactured in order to meet the demanding requisites. The first is a fast (160 MSps) and high-resolution (16 bits) Analog to Digital and Digital to Analog (A|D|A) Convert Board, hosting two A-D and two D-A converters controlled by an FPGA. The onboard logic is also responsible for service and host interface handling. The latter board is an Analog to Digital Only (A|D|O) Converter, derived from the A|D|A, with an analog front side stage made of four A-D converters. Timing synthesis and distribution from a MicroTCA Central Hub (MCH) slot can be provided by means of a custom MicroTCA Timing Central Hub (MiTiCH), specifically designed for accurate (sub ps range) timing distribution over uTCA backplanes. The overall systems' architectures, together with the AMCs and MCH concept and functionalities, are described hereafter. A summary of the achievements, for each specific use case, together with our experience in the field with the new architecture, are then summarized.

SYSTEMS GENERAL REQUIREMENTS

In spring 2009 a team specialized in digital electronics had been put together by the area leader of the FERMI timing and diagnostics, to develop a common acquisition and processing platform to be interfaced to the machine control system. The goal of the diagnostics uTCA crates, named back-end systems, was to cover the control of 25-30 stations spread along the machine in both the linac and the undulator areas. The ADC count summed up to about 100 inputs, while the DAC output had been estimated to 40 in groups of two fast and two slow converters. Extra general purpose IO capabilities for control and monitor had also been requested.

* Work supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3
# A. Borga, was at Elettra Sincrotrone Trieste S.C.p.A., timing and diagnostics group. He is now at NIKHEF, Electronics Technology department, Science Park 105, 1098XG Amsterdam, Netherlands.

The need for a modular system was therefore obvious. The main facility objective was to lase 19 months later; consequently the development was to be kept realistic, yet innovative because of its tight constraints. After a survey of suitable system architectures, the choice for uTCA was made. Even if very attractive, xTCA for physics was at the time still in its embryonic stage. Designer decided to avoid commercial solutions for two reasons: (i) none of the offers were fulfilling all systems' criteria and the numbers in play wouldn't attract vendors to customize their products; (ii) none had the desired degree of openness required to truly operate, maintain and upgrade such devices. A custom or open design is intrinsically, from hardware to software, under complete control of developers. Costs and manpower were properly scaled to cover the effort required to start with uTCA. The standard had been chosen for its modularity and size, its backplane bandwidth capabilities, and the robustness of modules' supervision. Of fundamental relevance also the fact that MicroTCA had the scalability and the potential for future expansion, characteristics desired by the designers during the conception stage.

BACK-END OVERVIEW

The uTCA back-end system (Figure 1) is a hardware layer interface between the tunnel frontend devices, specific for each diagnostics monitor, and the machine control system. The communication to/from frontends is application dependant; while the data transfer to the control network devices is Ethernet UDP/IP based. Users in the control room can monitor and control devices through Linux real time and Tango servers and panels. Inside the uTCA the clock can be distributed via the backplane, while all other signals are connected via front panel connectors.

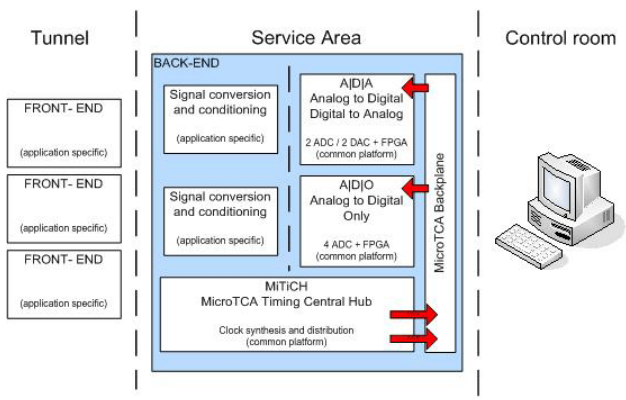

Figure 1: Block diagram of a diagnostic back- end system.

Besides Commercial Off-The-Shelf (COTS) devices like Shelf Managers, CPUs and hard drives; the uTCA back-end crate is conceived to host three types of modules: (i) **A|D|A and A|D|O AMCs**, custom modules described later in this article; (ii) **Side Transition Modules (STM),** interface transition cards (in AMC format) that adapt front-end signals to the inputs and outputs of A|D|A and A|D|O, and communicate with them through fine pitched flat cables; (iii) **Clocking and shelf management MCH**, MiTiCH like modules for card monitor and/or clock distribution.

A|D|A MODULE ARCHITECTURE

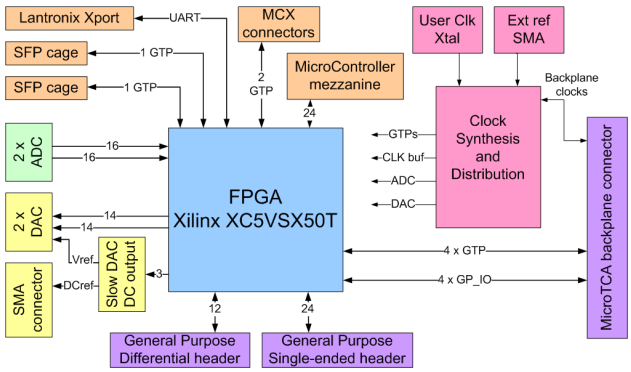

Figure 2: A|D|A AMC module block diagram.

The main purpose of the Analog to Digital and Digital to Analog (A|D|A, Figure 2) converter AMC [5] is acquisition, processing, and generation of fast analog signals. The architecture is based on a Xilinx Virtex-5 FPGA responsible for the data handling of all the external inputs and outputs, the data processing, and the interface to the control system. Extensive board documentation can be found in [6].

A|D|O MODULE ARCHITECTURE

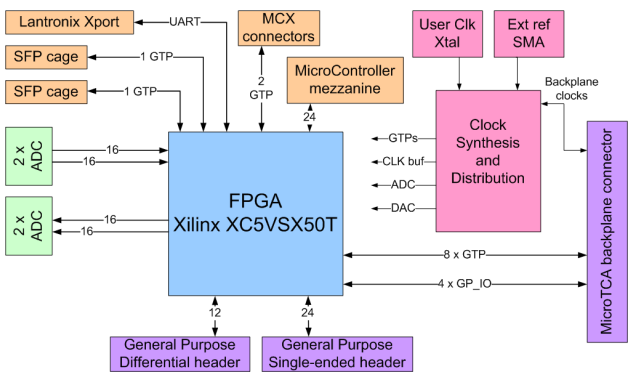

Figure 3: A|D|O AMC module block diagram.

The Analog to Digital Only (A|D|O, Figure 3) converter AMC [7] is derived directly from A|D|A. It is based on the same FPGA responsible for the same generic tasks. The main difference between the two cards is the front-end that in the A|D|O case in made of 4 A-D converters. The backplane connectivity and the clocking schema has both been enhanced and improved.

MITICH MODULE ARCHITECTURE

MCH Carrier Board

The uTCA standard specifies [3] the delivery of power on a backplane connector (tongue 1) physically separated from the one devoted to clock distribution (tongue 2). The development of a base board to provide power to the clock card was therefore necessary (Figure 4). The availability of space on the base board allowed the implementation of additional test features, extender like, for backplane high-speed connectivity characterization. Evaluation of the I^2C control bus for Intelligent Platform Management Interface (IPMI) [4] used for shelf management in uTCA systems had been also predisposed.

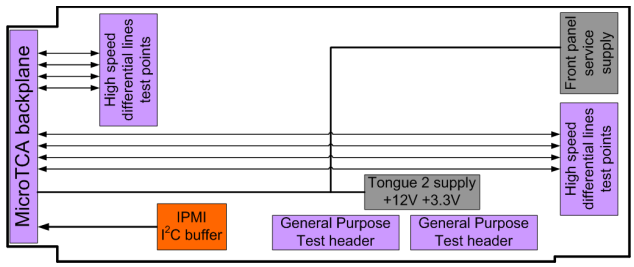

Figure 4: MiTiCH MCH tongue 1 block diagram.

MiTiCH Block Diagram

MiTiCH is a MicroTCA Timing Central Hub (Figure 5) [8] compliant to the uTCA mechanical specifications for MCH tongue 2. Its purpose is the synthesis and distribution of clock signals. To enhance its flexibility, a future revision of the card will host a vector modulator for RF phase control up to S-Band. The key component is an AD9516-4 frequency synthesizer, controlled by a microcontroller, interfaced to the network via a Lantronix. Two stages of fanout buffers distribute two frequencies to up 12 AMC modules on the backplane.

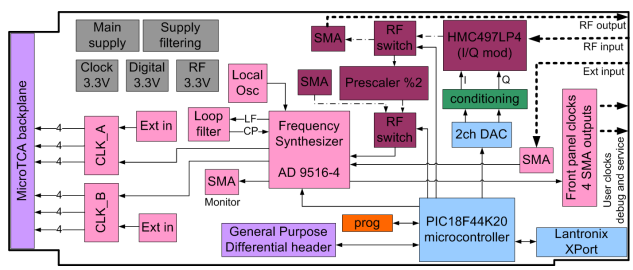

Figure 5: MiTiCH MCH tongue 2 block diagram.

The Charge Pump feedback filter circuit of the PLL can be tuned onboard changing its passive elements; alternatively the internal VCO can be controlled with an external voltage. Characteristics of the circuit can by comfortably studied with the Analog Devices ADIsim-CLK™ tool. Frequencies can be derived either from internal oscillators or external references.

FIRMWARE AND CONTROL SOFTWARE

The idea behind the **firmware** architecture (Figure 6) for both the A|D|A and the A|D|O cards is to provide black box core logic to support a user space containing application specific functions. Three blocks had be identified and developed separately. (i) The control and monitoring block interfaces the card to the controls network. Data flows through an internal memory mapped RAM based space, providing an independent and well defined separation between the different blocks. (ii) The interface layer consists of a series of buffers controlled by state machines collecting and storing data to and from the digitizers. (iii) The clock and timing section exploits digital clock management.

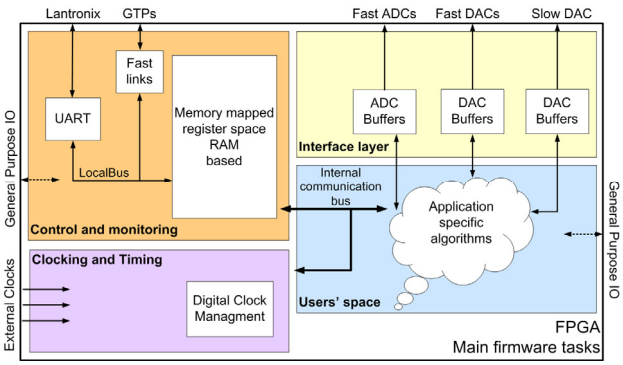

Figure 6: block diagram of the firmware sub-modules.

The **control network** bunch-by-bunch acquisition system for both monitors is based on VME PowerPC field stations. Each crate hosts a MVME7100 board running Linux with the Xenomai realtime extension and Tango control system software. One of the four Gbit Ethernet ports onboard is reserved for A|D|O and A|D|A communication. Upstream, at each machine shot, the AMCs acquire information from the field and transmit it to the control system via UDP/IP. A Xenomai real-time task running at the kernel level extracts from a dedicated Ethernet port, directly from the interrupt handler, the UDP data payload and performs further computation. A Tango server exports to the control system level the information collected by the real-time task. Downstream, a Tango server can interact with hardware; e.g. in the C-BPM case two slow loops regulate the amplitude of calibration signals and the gain level of analog front-ends.

BACK-END SYSTEMS COMMISSIONING

During the commissioning of the FEL, the diagnostics monitors based on the uTCA back-end were installed and put into operation. The following paragraphs will describe each specific application goal and achievements.

The BAM Case

Figure 7 shows a block diagram of a complete BAM station. In this setup, the back-end enclosed in a 1U uTCA crate consists of: one A|D|A, 1 Signal Conditioning Board (SCB) STM [1], and two 12 GHz photo-diodes.

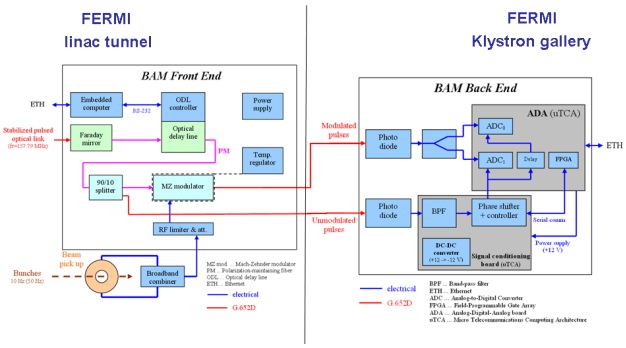

Figure 7: BAM system architecture.

The goal was to deliver three stations to characterize the FEL measuring its beam arrival time in strategic locations, with an accuracy of less than 20 fs. Major problems due to EMI interference inside the uTCA crate, forced designers to split the functionalities in separate crates. A custom chassis hosting the SCB and the Photodiodes had been therefore built. Installing two stations the goal of demonstrating the system principle was accomplished successfully, and an average system resolution of 7.66 fs was confirmed. Using BAM stations, measurements of the machine bunch compressor and some studies on the linac stability performance are now routine tasks of operators.

The C-BPM Case

In order to operate a C-BPM station the following modules are required: one A|D|A, one A|D|O, one MiTiCH, one OptioIO STM [2]. In this configuration, the back-end system enclosed in a 9U uTCA crate can host up to 3 C-BPM stations (Figure 8). The MiTiCH and one of the two A|D|A are shared between two monitors. The goal set was the delivery of 10 stations to operate the FEL with a beam position measurement of 1 um or better.

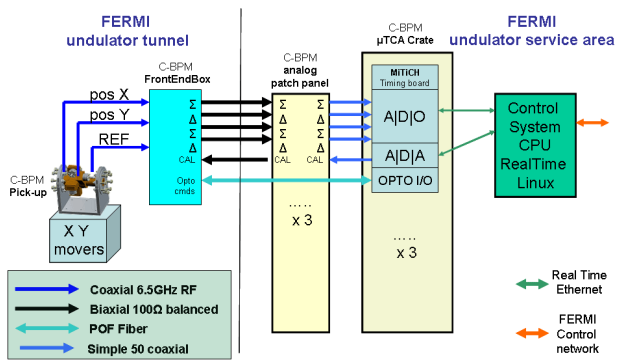

Figure 8: C-BPM system architecture.

EMI problems caused by the uTCA original 220 VAC PSU forced its replacement; no other issues were experienced in this case. All planned systems were installed and successfully commissioned delivering monitors with an average resolution of 1.7 um. Exhaustive documentation on system calibration and position calculation can be found in [9] and [10].

To meet the final resolution specification, further fine tuning of the frontend electronics is planned. The instruments had been of fundamental importance to transport the beam along the undulator chain to achieve FEL light in December 2010. Beam transport and fast trajectory feedback [11] are now control room routine operations based on these devices.

OTHER UTCA DEVELOPMENTS

For future system enhancement and to fulfil complete standard compliancy, other system features were tested. Figures 9-10 show a schematic view of two uTCA advanced functionalities:

1. Intelligent Platform Management Interface (IPMI)
2. Fast backplane connectivity to a CPU via PCI Express

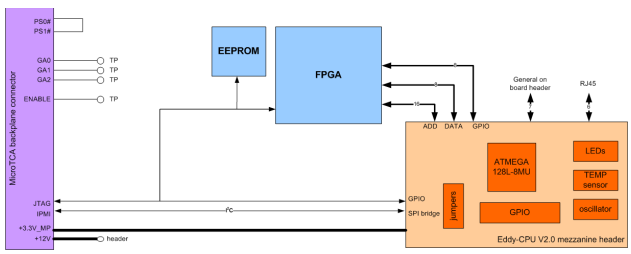

Figure 9: IPMI AMC controller .

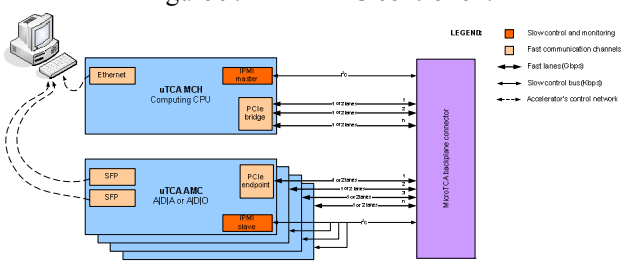

Figure 10: Fast AMC connectivity.

In collaboration with DESY in the framework of the IR-UV-X EuroFEL-PP, the above tasks were successfully carried out on an intensive measurement session at Elettra. (i) An Atmega 128L-8MU evaluation kit, wired to and A|D|O, proved the capability of the board to communicate to a commercial N.A.T. MCH for shelf management: hot swap and basic current and temperature readout and monitor were performed. (ii) A|D|O was successfully capable of transferring and receiving data via PCI Express to an ADLink CPU AMC1000 (Intel x86 64bit) and Sanblade SATA HDU, at a rate of 4 lanes at 2.5 Gbps (10 Gbps). The operating system and drivers used for the test were Linux based.

FIELD EXPERIENCE WITH UTCA

In general, the choice for uTCA as system architecture had been proved to be correct. It is a robust and reliable platform (5 machine runs without faults) handy to service and maintain. Especially working in the laboratory with its advanced functionalities, we had the chance to thoroughly explore the technology's potentials. EMI weakness in the crates evaluated were unexpected. Never the less the problems have been tackled and solved. We hope, especially in view of the physics extension (xTCA), that extra care on those issues will be taken by crate manufactures. We firmly believe that uTCA as is, will remain a valuable alternative for small scaled systems or modular systems were integration on AdvacedTCA (ATCA) blades is possible.

CONCLUSIONS AND OUTLOOK

Presently all systems required to operate the first FEL line (FEL1) of FERMI had been successfully installed and almost all commissioned. The total number of cards produced and tested sums up to 24 A|D|A, 18 A|D|O, and 4 MiTiCH. The number of uTCA crates on the field is 6. Those numbers will soon grow as the second FEL line will be commissioned. The platform and its modules are solid foundations for R&D in the digital electronics domain that we wish will continue also in the future.

ACKNOWLEDGMENTS

The author thanks all the Colleagues from the Timing and Diagnostics group at Elettra for the great professional collaboration and the pleasant social company. Special thanks to Mauro Pontremoli, TVR S.r.l, SCEN S.r.l, Officine Barnobi, and Piergiorgio Tosolini. Thanks to Patrick Gessler (and DESY) for the fruitful information exchange on uTCA related issues and developments.

SOLID STATE DIRECT DRIVE RF LINAC: CONTROL SYSTEM

T. Kluge, M. Back, R. Fleck, U. Hagen, O. Heid, M. Hergt, T. Hughes, R. Irsigler, J. Sirtl
Siemens AG, Erlangen, Germany
H. Schroeder, ASTRUM IT GmbH, Erlangen, Germany

Abstract

Recently a Solid State Direct Drive® concept for RF linacs has been introduced [1]. This new approach integrates the RF source, comprised of multiple Silicon Carbide (SiC) solid state Rf-modules [2], directly onto the cavity. Such an approach introduces new challenges for the control of such machines namely the non-linear behavior of the solid state RF-modules and the direct coupling of the RF-modules onto the cavity. In this paper we discuss further results of the experimental program [3] [4] to integrate and control 64 RF-modules onto a lambda/4 cavity. The next stage of experiments aims on gaining better feed forward control of the system and on detailed system identification. For this purpose a digital control board comprising of a Virtex 6 FPGA, high speed DACs/ADCs and trigger I/O is developed and integrated into the experiment and used to control the system. The design of the board is consequently digital aiming at direct processing of the signals. Power control within the cavity is achieved by an outphasing control of two groups of the RF-modules. This allows a power control without degredation of RF-module efficency.

MATERIALS AND METHODS

The system decomposition as shown in Figure 1 separates the system into two sub-systems, the control system and the cavity system (all block-diagrams are SysML [5] internal block diagrams (ibd)).

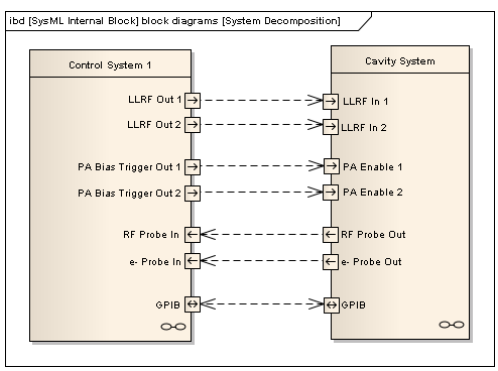

Figure 1: System Decomposition.

The cavity system (Figure 3) contains a 150MHz lambda/4 resonator that has a circumferential slot that separates the resonator into two conducting parts electrically isolated from each other. The current on the inner resonator wall is driven by a number of RF-modules each of which utilizing 8 SiC transistors in a parallel push-pull configuration for amplification of the drive signal. The power for the pulsed operation of the RF-modules is stored in a capacitor bank on the RF-module that is charged by a high voltage power supply unit (HVPSU). The charging voltage can be controlled by the control software. The drive signal for the transistors on the RF-modules comes from a pre-amplifier stage (PA) that amplifies the low level RF (LLRF) signal, splits and phase-shifts the amplified signal and adds a bias voltage to each output thus providing two ($\pm$180) drive signals for each RF-module. The operation point of each PA has to be set with a trigger pulse that starts before the LLRF arrives and stops after it. A calibrated antenna measures the electrical field in the cavity and is also able to detect currents caused by field emission, multipacting, ionization effects and field break-downs. We grouped the RF-modules into two groups allowing individual LLRF signals for each RF-module group (for reasons described later).

The first stage of experiments focused on demonstrating power combining and stable operation of the RF-modules on the cavity. Results with 32 RF-modules have been published in [3] and [4]. Since then the experiment has been moved to a new bunker and upgraded to run with 64 RF-modules in order to achieve higher electrical fileds within the cavity.

The analog control system for driving these experiments is depicted in Figure 2. It uses an Agilent N5181A MXG Analog Signal Generator to provide an RF-pulse with a certain frequency and amplitude set by the control software. The length of the RF-pulse is controlled by a trigger. The signal is split up in order to provide both (identical) LLRF output signals. The NI-Rack is a National Instruments (NI) PXI-1042Q chassis that hosts the control computer (NI PXI-8110 controller) and the timing system (NI PXI-7851R FPGA and NI PXI-6653 timing module). The timing system provides a clock signal and freely programmable triggers with 25ns resolution. The two oscilloscope are LeCroy Wave Runner 104MXi-A. Scope1 is software controlled and serves as a data acquisition device, the LLRF signal and the probe signals can be read by the control software. Scope2 independently of the control system software shows control signals from the system. The custom made breakout box optically decouples the NI rack from the experiment.

Figure 5 illustrates the control software concept. A LabVIEW [6] program with a graphical user interface (GUI) has been used for controlling the experiment. It takes care of all configuration and persistent data storage issues. Interactive operation of all software controlled devices can be achieved by device specific dialogs. The configuration scheme of the program allows it to easily add extensions (applications) that perform automated tasks.

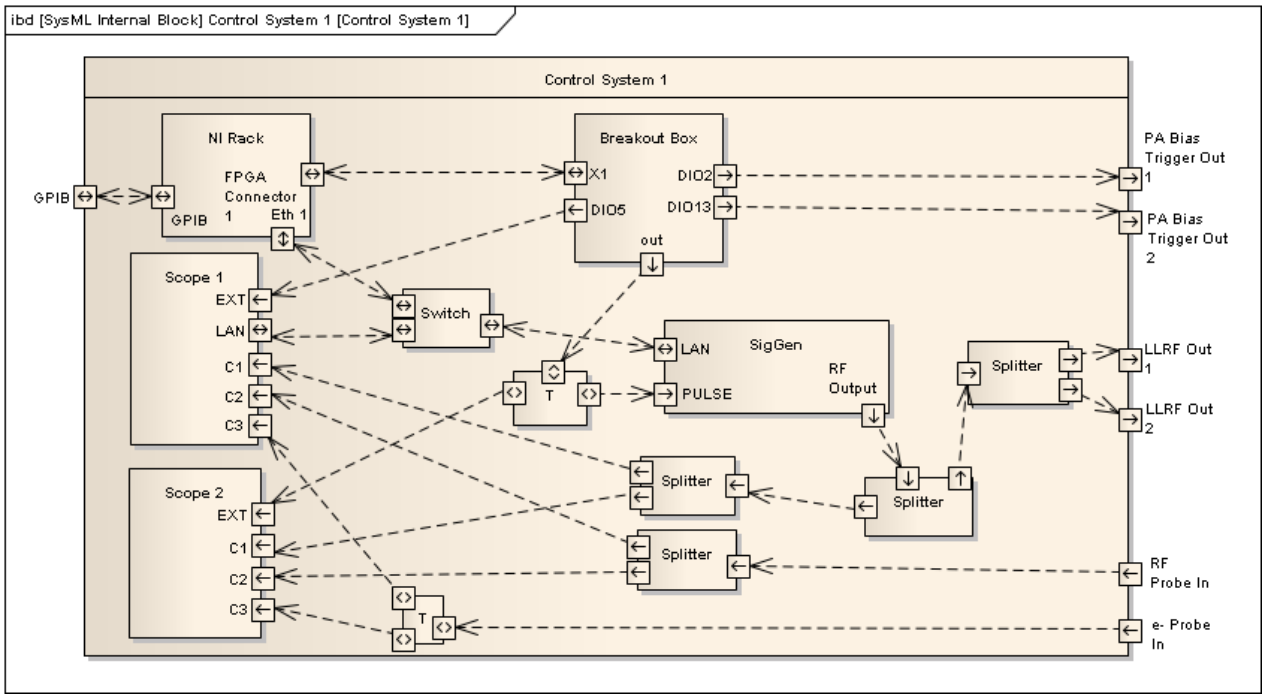

Figure 2: Analog Control System.

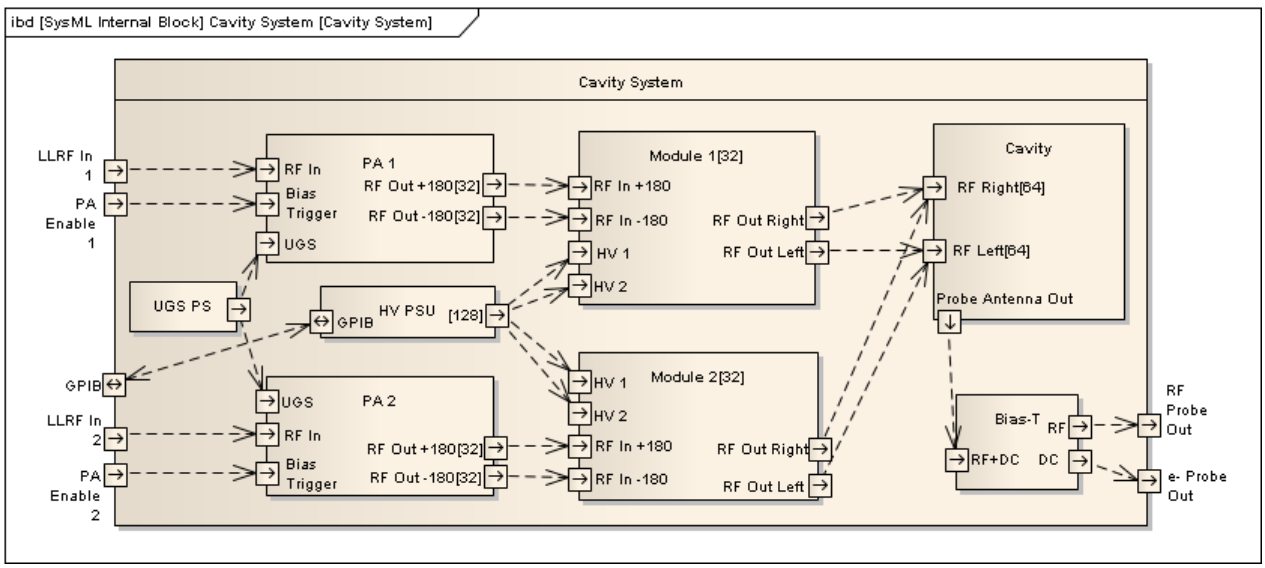

Figure 3: Cavity System (to control two groups of RF-modules).

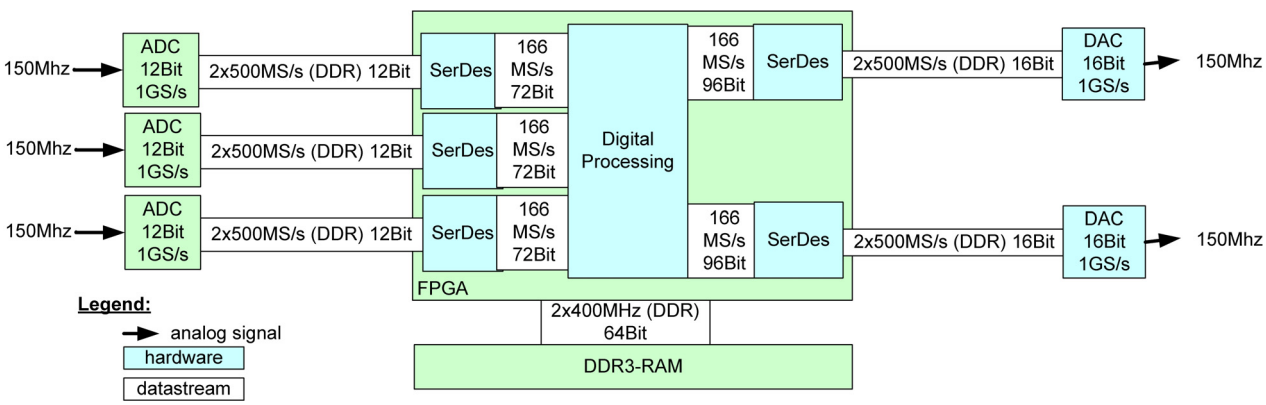

Figure 4: Data streams in the SCCRT.

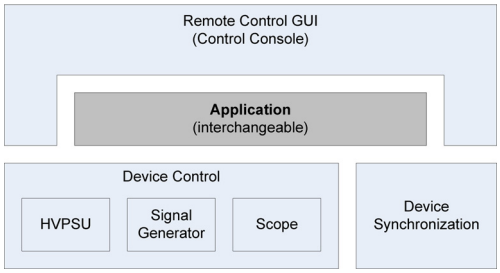

Figure 5: Control Software Concept.

Operating the directly driven cavity within the contect of an accelerator requires the ability to create an E-field with pre-defined and stable amplitude, frequency and phase during the whole particle injection phase of a macro-pulse. The analog control system used for the RF-module integration does neither have the control capabilities nor the timing accuracy required to achieve this.

The semiconductor driven RF-modules are non-linear time variant devices. In particular, the output power decreases over time due to discharging of the capacitor banks and self-heating effects of the SiC transistors during the pulse. The SiC RF-modules have their highest efficiency at maximum output power. In order to preserve the high RF-module efficiency while controlling the power fed into the cavity we are aiming at an outphasing control [7] like illustrated in Figure 6. Two groups of RF-Modules are driven separately with phases φ_1 and φ_2 and maximum output amplitude V_0. The cavity gap works like a combiner and inserts only the vector-summation V_{res} and φ_0 where

$$V_{res} = V_0 \cos\left(\frac{\varphi_1 - \varphi_2}{2}\right) \quad (1)$$

and

$$\varphi_0 = \frac{\varphi_1 + \varphi_2}{2}. \quad (2)$$

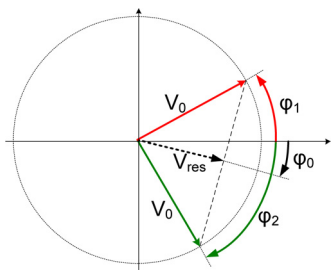

Figure 6: Outphasing Control Concept.

This requires that the control system can provide two LLRF signals that at least differ in their phases. We also would like to run measurements for detailed system identification. So we have to be able to acquire probe signals from the cavity and in the future also from the individual RF-module groups. We are expecting that these signals will have to be used in the future in order to realize a feedback control loop for increasing the accuracy of the cavity field. Therefore we decided to build a digital control system component called SCCRT (subsystem cavity controller real time) that gives us the required LLRF control and data acquisition capabilities and flexibility. The data streams in the SCCRT are illustrated in Figure 4. The core of the system is a Virtex 6 FPGA running at 166MHz. We have two RF output channels and three RF input channels for data acquisition. The 16 bit DACs and the 12 bit ADCs are running at 1GHz allowing the system to be used for RF frequencies up to 500MHz. The DDR RAM can be used for storing pre-defined RF-shapes and also for storing acquired RF and logging data.

The SCCRT furthermore can provide output trigger signals for synchronization of cavity system components. External events should be recorded and processed by the SCCRT as well, so the SCCRT also has input triggers. By handling all timing relevant issues within a single component we are aiming at maximum accuracy and minimum jitter. The SCCRT contains an internal 1GHz master clock.

The first revision of the SCCRT has recently been introduced in detail in [8].

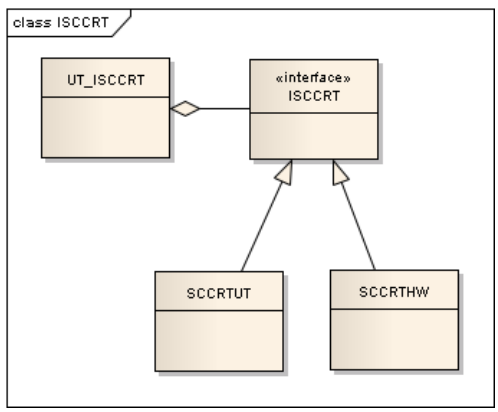

Figure 7: SCCRT Driver Class Diagram.

A LabVIEW [6] object oriented driver interface class (ISCCRT) has been used for defining the functionality and the programming interface for the first revision of the SCCRT, see Figure 7. The first driver client implemented is the class UT_SCCRT that provides a graphical user interface (GUI) for interactive tests of the driver. The class SCCRTHW provides the "real" driver communicating with the hardware while the class SCCRTUT is an implementation intended for validating that the unit test GUI is working correctly. Like intended, the use of the interface class allowed us to separate and parallelize the development of the software components. So the test GUI was available when the first hardware samples have been ready.

The next stage of experiments will start with the integration of the SCCRT into the control system replacing significant parts of the analog control system (see Figure 8).

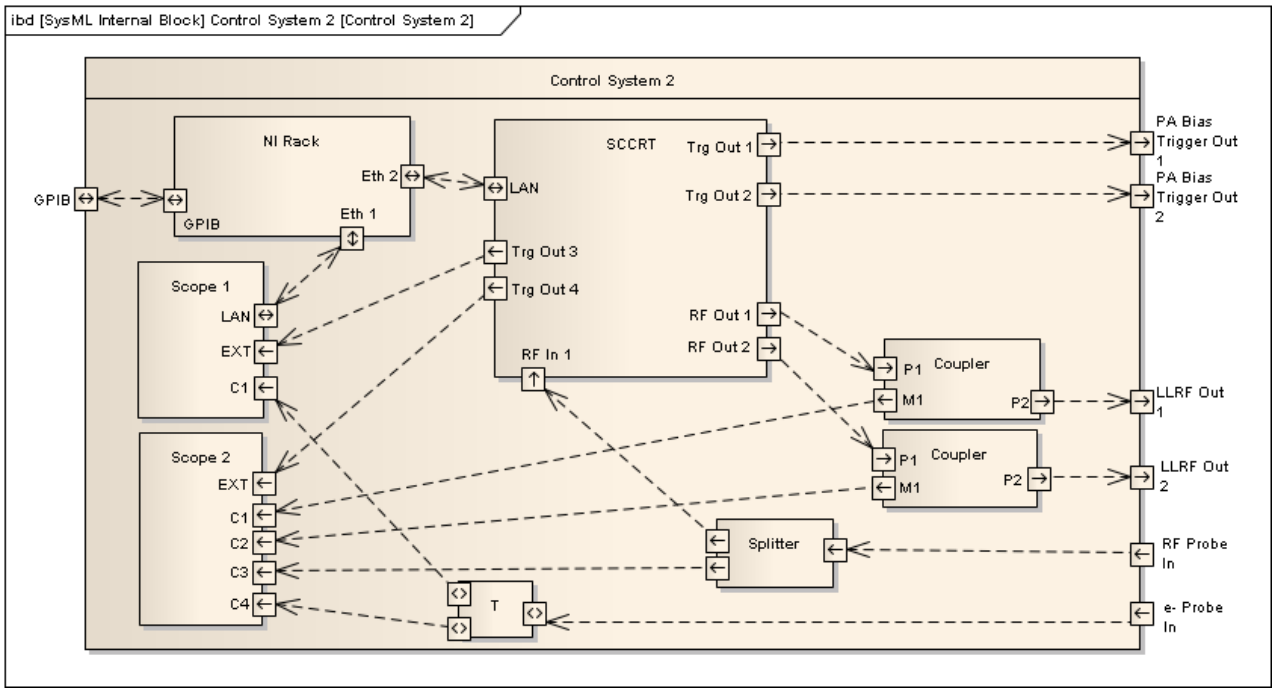

Figure 8: Digital Control System.

RESULTS

First commissioning tests with the 64 RF-modules have been carried out using the analog control system. At 150MHz and a RF-module supply voltage of 160V we have measured an E-field inside the cavity gap of approximately 66MV/m and a transmitted power of approximately 120kW.

The first revision of the SCCRT hardware has been assembled, the FPGA code is developed as well as the LabVIEW driver code. We have started the unit tests of the SCCRT.

NEXT STEPS

- Complete integration of the digital control system.
- The digital control system will be used for testing the outphasing amplitude control approach.
- The digital control system should be used for system identification purposes for gaining information for regulator design.
- The FPGA on the digital control system will be reprogrammed in order to support a closed loop operation with a PI regulator.
- Power injection tests with higher RF-module supply voltages should take us to the electrical field breakdown limits.

ETHERBONE - A NETWORK LAYER FOR THE WISHBONE SoC BUS

M. Kreider, W. Terpstra, GSI Helmholtz Centre for Heavy Ion Research, Darmstadt, Germany
J. Lewis, J. Serrano, T. Włostowski, CERN, Geneva, Switzerland

Abstract

Today, there are several System on a Chip (SoC) bus systems. Typically, these buses are confined on-chip and rely on higher level components to communicate with the outside world. Taking these systems a step further, we see the possibility of extending the reach of the SoC bus to remote FPGAs or processors. This leads to the idea of the EtherBone (EB) core, which connects a Wishbone (WB) Ver. 4 Bus via a Gigabit Ethernet based network link to remote peripheral devices.

EB acts as a transparent interconnect module towards attached WB Bus devices. Address information and data from one or more WB bus cycles is preceded with a descriptive header and encapsulated in a UDP/IP packet. Because of this standard compliance, EB is able to traverse Wide Area Networks and is therefore not bound to a geographic location.

Due to the low level nature of the WB bus, EB provides a sound basis for remote hardware tools like a JTAG debugger, In-System-Programmer (ISP), boundary scan interface or logic analyser module. EB was developed in the scope of the WhiteRabbit Timing Project [1] (WR) at CERN and GSI/FAIR, which employs GigaBit Ethernet technology to communicate with memory mapped slave devices. WR will make use of EB as means to issue commands to its timing nodes and control connected accelerator hardware.

PURPOSE

EB is a network protocol meant for fast, low level software to hardware or hardware to hardware communication. It connects two distant WB SoC buses and is capable of direct memory access to attached devices. EB shall be used in GSI/FAIR and CERNs timing nodes as well as for remote debugging and programming, making hard to reach embedded systems easier to deploy and maintain.

RELATED WORK

There are many different examples of protocols for direct data exchange available. Among the most commonly used low-level were Myrinet in the supercomputing sector (almost completely replaced now by Ethernet based equipment) and different Remote Direct Memory Access (RDMA) [2] implementations. While there are pure software implementations of RDMA, their latencies cannot compete with hardware implementations like Infiniband [3] or iWARP [4], which can can achieve latencies below 7μs. However, these are mostly optimised for maximising throughput, while latency is still a secondary factor. There are also high level protocols available like CORBA [5] and SOAP [6], which aim for abstract software to software communication in heterogeneous environments. While being very versatile, due to their higher logistics overhead and generic nature, they are not well suited for fast communication between hardware and hardware or hardware - software. All of the above have in common that they are not tied to a specific underlying bus protocol of their endpoints. While they of course keep data content, they will not preserve syntax during transport.

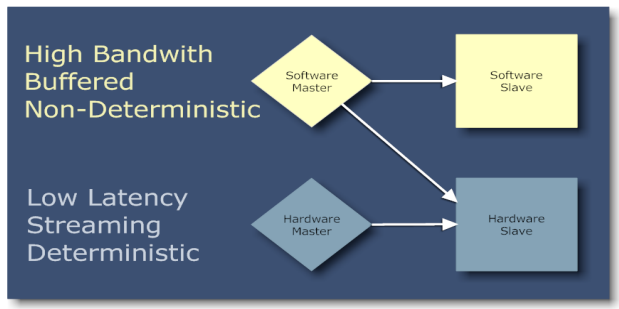

Figure 1: Compatibility between EB node types.

ARCHITECTURE

General Considerations

Since bus protocols can differ quite strongly in their workings and packet layout, conversion between them can severely reduce fidelity. For EB, we therefore chose Wishbone V4 as a concrete bus implementation, while leaving the underlying transport protocol open. There are two categories of EB devices under development: Buffered, non deterministic software modules and low-latency, deterministic streaming hardware cores (Fig. 1).

Software nodes are used for all applications where determinism and latency are not the main issue, but interoperability and fidelity of bus signals are. One example would be a developer's computer, remotely connected to the JTAG module of an embedded system elsewhere on the premises. Figure 2 shows an example block diagram of such a setup.

Hardware nodes operate in full streaming mode, They are fully deterministic and made to cut latency down to the minimum. An application example would be an endpoint of a timing system, receiving commands to generate a pulse at a specific execution time. The deterministic characteristics of EB ensure that available time frame for delivery does not vary, while streaming provides low latencies, reducing the time the control system needs to buffer. Hardware implementations are of course not as flexible as software.

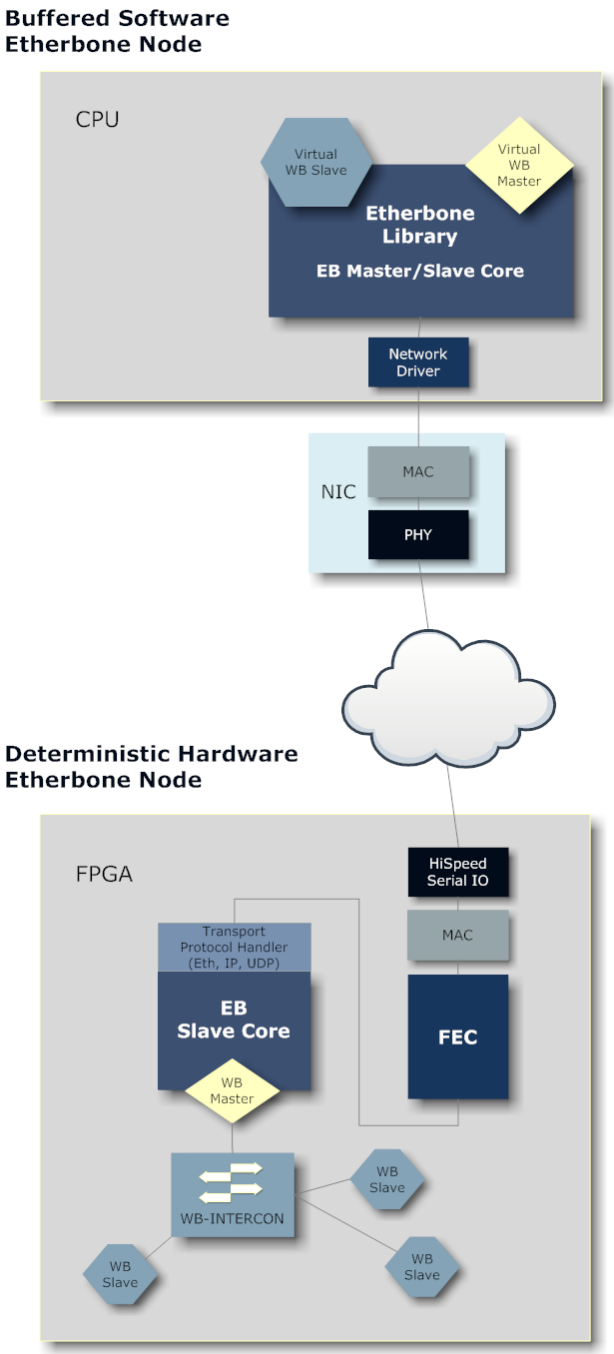

Figure 2: EB Slave node.

Methods and Test Implementation

Our current SW/HW test implementation utilises UDP/IP as a transport protocol. As a requirement, EB needs duplicate free transmission, which UDP alone cannot guarantee. It is therefore assisted by a Forward Error Correction (FEC) Scheme on OSI layer II. In order to be fully deterministic and to achieve lowest latency possible, EB needed to be fully streaming capable, ideally introducing no additional delay to passing data. A hard timeout is enforced when waiting for replies to EB requests, depending on the given time frame. The main problem is in the IP and UDP packet headers, which contain length information and checksums on the payload. On the Ethernet layer for example, the Cyclic Redundancy Check (CRC) follows the payload, so on the fly processing or insertion is not a problem. This is not the case with UDP/IP, where prior knowledge about the payload is necessary. For low latency streaming, we had to resolve the dependencies between packet header and payload. An example for a concrete implementation can be found in Figure 3, showing the internal layout of the Hardware Description Language (HDL) of a deterministic EB slave node.

Like the underlying WB bus, EB has master and slave nodes [7], which form complementary pairs. This leads to a bridge architecture, where an EB master accepts bus operations from local WB masters for transfer to a remote node. EB slaves therefore have a WB master interface and form the remote representation of the local WB master.

TRANSPORT PROTOCOL

The EB protocol has been designed to be deterministic with a focus on minimal latency. It also needed to be able to use standard transport layer architectures. Since WR utilises Ethernet technology, making EB interoparable with GigaBit Ethernet standard was an obvious choice in the development. Raw Ethernet frames however were not an option, because they cannot pass routers and firewalls without special configuration. So a widely supported protocol with very low overhead was needed, and the choice fell to UDP [8].

Packet Length

The UDP/IP Header requires packet length fields before the payload. To avoid waiting for packet completion, streaming EB replies are the same length as the corresponding request, making the full header knowable in advance. EB counters every incoming read operation by an outgoing write operation, while incoming Writes are answered with zero padding. Without any need for exceptions to the rules, these are treated as empty EB records, the result is similar to a no-operation instruction in a CPU.

Checksums

The IP checksum is only dependent on fields of the IP header. This includes source and destination address, IP packet options and the packet length field. When replying to a request, almost all information required can be taken from the incoming packet header, except for length fields, source IP address, IP checksum and UDP port. Source address and port are already known to the node, which leaves the payload length and the checksum itself [9]. Due to the symmetry we introduced, length is also known in advance and the IP checksum of the reply can be already be calculated after header reception. With this, all reply header information is available at the beginning of the incoming

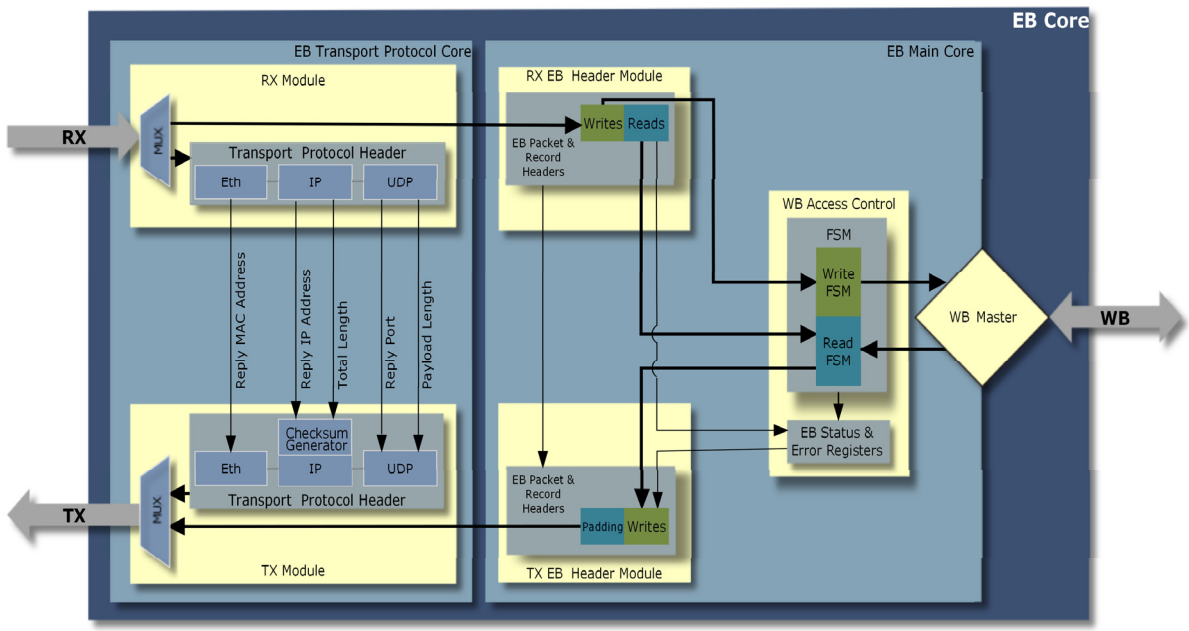

Figure 3: EB Slave node.

payload. This eliminates all wait times for payload reception, trading bandwidth for latency. The UDP Checksum is purely dependent on payload, but UDP protocol specifications allow the checksum to be set to zero. This signals the recipient "not used" [8]. Since we use a more powerful FEC in addition to the CRC, the UDP checksum can be omitted without risking data integrity.

ETHERBONE STRUCTURES

Packet Layout

A full EB Datagram is shown in figure 4. It consists of a header block and one or more record headers with matching Write or Read operations.

The header block starts with a magic word and two bit masks, used to signal the used WB bus width and address size. There is also the option to set a probe flag, which is used for negotiation of usable bus and address widths between two devices. A Probe-packet is always padded to the maximum alignment, 64 bit in our test case to ensure compatibility.

A record header contains a set of flag bits, stating optional information about source and destination, like the use of FIFO mode, etc. The flags are followed by the number of write and read operations in the record, this can be a number between zero and 255 if no feedback is necessary (assuming sufficient free space in the packet). If the bus is wider than the record header, it will be padded.

After the record header follow bus operations, Writes first, then Reads. Bus Operations are not mandatory, an EB record can therefore be empty, contain Writes, Reads, or both. Each of these blocks is preceded by an address field. For a Write, this field signifies the target start address on the slave; for a Read it is the address to which the read values shall be written to on the master.

Communication

Negotiation A typical EB connection starts by sending a probe packet to a slave. It solely consists of the header block with all possible bus and address sizes the master supports and a set probe flag. The slave then sends back the intersection of the offered modes and the one it supports itself. The result shows all possible bus and address widths the EB master can choose from for communication with this particular slave device, completing the negotiation. In the next step, a normal EB packet is sent, containing one or more EB records. The slave will reply with the bus width and address size chosen by the master in the request header.

Atomics EB supports atomic WB bus operations. While the cycle line is held, so is the connection to the target slave through a WB interconnect. Each Etherbone record comes with the option of ending the current bus cycle on completion or keeping it to the next record. With this mechanism, bus ownership can be held over several EB records, avoiding interference to the operation by other bus devices.

Symmetry Equal packet length of in- and outgoing traffic is essential for EB streaming mode. In order to keep equal length between request and reply, results from Reads are converted to write operations while Writes are turned

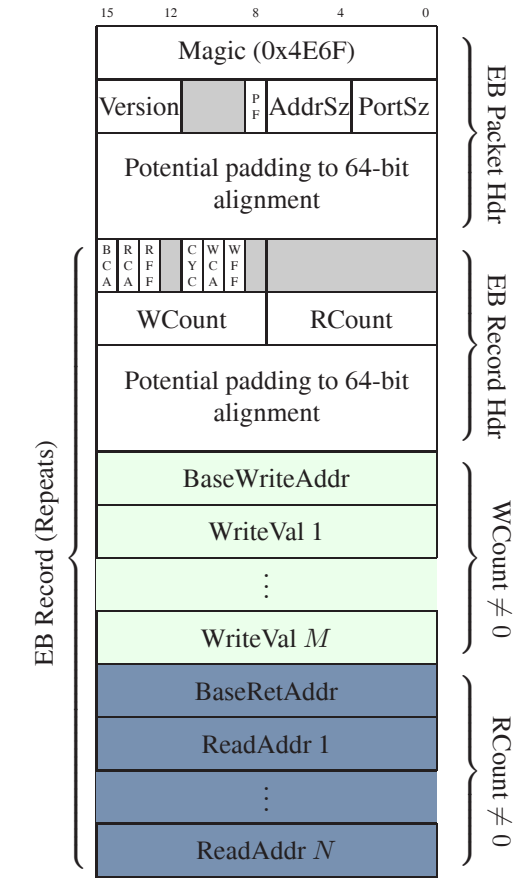

Figure 4: Etherbone v0.2 Message Format.

into empty Records, i.e. padding. This makes the length field of UDP/IP headers known in advance and resolves all header/payload dependencies.

Addressing EB Write operations are Values to be written, while Reads are addresses to be read. Write addresses therefore need to be generated by an increment to the start address. This increment can either be zero, in which case the target is treated as a FIFO, or match the byte alignment master and slave agreed on. This implies Writes to be sequential, while Reads can be random access. A WB master must keep track of read addresses in order to correctly interprete the answering Write.

Management EB also supports the use of a configuration space, an address space that is not associated with the local WB bus and only concerns the EB node itself. Here, settings like the MAC address or status information like the error log are kept. If the flag is set, all following operations will not be put on the bus but will point to the config space instead. If feedback for success of operations is required, a shift register in the config space can be read to supply the error bit for the last 32 operations on the WB bus interface.

CONCLUSION

Time driven HDL simulation and minor tests on evaluation boards for GigaBit Ethernet links show possible latencies below 1 μs. Further tests on final WR hardware later this year have yet to confirm these values, but intermediate results show EB as a well suited candidate for control systems and remote tools alike.

OUTLOOK

With open EB hardware and software implementations becoming available as open source projects, chances for it becoming a widely accepted WAN remote bus protocol within the timing and control systems community are increasing. Our next task will be full integration with GSI and CERN's next generation timing system. For GSI, this will happen on the example of a proton linear accelerator, the first component to be deployed in GSI's FAIR extension. Next steps will be the completion of a remote toolbox, containing an ISP and Debugger for use with our network capable embedded systems.

Abstract

The Large High Altitude Air Shower Observatory (LHAASO) project is designed to trace galactic cosmic ray sources by approximately 10,000 different types of ground air shower detectors. Reconstruction of cosmic ray arrival directions requires a precision of synchronization down to sub-nanosecond, a novel design of the LHAASO timing system by means of packet-based frequency distribution and time synchronization over Ethernet is proposed. The White Rabbit Protocol (WR) is applied as the infrastructure of the timing system, which implements a distributed adaptive phase tracking technology based on Synchronous Ethernet to lock all local clocks, and a real time delay calibration method based on the Precision Time Protocol to keep all local time synchronized within a nanosecond. We also demonstrate the development and test status on prototype WR switches and nodes.

INTRODUCTION

Gamma ray source detection above 30TeV is an encouraging approach for finding galactic cosmic ray sources. All sky surveys for gamma ray sources using a wide field of view detector is essential for population accumulation for various types of sources above 100GeV.

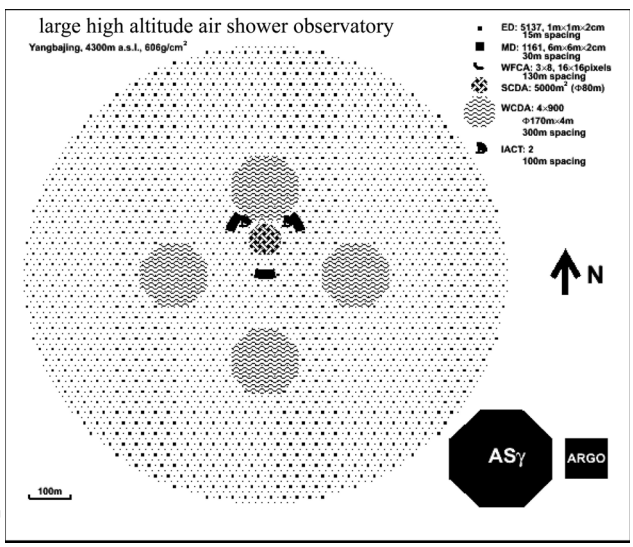

Figure 1: Layout of LHAASO observatory.

In order to target those objects, a large air shower particle detector array of 1Km^2 (the LHAASO project [1]) at 4,300 m a.s.l. is proposed, which is designed to cover a wide energy region from 30TeV to few EeV by combining together with many air shower detection techniques. The layout of the LHAASO observatory is shown in Fig. 1.

- KM2A: particle detector array with an effective area of 1km^2, including 5,137 scintillator detector (1m^2 each) to measure arrival direction and total energies of showers; 1,200 μ detectors to suppress hadronic shower background.
- WCDA: water Cherenkov detector array with a total active area of 90,000m^2 for gamma ray source surveys.
- WFCTA: 24 wide FOV Cherenkov telescope array
- SCDA: 5,000m^2 high threshold core-detector array.

To reconstruct the direction of cosmic rays, the arrival time difference of shower particles to each individual detector is measured using a uniform clock frequency. Differing from the classical structure which uses a central trigger as a common stop for measuring arrival time difference [2], a readout scheme without the central trigger is expected which means each individual detector will be self-triggered and the event must be precisely time tagged with a common time stamp reference.

Considering the pointing accuracy in reconstruction and the dimension of the detector array, a clock and time system is required to distribute time and clock to 10,000 nodes within 1 square Km area. Each node must have a local clock which is locked to a primary reference clock and have a local time with an accuracy of less than 1ns relative to the common reference.

There are also other considerations for this time and clock distribution system. Since it is neither practical nor realistic to manually calibrate the cable length of thousands of detectors, the system must have the capability to automatically calibrate and compensate the propagation delay caused by different cable length, temperature and mechanical stresses variation. The system should also be low cost, high reliable and low power consumptive.

EXISTING TECHNOLOGIES

Certain technologies exist for military, industry and commercial purposes with different features and performances:

- Radio/satellite navigation systems: like radio station, Global Positioning System (GPS), Global Navigations Satellite System (GLONASS), Galileo and Beidou.

*Work supported by Tsinghua University under collaboration with White Rabbit project (CERN) and National Science Foundation of China (No.11005065)
#ggh@tsinghua.edu.cn

- Wireless telecommunication: the commercial wireless telecommunications like CDMA, WCDMA, WiMAX/LTE also provide a time distribution.
- Physical Layer (Layer 1) synchronisation: like SONET/SDH, Gigabit Passive Optical Network (GPON), and Synchronous Ethernet.
- Packet-based synchronisation: like NTP, IEEE1588-2008 PTP, Circuit Emulation Services (CES) encapsulation and the future UTI J.211 from ITU-T.
- Ethernet based real-time network: like ProfiNet, EtherCAT, SERCOS III, INTERBUS and etc.

Method	Ability	Accuracy jitter	Medium	Layer	Complexity	Manageability
Radio Clock	Time	10ms	Wireless	Layer 1	Simple	No
NTP	Time	1ms	Wireless	Layer 3	Complex	No
CDMA	Time/Freq	10μs	Wireless	Layer 2	Complex	?
WCDMA	Time/Freq	3μs	Wireless	Layer 2	Complex	?
WiMAX/ LTE	Time/Freq	1μs	Wireless	Layer 2	Complex	?
GPS	Time/Freq	14ns	Sat – earth	Layer 1	Simple	No
PTPv2	Time	~ns	Ethernet	Layer 2	Complex	Yes
UTI J.211	Time/Freq	1ns	Cable	Layer 1	Simple	Yes
SDH/SyncE	Freq	10ps	Ethernet	Layer 1	Simple	No
White Rabbit	Time/Freq	<1ns	Fiber GBE	Layer 1, 2	Complex	Yes
Optical carrier sync	Freq	<50fs	Fiber	Layer 1	Ultra complex	Yes
Optical Frequency Comb distribution	Time/Freq	<10fs	Fiber	Layer 1	Ultra complex	Yes

Figure 2: Existing time distribution technologies.

Figure 2 lists the major features of several existing technologies. The PTPv2 and SDH/SyncE show the potential capability to be applied for the time and clock distribution in LHASSO project.

Facing the requirement of controlling thousands of nodes over few kilo-meters around large particle accelerate instruments, a novel technology, White Rabbit [3][4][5], has been developed in the frame of CERN's (and GSI's) renovation projects.

The White Rabbit technology shows a great applicability for LHAASO project:

- It can distribute clock and time with required accuracy
- It is possible to extend to 10,000 nodes.
- It has the feature of automatic link delay measurement and compensation.
- It has high reliability to support plug&play, no further tuning needed.
- It is an enhancement of existing data transmission links; does not need dedicated fiber or cable, which is cost effective.

WHITE RABBIT

White Rabbit is a combination and improvement of several technologies including synchronous Ethernet, precision time protocol, DMTD phase tracking and deterministic routing protocol.

Synchronous Ethernet

Synchronous Ethernet is a special extension of standard IEEE802.3 Ethernet standard where the recovered RX clock from its master is used as its own TX clock, making the whole system synchronous. With Synchronous Ethernet technology, the entire network can share a common clock to avoid any clock rate difference between nodes. This is done in hardware and is the basis for the PTP fine measurements.

Precision Time Protocol (IEEE1588)

The PTP [6][7] protocol synchronizes local time with the master time by measuring and compensating the delay introduced by the link. Link delay is measured by exchanging packets with precise hardware transmit & receipt timestamps which is explained in Fig. 3.

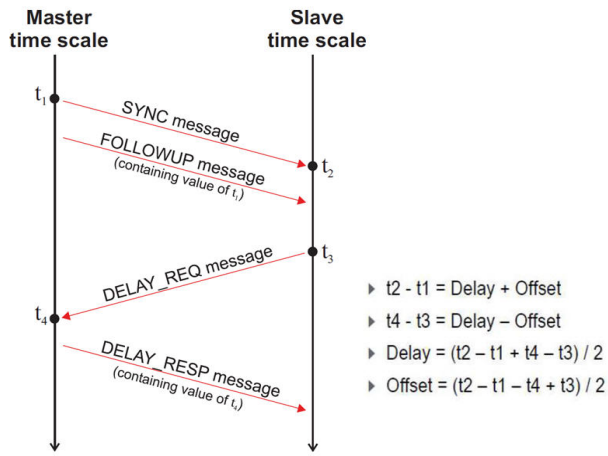

Figure 3: PTP timing process.

The Synchronous Ethernet technology provides the same clock frequency to the whole network which simplifies the PTP calculation that there is no clock rate difference but only time delay.

DMTD Phase Tracking

The measurement of standard PTP is limited by the clock frequency, a fine delay measurement of less than one clock cycle can be achieved by detecting the phase shift between transmit and receive clock on the master side.

A digital Dual Mixer Time Difference [8] (DMTD) clock measuring logic is shown in Fig. 4, which is easy to implement in a modern FPGA device.

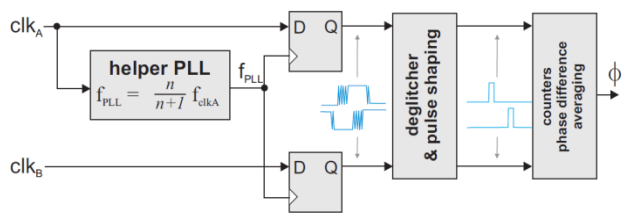

Figure 4: Digital DMTD.

DEMONSTRATION SETUP AND TEST

To evaluate the performance of Write Rabbit technology, a test system has been setup, including one WR switch and one receiver node, as shown in Fig. 5.

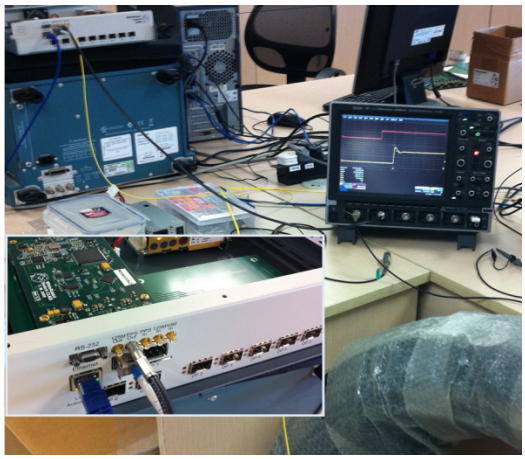

Figure 5: Demonstration setup.

The White Rabbit switch is a standalone device, the receive node is provided as an IP core and is tested on a PCI-E FMC carrier board, as shown in Fig. 6.

Figure 6: Slave node (SPEC).

The delay between the PPS of the switch and the receiver node is measured with a oscilloscope. The results are listed in table 1, which shows that the fiber length difference is transparently measured and compensated.

Table 1: Fiber Length Compensation Measurement

Fiber Length	PPS delay	
	Mean[1]	Sdev[2]
30cm	121.02ns	115.49ps
1km	125.72ns	110.66ps
5km	127.62ns	105.14ps

Note 1: the delay mainly comes from the length difference of the coaxial cables used for measurement.

Note 2: the deviation mainly comes from the test signal drive circuit.

The link was forced to re-establish to verify the stability of the time reconstruction. As presented in table 2, the peak-peak deviation among different runs is less than 100ps. The average shows a slight linear relation with the length of the fiber which is caused by the asymmetric delay factor of the 1550nm and 1390nm lights used for upstream and downstream respectively. This effect can be further reduced by calibrating and tuning a corresponding parameter in the delay calculation, which can be specific for certain optical fiber and transceiver.

WHITE RABBIT DEPLOYMENT IN LHAASO

Since the LHAASO project has around 10,000 nodes to be synchronized, a hierarchical structure of up to 3 levels must be implemented. The synchronization accuracy across multi-level switches is essential for this structure and a test for this purpose will be carried out soon.

Table 2: Repeatability of Recovered PPS (Unit: ns)

#Run	30cm	1km	2km	3km	4km	5km
Run 1	16.05	15.89	15.82	15.78	15.67	15.57
Run 2	16.05	15.92	15.89	15.76	15.64	15.65
Run 3	16.02	15.93	15.86	15.72	15.67	15.65
Average	16.04	15.91	15.86	15.75	15.66	15.62
Peak-Peak	0.03	0.04	0.07	0.06	0.03	0.08
Link delay	473	10305	20145	29969	39801	49641

A Rubidium/Caesium module provides a high accurate clock source as the external reference of the top switch, all the nodes will then trace this clock to recover a local clock; a high-precise GPS receive module provides a UTC time information as well as a Pulse per Second (PPS) signal to the top switch, all detector nodes will follow to re-establish a local time with an accuracy of less than 1ns.

Each type of detector in LHAASO project has its dedicated readout electronics to resolve the specific design issues. To save the cost and man-power of implementing the synchronized clock and time function among all detectors, a LHAASO wide clock and time mezzanine (CTM) will be developed to handle all the delicate details of white rabbit technology, each detector electronics will carry one CTM through a simple and straightforward interface.

The block diagram of CTM is shown in Fig. 7.

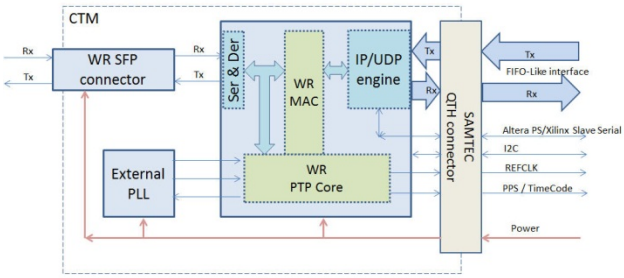

Figure 7: block diagram of CTM.

The CTM contains few major components:

- SFP connector: perform the O/E and E/O conversion.
- External PLL: to improve the precision of clock phase adjustment.
- FPGA: to implement the White Rabbit PTP core IP; it will also include a small IP packet process engine to simplify the interface to external logic as a FIFO. The engine can also provide a FPGA reconfiguration link for dynamic updating of external FPGA.
- Connector: a high-speed type from SAMTEC.

The recovered clock is directly feed to external logic, the time information will be encoded into a wide used format like IRIG-B such that the external logic will treat the CTM as a standard UTC device.

SUMMARY

The future LHAASO project requires high precise time and clock synchronization among thousands of detectors nodes. A novel design based on the White Rabbit protocol that could provide sub-nanosecond precision clock and time stamp distribution over the DAQ Ethernet fiber has been proposed. A preliminary test between a pair of master/slave nodes is presented and shows <0.4 ns rms time jitter between recovered master/slave PPS signals over different fiber lengths.

A REMOTE TRACING FACILITY FOR DISTRIBUTED SYSTEMS

F. Ehm, A. Dworak, CERN, Geneva, Switzerland

Abstract

Today, CERN's control system is built upon a large number of C++ and Java services producing log events. In such a largely distributed environment these log messages are essential for problem recognition and tracing. Tracing is therefore vital for operation as understanding an issue in a subsystem means analysing log events in an efficient and fast manner. At present 3150 device servers are deployed on 1600 diskless frontends and they send their log messages via the network to an in-house developed central server which, in turn, saves them to files. However, this solution is not able to provide several highly desired features and has performance limitations which led to the development of a new solution. The new distributed tracing facility fulfils these requirements by taking advantage of the Streaming Text Oriented Messaging Protocol (STOMP) and ActiveMQ as the transport layer. The system not only allows storing critical log events centrally in files or in a database but also allows other clients (e.g. graphical interfaces) to read the same events concurrently by using the provided Java API. Thanks to the ActiveMQ broker technology the system can easily be extended to clients implemented in other languages and it is highly scalable in terms of performance. Long running tests have shown that the system can handle up to 10.000messages/second.

INTRODUCTION

The Controls Middleware (CMW) project was initiated at CERN [1] in 2006 to provide a unified communication middleware for operating the particle accelerator infrastructure. This includes communication with servers that directly operate hardware sensors and actuators. It enables for example operators in the CERN Control Centre (CCC) to control equipment remotely via in-house developed Graphical User Interfaces (GUI).

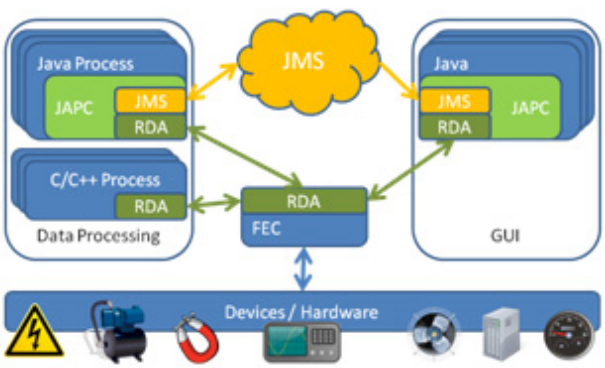

Figure 1: A simplified architectural overview on CERN's control system middleware components.

As illustrated in Figure 1 the CMW middleware is formed by a CORBA-based solution (RDA libraries) and a JMS based messaging infrastructure. Both cover similar use cases but they target at different system environments. JMS is used for high level middleware services and RDA for low level services running on hardware where very low message latency is demanded. The RDA library for example, is required by around 4000 Front End Servers (FES) running on 1600 Front End Computers (FEC) to allow getting/setting of hardware parameter values remotely.

Tracking potential issues in the middleware communication library layer is not an easy task as the involved services are distributed among many machines. In fact, there are two main problems:

- FECs are diskless systems running a real time LynxOS [2] operating system. Because there is no storage media it is not possible to write log messages to a local file.
- For other services which do have local disk storage it is difficult to correlate log events among them because files are distributed on various machines. Hence, accessing the data is a time consuming manual operation and slows down problem analysis.

Therefore, in the early days of CMW the idea of having a remote tracing facility was initiated and implemented. It allows collecting log events coming from RDA servers and from a subset of the middleware services.

THE CURRENT SYSTEM

In the current system log events are generated by the FECs and sent via UDP to a Java based central log server in plain text format. This server in turn converts the messages and writes them to a size-based rotating file.

Next to this, the CMW Admin GUI connects to the server and displays the log events received. It also allows setting a new log level via the RDA library remotely.

It is important to mention in this context that the services on FECs are hard real time processes which should be affected as little as possible by any other activity running on the same machine. Therefore, the communication between the CMW modules and the central log server is based on UDP as it is non-blocking.

Since the initial deployment this setup has been very useful for problem analysis and tracing. In particular the fact that a GUI enables a fast and easy information access makes it crucial for operation.

However, the demands have changed over time and the following problems have been identified:

- When setting a new log level in the CMW module all connected CMW Admin GUIs receive messages from the new level.

- Messages are lost due to a single threaded message acceptor in the central server.
- All messages go to one size based rotating file. When one source sends many events there is the risk that messages from other sources will be dropped.
- More messages need to be handled by the system since more services than originally planned are deployed.
- The C++ library only allows sending data to a remote host but not to a local file or to console output.

As a result of these problems it was decided to review and to implement a new central log event service.

REQUIREMENTS

As a first step towards a future solution the following requirements and limitations were defined:

- The new system must support log events from Java and C++ sources. Other languages may be supported.
- For C++ programs a lightweight library with little dependencies providing an easy API for storing events locally and sending them remotely should replace the old one.
- Operation overhead should be as low as possible and sufficient monitoring information must be provided.
- TCP for reliable and UDP for unreliable transport should be supported.
- Backward compatibility to legacy sources must be guaranteed.
- Support for precise timestamp information like microseconds and time zone where applicable.
- The log viewer must be provided as a standalone application, as well as a module which can be integrated into existing Java based diagnostic tools.
- Users should be able to read log messages remotely from a graphical user interface or via a console command *online* and *offline*. Online means that events are passed immediately to the client whereas offline means that the client has to actively poll for new events.

Restrictions

It should be mentioned that restrictions for the new system have also been defined:

- No operation critical system should depend on the distributed log event service.
- Messages may be lost due to inherent characteristics of the UDP transport layer.
- Only services running unattended are targeted to be used. This excludes highly dynamic user programs such as GUI's or console commands.

EXISTING MARKET SOLUTIONS

Collecting and storing log events from processes running on a Linux/Unix system is a well explored area and standardized for example via the widely used *syslog* protocol [3]. Here, processes send messages to a service running locally. The default for most Linux derivatives is *syslogd* which stores these events to local disk or forwards them to a remote syslog service via UDP. Other implementations like *rsyslogd*, *msyslogd* or *syslog-ng* exist and provide more features than syslogd. In addition, there are commercial and non-commercial tools to do analysis on the collected data. They allow an easier access via graphical interfaces (e.g. *Chainsaw* [4]) and partly provide extensive search and trending capabilities (e.g. *LogZilla* [5] and *Splunk* [6]).

Why Can We Not Take Existing Solutions?

As for the acquisition layer some of the present syslog implementations cover parts of the requirements but the main problem resides within the protocol itself. It contains limitations such as the missing support for microseconds and the maximum payload length of 2048 Bytes. Apart from this, none of the present syslog libraries supports setting the log level remotely

As for the C++ logging library there are many solutions available. However, most of them are in an early phase of development, do not support fully the requirements, are not stable enough or their dependencies are not supported on the current FECs.

Most of the existing GUI applications which are able to read events online are language dependent and connect directly to the log source. However, the new system requires reading log events from sources implemented in various languages and forbids direct connection.

Products like LogZilla or Splunk operate offline and provide fully featured tools for analysis and charting. However, they are proprietary solutions and do not allow to be integrated into existing in-house developed tools.

THE NEW ARCHITECTURE

Because there is no existing solution which satisfies the previously listed requirements a new central log event service has been implemented in Java and C++. As Figure 2 shows the *Converters* are responsible for accepting incoming log events, converting them into an internal common message format and sending them to the messaging service where they again can be read out by a *LogReader* or by a simple console reader.

Additionally, selected data may be stored permanently into a database or into local files.

The Log Sources

A program which requires sending data to the central service has two possibilities to do so: the first is the Linux standard syslog protocol and the second the newly developed *CMWlog*. Both can be used from C++ and Java. The main difference is that CMWlog supports microseconds and time zone information as well as TCP and UDP. It facilitates the STOMP [7] message frame and hence, is clear text based. STOMP is an open source protocol chosen for many messaging solutions [8] from various vendors and has gained great popularity in recent

years. Because it is so largely supported it was chosen for this project.

To allow Java based systems without the introduction of a large dependency set a new extension for the widely used Log4J [9] framework has been written.

The New C++ Log Library

CMWlog is a simple but full-featured logging library for C++ programs which - to a reasonable extent - resembles the Log4j Java library, providing flexible logging to files, to network, or to other destinations. It was developed to replace the old CMW logging library supports several platforms such as Linux and Windows but also old PowerPCs running LynxOS.

The library is fully configurable from the code or via configuration files. Like the previous version it supports setting the effective log level remotely. At the same time CMWlog is written to be thread-safe and it represents small memory footprint and resource consumption which is extremely important for previously mentioned old systems. Another important feature is the non-blocking method calls from the running user thread and proper behaviour in case of I/O errors not to affect time critical user's code execution.

The library utilizes concepts like *Loggers* and the *Appenders* [9]. These allow a high flexibility when channelling log events to different destinations such as standard output, files, or sending to a remote host. If required, the modular architecture of the library facilitates to be extended to other output destinations.

The Converters

A Converter is protocol-specific and hence accepts log messages only from particular remote sources. Internally, it is implemented using the Apache Camel [10] open source routing framework which features a very rich set of functionalities helping to reduce the development massively. It handles socket and thread operations and passes the received content to the user code. Here, the data is then turned into an internal common log message and subsequently sent off to the broker via TCP.

Currently, there are three converters. The first receives messages following the RFC5424 syslog format. The second reads messages coming from the new CMWLog log sources and the last one ensures backward compatibility with old legacy sources.

It is very simple to add new converters and thus to extend the usage to other log protocols. A concrete example for this is to accept also binary objects coming from Java programs using the Log4J or SL4J [11] log library.

To ease the operation monitoring metrics as well as management features such as blacklisting of log sources are exposed via the JMX [12] interface.

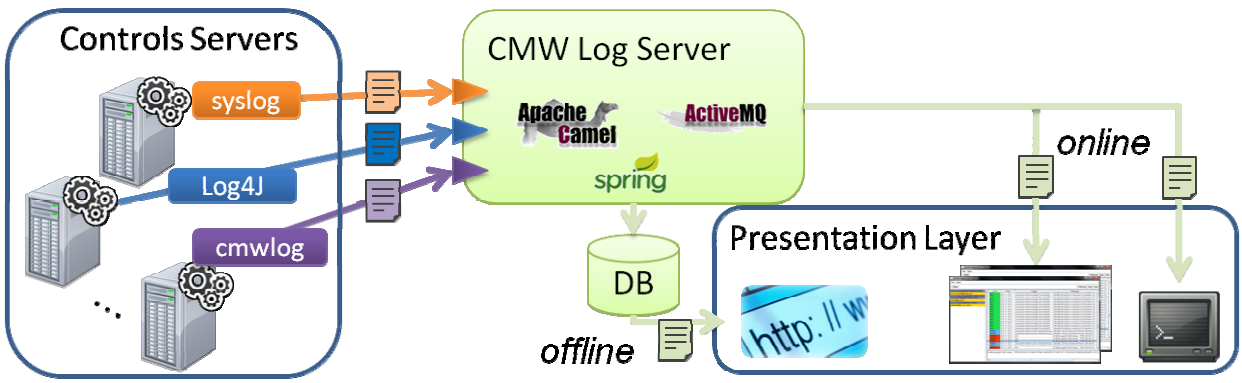

Figure 2: Architectural Overview of the new CMW tracing service.

Distribution of the Data

After a Converter have accepted and converted a log event it is then sent via JMS to a central messaging bus provided by the Apache ActiveMQ [13] product. ActiveMQ supports failover and clustering mechanisms, and has been used in the CERN controls system since 2005. As it has proven to be very reliable it was a natural choice for distributing log events to a potentially large set of client applications.

Data arriving at the broker is organized internally in topics. That is, each log source is identified globally by a unique identifier which maps in the broker to one specific topic. Clients may then read messages from one or more log sources by subscribing to one or more topics.

Storing Log Events Permanently

In order to fulfil the requirement of storing log events into a permanent storage two independent modules have been added to the system (see Figure 2). The *FileWriter* writes into size-based rotating files so disk space is not exceeded. At the same time the *DbWriter* pushes the data into a database (i.e Oracle or MySQL). In order to reduce storage usage, project specific policies on how long the data need to be kept have been put in place. For the CMW project, for example, data with warning and error severity are stored for one month only.

The Log Viewer

To finally view log events online and in real-time a graphical user interface (GUI) has been created. It displays the loggers in a tree structure and allows fine control of the desired levels. The messages are displayed in a table using a different colour for each severity.

The interface can run as a standalone application or as an integrated component within other GUIs. Moreover when connected to an RDA server it can remotely change the log level of the source easing on-the-fly problem tracing.

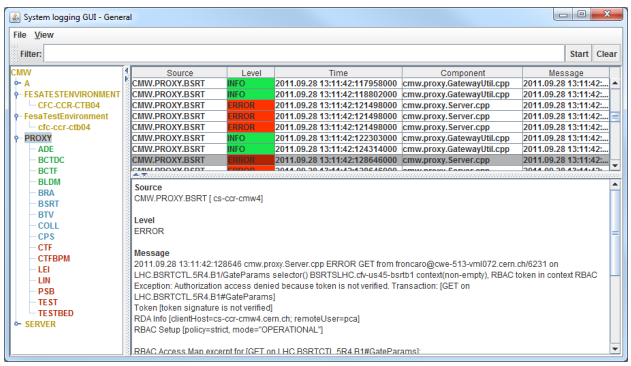

Figure 3: Example of the CMW log event viewer.

In addition, data can be viewed offline via an oracle driven web interface which provides sophisticated data filtering and selection tools. In case of an incident like a system or service crash this information can be very useful for later analysis. Another example is comparing trace messages produced by different sources at a given time with messages from another time. This gives the possibility to identify relationships between incidents.

PERFORMANCE TESTING

The new system has been deployed and tested in the very early stages of development. The focus was put onto the messaging broker as it handles most of the workload. For this, an ActiveMQ 5.4 message broker was installed on a 16 Core HP G6 server with 8GByte Memory. In order to simulate future workload two producers where set up on different machines sending in total 10.000 log events per second at constant rate via 1000 connections (TCP) to the broker. Each of these events contained a payload of 500 Bytes.

On the reading side 15 Java client applications where started each subscribing to a subset of the published data. Because one message is multiplied by the number of subscribers the effective outgoing message rate resulted in 30.000 messages per second. These performance numbers are slightly above the estimated future load to allow a better dimensioning of the system so bursts are handled safely, as well.

This test setup ran for 48 hours without any problems showing that ActiveMQ handles reliably the simulated load.

EXTENDING TO OTHER FIELDS

Because of its flexibility and simple use the new system has been investigated for transporting and storing important deployment and configuration feedback messages coming from kernel modules running on FECs. This feedback channel is currently missing but highly demanded. Developers have no means to verify the correct installation or reconfiguration of those modules.

Therefore, feedback messages were tested to be sent to the CMW tracing system and subsequently inserted into the database. This was successful and confirmed that the proposed system is a mature solution.

The same channel could possibly also be used for normal Java or C++ programs services. Information about the version, installation time and configuration could be collected centrally in a database for further use like viewing deployment history.

SUMMARY

The new tracing system fulfils all requirements and has been tested for performance and stability. It is designed to serve multiple reading applications for many equipment or service experts without putting additional load onto the log source and it offers to store the log events in a database or size-based rotating files. Users have the possibility to read messages online via a graphical user interface which was integrated into existing operation and diagnostic tools in the CERN control system. As data is also stored in a database the usage of existing market solutions for analysis is possible.

Because it allows being easily extended to other log protocols like Log4J or SNMP it offers an interesting solution to a larger field of activity.

COORDINATING SIMULTANEOUS INSTRUMENTS AT THE ADVANCED TECHNOLOGY SOLAR TELESCOPE

S. Wampler, B. Goodrich, E. Johansson, National Solar Observatory, Tucson, AZ, U.S.A

Abstract

A key component of the Advanced Technology Solar Telescope control system design is the efficient support of multiple simultaneously operating instruments sharing the light path provided by the telescope optics. The set of active instruments varies with each experiment and possibly with each observation within an experiment. The flow of control for a typical experiment is traced through the control system to present the key aspects of the design that facilitate this behavior. Special attention is paid to the role of ATST's Common Services Framework in assisting the coordination of instruments with each other and with telescope motion.

INTRODUCTION

The Advanced Technology Solar Telescope (ATST) [1] is being constructed atop Haleakalā on the island of Maui, Hawaii. With a 4m off-axis primary mirror, ATST is the world's largest solar telescope and includes fully integrated adaptive optics, an unvignetted light path, a 16m rotating Coudé lab and numerous other novel features. ATST is designed to be operated as a laboratory with multiple instruments sharing the light path. Each instrument includes one or more science cameras, each delivering data to the ATST Data Handling System (DHS) at up to 1GBps [2]. During observations, the active set of instruments must cooperate and coordinate with telescope motion and light-path adjustments.

The ATST control system manages this cooperation and coordination using a pair of principal systems: the Observatory Control System (OCS) and the Instrument Control System (ICS). The ICS manages the coordination of the individual instruments while the OCS coordinates the Telescope Control System (TCS) actions with the ICS. This separation allows the OCS to focus on large-scale coordination of an entire experiment (for example, instructing the ICS to prepare instruments while the TCS is active) without having to deal with the additional complexity of managing a cooperating set of instruments. Meanwhile, the ICS focuses on the coordination of the active instruments within an individual observation without having to deal with the coordination of telescope motions with those instruments.

All of the ATST *principal* software systems (OCS, ICS, TCS, and DHS) are built using the ATST Common Services Framework (CSF) [3] which provides significant support for their operation in a highly distributed environment. CSF is built on a container/component model with containers providing essential services and lifecycle management to application components. Components are the fundamental building block for all ATST applications. A special form of component, the *controller*, implements a command/action/response model for device control [4] where configurations describing changes of state are submitted to controllers. Controllers then act upon these configurations and, sometime later, report their success or failure in achieving the target state. Services are provided based as much as possible on need and not implementation. For example, CSF provides a middleware-neutral interface for communications among components. CSF also provides substantial *technical architecture* support (how something must be implemented to integrate into ATST software), allowing software developers to concentrate more on the *functional behavior* of their code (what needs to be done to accomplish a task). The topmost layer of CSF, *Base* [5], maps the generic service framework provided by the lower levels of CSF into a technical architecture more tailored towards the actions performed in observatory operation. Base provides motion controllers, hardware connection services, and numerous other pieces commonly needed when controlling mechanical devices. Often a software developer need only adjust an existing motion controller's parameters to produce a specific mechanism control application. Typically, this simply requires adjusting some property values in a database.

EXPERIMENTS

Observing with ATST is organized into *Experiments*. An Experiment is a formal description of the behavior of ATST required when carrying out the activities associated with a scientific proposal. The Experiment includes a description of the science goal, the conditions that must be met to perform the science, what instruments are required to obtain the data, and a *Program* describing how the data is to be collected using those instruments. The OCS executes the Program to produce *Observing Blocks*. Observing Blocks are the smallest schedulable section of a Program. Each Observing Block contains a list of the instruments that are active when the block is executed, a script that coordinates the TCS and ICS actions during that execution and parameters for configuring the ICS, TCS, DHS, and the instruments for proper behavior. When the Observing Block is to be executed, the OCS runs the script using a CSF-provided script executor pool and passes all of the parameters to the script. The use of a script to manage the coordination of the TCS and ICS maximizes the flexibility available within ATST's laboratory structure. Because the script executor resides in an ATST Java container, the scripts have full access to the facilities provided by CSF, easing the development effort.

Figure 1 shows a simplified (monitoring code, checks for external cancelation, and most comments have been stripped) script used when executing an Observing Block that performs a mosaic observation around some target

```
from atst.ocs.util import Mosaics  # Other imports provided automatically

tcs = App.connect("atst.tcs")   # Establish connections to TCS and ICS
ics = App.connect("atst.ics")

# Get the list of relative positions for the specific type of mosaic
pos = Mosaics.mosaicFactory(paramSet)

# Get the current target position on the Sun.
curLoc = tcs.get(Misc.setTarget("atst.tcs", 0.0, 0.0))
target = curLoc.getDoubleArray("atst.tcs.target")
oldx = target[0]
oldy = target[1]

mosaicType = paramSet.getString("atst.ocs.script:mosaicType")
Log.note(mosaicType+' mosaic start about ('+`oldx`+','+`oldy`+'):'+
                    paramSet.getId())
icsAction2 = None
for i in range(0, len(pos)):  # Step through mosaic positions
    x = oldx+pos[i][0]        # Get absolute position
    y = oldy+pos[i][1]

    psIcs1 = paramSet.selectOnPrefix("atst.ics.")
    psIcs1.insert(Attribute("atst.ics.tcsConfigured","false"))
    icsAction1 = submit(ics, psIcs1) # Tell ICS to configure instruments

    # If not first time through the loop, must block here until previous
    #    ICS action completes before moving telescope!
    if icsAction2 is not None:
        icsAction2.waitForDone()

    # Move the telescope and block until in position.
    psTcs1 = paramSet.selectOnPrefix("atst.tcs.")
    psTcs1.merge(Misc.setTarget("atst.tcs", x, y))
    submitAndWait(tcs, psTcs1)

    # TCS is now ready, tell ICS it's ok for instruments to collect data
    #   (makeConfigROE() adds the necessary parts to the configuration.)
    psIcs2 = makeConfigROE(psIcs1)
    icsAction2 = submit(ics, psIcs2)  # More efficient to delay blocking

# Out of loop, block here until last ICS action completes
if icsAction2 is not None:
    ics2.waitForDone()

tcs.set(curLoc)             # Return to starting point
Log.note(mosaicType+' mosaic done about ('+`oldx`+','+`oldy`+')')

App.disconnect("atst.tcs")  # Close connections
App.disconnect("atst.ics")
```

Figure 1: An OCS mosaic script (Jython code).

feature on the Sun. The script interleaves and coordinates instrument actions with telescope motions for efficient observing. Note that the script does not worry about the individual instruments – that is left to the ICS. Similarly the ICS does not need to worry about telescope motions – the OCS script tells the ICS when the TCS is properly configured and when it is not.

INSTRUMENT CONTROL SYSTEM

The Instrument Control System is the principal system responsible for the simultaneous operation of the ATST facility instruments. It is a layer of software between the OCS and the instruments that implements a simple control interface for the instruments and relieves the OCS of the burden of managing them. The ICS responds to OCS commands and events, coordinating and distributing them to the various instruments as required. The ICS presents a single narrow interface to the OCS while coordinating the actions of the instrument controllers underneath it.

The ICS requires no specific knowledge about the instruments to be controlled. All information about the instruments used in an experiment and their parameter settings is passed by the OCS through the ICS, which uses a list of participating instruments to extract and forward the parameters to the appropriate instrument controllers (ICs). All ICs, which do have detailed knowledge about their underlying instruments, use the same standard narrow interface. This allows new instruments to be added without having to modify the interface or any existing ICs. If an instrument implements the ATST Facility Instrument Interface it can be controlled by the ICS. This is true for both facility instruments as well as visitor instruments.

The ICS consists of two main components: the Observation Management System (OMS) which provides the interface to the OCS, and a set of Instrument Adapters (IAs) which provide a standardized interface between the OMS and their respective Instrument Controllers. A context diagram illustrating the structure of the ICS is shown below in Figure 2.

The interface between the OCS and ICS is configuration-based and essentially stateless. Commands from the OCS are directed to the ICS using CSF configurations. The configurations are used to send the

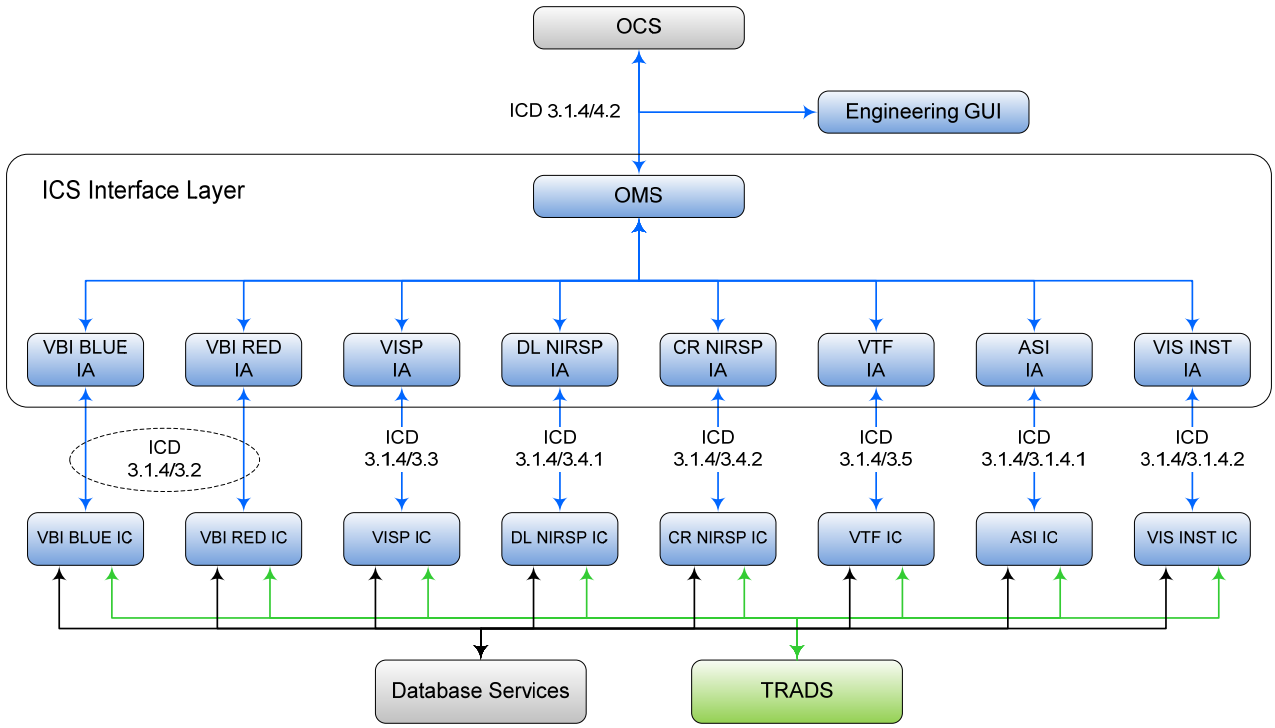

Figure 2: A block diagram of the Instrument Control System, illustrating the two main components, the Observation Management System (OMS) and the Instrument Adapters (IAs). Also shown are the Instrument Controllers (ICs) for the first generation ATST instruments, the Time Reference and Distribution System (TRADS), and the Database Services. Interfaces between the IAs and ICs define the specific observing parameters used by the instrument and passed down from the OCS.

appropriate observing parameters to the instruments, and typically include the following: a set of global experiment parameters, a list of instruments participating in the experiment, a list of those instruments that must complete their actions before the operation is considered complete, and all relevant parameters set by the user for each of the instruments. The ICS parses and interprets these configurations, extracting and forwarding the appropriate portions to each instrument in the observation. It checks on the readiness of the instruments and instructs each one to set itself up for the selected observing mode according to the parameters in the configuration. The ICS notifies the OCS when all instruments are properly setup (or not) for the observing mode.

As soon as the TCS is in position, the OCS notifies the ICS that the instruments may begin their individual observing actions for this mode (this may occur before the instruments have completed their setup activities). As soon as each instrument has completed its setup, the ICS notifies it to begin its observing actions. The ICS then monitors the instrument controllers for completion and sends status information back to the OCS.

After the OCS has notified the ICS that the instruments may begin observing, it may send one or more configurations to the ICS in preparation for the next Observing Block. The parameters in these configurations will be sent to the appropriate instruments as soon as possible, allowing them to setup for the next observing block as soon as they have completed the current one. This is referred to as *pre-configuration* and is done to maximize the efficiency of the observing process.

The ICS monitors the completion status of the participating instruments. When all of the instruments which are required to complete their observations for this observing block have completed their observing actions, the ICS terminates the observing activities of the remaining participating instruments and sends the final completion notification to the OCS.

New observing blocks are executed by repeating the pattern described above. This process repeats until all the observations for an experiment are completed or the experiment is cancelled or aborted by the operator.

INSTRUMENTS

The control of individual instruments is implemented by the ATST instrument developers. To facilitate the development of the instrument control software by these institutions, the ATST software team has developed a set of standard controllers and components that may easily be used to implement an Instrument Controller. This is called the Standard Instrument Framework (SIF). The SIF components are implemented using the Base and CSF components described earlier and consist of Management Controllers that control several other sub-controllers, Mechanism Controllers that control several Motion and Hardware Controllers, Detector Controllers that control one or more Camera systems, and an Instrument Sequencer that provides scripting support using an

embedded Jython scripting engine. Runtime access to observing scripts and parameter sets are provided through CSF database services. Motion Controllers and Hardware Controllers for control of standard motion control devices and hardware devices are provided as well. The Time Reference and Distribution System (TRADS) provides support for high resolution synchronization of instrument activity with absolute time and is the primary means of coordinating instrument mechanisms, cameras and polarization modulators with each other.

The ATST Instrument Partners are free to implement their Instrument Controllers using as desired using these tools as long as they meet the ATST Facility Instrument Interface.

Example of Instrument Control

Instruments are controlled by sending them CSF *configurations,* which are tables containing all the necessary attributes to execute a particular observing mode. As an example, the Visible Broadband Imager (VBI), which is a high-speed imager with a filter wheel, camera position and focus adjustment, might use the following attributes to execute a typical observation:

Table 1: Visible Broadband Imager Attributes

Name	Meaning
.experimentId	A unique ID for the experiment
.observationId	A unique ID for the observation
.obsMode	The current observing mode
.tscConfigured	A flag indicating if the telescope is in position and observing may begin
.paramSets	A list of parameter sets to be used
.paramSetSeq	The sequence in which parameter sets are to be used
.scriptName	The observing script to be run
.numCycles	The number of times to cycle through the parameter sets
.continueFlag	A flag indicating whether to continue after all cycles have been completed

A parameter set is a named collection of commonly used parameters that is downloaded from a database at run-time and passed to the script engine as an attribute. In this example a parameter set might contain the following parameters:

- The desired filter
- A map of camera field positions
- Camera setup parameters:
  - Exposure time
  - Number of frames
  - Binning
  - Region(s) of interest
- Data processing plug-ins to use

At run-time, a *configuration* with the above attributes is sent to the instrument. The instrument begins by setting all of its various devices into the proper position or mode as specified by the attributes. When everything is in position, the instrument checks to see if the telescope is in position and ready for observing to begin. If so, the observing script is run using the parameter sets and data recording commences. If not, the instrument waits patiently for the *.tcsConfigured* flag indicating it is time to start.

STATUS

The split in coordination roles, where the OCS handles high-level coordination between the TCS and ICS while the ICS handles the detailed coordination among a set of active instruments simplifies implementation of these tasks. An end-to-end simulation has been developed to test system behavior and a number of experiments have been run through this simulation, illustrating the functional correctness of this approach. The support provided by CSF at all levels of the control flow has greatly reduced the amount of specialized code that is required.

ACKNOWLEDGEMENTS

The National Science Foundation (NSF) through the National Solar Observatory (NSO) funds the ATST project. The NSO is operated under a cooperative agreement between the Association of Universities for Research in Astronomy, Inc. (AURA) and NSF.

The ATST represents a collaboration of 20 plus institutions, reflecting a broad segment of the solar physics community. The NSO is the Principal Investigator (PI) institution, and the co-PI institutions are the High-Altitude Observatory, New Jersey Institute of Technology's Center for Solar Research, University of Hawai'i's Institute for Astronomy, and the University of Chicago Department of Astronomy and Astrophysics.

THE LABVIEW RADE FRAMEWORK DISTRIBUTED ARCHITECTURE

O. Ø. Andreassen, D. Kudryavtsev, A. Raimondo, A. Rijllart, V. Shaipov, R. Sorokoletov, CERN, Geneva, Switzerland

Abstract

For accelerator GUI applications there is a need for a rapid development environment to create expert tools or to prototype operator applications. Typically a variety of tools are being used, such as Matlab or Excel, but their scope is limited, either because of their low flexibility or limited integration into the accelerator infrastructure. In addition, having several tools obliges users to deal with different programming techniques and data structures.

We have addressed these limitations by using LabVIEW, extending it with interfaces to C++ and Java. In this way it fulfils requirements of ease of use, flexibility and connectivity, which makes up what we refer to as the RADE framework.

Recent application requirements could only be met by implementing a distributed architecture with multiple servers running multiple services. This brought us the additional advantage to implement redundant services, to increase the availability and to make transparent updates.

We will present two applications requiring high availability. We also report on issues encountered with such a distributed architecture and how we have addressed them.

The latest extension of the framework is to industrial equipment, with program templates and drivers for PLCs (Siemens and Schneider) and PXI with LabVIEW-Real Time.

INTRODUCTION

Integrating equipment and software in CERN accelerators like the LHC, which contains more than 1200 dipole magnets, more than 8000 other superconducting magnets operating at temperatures down to 1.9 K and with currents up to 12000 A is a great challenge [1]. When one also adds its size into the equation (27 Km) it doesn't ease the task of operating this marvellous machine.

With the RADE (Rapid Application Development Environment) framework and LabVIEW we have managed to ease the job of integrating new and existing projects into all the different disciplines at CERN [2]. With our distributed architecture the user does not have to update their RADE libraries, we maintain them on our server and ensure compatibility with new releases as long as the underlying protocol or library does not become deprecated or replaced.

ARCHITECTURE

In computer programming, a software framework is an abstraction in which software providing generic functionality can be selectively changed by user code, thus providing application specific software. It is a collection of software libraries providing a defined application-programming interface (API) [3].

LabVIEW already gives you the foundation needed to do fast programming by providing an integrated development, debug and deployment environment based entirely on graphical programming, as well for the code, as for the GUI development. In addition it gives you a powerful and flexible set of analysis and math libraries out of the box.

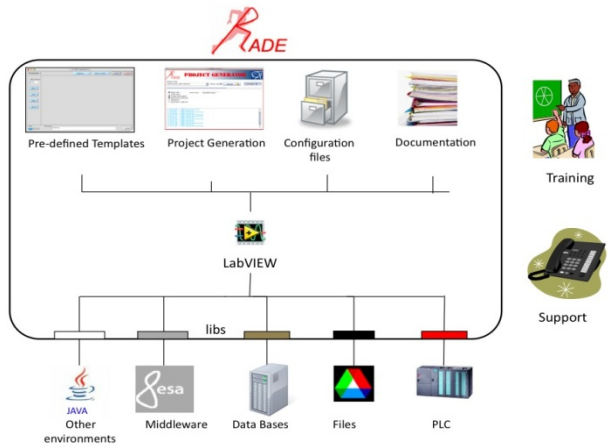

Figure 1: RADE Architecture.

Our development effort is thus concentrated on the integration into the CERN accelerator control and storage infrastructures, with an objective of making the deployment and maintenance of the framework transparent for the users, yet always up-to-date with the latest dependencies and additions.

Total Package

The RADE framework also aims to give users a total package for development, maintenance and support (Fig 1), making it quick to implement yet highly stable, maintainable and flexible through well defined development templates, guidelines and documentation.

Currently we are working on expanding this framework and do a "total integration" in LabVIEW at CERN.

Templates, documentation, source control, updates, and libraries are being added to the foundation as the testing of them finishes.

By adding a layer on top of LabVIEW we can synchronize the client installation with our Subversion (SVN) [4] and data repositories.

Project Generator

In addition a project generator (Fig. 2) has been created which can be called through the native menus of LabVIEW.

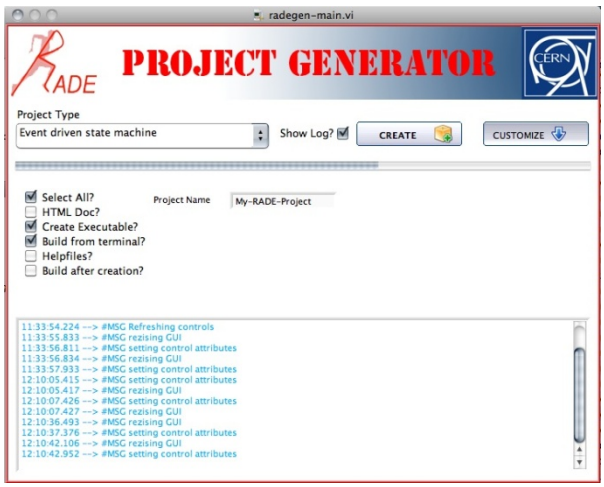

Figure 2: RADE Project Generator.

The Project Generator will create a skeleton project and folder structure for the user, and if desired store this project on our SVN repository dedicated for user projects. It also automatically generates documentation, executable files, help files, and integrates system and RADE components into the project so that if the user at a later point would like to update or retrofit his sources to a later version of RADE, he can do so.

RADE LIBRARIES

The RADE libraries consist of several communication layers (Fig. 3), adapted to the necessary protocols. It also makes use of a distributed architecture where several redundant servers host the communication and analysis libraries. These can potentially be written in any software language, but we mainly use the CERN Java packages and native LabVIEW servers that communicate with the LabVIEW client through sockets.

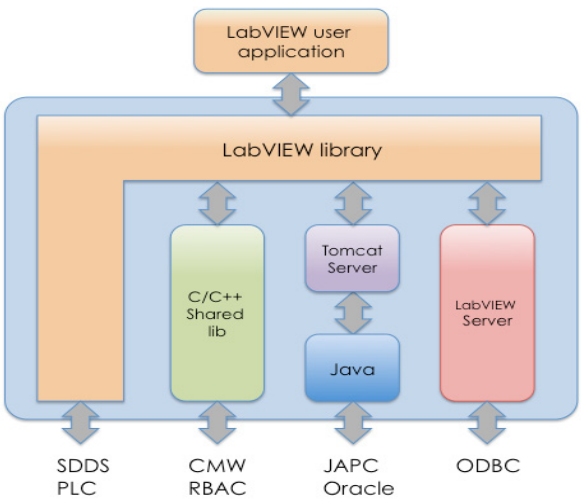

Figure 3: Library layers in RADE.

Java interface

The Java API for Parameter Control (JAPC) is a communication layer to control accelerator devices from JAVA [5]. Client programs can access JAPC parameters with set and get actions or by subscribing to the data. JAPC is a unified Java API for almost all parameters present in the control system. The diversity of devices is handled below the JAPC interface where each kind of device has its own implementation.

In the RADE framework we have implemented a LabVIEW to JAPC interface using a Tomcat server (Fig. 3) as mediator. The same mechanism is used to access ORACLE databases.

CMW Wrapper

The Common MiddleWare (CMW) API incorporates Set, Get and monitor actions like the JAPC API, but it is written in C++ and runs locally with the client [6].

We implemented the LabVIEW to CMW interface (CMW wrapper) by wrapping the C++ API into call back functions and turning it into a shared library, which is called by LabVIEW using the call library interface node.

The Toolkit was designed to be cross platform so the dependant libraries can be compiled on any platform supported by the CMW API (Mainly Linux and Windows).

SDDS Library

SDDS stands for Self Described Data Set [7]. This file format is commonly used at CERN and can contain any kind of data. This standard is used in the LHC to store equipment data (currents, voltages, levels etc.), used to inform the domain experts about the system health.

Since a failure in the machine can produce more than 10.000 files in a single dump, the SDDS library was designed to index and read only the requested portion of a file, improving reading speed and saving time when performing analysis.

PLC Library

The communication to the PLC is written in standard LabVIEW using the "Fetch-Write" protocol from Siemens through TCP-IP. The "Fetch-Write" has to be declared in the PLC to authorise external devices accessing its data blocs. For more flexibility we are developing a wrapper for LIBNODAVE [8], an open source library to access Siemens PLCs.

RADE IN THE LHC DASHBOARD

The LHC Dashboard project aims to provide a single entry point to the monitoring data collected from the experiments and equipment associated with the LHC.

The Dashboard collects information from multiple sources, treats the data and renders it as a set of web

pages. It covers various activities of the LHC making up a complete picture of what goes on in the machine. By using RADE in the dashboard we have managed to make a very flexible and powerful data-mining tool where we, with little effort, can obtain new data and display this for our users on demand. Currently development is ongoing using RADE for expanding the dashboard, making a fully flexible, user driven web interface where we can render any data from the various activities at CERN on request. The page will consist of a large library of gadgets where the users can select what to see in a customized view.

RADE IN HARDWARE COMMISSIONING

Hardware Commissioning is the phase where tests are carried-out by the specialized teams to qualify the individual systems of the LHC for operation (vacuum, cryogenics, quench protection, interlocks, powering, etc.). The interaction of each system and its partners are verified and the circuit will be powered up to nominal current [9]. This is repeated for every circuit. Commissioning the LHC requires powerful diagnostics to identify faults in the equipment protection systems. This diagnostics tool, called herein the post-mortem system (Fig. 5), has the role of grouping and analysing transient data recorded in the LHC equipment.

The Hardware Commissioning software architecture consists of three parts. The first is the Sequencer written in JAVA, executing the tests. The second is the data collection and storage. The third is the data analysis made with RADE and LabVIEW.

With RADE the Post Mortem Framework is highly flexible. It allows us to quickly adapt to changes and new demands, and validate them on a set of reference tests, when performing the crucial analysis of the LHC equipment. All RADE facilities have been used during the implementation of the Post Mortem analysis.

In 2011, 6092 tests where executed (Fig. 6) (3 week campaign). From these, 3204 where automatically approved by software using RADE.

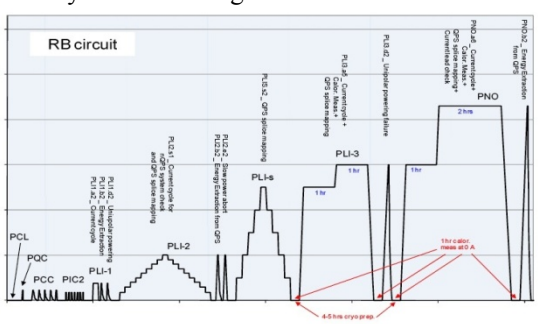

Figure 6: HWC Dipole Tests.

ISSUES

Having a distributed architecture is highly flexible. You can re-route clients to one server while performing updates on the other. On the other side one is vulnerable as well. If the server goes down, if there is a critical bug

Figure 4: The LHC Dashboard.

in the software running or by any other means a problem in the chain that blocks, all users are affected.

Since most of the software dependencies are developed and maintained by third parties, who again have dependencies on other repositories and machines, we have to make sure that the source running on the server is up to date and in synch with versions. Since the servers are redundant, users will transparently connect to the available source. This can be a problem since a

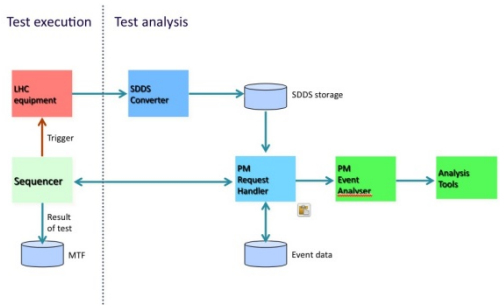

Figure 5: Post Mortem System.

connection or request that manages to block the server could potentially be re-directed to the secondary machine and block that one as well if executing the same request.

To cope with these issues we have to constantly analyze the system integrity and add logic, which identifies problems and prevents them from happening.

CONCLUSIONS

The flexibility and short development time experienced when using RADE in, amongst others, the presented project examples show that the RADE framework is an excellent and powerful tool that can be used to cope with challenges in an environment that quickly and constantly changes. One has however to take care when using a distributed architecture since introduction of new "features" or changes can quickly cause unforeseen problems that affect many users. On the other side the flexibility and convenience of having a distributed architecture trumps the downsides by far.

INTEGRATING ETHERCAT BASED IO INTO EPICS AT DIAMOND

R. Mercado, I. Gillingham, J. Rowland, K. Wilkinson
Diamond Light Source, Oxfordshire, UK

Abstract

Diamond Light Source is actively investigating the use of EtherCAT-based remote I/O modules for the next phase of photon beamline construction. Ethernet-based I/O in general is attractive, because of reduced equipment footprint, flexible configuration and reduced cabling. EtherCAT offers, in addition, the possibility of using inexpensive Ethernet hardware, off-the-shelf components with a throughput comparable to that of current VME-based solutions. This paper presents the work to integrate EtherCAT-based I/O to the EPICS control system, listing platform decisions, requirements considerations and software design, and discussing the use of real time pre-emptive Linux extensions to support high-rate devices that require deterministic sampling.

INTRODUCTION

Diamond Light Source is a third-generation synchrotron light source which started operations in 2007. The current operational state includes twenty photon beamlines, with a further twelve beamlines due to be completed by 2017. Of these, three are in advanced stages of design and construction.

Diamond's control system is based on the EPICS control system toolkit[1][2]. In the current control system, generic I/O is interfaced through a range of VME hardware. This architecture is being reconsidered in the context of the next phase of beamline construction [3]. In the new architecture most I/O functionality, including motion control, video and I/O for analogue and digital signals, will be realised through Ethernet-attached I/O.

Ethernet-based I/O allows the replacement of VME crates by 1U x86 PC as the EPICS input output controller (IOC) servers. This saves rack space and uses easily replaceable standard computing server hardware, available from many manufacturers; configuration is made more flexible because signals do not need to be concentrated in a single crate. The use of Cat6 cabling is an additional advantage.

ETHERCAT

EtherCAT[4][5] is a real-time Ethernet protocol that relies on conventional Ethernet frames with very short cycle times and efficient bandwidth utilisation. The protocol uses the full duplex mode of Ethernet; each communication direction is operated independently of the other.

EtherCAT operates with a master that passes EtherCAT telegrams to a series of EtherCAT slaves. The EtherCAT master uses standard Ethernet controller hardware, whilst the slaves use a custom slave controller. The slaves process the incoming telegrams directly; they extract or insert user data and transfer the telegrams to slaves downstream, each slave introducing a delay of a few nanoseconds. The last EtherCAT slave automatically returns the processed telegram back to the master as a response telegram.

Each EtherCAT slave includes a controller with a Fieldbus Memory Management Unit (FMMU), which allows the mapping of logical addresses in the telegram to physical ones within the slave. The FMMU converts logical addresses to physical ones via an internal table, configured at slave initialisation. It is able to address physical locations down to the level of individual bits and is configured at start-up.

The telegram structure, combined with the FMMU capabilities, allows several slaves to be addressed in a single Ethernet frame. This characteristic significantly reduces the overhead in comparison to other Ethernet fieldbus protocols and is well suited to addressing devices that may have a payload of only a few bytes, such as digital I/O devices, typical of industrial automation.

The registers in each slave that can be mapped by the FMMUs are known as Process Data Objects (PDOs). After configuration the primary EtherCAT telegram present on the bus is Logical Memory Read and Write (LRW). This exchanges PDO data bi-directionally between the master and multiple slaves.

EPICS SOFTWARE COMPONENTS

Diamond EPICS soft IOCs typically run on x86 Linux servers. Prior to interfacing EtherCAT, there had not been a requirement for deterministic sampling on this platform, as operations that relied on more precise timing were delegated to dedicated VME hardware. x86 servers therefore typically ran a standard RedHat Linux kernel. To enable the deterministic performance of EtherCAT, a Real Time Linux kernel was required for servers running the EtherCAT master. The details are described in the next section.

A further requirement that was considered was the need to segregate functionality into separate IOCs that could be maintained separately, for example for separate technical areas. To realise this, multiple EPICS IOC instances needed to have access to every EtherCAT bus scanner. The resulting architecture is shown in Figure 1.

In the physical realisation, a server has a minimum of two Ethernet interfaces, one for standard TCP/IP traffic and an EtherCAT-dedicated interface. There is a single master for every EtherCAT-dedicated interface. The current deployments have one such interface per server, but more could be used if the application requires further segregation of components within the same EPICS IOC server.

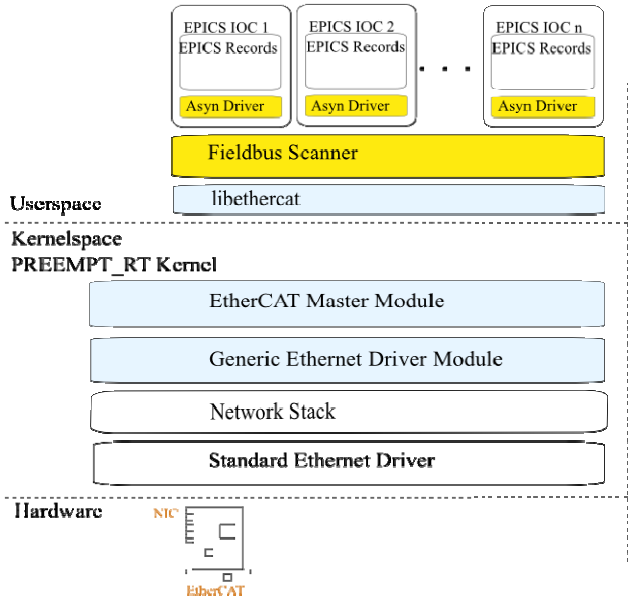

Figure 1: Software components. Cyan represents elements from Etherlab, whilst yellow represents elements from Diamond.

REAL-TIME LINUX

Timing jitter in the EtherCAT bus master process results in irregular bus cycles, which result in missed samples. A standard Linux kernel running a desktop configuration on a multi-core machine misses approximately 0.1% of bus cycles when running at a bus rate of 1 kHz, as measured using a slave device with an internal clock and cycle counter.

The kernel patch pre-empt real-time (PREEMPT_RT) reduces latency and adds the ability to pre-empt most kernel critical sections. It is actively developed by RedHat, and commercial support is available as the MRG product [6]. PREEMPT_RT was chosen over harder real-time Linux systems such as RTAI [7] or Xenomai[8] because of the standard API, minimally disruptive installation and acceptable performance for EtherCAT applications.

Installation of PREEMPT_RT is realised by means of a kernel RPM and configuration scripts to assign kernel thread priorities. The user space APIs are unchanged as the necessary calls are already present as part of the POSIX ADVANCED REALTIME standard[9], so that applications can be developed and tested on a standard system, albeit with reduced performance. For this application Diamond is using kernel 2.6.33.9-rt31, from MRG 1.3.

The following API features are used in the EtherCAT master:

- high-precision timers using clock_nanosleep
- mlockall, to prevent the process image paging
- SCHED_FIFO pthread scheduling
- PTHREAD_PRIO_INHERIT mutexes

No missed cycles are observed when using PREEMPT_RT, under CPU loaded conditions and an EtherCAT bus rate of 1 kHz. Table 1 shows the difference in latency measured using the cyclictest tool. Note that Kernel 2.6.18 is the standard kernel for RHEL5 and does not have high-precision timers, kernel 2.6.33 has high-precision timers but is not fully pre-emptable, and kernel 2.6.33-rt31 has the PREEMPT_RT patch applied.

Table 1: Timing Latency

Kernel	Mean	Max
2.6.18	1630 us	2745 us
2.6.33	52 us	243 us
2.6.33-rt31	5 us	54 us

ETHERCAT MASTER

Diamond uses the EtherCAT master from etherlab.org[10], an open-source kernel module that implements the EtherCAT master state machine and FMMU configuration. The generation of bus cycles is left to the user. This allows the master to work with a variety of different real-time Linux implementations. The master also provides patched network drivers for some common network cards to support interrupt-free operation and thus reduced latency. However these were not required as the generic interface, which uses PF_PACKET raw sockets, provides acceptable performance. To achieve this, it is necessary to disable interrupt coalescing in the network driver to allow high bus rates (up to 10 kHz).

The EtherCAT master modules have been packaged into a Dynamic Kernel Module Support (DKMS) RPM that is built automatically at boot time if the kernel is upgraded.

BUS SCANNER

The Bus Scanner generates bus cycle packets at a steady rate and multiplexes EtherCAT bus access between clients over a pre-threaded UNIX domain stream socket for inter-process communication (IPC). This provides functional isolation at the record level by allowing multiple EPICS IOCs to share the same bus, but restart separately. Broadcast protocols such as UDP or shared memory were not chosen because of the low number of expected clients and the added complexity of implementing connection management and reliability. Real-time and non-real-time tasks are decoupled by the use of message queues implemented using pthread mutexes and condition variables, with priority inheritance to prevent priority inversion.

On start-up the Bus Scanner reads a configuration file, configures the FMMUs, and puts the slave state machines to into operational (OP) mode. The bus cycle timer is then started, and every 1ms the LRW frame is sent and received. The PDO data is pushed on to each client queue in non-blocking circular buffer mode. Write commands

from each client are added to the Scanner command queue in blocking mode, and merged into the local copy of PDO memory ready for the next bus cycle. The Bus Scanner also distributes the FMMU assignments to the clients on connection, as the clients are responsible for unpacking the PDO memory.

Scanner Configuration

The scanner configuration XML file is generated from a bus configuration XML file and a directory of EtherCAT Slave Information (ESI) files provided by the slave vendors. The bus configuration maps bus positions to unique names and also selects the oversampling rate for the Beckhoff eXtreme Fast Control (XFC)[10] devices that can produce more than one sample per bus cycle, as below:

```
<chain>
  <device type_name="EL2004" revision="0x00100000"
position="1" name="OUT0" />
  <device type_name="EL3702" revision="0x00020000"
position="2" name="RF0" oversample="11" />
</chain>
```

The ESI files describe the named registers present in each slave.

ASYN DRIVER

The EPICS device support for the EtherCAT Scanner uses the asynPortDriver C++ class. On iocInit the bus configuration is read over the UNIX socket used for IPC. One port is created for each slave, and one for the bus master status. Port names for each device and asynInt32 parameters for each register are automatically generated from the device names assigned in the bus configuration file and the register names in the ESI file. Additional ports can be instantiated to support oversampling devices and to add triggered circular buffers to any channel. Test templates are generated from the ESI file for each device using the Python libxml2 library, but the final template for each device is hand-written to comply with record naming and interface conventions.

EtherCAT port drivers implement the ProcessDataObserver interface. The socket read thread maintains a list of observers and calls a method on this interface to deliver PDO data on each bus cycle. The port driver unpacks the appropriate registers from the PDO data using the PDO mapping information provided by the scanner on connection, and writes the asynPortDriver parameter cache. An epicsMessageQueue delivers write commands from the port drivers to the socket write thread.

The master port driver reports network cable link status, number of connected slaves and slave state mode bits. One limitation of the current device support is the inability of the asynPortDriver to return an alarm; this will be fixed in a future release of Asyn.

PROGRESS TO DATE

The EPICS implementation was tested with slaves from Beckhoff (Verl, Germany), SMC Pneumatics (Tokyo, Japan) and National Instruments (Austin, TX, USA). Most slaves tested are from Beckhoff, and these come with comprehensive ESI files. The National Instruments backplane needed its configuration EEPROM to be pre-programmed before it could be used with the Etherlab master. Products from SMC Pneumatics have limited availability of slave information files, and for National Instruments, the re-configurable EtherCAT backplane does not lend itself to a fixed file entry. Diamond is also investigating with National Instruments whether higher data rates can be supported as with Beckhoff XFC slaves.

As part of Diamond's latest build phase, EtherCAT technology is being incorporated into new beamline front-ends. The build tree for each IOC incorporates generation of the scanner configuration XML file. A Python script is used to expand the simplistic XML description in the build tree into the full XML configuration file. All the Asyn ports are auto-generated at start-up, simplifying the IOC boot script.

The transition from VME based IOCs, running VxWorks to Linux PC IOCs with EtherCAT, has been relatively straightforward. Very few changes were required to the client EPICS applications. Modifications mainly consisted of substituting the new Asyn port names in place of VME I/O references, along with the creation of new, simpler IOC boot scripts.

CONCLUSION

EtherCAT was integrated with the EPICS control system toolkit on a Linux Real-time platform. EtherCAT devices are configured and scanned using the Etherlab open-source master. The bus scanner communicates with an Asyn driver making I/O signals and configuration information available to EPICS IOCs. The bus scanner broadcasts the PDOs to several soft IOCs that can run in the same server for segregation of technical areas. The configuration in the scanner process is reused in the Asyn driver. The driver automatically creates at start-up one port per slave and one port for the master status.

The solution is being adopted for future control system deployments in the next phase of photon beamline construction at Diamond Light Source.

Abstract

The TRT is one of the ATLAS experiment Inner Detector components providing precise tracking and electrons identification. It consists of ~350000 proportional counters (straws) which have to be filled with stable active gas mixture and high voltage biased. High voltage settings at distinct topological regions are periodically modified by closed-loop regulation mechanism to ensure a constant gaseous gain independent of drifts of atmospheric pressure, local detector temperatures and gas mixture composition. Low voltage system powers front-end electronics. Special algorithms provide fine tuning procedures for detector-wide discrimination threshold equalization to guarantee uniform noise figure for whole detector. Detector, cooling system and electronics temperatures are continuously monitored by ~ 3000 temperature sensors. The standard industrial and custom developed server applications and protocols are used for devices integration into unique system. All parameters originating in TRT devices and external infrastructure systems (important for Detector operation or safety) are monitored and used by alert and interlock mechanisms. System runs on 11 computers as PVSS (industrial SCADA) projects and is fully integrated with ATLAS DCS.

INTRODUCTION

TRT Detector

The TRT (Transition Radiation Tracker) is a part of the Inner Detector [1] tracking system of ATLAS experiment built at CERN for the Large Hadron Collider (LHC). It covers $|\eta|<2.5$ in pseudo rapidity at radii between 128 and 206 cm, allows for electron-pion separation at 97% level and provides continuous tracking with accuracy ~120 μm/point. The detector has three parts – barrel and two end-caps – which consist of arrays of the thin walled proportional counters – straw tubes. The barrel detector contains 96 parts called modules (3 layers of 32 modules). The end-caps consist of 14 'wheels' each, where wheel is functionally divided into 32 sectors. Each module and sector has its own individual electrical services (HV, LV, timing etc). The straw configuration gives ~36 space measurement points in whole TRT acceptance. The detecting elements act as drift tubes ensuring the tracking function and measure energy deposit in specially chosen active gas allowing for efficient detection of the transition radiation photons thus performing identification function.

ATLAS Detector Control System (DCS)

The ATLAS DCS is a large distributed hierarchical control system integrating all subdetectors and infrastructure systems. PVSSII from ETM [2] is a commercial product chosen as a standard SCADA for CERN control systems. The CERN Joint Controls Project (JCOP) Framework [3] provides guidelines and components for integration of commonly used hardware and services into a homogenous control system. ATLAS Central DCS group provides ATLAS-specific guidelines and framework components. The Finite State Machine (FSM) [4] component is used to build and integrate ATLAS DCS hierarchy providing scalability and powerful tools for partitioning of large systems. The main FSM building blocks modelling behaviour of hardware objects are Device Units (DU) and groups of devices are Control Units (CU). States and statuses propagate up in the FSM hierarchy, while commands propagate down the tree. For each FSM node in a hierarchy, two GUI operator panels (primary and secondary) have to be developed. Operator panels can be extended by expert oriented elements controlled by Access Control. The effort needed for design and construction of the control system for LHC experiments in many cases surpasses the possibilities and available manpower of groups involved. This has resulted in wide use of commercial equipment and software tools making the tasks possible to achieve. OPC (OLE for Process Control) standard has been adopted by CERN as one of the mandatory specifications for commercial equipment purchased for LHC experiments.

THE TRT DCS

The TRT DCS subsystems controlling hardware directly connected to the detector are organized to follow Data Acquisition architecture – End Cap A , End Cap C, Barrel A and Barrel C FSM nodes. Each of them contains High Voltage, Low Voltage and Temperature nodes. All other FSM sub-trees are grouped under an Infrastructure node. Four PCs control LV Distribution and Temperatures Monitoring Systems, three PCs control HV

Distribution System, one PC is assigned to infrastructure and whole hierarchy is supervised by top located PC.

High Voltage Distribution System

The TRT High Voltage is based on HVSys company Multichannel Crates with SC508 controllers [7]. The SC508 controller provides communication through RS-232 interface with custom designed protocol. There is no parameters' polling loop embedded in HVsys crate firmware. A boot up message is the only one which the crate sends out autonomously. Six HVSys crates are located in ATLAS underground counting room, 1984 individual lines of length ~70 m distributes HV for both End Caps and Barrel. Three PVSS projects control ~14000 set-point registers and monitor ~18000 measured values and statuses.

A custom OPC DA server was developed (using Softing OPC Toolbox) as an integration middleware for TRT HV PVSS projects. SC508_OPC supports calibration files for Digital-to-Analogue Converter (DAC) and Analogue-to-Digital Converter (ADC) of each HV Cell. One of the main difficulties during commissioning was tuning of performance of HV PVSS systems. The 2-port PCI/RS232 interface cards showed to be more efficient communication solution than USB HVSys crates interfacing. The separate OPC server threads are handling each of serial ports. Separate "fast transaction" queues support commands and status information handling. Each OPC server handles 9 OPC groups defined in order to spread in time PVSS Event Manager load during periods of full TRT Detector transition between HV operational states.

The FSM for HV systems adopts majority logics for states decoding. It allows a small fraction of cells to be tripped or recovering without data taking disturbances.

Two guarding mechanisms were added when an operational experience has been cumulated:

- There are values stored locally in HV cells which do not need to be changed during states transitions. They define cell's behaviour during over-current hardware trip procedure. Trip registers values are refreshed to prevent their corruption - one cell every 3 min.
- A watchdog covering a full communication path for each of HV crate was developed. One HV spare cell per crate is used for it. Each 3 minutes a new HV set-point value is sent to a Watchdog Cell. The read back from set-point register and the output voltage value are compared with a previous watchdog setting. HV watchdog is a very sensitive tool for detecting cases when system suffers from PVSS OPC Client memory leaks, internal HV crate communication problems, OPC server operation slow down or other HV communication degradation.

Low Voltage Distribution System

The Low Voltage TRT system has been detailed elsewhere [8]. The TRT performance and good quality data readout depend on proper level of supply voltages, assuring the correct operation of the Front End (FE) electronics during life cycle of the experiment.

The data/control flow in the LV FE part during standard detector operation is the following:

- Output voltages, currents and intermediate board's (LVPP - located within ATLAS detector) temperatures are continuously monitored in the PVSS projects. These data are read out over CANbus via CanOpen OPC server from the ELMB [5] embedded on the board.
- Settings of DACs (defining output voltage level) are read back from the LVPP employing TRT custom Dynamic Link Library (DLL), embedded as an extension to PVSS CTRL scripting language. This readout is performed after every change of DAC values, before switching on voltages, and on demand.
- OCM (Over Current Monitor) values are read back from the LVPP with mentioned TRT custom DLL every 20 minutes.
- Values of supply voltages and temperature directly at the FE: Voltage/Temperature (VT) are read by the Data Acquisition (DAQ) system and are sent to the DCS via the DCS-DAQ Communication (DDC) mechanism. This readout is done at every run start and on demand.
- All operations (switching on/off, writing new DAC setting to the hardware, etc.) in the LV FE system are executed by FSM commands, available from PVSS FSM GUI. These commands are transmitted via CANbus employing already mentioned TRT custom DLL.

Temperatures Monitoring

The TRT detector operates in ambient temperature. It should be kept in proper temperature ranges because of detector and electronics safety and mechanical structure stability. The detector is exposed to heating coming mainly from FE electronics. It can also suffer from cooling which comes from the silicon detectors placed inside the TRT, when the insulating envelope heaters fail.

Two types of temperature sensors are installed in the TRT detector:

- NTC, mounted directly on the FE electronic boards.
- PT1000, mounted on different structures in the detector.

The following are groups of sensors installed on different parts of the detector:

- 1720 NTC's on FE boards - acting an important role in LV interlock
- 496 PT1000's on FE boards cooling pipes
- 160 PT1000's on mechanical structure of the detector
- 288 PT1000's between detector modules in Barrel and in straw's cooling CO_2 flow – acting as sensors for mean temperature calculations for GGSS to HV feedback.

- 48 PT1000's on heat exchangers cooling pipes in End Caps
- 32 PT1000's on input pipes of straws' cooling CO_2 flow in Barrel

Sensors' values are monitored by ELMB embedded on the TTC PP boards. Calibration constants were measured for each cable with a PT1000 sensor and are used in CanOpen OPC server configuration files.

Alarm limits are set individually for each sensor. They trigger emergency and notification actions and are used in temperature FSM nodes.

TRT Infrastructure Subsystems

There are following auxiliary subsystems fully integrated with TRT DCS, but not connected directly with a detector:

- Maraton Bulk Power Supplies which deliver primary LV for LVPP distribution boards (and other Patch Panel boards) and DAQ VME Crates are commercial devices delivered by WIENER company. A common OPCserver handles both types of devices, merging Maratons' Ethernet communication with CANbus one for VME crates. Framework components are supported by CERN EN/ICE group.
- The Hardware Interlock box for LV system is supervised by built-in ELMB's, thus it can be monitored using a standard middleware layer.
- CANbuses Power Supply Units deliver voltages for 25 CANbuses used in the TRT. Standard tools delivered by ATLAS DCS group were used for integration to TRT DCS. The above Infrastructure nodes are controlled from one PVSS system.
- To achieve the necessary performance of the TRT, the gas gain should be kept constant. It depends on actual active gas composition, concentration of impurities, ambient pressure, local detector temperature and high voltage bias which can be used as a parameter compensating drifts of other values. The dedicated standalone Gas Gain Stabilisation System (GGSS) was developed. The standalone process running in closed loop collects Fe^{55} spectra from reference straws with TRT active gas flowing through and corrects HV biasing sensors as to keep spectra peak positions at required level after every iteration. GGSS is a source of reference HV value and reference temperature which are used by TRT High Voltage Systems for periodical corrections of HV cell's output voltages. A detailed description of hardware architecture and a stabilisation algorithm can be found in [9]. A dedicated Distributed Information Management (DIM) server [6] integrated with the stabilization process is used to send stabilization results and status messages to PVSS system and receive commands from FSM. The normalized HV reference value calculation was added as a result of operational experience. It is a difference between measured reference HV and a predicted value calculated on base of atmospheric pressure and local temperature measured values. Normalized HV reference is a very sensitive parameter guarding active gas composition.
- The Active Gas Chromatograph is a commercial standalone system running on one PC and integrated with TRT DCS by periodically fetching analysis results from an output file.

ATLAS Infrastructure Subsystems

The TRT detector uses centrally delivered and maintained infrastructure hardware and services. It's very important to monitor parameters which directly can influence the detector operation. One can copy or subscribe needed data from Information Services Systems or PLC's which control external systems. The following external systems parameters sets are integrated within TRT DCS Infrastructure node:

- Active Gas System – delivers a gas mixture (70% Xe, 27% CO_2, and 3% O_2) circulating in closed loop system.
- Straws Cooling – removes heat dissipated in straws by ionisation. It circulates (CO_2) between straws.
- FE electronics & Cables Cooling – liquid (C_4F_{16}) circulation.
- Detector Safety System – displays triggers & action bits from hardware matrix.
- Common Infrastructure Control – controls racks and environmental sensors.
- PVSS Systems Overview – monitors and controls SCADA managers and OPC servers states in all DCS computers.

TRT DCS OPERATIONAL AUTOMATION

Software Safety Interlocks

There are two software interlock mechanisms implemented in the TRT DCS system. The LV interlock monitors temperatures measured on FE electronics boards. It switches off the FE LV in case of overheating. The HV interlock is triggered when Active Gas composition or its flow became not safe for straws (danger of discharges) or when humidity in racks housing HV power supplies became too high (danger for HV power supplies). It sequentially sets action flags (SAFE_HV, PREPARED, OFF) after programmable delays. All HV cells DU's call back functions perform required actions and block operator actions to set higher voltages until flags are active.

GGSS to HV Feedback

The GGSS provides reference HV and reference temperature for actual active gas mixture. Selected groups of temperature sensors are used to calculate mean temperature in different detector regions. Each 3 min. a timer triggers execution of a script which checks if GGSS references can be trusted and loops over all connected to detector HV cells performing the following steps:

- Checks if corresponding region temperature can be trusted.

- Calculates a new HV cell's set-point (basing on HV reference and temperatures difference between region and GGSS straws box).
- Checks if a new set-point value doesn't exceed acceptable range.
- Sends a new set-point value to HV cell, if all safety checks succeeded. If any of them fails, the GGSS to HV feedback is disabled till expert checks a situation and re-enables it.

The GGSS feedback corrects HV set-points for cells which are switched to state ON by FSM commands only, thus not interfering with manual operator or expert actions.

Cell Automatic Trip Recovery

The HV cells trips are usual events during the TRT detector operation and have to be carefully handled by experts who decide:

- which of the often tripping cells can be automatically switched back on,
- how many times the cell can be recovered (per day and since last counter reset),
- how long the automatic action has to be delayed.

After a delay HV cell's DU call back function automatically sends a sequence of commands to set a nominal voltage. Automatic trip recovery is performed when the trip happened from cell's ON state only.

LV Settings Equalisation

The distances between LVPP's and the detector FE boards range from 11 to 14 m. Also the current consumption of FE boards differs according to their function within the detector. There are in total 1792 FE boards in the system, each supplied with 3 voltages. Voltages levels at FE should be equal to nominal, so each voltage in the LVPP should be set to a unique value. Setting voltages levels is done via DACs (Digital-to-Analogue Converters) in the LVPP's. The setting is done after each longer shutdown period, board replacement or at any time, when there are some doubts on proper detector performance.

The Low Voltage Equalization Procedure has been prepared for this purpose. Its usage is foreseen not only for setting DAC values but also for debugging and checking the entire LV system in case of problems with operation of FE electronics. The Low Voltage Equalization Procedure consists of an external DAQ LV Equalization application calculating DAC values and mechanisms in PVSS project, including Framework components, which set these values to the hardware.

The DAQ LV Equalization application is performing calculations of DAC settings, and alarm limits for voltages and currents for each voltage type in individual FE board. Primary calculations are based on direct VT readout from the FE. The following, second way of calculations is for comparison and checks. Input parameters for this method are voltages and currents in the LVPP's and previous DAC settings, which are stored in the PVSS archive. These calculations are based on hardware topology, cables resistance and connection of grounds. Calculation results predict values of DAC settings and limits of alarms. They are stored in recipes in the Configuration DB and applied to the hardware from the PVSS project.

A PL/SQL API interface - consisting of a set of routines stored in the Oracle database server, being a part of the Configuration DB schema and allowing access to database data has been developed. These routines, called API Stored Procedures, are used by the DAQ LV Equalization application for fetching necessary data from the PVSS archive and storing output data to recipes in Configuration DB.

CONCLUSIONS

The TRT DCS is operating the detector very stably and reliably and is an important factor for detector safety, excellent performance and good quality of data taken during LHC collisions.

The hardware failures can't be avoided in such a big and complex system. Some of them can be recovered without stopping the ATLAS data taking, especially during LHC collisions, but a dedicated DCS tools for it need to be developed. HV cables „hot swap" to a spare (free) connector position tool is already in operation, the other will come in a near future.

TURN-KEY APPLICATIONS FOR ACCELERATORS WITH LABVIEW-RADE

O. Ø. Andreassen, P. Bestmann, C. Charrondière, T. Feniet, J. Kuczerowski, M. Nybø, A. Rijllart,
CERN, Geneva, Switzerland

Abstract

In the accelerator domain there is a need of integrating industrial devices and creating control and monitoring applications in an easy and yet structured way. The LabVIEW-RADE framework provides the method and tools to implement these requirements and also provides the essential integration of these applications into the CERN controls infrastructure.

We present three examples of applications of different nature to show that the framework provides solutions at all three tiers of the control system, data access, process and supervision.

The first example is a remotely controlled alignment system for the LHC collimators. The collimator alignment will need to be checked periodically. Due to limited access for personnel, the instruments are mounted on a small train. The system is composed of a PXI crate housing the instrument interfaces and a PLC for the motor control. We report on the design, development and commissioning of the system.

The second application is the renovation of the PS beam spectrum analyzer where both hardware and software were renewed. The control application was ported from Windows to LabVIEW-Real Time. We describe the technique used for a full integration into the PS consoles.

The third example is a control and monitoring application for the "CLIC two beam test stand". The application accesses CERN front-end equipment through the CERN middleware, CMW, and provides many different ways to view the data. We conclude with an evaluation of the framework based on the three examples and indicate new areas of improvement and extension.

INTRODUCTION

At CERN there are different frameworks for application development, communication and front-end tasks programming. Adding specialized instruments that use dedicated software while making use of different frameworks can become a difficult and time consuming task. This led us to create the RADE framework a few years ago: a Rapid Application Development Environment realized in LabVIEW that covers all three control tiers. With the RADE framework developers and engineers don't have to cope with all the different interfaces and hardware and can focus on the job at hand, creating turnkey control and monitoring applications in a quick, stable and flexible way.

RADE

The RADE framework aims to give users a total package for development, maintenance and support, making it quick to implement flexible, stable and maintainable through well defined development templates, guidelines and documentation [1].

Templates, documentation, source control, updates, and libraries are all part of the framework, ready to be used in a few clicks.

The RADE distributed architecture provides a quick and flexible mean to interface with almost all equipment at CERN. Databases, frontends, file systems, PLC's and servers are all reachable through RADE. If a toolkit, protocol or library is missing it can easily be added to one of the framework's application servers or added on to the framework's native library package [2].

APPLICATIONS USING RADE

RADE can, with its high flexibility and wide range of libraries, be used in almost any control or monitoring application. Three applications covering different needs are shown here.

The LHC Collimator Survey Train - Multiple Alignment Control System (MACS)

The beam cleaning insertions in point 3 and 7 will become one of the most radioactive zones in the LHC. It was obvious since the beginning that standard alignment measurements will no longer be possible due to the high radiation level of up to 4mSv/h. The concerned zone is a 500 m long straight section of the LHC tunnel with 37 collimators and 26 reference magnets to be measured. The precision should be comparable to the rest of the LHC ring; meaning 0.15 mm in a sliding window of 200 m. Conventional measurements would take 4 days for a team of 3 people. The measurements must either be extremely reduced or one had to find a way to execute the measurements remotely controlled. Reducing the measurements is not considered as an option, as the collimation system is one of the most important parts of the machine protection system.

The basic strategy [3] was to use as much as possible off the shelves components. Various options have been studied, and finally a combination of two different techniques has been chosen. The system is based on a "MoveInspect" photogrammetric measurement system from AICON 3D Systems. This is a fast, precise and non-tactile way to measure the sockets of the radioactive collimators. This system is limited to a relatively small

volume and a considerable effort is needed to cover the 500 m of LHC tunnel.

In order to cover the whole zone, a stretched wire reference is used. More precisely, 5 overlapping and fix installed wires are used to connect the different acquisition volumes of the camera system. The aim is to measure the position of the collimators with respect to the surrounding reference quadrupole magnets at the extremities of the wires.

The software developed for the train project has been made using LabVIEW. The software is divided into two parts, the sequencer (Fig. 1) running on the train and communicating with instruments, and the remote GUI giving information to the user who will be positioned outside the tunnel. The application communicates with the PLC on the train using the "Fetch-Write" protocol from Siemens™ through TCP-IP. The other instruments in the systems (ie MoveInspect Camera system from AICON™, Wyler™ Zerotronic inclination sensors, Aeroel™ XLS35 laser micrometer) have been controlled using separate homemade drivers, communicating either through TCP or RS232 protocols.

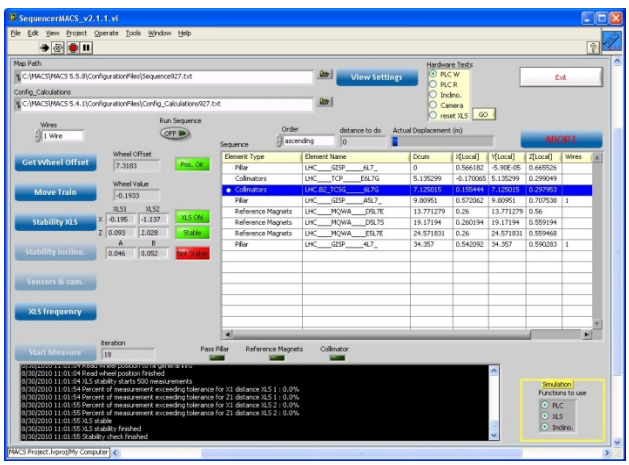

Figure 1: MACS Sequencer panel.

The sequencer is the main software and takes over the control of the whole train once activated. The remote GUI gives the operator the progress and status of all running applications, such as status of all sensors, results of stability tests, measurements and final results. In addition to the MACS software some other programs are used. The AICON MoveInspect software for the cameras, the CERN SU software Chaba for transformations and LGC++ are used finally for the calculation of the alignment.

Renovation of the PS Beam Spectrum Analyzer

The PS Beam Spectrum analyser was a single Windows based PXI crate from National Instruments, hosting dedicated RF cards used to perform Spectrum analysis on RF signals from the PS.

The analyser was mainly designed to perform spectrum and other frequency analysis on RF signals in the PS, but it is also used to do spectrum analysis on OASIS signals [4], which are obtained from remote hardware through a standard protocol.

Since this system is an integral part used to diagnose the RF signals in the PS, operators didn't think the application, running on Windows, was properly integrated into the CERN Control Room (CCC) consoles running Linux.

The PXI solution had so far worked fine, so it was decided that the new system would have a similar setup, but with the user application on the Linux console (Fig 2).

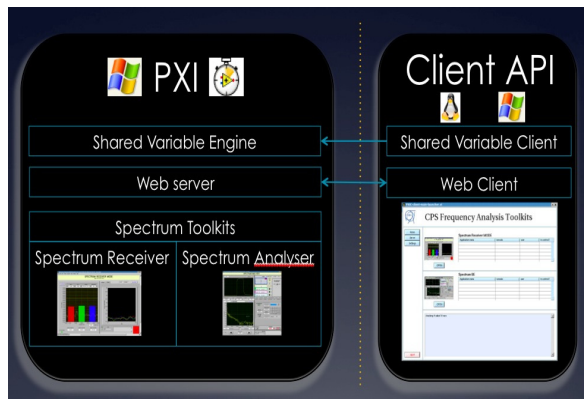

Figure 2: Spectrum Analyzer concept.

Two sets of PXI front-ends with a real time operating system called ETS and dedicated RF cards where installed and the existing software on Windows was converted into a split client-server application making use of LabVIEW remote panels and RADE [5].

The client part (Fig. 3) was adapted to the Linux system running on the consoles in the CCC and the server part was compiled for LabVIEW Real Time (ETS).

The communication between server and client was done using Shared Variables, a standard LabVIEW protocol, and the server would control its real time applications through a state machine based master.

This implementation concept proved quite powerful since any analysis application could later be added to the server and called from the client running in the CCC, and several applications still under development will be added at a later stage.

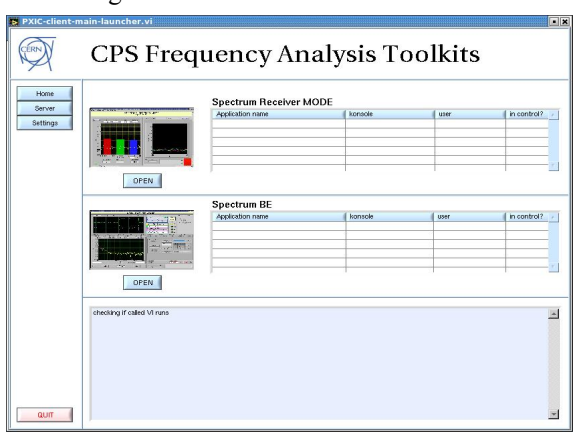

Figure 3: Spectrum Analyzer Linux Client.

With the use of LabVIEW and RADE the conversion of the old software and the installation of the new systems went quite smooth. A few adjustments to the real time headless environment had to be done.

Two-Beam Test Stand

The Two-Beam Test Stand (TBTS) in the CLIC experimental hall (CLEX) is aimed to test the two-beam acceleration scheme for CLIC, an electron-positron collider project. Beam stability, beam loss issues and RF structures are studied in this set-up.

All the signals are acquired through FESA devices, which are easily accessible using the CMW wrapper or the JAPC interface. The aim for this project is to be able to visualise the Beam Position Monitor (BPM) and RF signals in many different views such as horizontal vs. vertical graph or beam intensity or as a history graph. The BPM are probably the most important diagnostic devices used from the beginning.

First one needs to make sure that the beam actually gets to the dump and that it has roughly the same amplitude all the way. The RADE framework has been used to run the acquisition as a server task. Each graphical user interface then acts as a client taking only the necessary data to display in the appropriate format, without unnecessary data duplication.

The beam can be followed from the LINAC to TBTS within a single view (Fig. 4). When the beam is ready to be sent to the desired experimental area, the user can switch to a dedicated GUI to the see the beam position in time (Fig. 5).

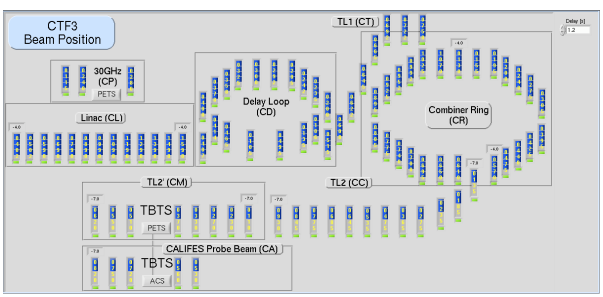

Figure 4: CTF3 beam position.

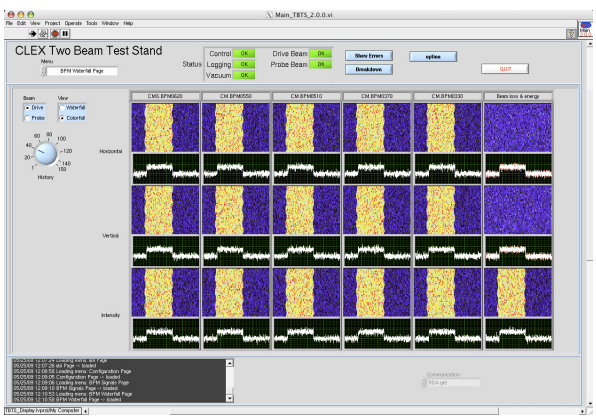

Figure 5: TBTS waterfall display.

The user can also adapt the current in the magnets directly from this application using RBAC and RADE [5]. Right clicking on the synoptic allows the operator to have access to magnet and valve parameters (Fig. 6).

Using the same scheme, a second application has been created for CALIFE experiment, still in the CLIC experimental hall (CLEX).

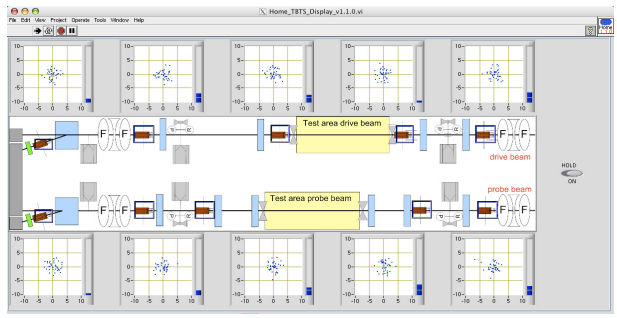

Figure 6: TBTS beam position and magnet controls.

CONCLUSION

The described examples above all use different technologies and techniques for communication and controls between software and equipment. The RADE framework and LabVIEW made it possible in a convenient and flexible way to realize the projects in a uniform environment within a reasonable time.

WEB-BASED CONTROL APPLICATION USING WEBSOCKET

Y. Furukawa
SPring-8/JASRI, Kouto, Sayo-cho Hyogo, 679-5198, Japan.

Abstract

The WebSocket [1] allows asynchronous full-duplex communication between a Web-based (i.e. JavaScript-based) application and a Web-server. WebSocket started as a part of HTML5 standardization but has now been separated from HTML5 and has been developed independently. Using WebSocket, it becomes easy to develop platform independent presentation layer applications for accelerator and beamline control software. In addition, a Web browser is the only application program that needs to be installed on client computor. The WebSocket-based applications communicate with the WebSocket server using simple text-based messages, so WebSocket is applicable message-based control system like MADOCA, which was developed for the SPring-8 control system. A simple WebSocket server for the MADOCA control system and a simple motor control application were successfully made as a first trial of the WebSocket control application. Using Google-Chrome (version 13.0) on Debian/Linux and Windows 7, Opera (version 11.0) on Debian/Linux and Safari (version 5.0.3) on Mac OS X as clients, the motors can be controlled using a WebSocket-based Web-application. Diffractometer control application use in synchrotron radiation diffraction experiment was also developed.

INTRODUCTION

Web-based applications have many advantages over custom-built applications developed using Graphical User Interface (GUI) building toolkits: 1) platform independence; 2) easy to develop; 3) and easy to distribute the latest version. Based on these advantages, there have been many attempts to introduce Web-based applications for accelerator and experimental control.

Platform independence comes from the fact that most major Web browsers can run not only on traditional personal computer or workstation OSs such as Microsoft Windows, Mac OS X, most Linux distributions, Solaris, and FreeBSD, but can also run on mobile device OSs, such as Android OS and iOS. This gives us many candidates for an operator console and different styles of operation of accelerators and physical experiments. Using a mobile device, operators can access equipment besides it, and can easily troubleshoot the devices, if required.

There are many tools available for developing Web-based applications, including independent design and development tools such as Microsoft Visual Studio and Eclipse, and built-in browser tools. It is easier to develop applications using these tools than to use other language and tool kits.

A Web-based application is loaded from a Web server before every execution. It is easy to maintain the latest versions of all the running applications because you need to replace the Web application on the web server; you need not distribute and ask your application users to install a new version.

Despite these advantages, Web-based applications have a big disadvantage, i.e. a Web-application (HTML-based application) cannot make a full-duplex communications with a server application because the HTTP communication starts only from a client. This means that a server cannot send any information to a client without access from the client.

To solve this problem, a “long polling” mechanism was introduced in “Comet” [3]. A Comet server does not respond immediately to the client request (usually XHR is used). It waits for a server event, and the server then responds to the client with information on the event. Actually, the Comet server has to respond with in a definite time (usually 30 s) because Web browsers detect HTTP session time out.

This mechanism works well. However, it requires that an HTTP communication session be started for every long polling request. This results in a heavy; load on the Comet server and it is impossible to send information on client events to the Comet server during long polling periods. This means that it is difficult to realize a “true” control application using Comet.

The WebSocket [1] protocol was proposed to give true full-duplxy communication ability to Web-based applications in the context of HTML5. WebSocket is currently independent of HTML5 standardization, but is one of the important components of HTML5.

WebSocket is very easy to handle in a Web-based application, i.e., it can be easily handled in a program written using JavaScript. WebSocket can handle text and binary data. However, it is easy to handle text data in a JavaScript application. This means that it is easy to develop a WebSocket-based application for a text-message-based control system like MADOCA[6] or STARS[7]. Once you make a gateway from the WebSocket to your control system, you can make JavaScript-based applications. Therefore, a gateway (WebSocket server) to the MADOCA was built and several Web-based applications were tested, as described in the following sections.

SERVER APPLICATION

A schematic of a control system with WebSocket and MADOCA is shown in Fig.1. A WebSocket server has been newly built as a gateway to the MADOCA control system. The server has to treat the negotiation phase of

the WebSocket protocol. This protocol has been revised and the latest version is hybi-10[4] but most Web browsers are implemented on hybi-00[5]; therefore, our WebSocket server is implemented on the basis of hybi-00. The WebSocket server can co-exist with an HTTP server using the same port, i.e., 80 (or 443). In this case, the Web server has to treat the negotiation phase of the WebSocket, while our WebSocket server is running on port 10101 because of continuity of service. To control optical components in the SPring-8 X-ray beamlines, a request server is introduced for the beamline control system on the port 10101.

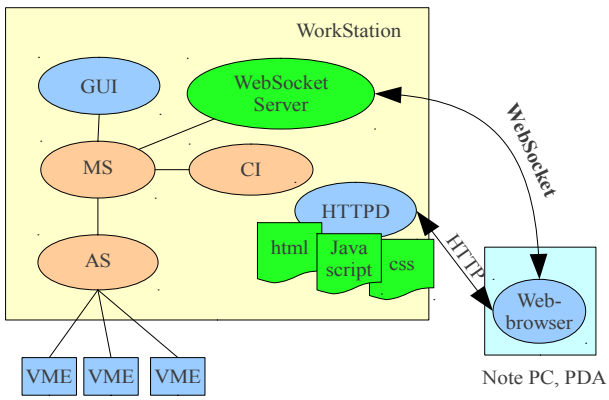

Figure 1: A schematic of WebSocket and MADOCA control system. Orange faced component, MS (Message Server), CI (Command Interpreter) and AS (Access Server) are standard MADOCA components [6]. Green faced components are newly developed for WebSocket Application.

This server is a simple socket server and with a small modification, we can adapt the server for both simple socket service and WebSocket service. The server decides which service is required from the first received string. For the simple socket service, the MADOCA format message will be received and for the WebSocket service, the format defined in hybi-00 or hybi-09 will be received, which is the same as an HTTP request, i.e., " GET /demo HTTP/1.1" or "GET /ws HTTP/1.1". After establishing a connection with a client, the WebSocket server receives MADOCA format from the client and sends it to a MADOCA-based control system. The WebSocket server then receives results from the MADOCA-based control system and sends them back to the client.

CLIENT APPLICATION

Client applications are written in JavaScript. In JavaScirpt, you can open the WebSocket using the "ws" object, as shown below

```
ws = WebSocket("ws://<hostname>[:port]");,
```

send a message with

```
ws.send(<message>);,
```

and receive a message with

```
ws.onmessage() = function(event) {
    var message = event.data;
    …
}.
```

Note that the receive routine is called asynchronously. So you need to handle it with an event-driven handler.

As shown above, the WebSocket interface can be handled very easily.

EXAMPLES

A stepper motor control GUI was developed for the first case of the WebSocket application as shown in Fig.2. The user can watch the motor status, can control motor rotation and can modify motor parameters using this Web page.

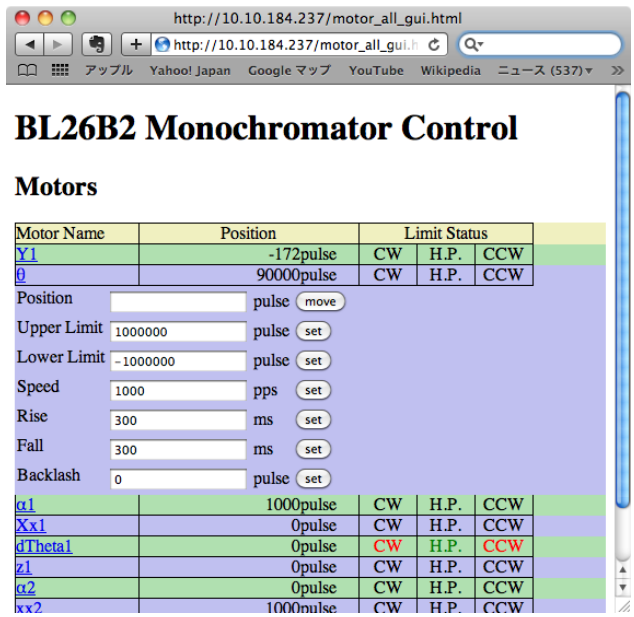

Figure 2: Web-application for stepper motor control.

A more complicated example shown in Fig. 3. is a user interface for a diffractometer control system at the SPring-8 diffuse scattering beamline. This Web page was designed using BlueGriffon™[8] which is a useful tool for building Web pages. Using this Web page, a diffractometer user can tune the slit and detector conditions and make a series of X-ray diffraction measurements. The scan results are shown in real time in the graph area which is realized by a "canvas" element defined in the HTML5 specification. In this case, the "RGraph" library [9] is used to draw the graph in the canvas element.

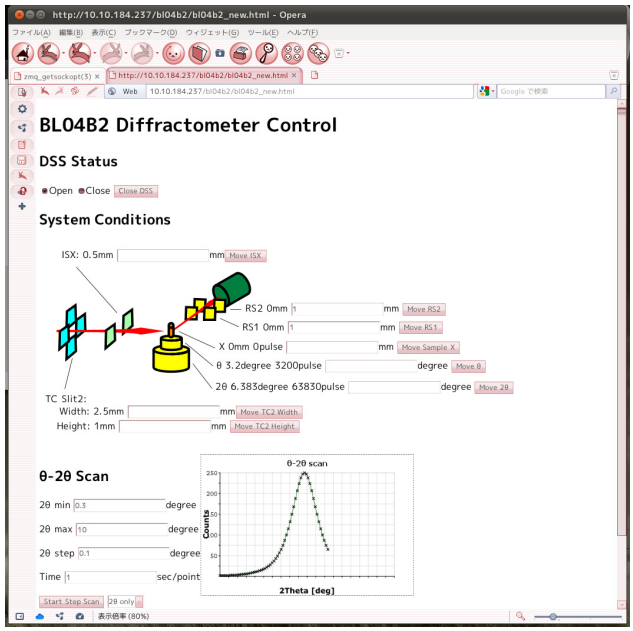

Figure 3: A diffractometer control Web-application.

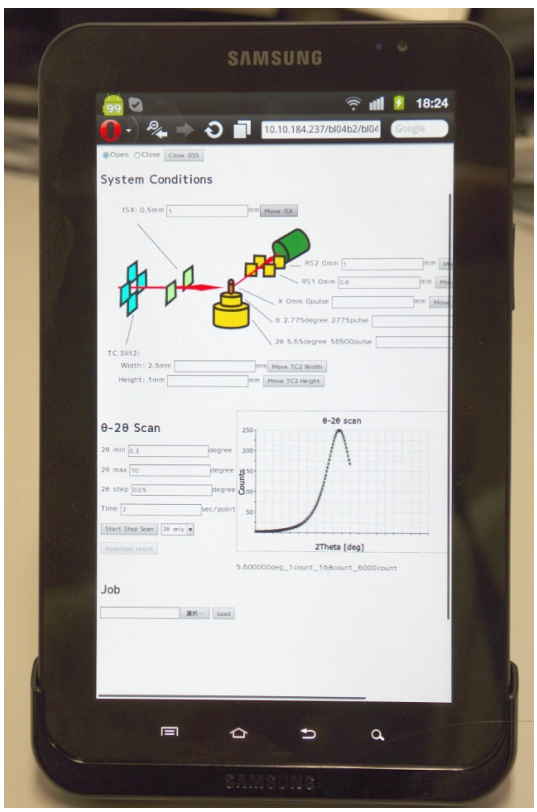

Figure 4: The diffractometer control Web-application running on a mobile device (SAMSUNG Galaxy Tab).

AVAILABLE WEB BROWSERS

The Following Web browsers were tested using the diffractometer-control GUI on a PC, and it was found to work well: Google-Chrome 13.0 on Windows, Debian/GNU Linux and Ubuntu 11.04; Safari on Mac OS X; Firefox 4 on Ubuntu 11.04; and Opera 11.50 on Debian/GNU Linux and Ubuntu 11.04. For Opera and Firefox, WebSocket is disabled as default, so you need to turn on it using "about:config."

Web browsers on mobile devices, Opera Mobile 11.10 on Android OS 2.3.3 (you need to enable WebSocket) and Safari on iPad (1st generation) were available for the WebSocket client. Fig. 4 shows a diffractometer control running on "SAMSUNG Galaxy Tab" which is an Android based tablet with a 7 in LCD screen.

CONCLUSION

As shown in this paper, Web-application can be built using the WebSocket protocol. I have to emphasize that no add-ons are required for executing WebSocket-based applications, just an HTML5 based Web browser. HTML5-based Web-applications provide freedom from the platform, so you can use Web-based applications not only in the central control room but also with various type of equipments. This means the Web-application can be used for local tuning or trouble shooting of the equipment. The web-based application is also useful for remote experiments. You can easily maintain the newest application running on the remote user's PC because the application is loaded from the Web server every time it has to be executed.

LIMA: A GENERIC LIBRARY FOR HIGH THROUGHPUT IMAGE ACQUISITION

A. Homs#, L. Claustre, A. Kirov, E. Papillon, S. Petitdemange, ESRF, Grenoble, France.

Abstract

A significant number of 2D detectors are used in large scale facilities' control systems for quantitative data analysis. Common control parameters and features can be identified in these devices, but most of manufacturers provide specific software control interfaces. A generic image acquisition library, called LIMA, has been developed at the ESRF for a better compatibility and easier integration of 2D detectors to existing control systems. Its design is driven by three main goals: i) control system independence; ii) a rich common set of functionalities, providing alternative software solutions when not implemented by hardware; and iii) intensive use of multi-threaded algorithms synchronised by events for ensuring performance of high throughput detectors. LIMA currently supports a dozen of image detectors from different manufacturers, half of them being integrated by collaborating institutes and manufacturers. Although still under development, LIMA features so far basic image transformation, processing and reduction, fast data saving on different file formats, among other features. Its modular design allows not only the extension of generic hardware and software functional blocks, but also the integration of user-defined post-processing algorithms.

INTRODUCTION

The standard beamline (BL) control software at the ESRF is basically built on top of SPEC, a versatile hardware control application, and a variety of distributed device servers accessed through the TACO and TANGO middlewares. A considerable number of 2D detectors have been interfaced in the past using common generic CCD TACO and TANGO device server interfaces, notably simplifying the client SPEC code. However, the real code implementing the configuration and control of the image acquisition process was copied and/or rewritten on each new detector. Moreover, new features had to be manually added on existing detectors, which resulted unpractical in many cases.

In order to go a step further in the standardisation of the control of these devices, we have developed a generic Library for IMage Acquisition (LIMA) [1]. It provides the common functionality expected from 2D detectors, exploiting the hardware capabilities to their maximum extent, and complementing by software the rest features not provided by the detector.

BUILDING BLOCKS

A key design goal was to not degrade the performance of high throughput detectors. This implied the use of parallelisable multi-threaded algorithms for an optimum usage of multi-CPU/cores in modern PCs, and their corresponding event-based synchronisation. The result was the development of ProcessLib, an auxiliary multi-threaded image processing framework. It manages the execution of arbitrary sequences of tasks, combined in chained and/or parallel configurations. Once added to the run queue, a task is executed as soon as a working thread is available, normally when a CPU/core is idle. The asynchronous notification of the task end is implemented through callbacks.

Another basic element developed for LIMA is a message logging framework for code tracing and debugging. It can be dynamically configured to enable/disable individual functional blocks, and, in an independent way, to change the log verbosity. The output trace is indented following the function call stack, which is different for each active thread. Special efforts were made to reduce code execution slowdown when no trace is active, while keeping this dynamic, thread-safe behaviour.

The core of the library has been written in C++ and Python wrapping through SIP has been implemented for most of the classes.

LIBRARY STRUCTURE

The general LIMA layout is shown in Fig. 1.

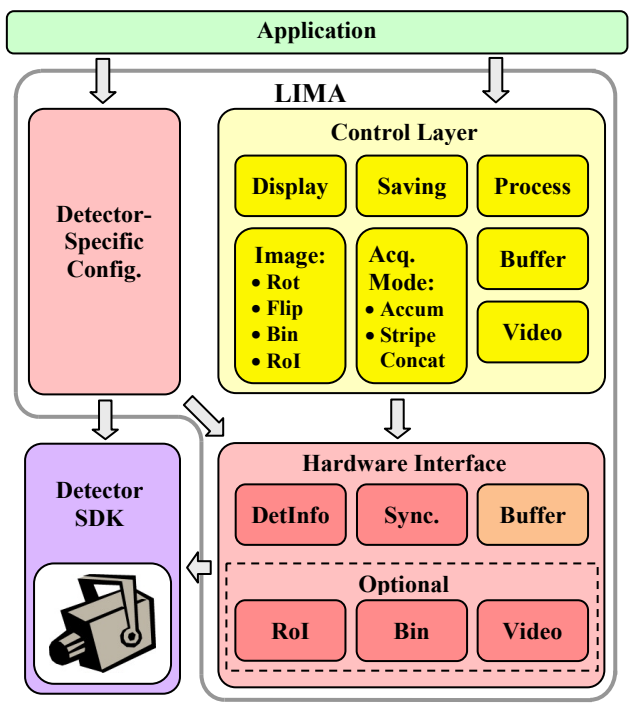

Figure 1: General LIMA layout.

#alejandro.homs@esrf.fr

The library structure divided into two main layers: control, containing the common control and processing code, and hardware, implementing the detector-specific part. The control layer provides the library interface to the high level application. User requests to configure and control the acquisition are gathered by the control layer, so the hardware layer functionality is limited to the generation the image frames in a best-effort basis. The control layer is responsible of: i) adapting the received image geometry if it does not match the user requests, and ii) execute the frame processing chain.

Hardware Layer

The detector-specific code, called "hardware plug-in" must implement a well-defined "hardware interface". It provides basic acquisition start/stop/status control as well as entry points to functional blocks, corresponding to the hardware capabilities. Only three control blocks are mandatory:

- Detector information: name, model, dimensions.
- Synchronisation: internal/external trigger, exposure time and sequencing.
- Image buffer management, for which helper classes are provided with a default behaviour.

All the other capabilities are optional. They include:

- Pixel binning (scaling).
- Sub-image / region-of-interest (RoI).
- Image horizontal / vertical flip.
- Shutter control.
- Video cameras: standard mono/color image formats and gain settings.

This modular design simplifies the integration of new hardware functionality without recoding existing hardware plug-ins.

One important requirement imposed on the hardware plug-in is its responsibility of generating events on every acquired frame. In case the detector API does not provide this feature and relies on blocking/polling interfaces, auxiliary thread management helper classes are provided to simplify the implementation of frame ready callbacks.

As a general rule, the hardware layer is queried to check if it can completely or partially satisfy a particular user request. For instance, when the user asks for a pixel binning combination that is not implemented, the hardware layer replies with the highest binning it can provide. The same best-effort approach should be followed with RoIs, where some hardware alignment constrains might require returning a region bigger than the requested one. The user can always select if a feature is to be implemented entirely by hardware, by software or by a combination of both.

It is worth to remark that to add support for a new detector its only required to implement:

1. The detector information control block
2. The synchronisation control block
3. Acquisition start/stop/status control and frame-ready callbacks

This can be coded either in C++ or Python. Such a minimal implementation will already provide the user with a fully operational system exporting all the common software features.

Control Layer

A modular approach is also found in the control layer, the core of LIMA and its most complex element. Different functions are activated through individual blocks, all of them coordinated by a global control class. The user configures the acquisition using these different modules, many of them implementing parameter caches to minimise hardware access. Once all the settings have been fixed, a "prepare acquisition" command synchronises the hardware configuration, including the (sometimes slow) memory buffer allocation. This minimises the delay in the "start acquisition" command, which can add undesirable latencies in the software synchronisation with other devices like motors or LIMA detectors.

The dynamics of the control layer starts with the "hardware frame ready" callback. The first task to accomplish is the software frame reconstruction, needed if the detector pixel readout sequence does not correspond to its real geometry [2]. Even if this is a detector-specific functionality, it is performed in the control layer to exploit the ProcessLib capability of parallel processing different frames on different CPU/cores.

Individual counters are updated as the frame progresses in the processing chain: last-image-acquired (hardware), last-base-image-ready (geometric reconstruction and transformations), last-image-ready (basic processing), last-image-saved (data storage), etc. The user can register to an acquisition status callback that notifies each time these image counters progress.

Detector-specific Configuration

The control layer provides a user interface to standard acquisition parameters. However, virtually all detectors implement specific settings, which can range from chip timing and readout configurations to generic I/O signal management and ADC gain/threshold levels. To avoid a complex generic infrastructure for these controls, the hardware plug-in is responsible to directly export them to the user through a detector-specific control block. The control layer is not aware of such parameters, so mechanisms have been foreseen to notify important changes that affect the acquisition. For instance, a "max image size changed" callback must be implemented by the hardware if the user can select among detector profiles with different effective image sizes.

AVAILABLE FEATURES

Geometric Transformations

Four basic image transformations are implemented: image rotation (90º, 180º, 270º), horizontal and/or vertical flip, pixel binning (scaling) and RoI (sub-image). From the user coordinates point of view, they are applied in that

order. This means that binning factors include the rotation mode, and RoI coordinates are relative to binned pixels. The simultaneous activation of these transformations requires more complex calculations when some of them are either totally or partially done by hardware. In addition, the implementation of arbitrary pixel binning combinations, including values that are not integer divisors of the detector size, is under development.

Some scientific techniques exploit 2D detectors to measure 1D spectra in image stripes. Pixel binning in one dimension is normally used to improve signal to noise ratio. Such configurations can lead to a very high frame rate (above 1 KHz), interesting in time-resolved experiments [3]. To keep performance under these conditions, LIMA implements the stripe concatenation mode, where a long sequence of many frames can be read/saved at once as a single concatenated image without additional memory copies. In case the original 2D images are required for analysis (i.e., no binning applied), the same stripe calculation can be obtained by the independent RoI-to-spectrum software operation.

Basic Image Processing

Hardware detector constrains can limit the pixel integration either in exposure time (Frelon) or in dose (Maxipix [2]). A simple solution to this problem is provided through the frame software accumulation. It is activated by specifying a maximum frame exposure time; the control layer programs the real number of hardware frames depending of the requested total exposure. In addition to the accumulated image, a saturation pixel mask can also be obtained from the algorithm, important to detect non-linear software artefacts.

Basic image processing algorithms like background subtraction, flat-field correction and pixel masking are already integrated. Standard calculations used for Beam-Position-Monitoring (BPM) including intensity sum, average, std. deviation, min/max and centroid position are also available in a per-RoI basis. That is, the so-called "RoI-counters" are calculated in parallel on multiple sub-images for each frame. The history of the all the RoI-counters is available during and/or after a sequence of images (scan).

Data Saving

Data storage is a key element in high performance image acquisitions. In addition to the detector images, meta-data describing the acquisition environment, including user-supplied meta-data, must be saved. The meta-data concept is called "frame-header" in LIMA and is implemented in the core of ProcessLib as key→value maps. Three levels of meta-data are identified:

- Static: does not change during the life of the process (detector-specific: model, serial number).
- Common: is shared by all the frames in an acquisition sequence (user-defined sample name, sequence start date/time).
- Frame: specific information when frame was taken (high resolution time stamp, instantaneous internal and/or external counters values).

There are three file saving modes currently implemented in LIMA. They differ in the way to trigger the saving of each frame: manual (user request), auto-frame (frame is ready) and auto-header (both the frame and its user-defined header are ready).

The following file formats are currently supported:

- EDF: ESRF Data Format
- Nexus/HDF5: part of the Common Data Model (CDM), developed by SOLEIL and ANSTO
- CBF: Crystallographic Binary Files. It is optimised in LIMA with parallel frame compression.
- Raw

The library also allows the parallel saving of multiple file streams on different medias. This data replication technique has proven to be efficient in high throughput detectors when multiple endpoints (PC, file servers) must receive the same data. Data endpoints examples include: online data analysis workstation, central data storage server (backup, long-term archiving) and local NAS with BL user disks (to be brought to their home institute).

Online Visualisation

Online data visualization is required in must of the cases as a direct feedback of the acquisition evolution. Current LIMA display mechanisms export the image data to a channel, to be read by a separate client application that performs the real visualisation. One method publishes the data on the standard ESRF SPEC Shared memory (SPS). A second method exports the generic LIMA video interface through the TANGO LIMA server. In each case, a dedicated client Qub/Qt4-based application shows the live image.

External Software Plug-ins

Finally, user-defined software plug-ins can be used to execute arbitrary image-based operations. An entry point in the control layer completely exports the ProcessLib functionality, allowing an external code to be called on every frame. Again, the external software operation can be implemented C++ or Python.

PROJECT STATUS

Supported Detectors

The list of currently supported detectors is:

- Camera simulator: a pure software plug-in
- ESRF Espia-based Frelon camera and Maxipix detectors (Single chip, 2x2 and 5x1 chip arrays)
- Dectris Pilatus and Mythen
- GigE Basler and Prosilica cameras
- ADSC and MarCCD detectors
- XPAD pixel detector
- Roper Scientific cameras through PVCAM
- PCO.Dimax (under development)

Current Applications

The first application on top of LIMA was the ESRF Frelon TACO device server; aimed to be 100 % compatible with its predecessor. The existence of an important amount of SPEC code for different Frelon-based experimental setups allowed the fast commissioning and validation of the basic LIMA elements.

In parallel, a generic LIMA TANGO device server was developed, with the ESRF Maxipix detector as its first specific hardware plug-in. As new hardware plug-ins were added, this new TANGO interface gradually exported the full LIMA potential: multi-chip reconstruction, RoI-counters, frame accumulation, background/flat-field, video and so on. New SPEC code has been written to efficiently exploit this new 2D detector functionality.

A different YAT-based TANGO server interface has been developed and maintained by SOLEIL Synchrotron, allowing LIMA integration in their control system.

Finally, an X-BPM TANGO server on top of LIMA has been developed; its installation currently uses Basler cameras.

Operating Systems

LIMA has been mainly developed on Linux operating systems, mainly on SuSE Linux 8.2 (i686) and on RedHat EL 5 (x86_64). It has been later ported to RedHat EL 4 (i686) and OpenSuSE 11.2 (i686 & x86_64).

A Windows portage has been made by coding basic thread management primitives. After the validation of the camera simulator, real hardware plug-ins like the PCO.Dimax are under development.

Performance

The first validation of LIMA performance has been made with the ESRF Frelon HD camera controlled by a Transtec X2100 Workstation (Dual Intel Xeon @ 2.66 GHz, 32-bit). Continuous Frame-Transfer-Mode acquisitions at 30 frames/sec (120 MBytes/sec) can be performed with active SPS online display and parallel data saving. Higher frame rates (about 1000 frames/sec) can be achieved on the same PC in stripe (spectrum) mode with hardware binning and Kinetics hardware RoI. As with its non-Lima predecessor, debugging output must be disable to not slowdown acquisition.

The most recent high performance LIMA validation has been done at the ID03 ESRF BL with the Maxipix detector in single-chip configuration. The control PC is a more powerful Ecrin/Trenton server (Dual Quad Core Xeon E5335 @ 2.0 GHz). Acquisitions at the maximum frame rate (about 1500 frames/sec), limited only by the maximum Espia board data rate (180 MBytes/sec), are possible with parallel saving and 5 active RoI-counters definitions.

Code Repository

The LIMA source code is available under the Gnu Public License at the European Phonton-Neutron (EPN) Science Campus Web site [1]. Its development is managed by GIT; the repository can be accessed at [4]. The official project documentation can be found at [5].

ACKNOWLEDGEMENTS

Important contributions in hardware plug-ins and Nexus file saving format have been made by F. Langlois, A. Noureddine, A. Buteau and X. Elattaoui from SOLEIL Synchrotron inside a collaboration framework on LIMA development. In the same way, M. T. Nuñez-Pardo-de-Vera (PETRA III/DESSY) and C. Nielsen (ADSC) have also implemented specific hardware plug-ins.

CONCLUSIONS

A generic Library for IMage Acquisition (LIMA) has been developed for controlling high throughput 2D detectors. It allows the optimum exploitation of hardware optimizations, like pixel binning and RoIs, but it also provides software alternatives for detectors that do not implement them. A common set of software image operations (geometric transformations, processing, calculations, saving and visualization) is available for all the detectors. Their multi-threaded nature notably increase acquisition performance on multi CPU/cores PC. The modular library design simplifies the integration of new hardware and software functionality (plug-ins). An increasing number of supported detectors are already used in Synchrotron facilities with good performance results.

COMETE: A MULTI DATA SOURCE ORIENTED GRAPHICAL FRAMEWORK

G. Viguier, K. Saintin, Y. Huriez, M. Ounsy
SOLEIL Synchrotron, Gif-sur-Yvette, France.
R. Girardot, EXTIA, Sèvres, France

Abstract

Modern beamlines at SOLEIL need to browse a large amount of scientific data through multiple sources that can be scientific measurement data files, databases or TANGO control systems.

We created the COMETE[1] framework because we thought it was necessary for the end users to use the same collection of widgets for all the different data sources to be accessed. Conversely, for GUI application developers, the complexity of data source handling had to be hidden. As these two requirements are now fulfilled, our development team is able to build high quality, modular and reusable scientific oriented GUI software with consistent look and feel for end users.

CONTEXT

The SOLEIL ICA team is in charge of the control system and data reduction software on the beamlines. In the early years of development at SOLEIL, ICA has focused on the control system; today, however, the NeXus storage system is fully integrated into the control system through a set of dedicated devices. It is therefore possible to record any data coming from Tango devices into a NeXus file; SOLEIL beamlines produce daily experimental data files with sizes ranging from a few MB up to 100 GB. This is why there is a huge demand for data reduction applications.

The ATK[2] toolkit helped us to quickly develop applications dedicated to the control system and its supervision. The problem is that ATK is intimately linked to TANGO.

Data reduction software on the other hand is based on the experimental data NeXus file format and doesn't have a dedicated graphical toolkit. It is in this context that SOLEIL launched the COMETE project to propose a multi data source toolkit to help engineers to develop applications independently of the data source.

THE COMETE SOLUTION

Architecture

COMETE is a framework composed of three parts (Fig.1):

1. A set of graphical components (widgets) that are completely dissociated from a data source or even a data type.
2. A data source compatible with the graphical component, each corresponding to a data type.
3. Between the widgets and the data source, a communication layer called DataConnection Management.

Each component of this architecture will be described in the following sections.

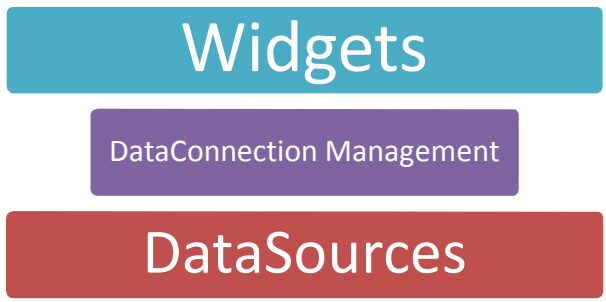

Figure 1: Comete Project Architecture.

Widgets

Comete Widgets are available in three implementations (Swing, SWT & AWT) and therefore integrate well into any existing JAVA software (Fig. 2). Anyone can use this set of widgets because they are based on the three major toolkits. In fact, a Comete Widget is a standard component with some code that makes it connectable to any COMETE data source.

COMETE components are dedicated to scientific data but anyone can easily add new widgets or use the existing components in another context.

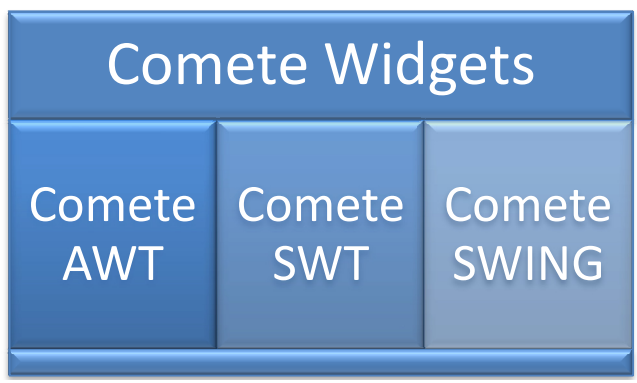

Figure 2: Comete Widget implementations.

The current widget can display:

- scalar data (textfield, spinner, wheelswitch, slider, etc.)
- spectrum data (chart viewer)
- images

Our image viewer is based on ImageJ [3] which is a popular image processing application. ImageJ is already used by many scientists, so it is very easy for them to use our viewer and they can run their old macros through our Java applications. Since our viewer encapsulates ImageJ, it has the same amount of image processing features as illustrated in Fig. 3.

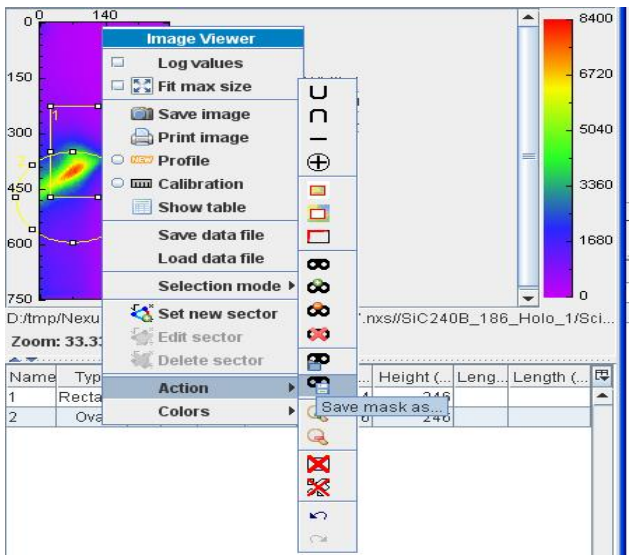

Figure 3: Comete Image Viewer features.

DataConnection Management

The DataConnectionManagement module is a layer that allows connection between two entities, called "target" and "data container".

This system implements a Mediator pattern, as well as various other patterns such as Strategy, Observer etc. Mediator was chosen instead of MVC pattern because our two entities had to be completely independent from each other and from the system evolution.

The focus for this project is to provide COMETE with a solution to connect a widget with a data source, like Tango or NeXus, in a generic way. That means this system is an abstraction of these entities, and provides useful tools to make them communicate without knowing their type.

For example, thanks to the Comete architecture, anyone can superimpose a spectrum coming from a NeXus file with the same spectrum from the control system (see Figure 4).

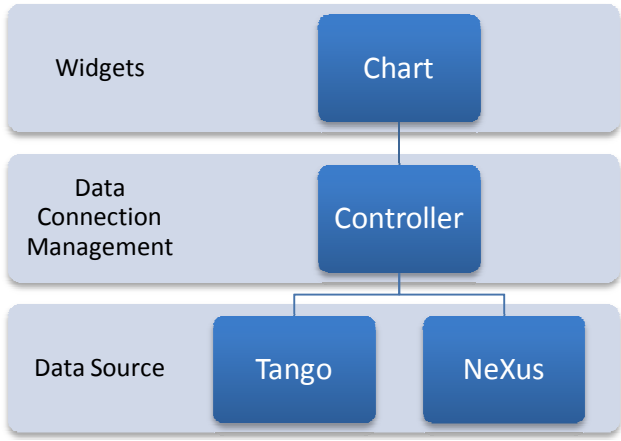

Figure 4: A widget connected to two sources.

DataSources

When someone wants to add a new data source to Comete, the only thing to do is to implement a class called AbstractCometeDataSource. This will make sure that the COMETE controller will be able to send data to the widget and vice-versa.

We made a TANGO implementation for control system software and we are working on a NeXus implementation for data reduction software. We plan to implement a data source for databases because we have an archiving system[4] built on ORACLE systems. Finally, we will have a data source for our sequencer software (Passerelle[5]) and thus enable our users to modify their sequences through our Java software.

CometeBox

The CometeBox module aims to simplify the use of COMETE. The fact that COMETE is a group of six different modules and the complexity of the architecture, especially the widget / source connection, makes it in fact difficult to use.

CometeBox operates on two levels. The first is for connection management: ordinarily, we need about ten to fifteen lines of code to make connections properly between entities, calling numerous functions coming from interconnected projects. With CometeBox, this is reduced to one line: one call to the correct function (Fig. 5).

The second goal of CometeBox is to centralize data handling: the connection process needs a wide range of data, some of them holding the same information. With CometeBox, this data is gathered and only information that is really necessary is stored.

NeXus

- NexusKey key = new NexusKey();
- NexusKeyTool.registerAttribute(key, "myfile", "dataset);
- chartBox.connectWidget(chartViewer, key);

Tango

- TangoKey key = new TangoKey();
- TangoKeyTool.registerAttribute(key, "mydevice", "attribute");
- chartBox.connectWidget(chartViewer, key);

Figure 5: Connect a widget to a data source in 3 lines.

Performance

Five years ago, SOLEIL scientists were working with spectrum detectors or small image cameras. Performance was not a big deal because the data flow was not really impressive. Today this is not true, scientists are buying fast acquisition detectors with big CCDs and they store each frame into NeXus files.

COMETE needs to have a fast and efficient mechanism to transfer data from the source toward the widget. The first version of COMETE was really slow because it was only based on Java objects (*for example: each integer transferred was converted into an Integer Java object*). We thought that this would make COMETE a modern Framework but the memory footprint of every COMETE data reduction program was too expensive. Then we changed our philosophy from 'all object' to 'no object'. That means that today, each data item is transferred through COMETE as a primitive type. Today we are able to load stacks of images from our high data throughput multi detectors experiments [6] in a reasonable time.

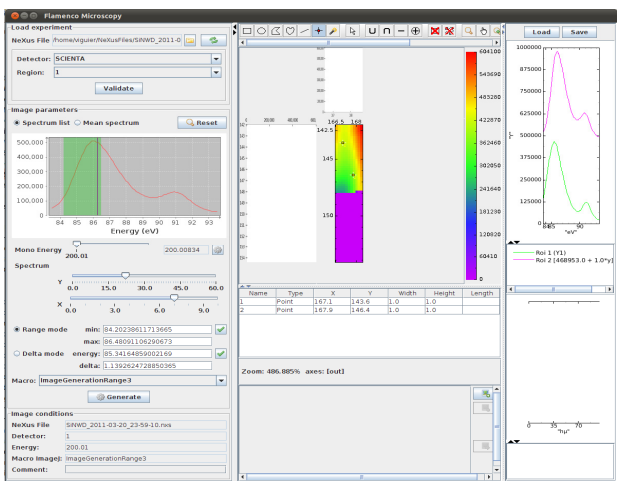

Figure 6: Data reduction software dedicated to microscopy.

EXAMPLES

Fig. 6 and Fig. 7 are two examples of graphical applications based on COMETE and using the same component list with different data sources.

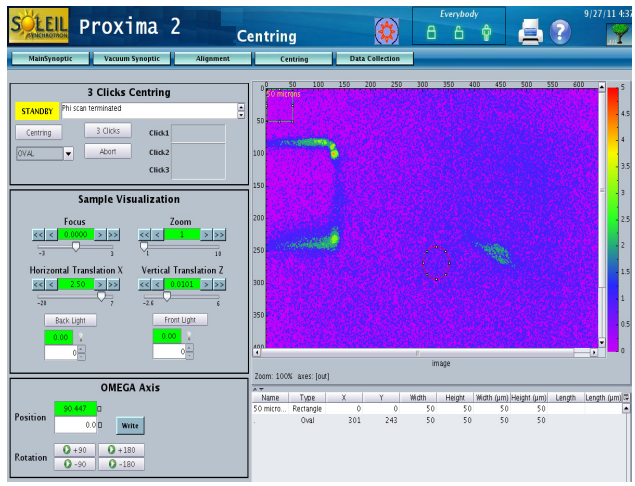

Figure 7: MXCube clone on PX2 beamline.

CONCLUSION

Today COMETE is a great tool for SOLEIL's developers. NeXus novices are able to build smart and effective data reduction software; anyone can develop a new supervision application without the help of TANGO gurus. In the future, we plan to optimize COMETE by implementing new refreshing systems. Data Reduction developers are looking forward to another feature: a mechanism of filters between the data source and the widget. Multiple filters can then be stacked and applied in a given order to an original Data Source to transform it to the final Data Source that will be really viewed by the COMETE widget.

FLOATING-POINT-BASED HARDWARE ACCELATOR OF A BEAM PHASE-MAGNITUDE DETECTOR AND FILTER FOR A BEAM PHASE CONTROL SYSTEM IN A HEAVY-ION SYNCHROTRON APPLICATION*

Faizal Arya Samman, Pongyupinpanich Surapong, Christopher Spies and Manfred Glesner
FG Mikroelektronische Systeme, Technische Universität Darmstadt, Darmstadt, Germany

Abstract

A hardware implementation of an adaptive phase and magnitude detector and filter of a beam-phase control system in a heavy ion synchrotron application is presented in this paper. The main components of the hardware are adaptive LMS filters and phase and magnitude detectors. The phase detectors are implemented by using a CORDIC algorithm based on 32-bit binary floating-point arithmetic data formats. The floating-point-based hardware is designed to improve the precision of the past hardware implementation that were based on fixed-point arithmetics. The hardware of the detector and the adaptive LMS filter have been implemented on a programmable logic device (FPGA) for hardware acceleration purpose. The ideal Matlab/Simulink model of the hardware and the VHDL model of the adaptive LMS filter and the phase and magnitude detector are compared. The comparison result shows that the output signal of the floating-point based adaptive FIR filter as well as the phase and magnitude detector agree with the expected output signal of the ideal Matlab/Simulink model.

INTRODUCTION

In a synchrotron, different modes of coherent longitudinal beam oscillations may occur due to an initial mismatch or to non-linearities such as wake fields. These oscillations are characterized by their mode number m and n [4] and take place at the characteristic synchrotron frequency, which depends on the system state (more precisely, on the magnetic flux derivative, accelerating voltage, and particle energy). In order to eliminate undesired dipole oscillations, a beam phase control system [5] has been devised, which was initially designed to deal with in-phase dipole oscillations ($m = 1, n = 0$) only [5]. The addition of amplitude detectors is intended to make it suitable for damping higher-order modes [4, 6].

This paper presents a new floating-point based architecture designed to improve both the precision and processing speed of the digital controller over previous implementations [2, 11]. The floating-point arithmetic units are used to overcome issues with explosive divergence and stalling effects caused by fixed-point implementations [8]. Such problems may arise due to input or output signal saturation caused by changes in the dynamic signal range at runtime. Using a floating-point representation eliminates the need for input and output scaling that would have to be performed in a fixed-point implementation to accomodate these changes. A floating-point implementation can also be adapted to different dynamic range requirements of other control applications and is therefore more suitable for an integrated circuit implementation (ASIC).

In the following section, the digital signal processing chain of the beam phase control is presented. Its core components are phase and magnitude detectors and adaptive filter blocks, which are discussed in the subsequent sections.

BEAM PHASE CONTROL

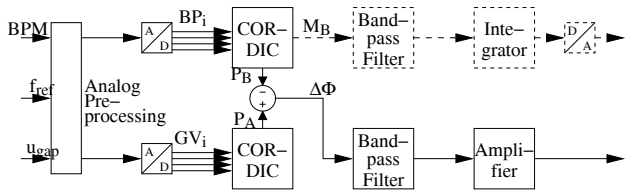

Figure 1: Block Diagram of the Beam Phase Signal Processing.

The signal processing pipeline implemented in the DSP system is shown in Fig. 1. It performs the following steps:

1. Some analog preprocessing is performed on both the gap voltage and the beam position signal [3]. Note that the beam position signal is quite noisy and has a high level of uncertainty since the bunch may have an arbitrary shape.

2. Four successive samples are used to form the in-phase and quadrature components of both signals.

3. The phase of both signals is computed using Alg. 3.

4. The phase difference is fed into a programmable FIR filter in order to eliminate noise and other disturbances in the phase difference. The filter is tuned to a frequency slightly above [5] the synchrotron frequency and has to be re-tuned continuously since this frequency changes.

5. The output of the filter is fed into a variable-gain controller whose gain also depends on the characteristic frequency. This controller yields a frequency correction which is then applied to the cavity in order to intentionally mistune it, thereby pulling the bunch back to its desired position.

BPM is the signal from the beam position monitor. u_{gap} is the voltage across the gap of the reference cavity. f_{ref} is the reference frequency (see [3]). Future extensions [6] are

dashed. In order to enable real-time processing, the phase detector and filtering blocks have been implemented on an FPGA.

PHASE-MAGNITUDE COMPUTATION

Architecture for Phase-Magnitude Computing

The phase and magnitude of the beam signal are detected by using a CORDIC (COordinate Rotation DIgital Computer) algorithm. The drawback of a conventional CORDIC algorithm is its high computation latency [7]. To accelerate the computation, an increment of rotation angle on each iteration becomes one solution. A double-rotation CORDIC algorithm is proposed as depicted in Alg. 1. In the double-rotation CORDIC algorithm, the rotation angle is extended two times (2ϕ) of the conventional CORDIC.

Algorithm 1 MICRO-DRCORDIC-VM

Input: : $X_i, Y_i, Z_i, T, \delta_i$
Output: : X, Y, Z, δ_{i+1}
$X = X_i - 2^{-2\cdot i-2} \cdot X_i - \delta_i \cdot 2^{-i} \cdot Y_i$
$Y = Y_i - 2^{-2\cdot i-2} \cdot Y_i + \delta_i \cdot 2^{-i} \cdot X_i$
$Z = Z_i - \delta_i \cdot 2 \cdot T$

The double-rotation CORDIC algorithm using the redundant method was proposed by Takagi et al. [13]. With the redundant method, the rotation direction of the double-rotation CORDIC algorithm is $\delta_i \in \{-1, 0, 1\}$. However, using the redundant method, the scaling factor is not constant and has to be calculated at run-time. To overcome this problem, we propose the double-rotation CORDIC algorithm as presented in Alg. 2 using the non-redundant method and with a constant scaling factor. Thereby, the online computation problem [1], as well as the scaling problem are also eliminated.

$$\begin{bmatrix} X_N \\ Y_N \\ Z_N \end{bmatrix} = \begin{bmatrix} K_{dr}\sqrt{X_0^2 + Y_0^2} \\ 0 \\ \arctan\dfrac{Y_0}{X_0} \end{bmatrix} \quad (1)$$

Algorithm 2 DRCORDIC-VM

Input: : $X_{in}, Y_{in}, N, LTAN, K_{dr}^{-1}$
Output: : X_{out}, Z_{out}
X_0=X_{in}, Y_0=Y_{in}, Z_{in}=0, δ_0=1 {Initialization}
if $Y_0 \geq 0$ **then**
  δ_0=1;
else
  δ_0=-1;
end if
for $i = 1 to N$ **do**
  [X, Y, Z]=MICRO-DRCORDIC-VM($X_o, Y_o, Z_o, TLUT(i), \delta_i$)
  if $Y \geq 0$ **then**
    δ_{i+1}=1;
  else
    δ_{i+1}=-1;
  end if
  $X_0 = X$
  $Y_0 = Y$
  $Z_0 = Z$
end for
$X_{out} = X \cdot K_{dr}^{-1}$; Z_{out}=Z

The constant scaling factor for the double-rotation CORDIC is given by $K_{dr} = \prod_{i=1}^{N}(1 + 2^{-2i-2})$ which approximately equals 1.084727 ($K_{dr}^{-1} = 0.9219$), and the maximum and minimum rotation angle $\sum_{i=1}^{N} 2tan^{-1}(2^{-i-1})$ is in the range of [-0.9885,+0.9885].

Alg. 3 shows the computation of the beam phase and magnitude based on online measurements of the gain voltages GV_i and beam position BP_i signals [2], which is illustrated in Fig. 1. The beam phase difference signal ($\Delta Phase$) is obtained from the difference between the phase detection signals P_A and P_B of the gap voltages GV_i and beam positions BP_i signals, respectively.

Algorithm 3 BEAM Phase and Magnitude

Input: : GV_1,GV_2,GV_3,GV_4,BP_1,BP_2,BP_3,BP_4
Output: : $M, \Delta\Phi$
$Q_{1A} = GV_1$; $I_{1A} = GV_2$; $Q_{2A} = GV_3$; $I_{2A} = GV_4$
$Q_{1B} = BP_1$; $I_{1B} = BP_2$; $Q_{2B} = BP_3$; $I_{2B} = BP_4$
$\Delta X_A = Q_{1A} - Q_{2A}$
$\Delta Y_A = I_{1A} - I_{2A}$
[M_A, P_A]=DRCORDIC-VM($\Delta X_A, \Delta Y_A, N, TLUT, K_{dr}^{-1}$)
$\Delta X_B = Q_{1B} - Q_{2B}$
$\Delta Y_B = I_{1B} - I_{2B}$
[M_B, P_B]=DRCORDIC-VM($\Delta X_B, \Delta Y_B, N, TLUT, K_{dr}^{-1}$)
$M = M_B$
$\Delta\Phi = P_A - P_B$

The architecture of the 3-stage double-rotation CORDIC algorithm for the beam phase-magnitude detection is illustrated in Fig. 2. The 3-stage pipeline architecture is designed to improve the performance of the beam-phase detector.

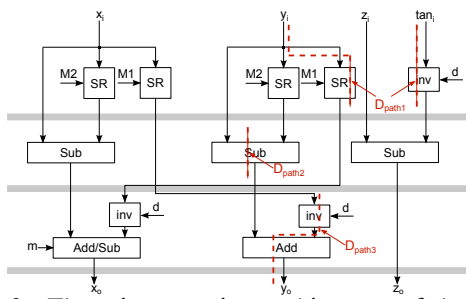

Figure 2: The micro-rotation architecture of the 3-stage double-rotation CORDIC algorithm, where $M_1 = -i$, $M_2 = -2i - 2$ and $d = \delta_i$.

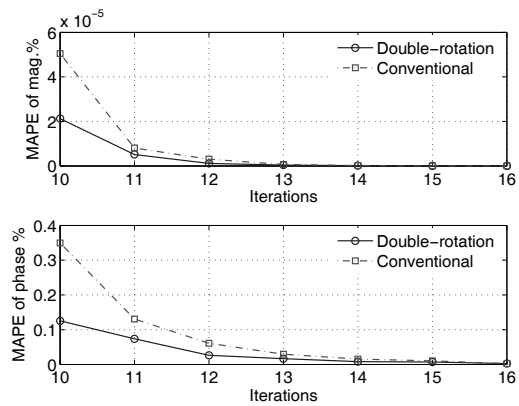

Figure 3: MAPE comparison of the conventional CORDIC and the double-rotation CORDIC.

Figure 3 depicts the performance comparison between the conventional and the double-rotation CORDIC algorithm by using the MAPE metric. MAPE stands for

Mean Absolute Percentage Error and is a statistical measurement of the CORIDC output accuracy formulated by $\frac{1}{n}\sum_{s=1}^{n}|\frac{c_s - m_s}{c_s}|$, where n is the number of measurements, c_s is the CORDIC output and m_s is the ideal output. The figure shows that the double-rotation technique gives better accuracy with the same number of iterations. In other words, for the same MAPE value, the double-rotation CORDIC requires less interations.

Simulation and Synthesis Results

The simulation result of the double-rotation CORDIC algorithm for the beam phase signal detection is depicted in Fig. 4. The figure presents the beam input signal, the reference signal and the the output of the phase detector. The output of the beam phase detector (beam phase signal) is interfered with noisy signal. Therefore, the noise signal should be filtered to acquire the noise-free beam phase signal. The filtering issue is described in the next section.

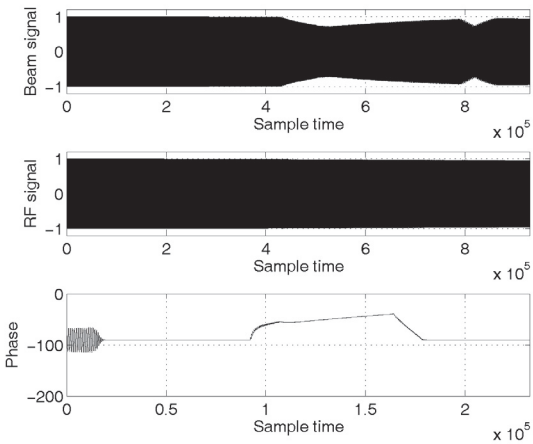

Figure 4: Beam input, reference and beam phase signals.

Table 1 shows the synthesis results of the micro-rotation of the double rotation CORDIC algorithm onto a Xilinx FPGA vlx110t-2ff1738 for different implementations (in terms of the number of pipeline stages). Logic area comparisons between the conventional (CV) and the double-rotaion (DR) CORDIC architectures are presented in the table.

Table 1: Synthesis Results on Xilinx FPGA vlx110t

CORDIC	Utilization			Min. Delay (ns)	Max. Freq. (MHz)

PHASE DIFFERENCE SIGNAL FILTERING

Filter Architecture

The noise in the phase difference of the beam signal shown in Alg. 3 is filtered by using adaptive FIR filter in which the filter parameters are adaptively tuned by using a least-mean-square (LMS) algorithm. The hardware architecture of the adaptive FIR filter is designed by using the combination of serial and parallel structures. This combination is made to fulfill the time constraint of the application and the area constraint of the FPGA device. Figure 5 presents the serial-parallel architecture of the adaptive FIR filter with 64 taps. Two registers are controlled by a control unit and are used to store the sampled input signal $x(k-j)$ and the filter parameters w_j. The filter output computation is implemented in serial, while the filter parameter adaptation algorithm is implemented in parallel.

Floating-point adder, multiplier and multiplier-accumulator units were used in the filter architecture. The operands are IEEE single-precision binary floating-point numbers [12], i. e. they have 1 sign bit, 8 exponent bits and 23 mantissa bits. The floating-point adder architecture consists of three stages: exponent difference and alignment, adding/subtracting combined with leading-on-detection and normalization stage.

The floating-point multiplier architecture also consists of three stages: exponent adding and mantissa multiplication, mantissa shifting and normalization stages. In the normalization stages, the arithmetic computing results are normalized into the standard 32-bit (single precision) binary floating point format. The normalization stages include also the zero and infinity detections of the data values according to the IEEE standard [12]. This approach is the same as the one used in other projects documented in available literature [8].

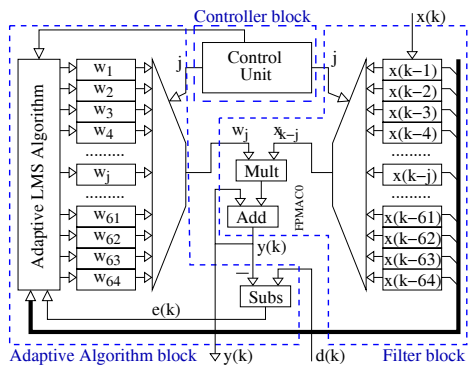

Figure 5: Adaptive FIR Filter architecture with 64 taps.

Simulation and Synthesis Results

Figure 6 shows the input-output signals of the adaptive filter, the desired output signal and the error signal between the filter output and the desired output signals. The main challenge of the adaptive FIR filter hardware in practice

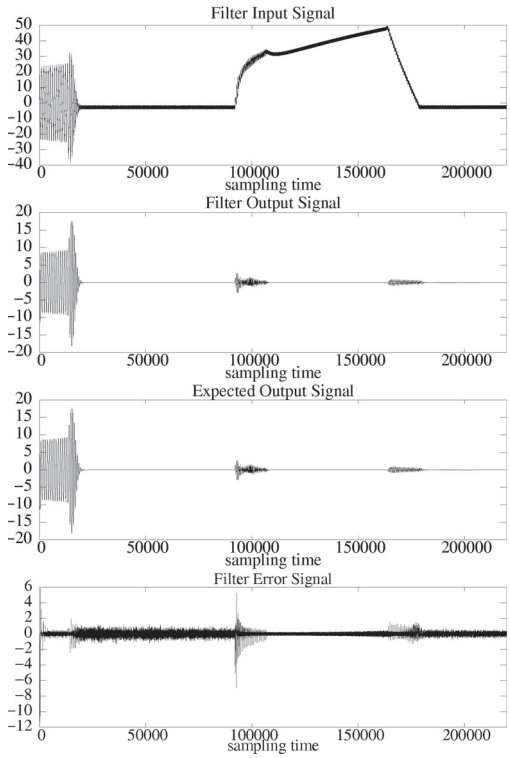

Figure 6: Filter input-output signals.

Table 2: Synthesis Result on FPGA Virtex 5 Device

	Utilization	% of Total
Number of slice registers	38,549	31%
Number of slice LUTs	75,485	61%
Minimum Delay	7.462 ns	
Maximum Frequency	134.018 MHz)	

is the generation of the expected filter output. At present, the expected signal is calculated off-line. In the simulation results shown above, the signal was captured from a system model [9, 10]. We are working on a hardware implementation of a simplified system model that can serve as a reference in the future.

The adaptive FIR filter with LMS algorithm has been implemented on the Virtex5 FPGA device (device type 5vfx200tff1738-2). The device has a total number of 200k logic gates. The synthesis result is shown in Table 2.

CONCLUSIONS AND OUTLOOKS

The beam phase-magnitude hardware detector based on the double-rotation CORDIC algorithm has been presented. Compared to the conventional CORDIC algorithm, the double-rotation CORDIC algorithm provides better accuracy. The adaptive FIR filter architecture that combine serial and parallel computation modes is also presented. The adaptive LMS algorithm is driven by the error signal between the filter output and the desired signal. For now, the desired signal is calculated off-line. In the future, we plan to include a simplified system model in order to supply the adaptive FIR filter with an expected signal that is not known a priori.

SPI BOARDS PACKAGE, A NEW SET OF ELECTRONIC BOARDS AT SYNCHROTRON SOLEIL

YM. Abiven*, P. Betinelli-Deck, F. Blache, J. Bisou, F. Briquez, A. Chattou, J. Coquet, P. Gourhant, N. Leclercq, P. Monteiro, G. Renaud, JP. Ricaud, L. Roussier,
Synchrotron Soleil, Paris, France

Abstract

SOLEIL is a third generation Synchrotron radiation source located in France near Paris. The Storage Ring currently delivers photon beam to 23 beamlines.

As the machine and beamlines improve their performance over time, new requirements are identified. On the machine side, new implementation for feedforward of electromagnetic undulators is required to improve beam stability [1]. On the beamlines side, a solution is required to synchronize data acquisition with motor position during continuous scan.

In order to provide a simple and modular solution for these applications requiring synchronization, the electronics group has developed a set of electronic boards known as the "SPI board package".

This paper describes the development conducted and the results obtained with this solution.

REQUIREMENTS

Since accelerators and beamlines work and received users, operational feedback has enabled us to identify requirements to improve systems. The two main requirements are the improvement of beam stability during undulator movement and the enhancement of the beamlines scan. The translation of these two requirements in terms of control is as follows:

- Upgrading control of Electromagnetic undulators to improve the feedforward
- Developing an optimized control for EMPHU (rapid undulator combining coils and permanent magnets).
- Processing encoder signals:
  - Interfacing incremental encoder signals with our standard counter board
  - Protocol Conversion
    - incremental encoder signals into « PULSE » and « DIR »
    - single turn absolute encoder to multiturn absolute encoder…
    - generating trigger or synchronization from encoder signals
    - calculation on multiple encoders
    - duplication of encoder signals

Moreover our strategy for these developments not only considers technical aspects but also budget and working load. The R&D activity of the ECA (Electronic Control and Acquisition) group is shared with accelerators and beamline operation. Considering these aspects, it is crucial for a small team with a small budget like ours to coordinate developments well and choose a technical solution that is easy to implement and maintain.

In order to offer a solution to these requirements, the ECA group has implemented the following architecture.

ARCHITECTURE

In the SPI board package architecture (Figure 1), the boards can be connected together in a daisy chain and communicate with the controller via a SPI (Serial Peripheral Interface) Bus. Communication with the control system is done via Ethernet.

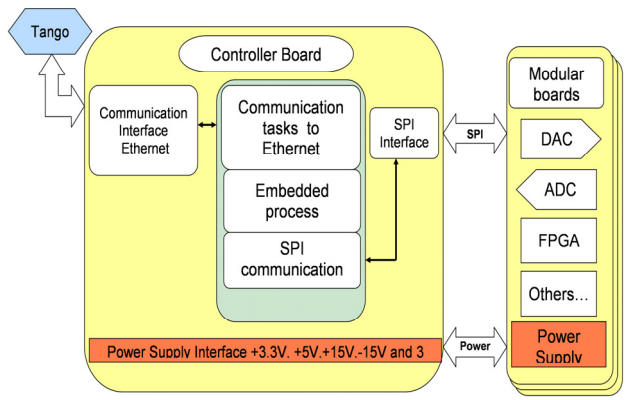

Figure 1: Functional diagram of the SPI BOARD PACKAGE.

The goal of this architecture is to give us a platform on which we can develop specific solutions with simple, reliable and durable tools. The platform is suitable in particular for applications with synchronization requirements, which are managed by implementing the process at low level.

Furthermore, this platform is modular. Each board can be connected with others as needed. And it enables us to deliver solutions for applications with an analog interface or motion interface (encoder side). Finally it's easy to connect it to the Soleil control network.

*yves-marie.abiven@synchrotron-soleil.fr

TECHNICAL CHOICES FOR PROGRAMMABLE COMPONENTS

In order to give a solution for the requirements identified in 2007, initial versions of boards were developed with basic components which allowed us to start quickly and validate the architecture. The first version of the controller board is built around an 8051 microcontroller communicating via Profibus to the supervision. For the board processing encoder signals, we use a basic SPARTRAN III FPGA Xilinx [2].

Microcontroller

Thanks to this experience with the first boards, an upgrade of the controller board called SPICONTROLLER has been approved for a more powerful microcontroller with an Ethernet interface. After analysing the market states for microcontrollers and microprocessors, ARM cortex M3 technology was selected.

The choice of this device takes into account the state of the technology, the price and the investment required for the development tools and test bench.

The device selected for the development is the Texas Instruments [3] LM3S9B96 for the following characteristics: Multipurpose microcontroller used in industry and medical applications: Integrated Ethernet controller, Ethernet 10/100 MAC&PHY, On-chip Memory: 256KB Flash, 96KB SRAM, 80MHz Cortex Processor Core, 2 SPI interfaces.

For the embedded software of the SPICONTROLLER, after evaluating different operating systems and TCP/IP stacks, we selected RTX and TCPnet.

The choice to use this OS and TCP/IP stack is motivated, after evaluation of other OSs and stacks, by the full set of configurations and the ease of configuration via a wizard in the Keil [1] framework.

FPGA (Field Programmable Gate Array)

The FPGA selected for the SPIETBOX was chosen because it had sufficient capacity in terms of pins, cells etc., to implement the first requirement of protocol conversion for encoders (figure 2).

Furthermore this FPGA was already used by the team on the TIMBEL cPCI board [4]. The experience with this component allowed us to quickly design the SPIETBOX. This board is now also used to implement more complex applications such as “Synchronization of Goniometer and Pilatus detector for continuous scan” This application is presented below in the results section.

For that reason, we are envisaging, for future requirements, improving the performances of the FPGA and the input and output of the board.

But before considering an upgrade of the SPIETBOX, a review of the first experience and an analysis of the new requirements must be carried out.

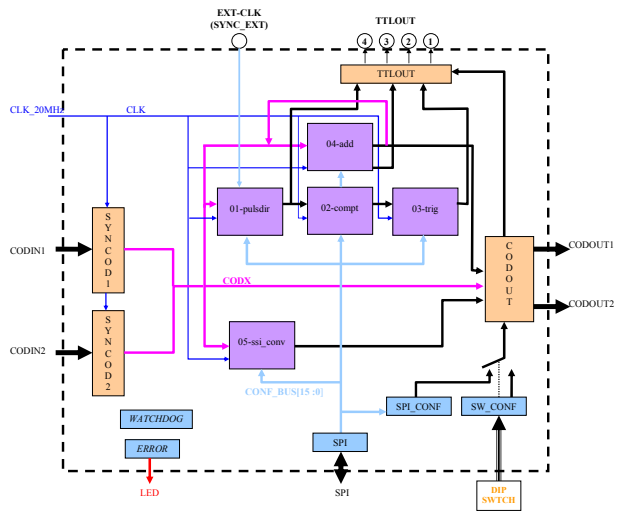

Figure 2: FPGA architecture of protocol conversion for encoders.

BOARDS

To date, the ECA group has developed the following set of boards:

- SPICONTROLLER: controller board with Cortex M3 microcontroller.
- SPIDAC: DAC 4 channels board, 16 bits, ±10V range
- SPIADC: ADC 4 channels board, 16 bits, ±10V range
- SPIETBOX: Processing encoder signal board based on Xilinx FPGA SPARTAN III, 4 Encoder inputs/outputs, 4 TTL Outputs, 1 SPI interface (Works in standalone or connected to SPICONTROLLER

This set of boards is integrated in a low cost standard 3U, 19” crate as shown on Figure 3.

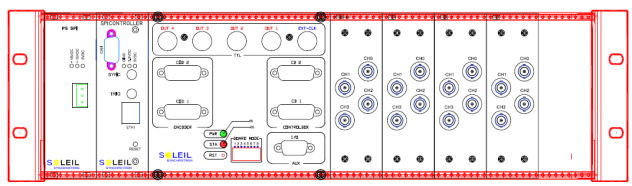

Figure 3**:** SPI Boards integration**.**

SOFTWARE STANDARDIZATION

To ease the integration of the SPICONTROLLER in the control systems, a generic memory structure has been specified. The memory is organized in 32 bits data block Registers with the following organization: State, Status, Error, Command, RW and Read Attributes.

You can have as many blocks as you have identified objects or functions.

This organization of the memory fits with the requirements of the generic Tango [5] device server known as SPIdataviewer. This server is designed to be

easily configured to access the memory of the SPICONTROLLER.

RESULTS

In this part, we describe two applications of the SPI board Package already in production.

Upgrade of the Control of HU256 Electromagnetic Undulator

Each HU256 undulator[6] is driven by a total of fifteen power supplies including three main power supplies, four correction power supplies and eight so-called modulation power supplies. Whereas the main power supplies generate the 256 mm period, 3 m long periodic magnetic field, which makes the electron beam radiate, the correction power supplies create short extremity magnetic fields in order to cancel the residual closed orbit distortion caused by the undulator magnetic defects. Finally the modulation power supplies modulate some field peaks, allowing the so-called quasi-periodic mode, in order to decrease the intensity of the radiation higher harmonics.

Since they were installed, the three HU256 undulators used to be driven using the Profibus interface, but many transitory variations could be observed on the electron beam orbit, perturbing the radiation stability for all the beamlines as shown on Figure 3. An analysis determined that these effects were caused by non-synchronization between the different power supplies.

The upgrade of the system entails generating synchronized analog signals with the SPICONTROLLER in order to drive the power supplies. This evolution allowed improved synchronization of the power supplies, leading to a decreasing of the orbit transitory perturbation and thus as shown on Figure 4, reduced use of the SOLEIL storage ring fast orbit feedback.

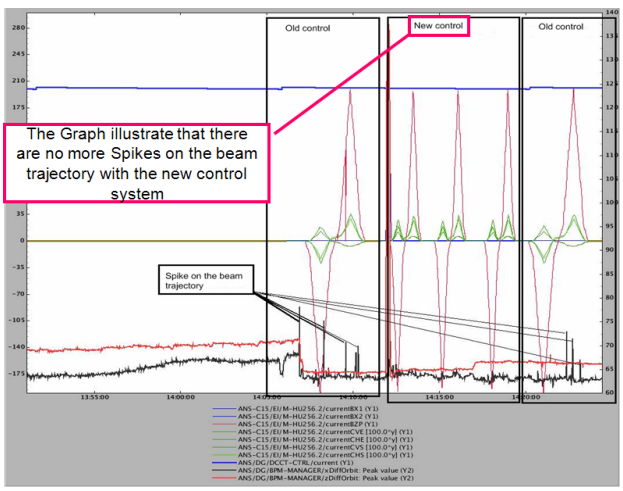

Figure 4: Acquisition showing the difference between old and new control system of HU256 undulators.

Synchronization of Goniometer and Pilatus Detector for Continuous Scan

On PX1 beamline [7], when a continuous scan is done acquiring Frames on Pilatus detector during goniometer movement, the following architecture (Figure 5) has been implemented to:

- Synchronize goniometer position, Shutter aperture and Pilatus acquisition
- Check that acquisition is well done.

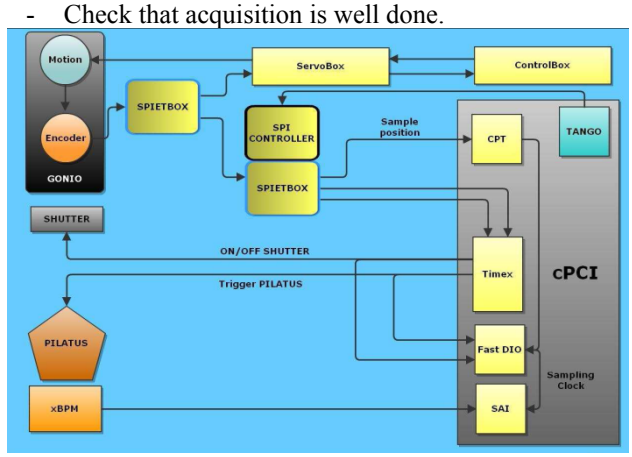

Figure 5: Architecture for PX1acquisition with Pilatus.

The Pilatus detector allows four acquisition modes that are four different ways to synchronize acquisition. In this architecture these synchronizations are implemented in the SPIETBOX managing the following signals: encoder position, trigger to and from the Pilatus, shutter trigger.

The SPICONTROLLER is used to configure the different modes and to transfer some information along the process. The information coming from the SPIETBOX and beam intensity from XBPM are logged for diagnosis along the process.

At the moment in the most used acquisition mode with Pilatus internal clock (Figure 6), the SPIETBOX sends a trigger to start the detector which uses its own internal clock to take the images.

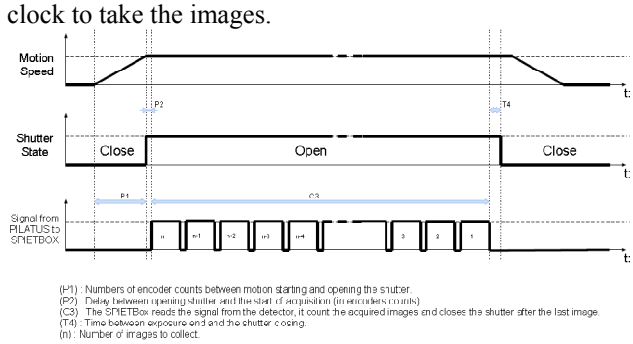

Figure 6: Timing of the most use triggering mode.

The advantages of this architecture using the SPIETBOX are to have good correlation between data acquisition and motor movement thanks to hardware synchronization. It enables the scientists to have a quick validation of the acquisition, thanks to the logging of all experimental conditions. Lastly, it simplifies control of the Pilatus detector's modes.

CONCLUSION

This platform allows us to embed process close to the hardware with open tools. Thanks to this solution we improve the performances of applications requiring beam stability or synchronization of multiple detectors acquisition.

The next step to increase calculation possibilities with this platform is to upgrade the SPIETBOX but we are also considering developing a co-processing board for SPICONTROLLER based on DSP or FPGA.

Future applications using this solution will include:

- Upgrade of HU640 Undulators to improve switching performance.
- Control of Emphu Undulators.

Finally all these boards are interesting for other synchrotron facilities that have the same requirements. In order to collaborate with them, the ECA group shares a part of these developments through the “Open Hardware Repository (OHR) [8]” platform.

FABRIC MANAGEMENT WITH DISKLESS SERVERS AND QUATTOR IN LHCb

P. Schweitzer*, E. Bonaccorsi, L. Brarda, N. Neufeld, CERN, Geneva, Switzerland.

Abstract

At CERN LHCb experiment (Large Hadron Collider beauty), in order to reconstitute and filter events, a huge computing facility is required (currently ~1500 nodes). This computing farm, running SLC (Scientific Linux CERN) [1], a Red Hat Enterprise Linux (RHEL) [2] derivate, is net booted and managed using Quattor [3] to allow easy maintenance. LHCb is also using around 500 diskless Credit Card PCs (CCPCs) embedded in the front end electronic cards. To go farther than the limited Red Hat provided (and now deprecated) netboot tools, a new solution has been designed and will be shortly presented in this paper.

LINUX DISKLESS

All these computing nodes get their operating system (Linux) from some dedicated servers (each server is controlling a slice of the farm).

Boot Process

The node's boot ROM sends a DHCP query. Its server replies with the IP address to use and the location of the pxelinux.0 stage 2 loader file. The node gets this file by TFTP and starts it. The stage 2 boot loader then loads the Linux kernel and initial ramdisk and gives the control to the initialisation script located in the ramdisk.

This script has to setup the networking, mount the root file system from the server and switch to this NFS root. It then passes the control to the usual Linux initialisation scripts.

For many reasons, the running Linux needs to write files in many locations. We will now see the Red Hat way of making these files writeable and the problems and limitations of this method. Then we will talk about what was developed to circumvent these problems and limitations.

Diskless: Red Hat Way

Up to RHEL5, Red Hat had a package named system-config-netboot to setup diskless servers. It was a set of python and bash scripts that were setting up the dhcpd and tftpd servers, customising the shared root file system and making the initial ramdisk for the diskless nodes.

To make some files of the root file system writeable for the nodes, with possibly different contents, the initialisation script from this package was making the following actions after having mounted the root file system:

- Mount the 'snapshot' directory from the server, in read/write mode. This directory contains one sub-directory per node and two files with the list of the files that need to be writable.
- Remount (using the bind mount option) each of these files from the node's snapshot to the root file system.

There are two problems with this method:

- Only files or folders of the fixed list can be writeable. To add a file to that list, we have to reboot the nodes after the file list modification.
- The mount table is 'polluted' by all these remounts.

Diskless: New LHCb Way

To add flexibility to the diskless nodes handling, we had the idea of using file system union, which is usually used on Linux live media (CDs, DVDs or USB keys). As LHCb is using Scientific Linux CERN 5 in production and SLC 6 has been released and will go in production, the new system had to support both.

FILE SYSTEMS UNION

The principle of the file system union is to join several file systems, at least one read-only (generally) and one read-write and use that union as a normal Linux file system. The behaviour is the following:

- When creating a file, the file is directly created on the read-write file system.
- When writing a file, if the file only exists only on the read-only file system: the modified file (called copyup) is written on the read-write file system with the same name and hides the read-only version.
- When erasing a file, if the file only exists on the read-only file system: a whiteout file (filename prefixed by '.wh.') is written on the read-write file system to hide the file.

Table 1: Union File Systems Evaluation

		Feature				
		mode	**Copy on write**	**NFS branches**	**Kernel specific rebuild**	**Metadata separation**
Implementation	UnionFS [4]	kernel	Yes	Yes	Yes	No
	Aufs [5]	kernel	Yes	No	Yes	No
	Funionfs [6]	FUSE [8]	Should be	Yes	No	No
	Unionfs-fuse [7]	FUSE	Yes	Yes	No	No

- Renaming a file is done by copying the old file under the new name on the read-write file system and hiding the old file with a whiteout file.

Several implementations of file system fusion were evaluated. Table 1 shows the result of this evaluation.

We first tried to make the union on the nodes during diskless initialisation but finally choose to do it on the server, and NFS exports the "unioned" file system. Client side union was just using too much memory on the CCPCs.

An Union File System Designed for Diskless

While evaluating union file systems implementations, it became clear that none was perfect for net booted nodes. All were designed with totally different goals than ours.

One of the big problems was that too many copyups were made on the read-write file system.

So we decided to implement an union file system designed for diskless systems, with the following functionalities:

- union between only one read-only and one read-write file systems
- if only the file metadata are modified, then do not copy the whole file on the read-write files system but only the metadata (stored with a file named as the file itself prefixed by '.me.')
- check when files on the read-write file system can be removed

As a proof of concept, a first version of this new union file system, named PierreFS (until we find a better name) as been developed and successfully tested: the read-write file system was only containing configuration files configured by our Quattor configuration system and runtime files in /var. Even library pre-linking, which was making a lot of copyups in other implementations did none in PierreFS.

The next step will be the implementation of this file system directly as a module for the kernel, without the use of FUSE. This is a huge work that will make it more efficient using less memory. Of course, it will have to be compatible for both SLC5 and SLC6 kernels.

QUATTOR COMPONENT

The LHCb experiment is using the Quattor toolkit to manage the configuration of all its Linux servers and nodes.

In the previous Quattor component in charge of the diskless configuration, supporting the Red Hat way, many things were done by the Red Hat system-config-netboot package. Some of the scripts in this package were buggy, with no output in case of problems. Red Hat totally removed that package in RHEL6, the distribution SLC6 is based on.

As the Quattor component itself was not really maintainable, it was decided to completely rewrite it to make it more efficient and modern, and handle completely the new diskless model, of course without using the system-config-netboot scripts.

System-config-netboot Replacement

In this package, several scripts were used by the Quattor component:

- pxeos & updateDiskless were in charge of copying the kernel and building the diskless specific initial ramdisk (initrd.img): in the new component, updateDiskless repackaged, is still used for SLC5 while rracut is used for SLC6. CCPCs are a special case as they do not support pxe: the wraplinux utility is used to create the nbi file containing the kernel and the ramdisk together.
- pxeboot was in charge of making the pxe configuration files for the nodes. The functionality is now in the Quattor component.
- mkdiskless was used to customise the shared root file system for diskless use. The functionality is now in the Quattor component, with a possible call to an external script.

Other Improvements

Rewriting the component gave us the possibility to greatly improve it and simplify the setup of diskless servers.

In the previous setup, the root file system shared by all nodes was created by copying the server root file system

at the end of its installation. It was not possible to have clients with a different architecture or a different version of the Linux distribution. We added the functionality to create the shared root file system for any Linux distribution and architecture, by using the '--installroot' parameter of the yum command. The only thing we have to do is to provide the component a yum configuration file. We can even have one server with many shared root file systems, each with different versions of the distribution and/or different settings. Like this, we can have a node running SLC5, just change some settings on the server, and then have a restart under SLC6.

The dhcpd configuration part now has better support for subnets and the generated files follows more closely the standard, using dhcpd groups to avoid repeating the same options for all hosts.

The diskless component also keeps track of the created and administrated nodes. That way, in case of deletion of a node in the configuration, it can properly remove it, without leaving leftovers. It also handles configuration changes on the nodes (MAC address change, IP address change).

Changes to Another Component

To configure the shared root file systems, the Quattor component runs the Quattor utilities "chrooted" in these root file systems. To ensure proper run of Quattor inside of Quattor, the proc pseudo file system is mounted just before the change root and the Quattor run. This allows locks consistency, but also enables mounting/dismounting. That is why the Quattor NFS component has been fixed to add an option that makes this component only write configuration and not attempt any mount or dismount.

CCPC Support

This new diskless component also comes with a great improvement since it adds CCPCs management into Quattor. Some more tweaks are done on the CCPCs shared root file system and snapshots, as disabling Quattor on them (that would have taken too many resources).

SIDE EFFECTS

On a side note, the use of a FUSE file system as root file system has exposed a bug in the Linux kernel (that appears to be well-known). A workaround has been deployed in the ramdisk init script.

Also, the use of this file system helped revealing security vulnerability in the Linux kernel. Effects of that security vulnerability are really limited and only allow someone who does not have access on a directory to read its contents. Since it is hard to reproduce it out of the box, it has not been reported yet (no easy test-case).

CONCLUSIONS

The concept of using file system union to make diskless systems easier to manage has been successfully tested. We even have new use cases where the way of doing diskless nodes system does not work (eg: Dell management tools, which want to write some inventory files in many places).

The new Quattor diskless component, together with PierreFS will go in production during the next winter shutdown. It will allow us to better manage the Credit Card PCs, which are not supported by the current system. It will also ease the management of the LHCb event filtering farm. With the support of several Linux distributions on the same server, we will be able to easily test SLC6 on the farm nodes, with the ability to go back to SLC5 with a simple reboot of the nodes.

The new file system has been published on SourceForge [9] and the work to integrate it to the kernel will start in October 2011.

MANAGEMENT TOOLS FOR DISTRIBUTED CONTROL SYSTEM IN KSTAR

Sangil Lee, Jinseop Park, Jaesic Hong, Mikyung Park and Sangwon Yun
National Fusion Research Institute, Gwahangno 113, Yuseong-Gu, Daejeon 305-333, KOREA

Abstract

The integrated control system of the Korea Superconducting Tokamak Advanced Research (KSTAR) has been developed with distributed control systems based on Experimental Physics and Industrial Control System (EPICS) middleware. It has the essential role of remote operation, supervising of tokamak device and conducting of plasma experiments without any interruption. Therefore, the availability of the control system directly impacts on the entire device performance. For the non-interrupted operation of the KSTAR control system, we have developed a tool named as Control System Monitoring (CSM) to monitor the resources of EPICS Input/Output Controller (IOC) servers (utilization of memory, cpu, disk, network, user-defined process and system-defined process), the soundness of storage systems (storage utilization, storage status), the status of network switches using Simple Network Management Protocol (SNMP), the network connection status of every local control sever using Internet Control Message Protocol (ICMP), and the operation environment of the main control room and the computer room (temperature, humidity, electricity) in real time. When abnormal conditions or faults are detected by the CSM, it alerts abnormal or fault alarms to operators. Especially, if critical fault related to the data storage occurs, the CSM sends the simple messages to operator's mobile phone. In addition to the CSM, other tools, which are subversion for software version control and vmware for the virtualized IT infrastructure, will be introduced.

INTRODUCTION

EPICS [1] was adopted as a middleware of the KSTAR Integrated Control System (KICS) [2,3] to integrate and control a lot of network-based distributed systems for tokamak operation and plasma experiment. As well known, EPICS is a set of open source software tools, libraries and applications developed collaboratively and used worldwide to create distributed soft real-time control systems for scientific facilities such as particle accelerators, telescopes and other large scientific experiments. Also, Qt-SDK [4] was used as a tool for developing user interface in KSTAR. The KSTAR Widget Toolkit (KWT) [5,6], which is a name of libraries developed on Qt-SDK, had been considered in the view of the following functions:

- Easiness of development
- Maximum effectiveness for user interface
- Performance of visibility
- Software reusability
- Flexibility for requirements of operators
- Independence from OS Platform

CONTROL SYSTEM MONITORING

The KSTAR control system is composed of a lot of local control systems distributed in the vicinity of the KSTAR to operate tokamak, perform experiments and obtain data. The availability of the control system directly results in success or failure of tokamak operation and plasma experiments whereby the Control System Monitoring (CSM) was developed for the purpose of monitoring and supervising the entire control system and IT infrastructure. The CSM consists of two KWT widgets; "BlinkLine" and "CABlinkLabel". The two widgets among many KSTAR widgets were developed only for use in the CSM. Figure 1 shows the configuration of software module configuration for the CSM.

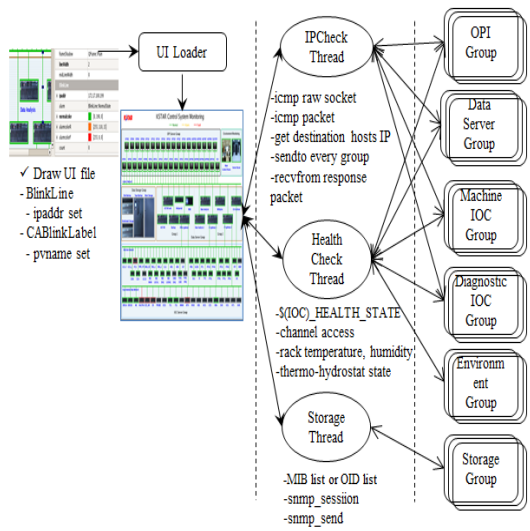

Figure 1: Control System Monitoring software module.

Network Monitoring

"BlinkLine" widget has "ipaddr" property to write IP address for monitoring the network status of IOC server. If "BlinkLine" widget flashes in red, it means that the IOC server has some network problems or has gone into shutdown state. In Figure 1, the "IPCheck Thread" gets IP address from "ipaddr" property of all "BlinkLine" widgets and sends ICMP messages to all host destinations using the "sendto" UDP socket at the same time. The ICMP messages are typically generated for responding to errors in IP datagrams, for diagnosis or routing purposes. In addition, ICMP errors are always reported to the source IP address of the originating datagram. After sending ICMP messages, "IPCheck Thread" receives the response messages using "recvfrom" UDP socket. The request IP list and the response IP list are the same in the normal

state of all networks and all "BlinkLine" widgets display in green. If a problem happens in the connections of some IP addresses, the "BlinkLine" widgets related to those IP addresses will blink in red or orange color.

Server Group Monitoring

The "CABlinkLabel" widget has two alarm states. One is the alarm state blinking in yellow for reporting abnormal status in IOC server's resource. The other is the alarm state blinking in red for IOC server problem. Left-clicking on the "CABlinkLabel" widget generates a resource dialog window to inform a user about the resource status of the IOC server in detail. All servers have their own resource information in the form of EPICS record as follows:

- CPU Load (Idle, Nice, System, User)
- Memory (Available, Used, Free, Swap)
- Heartbeat Count
- System Information (IP address, Up time, Disk, etc)
- Network Packet (In-bound, Out-bound)

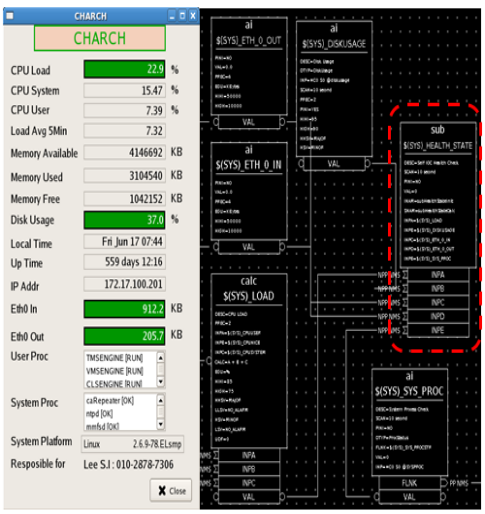

Figure 2: Heath state logic EPICS database.

IOC Health State Logic: $(IOC)_HEALTH_STATE

- Alarm:
  - CPU Load >= 85% or
  - Disk Usage >= 95% or
  - Ethernet Packet >= 20Mbytes or
  - User-defined System Process bit count >= 1
- Normal:
  - CPU Load < 85% and
  - Disk Usage < 95% and
  - Ethernet Packet < 20Mbytes and
  - User-defined System Process bit count == 0

Environment Monitoring

In order to use stable IT resources, it is important to maintain an optimal environment in the control room and the computer room. We have used National Instrument (NI) DAQ modules (cFP-2120, NI cFP-RTD-124 and cFP-DI-304) to monitor the temperature of server racks, the relay signals of thermo-hydrostat and the water leak sensing signals of High Performance Computer (HPC). As shown in Fig. 2, EPICS channel access can be achieved through Ethernet communication between EPIC IOC driver support module and NI module.

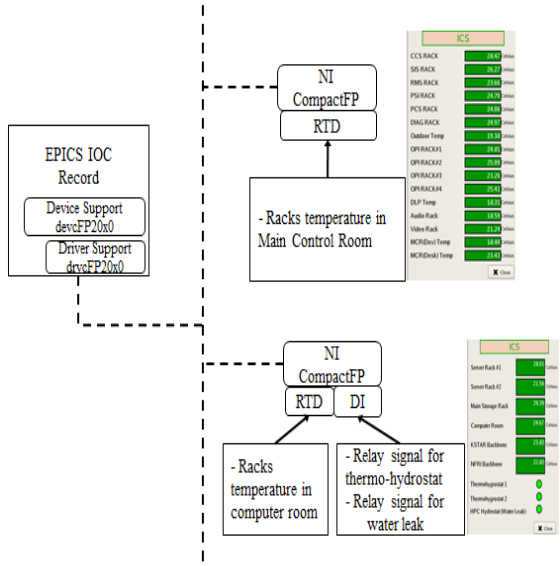

Figure 3: Environment monitoring using NI cFP.

The two "CABlinkLabel" assigned to "Main Control Room" and "Server Room" in Figure 3 blink according to the following alarm logic.

Environment Alarm Logic:

- Main Control Room: ICS_CTRLROOM_TEMP
  - Alarm: 1 rack's temp among 16 racks' temp >= 32 °C
  - Normal: every rack temp < 29 °C
- Computer Room: ICS_SERVERROOM
  - Alarm: 1 rack's temp among 6 racks' temp >= 32 °C or 1 thermo-hydrostat of 2 thermo-hydrostats == alarm or water leak for HPC cooling line == alarm
  - Normal: every rack temp < 29 °C and 1 thermo-hydrostat of 2 thermo-hydrostats == alarm and water leak for HPC cooling line == alarm

Storage System Monitoring

The storage system monitoring has not been fully implemented so far. Some modules were developing using SNMP which is the standard operations and maintenance protocol for the Internet. The SNMP-based management not only produces management solutions for systems, applications, complex devices, and environment control systems, but also provides the Internet management solutions supporting web services. The storage system of KSTAR is also in the form of a management system using SNMP. "Storage Thread" in Figure 1 is being implemented the storage system monitoring module by using the Management Information Base (MIB) that is provided by storage manufacturer. Table 1 shows all IT resources being monitored by the CSM for KSTAR operation.

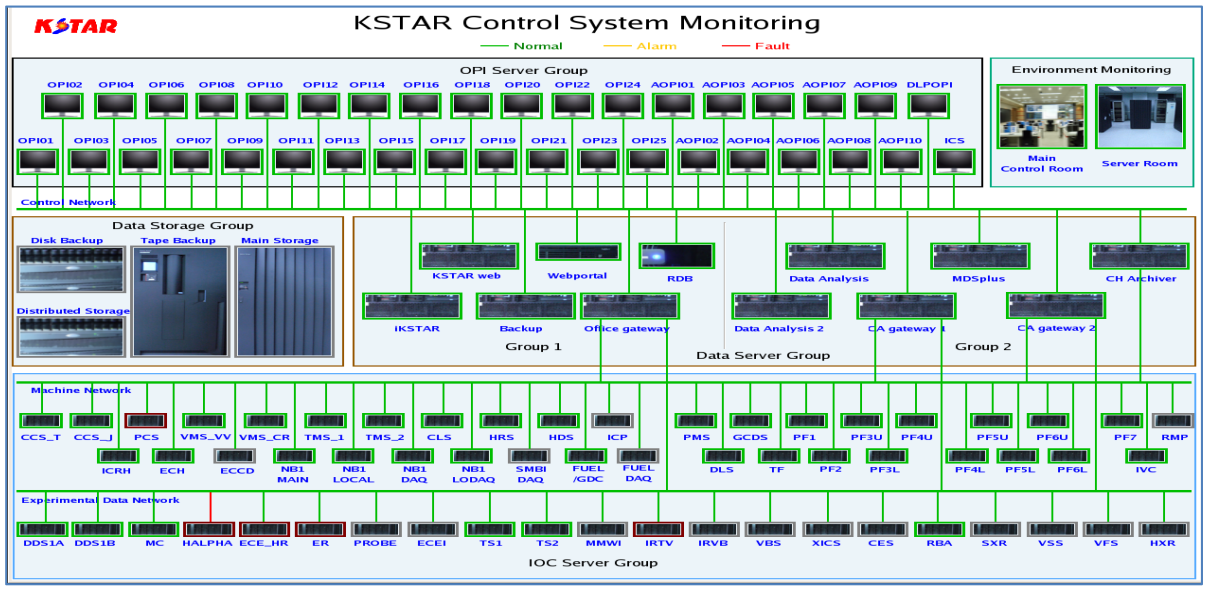

Figure 4: KSTAR Control System Monitoring user interface.

Table 1: IT Resources for KSTAR Operation

Group	Number of server	OS Platform	Network
OPI	35 Servers	Linux	Control
Data	12 Servers	Linux/Window	Control
Plant IOC	37 Servers	Linux/Window	Machine
Diagnostic IOC	21 Servers	Linux/Window	Experiment
Storage	4 Storages		Local
Environment			Control

The Figure 4 shows that the CSM is supervising the entire control system and IT infrastructure for KSTAR operation.

Short Message Service (SMS) System

SMS is a text messaging service component of mobile communication using standardized communication protocols that allow the exchange of shot messages between mobile phone devices (http://en.wikipedia.org/wiki/SMS). Basically the KSTAR Supervisory Interlock System (SIS) manages all the alarms received from the 13 local interlock subsystems and transmits simple alarm messages to operators in charge of the systems which operate for 24 hours a day, such as vacuum pumping system, cryogenic systems, control systems and so on. When the CSM detects any serious problem in main servers like a system shutdown, it notifies the problem to the SIS at once via hard-wired signals. Next, the SIS transmits the alarm messages to a SMS server through RS232 communication and the SMS server relays the alarm messages to CDMA devices. Finally, the operators received the messages correspond to the problem according to emergency procedures.

VERSION CONTROL AND SOFTWARE DEPLOY

Overall, software version control is very important. In particular, it is more important in case that many developers must cooperate with each other or development should be carried out under the distributed environment over a long period of time. The first use case of a tool for software version control was Concurrent Version System (CVS). Later, it was changed to Subversion [7] for some merits as follow:

- Commit unit as work had changed, not a file
- Atomic commits
- Binary file support
- File and directory renames with Unicode.
- Directory version control

Source Code Version Control

Software development in a distributed environment means that the developed codes are distributed more widely and possibility of wrong programs may increase. To create an EPICS IOC, we generate many kinds of files such as c/c++, h, db/vdb, dbd, config, template, st/stt, makefile and so on. It is likely to cause some bugs in programs if we modify or change these different types of files after a long time without software version control. In addition, the necessity of software version control becomes more prominent when program development is carried out by outside contractors.

Software Deploy Management using Subversion

Subversion supports the binary file formats for version control. As shown in Table 1, there are 105 servers for KSTAR operation. Deploying and compiling the source code in every server are very difficult and often a large burden. For these reasons, we installed the linux OS as far as possible to maintain the binary file compatibility and

binary files generated by linux machines work properly in all linux servers except for only a few cases. Therefore, it is possible to deploy the binary modules (libraries or execution files) even if they are generated by a virtualized development server. In particular, it is more suitable for deploying OPI programs because they are modified frequently. The following is the procedure for deploying the binary file.

- Software development in virtualized developing server (source code development and compile)
- Software testing in virtualized distributed servers (software verifying in runtime)
- Commits binary software in SVN server
- Deploying binary software (object files or execution files)

VIRTUALIZATION FOR DISTRIBUTED ENVIRONMENT

Recently, green IT has emerged as a buzzword in the IT industrial field, and among the green IT technologies the computer virtualization technology has the lead. Virtualization of computer (server and desktop) within a limited environment increases the effectiveness of IT resources and reduces costs. As hardware performance and virtualization technology have been improved, a virtual machine has been substituted for a stand-alone server. For the purposes of server redundancy and cost saving, KSTAR has also adopted the virtualization in servers being less intensive against CPU utilization.

The virtualized servers are implemented using ESX/ESXi hypervisor of vmware [8].

Servers virtualized in KSTAR:

- Virtualized OPI servers for remote experiment participants (10 remote OPI servers)
- Virtualized servers for software testing
- Virtualized development servers
- Operation of virtualized EPICS gateway servers

To use the reliable and verified software for KSTAR, new software should be tested and verified first in the virtualized environments which are simulating the real environments before application. In the future, this virtualization will be extended to the data service servers after testing and pre-verification.

FUTURE WORKS

As the KSTAR experiment campaigns have continued, the longer pulse plasma has been achieved and the more data has been obtained. It has led to lacks in network bandwidth and server resources; moreover the shortages become more prominent in the 2011 campaign. To mitigate the insufficiency and enhance the performance of the infrastructure, we will perform the upgrades as follows:

- Completion implementation of storage monitoring system using SNMP in the CSM
- Consideration of clustering server system
- Implementation of fault tolerant server
- Load balancing for data service
- Virtualization for data service

CONCLUSIONS

The CSM has been developed using several standard protocols for monitoring and supervising the entire control system and IT infrastructure to assist the non-interruptible tokamak operation and successful experiments of KSTAR. The faults or alarms detected by the CSM are immediately reported to the operators by the helps of the supervisory interlock system and the SMS system. The operators then quickly restored the problems according to the emergency procedure. As a result of this process, the KSTAR was able to perform the continuous operation and experiment without interruption during the four months. The use of subversion for software version control minimized the human errors due to the wrong software management and helped the stable operation of KSTAR. Through the virtualization adopted in the KSTAR, the time and cost for consisting of IT infrastructure was reduced for the sudden demands of operation. Overall, software testing into the virtualized environment before applying to the real environment increased the stability of the KSTAR operation.

RELIABILITY IN A WHITE RABBIT NETWORK

Maciej Lipiński, Javier Serrano, Tomasz Włostowski, CERN, Geneva, Switzerland
Cesar Prados, GSI, Darmstadt, Germany

Abstract

White Rabbit (WR) is a time-deterministic, low-latency Ethernet-based network which enables transparent, subns accuracy timing distribution. It is being developed to replace the General Machine Timing (GMT) system currently used at CERN and will become the foundation for the control system of the Facility for Antiproton and Ion Research (FAIR) at GSI. High reliability is an important issue in WR's design, since unavailability of the accelerator's control system will directly translate into expensive downtime of the machine. A typical WR network is required to lose not more than a single message per year. Due to WR's complexity, the translation of this real-world-requirement into a reliability-requirement constitutes an interesting issue on its own – a WR network is considered functional only if it provides all its services to all its clients at any time. This paper defines reliability in WR and describes how it was addressed by dividing it into sub-domains: deterministic packet delivery, data resilience, topology redundancy and clock resilience. The studies show that the Mean Time Between Failure (MTBF) of the WR Network is the main factor affecting its reliability. Therefore, probability calculations for different topologies were performed using the "Fault Tree analysis" and analytic estimations. Results of the study show that the requirements of WR are demanding. Design changes might be needed and further in-depth studies required, e.g. Monte Carlo simulations. Therefore, a direction for further investigations is proposed.

INTRODUCTION

The WR project is a multi-laboratory, multi-company, international effort to create a universal fieldbus for control and timing systems to be used at CERN, GSI and possibly other such facilities. The rationale behind WR, the choice of the technologies and technical details of its functioning have been already described in a number of papers [1], [2], [3]. The resilience and robustness is one of the key features of any fieldbus. This article presents a study on the reliability of a White Rabbit Network (WRN) assuming a basic knowledge about WR.

Reliability is defined as the ability of a system to provide its services to clients under both routine and abnormal circumstances. It can be estimated by calculating the probability of the system's failure (P_f). The lesser the probability of WRN failure, the higher its reliability. Thus, in this article we identify critical services of a WRN based on the study of WR's requirements. Then, we analyze each critical service to identify possible reasons for their failure and propose targeted counter-measures to increase reliability. Finally, their impact on the overall system reliability is studied to identify the highest contributor and the focus for the further studies.

DEFINITION OF RELIABILITY IN A WRN

A WRN, consisting of White Rabbit Switches (switches) connected by fiber or copper, is meant to transport information among White Rabbit Nodes (nodes). We distinguish two types of information distributed over the WRN: (1) *Timing* (frequency and Coordinated Universal Time) and (2) *Data* (the Ethernet traffic). This translates into two types of services provided by the WRN which have their own requirements and can be handled separately. The requirements are defined by GSI and CERN as the prospective users of WR to control their accelerators.

Timing Distribution

Timing is distributed in the WRN from a switch/node called Timing Master (TM) to all the other nodes/switches in the network. All the devices in the WRN lock their frequency (syntonize) and adjust their local clocks (synchronize) to that of the TM. The deviation between the clock of the TM and that of any other node/switch is called **accuracy**. A stable and continuous synchronization of all the nodes with an appropriate accuracy is the key requirement of the Timing Distribution in the WRN.

Data Distribution

The critical data distributed over the WRN is the one carrying sets of commands (events) which are organized into Control Messages (CM). The CMs are sent by a privileged node (Data Master, DM) in the payload of the Ethernet frame(s). Therefore, the Data Distribution in the WRN is broken into (1) *Control Data (CD)* – the Ethernet frames carrying CMs, critical, and (2) *Standard Data (SD)* – the Ethernet frames which do not carry CMs, non-critical. The reliability of the WRN depends on the successful delivery of the CD to all the designated nodes. The CMs are always broadcast within a VLAN , which can span the entire network. The worst-case upper bound of their delivery latency from the DM to any node in the network, regardless of it's location (**maximum distance from the DM**), is required to be guaranteed by the network – this is **a determinism** requirement.

Reliability of the WRN

The reliability of the WRN relies on the **deterministic** delivery of the CD to all the designated nodes and their

sufficiently **accurate and stable synchronization**. This means that the WRN is considered non-functional if one or more of the following occur:

- A node is synchronized with insufficient accuracy.
- A designated node receives corrupted CD or no CD.
- The upper-bound delivery latency has been exceeded.

Unreliability is translated into the number of CMs considered lost (not delivered, delivered corrupted or in a non-deterministic way) in a given period of time. During this time, the synchronization must be always of the required quality. Quantitative requirements of the accelerator facilities are listed in Table 1.

Table 1: GSI's and CERN's Requirements Summary

Requirement	GSI	CERN
Max latency	100 µs	1000 µs
CM failure rate	$3.17 * 10^{-12}$	$3.17 * 10^{-11}$
CMs lost per year	1	1
d_{max} from DM	2 km	10 km
CM size	200–500 bytes	1200–5000 bytes
Accuracy	probably 8 ns	1 µs to 2 ns

FAILURE STUDY

One of the main possible reasons for WRN failure, which affects both Timing and Data Distribution, is a malfunction of its elements (switches or links). Since the distribution of information in the WRN is of one-to-all character (Data/Timing Master to all nodes), all the elements of the WRN are considered Single Points of Failure (SPoF)[4]. Malfunction of any SPoF results in failure of the entire system. SPoFs can be eliminated by introducing redundancy of the system components. Due to its special features (distribution of frequency over physical layer) and strict requirements (determinism, low data loss), the number of possible redundant topologies of the WRN is restricted, as explained in the following sections.

Imperfections of the physical medium as well as switching between redundant elements of the network (which takes time) can cause loss or corruption of data. The deterministic and mostly broadcast character of the data distribution in the WRN enforces application of the Forward Error Correction (FEC) – adding redundant information on transmission to enable recovery of lost or corrupted data on reception. This brings constant data overhead and the probability that the added redundancy is not sufficient to recover the data. However, it is the price to pay for ensuring low latency and determinism of data delivery in the WRN.

The delivery latency of an Ethernet frame varies with cable length and the number of hops (switches) it has to traverse to reach its destination, the traffic load on the way and the assigned Class of Service (CoS). Therefore, to ensure the required determinism of the CD delivery, we need to make sure that there is no congestion of Ethernet frames carrying CMs. Moreover, the number of hops (the latency introduced by them) needs to be sufficiently small, which can be done by restricting the topology.

The resilience of the Clock Distribution translates into continuous and stable synchronization of all the nodes and switches in the WRN (Table 1). Although, the network redundancy eliminates SPoFs, the switch-over between redundant elements might introduce instability and render the network unreliable despite the costly redundancy. Therefore, a seamless switch-over between redundant clock paths needs to be ensured. Another reason for the deterioration of the synchronization accuracy is the variation of external conditions (e.g. temperature) which needs to be compensated.

DETERMINISM

A carefully configured and properly used WRN offers deterministic Ethernet frame delivery thanks to the implementation of CoS and the fact that the delay introduced by the switch can be verified by analysis of **publicly available source code** [5]. Such analyses were performed to verify the worst-case upper bound delivery latency of a CM against the requirements listed in the Table 1. The results, presented in Table 2 (*Store-and-forward* column), take into account the fact that a CM is encoded into 4 Ethernet frames (as required by the FEC and described in the next Section), it is sent with the highest priority (CoS) and it always traverses 3 hops.

Table 2: Control Message(CM) Deliver Latency Estimations

CM size	CM deliver latency			
	Store-and-forward		Cut-through	
	GSI	CERN	GSI	CERN
500 bytes	221 µs	283 µs	76 µs	118 µs
1500 bytes	285 µs	325 µs	102 µs	142 µs
5000 bytes	324 µs	364 µs	162 µs	202 µs

The analysis revealed that GSI's requirements are not fulfilled: the upper-bound delivery latency for the required size of CM and max distance of 2km is greater then 100 µs.

The solution to decrease delivery latency is targeted into the CD only and takes advantage of its characteristics (broadcast within a VLAN, sent by privileged node). We propose to break the highest priority of the CoS into two (unicast and broadcast) and use the highest priority broadcast Ethernet traffic only for the CD. Moreover, this particular traffic shall be forwarded using the cut-through method (unlike the store-and-forward method used normally in the switch) which can be effectively fast for the broadcast traffic with a single source (DM). The results, presented in Table 2 (*Cut-through* column), show a significant improvement. The solution requires hardware-supported cut-through forwarding in the switch as described in [6].

DATA RESILIENCE

Forward Error Correction

The objective of the FEC scheme is to decrease the loss rate of the CMs, preferably, to less then one per year. WR uses as a physical medium Fiber Optic and CAT-5. The number of received corrupted bits compared to the total number of received bits is called Bit Error Rate (BER). The value of BER characterizes a physical medium and can be used to characterize the entire switched network. A WRN can be seen as a Packet Erasure Channel (PEC) or as a Binary Erasure Channel (BEC) depending on the effect of a bit error on the frame. If the frame is lost (e.g. dropped by the switch due to a corrupted header or lost during switch-over between redundant components), the WRN is a PEC. If the bit error happens in the link between a switch and node, a corrupted frame can be used (optional) to attempt frame recovery. In such case, the channel is called BEC. Each type of channel requires a different FEC solution. Therefore two concatenated FECs are used in WR. Reed-Solomon (R-S) coding is used for the PEC and allows to encode k original-frames into n encoded-frames ($n > k$). Reception of any k encoded-frames can be used to decode the original frames. Hamming coding with additional parity (SEC-DED) is used for the BEC and allows to detect up to two simultaneous bit errors and correct a single error. These two schemes (R-S and Hamming) are combined to encode each CM – it is split into two and encoded using R-S into four messages (two original and two with redundant data). Each of the four messages is then encoded using Hamming. Such encoded messages are sent in a burst of 4 Ethernet frames. Reception of any two of these frames enables to decode the original Control Messages. A systematic analysis, using the BER characteristic of the WRN, proves that the presented FEC scheme guarantees less than single CM lost per year due to physical medium imperfection, as can be seen from Table 3.

Table 3: GSI and CERN FEC Characteristics

Parameter	GSI	CERN
Control Message length	500 bytes	1500 bytes
Control Message per year	$3.145 * 10^{11}$	$3.145 * 10^{8}$
Max Bit Correct.	1	1
Payload Length	294 bytes	854 bytes
Num Encoded Frames	4	4
Needed Frames to Receiver	2	2
Probability of Loosing a CM	10^{-14}	10^{-13}

Rapid Spanning Tree Protocol (RSTP)

In an Ethernet network with redundant topology, the problem of loops (causing "broadcast storms") is handled by the Rapid Spanning Tree Protocol (RSTP) . It creates a loop-free logical topology by blocking appropriate ports in switches, and unblocks them in case of topology break (due to element failure).

The functionality provided by the RSTP is essential for the WRN. However, the convergence speed provided by the standard implementation of the RSTP (milliseconds at best) would cause many CMs to be lost during the process. This is not acceptable, we need a solution which is fast enough to prevent loosing the CMs at all. Since we know the size-range of the CMs (Table 1) and how they are FEC-encoded into Ethernet frames, we can calculate the maximum value of the convergence time: 3 µs. This time is smaller than the duration of transmitting a single frame with FEC-encoded CM – this ensures that no more than two frames with FEC-encoded CM are lost, thus the CM can be recovered.

In order to achieve a convergence time of 3 µs, the switch-over between active and backup connections needs to be performed in the hardware as soon as the link-down is detected. It can only be done if the alternative topology is known in advance. The knowledge of alternative topology is translated into an RSTP-assignment of alternative and backup roles of switch ports, i.e at least one port with alternative role must be identified in every switch (except the topology-root switch). If we ensure, by restricting the topology, that RSTP identifies the alternative links, we can use its data to feed the hardware, consequently achieving the required convergence time and staying standard-compatible: the hardware switch-over is just a faster RSTP-driven convergence. The required topology restrictions, described in [6], greatly overlap with these imposed by the Time Distribution.

CLOCK DISTRIBUTION

A seamless switch-over between redundant sources of timing (uplink ports) is heavily supported by the Clock Recovery System (CRS) [2] of the switch and the WR extension to PTP (WRPTP)[3].

Figure 1 presents an example where a switch (timing slave) is connected (by its uplinks 1 & 2) to two other switches (primary and secondary masters) – the sources of timing. On both uplinks the frequency is recovered from the signal and provided to the CRS. Similarly, WRPTP measures delay and offset on each of the links and provides this data to the CRS. The modified Best Master Clock (mBMC) algorithm [3] decides which of the timing masters is "better" and elects it the primary, the other is considered secondary (backup). The information from *uplink 1* (primary) is used to control the CRS and adjust the local time. However, at any time all the necessary information from the *uplink 2* is available and a seamless switch-over can be performed in case of primary master failure [2].

In addition to the switch-over-related synchronization instability, the variation of external temperature can cause an accuracy degradation. This problem, however, is solved by the PTP standard itself. By frequent link delay measurements, the fluctuation is compensated.

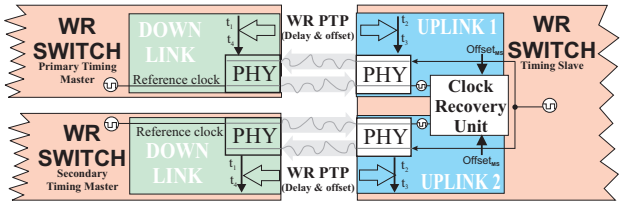

Figure 1: Seamless switch-over.

OVERALL RELIABILITY

The final equation of the WRN reliability is a sum of the data and clock distribution reliabilities. The clock distribution is assumed to be sufficiently accurate as long as there is a connection between the TM and all the nodes. The same applies to the CD distribution: as long as there is a valid connection, the FEC makes sure that the data is delivered with a sufficient reliability and the latency calculations prove it to be deterministic while the congestion is prevented by CoS and limited number of data sources (DM). Consequently, the overall reliability is strongly dependent on the WRN topology, which needs to be appropriate for the proposed solutions (SyncE, H/W-supported RSTP, upper-bound latency).

For the comparison of different network topologies, we consider the reliability of a network of switches. Each node is connected to such a network with M links (each to a separate switch). The value of M reflects the level of redundancy (M=1 for no redundancy, M=2 for double redundancy, etc).

In the calculations of the network reliability we used the idea of Mean Time Between Failure (MTBF) and its relation with the failure probability presented in [4] (a very simplified mathematical model). In order to calculate the MTBF of the entire network, we need the MTBFs of each network component: switches and links. Since the WR switches are still under development (no MTBF measured), we used representative values for CISCO switches (2, 10 and $100{*}10^4$[h]). Two estimation methods were used: "Fault Tree analysis" [7] and analytic. Both provide just rough estimations of the reliability. The former allowed to estimate two-terminal reliability (DM to single node) of simple non/double/triple-redundancy topologies (P_f). The most desired value is the all-terminal network reliability ($P_{f\_Network}$), where : $P_f < P_{f\_Network} < N_{nodes} * P_f$. Table 4 presents rough estimations of $P_{f\_Network}$ using analytic calculations for the three considered topologies ($MTBF_{Switch}$=200 000[h]). However, to meet the requirement of ≈2000 nodes and only three network layers (hops), the Data Master node is connected to more separate switches than the level of redundancy (M). The estimations show that a triple redundancy topology can barely satisfy the requirements by CERN (Table 1).

Table 4: WRN Topologies's Reliabilities

Redundancy	Switches	P_f	MTBF[h]
No	127	$2.08 * 10^{-3}$	$5.77 * 10^3$
Double	292	$4.71 * 10^{-7}$	$2.55 * 10^7$
Triple	495	$3.06 * 10^{-11}$	$4.08 * 10^{11}$

CONCLUSIONS

A WRN must be considered as an ordinary Ethernet network with extra optional built-in features which, when properly used, can make it robust and more reliable. This, however, comes at a price of topology restrictions and redundant elements (money). The reliability study described in this article and detailed in [6] presents areas which need to be addressed to increase the reliability of a WRN. The development of WR is an on-going effort and some of the suggested solutions have been already properly investigated or developed (FEC, clock distribution) while the others need further verification (RSTP, cut-through forwarding). Suggested solutions enable to fulfill the requirements set by CERN and GSI. However the costs might trigger double-checking and re-justifying of at least two of them: upper-bound latency by GSI and the number of CMs lost per year. The former requires additional development efforts to achieve the required 100 µs. The latter requires a high level of network redundancy (triple or more) which is very costly. Since the network topology and its reliability calculations turned out to be the greater factor in the overall system reliability, it is necessary to perform more precise calculations and simulations to verify the rough estimations. This might include different techniques (e.g. Monte Carlo simulations) but also more real-life use cases (i.e. of the network layout suggested in [8], which was not available at the time of described study). Especially, we need to take into account and include into calculations the fact that not all the nodes connected to the WRN are equally critical in real-life applications.

STATUS OF THE RBAC INFRASTRUCTURE AND LESSONS LEARNT FROM ITS DEPLOYMENT IN LHC

I. Yastrebov, W. Sliwinski, P. Charrue, CERN, Geneva, Switzerland

Abstract

The distributed control system for the LHC accelerator poses many challenges due to its inherent heterogeneity and highly dynamic nature. One of the important aspects is to protect the machine against unauthorised access and unsafe operation of the control system, from the low-level front-end machines up to the high-level control applications running in the control room. In order to prevent an unauthorized access to the control system and accelerator equipment and to address the possible security issues, the Role Based Access Control (RBAC) project was designed and developed at CERN, with a major contribution from Fermilab laboratory. Furthermore, RBAC became an integral part of the CERN Controls Middleware (CMW) infrastructure and it was deployed and commissioned in the LHC operation in the summer 2008, well before the first beam in LHC. This paper presents the current status of the RBAC infrastructure, together with an outcome and gathered experience after a massive deployment in the LHC operation. Moreover, we outline how the project evolved over the last three years and give an overview of the major extensions introduced to improve integration, stability and its functionality. The paper also describes the plans of future project evolution and possible extensions, based on gathered users requirements and operational experience.

INTRODUCTION

In high energy and high intensity accelerators as the LHC, the energy stored in the beams is orders of magnitude above the damage level of accelerator components like magnets. Uncontrolled release of this energy can lead to serious damage of equipment and long machine downtimes. In order to cope with these potential risks CERN has developed a multi-pronged approach for machine safety that includes Role-Based Access Control (RBAC) [1] system. The main objectives of the project are: protection of accelerator equipment and control system against unauthorized access; definition of the operational access rules (who can do what and when) and providing facility to trace and audit the access requests.

The project was started in 2006 and was successfully commissioned and deployed for LHC in 2008, well before the first beam. Nowadays, RBAC protects all LHC equipment and selected experiments equipment against unauthorized access. Since 2008, the project has significantly evolved, following new operational requirements and collected users feedback.

RBAC ARCHITECTURE

Development of RBAC started in 2006, when the core part of the LHC control system was already in place. It was built on top of the existing software components and became an integral part of the Controls Middleware (CMW) [2] project. CMW provides communication infrastructure for all CERN accelerators, which is composed of centrally managed services (e.g. Directory Service) and middleware libraries (client/server) for all operational platforms. It implements two communication models: request-reply and publish-subscribe, organized in client-server relationships. By invoking the device access methods (i.e. *GET*, *SET* and *MONITOR*), clients can read, write and subscribe to device property values. Within this model, authentication (A1) is done on the client side and authorization (A2) is imposed on the server side by interception of the incoming client requests. The overall RBAC architecture including flow of an authentication token, accompanying every request, is illustrated in Figure 1.

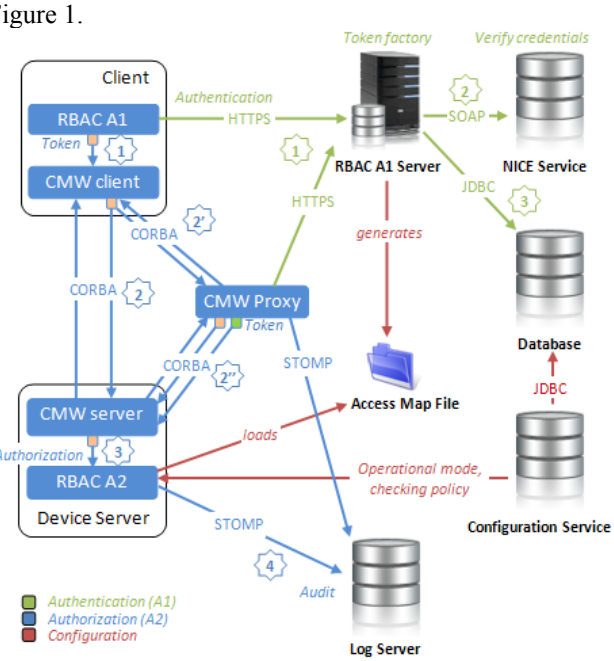

Figure 1: The overall RBAC architecture.

Configuration

Access rules are defined by equipment specialists for every device class. They are stored and managed centrally in the Controls Configuration Database [3]. Access map is a tab-separated text file, located on NFS, inside the CERN's technical network, which is in fact a snapshot of the database access rules for a given CMW device server. Every access map is digitally signed by the central RBAC A1 server to prevent against unauthorised modifications by third parties.

Authentication (A1)

The purpose of authentication is to verify the digital identity of a principal. If the authentication process succeeds, its result is a digitally signed authentication token that is returned to the application. The token is a short-term uniform substitute of the real credentials. It is issued by the central A1 authentication server that can reliably verify the users identity [3]. Authentication is a 3-step process: application sends request over encrypted HTTPS channel (1); authentication A1 server verifies credentials using remote, encrypted SOAP access to the NICE service (2) and then in case of success returns a token containing users roles and other details extracted from the Controls Configuration Database (3) [4].

Authorization (A2)

Authorization is the process of verifying that a known identity has an authority to perform a certain operation. Prior to authorization, a client application has to be authenticated (1). Following, it can use the obtained token to interact with various parts of the control system: access the equipment devices directly (2) or through a proxy (2') or another middle-tier server. Front-ends and the middleware library that are receiving such calls verify the token, thus confirming the identity of the remote party and can use it as a base for authorization (3) [5].

OPERATIONAL DEPLOYMENT IN 2008

During the deployment campaign in 2008, RBAC was successfully integrated in all layers of the LHC control system (see Figure 2).

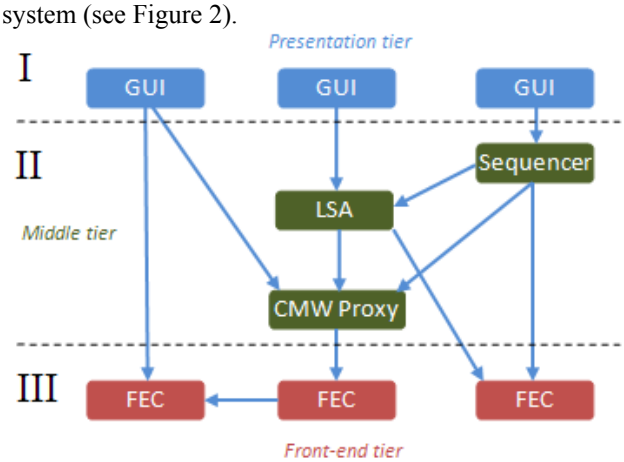

Figure 2: Layers of the Control System using RBAC.

In the presentation tier (I), RBAC authentication library was introduced for client applications running in the CERN Control Centre (CCC), where all CERN accelerators are controlled by the Operation team. For Java clients, RBAC provides login services, Spring (open-source, lightweight container for Java) beans and GUI components targeted for quick and easy integration of RBAC into existing applications.

In the middle tier (II), security components provided by RBAC were integrated in the high-level control systems (e.g. LSA, Sequencer) that help operators and physicists to commission, monitor and control the LHC machine. RBAC became an integral and core component of all major control subsystems including: LHC Software Architecture (LSA) [6], Software Interlock System (SIS) [7], Sequencer [8] and CMW Proxies.

In the front-end layer (III), RBAC integrates with CMW and Front-End Software Architecture (FESA) [9]. At this level the software is written in C++ and it uses RBAC A2 authorization library. Selected front-end machines might also use the A1 authentication service in order to communicate with protected equipment accessible through other front-ends.

To facilitate the introduction of RBAC into such a large and distributed system the algorithm of dynamic authorization was designed. It takes into account not only the access rules, but also an internal state of the subject under question. For RBAC, three different checking policies were introduced: NO-CHECK (no protection, no authentication required), LENIENT (access restriction for protected properties, authentication is optional) and STRICT (authentication and authorization is obligatory). They treat differently the access rules and have different requirements for the authentication token. For each front-end server the associated checking policy is stored in database, from where it is propagated to the running servers by the CMW Configuration Server and it can be changed at runtime from the administrative GUI application. The major advantage of this approach is the possibility to make a phased introduction of the access control in a large, distributed system as LHC.

During the deployment campaign in 2008 and 2009, the STRICT policy was enforced for all equipment systems in LHC and LENIENT policy for all other machines, i.e. injector chain (e.g. PS, SPS).

EVOLUTION OVER LAST 3 YEARS

Over the last 3 years the RBAC infrastructure has been significantly improved in order to comply better with the operational requirements and to provide seamless integration with all layers of the control system. In this section we list the most important changes in the project, which were introduced over the last 3 years.

Temporary Roles

In 2009, the concept of temporary roles was introduced. It brings the possibility to assign a certain role to some user (e.g. piquet role to an equipment expert) and grant him specific access rights but only during the limited intervention time. After that time the role is automatically revoked for that user.

Critical Roles

The Management of Critical Settings (MCS) [10] system is aimed to protect the most critical parameters in either potentially dangerous equipment or protection devices (e.g. Beam Loss Monitors, Collimators). It is complementary to the RBAC infrastructure. Both systems, RBAC and MCS, are fully integrated in the

control system for LHC and SPS and were successfully commissioned already before the first beam in LHC. In addition to RBAC's authentication and authorization MCS provides a mechanism to guarantee data integrity at all times using the digital signatures.

RBAC was extended to provide management of the public/private key pairs (stored in the private, local key store) as a part of the role management module. RBAC database keeps association of the critical MCS roles with the public/private key pairs. The private keys are always kept secret and never leave the RBAC A1 server. The digital signatures are generated by the RBAC A1 server using the private key from the key store. The public keys are made available to front-ends, namely to FESA servers and other applications, which verify the MCS signature.

For MCS roles several additional restrictions were implemented in RBAC: role lifetime constraints and limit of active critical MCS roles in a token.

Operational Mode

During accelerator shutdown or technical stop it is often necessary to allow access to machine for a wider range of users than during normal operation. In such cases an expansion of the access rules is not always desirable and appropriate. Firstly, it may weaken the system security and secondly it requires significant administrative costs. To address this problem notion of the *Operational Mode* was introduced to the access rules as an additional condition, which facilitated extensions of the access rules for non-operational interventions, while keeping operational access rules unchanged.

Support for CMW Proxy

CMW Proxy servers act as an intermediary layer between clients and actual front-end servers. A typical use-case for a proxy is to reduce the number of open connections to the front-end and to reduce the load that is associated with processing of subscriptions. When several clients subscribe on the same property, proxy establishes just one connection to the front-end and then broadcasts updates to all interested clients. The major security issue in this model is how to enforce the access control for subscriptions.

In order to address this problem authentication for CMW Proxies was introduced. At start-up, each proxy performs authentication by location, without using stored credentials and obtains a token that contains the 'CMW-PROXY' role. Access rules for devices working behind a proxy must allow the client subscriptions on desired properties for that role. This approach has several advantages. First, being very simple, efficient and non-intrusive it enforces access control in a single place. Second, it helps equipment specialists to impose usage of a proxy for certain devices thus preventing direct access and performance problems.

Virtual Devices

Virtual device is a special type of device that usually represents a unit of high-level business logic, which is not deployed on a physical front-end machine. A typical use-case for a virtual device is implementation of the high-level control parameters on top of existing physical devices. Since there is no front-end device server, which hosts a virtual device it is problematic to enable authorization. Therefore, RBAC framework was extended to provide a lightweight authorization scheme for any type of device, including both hardware and virtual. In this case authorization is performed by requesting RBAC A1 server that checks privileges for the supplied token.

QUALITY ASSURANCE

After introduction and commissioning of the new extensions, RBAC project team focused on test-driven development for C++ and Java components, in order to improve the overall quality and reliability. In the following paragraphs the detailed description of this process is presented.

Quality Assurance and Testing

A major effort was invested in preparing the tests for all core components. All tests can be split into 3 groups: *unit tests* that verify functionality of individual classes; *integration tests* for libraries that guarantee compatibility between different versions and *system tests* for the whole set of products. System testing verifies that the completely integrated system meets the requirements. For this, the setup called Testbed [11] was used, to test core control components before their operational deployment. For integration testing Bamboo server was used that provides the Continuous Integration environment. Each source code update in the core components triggers recompilation and execution of all unit tests. Next, code is analysed with the Clover tool that computes the code coverage and detects most risky and most complex classes and generates a detailed report. An example report is demonstrated in Figure 3.

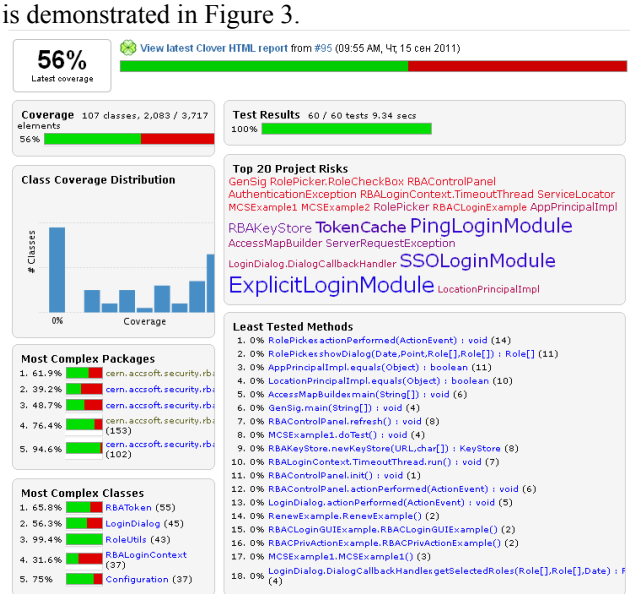

Figure 3: Example of the Clover report for RBAC.

Performance Improvements

Authorization check is performed for each access to front-end, therefore it should execute fast and should not hinder the performance of CMW. Having this in mind, the authorization algorithm was completely redesigned, which resulted in 10 times performance gain.

Codebase Refactoring

During last 3 years a major effort was invested into refactoring of the RBAC codebase. Most components were significantly redesigned and improved. The main aspects of refactoring: removal of code duplication, separation of interfaces from implementation, usage of dependency injection to reduce coupling and make the code more testable, split of heavy classes to make them more cohesive and reusable, code documentation.

For RBAC components written in C++ the new release system based on Maven [12] is used since 2011. It helped to standardise and to unify the development process by introducing versioning and dependency management.

STATUS OF THE PROJECT

The RBAC infrastructure was integrated with all layers of the CERN Control System and successfully deployed and commissioned in LHC.

Collected Experience

Lessons learnt from RBAC deployment in LHC:

1. Close collaboration with equipment experts and the Operation team in CCC was essential for successful deployment and operation of RBAC.
2. The crucial success factor was the staged deployment strategy: new functionality was tested during several 1-3 days LHC dry-runs, then verified during machine checkout and commissioning phases before the final deployment for beam operations.
3. Dynamic authorization based on several checking policies allowed for step-by-step introduction of RBAC without interrupting the running systems.
4. Several administrative tools had to be upgraded to support introduction of RBAC; to provide additional diagnostics and to allow changing checking policies for device servers in the runtime.
5. Better logging and diagnostics at all layers was required. This was a critical requirement for debugging and helped to solve many issues.
6. Database driven approach provided means for enforcing data consistency and simplified development of web-based administrative forms.
7. Configuration of access rules for sub-systems (e.g. BLM, BPM, Collimation) was delegated to equipment experts (reduced administration costs).

Future plans

This paragraph lists the major new features that are planned for implementation in the coming year:

1. Introduce Spring framework in RBAC server.
2. Make authentication server resistant to the database connection failures.
3. Revise the authentication by location mechanism and make it more secure.
4. Automate propagation of the access rules from database to the running device servers.

CONCLUSIONS

The RBAC project was developed at CERN, with a major contribution from Fermilab laboratory. It was successfully deployed and commissioned in LHC operations in the summer 2008.

The system successfully passed many centrally organized tests. The feasibility, performance and overhead of RBAC were experimentally evaluated. The results show that the overhead is acceptable and the chosen approach can be effectively used to enforce access control in the CERN control system.

Currently RBAC is used to protect all LHC equipment and selected equipment of other machines. Nevertheless, there are still few areas where current implementation can be improved and extended in order to expand the area of its applicability.

DEPENDABLE DESIGN FLOW FOR PROTECTION SYSTEMS USING PROGRAMMABLE LOGIC DEVICES

M. Kwiatkowski*, B. Todd†, CERN, Geneva, Switzerland

Abstract

Programmable Logic Devices (PLD) such as Field Programmable Gate Arrays (FPGA) are becoming more prevalent in protection and safety-related electronic systems. When employing such programmable logic devices, extra care and attention needs to be taken. The final synthesis result, used to generate the bit-stream to program the device, must be shown to meet the design's requirements. This paper describes how to maximize confidence using techniques such as Formal Methods, exhaustive Hardware Description Language (HDL) code simulation and hardware testing. An example is given for one of the critical functions of the Safe Machine Parameters (SMP) system, used in the protection of the Large Hadron Collider (LHC) at CERN.

CERN is also working towards an adaptation of the IEC-61508 lifecycle designed for Machine Protection Systems (MPS), and the High Energy Physics environment, implementation of a protection function in FPGA code is only one small step of this lifecycle.

The ultimate aim of this project is to create generic techniques and methods applicable to any PLD based system requiring a rigorous implementation and verification.

CERN AND THE LHC

The Large Hadron Collider is the world's most powerful particle accelerator. To reach the new frontiers of physics a centre of mass collision energy of 14 TeV is needed, giving a stored beam energy over 100 times higher than in any other machine (Figure 1).

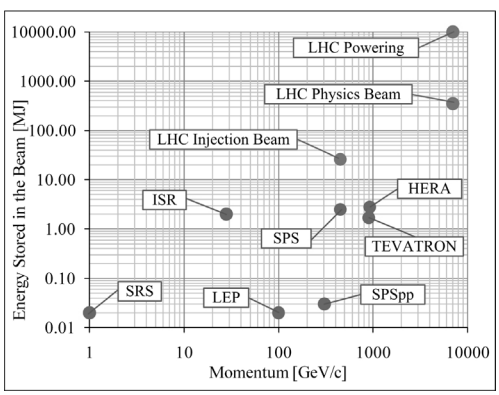

Figure 1: LHC Stored Energy versus other HEP machines [1].

* maciej.kwiatkowski@cern.ch
† benjamin.todd@cern.ch

The LHC is designed to accelerate two counter-rotating beams of $3.2 \cdot 10^{14}$ protons from an injection energy of 450 GeV to a collision energy of 7 TeV. At design values, the peak energy stored in each beam is equivalent to 362MJ, enough to heat and melt around 500kg of copper. A field of 8.3 Tesla is needed to hold the LHC beam in 27km circumference of the machine, this magnetic field is generated by 1232 super-conducting dipole magnets, each having a forward current of almost 13kA, being maintained less than two degrees above absolute zero (-273 degrees Celsius) in a bath of superfluid helium. At design energy, the total stored energy in the LHC magnet powering system is around 10GJ, and a loss of only $10^{-8} - 10^{-7}$ of the nominal beam [2] into one of the superconducting magnets will lead to a quench, where the magnet heats up, becomes resistive and must be switched off to prevent damage.

A complex MPS has been designed to mitigate the risks due to stored beam and magnet energy, a fundamental part of the MPS is the Safe Machine Parameters Controller (SMPC).

SAFE MACHINE PARAMETERS

For the correct protection of the LHC and its accelerator complex, several parts of the MPS require information about the machine's operational parameters. Values such as beam intensities, machine energies, squeezing factors, amongst several others, must be broadcast around the accelerator complex to correctly configure the MPS, and sent to the extraction interlock systems to ensure the correct interlocking of beam transfer between the Super-Proton Synchrotron (SPS) and the LHC.

These parameters are referred to as Safe Machine Parameters (SMP), as they must be generated and distributed

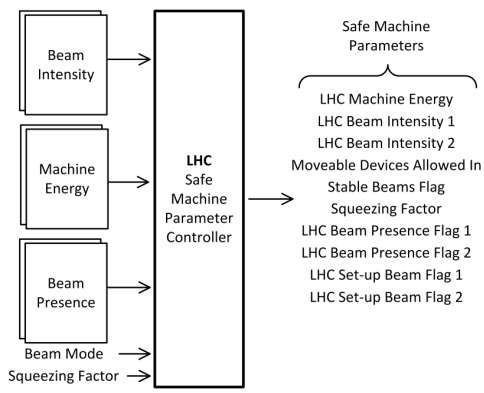

Figure 2: Safe Machine Parameters System.

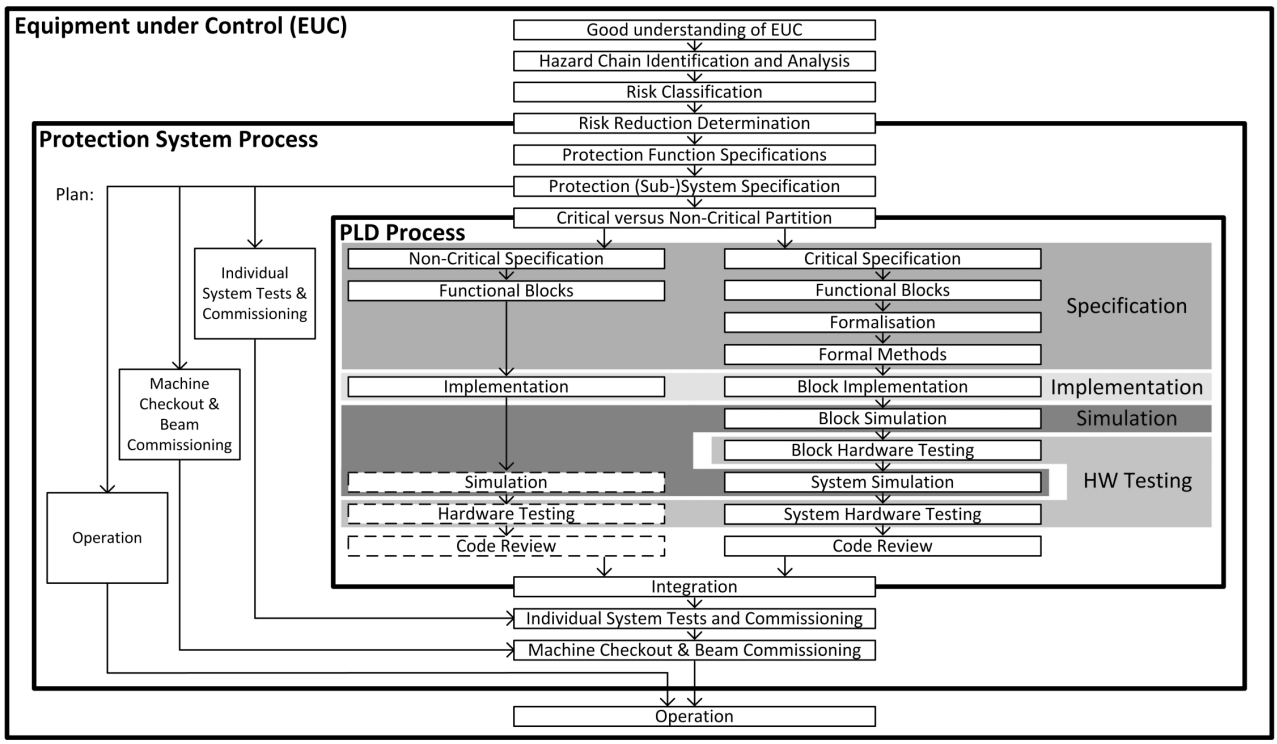

Figure 3: Machine Protection System Lifecycle Based on IEC-61508 E/E/PE Lifecyle.

around the accelerator complex with high dependability (safety, availability and reliability). The SMPC was developed to derive these SMP, taking information from several source systems and providing it to client system, as shown in the Figure 2.

The outputs of the SMPC either go directly to the extraction interlock controllers, or are broadcast around the machines using the General Machine Timing (GMT) network. These different parameters address two principle types of risk: risks during the extraction and transfer of beam from the the SPS into the LHC, and risks during LHC phases following the injection process.

The first group presents particularly tight requirements in terms of time and accuracy, as the transfer of beam from the SPS to the LHC is a very fast process, a single extraction of beam from the SPS is already capable of quenching and damaging LHC magnets.

The SMPC plays a key role in the protection of the LHC and its injector complex.

MACHINE PROTECTION SYSTEM LIFECYCLE

Requirements for the MPS, including the SMPC, came from decades of work and substantial investigations into the performance of the LHC and its MPS, following a deep-thinking argumentative approach. The risks due to LHC stored beam and magnet energy do not pose a threat to personnel or the environment, as as such are not a hard, legal requirement of the LHC project. Nevertheless, there are significant advantages to be gained by considering the development of the MPS as if it were a safety system, being legally required.

During the development of the SMPC, and some of the other MPS sub-systems, such as the Beam Interlock System and Powering Interlock Controllers, common themes and ideas have began to emerge. The combination of these ideas has led to the concept of a MPS Lifecycle (MPSL), based on the IEC 61508 overall system lifecycle. The MPSL concept allows a consistent approach to the evaluation of existing parts of the MPS, whilst at the same time providing a framework for the development of new protection systems. Figure 3 shows this proposed MPSL.

The part of the MPSL which is relevant to the programmable logic device flow is that related to the implementation of so-called Protection Functions (PFs) which are being established using devices such as FPGAs. The following sub-sections detail some of the key concepts of the MPSL, before concentrating on those parts relevant for PLDs.

Equipment Under Control

The Equipment Under Control (EUC) must be well understood by protection system designers, in CERN's case, the EUC can be considered as the particle accelerator and its associated mechanical, electric and electronic equipment. To realise such complex systems, experts from many domains must work together to establish potential hazards and the effects these have on the EUC. Based on this risk analysis approach, each risk should be assessed and classi-

fied. Risk being a combination of the probability of occurrence and the severity of a hazardous event and it is usually expressed qualitatively (qualitative risk analysis).

Protection System Process

The designers are then to conceive mitigations for these risks by working on two fronts: working to reduce the likelihood of the hazardous event, and by working to reduce the consequences of such an event were it to occur. The ultimate goal of this is to reduce risks to acceptable levels, another way is to use the phrase "As Low as Reasonably Possible" (the ALARP principle). This means that for each risk that is identified, a reduction is needed to achieve the ALARP level. The higher the risk the larger the required Risk Reduction Level (RRL).

Several approaches can be used to reduce risks, some of which result in the creation of PFs. It is possible that several risks can be mitigated by many PFs, and the PFs can be spread across many sub-systems.

In the case of the LHC MPS, one of these sub-systems is the SMP system, which is required to implement several PFs, by exploiting PLDs.

PROGRAMMABLE LOGIC DEVICE PROCESS

The PLD design process starts with clear separation of what is part of the PFs from other non-critical functions. Functions that are part of the PF are to follow this PSL process, whereas those functions that are non-critical are not needed to have the same levels of rigour. The conceptual separation of the critical from non-critical functions should be followed through to the hardware realisation. Hardware must not mix critical and non-critical functions! If no other choice exists, then non-critical functions which share common devices with critical ones must also be verified using the full protection system process.

In case of the SMPC each printed circuit boards has two separate FPGA devices for functions. The first, a control FPGA device, is tasked with critical functions, the second, a monitor device, records and supervises the operation of the control device and implements the non-critical functions. For example, the online monitoring of the SMPC, which is important but not critical for the protection of the EUC.

Specification Phase

Each critical function must be decomposed into functional blocks, ones which lend themselves easily to analysis and understanding. In addition, each must be capable of being readily specified using a formal language.

For example, the block diagram of the SPS Setup Beam Flag (SBF) is shown on Figure 4. This flag is used in the process of beam injection from the SPS to the LHC accelerator. The SPS SBF is a function of SPS beam intensity, to increase availability the intensity information is redundant,

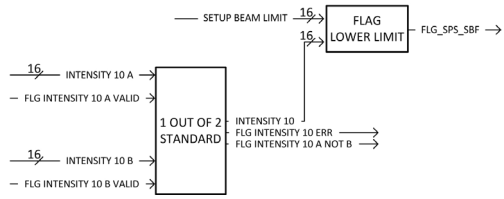

Figure 4: Setup Beam Flag blocks example.

being merged into one value. The one out of two block selects valid intensity value, when both of the sources are not valid the fail safe value is applied. The limit block compares calculated intensity value to a predefined threshold (SETUP_BEAM_LIMIT).

The formal specification of the SPS SBF calculation is presented on Figure 5. Error and selection flags (FLG_INTENSITY_10_ERR, FLG_INTENSITY_10_A_NOT_B) are not formalized because they are used for the monitoring purpose and they do not belong to the critical functionality. The key strength of this Predicate Logic formal language is in interpretation: if correctly written, it can only be understood by designers in a single way, which is not always the case for a traditional specification. The formal language also allows a formal verification of some design parameters, allowing a mathematical verification the completeness and the consistency of the specification.

```
FAIL_SAFE_HIGH_INTENSITY : int := 6.5535 * 10^14;

SPS_SMPC_SBF (
   SETUP_BEAM_LIMIT : int,
   INTENSITY_10_A : int,
   FLG_INTENSITY_10_A_valid : bool,
   INTENSITY_10_B : int,
   FLG_INTENSITY_10_B_valid : bool,
   FLG_SPS_SBF : bool
   ) :=
      exists INTENSITY_10 : int. (
      (INTENSITY_10 =
         if FLG_INTENSITY_10_A_valid then INTENSITY_10_A;
         if else FLG_INTENSITY_10_B_valid then INTENSITY_10_B;
         else FAIL_SAFE_HIGH_INTENSITY;
      )
      AND
      FLG_SPS_SBF =
         if INTENSITY_10 <= SETUP_BEAM_LIMIT then TRUE;
         else FALSE
   );
```

Figure 5: Setup Beam Flag in Predicate Logic.

Implementation Phase

Each of the smaller functional blocks which were conceived in the previous step are then implemented. Each block should be the correct size as to be simulated completely before being integrated into the sub-system. When all the blocks are implemented and have passed simulation, the complete system can be composed by connecting the blocks together. The actual implementation phase is a very small part of the overall time spent on PLD firmware development. The vast majority of the time is spent on simulation and testing. Hardware Description Language

(HDL) code, such as VHDL or Verilog, is written to describe PLD function, HDL languages should not be associated with programming languages but rather with modeling tools. The designer should always know what the expected result of the synthesis process is to be, this should be also verified using the output of synthesis tools. This kind of verification is much easier when the blocks are small and readily understood.

Software Simulation Phase

Software simulation is carried out on the block level as well as on the system level. Simulation with code coverage is a fundamental requirement for critical functions. A software test-bench is required, which should wrap the Unit Under Test (UUT) inside Bus Functional Models (BFMs), passing stimuli to the UUT and recording its responses. Behaviour which is not specified for the block or the subsystem can be detected and fixed, at the same time the test-bench should evolve to include new conditions as the weaknesses in code coverage are identified. It is preferred that a critical function achieves full code coverage.

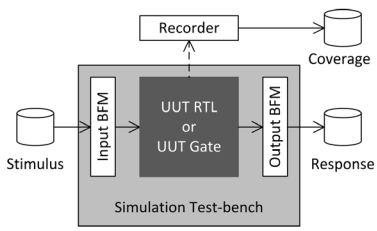

Figure 6: Software simulation with code coverage.

Hardware Testing Phase

Once the smaller blocks have been implemented, simulated and combined, the real hardware can be generated. This is then tested using a dedicated hardware tester. Hardware testing is obligatory on the system level but optional at the block level, this is due to technical difficulties in realising good test equipment and also the cost of the hardware tester construction must be considered. On the other hand, a complex block may warrant the investment of time and money in a dedicated test hardware.

The hardware tester generates input stimulus and checks the response of the Device Under Test (DUT), in much the same way as the simulation test-bench, but this time using real signals, logging real results. Its advantage over the software simulation is its speed and the possibility to introduce real distortions, such as noise on a signal. A very useful hardware testing tool provided by device manufacturers is an Embedded Logic Probe (such as Xilinxs ChipScope or Alteras SignalTap). The probe is integrated with the design and finally programmed into PLD DUT. It uses device memory resources for recording selected internal or external signals, thus the critical device must have spare cells and memory to accommodate this. With this analyzer in

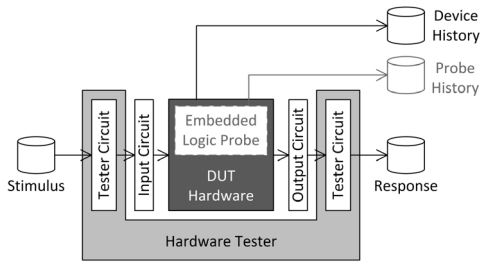

Figure 7: Hardware tester.

place it is possible to record internal signals using a variety of trigger conditions. A typical setup with an embedded logic probe is shown on Figure 7.

Code Review

Finally, once all elements have been proven to function as expected, the HDL code should be reviewed via at least an internal audit, and preferable including an external audit too. A key element during this phase is good documentation and especially a clear depiction of the formalised version.

CONCLUSIONS

All the phases described above should be documented and kept to form a basic safety case. When bugs or mistakes are found it will help to identify weak points of the test cases, testing processes, and even weaknesses in the design specification. All of this information can be used to correct future implementations. In addition, a clever selection of the design partitioning, and basic functional block requirements vastly increases HDL code reusage: thus the invested time in test benches and verification is also saved, and it is possible to reuse the same well verified blocks in the future designs.

The MPSL presented gathers many elements which have been often used in the development of systems at CERN, but are not necessary currently being done in a complementary and systematic way. These concepts and ideas are very much a work in progress, at the same time it is evident that such an approach encourages both designers, and those that specify designs to use good practices, and really understand what they require of a system. In doing this the confidence in the final system can be increased.

Abstract

SACLA (SPring-8 Angstrom Compact free electron Laser), which comprises an 8 GeV linear accelerator and undulators, was constructed. Its radiation safety interlock system was designed to protect personnel from radiation hazards. This system controls access to an accelerator tunnel and monitors safety devices. It controls permission signals for accelerator systems in accordance with safety conditions. When a safety condition is not satisfied, the system turns off the permission signal, thereby terminating the electron beam. In particular, when the bending magnets controlling the beam transport route are not properly excited, the system must terminate the beam within 16.6 ms. Therefore, as part of this system, a beam route interlock was constructed to rapidly evaluate the correctness of the beam route. We developed a new optical module to transmit the permission signal at high speeds, over a long distance. The system achieved a response time of less than 6.7 ms.

INTRODUCTION

SACLA was constructed at the SPring-8 site. It generates high-intensity X-ray lasers using an 8 GeV linear accelerator and undulators. Beam commissioning began at the end of February 2011 [1]. The layout of SACLA is shown in Figure 1. The electron beam is generated by an electron gun (GUN) with a repetition rate of up to 60 Hz. The beam is accelerated to 8 GeV by the following series of RF accelerator cavities: pre-buncher (238 MHz), booster (476 MHz), L-band (1428 MHz), S-band (2856 MHz), and C-band (5712 MHz). The accelerated beam is switched by a switching magnet into two beamlines: BL1 and BL3. The beam is injected into the undulator to generate X-ray lasers that are transported to the experimental facility. Finally, the electron beam is bent toward a beam dump by a dump magnet and then safely disposed.

To protect personnel from radiation hazards, the radiation safety interlock system (safety interlock system) was designed and constructed [2] [3]. The safety interlock system manages access control and monitors safety devices. It controls permission signals for accelerator systems in accordance with safety conditions. When permission signals are turned off, the operations of the GUN, beam chopper, and RF are inhibited.

The safety interlock system needs to be reliable and stable. In addition, the system requires specific functionality, as described below.

First, fast beam termination is required. When the electron beam deviates from the beam dump, the electron beam generates unexpected radiation. Therefore, when this situation is detected, the next beam injection should be avoided, i.e., the safety interlock system needs to terminate the electron beam within 16.6 ms.

The other specific functionality concerns the transmission line of the permission signal. SACLA is a large facility whose total length is approximately 700 m. The accelerator section is approximately 400 m long. Within the klystron gallery of this section, 73 RF systems are distributed and placed. Thus, the permission signal must be transmitted over a long distance to a large number of accelerator systems. Moreover, to achieve fast beam termination, a high transmission speed is required.

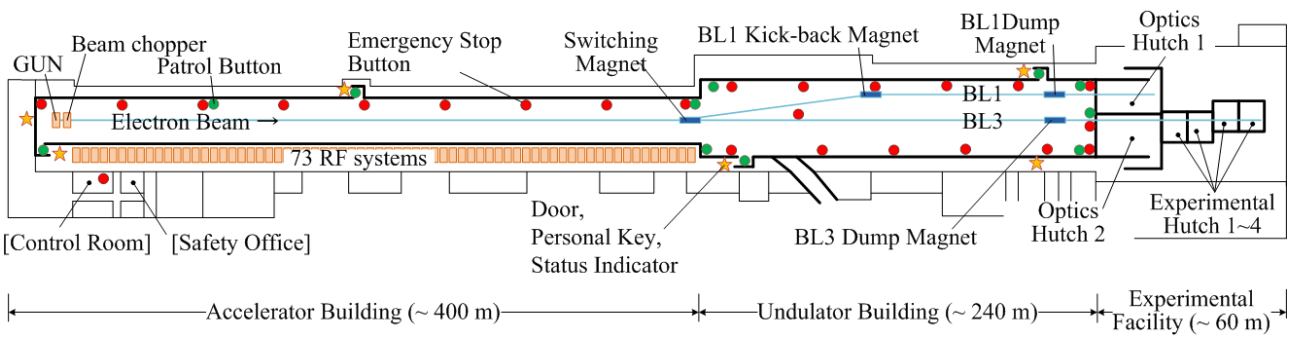

Figure 1: Layout of SACLA and the equipment related to the radiation safety interlock system.

#kago@spring8.or.jp

SAFETY INTERLOCK SYSTEM

Overview

We constructed the safety interlock system which consists of the following three interlock systems and a permission transmission system: a central interlock system (CIS), an emergency interlock system (EIS), and a beam route interlock system (BIS). Figure 2 shows a schematic view of the safety interlock system.

The CIS supervises the doors of the accelerator tunnel, personal keys, patrol buttons, status indicators, the safety signal from the beamline interlock system, and other safety systems, such as the radiation monitoring system. The CIS provides the access control to the accelerator tunnel, search confirmation, and indications about the accelerator operation.

The EIS monitors the emergency stop buttons. When an emergency stop button is pushed, all permission signals are turned off.

The BIS supervises the current of the electromagnets. To ensure that the electron beam is discarded into the beam dump, the BIS evaluates the beam route based on the excitation status of four electromagnets: the BL1 and BL3 dump magnets, the switching magnet, and the kickback magnet. If the dump magnet is not properly excited, the electron beam deviates from the beam dump core. In this case, the BIS turns off the permission signal for the GUN and the beam chopper within 16.6 ms.

The permission transmission system transmits the permission signal to the GUN, beam chopper, and 73 RF systems distributed over 400 m.

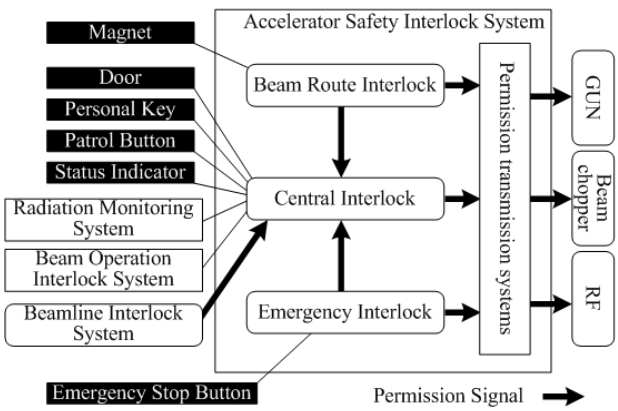

Figure 2: Schematic of the radiation safety interlock system.

The safety interlock system is required to be reliable and stable. At the SPring-8 site, programmable logic controllers (PLCs, Mitsubishi) have been used to construct interlock systems for 5 accelerators and over 50 beamlines [4]. PLC networks (MELSECNET/H) have also been utilized to input/output status signals from distant locations. We have operated them for over 14 years. PLCs present very few problems during their operation. Based on our experience, PLC-based systems are highly reliable and stable. Thus, to take advantage of these attractive characteristics, we based the CIS, EIS, and BIS development on PLCs.

Beam Route Interlock System

The BIS requires fast beam termination. However, this is difficult to achieve using PLC networks because the communication time is slower than the required response time. In addition, the PLC processing time depends on the size of the ladder program. Thus, we designed the BIS shown in Figure 3.

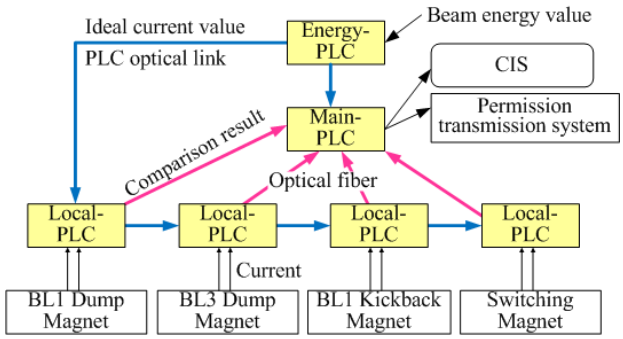

Figure 3: Schematic of the beam route interlock system.

We used several PLCs: Energy-PLC, Main-PLC, and Local-PLCs. The Energy-PLC and Main-PLC were installed in the safety office. The Local-PLCs were installed in the rack located near the power supply of the magnet approximately 600 m from the safety office. An optical PLC network used for data communication in slow control applications was used to connect the PLCs. The Energy-PLC executes high-load tasks, such as calculating the ideal currents for the magnets. The ideal current values are delivered to the Local-PLC via the PLC network. The Local-PLC inputs an analog signal proportional to the current of the magnet and compares the ideal value with the measured value. Then, the comparison result is sent to the Main-PLC. Because PLC networks cannot transmit signals within a few milliseconds, we used a direct fiber optic I/O connection between the Local-PLC and Main-PLC. The Main-PLC evaluates the beam route based on the comparison results and generates the permission signal.

We measured the response time of each device. The response times of the Main-PLC and the Local-PLC were both less than 3.0 ms.

Permission Transmission System

The permission signals for the GUN, beam chopper, and RF systems are generated by each interlock system. To achieve fast beam termination, the permission signals for the GUN and beam chopper must be stable and must have fast transmission speeds. Conversely, the permission signal for the RF systems is required to transmit over long distances and to a large number of systems. Therefore, PLC networks or metal cables cannot be used in the transmission line.

Thus, we developed a new optical module to transmit the permission signals and used it to construct the permission transmission, as shown in Figure 4. There are three permission transmission lines for the GUN, beam chopper, and RF systems. Permission signals are sent from the CIS, first, to module (A), and then, to module (C) via module (B). Module (C) outputs the signals to the target devices. Permission signals are transmitted from the EIS and BIS by inputting them to module (B) of the GUN and RF systems.

Two optical-fiber cables were used to connect the modules and ensure signal transfer. One of the fibers was used to send a static signal and the other was used to transmit the pulse signal (1 kHz) of the heartbeat. The transmission line for the RF systems used a total of 76 modules, and the total length of the optical fiber was more than 1.5 km.

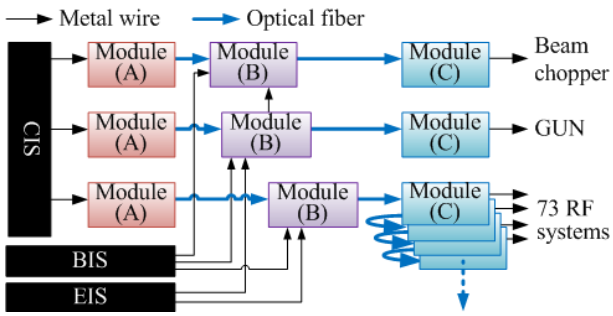

Figure 4: Schematic of the permission transmission system.

Figure 5: The newly developed module with a rack-mount unit of size 2U.

Figure 5 shows the developed module. A complex programmable logic device (CPLD) was utilized to reduce the processing time. To avoid noise, the circuit board was carefully designed. The modules are connected in a daisy-chain scheme and the distance between modules can be extended to up to 1 km. In the case of RF systems, the measured transmission delay time was less than 0.3 ms.

To verify reliability and stability, we conducted several tests, such as the electrical fast transient/burst test (international standard IEC 61000 4-4) and the long time operation test in the SCSS test accelerator [5]. The module passed all the tests.

MEASUREMENT OF RESPONSE TIME

We tested the total response time of the BIS and the permission transmission system. We chose the Local-PLC for the BL3 dump because it had the longest wiring from the Main-PLC. We measured the response time from the interlock action of the Local-PLC to outputting a permission signal from the module for the beam chopper. Figure 6 shows the 10,000 measurements obtained. The slowest response time measured was 6.7 ms, clearly satisfying the target value of 16.6 ms.

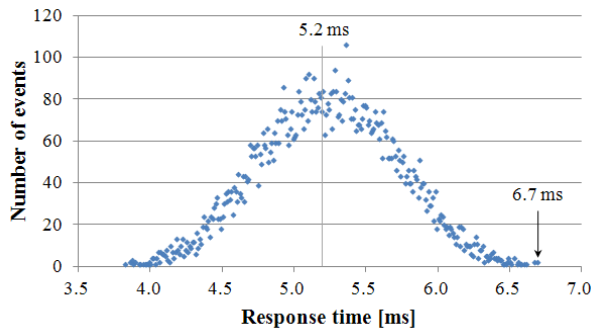

Figure 6: Total response time of the BIS and permission transmission system. The average response time was 5.2 ms with a standard deviation of 0.8 ms. The slowest value measured was 6.7 ms.

CONCLUSION

We constructed a radiation safety interlock system for SACLA. To stop the electron beam injection within 16.6 ms, an interlock system using multi-PLCs and an optical module were developed. The optical module was able to transmit a permission signal over a long distance to numerous accelerator systems. The radiation safety interlock system achieved a response time of less than 6.7 ms. The operation of the system commenced at the end of February 2011.

TANGO CONTROL SYSTEM MANAGEMENT TOOL

P. Verdier, J.L. Pons, F. Poncet, ESRF, Grenoble, France
N. Leclercq, Soleil, Gif-sur-Yvette, France

Abstract

TANGO [1] is an object oriented control system tool kit based on CORBA initially developed at ESRF[2]. It is now also developed and used by Soleil, Elettra, Alba, Desy, MAX-Lab, FRM II and some other labs. The TANGO concept is a fully distributed object oriented control system.

That means that several processes (called servers) are running on many different hosts. Each server manages one or several TANGO classes. Each class could have one or several instances (call devices).

This poster will show existing tools to configure, survey and manage a large number of TANGO components.

GOAL

The first goal is to know at a quick glance, if everything is OK in a control system, and otherwise to be able to diagnose a problem and solve it.

The second goal is to configure the control system and its components.

The third goal is to have long term analysis on components (logs, statistics, usage,....)

PRINCIPLE

On each host to be controlled, a device server (called Starter[3]) takes care of all device servers running (or supposed to be running) on this machine. The controlled server list is read from the TANGO database. A graphical client (called Astor[4]) is connected to all Starter servers and is able to:

- Display the control system status and component status using coloured icons,.
- Execute actions on components (start, stop, test, configure, display information, …)
- Execute diagnostics on components.
- Execute global analysis on large number of crates or database.

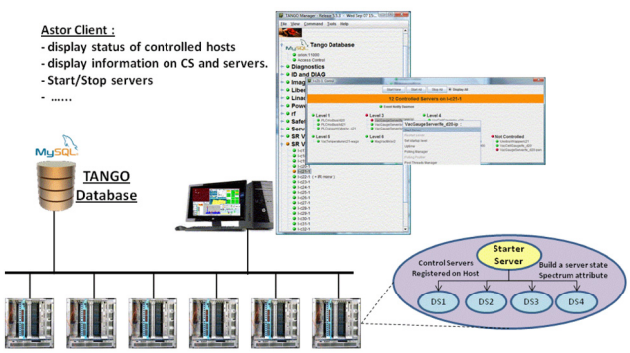

Figure 1: Astor/Starter principle.

STARTER DEVICE SERVER

This Tango device server, written in C++, is dedicated to control system management. An instance of the Starter must be running on each host in the control system.

Controlled Servers Status

When a Tango device server starts, it registers itself automatically in the TANGO database as running on specified host. At start-up, the Starter takes this list of servers registered on the host .

Periodically, a system call gets the list of running processes. For each controlled server, the Starter checks if the server is the running processes list. If it is running a second check is done by a ping on the administrative device to know if the server is alive. And finally a list containing the server names and their status is built.

Starting Servers

For each server, a control level can be defined. Level 0 means not controlled. At start-up, the Starter takes a list of servers registered on the host and its control level. Starting at level 1 to level n, if the specified server is not already running, the Starter tries to start it.

In order to not overload the database, the servers are started sequentially. To start the next server, one of the following conditions must be met:

- Server is alive.
- Server has failed.
- Time out.

A server can be started at any time on a command from a client. Using the same manner, a client command is able to start all servers having the same control level.

It is possible to configure the starter, using a property, to re-start a server automatically if it fails. This property defines a minimum time that has be running, to ensure that this server is able to run a bit.

Implementation

The Starter device server is supported for 3 operating systems:

- Windows.
- Linux
- Solaris

One of the main problems has been the different API's for system calls. Mainly to get running processes.

ASTOR – CLIENT TANGO MANAGER

A graphical client, using the java swing frame containing a tree to display the control system status.

On top of the tree we can find:

- The database status
- The access control status (if activated).

FEATURE OVERVIEW

Control System Status in a Quick Glance

The host status read from the Starter device server is displayed on a tree using coloured icons.

- Green if all controlled servers are running
- Blue if at least one server does not respond (start-up phase)
- Orange if at leas one controlled server is stopped
- Red if the starter itself does not respond.

The hosts can be grouped under branches by usage, operating system or whatever.... The status of the hosts under a branch is reported to the branch node.

Executing Actions on Tango Device Servers

A panel can be opened on a crate for more details. The status of each server is also displayed by a coloured icon.

- Green if the server is running
- Blue if the server is running but not responding.
- Red if the server is not running.

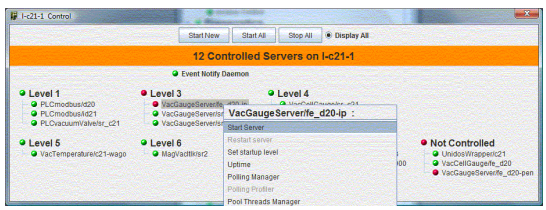

Figure 2: Host panel for server management.

By a right click on a server, a pop up menu is displayed to have an action or information on this server.

- Start/Stop servers.
- Test devices (single command or attribute).
- Check device states.

With one of the top buttons, you can start or stop all controlled servers registered on the specified host.

Using the same approach you can start a new device server. It will become a controlled server after you have chosen the control level.

On the host panel (Figure 2), the displayed status, is the server status, and not the device status, as most of the people belong. The specified server is able to serve many devices, and a simple icon cannot represents a combination of several status.

To know the status of each device select the item “Check States” and a panel showing devices status, sorted by classes.

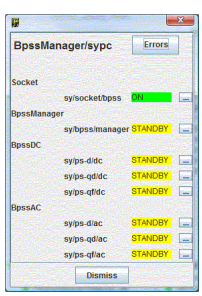

Figure 3: Device status panel.

Configure and Display Information

A database browser (called Jive) can be launched to edit device or class properties (see Figure 4).

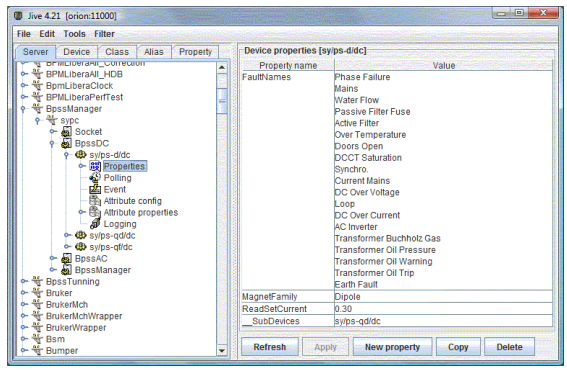

Figure 4: Jive (database browser).

It is also used to have information as to where a server is running, on which port, uptime,... Or to add new components, test devices (see Figure 5) and start a generic panel (called ATKpanel) to monitor devices (see Figure 6).

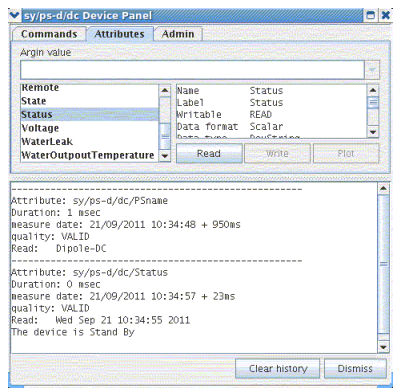

Figure 5: Device test panel.

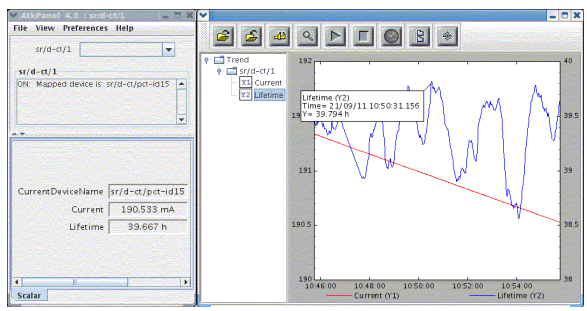

Figure 6: Device monitoring panel.

A wizard is available to guide the user to create a new server and to set class and device properties

Jive is able to set the polling period for device attributes and to set event parameters.

Help to Debug

To help debug a device, Jive and Astor propose a viewer (called LogViewer) to display on a specified device several outputs levels (see Figure 7). These outputs are time stamped and can be filtered to improve analysis.

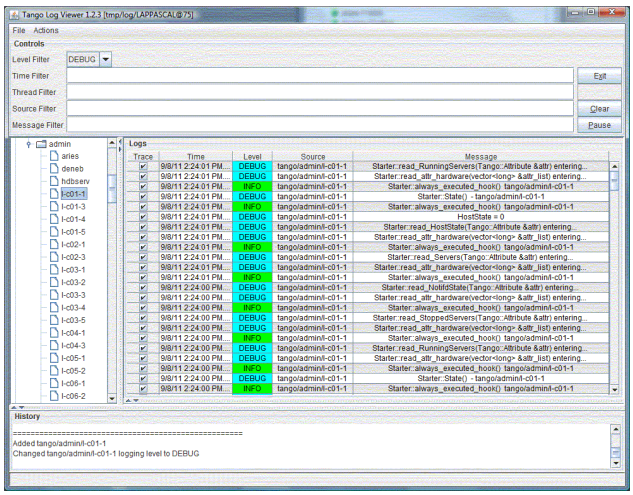

Figure 7: LogViewer (device outputs).

Attribute Polling Configuration and Tuning

A Tango device attribute can be polled periodically. To configure this polling, a diagnostic tool is available. It displays when each attribute has been polled the last four times (see Figure 8) and how much time was required to read and set it. It is very useful to tune the device attribute polling when a server has several devices with many attributes each. Or in case of a hardware problem with time out in reading.

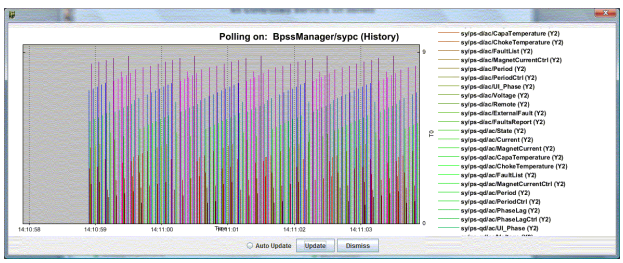

Figure 8: Polling profiler.

By default, a single thread is started to poll attributes. In case of several devices, a pool of threads is available. Astor proposes a graphic tool to distribute device(s) by thread as shown in Figure 9.

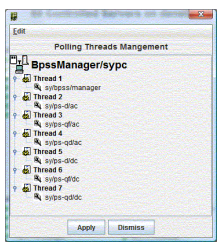

Figure 9: Pool of threads management.

Events Configuration and Test

Tango communication between client and server, could be done on events. A client subscribes to on event (e.g. an attribute change value) and will be waken up when this event will be pushen by the device. To configure and test events , Astor proposes a tool able to browse database to select device attribute, configure event parameters (period, change value, …) and start a test to check if events are received as expected (see Figure 10).

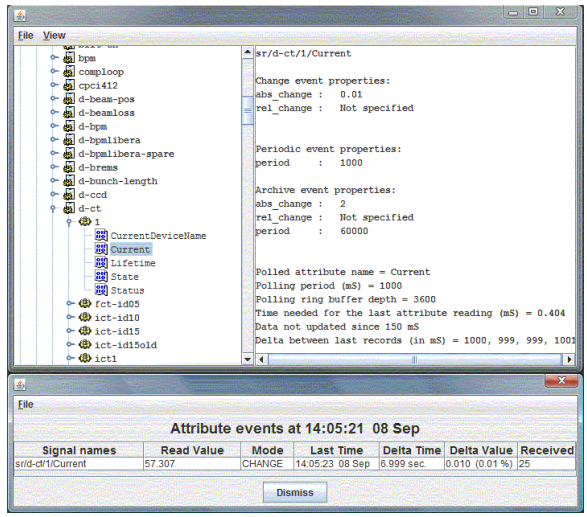

Figure 10: Event configuration and test panel.

Server Statistics

When a server, started by the Starter, is stopped by another way than a command on the Starter (kill signal, core dump, ...), this event is logged in a file. When the server is re started by the Starter, this information is logged too, Astor proposes to get information from this file for one host (see Figure 11) or for all controlled hosts, and compute statistics an availability for servers (see Figure 12).

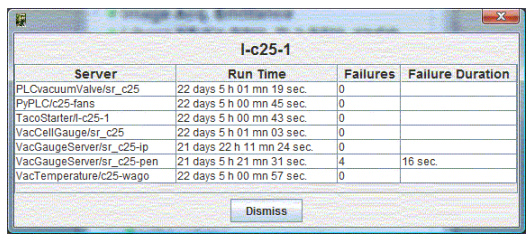

Figure 11: Statistics on a host.

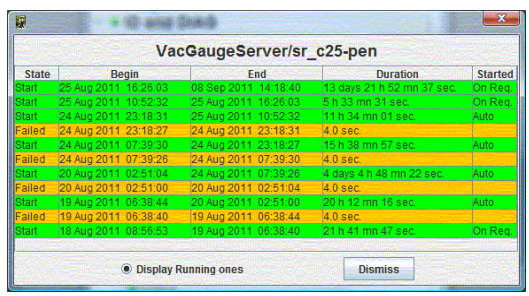

Figure 12: Statistics on a server.

Miscellaneous

Astor propose also:

- Simple logging about start/stop servers
- A panel to send command on several servers.
- A panel to show server usage (useful for large number of instance).
- A panel to configure control access if it is activated.

CONCLUSIONS

The couple Starter/Astor and related tools, are very useful to manage a large number of servers running on several hosts distributed around an accelerator or a large experimental physic control system. They help to configure diagnose problems, and for doing analysis and statistics.

INTRODUCTION

An increasing number of synchrotron beamlines need to use several detection techniques in parallel, and in fast acquisition modes. For example, a scanning microspectroscopy beamline could simultaneously collect data from two-dimensional (2D) position-sensitive X-ray detectors, one-dimensional (1D) energy-dispersive fluorescence analyzers, and several single-element beam intensity monitors.

Continuous scanning modes for fast data collection are required for scientific experiments conducted on such beamlines. That is, measuring signals from all detectors "on-the-fly" while actuators are moving, in order to avoid significant time overheads that are introduced by motor settling times in step-scan mode, and allow an experiment to be completed within a reasonable time frame. The implementation of this so-called "flyscan mode" is made possible by the progress in detector technology and the high photon fluxes available from 3rd generation synchrotron sources such as Soleil. The large amount of data produced in such an experiment has to be managed, either off-line and on-line, using software tools to analyze the data quality during collection and for categorizing and retrieving information for further scientific analysis.

Relying on our Tango [1] based software distributed architecture, a set of C++/java libraries, Tango devices and GUI applications has been developed to fulfill these requirements: (*i*) modularity, in terms of the number and type of detectors; (*ii*) performance, to handle these large data volumes; and (*iii*) data management, to store and retrieve information in a coherent way.

Taking as an example the challenging data acquisition demands of the future Soleil beamline Nanoscopium, this paper will present the status of development, deployment and operation of this "distributed fast acquisition system for multi-detector experiments".

THE SCIENTIFIC CASE OF THE NANOSCOPIUM BEAMLINE

The Nanoscopium beamline of Soleil will be dedicated to state-of-the-art scanning X-ray imaging techniques in the 5 – 20 keV range. It will provide unique research opportunities by combining the analysis of sample chemistry, *via* X-ray fluorescence and absorption spectroscopy, with structural analysis from coherent diffractive imaging at high spatial resolution (= 30 nm) in two and three dimensions. Elemental distributions and oxidation states can be quantified at the trace level in geological and biological samples for most of the elements starting from Ti. Fluorescence spectroscopy will target elements as light as phosphorous. The beamline is in the construction phase and will be operational in 2013.

These different detection schemes are to be used in flyscan mode in order to measure statistically relevant sample areas (up to several mm^2) and to perform tomographic scans without significant time overhead. Fast data collection will also result in reduced degradation of the cryo-cooled samples during the imaging experiments. Figure 1 shows a typical simultaneous detection mode.

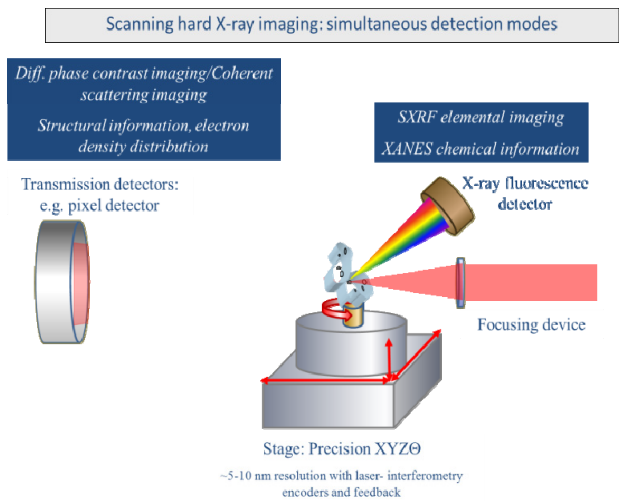

Figure 1: Schematic illustration of a multiple-detector fluorescence microspectroscopy experiment.

Multi-Detector Fast Acquisition System (FLYSCAN) Specifications

- Acquisition subsystems are independent and are synchronized by a common master clock trigger signal;
- Acquisitions must be done while systems are in motion to minimize data collection time;
- It must be possible to add a new acquisition subsystem to the experiment, without having to change existing software;

- Acquisition systems are running on various hosts (or crates), distributed on a TCP/IP network;
- All data collected on these various and independent subsystems must be recorded in a unique set of NeXus [2] files, encapsulating sufficient "metadata" (*e.g.,* experiment and sample identifiers, beamline parameters, time and date stamps) to simplify data reduction and analysis, facilitate reprocessing of the data in the future;
- Data organization within the files must be decoupled between acquisition and data processing to be able to add/remove detectors into the acquisition system without impacting data processing applications, even though the data organization within the files may be different.

SOFTWARE ARCHITECTURE

Data from each detector are collected by independent software applications (in our case Tango Devices), assuming all acquisitions are triggered by a unique master clock. Then, each software device streams its own data onto a common disk space, known as the spool (see Fig. 2). The data are stored in independent temporary NeXus files, with the help of a dedicated high-performance C++ library called NeXus4Tango. A dedicated asynchronous process, called the DataMerger, monitors the spool, and gathers all these temporary files into the final experiment NeXus file stored in SOLEIL common Storage System. Metadata describing the context of the data are also added in the final file by the DataRecorder device. All these actions are sequenced into a measurement process (Matlab, Python, Passerelle…)

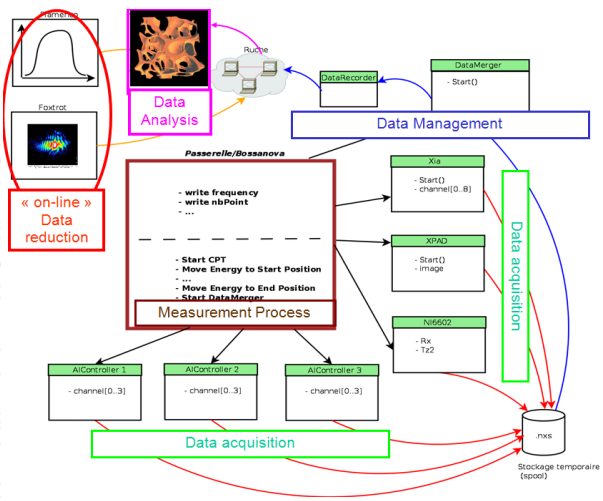

Figure 2: Data flow during the flyscan experiment. Multiple detector processes stream raw files to a temporary storage (spool), which are merged with metadata for permanent storage.

THE ACQUISITION COMPONENTS ON OUR NANOSCOPIUM PROTOTYPE

Acquisition subsystems used on the test bench for Nanoscopium are the following:

- An ADLINK DAQ-2005 analog-to-digital converter (ADC) board receiving signals from Si photodiodes measuring the X-ray beam intensity;
- A National Instrument (NI) PCI-6602 counter acquiring encoder positions of the 2 stages axis;
- A fast 2D photon-counting pixel array, XPAD [3], able to acquire up to 960 lines x 560 columns at 650 frames per second. (the XPAD is controlled with the LImA framework [4])

The master clock is another NI PCI-6602 configured as a trigger generator.

FIRST EXPERIMENTAL RESULTS

The FlyScan prototype has been deployed on the SOLEIL METROLOGIE beamline [5]. Official beamtime of few days has been dedicated to test in real condition this new acquisition system mode in the case of scanning differential phase contrast experiment [6].

In this experiment, a mapping (400 pixels x 40 lines) with a focused beam of a cross-nylon fiber was done in continuous mode. A master clock pulsed at 83 Hz (12 ms period), starts the acquisition of:

- The beam intensity (Fig. 3(a));
- The positions of the sample stages (Fig. 3(b));
- An image of the transmitted defocused beam (Fig. 3(c)) taken with one XPAD module (120 lines x 560 columns).

In order to construct differential phase contrast image, the center of gravity is calculated, on-line or off-line, on each XPAD image, along vertical and horizontal direction (Fig. 3(d) (e)).

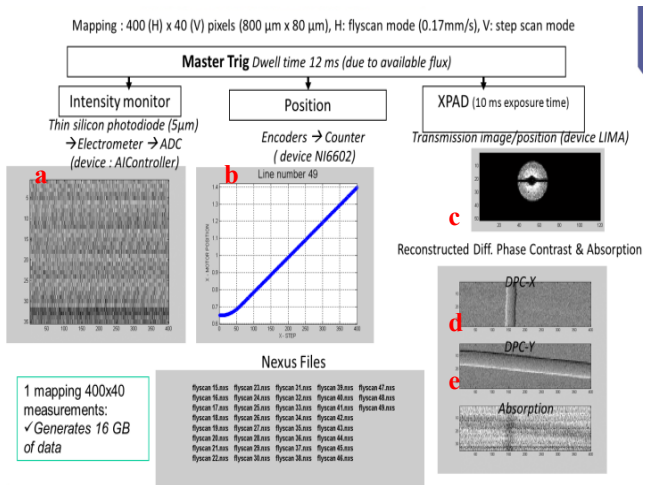

Figure 3: 1st results.

The architecture proved to be modular in terms of number and type of detectors. We have been able during the tests to easily integrate another 2D Detector (a Basler CCD camera).

DATA MANAGEMENT

Data Size and Network Throughput

There are two factors that have to be carefully taken into account: the volume of data and the speed of acquisition. A square mapping of 400 lines by 400 columns, with the same dwell time of 12 ms per point, generates 160 GB in 31 minutes (neglecting overheads incurred due to transferring the data over Ethernet and storing the files on hard disk). We estimate that once network and data storage performances are optimized (*using recent technologies like SSD disks and 10 Gbits Ethernet*), a single beamline such as Nanoscopium, working in flyscan mode with 2ms dwell time per point, could generate several hundred terabytes of data per year. This will present challenges to the data storage infrastructure and data processing capabilities.

Data Access

The software architecture proved to be modular and flexible at the Data Acquisition level. Nevertheless, the internal organisation of data with NeXus files changes depending on the number and types of detectors integrated in the data acquisition system. To hide these data organisation details to data analysis applications, SOLEIL develops with ANSTO the CommonDataModelAccess library [7].

CDMA is made of a core API that access data through a data format plugins mechanism and scientific applications definitions (i.e. sets of logically organized keywords defined by scientists for each experimental technique). Using an innovative "mapping" system between applications definitions and physical data organizations, the CDMA allows to develop data reduction applications regardless data files formats AND organizations.

Online Data Reduction

Because of the very large amount of data, it became evident already during the first experiments that data reduction applications should provide on-line data quality indicators to ensure whether the experiment is running as expected. The java COMETE [8] framework developed at SOLEIL allows us to reduce in "real-time" the large stack of raw images and spectrums to a small subset of reduced data, like for example reducing 160,000 XPAD images to the four images presented in this paper.

CONCLUSION/PERSPECTIVE

The following technical objectives are planned to be fulfilled before the end of 2011:

- stabilize all software components at the acquisition system level *(XPAD detector library , Tango device, Nexus4Tango library)*
- add the fluorescence XIA detector
- enrich existing COMETE data reduction applications
- integrate the CDMA C++ port within MATLAB and python to start integration in scientific data analysis applications

After the realisation, stabilisation, and test of the Nanoscopium prototype, an important project management phase will be to deploy FlyScans measurements on SOLEIL beamlines on a large scale basis, taking into account the impact on our data storage infrastructure and processing capabilities *(cluster and GPU)*.

We believe that this project is an important step for SOLEIL to prepare our computing resources to the scientific data deluge announced since years, but which is now becoming a reality.

EXPERIENCES IN MESSAGING MIDDLEWARE FOR HIGH-LEVEL CONTROL APPLICATIONS*

Nanbor Wang†, Svetlana Shasharina, James Matykiewicz, and Rooparani Pundaleeka
Tech-X Corporation, Boulder, CO 80303, U.S.A.

Abstract

Existing high-level applications in accelerator control and modeling systems leverage many different languages, tools and frameworks that do not interoperate with one another. As a result, the accelerator control community is moving toward the proven Service-Oriented Architecture (SOA) approach to address the interoperability challenges among heterogeneous high-level application modules. Such SOA approach enables developers to package various control subsystems and activities into "services" with well-defined "interfaces" and make leveraging heterogeneous high-level applications via flexible composition possible. Examples of such applications include presentation panel clients based on Control System Studio (CSS) and middle-layer applications such as model/data servers.

This paper presents our experiences in developing a demonstrative high-level application environment using emerging messaging middleware standards. In particular, we utilize new features in EPICS v4 and other emerging standards such as Data Distribution Service (DDS) and Extensible Type Interface by the Object Management Group. We first briefly review examples we developed previously. We then present our current effort in integrating DDS into such a SOA environment for control systems. Specifically, we illustrate how we are integrating DDS into CSS and develop a Python DDS mapping.

BACKGROUND AND INTRODUCTION

Accelerator control systems (ACS) coordinate the interactions among control hardware, data acquisition instruments, logging and data storage devices, and operator's interface. High-level accelerator control applications encompass activities such as operator control panels, tune measurement, orbit control, parameter save/restore, feedback, optic optimization, and parameter scanning that allow physicists and operators to control and reason accelerator behaviors in physically meaningful abstractions. There exist many tools and frameworks to help bring modern software engineering practices to the development and integration of lower-level hard real-time controls and the high-level soft real-time applications with great success.

Emerging Trends and Challenges

Control systems are often built on top of a set of existing tools and platforms that suit the needs of their target platforms. For examples, the EPICS [1] toolkit provides a standard for low-level controller architecture and a set of interoperable tools and engineering applications to assist control system developments. Depending on the scale of the target accelerator, high-level applications are often developed as a monolithic Graphical User Interface (GUI), a simple script, or a library routine. As in the case of generalized ACS control environments, many tools and frameworks such as Unified Accelerator Language (UAL) and Matlab Middle Layer Toolkit (MMLT), are available to assist the integration and interaction among high-level applications and device controllers (built, *e.g.*, using EPICS.)

All the different development environments and tools do not generally interoperate with one another. This is not a major issue for small- or medium-sized accelerators. However, such *ad hoc* approach no longer scales for modern large-scale accelerator facility such as the new NSLS-II, Project X, and the Intensity Frontier. Several Design Reports have called for a separate "service tier/middle layer" to provide devices and functional abstractions as units of integration.

SOA: Service-Oriented Architecture

SOA [2,3] has gained widespread acceptance in the business/enterprise software world as it has shown to facilitate the integration and composition of disparate software services across enterprises and businesses boundaries. Applying SOA principles in ACS is a promising approach in isolating and managing the complexity. In fact, many existing accelerator control systems have already adopted many SOA guidelines and principles. To address the needs and challenges of next-generation, large-scale accelerator control systems, we are enhancing the SOA environment for next-generation large-scale accelerator control systems to manage the complexity and contain the cost of developing future accelerator control systems and upgrading existing ones.

Message-Oriented Middleware

Traditionally, a SOA is often constructed on top of point-to-point request-reply, client-server communication middleware technologies. Middleware serves as the standard communication bus among different service. Examples of well-established SOA middleware include SOAP-based and RESTful Web Services, CORBA and Java RMI. However, there are still limitations with these point-to-point, request-reply, RPC-styled communication model as they impose scalability issues as the size and complexity of accelerator control systems grow.

The emerging DDS [4] is a new class of Message-Oriented Middleware (MOM) standard specified by the

*Work partially supported by US Department of Energy under contracts #DE-FG02-08ER85043 and #DE-SC-0000842, and Tech-X Corporation.
†nanbor@txcorp.com

Object Management Group (OMG). DDS complements RPC-styled client-server middleware and address their many limitations. DDS is a natural extension to many existing accelerator control frameworks. Furthermore, because DDS inherently supports many quality-of-service (QoS) policies such as message priority, rate, reliability, and deadline, that are necessary for mission-critical applications, DDS is a natural selection to act as the alternative service-bus in a SOA for control systems.

Figure 1 illustrates a SOA for high-level accelerator environment where applications exchange data using DDS as the common standard service bus. As shown in the figure, client applications can readily act as gateways to another enterprise service bus such as Web Services.

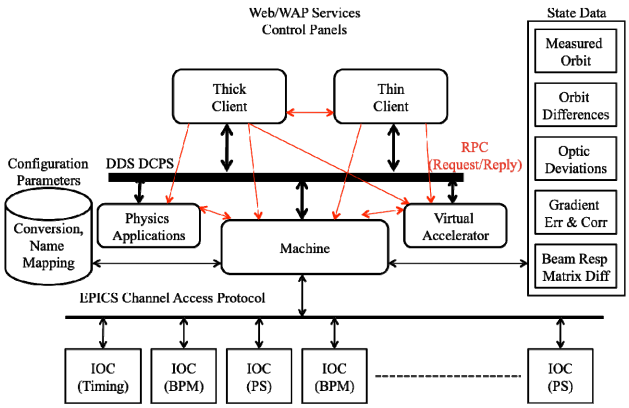

Figure 1: SOA for high-level applications over DDS.

DESIGNING DDS APPLICATION THROUGH PERFORMANCE TESTING

Because there are many ways to configure a DDS system, to better emulate various operation scenarios easily, we developed a DDS performance test suite and performed benchmarking tests with it. With the test framework, users will be able to develop various DDS runtime scenarios and experiment with various QoS policy combinations and evaluate their effect to the overall system performance. We design the test suite to be portable so that ACS developers can evaluate different DDS implementations easily.

Our performance test suite is built on top of the generic benchmarking application similar to the open-source Touchstone performance tool. Touchstone's benchmarking application provide the mechanism to instantiate test components such as transceiver and transponder for latency test, via special DDS messages for a set of control topics. Users can design and instantiate tests of different scales and with different combinations of QoS policies easily. Such approach allows users to create scenario-based performance evaluations easily.

Accessing the performance of messaging systems and overall applications provide critical information to help making key design decisions such as:

- Selection of DDS implementations: Different DDS implementations make different tradeoffs and adopt different implementation strategies to realize the movement of data from publishers to subscribers according to the QoS policies specified by all the entities involved. Some implementations also make such strategies configurable. Therefore, certain implementations or configurations perform better under certain operation environment while others ay scale better.
- Assisting in DDS configuration: DDS supports a rich set of QoS policies. Configuring a system using different sets of policies can affect the overall performance in different ways. For example, setting priority on one data stream can affect the overall behaviors of other data streams. Being able to perform tests to observe system behaviors at similar scales can provide essential guidance on design strategies.

EXAMPLE MIDDLE-LAYER SERVERS

To demonstrate the three-tier high-level application architecture, we implemented a general-purpose web-based optimization service with the help from our collaborator at Brookhaven National Lab (BNL). The service allows users to perform Twiss calculation and lattice optimization over the web.

Figure 2 illustrates the overall architecture of such a general-purpose web-based optimization service. This simple service allows accelerator physicists to submit lattice and optimization files to the service and returns the visual results of twiss calculations. This example provides

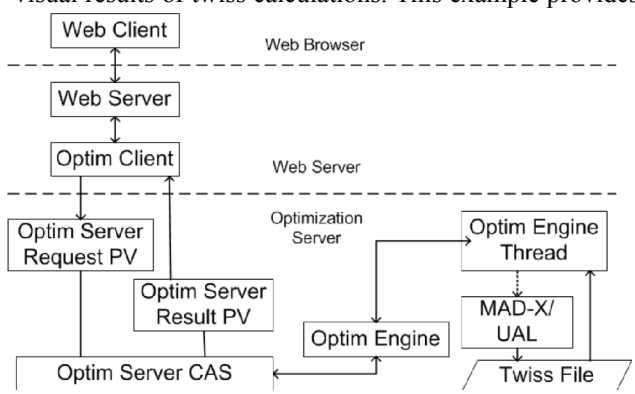

Figure 2: Example architecture of a middle-layer server.

an example "Software as a Service (SaaS)" prototype. It demonstrates the core idea on SOA using DDS and lays down the foundation for further, more complicated services. We implemented the prototype service using both MAD-X and UAL as the underlying compute engine. For messaging between the Web Server and the Optimization Server, we used both DDS and the experimental EPICS-DDS [5].

INTEGRATING DDS WITH THE CONTROL SYSTEM STUDIO

Fermilab's Intensity Frontier examplifies another usage scenario for a dual-message-bus SOA. There, they employ both DDS and EPICS in the control system. Subsystems that require real-time responses are built on

top of EPICS. Higher-level applications use DDS instead as the messaging mechanism.

There is a need to aggregate information and control various systems running on either EPICS or DDS together. Therefore, we are developing plug-ins for publishing and subscribing DDS topics from within the Control System Studio (CSS) [6]. The prototype plug-ins are modeled after org.csstudio.platform.libs.epics and its UI plug-ins. Another com.txcorp.soaac.css.dds.pv plug-in provides methods for publishing and subscribing topic-specific variable. Using our prototype, CSS widgets can subscribe or publish to variables as DDS topics using the familiar URI syntax such as "dds://topicname".

Although our prototype plug-ins demonstrate that DDS can be integrated into the CSS environment seamlessly, there are several limitations in our current design that we are working to improve:

1. Currently, we model the DDS topic structure closely after the EPICS PV data structure. We are working to relax this restriction so that a widget can subscribe to arbitrary variable within a DDS topic, e.g., "dds://device/part#control_point".
2. For a CCS application to subscribe to certain topics, their type-specific implementation must be generated and compiled into a .jar file, which then must be loaded into the application. We are working on adding support for a CSS application to read in topic structure and QoS definitions as XML files during runtime. This enhancement will eliminate the needs to compile and load application specific code into the CSS library.

SUPPORT PYTHON-DDS MAPPING (PYDDS)

Python language is a very versatile dynamic, object-oriented language that has gained great popularity among sceintists. Many scientists have expressed interests in interacting with DDS-based systems directly from within their Python codes. We have previously experimented with using DDS in Python. As illustrated in Fig. 3, our previous implementation of Python DDS support wraps all the topic-specific C/C++ codes generated by DDS tools into Python using SWIG or Boost.Python.

Although this approach serves the purpose, it is not compatible with Python's dynamic programming style. In particular, extra-steps outside of Python are required to generate the topic-specifc python mapping. Furthermore, when topic structures change, these wrappers have to be regenerated and repackaged in order for the actual Python application to use them. All these limitations interrupt the natural workflow of programmers and are not compatible the the dynamic language nature of Python.

In order to address these limitations, we are developing a new Python DDS (pyDDS) implementation. As shown in Fig. 4, we have moved the generation of topic-specific codes into Python. These topic-specific codes in-turn interace with generic DDS services. Using this approach, applications can source in topic structure definitions at

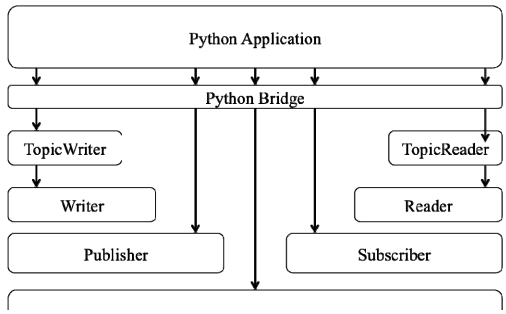

Figure 3: A straightforward Python DDS wraps generated topic-specific codes.

run time and generate the topic-specific readers and writers on the fly as pure Python classes. By eliminating the need to generate and load topic-specific wrappings in separate steps, the new pyDDS library is more compatible with dynamic programming nature of Python and also more easily accepted by Python developers.

The following listings demonstrate how to interact with a DDS data topic from within Python:

```
# First thing to do to use pydds
import pydds;
```

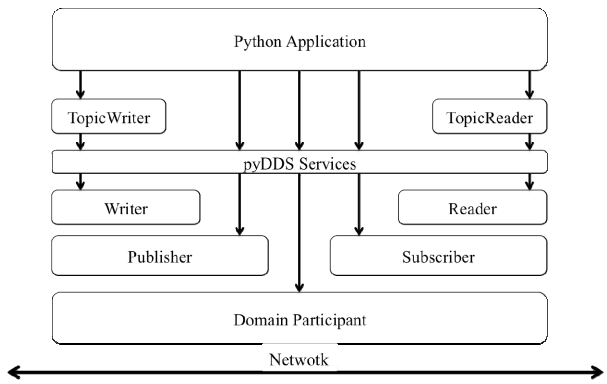

Figure 4: The new pyDDS implementation takes advantage of Python's dynamic language features.

To Join a Data Domain:

```
# Uers defines the dataspace runtime
# and pass it in to various other
# operations that need it.
 myDataspace =
   pydds.connect_dataspace
    ("Domain name", "Partition name")
```

To Manipulate QoS Policies:

```
myQoS = pydds.create_qos()
myQoS.set_reliable (3000000)
myQoS.set_transient()
myQoS.set_keep_last (3)
```

To Create Topic Reders/Writers:

```
# Creating/Finding a topic in global
# data space. Last argument specifies
# the URI to the topic definitions
helloTopic = pydds.createTopic
 ("TopicName",
  myDataspace,
  myQoS,
  file:///HelloWorld.idl#HelloTopic)

# Now create reader/writer objects
helloReader =
 helloTopic.create_reader(readerQoS)
helloWriter =
 helloTopic.create_writer(writerQoS)
```

To Write and Read Data Samples:

```
# Creating a sample
helloSample =
 helloTopic.create_sample
  (message = "John Smith",
   repeat = 3)

We plan to model listener-based callback data read interface after the Twist or Trellis libraries. Furthermore, we would also like to take advantage of the emerging eXtensible Type Standard which is being ratified by the OMG [7,8].

CONCLUDING REMARKS

This paper describes how a dual-service-bus SOA provides an ideal development environment that promotes modulization of high-level application components and facilitates dynamic composition of high-level applications. In the context of the high-level application environment, it means flexibility in selecting and connecting the most appropriate modeling algorithms and programs. To support such use case, we are bringing the next generation data-centric publish-subscribe middleware called DDS to this environment by investigating various usage scenarios and programming patterns of DDS in ACS. Furthermore, we are developing tools and libraries to enable ACS developers to leverage the new technologies. We developed a DDS performance test suite and used it to benchmark and evaluate various open source and commercial DDS implementations. We also implemented a set of example Web-based high-level application on top of open source DDS implementations.

Other than demonstrating how a ACS can utilizes DDS middleware technologies, we are also developing tools to help facilitate the adoption of DDS. We implemented a set of prototype plug-ins for Control System Studio to monitor and emit DDS data stream. We also developed a prototype Python mapping for DDS to enable Python applications to participating in DDS data exchange. We are in the process of hardening these prototypes and enhance their robustness and usability.

ACKNOWLEDGMENTS

The authors would like to thank Nikolay Malitsky of Brookhaven National Lab for his help in formulating the middle-layer server examples. Similarly, we wish to thank Jim Kolwalkoski, Marc Paterno, Kurt Biery, and Erik Gottschalk of Fermilab for discussing the needs and requirements of their projects.

RUNNING A RELIABLE MESSAGING INFRASTRUCTURE FOR CERN'S CONTROL SYSTEM

F. Ehm, CERN, Geneva, Switzerland

Abstract

The current middleware for CERN's Controls System is based on two implementations: CORBA-based *Controls MiddleWare* (CMW) and *Java Messaging Service* (JMS). The JMS service is realized using the open source messaging product *ActiveMQ* and had became an increasing vital part of beam operations as data need to be transported reliably for various areas such as the beam protection system, post mortem analysis, beam commissioning or the alarm system. The current JMS service is made of 18 brokers running either in clusters or as single nodes. The main service is deployed as a two node cluster providing failover and load balancing capabilities for high availability. Non-critical applications running on virtual machines or desktop machines read data via a third broker to decouple the load from the operational main cluster. This scenario has been introduced last year and the statistics showed an uptime of 99.998% and an average data serving rate of 1.6GByte per minute represented by around 150 messages per second.

Deploying, running, maintaining and protecting such messaging infrastructure is not trivial and includes setting up of careful monitoring and failure pre-recognition. Naturally, lessons have been learnt and their outcome is very important for the current and future operation of such service.

THE CERN CONTROL SYSTEM

Today, the CERN control system is constructed as a three-tier architecture with real-time processes reading signals from the equipment, data processing services and graphical interfaces to display the data.

The signals produced by the accelerator equipment are read out by real-time C++ processes running on around 1600 so-called *Front End Computers* (FEC) and published further to higher level services where it is filtered, evaluated or correlated with other data. The elements in the last and highest level of this architecture are *Graphical User Interfaces* (GUI) mostly written in Java which display the data or let operators in the *CERN Control Centre* (CCC) take direct control on certain equipment by enabling them to set hardware parameters.

All involved components communicate via the Controls MiddleWare (CMW) to publish and/or exchange data. It is actually composed of two products: an in-house developed CORBA [1] based solution (RDA) and ActiveMQ [2], an open source implementation of the *Java Messaging Service* (JMS) [3] API.

RDA is implemented in C++ and Java and provides the point-to-point communication between the involved peers using a physical connection. This allows low latency with a high grade of control. The network and CPU load caused by distributing the data to the recipients resides on the publishing instance.

ActiveMQ is written in Java and was released the first time in 2004 and is in use at CERN for Beam Controls since 2005. It implements the JMS 1.2 specification and fulfils the *Message Oriented Middleware* paradigm where the communication between sender (*producer*) and the recipient (*consumer*) is relaxed by the introduction of an intermediary component (*messaging broker*). By using the JMS API application modules can be distributed over heterogeneous platforms and thus reduces the complexity of developing applications that span multiple operating systems and communication protocols. Producers publish data to the brokers and consumers register their interest in specific messages via the Publish-Subscribe (*Topic*) or Point-to-Point (*Queue*) mechanism. It is then the broker's responsibility to distribute the data reliably.

As a result of this intermediary broker and due to the additional network hop the communication latency increases. However, for the involved systems of the CERN Controls System this latency is acceptable.

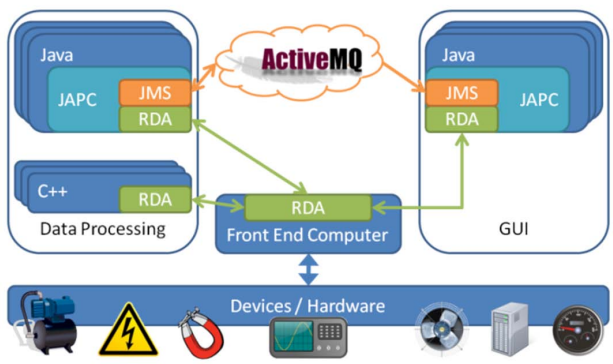

Figure 1: Usage of the Control System Middleware.

As shown in Fig. 1 the ActiveMQ infrastructure is deployed for service to service and service to GUI communication. CMW enables direct communication such as sending commands, tuning hardware equipment and monitoring their parameters. Although not required, data processing services using JMS are exclusively implemented in Java and services which use RDA may be C++ processes as well. In both cases the *Java API for Parameter Control* (JAPC) is used to abstract the underlying middleware.

Choice of a Centralized Messaging System

The main reason for having a messaging system such as ActiveMQ acting as a relay is the clear advantage of outsourcing the work of data distribution to a dedicated entity which is actually made for such a purpose. It originates from the stock market system where the same technology is used to serve thousands of consumers. The control system at CERN does not reach this number but shows very similar requirements in terms of flexibility, scalability and robustness.

CURRENT DEPLOYMENT

The current deployment of ActiveMQ installations consists of 14 brokers used for production and 4 for development. Depending on a project's needs either a single broker or a *broker cluster* for failover and load balancing purposes is set up. A cluster consists of usually two or more interconnected brokers which exchange information about producers and subscribers to forward a message if required. In case one of the brokers crashes clients automatically reconnect to another one in the same cluster.

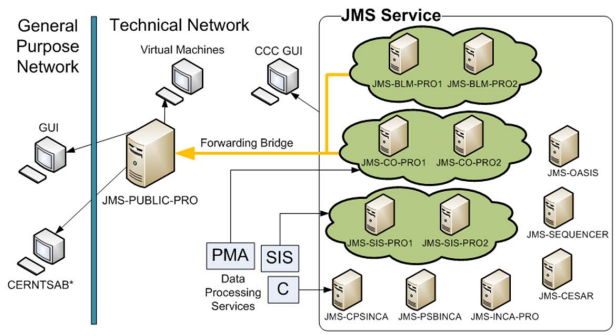

Figure 2: Overview of the Messaging Service.

As Fig. 2 illustrates there are currently 3 main clusters installed for selected middleware services such as the *Software Interlock System* (SIS) and the *Beam Loss Monitors* (BLM) system. The third one is called JMS-CO-PRO and is shared among projects. Alternatively, a project dedicated broker is deployed on the same machine as the related middle tier server. Because these are deployed as single instances it is irrelevant to have a redundant broker service (and hence a higher management load). Assigning

As Fig. 2 also shows that a *data forwarding bridge* to a broker for non-operational clients has been deployed. These clients are GUIs which are not used for beam operations but by developers or experts or as information displays running on windows terminal servers or on virtual machines. Data is forwarded from the main JMS Service to this public read out broker which again redistributes the data to the subscribers. This setup provides several advantages:

- First, a separation of critical clients from non-critical ones allows reducing the additional load caused by latter noticeably.
- Secondly, it enables reading data from outside the closed technical network without exposing the main service machines but a single broker.
- And thirdly, it gives the possibility to instantly remove load from the main service by shutting down the public read broker.

MONITORING

Like other services a messaging broker system needs to be carefully monitored to proactively identify upraising problems and to react to them accurately and immediately. Not only default machine metrics such as network, CPU and disk usage take part in this monitoring activity but additionally specific tools have been developed to collect more – broker specific - information.

Instrument JMX and Sending of a Test Message

One vital prerequisite for such tools is to be able to get an insight view into a running broker. ActiveMQ provides this functionality via the *Java Management Extensions* (JMX) [4] interface and it is easily integrated with existing diagnostic and monitoring tools. Only a subset of the exposed metrics is actually chosen to evaluate the broker health periodically. Information such as memory and storage usage as well as the processed messages since the last iteration is available. However, these numbers may not be sufficient to make a complete statement on the broker condition. Therefore, the *message processing speed* (mps) is measured every 5 minutes to evaluate the time a message takes to go through a broker or a full broker cluster. This is done by an external monitoring agent which sends and reads a test message and compares the submission and receive timestamp. Analogue to the connected applications a high latency is detected very quickly and subsequently treated as a potential problem.

Thresholds are used to determine the severity of the result to then inform service managers via eMail and the *Short Message Service* (SMS). As an example: an mps of 100ms would correspond to a warning, 1000ms to an error.

Topic Monitoring Tool

An in-house developed *Topic Monitoring Tool* (TMT) listens actively to all messages and stores statistics like throughput and size using the *Round Robin Tool* [5] database technology. This again can be used to visualize a history view on the average values like MRTG [6]. An example of the usage of this view is shown in Fig. 3. A producer sending at irregular high data rate was recognized (left red area) and a restart subsequently solved the problem (green area).

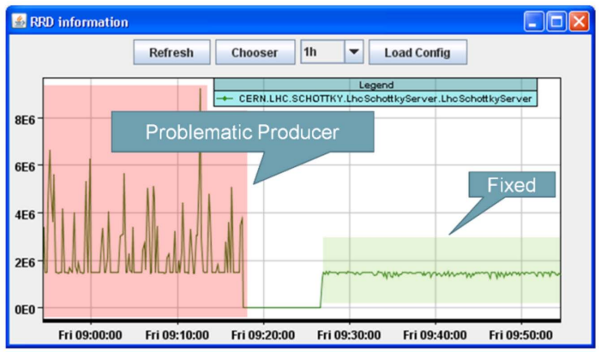

Figure 3: Detecting a producer problem using the TMT.

PERFORMANCE AND RELIABILITY

When it comes to performance and reliability ActiveMQ has proven to be very stable in the present environment and configuration. In 2010 the JMS-CO-PRO and BLM services handled together up to 2.57TByte per day in data volume and reached a service availability of 99.998%. This includes downtimes due to kernel and machine upgrades. Single broker services showed a lower availability in average because of missing redundancy. But 210 consecutive days of uptime with an average of 120 messages per second as one example shows that a single broker instance is very reliable.

Another example for load balancing is the BLM system: it sends out messages of 2 MByte which are read by a large set of consumers. While investigating delay of messages it turned out that the network card in the broker machine was actually a bottleneck. As a consequence, a second broker on a separate machine was deployed to balance the network load. Alternatively, binding the second broker to a second installed network card in the same machine would have had the same effect.

MESSAGE USAGE PATTERNS AND SERVICE LEVEL AGREEMENTS

The usage pattern varies from rather small messages at high frequency (1KByte payload at 100Hz) to large messages at low rate (2MByte payload at 0.5Hz). In case of latter for example, around 25 clients constantly request this data. Other services such as the *Post Morten Analysis* (PMA) system show a very different usage scenario: they send high bursts of small messages only after a beam dump.

Depending on the characteristics of the published data the number of reading clients may vary. In theory, all CCC consoles may read all data at the same time. However, in practice this is not the case. Due to the organization of the CCC an average of 20 GUIs is taken for the data distribution load. This means one message has to be delivered to 20 consumers.

Service Level Agreements

In order to protect a customized messaging service for a project *Service Level Agreements* (SLA) had been established. They describe on a high level the project's needs and message usage patterns and thus help to decide how to realize these requirements. Both sides then have to agree on the SLA and make sure that the rules are respected.

For example: the BLM SLA states that the messaging service must sustain a constant rate of 2MByte payload at 1Hz with 20-30 clients. If much more data is sent than agreed then there is no guarantee that the service will remain stable.

These SLAs also allow tracking of changes of the project's requirements and ease setting up monitoring thresholds. They are based on the experience from the *Large Hadron Collider* (LHC) startup in March 2010 where the amount of data which was estimated was exceeded by a factor of 2.5 (see Fig. 4). A possible messaging service failure was prevented by a precautious upgrade of the machines. This case shows that the prediction for load in such an environment with a great variety of applications (and developers) is not always definitive and final.

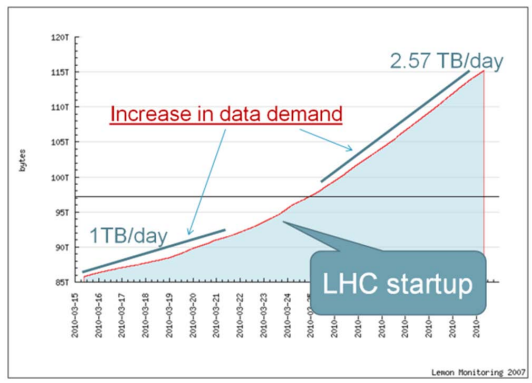

Figure 4: Data demand during start up of the LHC.

PROBLEM ANALYSIS IN PRODUCTION

When having a system which is vital for (beam) operations it is important to be able to quickly analyse a problem to reduce costly downtime. In contrary to a point-to-point communication like CMW a centralized messaging system always faces the problem of being a potential single bottleneck. However, there is also good side. Because of this single point of failure the problem analysis is limited to a fewer places.

For ActiveMQ there are the following instruments for such investigations:

- JMX console showing very detailed information like connections, subscriptions, etc.
- Test clients for reading data from topics
- Changing broker log level without a restart
- Dump of available data via JMX to a SQLite [7] database for easier extraction

The experience shows that most problems caused by an ActiveMQ broker were based on changes which were introduced shortly before (e.g. upgrade or configuration changes).

There is also the much more dangerous possibility that an effect occurs days or weeks later. For example: a new

broker version was tested in an integration test bed before going to production. After the upgrade the service ran smoothly for the next weeks but failed at a certain point due to a bug in the configuration settings of the broker software. As a result, the JMS-CO-PRO cluster was not available anymore to the clients and many critical services stopped working.

Unfortunately, there is no straight solution which is feasible in time and effort for such situations. As for many other services it must be noticed that such incidents may happen (although rarely) despite all monitoring and precautious actions which may reduce the probability but never eliminate such cases.

More important is the ability to know strategies and solutions to quickly resolve the situation.

SUMMARY

ActiveMQ was and is a good choice for decoupled messaging for the CERN's Control System and has proven to be very stable. In particular the strength of scaling linearly makes it inevitable for an environment where the number of reading applications is very dynamic and data demand is growing at the same time. Because unexpected high load is possible it is important to dimension machine resources sufficiently.

In this context, monitoring is a vital part of operation and the evaluation of the recordings must take influence on future deployment decisions. Effective service downtime is reduced by deploying a messaging service per usage domain or project.

It is highly recommended to set up SLAs to track the (growing) user needs. They help to adapt the system to usage scenarios before they are put into production and support setting up monitoring thresholds.

A LEGO PARADIGM FOR VIRTUAL ACCELERATOR CONCEPT

S. Andrianov*, A. Ivanov†, Eu. Podzyvalov‡, SPbSU, Saint-Petersburg, Russia

Abstract

The paper considers basic features of a Virtual Accelerator concept based on LEGO paradigm. This concept involves three types of components: different mathematical models for accelerator design problems, integrated beam simulation packages (i. e. COSY, MAD, OptiM and others), and a special class of virtual feedback instruments similar to real control systems (EPICS). All of these components should interoperate for more complete analysis of control systems and increased fault tolerance. The Virtual Accelerator is an information and computing environment which provides a framework for analysis based on these components that can be combined in different ways. Corresponding distributed computing services establish interaction between mathematical models and low level control system. The general idea of the software implementation is based on the Service-Oriented Architecture (SOA) that allows using cloud computing technology and enables remote access to the information and computing resources. The Virtual Accelerator allows a designer to combine powerful instruments for modeling beam dynamics in a friendly way including both self-developed and well-known packages. In the scope of this concept the following is also proposed: the control system identification, analysis and result verification, visualization as well as virtual feedback for beam line operation. The architecture of the Virtual Accelerator system itself and results of beam dynamics studies are presented.

INTRODUCTION

In modern accelerator physics there gives much attention both to the information support problems as a process of constructing the accelerator systems and the maintenance of corresponding experiments. In other words, it is necessary to create an integrated package of special software oriented for modeling of operating characteristics of an accelerator considered as a control system. Here we mean a distributed control system for both electromagnetic structural elements and a beam state. In the corresponding package is it necessary to take into account consider both the most important procedures like measurement of the beam, control elements characteristics and technologies required for a comprehensive evaluation design for each of these key questions before manufacturing and testing physical prototypes. In the VA package there are integrated different approaches to both numerical modeling problems beam dynamics and beam control system operation. More over, the corresponding approaches involve necessity to carry out a global optimization procedure of an accelerator in whole (or its components) with a given criteria family.

The Virtual Accelerator package implements a unique hybrid approach to modeling the dynamics of the beam, based on a combination of a large number of proven methods of analysis based on a combination of numerical and symbolic operations, in which the model as components of the accelerator and beam models are combined with virtual models and synthesized control fields. By combining environmental test and virtual simulation the package VA speeds up the design process and makes it more accurate and stable because it has a built-in validation of models based on test results.

The VA package allows users to:

- combine proven components models with virtual models of new components;
- develop reliable data on the beam with a virtual simulation and, if possible, the results of environmental tests;
- improve the accuracy and speed of simulation at the system level, using real data and reliable virtual model;
- adapt the virtual assembly control system for assessing critical characteristics of the beam;
- estimate the characteristics of the whole control system before natural testing of a prototype.

Virtual Accelerator package provides users a set of well-proven packages of modeling of dynamics (such as MAD, Trace3D, COSY Infinity, MaryLie and others developed by the authors of this article, see, for example, [1]), as well as the software package that allows you to implement the concept of a global optimization (see, for example, [2]). In the process of the corresponding research the model includes the necessary edge effects, nonlinear aberrations of different nature, the effects of space charge and so on. For problems of long-term evolution there is supposed to use different methods of symplectic integration. This gives us the necessary accuracy for long time evolution (it is very important for cyclic accelerators).

The VA package will provide “transparent” access to data modeling and its results, making it an integral part of the process numerical simulation and monitoring of existing accelerator facilities. Construction and integration of computational models with specific characteristics is a key point of virtual simulation. Therefore, the package should

* sandrianov@yandex.ru
† 05x.andrey@gmail.com
‡ podzyvalov@mail.ru

contain necessary tools to edit the structure of the accelerator control system, models of control fields, the description of the beam as a family of particles (including taking into account its charge), modeling and assembly for fast virtual models with the necessary visualization tools. The VA package allows users to combine a numerical model of the system-level virtual and the resulting test model components. It should also be pointed out that this package provides several opportunities for optimization of one or more of the criteria (including antagonist). With the help of neural network modeling techniques designer can determine the possible structures corresponding to their requirements. Using effective methods and optimization algorithms (e. g. using genetic algorithms, see, for example, [2]) one can find a set of appropriate solutions. The global optimization concept is proposed to use the method of finding rational alternative, based on the combination of the decision and Pareto method optimization using both integral criterion and using different methods and algorithms for accelerator modeling. This technique was tested for the solution of optimization problems of control systems particle beams [2]. It is also expected to use the methods and algorithms involving expert systems for optimization of complex systems with incomplete information. This approach allows the concept to use data mining methods and technologies for control problems in complex systems. For the analysis of investigated alternatives are used both numerical modeling procedures and the corresponding analytical model using the tools and techniques of Computer Algebra [3].

It should be noted that all above mentioned approaches are based on the LEGO-objects concept (see, for example, [4, 5, 6]), which on one hand allows to unify the mathematical objects at all stages of modeling and maintenance of the necessary computational procedures and on the other – to provide the necessary flexibility and scaling the appropriate software.

SOME PRINCIPLES OF THE LEGO-OBJECTS CONCEPT

The main idea of the LEGO-objects concept is based on a deep hierarchy of *elementary blocks* for presentation of both *physical elements* and corresponding *computational tools*. These blocks can be separated in three groups: the first corresponds to physical objects, the second has a virtual character and the third describes computational procedures. For the second type a beam line researcher can not relate such virtual block to any physical element. As an example of such *virtual element* the fringe field description block can be mentioned. These elementary blocks are used for decomposition of the whole physical system into a set of subsystems. The symbolic representation of these blocks allows to create databases of elementary classes of such subsystems. Manipulation by these classes is similar to manipulation by LEGO-blocks. The similar approach is developed in some works [7], but the authors do not use symbolic representation for solution to be found.

The first two types of LEGO-objects can be connected with objects having some different (not only physical) interpretation. LEGO-objects of the third type are accountable for computational procedures of different kind. As an example we can mention two groups of methods of integration: non-symplectic and symplectic integration methods. So the VA package has to involve other types of LEGO-objects which generated by operations above LEGO-objects of the first two types. All types of LEGO-blocks have corresponding presentation on at all phases of simulation process: from physical models up to computing models. Including and excluding any elementary block have to be realized quietly, without distortion of the whole model. This approach is an essence of the *dynamic modeling paradigm* [1].

The above pointed approach is based on a hierarchical sequence of approximation models, which can be built for an investigated beam line. The modeling process (including optimization procedures) has several major phases:

- *the initial phase of problems formalization on physical understanding level — creation of a set physical models for problem under consideration;*
- *construction of approximating models in conformity with experiments data — creation of a hierarchy of approximating models;*
- *the phase of problems formalization on mathematical understanding level — creation of a hierarchy of mathematical models;*
- *creation of computing models (including algorithms and corresponding software) realized mathematical models;*
- *realization of the computing process for modeling and optimization — a set of computing experiments;*
- *the phase of the interpretation of computing results and testing on adequacy to the physical model.*

The basic stages of computational processes are presented in Fig. 1. All presented modules are not only necessary for correct realization of computational experiments, but they gives designer effective tools for necessary computational experiments. It is necessary to note that usage of symbolic algebra tools give us additionally the necessary flexibility and effectiveness of the computational process.

The process of ordering and accumulation of used knowledge, decomposition of complex systems into a set of simple subsystems (real and/or virtual) must guarantee good maintainability, reasonability, and extensibility of designed codes for numerical modeling. On this step a researcher forms his understanding of practical problems under study. Complexity of modern problems have to lead to necessity of using of databases and knowledge bases ideology and corresponding tools. On this phase of modeling it is necessary to pay attention to classification and

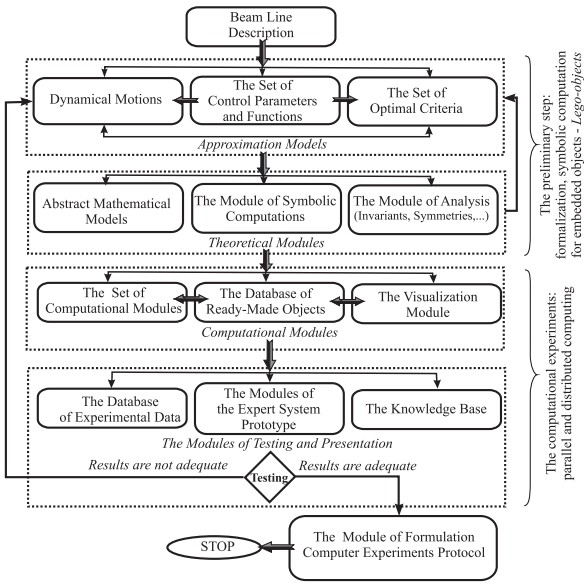

Figure 1: The total cycle of the computational experiment.

systematization of used knowledge about the problem under study (in term of LEGO-objects this means an in-depth classification and structuring). Similar approach may be suggested on the phase of mathematical models forming too. Moreover, the deep mathematical formalization helps researchers to create adequate mathematical models easily than it is done on the previous phases. Naturally effectiveness of computer algebra methods and codes usage depends on selected mathematical methods and tools. These methods must admit a deep hierarchy of LEGO-objects. These objects have their own characteristics needed for sewing together in a whole physical element.

All elementary blocks have their representatives on all phases of modeling process: from physical up to computing models. Including and exclusion either elementary block must be realized quietly, without distortion of the whole model. This approach is realized using dynamic modeling paradigm [8]. It should be note that the visualization procedures must be included to the computing model as its integral part. Indeed the results of visualization process help us understand dynamical processes occurred in either situation. Here it is necessary to tell some words about optimization procedure particularly. Usage of symbolic representation for problems under study can realize the corresponding optimization process more effectively (see, for example, [2]). As the conclusion it is necessary to note that realization of discussed approach allows to carry out the analysis in a special virtual laboratory – Virtual Accelerator, that is not only favorable from the economic point of view, but also allows us to investigate many effects more detail and carefully, usually this is unacceptable to only natural experiments.

CONCLUSION

The above described approach can be realized using two mathematical and computational frameworks. The first is enough traditional for the most published Virtual Accelerator concept: a combination well known and approved beam line packages and EPICS instruments. The second is based on the first approach (based on numerical modeling first of all) and more extended application of symbolic computational procedures. In our case we use the matrix formalism for Lie algebraic tools [9]. This approach gives the designer more effective and extensible toolbox. The most of modules presented on the Fig. 1 were realized using this formalism and were applied for different problems of beam physics (see, for example, [1, 10, 11]).

EUROPEAN XFEL PHASE SHIFTER: PC-BASED CONTROL SYSTEM

E. Molina Marinas*, J.M. Cela-Ruiz, J. de la Gama, A. Guirao, L.M. Martinez Fresno, I. Moya, A.L. Pardillo, S. Sanz, C. Vazquez, CIEMAT, Madrid, Spain

Abstract

The Accelerator Technology Unit at CIEMAT is in charge of part of the Spanish contribution to the European X-Ray Free-Electron Laser (EXFEL) [1]. This paper presents the control system of the Phase Shifter (PS), a beam phase corrector magnet that will be installed in the intersections of the SASE undulator system. Beckhoff has been chosen by EXFEL as its main supplier for the industrial control systems. Beckhoff Twincat PLC architecture is a PC-based control technology built over EtherCAT, a real-time Ethernet fieldbus. The PS is operated with a stepper motor, its position is monitored by an incremental encoder, and it is controlled by a Twincat-PLC program using the TcMC2 library, an implementation of the PLCopen Motion Control specification. A GUI has been developed in LabVIEW instead of using Beckhoff visualization tool. The control system for the first and second prototype devices has been developed in-house using COTS hardware and software. The specifications request a repeatability of ($\pm 50\mu$m) in bidirectional movements and ($\pm 10\mu$m) in unidirectional movements. The second prototype can reach speeds up to 15 mm/s.

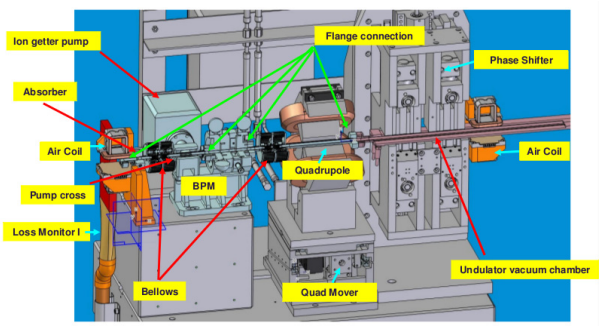

Figure 1: EXFEL Undulator System intersection.

INTRODUCTION

The undulator systems of the European XFEL have a total approximate length of 200 m. They are divided into cells which comprise a 5m long undulator segment and a 1.1 m long intersection, Fig. 1, where several devices needed to adjust the beam properties are located [2]. 92 sets of components for the intersections will be supplied by CIEMAT, as part of the spanish in-kind contribution to the European XFEL. The control system is also a part of this contribution.

* eduardo.molina@ciemat.es

One of the components of the intersection is the Quadrupole Mover (MV) [3], a biaxial (X-Z) moving table that aligns a 70 kg quadrupole magnet within ± 1.5mm in two dimensions with repeatability better than $\pm 1\mu$m. Two 5-phase stepper motors move the table in the horizontal and vertical directions. Positions are monitored with two LVDTs.

Another device is the Phase Shifter [4], see Fig. 2. Its function is to correct the phase of the electron beam with respect to that of the radiation field when the wavelength is changed. This is achieved by opening or closing the gap between two sets of magnetic modules geared by a double left-right hand threaded lead screw, which, in turn, is actuated by a stepper motor fitted with a 40:1 gearbox [5].

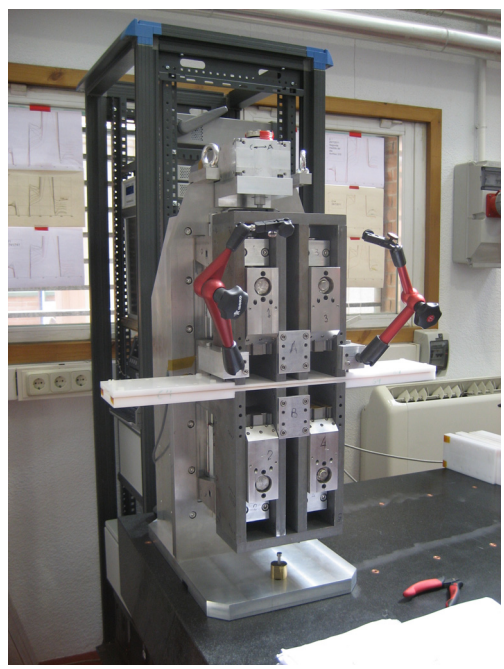

Figure 2: Phase Shifter.

The Intersection Control Rack (ICR) will house an EtherCAT bus coupler plus all the modules needed for operation of the PS and the Quadrupole Mover. Electrical protection modules and low-noise power supplies are to be mounted in order to improve its long term reliability. The bus coupler links the ICR to the Undulator Rack, where an embedded PC will control the corresponding undulator cell.

For protoype testing (MV, PS), dedicated control cabinets have been assembled with the required Beckhoff control modules (bus coupler and I/Os), along with motor drivers, power supplies and signal conditioning units. The

PLC control unit, for development purposes, is always a standard PC running Beckhoff Twincat PLC under Windows, with an extra Ethernet PCI card connected with a standard cat-5 cable to the EtherCAT bus coupler in the cabinet. To expand the possibilities of the native Beckhoff SCADA interface, a GUI has been written in LabView to operate the PS from the PC. This is part of CIEMAT's effort to produce a software which can be used for both testing and validation of the prototypes and the production batch.

In this paper, the components of the PS control system are presented in detail.

PHASE SHIFTER CONTROL SYSTEM

PC-based Automation

Many flavours of PC-based automation solutions are being offered nowadays by all major control technology companies. Due to increasing performance and decreasing cost of hardware components, embedded PCs equipped with flash memory cards or solid-state drives can be used in an industrial environment replacing the traditional PLCs.

Following hardware progression, many software packages populate the market, turning any PC into a real-time controller, and thus allowing programming, diagnostics and configuration of devices connected either to the PC directly or through fieldbus cards, while ensuring deterministic real-time behavior. There is also a growing presence in the automation industry of real-time communication protocols based on Ethernet which are gaining market share to traditional field buses due to the already important existing base of ethernet cabling. We have used one of these protocols, EtherCAT, released by Beckhoff in 2003 [6], which is, according to manufacturers, able to exchange many distributed signals with cycle times below 100 μs [7].

Control Hardware

The hardware modules have been selected according to the demands imposed by the design specifications When the gap aperture is under 20 mm, the magnetic forces are very strong. Therefore special care has been taken in the selection of the motor drive to supply the needed torque when operating in microstepping operation at the target speed.

Summarising, the main hardware components of the PS and its control system include:

- A 5-phase Oriental Motor stepper motor (RK 564 AMCE) and its driver (RKD514LM-C).
- A Renishaw optical encoder (RGH22D) with 1 μm resolution and homing mark.
- Beckhoff PLC modules, (see Fig. 3) , listed in Table 1.
- 2 Limit switches, Saia T85 5E4

The first PS prototype used a 2-phase stepper motor and was controlled directly with a Beckhoff module without motor driver. Such philosophy was later abandoned due to excessive mechanical noise and motor vibration. After extensive testing, the EL7041 stepping motor controller

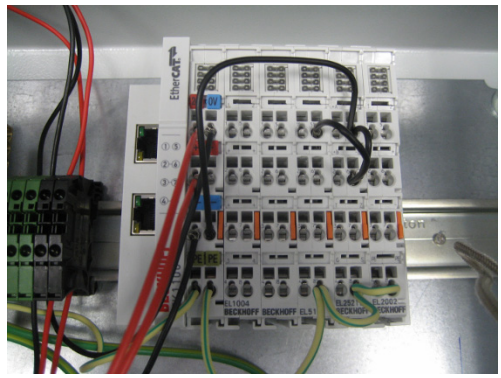

Figure 3: PS control modules before wiring.

Table 1: Beckhoff Modules Used

Module	Description
EK1100	EtherCAT coupler
EL1004	Digital inputs for limit switches
EL5101	Incremental encoder module
EL2521	Pulse train output for motor control
EL2002	Digital outputs for motor brake
EL3204	Terminal for temperature readings (PT100)

module was found to be responsible for this behaviour. A new release of this module, with an upgraded firmware and hardware, was tested afterwards with the same motor and the results were much better but still inferior to the option of equipping the PS with a motor and driver from the same manufacturer and using a Beckhoff pulse train digital output module to control the driver, a solution which gives a better performance and, subsequently, was adopted for the second PS prototype.

Software

The PS prototypes are controlled by a PC running Beckhoff Twincat PLC, that acts like a virtual machine running the PLC program. This program, developed at CIEMAT, has been coded in Structured Text following the IEC 61131-3 standard. Twincat PLC can run up to four PLC runtimes in a PC, and, specifically for motion control, Twincat PLC NC offers the TcMC2 library which is compliant with the PLCopen Motion Control standard [8]. CNC axes are referenced by the derived datatype AXIS_REF. Several function blocks (FB) are available for single or multiple axis control and reading their status variables.

As other projects were being developed at CIEMAT for EXFEL using stepper motors, it was decided to create a Twincat PLC library, MotorCommon.lib, to implement all these subsystems. This library uses a mix of basic function blocks available in the TcMC2 library and in-house developed functions better suited to the project needs. Any drive configured as an axis in Twincat PLC NC can be defined

as an instance of the *MotorControlWTimedBrakeAutoPow* function block. A wrapper (i.e. MoverMotor or PhaseShifterMotor) adapts the FB to any motor characteristics. For example, the PS stepper motor comes equipped with an electromagnetic brake and the motor windings can be activated or deactivated following an on/off signal. Due to the incremental nature of the position feedback, the PS wrapper defines also a homing procedure that has to be carried out when the device is started up or after an error. Every motor operational parameter, such as brake delay time, deadband position, backslash compensation, timeout and maximum operating temperature can also be configured.

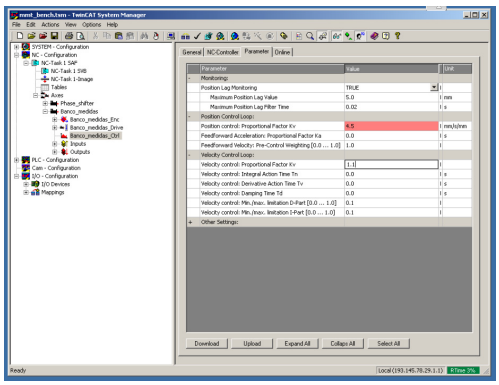

Figure 4: Axis configuration in Twincat System Manager.

The Twincat System Manager (see Fig. 4) is the configuration tool for the EtherCAT system, the PLC program, the I/O modules and the mechanical axes. A motor, or more generically a drive, can be defined as a Computer Numerical Control (CNC) axis and then linked to the corresponding modules. An axis has two basic elements, plus a third one: i) the actuator or drive, ii) the encoder or feedback, and iii) the controller or control policy. For instance, the PS axis is linked to both a pulse train output card (EL2521) and an incremental encoder card (EL5101). The controller can also be chosen and configured. The PS uses a position P control plus velocity PID with torque. The parameters for this controller have been manually tuned.

Although Twincat PLC comes with its own visualization tool, a classical SCADA GUI package, LabVIEW GUIs (see Fig. 5) have been developed in-house to take advantage of LabVIEW flexibility. The communication between LabVIEW and Twincat PLC has been achieved by using the Beckhoff TcADSdll.Dll library, which organises data exchange between Windows programs and Twincat. On top of that, a series of functions have been created to control the PLC from our GUI: start or stop the PLC, read variables and send data and commands. However this communication is asynchronous to the PLC cycle, forcing the Labview programm to constantly interrogate the TwinCAT server for changes in the status of signals. This could be a drawback for operation but does not pose any problem for testing and measurement. The validation of the series production will also be done automatically by a LabVIEW

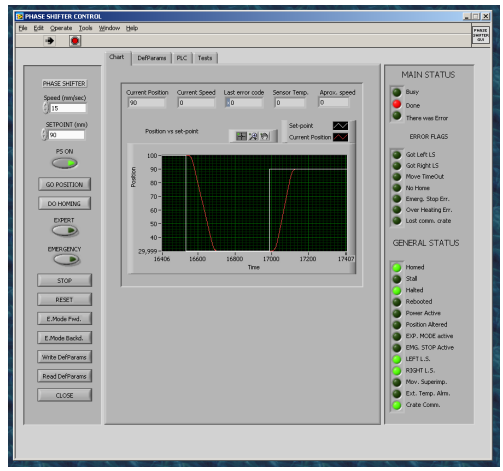

Figure 5: PS control LabVIEW GUI.

program, its development is under way.

RESULTS

The magnetic and mechanical measurements of the two prototypes have been reported in [9]. The first prototype achieved a repeatability of ($\pm 57\mu$m) in bidirectional movements, slightly over the limit, due to some mechanical problems that were corrected in the second prototype.

Some requirements have evolved over time, such as the gap opening speed. The latest request is that the PS shall follow the undulator, at speeds over 10 mm/s. Speeds up to 15 mm/s have been achieved with the second prototype. Preliminary measurements of this prototype, (see Fig. 6) show that positioning errors are within limits.

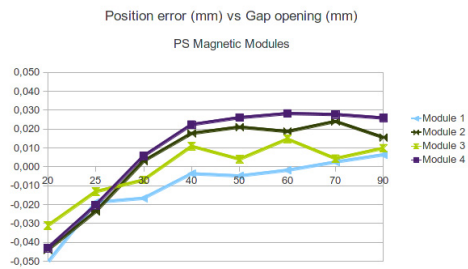

Figure 6: 2nd PS prototype preliminary measurements.

MAGNETIC MEASUREMENTS TEST BENCH

The Magnetic Measurements Test Bench (MMTB) (see Fig. 7) has been developed at CIEMAT as a tool to calibrate and measure the magnetic field of the Phase Shifter, in order to validate the magnetic design of the PS [10]. A linear actuator controlled by a dedicated Beckhoff module

moves a coil inside the PS gap. This coil is connected to a fluxmeter which integrates the magnetic flux, that is then read by a 24-bit ADC module to construct the $\overrightarrow{B}$ field integral after post-processing. The PLC controls both axes (PS and MMTB) and records position, speed and magnetic field values for further analysis. The position is monitored by an incremental rotational encoder. Its control software been written using the same libraries (PLC and LabVIEW) than the PS. Special care has been taken to synchronize the values that are written to a file by the PLC. Initially, after data analysis, a delay of a few milliseconds was found, dependent of the speed, so that in the Field Integral versus Position graph, the "in" cycle (when the coil is moved inside the PS) and the "out" cycle did not match. This is probably caused by the way the PLC works, as it reads the variables first and produces the timestamp at the moment of writing to the file.

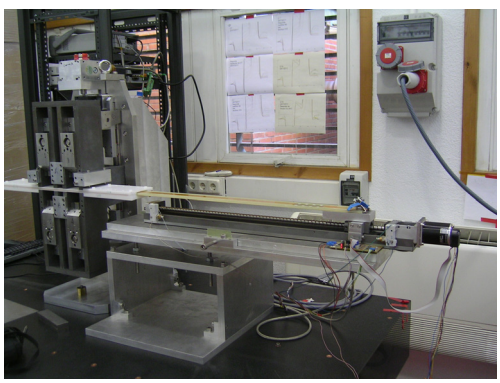

Figure 7: Phase Shifter and MMTB.

CONCLUSIONS

The Accelerator Technology Unit at CIEMAT is in charge of the design, manufacturing and delivery of several components to be installed in the 92 intersections of the Undulators System of the European XFEL, in particular, the Phase Shifter, the Quadrupole Mover and the Intersection Control Rack. All the control hardware has been implemented using commercial devices. In addition we have written a Beckhoff Twincat PLC library to encapsulate all devices as CNC axes within the Beckhoff architecture. GUIs have been created, based on an in-house developed LabVIEW library, able to communicate with the PLC runtime. As soon as the different prototypes have been available for testing in our labs, the integration of the control system has been quickly achieved. A fully automatic measurement procedure have been implemented. The first prototype achieved a repeatability of ($\pm 57 \mu$m), over the limit. The second prototype is now being tuned and the preliminary measurements have been satisfactory.

ACKNOWLEDGEMENTS

This work is supported by the CIEMAT and the Spanish Ministry of Science and Innovation under SEI Resolution of September 17th, 2009. The authors would like to express their gratitude to our colleagues at E-XFEL, mainly J. Pflüger and S. Karabekyan, for their encouragement and support during this project.

NSLS-II FILLING PATTERN MEASUREMENT*

Yong Hu#, Leo Bob Dalesio, Kiman Ha, Igor Pinayev, BNL, NSLS-II, NY 11973, U.S.A.

Abstract

Multi-bunch injection will be deployed at NSLS-II. High bandwidth diagnostic beam monitors with high-speed digitizers are used to measure bunch-by-bunch charge variation. The requirements of filling pattern measurement and layout of beam monitors are described. The evaluation results of commercial fast digitizer Agilent Acqiris and high bandwidth detector Bergoz FCT are presented.

INTRODUCTION

NSLS-II is designed to deliver photons with average spectral brightness in the 2 keV to 10 keV energy range exceeding 10^{21} ph/mm^2/mrad^2/s/0.1%BW [1]. This cutting-edge performance requires the storage ring to support a very high-current electron beam (500 mA) with sub-nm-rad horizontal emittance (~0.5 nm-rad) and diffraction-limited vertical emittance at ~8 pm-rad. To achieve this high-current (high intensity) requirement, NSLS-II will utilize a full-energy Injector which consists of a 200 MeV Linac, Linac to booster transport line (LtB), 3 GeV booster (BSR), booster to storage ring transport line (BtS). The Injector will operate in top-off mode and must supply ~ 7.3nC of charge once per minute. For single-bunch injection mode and a moderate repetition rate of a few Hz, replenishing this amount of charge would take a few seconds, occupying a significant fraction of the overall beam time. Therefore, multi-bunch injection (80~150 bunches) has been adopted, leading to minimal disturbance for user experiments.

In order to minimize intensity-correlated orbit oscillations due to uneven bunch patterns [2], we need to measure the filling pattern (also named bunch pattern or bunch structure) and then find a way to minimize bunch-to-bunch variation of current (or charge) if the variation exceeds 20%.

NSLS-II FILLING PATTERN

NSLS-II storage ring contains 1,320 RF buckets at 500 MHz. To alleviate the problems of ion trapping in the stored electron beam, approximately one-fifth of the buckets must be left empty. NSLS-II Injector will support uniform filling pattern in the storage ring. Two basic patterns were considered (two upper plots in Figure 1): uniform fill with the ion-clearing gap of about 20%; multiple uniform bunch trains with mini-gaps between them.

In addition to the nominal uniform fill, consideration is being given to specialized and complex bunch patterns: a single high-current bunch (named "camshaft" bunch, two lower plots in Figure 1) located in the middle of the ion-clearing gap; multiple camshaft bunches whose repetition rate is matched to the pulse format of modern pump lasers.

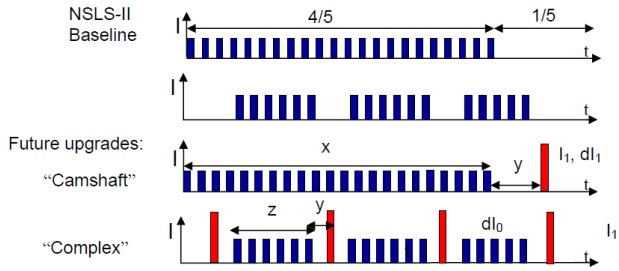

Figure 1: NSLS-II Filling Pattern [1]

One requirement [3] for NSLS-II filling pattern is that bunch-to-bunch charge variation should be less than 20%.

Filling pattern involves timing, diagnostics, injection / extraction, controls, etc. It will take efforts to implement arbitrary patterns for multi-bunch injection via filling pattern feedback. This paper focuses on filling pattern measurements: how to measure bunch structure and make this information available in EPICS [4]-based control system.

BEAM MONITORS

NSLS-II filling pattern measurement system provides relative bunch-to-bunch charge distribution along with the whole machine. This measurement requires combination of beam monitors (WCM, FCT, etc.), data acquisition (DAQ) and controls (fast digitizer, EPICS software, etc.) and Event Timing system [5]. Figure 2 shows the system architecture.

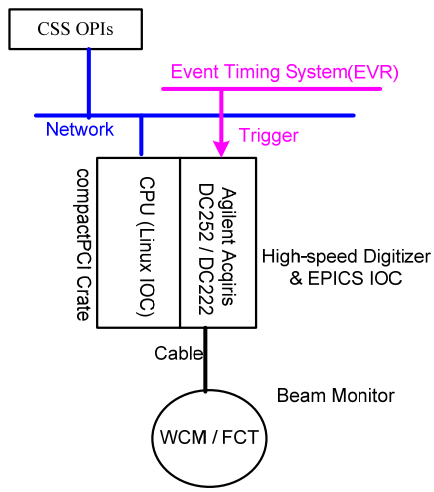

Figure 2: Overview of Filling Pattern Measurement

Since NSLS-II RF (Radio Frequency) is ~500 MHz, the bandwidth of beam monitors should be at least 500 MHz in order to distinguish individual bunch from the bunch-train (multi-bunch, 80~150 bunches). There will be 3 types of beam monitors distributed around the machine and all of them have very high bandwidth (>1 GHz): 5

* Work performed under auspices of the U.S. Department of Energy
# yhu@bnl.gov

wall current monitors (WCM) in Linac, 2 Bergoz FCTs (fast current transformer) in LtB, 1 FCT in BSR, 2 FCTs in BtS and 1 BPM (beam position monitor) button in Storage Ring.

Wall Current Monitor

The Linac diagnostics consist of five resistive WCMs to observe the longitudinal profile/bunch shape of the electron bunches after the gun, pre-buncher, and buncher. The WCM is formed by equally spaced broadband ceramic resistors mounted on a flexible circuit board, wrapped around a short ceramic break. The WCM has very high analog bandwidth at ~3GHz.

Fast Current Transformer

Commercial off-the-shelf Bergoz FCT, usually directly mounted on the beam chamber with a ceramic break and RF shielding, will provide electrical signal proportional to the charge of individual bunches. Its specification claims 1.75 GHz bandwidth with a 200 ps rise time. But our real measurements show only ~1 GHz BW which is still sufficient to get 500 MHz bunch-to-bunch information.

Beam Position Monitor

All BPMs in NSLS-II will utilize high precision 4-button pickup electrodes that are diagonally incorporated into the aluminium extrusion vacuum chamber. The diameter of BPM in the storage ring is only 7mm so that this kind of BPM has wide analog bandwidth (~ 2GHz) while minimum impact on the Ring impedance. The circulating current of 500 mA in the storage ring is expected to produce -1.1dBm signal into 50 Ω load at 500 MHz on BPM button. This signal is strong enough for filling pattern measurement.

CONTROLS

High-bandwidth filling pattern monitor requires high-speed digitizer to sample its analog output signal. According to the Nyquist sampling theorem, the minimum sampling rate of the digitizer required to discriminate 500 MHz bunch-to-bunch information is 1GS/s.

Hardware

Agilent U1065A Acqiris high-speed compactPCI digitizers (DC252 and DC222, 10-bit resolution, 2 GHz bandwidth, DC252 is 2-channel, 4 GS/s per channel, DC222 is 1-ch with 8GS/s) are selected for NSLS-II filling pattern measurement. Beam monitors associated with controls hardware in each sub-accelerator are listed in Table 1.

The cable length from the beam monitors to the digitizers is more than 100 feet. To reduce signal loss and attenuation, low loss RF cable LMR900 will be used. Although NSLS-II bunch length itself is very short at ~ 15 ps (RMS), the actual output signal from filling pattern monitor is Gaussian-shape pulse with ~ 1 ns width. In this case, 4 GS/s digitizer DC252 will provide at least 4 samples per bunch which should be sufficient to calculate individual bunch charge with appropriate algorithms such as Gaussian data-fitting and integrating samples' voltages.

Table 1: Filling Pattern Monitors & DAQ Hardware

Sub-accelerator	Beam Monitor	Digitizer
Linac	6 WCMs	3 DC252
LtB	2 FCTs	1 DC252
Booster	1 FCTs	1 DC222
BtS	2 FCTs	1 DC252
Ring	1 BPM	1 DC222

Software

NSLS-II beam diagnostics control system [6] will be completely based on EPICS. For OPI (operator interface) GUIs, CSS (Control System Studio) is our preference. The preferred operating systems are RTEMS (Real-Time Executive for Multiprocessor Systems) and Linux/Debian. For cPCI-based controls, the CPU board will be standardized as GE CT11 and diskless PXE booting Linux & EPICS driver is done by Debirf (DEBian on Initial Ram Filesystem [7]).

The EPICS driver for Acqiris digitizer is originally developed at SLAC. Several improvements are made at NSLS-II, including a few bug fixes and filling pattern related data processing.

Here's the basic implementation of our filling pattern measurement: the filling pattern EPICS IOCs will provide the following data: number of bunches (max. 150), normalized filling pattern (array data like filling[150]: 0.85, 1.00, 0.96, …), maximum bunch-to-bunch variation (i.e. $\Delta Q = 5\%$), individual bunch charge calibrated against ICT or DCCT or computed from integral voltage signal. If measured $\Delta Q < 20\%$, our job is done; If $\Delta Q >= 20\%$, we need to find out what's the cause and find a way to minimize ΔQ.

Here's our procedure to compute normalized filling pattern inside EPICS IOC software:

1) Search for positive (or negative)pulse peaks with peak threshold;
2) Gaussian-fitting on 5 samples (2 samples before the peak, 2 after the peak) and then integrate(sum) them;
3) Find the max. integrating value;
4) Normalize all integrating values against the max.

BENCH TESTS

We have performed bench tests on Bergoz FCT and Acqiris digitizer.

Bench Tests on FCT

We have purchased 5 Bergoz FCTs and performed acceptance tests. We have measured FCT bandwidth using network analyzer. Figure 3 shows that one of the FCTs has ~ 1GHz BW (-3dB).

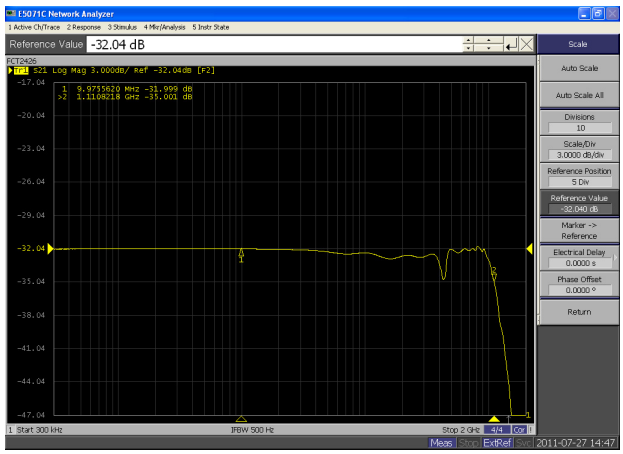

Figure 3: FCT Bandwidth Measurement

Bench Tests on Acqiris

We have completed performance evaluation on the ultra fast digitizer Acqiris DC252, including max. sampling rate at 8 GS/s by combining 2 channels to 1 channel (interleaving), effective number of bit (ENOB), etc. The input test signal is 500MHz sine wave, 0.9Vpp.

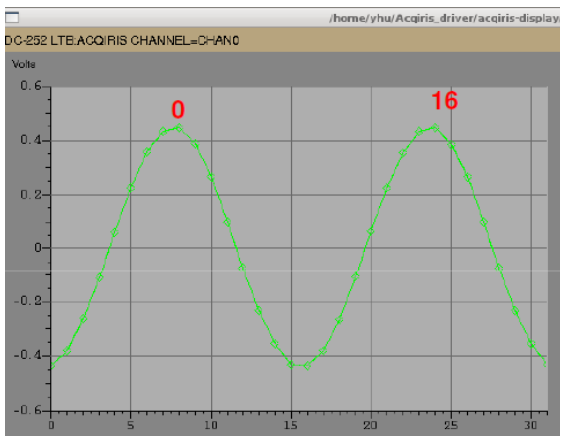

Figure 4: 8GS/s acqiris Digitizer.

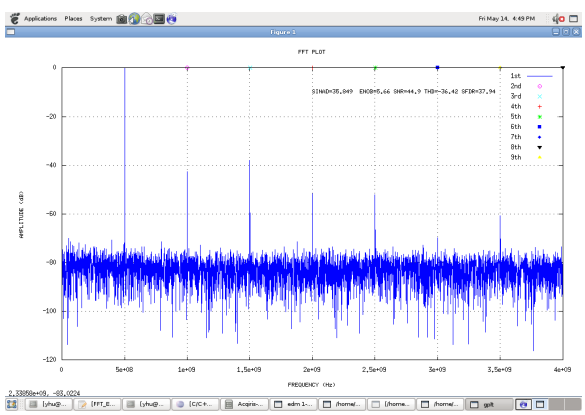

Figure 5: 7-bit ENOB after Sine-wave Data-fitting.

FILLING PATTERN SIMULATION

In order to test our algorithm software for filling pattern measurement as well as interface to Event timing system, we have setup a test stand to simulate filling pattern as shown in Figure 5.

- Timing EVG/EVR: provides 2 triggers, one is for triggering digitizer, the other for triggering pulse generator;
- pulse generator DG645: receive external trigger from EVR and then use burst mode to generate multiple pulses with 2ns width and 10MHz rate;
- FCT: input signal from DG645 and output to digitizer;
- Acqiris digitizer: triggered by EVR and acquire FCT signal;

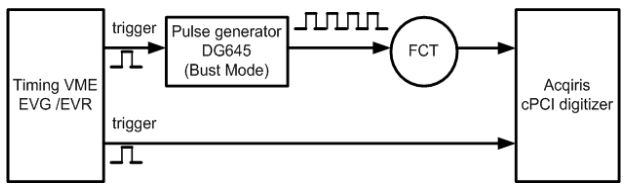

Figure 6: Filling Pattern Simulation.

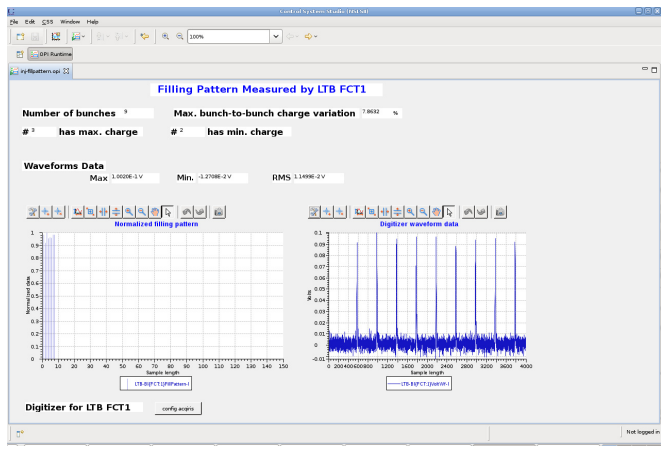

Figure 7: Filling Pattern Simulation Result.

CONCLUSIONS

Filling pattern measurement system is well understood and the controls hardware & software are well tested. We're ready for NSLS-II Injector installation and commissioning.

A NEW HELMHOLTZ COIL PERMANENT MAGNET MEASUREMENT SYSTEM*

Joseph Z. Xu and Isaac Vasserman, ANL, Argonne, IL 60439, U.S.A.

Abstract

A Helmholtz coil magnet measurement system was upgraded at the Advanced Phone Source (APS) to characterize the insertion device permanent magnets [1]. The system uses the latest state-of-the-art field programmable gate array (FPGA) technology to compensate the speed variations of the magnet motion. Initial results demonstrate that the system achieves a measurement precision better than 2×10^{-4}.

INTRODUCTION

Most insertion devices (IDs) at the APS are permanent magnet based [2]. Before the magnets are installed onto the IDs, each of them has to be characterized and sorted to ensure that the magnets in a single ID are even and as identical as they can be to minimize the integral fields and the phase errors of the device.

The APS Helmholtz coil system, designed to characterize magnets used in the APS permanent magnet IDs, has been recently upgraded. The system has improved the measurement precision by an order of magnitude. The system now consists of a pair of identical coils, a horizontal rotary table with two full ceramic spherical bearings, and a digital encoder on its main rotating shaft driven by a servo motor.

The control and data acquisition system is a PXI-based computer system. With the latest state-of-the-art field programmable gate array (FPGA) technology, the system is capable of synchronized measurements of position (0.05 degree in resolution), time (25 ns), and voltage (16 bit).

THEORY OF OPERATION

A Helmholtz coil consists of two identical circular coils placed coaxially and separated by a distance equal to the radius of the coils. When the two coils carry the same current in the same direction, it creates a near uniform magnetic field within the center region between the two coils. Therefore, a magnet placed within the center region can be treated as a magnetic dipole by a Helmholtz coil system.

Moving a magnet inside the coils causes the magnetic flux change that in turn generates a voltage signal in the coil:

$$V = -d\Phi/dt\,, \tag{1}$$

where V is the voltage, Φ is the magnetic flux, and t is time.

By rotating the magnet inside the Helmholtz coils, measuring the voltage signal in the coils, and integrating the signal over time, we have [1]

$$\Phi = -\int_{t_0}^{t_1} V(\theta.t)dt$$

$$= -\frac{1}{k} * (M_V * \sin\theta + M_H * \cos\theta) + C, \tag{2}$$

where V is the voltage signal, θ is the rotation angle, k is the Helmholtz coil constant, M_V and M_H are the vertical and horizontal components of the magnetic moment, respectively, and C is the offset constant.

$$k = \left(\frac{5}{4}\right)^{\frac{3}{2}} \frac{R}{\mu_0 N}\,, \tag{3}$$

where R is the coil radius, μ_0 is the free space permeability constant, and N is the number of turns in each coil.

Fitting the integral with a sinusoidal function of

$$A * \sin\theta + B * \cos\theta + C \tag{4}$$

we have the vertical component of the magnetic moment:

$$M_V = kA \tag{5}$$

and the horizontal component of the magnetic moment:

$$M_H = kB. \tag{6}$$

Usually magnet vendors provide the components of the intrinsic induction information.

$$B = \mu_0 m = \frac{\mu_0 M}{V}, \tag{7}$$

where m is the magnetization vector and V is the volume of the magnet. Hence the components of the intrinsic induction are

$$B_{V,H} = \mu_0 m_{V,H} = \frac{\mu_0 M_{V,H}}{V}. \tag{8}$$

SYSTEM DESCRIPTION

The Helmholtz coil magnet measurement system consists of the subsystems shown in Figure 1.

A set of Helmholtz coils that consists of a pair of identical coils are made of copper material and the support structure is of G-10. The mean diameter of the coils is 26 inches. The coils are mounted coaxially, separated by a distance of 13 inches. Each coil has 392 turns.

A horizontal rotary stage holds the magnet in the center region of the coils. The aluminum stage shaft is supported by two full ceramic spherical bearings. A magnet mounting stage is supported at the end of the aluminum shaft. The mounting stage is centered between the two coils. The stage is motorized, driven by a servo motor that coupled to the other end of the stage via a 10:1 rotary inline gearbox. A hollow-shaft rotary encoder is

* Work at Argonne was supported by the U. S. Department of Energy, Office of Science, Office of Basic Energy Sciences under Contract No DE-AC02-06CH11357.

Figure 1: Helmholtz coil magnet measurement system.

mounted inline on the stage shaft. The encoder has 360 degrees freedom with 0.05-degree resolution. The rotary encoder is used to accurately define the angular position of the magnet mounted on the rotary stage.

The FPGA reconfigurable data acquisition card has eight 16-bit-resolution analog inputs, 96 digital inputs/outputs, 25-ns time resolution, and 80-kB on-board memory. The digital I/Os are programmed to read the encoder positions. The analog inputs are configured to measure the coil signals synchronized with the position readouts and the time durations in real time.

A PXI shelf with a control card hosts the FPGA card and the software program.

SYSTEM CONTROL SOFTWARE

LabVIEW-based system software has been developed to coordinate the stage control and data acquisition. Figure 2 shows the schematic layout of the system control and data acquisition architecture. The system can be accessed via the Internet from anywhere anytime, wired or wireless, through the embedded http interfaces inside LabVIEW.

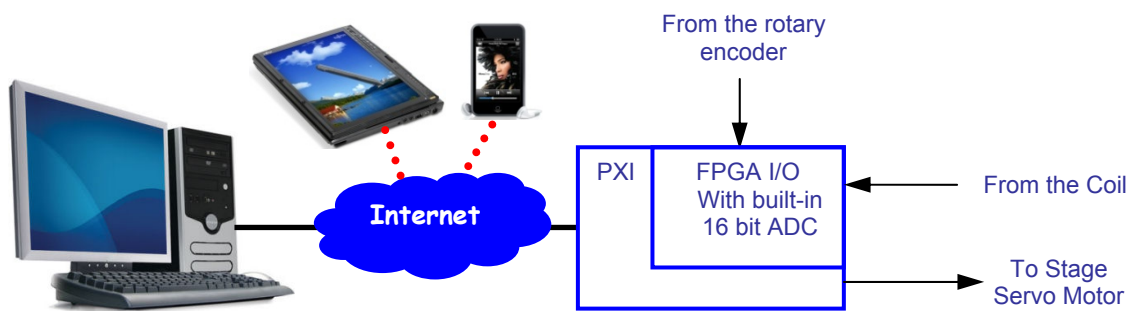

Figure 2: System control and data acquisition architecture schematic layout.

The system software has a main control and data acquisition interface and modules. The main control and data acquisition interface rotates the magnet stage and sets the FPGA hardware to wait for the magnet angular position to go to the start position. When the angular position hits the start position mark, the hardware will simultaneously write the following data to its memory on the fly:

1. The angular positions of the magnet with an angular resolution that can be set down to 0.1 degree per step.
2. The integrated Helmholtz coil voltage signals across each angular step with a rate of 4.3 μs per sample at 16-bit resolution.
3. The number of samples integrated within each angular step.
4. The time duration within each angular step.

When the magnet angular position reaches the 360 degree mark, the hardware sends an interrupt to the module. It integrates the signal, fits the integrated data with a sinusoidal function to extract the field integral components, and plots the raw data along with the fittings.

The measurement analysis and plot module reads the saved data file, analyzes the data, and plots the raw data along with the fittings and analysis results.

The advanced motion control module fine tunes the stage position and encoder readout. It has one submodule: the motor velocity and acceleration control and monitoring. The submodule sets and monitors the velocity and acceleration parameters of the servomotor.

The system parameter database module consists of three copies in a single file: the current, the backup and the default. The default copy is read-only. Each copy contains, among others, the motor velocity, acceleration and system calibration constants, encoder reference indexes, encoder resolutions, stage-gear ratio, motor-velocity ratio, motor-acceleration ratio, and motor resolutions. The system parameter database control module and its advanced system parameter database control module manipulate and manage the system parameter database.

The integral measurement FPGA firmware module resides on the FPGA reconfigurable card. It monitors the encoder position, the coil voltage, and time. It also interfaces with the measurement modules and submodules. The FPGA module executes all the tasks in parallel at the speed of 40 MHz.

The main control and data acquisition interface, each module, and submodule has its own GUI interface except for the FPGA firmware module. The main interface provides access to all the modules and the submodules. It checks the status of the FPGA reconfiguration data acquisition. If the FPGA card is not initialized or is running on different firmware, the module will download and initialize the card with the appropriate firmware. It also checks the status of the servomotor. If the motor is not initialized, it will try to reinitialize it.

SYSTEM CALIBRATION

The system calibration is the measurement of the Helmholtz coil constant k as defined in equation (3). Based on the design of R = 13 inches and N = 392, the k value shall be 0.09362 Ampere per Gauss. However, the real system k value has to be calibrated.

Hardware required for the calibration is a calibrated current power supply and a calibrated magnetometer. The DC current power supply used for calibration was a Kaithley 6221 DC current source. The magnetometer was a Bartington Instruments Mag-03 Magnetic Field Sensor. The calibration results are shown in table 1.

Table 1: Calibration Results

Field (G)	+100 mA	-100 mA
Mean value	1.081190	-1.081188
Standard deviation	0.000058	0.000032

Therefore, the k constant is 0.09249 Ampere per Gauss, which is very close to the design value of 0.09362 Ampere per Gauss.

MEASUREMENT RESULTS AND DISCUSSION

A typical magnet measurement taken with the Helmholtz coil measurement system is shown in Figure 3.

The file header field shows the basic parameters of the measurement. The rotary stage scanning speed was 2 revolutions per second. Each measurement consists of scans along the +y axis (+Mx/+Mz), +x axis (+My/+Mz), -y axis (-Mx/+Mz), and –x axis (-My/+Mz). Averaging over the components cancels the mechanical asymmetries of the system. The integral plot field shows a specific integrated raw scan along with its sinusoidal fitting. Next to the integrals field are the fitting parameters to that specific measurement. According to equations (5) and (6), the sine component represents the vertical component of the field integral while the cosine component represents the horizontal component. Below the integral field plot display are the magnetic moment components $m_{(ave)}$, the measurement errors $\sigma_{(err)}$, the moment density components $\rho_{(density)}$, the magnetic moment orientations $\theta_{(angle)}$, as well as the total moment M, and its orientation to the z axis θ_z.

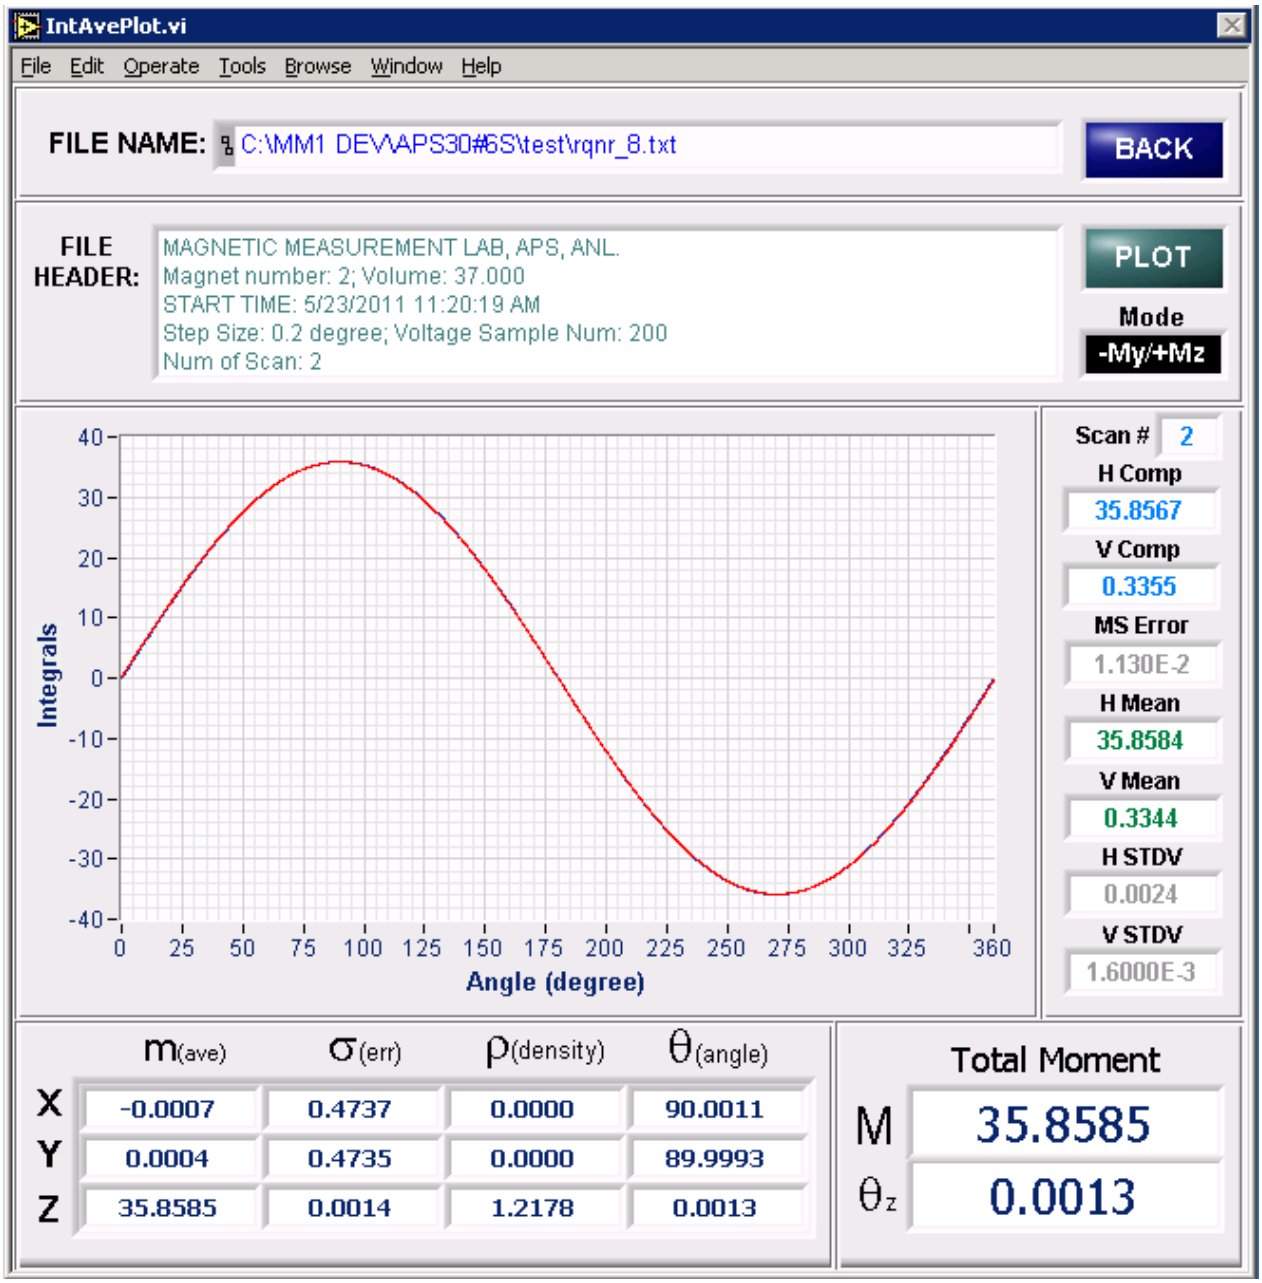

Figure 3: Magnet measurements.

CONCLUSION

A new Helmholtz coil magnet measurement system has been constructed, tested, and commissioned at the Advanced Photon Source. With the latest state-of-the-art FPGA technology, the system achieves measurement precision of 2×10^{-4}.

NSLS-II VACUUM CONTROL FOR CHAMBER ACCEPTANCE

H. Xu, L.R. Dalesio, M. Ferreira, H. Hseuh, D. T. Zigrosser, Photon Science Directorate, BNL, Upton, NY 11973, U.S.A.

Abstract

The National Synchrotron Light Source II (NSLS-II) uses extruded aluminium chambers as an integral part of the vacuum system. Prior to installation in the Storage Ring all dipole and multipole chamber assemblies must be tested to ensure vacuum integrity. A significant part of the chamber test requires a full bakeout of the assembly, as well as control and monitoring of the titanium sublimation pumps (TSP), non-evaporable getter pumps (NEG) and ion pumps. Data that will be acquired by the system during bakeouts includes system temperature, vacuum pressure, residual gas analyzer (RGA) scans, ion pump current, TSP operation and NEG activation. This data will be used as part of the acceptance process of the chambers prior to the installation in the storage ring tunnel. This paper presents the design and implementation of the vacuum bakeout control, as well as related vacuum control issues.

INTRODUCTION

The NSLS-II storage ring is made up of 30 cells and 30 straight sections. Each vacuum cell consists of five basic chambers; an upstream matching multipole chamber, a dipole chamber, a high dispersion section multipole chamber, a second dipole chamber, and a downstream matching multipole chamber. There are RF-shielded bellows connecting these chambers together. The straight sections, either 6.6 m or 9.3 m long between the cells are for insertion devices and for special sub-systems such as RF cavities, injection devices, , and so forth. [1]

Most of the NSLS-II storage vacuum chambers are made of extruded aluminium with specific cross-sections. These vacuum chambers allow in-situ bakeouts to 150˚C to help remove absorbents, such as water, and contaminants on the inner surface.

VACUUM CHAMBER BAKEOUTS

The vacuum chambers undergo at least two bakeout cycles prior to their installation in the storage ring. Once the chambers are instrumented with vacuum components such as NEG strips, small ion pump, gauging and RGA, they are prepped for the first vacuum bakeout. A turbomolecular pump backed by a dry mechanical pump is used to pump down the vacuum chamber and check for leaks using a helium leak detector. The vacuum level and residual gas composition are monitored during the bakeout using vacuum gauges and residual gas analyzer. The entire chamber will be baked at 150˚C for ~ 16 hours to remove absorbed water and other contaminants from the surfaces. At this stage most vacuum controllers are manually operated. RGA readings are logged with a local Windows computer. The NEG strip is powered and controlled by a DC power source with degassing and activation of NEG done manually.

The second vacuum bakeout occurs at the end of girder integration, after the installation and alignment of the magnets and chambers on the girder assembly, and with the integration of peripheral components, such as large ion pumps, TSP, photon absorbers, and vacuum gauges. A typical girder assembly ready for bakeout is shown in Figure 1.

Figure 1: Typical NSLS-II girder assembly

The final bakeout will be carried out in storage ring tunnel after the installation and alignment of individual chamber/magnet girders in the tunnel, the connection of the five girder chambers with RF shielded bellows and the mounting of the RF shielded gate valves at the ends of the cell. It's planned to take a similar approach to the bakeout of an entire cell in the storage ring. This paper focuses on girder bakeouts.

VACUUM GIRDER ASSEMBLY BAKEOUT

There are several variations of girder assemblies; hence the bakeout system must be flexible and adaptable to accommodate different zone configurations.

Each girder assembly is divided into several bakeout zones. The heating of the chamber itself is accomplished by the use of a rod heater inserted into a dedicated channel along the chamber length. Appendage components are heated using custom silicon heating jackets. All heating zones are controlled by a multiple zone bakeout system, a BNL design incorporating 12 or 24 Omega signal zone temperature controllers with solid state relays housed in a common chassis. Over temperature interlocks are provided to protect chamber assemblies from overheating. All temperature controllers are connected through RS-485 links. The 24 zone carts

will also be used for storage ring cell bakeout where up to 3 carts are needed for each cell.

The vacuum chamber is pumped down with a turbomolecular pump backed by a dry mechanical pump during the bakeout. The vacuum level and gas composition are monitored continuously using vacuum gauges and RGA during the bakeout. The temperature of the chamber is raised slowly by the cal-rod heater, and controlled by the programmable temperature controller with inputs from the installed type E thermocouples on the chamber surface. A ~ 2.5 hour ramp period is programmed to reach the designed temperature value. The entire vacuum chamber is then held at 150˚C for ~12 hours to remove absorbed water and other contaminants from the surfaces. The sputter ion pumps, titanium sublimation pumps, and NEG strips are degassed during the soak period.

Table 1 shows all the components and controllers used for one girder baking. The number may vary with different girder. The vacuum device controllers used for one girder are assembled in one rack.

CONTROL FOR CHAMBER BAKING

Overview

The core of the Experimental Physics and Industrial Control System (EPICS) [2] has been chosen as the basis for NSLS-II control system. Figure 2 shows the architecture of the EPICS based vacuum bakeout control system.

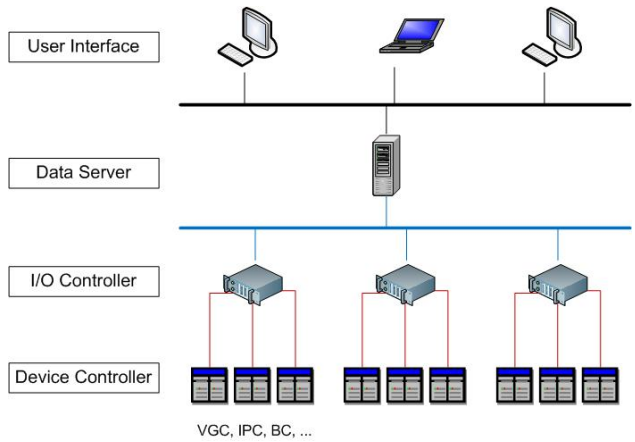

Figure 2: Control architecture for girder assembly bakeout.

Input and Output Controller (IOC)

Considering that the parameters to be monitored and controlled are much less than 1000 for girder bakeout system, we adopted soft IOC which runs on a Moxa DA-710 [3]. The Moxa works as both the IOC and terminal server. The DA-710 is based on the Intel x86 processor and runs on pre-installed Linux platform. It comes with 4 PCI slots for expansion modules and supports up to 32 serial ports.

Operator Interface

All of the monitor and control panels are created with software tools in Control System Studio (CSS) [4], which is an Eclipse-based collection of tools to monitor and operate large scale control systems.

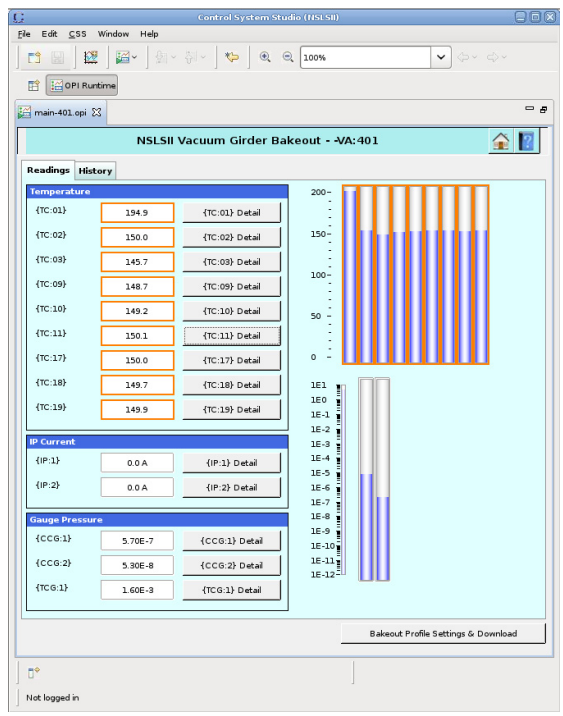

Figure 3: Main display screen for temperature readings and pressure readings.

A user-friendly interface was developed based on working experience with vacuum operators and engineers. The interface allows the operators to edit the desired ramp/soak profiles and provides the option to use predefined recipes. All zone temperatures, and gauge pressure readings are shown on main display panel as shown in Figure 3. Currently only local controls to the vacuum components are required. For future tunnel bakeout, remote controls will be required and provided.

Data Logging

Channel Archiver is used to log all temperatures, ion pump current, and gauge pressure readings. A low-cost Acer Aspire Revo series PC is used as the data server. This PC also works as the gateway between campus computers and I/O controllers due to network security issues. Users on the campus network are required to log onto the gateway computer to gain access to the girder bakeout system.

Data browser provides an easy way to review and analyze logged data. Figure 4 shows the historical view of the temperature readings.

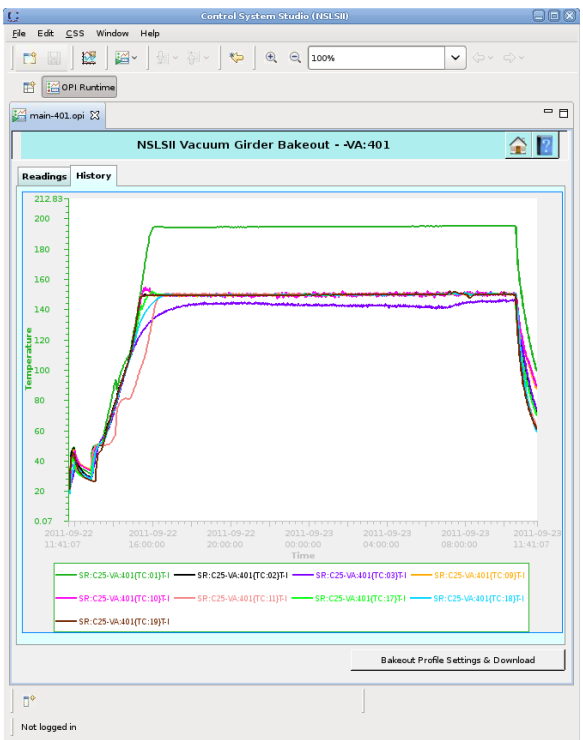

Figure 4: Historical data with data browser.

Interlock

It is necessary to have vacuum interlocks to protect vacuum assemblies from over pressure. The interlock is provided by a MKS 937B gauge controller. A Cold Cathode and Pirani gauge pair provides an adjustable setpoint that is hardwired to each of the vacuum controllers including the ion pump controller, tsp, bakeout cart and NEG controllers. The setpoint status can be monitored via the serial communication port of the gauge controller.

SUMMARY

To date, 4 fully assembled girder chambers have been processed and successfully baked. The girder bakeout control system has worked well. We're still learning from the girder bakeout and intend on improving system performance.

A PROGRAMMABLE LOGIC CONTROLLER-BASED SYSTEM FOR THE RECIRCULATION OF LIQUID C_6F_{14} IN THE ALICE HIGH MOMENTUM PARTICLE IDENTIFICATION DETECTOR AT THE LARGE HADRON COLLIDER

I. Sgura *, G. De Cataldo, A. Franco, C. Pastore, G.Volpe,
INFN sez. Bari and Dep. of Physics Via G. Amendola 173, 70126 Bari Italy

Abstract

The aim of this paper is to present the design and the implementation of the Control System (CS) for the recirculation of liquid Perfluorohexane (C_6F_{14}) for the ALICE High Momentum Particle IDentification detector (HMPID).

The HMPID is a detector of the ALICE experiment at the CERN Large Hadron Collider (LHC). It uses liquid C_6F_{14} as Cherenkov *radiator* medium in twenty-one quartz vessels for the measurement of the charged particles velocity.

The primary task of the Liquid Circulation System (LCS) is to ensure the highest transparency of C_6F_{14} to the ultraviolet light. In order to provide safe long term operation a Programmable Logic Controller-based CS has been implemented.

CS provides both automatic and manual operating modes, remotely or locally. Its finite state machine design minimizes the possible operator errors and provides a hierarchical control structure allowing the operation and monitoring down to a single *radiator* vessel. LCS is protected against unsafe working conditions by both active and passive measures. The passive ones are intrinsically guaranteed whereas the active ones are ensured via the control software running in the PLC. The human interface and data archiving are provided via PVSS, the Supervisory Control And Data Acquisition (SCADA) framework which integrates the full detector control.

LCS under CS control proved to meet all designed requirements thus enabling HMPID detector to successfully collect data since the very beginning of LHC operation.

INTRODUCTION

The ALICE-High Momentum Particle IDentification detector (HMPID) is a proximity focusing Ring Imaging CHerenkov (RICH), for the identification of charged pions and kaons in the range of $1 < pt < 3$ GeV/c and protons in the range $2 < pt < 5$GeV/c [1]. It consists of seven identical RICH modules exploiting large area CsI photocathodes for Cherenkov light imaging [2]. HMPID uses liquid C_6F_{14} as Cherenkov *radiator* medium in the twenty-one quartz vessels coupled to Multi-Wire Chambers (MWPC) equipped with pad segmented CsI photo cathodes.

LCS [3,4] is a closed, pressure-regulated apparatus which purifies, fills, re-circulates and empties the *radiator* vessels (Fig. 1). The Intrinsically safe working conditions are ensured by a gravity flow circuit preventing any accidental over-pressure.

Due to LCS complexity and its inaccessible location during the LHC operation, its safe long term operation is ensured then by a dedicated Control System (CS). This latter is integrated in the HMPID Detector Control System (DCS) [5, 6].

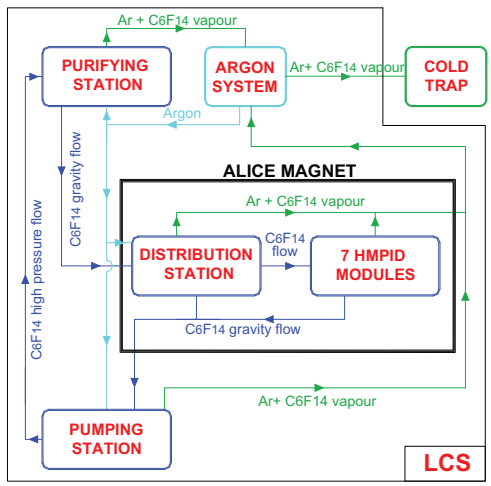

Figure 1: Block diagram of LCS: it consists of distinct stations interconnected and located in ALICE experimental area. The liquid is continuously pumped from the pumping station to the purifying station from where the liquid flows by gravity into the distribution station. This latter controls the flow rate in the *radiator* vessels from which the liquid returns in the pumping station where the cycle restarts.

THE C_6F_{14} CONTROL SYSTEM

Since 2003 C_6F_{14} CS has been conceived and implemented to fulfil the following requirements:

- to be highly reliable and scalable, as well as simple and robust;
- to be coherent and homogeneous with all detector control sub-systems;
- to be operable permanently and independently of the state of the other HMPID subsystems;
- to be able to take immediate actions for protecting all sensitive system components.

*corresponding author: irene.sgura@ba.infn.it

To fulfil these requirements a control system based on Siemens S7-300 Programmable Logic Controller (PLC) has been then chosen.

Architecture

According to the industrial automation standards ANSI/ISA 95, in C_6F_{14} CS architecture can be recognised three hierarchical levels: field level, control level and supervisory level (Figure 2).

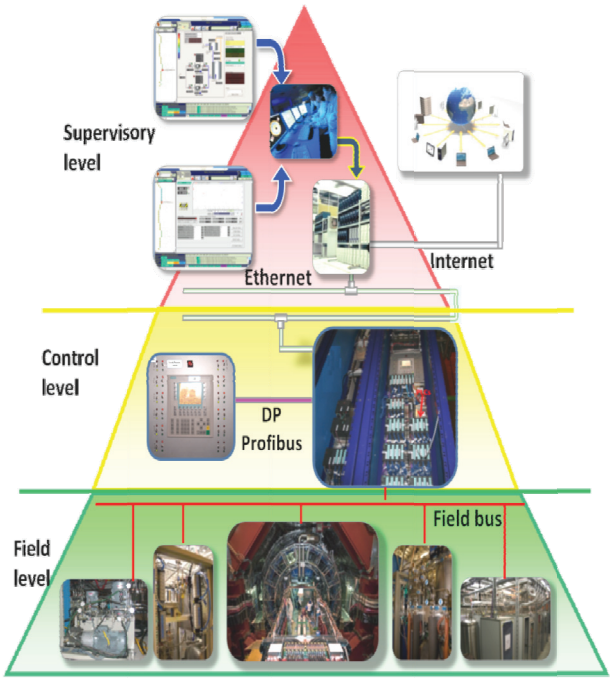

Figure 2: C_6F_{14} CS hardware architecture.

LCS represents the first level with all used sensors and actuators that work with industrial standard current and voltage ranges.

Control Level

The control level is the core where the control software processes run. It controls the underlying sensors/actuators by receiving and sending information through field buses.

Its design has been oriented towards the definition of elementary units (RICH $_{ith}$ 1< i <7, purifying and pumping stations) which can be controlled and monitored singularly in LCS. Figure 3 shows a schematic of the Rich unit which corresponds to one HMPID module.

The hardware of the control level consists of a network of Siemens S7-300 PLCs, one per control unit, reflecting the traditional Master-Slave requirements. They are interconnected using the PROFIBUS DP [7] communication protocol.

The Master PLC acts as gateway between the supervisory and control level (Figure 4).

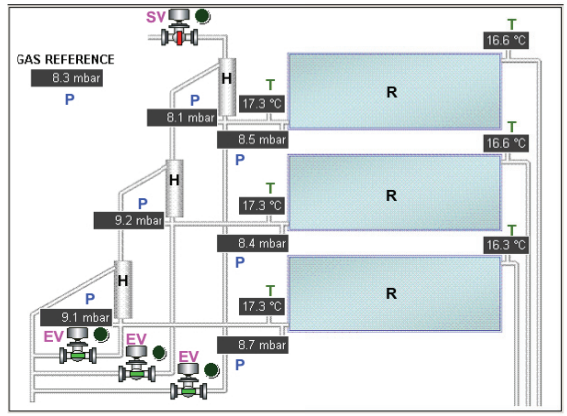

Figure 3: RICH$_i$ elementary unit: it consists of the i.th HMPID module's three *Radiator* vessels (R), the Header tubes (H) for supplying the matching *radiators*, the Pressure transducers (P), the Temperature sensors (T), the Supply and Emptying Valves (SV/EV) needed for module's operations.

This hardware architecture ensures:

- insulation of the control structure by the gateway to the external environment;
- remote implementation of the system's semantic verification procedure. Even if the operator commands are correct, the gateway verifies their compatibility with LCS state;
- local access via PROFIBUS DP by the Panel Operator LP (Figure 4), located in an accessible area during LHC operations. LCS can continue to work even if the supervisory level does not work. Both the local and remote control can be blocked by an hardware switch on LP, still ensuring monitoring.

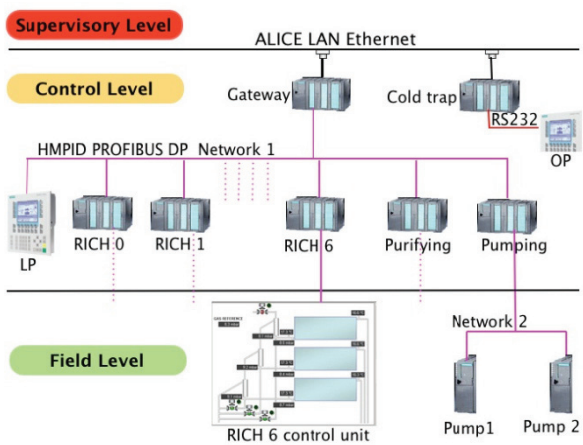

Figure 4: Hardware architecture of the control level.

The control system was developed in the environment Siemens STEP 7 [8] through the software tool Simatic Manager.

FSM Modelling

In order to automate LCS operation, the behaviour of each elementary unit has been modelled as a Finite State Machine (FSM), using Simatic S7 Graph language [9].

The unit behaves according to a state diagram and can move between defined states by means of executing actions. These actions are triggered either by the operator or by other events such as state changes of defined control-process.

According to the Cern JCOP prescriptions [10] three increasing severity alarm levels have been identified: WARNING, ERROR and FATAL.

Both the WARNING and ERROR allow the system to continue the normal operation. The FATAL level alarm is active when harmful conditions happen. In this case the CS has been designed to react automatically preventing permanent damages. In order to provide some flexibility during the commissioning phase, the automatic and manual operational modes are defined. In MANUAL state, the operator can directly check all the actuators, under its own responsibility, while the safety checks are always active.

In Figure 5 the state diagram of the RICH$_i$ FSM is shown.

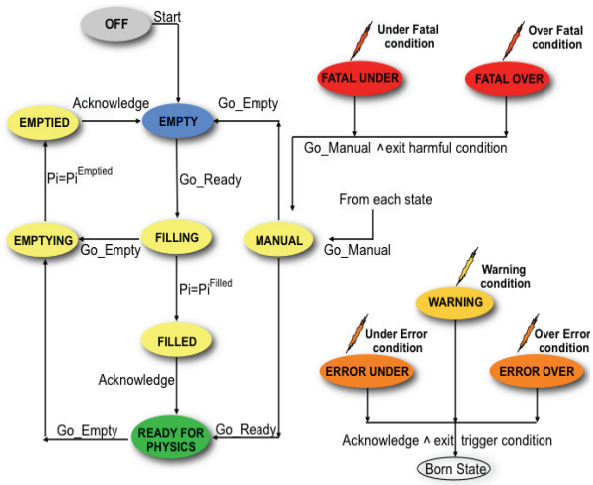

Figure 5: State diagram of the RICH$_i$ FSM. In "Ready for Physics" the *radiator* vessels are filled, the recirculation is active. A "FATAL OVER" condition rises when *radiator* vessel's pressure reaches 140 mbar. The control program reacts involving the entire module, closing the supply valve and opening the emptying valves. As the harmful condition has been recovered the Go_Manual command can be issued.

For each elementary unit, the FSM communicates to the field devices through a software interface implemented in Instruction List language (IEC 61131-3 standard). This latter reads the raw values from the sensors, it verifies the correct operation and converts the acquired data in engineering appropriate values according to the specific calibration curve. Furthermore, this interface receives the actions from the FSM block and converts them into the appropriate state value of the actuators. This approach guarantees the insulation of the FSM to the physical characteristics of the field devices and it eases the maintenance operations.

Supervisory Level

The supervisory level is the CS upper level. It supervises, via ALICE LAN Ethernet, the control process through a PVSS II as Supervisory Control And Data Acquisition (SCADA) system [11]. This level enables the interfacing and the integration in HMPID DCS. It provides the human-machine interfaces, alarm message handling and allows the data recording. The database is implemented as the ORACLE Real Application Cluster (RAC) [12]. All data stored in the archive are available for display and analysis using a graphical User Interfaces (UI).

The communication between the PLCs and PVSS has been established via the Siemens S7 driver [13] which is able to poll and write data to a Siemens S7 PLC.

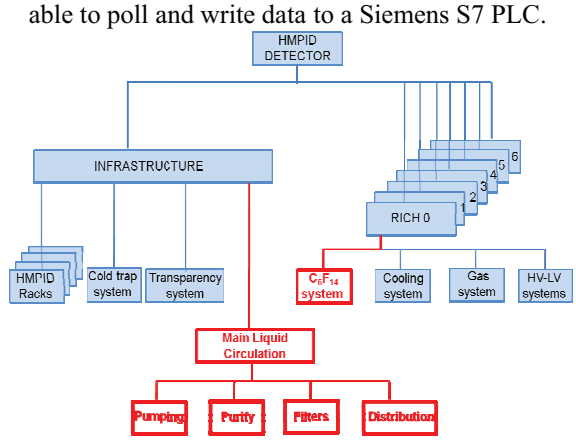

Figure 6: HMPID DCS control hierarchical structure.

Figure 6 shows the control hierarchical tree structure of HMPID DCS. It is type detector oriented hierarchy where HMPID is the top-node and 8 branches exist at the first level:

- seven for controlling the 7 HMPID modules. Each one hosts the control of the HMPID ancillary systems;
- one, called "infrastructure", dedicated to control all the other subsystem

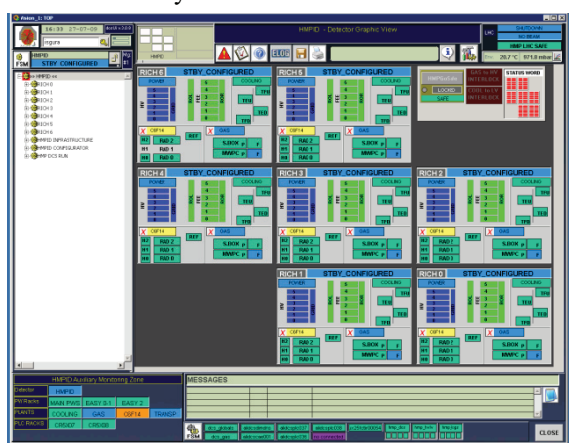

Figure 7: HMPID DCS UI.

Except for LCS, the FSMs of the other nodes are implemented in PVSS using the toolkit provided by the JCOP Framework and based on State management interface (SMI++)[14, 15]. The FSM browsing tree to navigate through the detector logic structure, relevant monitoring panels, and control elements is integrated in the standard UI developed for HMPID (Figure 7).

Figure 8 shows the UI RICH 0 liquid system (as seen in the FSM browser on the left side). As soon, CS registered a R_2 pressure value lower than the predefined threshold (red square in box 1), went immediately into a "FATAL UNDER" state, being the dominant alarm condition (as seen in box 1).

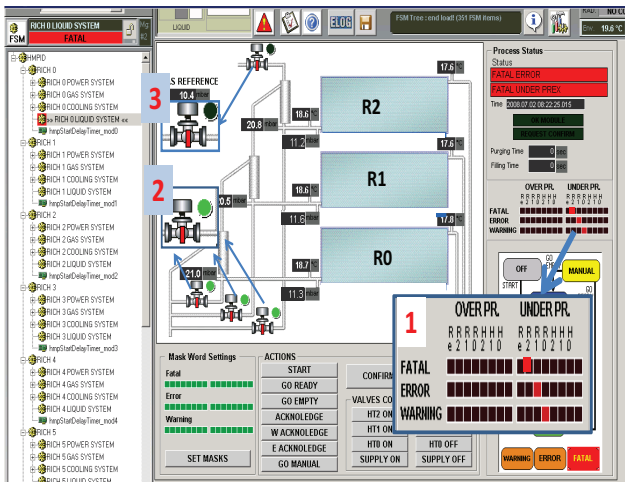

Figure 8: $RICH_0$ liquid system UI when in FATAL state.

It operated closing the emptying valves which are "normally open" (box 2) and the supply valve which is "normally closed" (box 3). At the same time HMPID DCS SMS system tool was enabled to send an alarm message to the expert operator via the GSM network mobile. When the harmful condition has been recovered the Go_Manual command can be issued.

CONCLUSIONS

C_6F_{14} CS was conceived and implemented according to the industrial standards using the Siemens S7 300 PLC as control devices, FSM structure for modular and automatic command execution and PVSS as SCADA environment.

CS allows LCS to run for 24 hours a day, correctly and safely. It is flexible, user friendly both for expert and no expert operator, coherent and homogenous with all the detector control sub-systems and it represents a cost-effective solution.

Moreover, CS showed an excellent capability to cope with harmful conditions that were not foreseen in the original LCS design.

Since the first LHC operation in 2008, LCS under CS control has enabled HMPID detector to successfully collect data.

Acknowledgements

We would like to thank A. Dell'Olio, M. Dell'Olio, Y. Leseneschal, J. Van Beelen and V. Rizzi for their fundamental contributions to the installation and cabling of the C_6F_{14} recirculation system and Control System. We would like also to thank Bosteels for the technical support.

TANGO INTEGRATION OF A SIMATIC WINCC OPEN ARCHITECTURE SCADA SYSTEM AT ANKA

T. Spangenberg*, K. Cerff, W. Mexner, KIT, Karlsruhe, Germany
Volker Kaiser, Softwareschneiderei GmbH, Karlsruhe, Germany

Abstract

The WinCC OA [1] supervisory control and data acquisition (SCADA) system (previous PVSS II) provides at the ANKA synchrotron facility a powerful and very scalable tool to manage the enormous variety of technical equipment relevant for house keeping, beamline, and machine operation. Crucial to the applicability of a SCADA system for the ANKA synchrotron are the provided options to integrate it into other control concepts even if they are working e.g. on different time scales, managing concepts, and control standards.

Especially these latter aspects result into different approaches for controlling concepts for technical services, storage ring, and beamlines.

The beamline control at ANKA was originally fully based on SPEC and is currently moved to TANGO [2] and SPEC [3] which has been fully integrated by expanding by TANGO server capabilities. This approach implies the essential need to provide a stable and fast link, which does not increase the dead time of a measurement to the slower WinCC OA SCADA system. The open architecture of WinCC OA offers a smooth integration in both directions and therefore gives options to combine potential advantages, e.g. native hardware drivers or convenient graphical skills.

The implemented solution will be presented and discussed at selected examples.

CHALLENGES

An important factor for the scientific excellence of a synchrotron is based on its beamlines and their rapid and precise measurement instrumentation and data collection. Obviously a huge number of specialised devices is to be managed. TANGO turned out to be an appropriate tool regarding the speed and the required flexibility for the experimental instrumentation. At the same time and time scale essential environmental information needs to be provided by the SCADA system.

The initially much slower SCADA provides at smallest engineering cost level the required long term stability and scalability and guarantees the robust control of PLCs and any house keeping equipment. But the different event execution times of WinCC OA in respect to TANGO requires an adoption of the data processing.

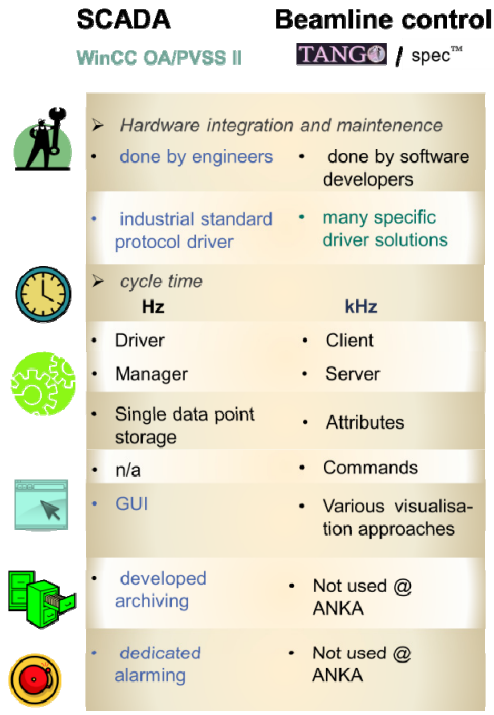

Figure 1: Comparison chart of basic features of WinCC OA and Tango based beamline control. Key benefits of the SCADA and TANGO used at ANKA are marked blue.

Both control systems show a certain analogy but at the same time different fundamental approaches. WinCC OA is set up on central event manager(s) which guarantee the consistency of the data, generate events, derived process values, and a bunch of other management functions. In contrast TANGO offers a clear client-server-concept. It results into a flexible and fast control structure which doesn't stand out ab inito as a clear interaction scheme or presentation concept.

Due to the fact that none of both systems may substitute the advantages of the other one a seamless cooperation needs to be sought.

SOLUTION

Both systems set up on TCP/IP communication and offer a complete API for Windows and Linux. The manager/driver concept of WinCC OA is comparable to TANGO server/client pair. Hereon set up the approach to combine manager – server and driver – client pairs.

At ANKA Linux was chosen as the main platform and all mangers have been designed to this environment. But there are no principle limitations to that operating system.

*thomas.spangenberg@kit.edu

The WinCC OA driver is in relation to TANGO a client which connects by multiple standard TANGO proxies to the servers. Polling and event based data point connections may be realised by the driver. The productive version at ANKA is based on polling. Some minor data type adaptions are done on driver level.

The TANGO server implementation for WinCC OA permits a straight forward read and write access to the WinCC OA data set. Supported data types of the current version are, integer, boolean, double, and string.

A WinCC OA data point and its addressed element are well described by its name which is a unique string and it is used as an index for the cache. Type and name are used to connect to the WinCC OA event manager and the requested value will be cached. Any change of it will update the cache.

Any update of a value is done in the comparable slow WinCC OA time scale. But a request to a successfully connected data point is handled by the TANGO server interface and is defined by the speed of C++ map. The response time of these maps is considerable shorter than 1ms and scales logarithmically to the size of these objects. In case of a higher workload the application is free scalable via the number of the server applications. Additionally the load to the WinCC OA event manager by multiple access of the same value from different clients is reduced by a cache mechanism, which effectively prevents the single threaded WinCC OA event manager to be blocked by an excessive number of client requests.

The write access to WinCC OA is indirectly feeding an input queue to the event manager. Again, timing issues needs to be considered. Requests from TANGO clients are queued and handled sequential with WinCC OA manager speed.

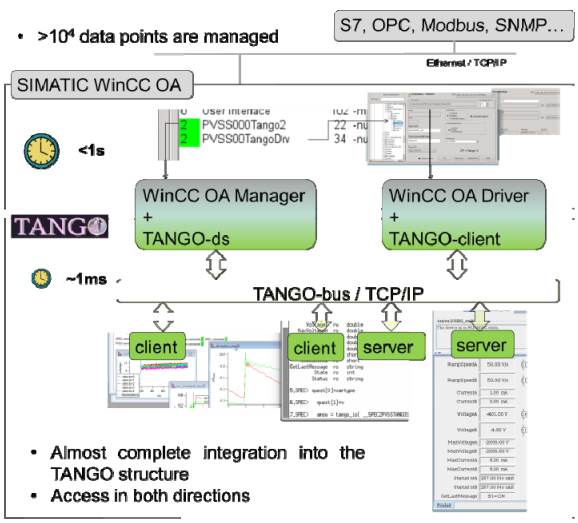

Figure 2: Schematic overview of the WinCC OA / TANGO interaction for beamline operation. The intrinsic time scale difference is managed by the developed WinCC OA manager and driver.

TECHNICAL CHALLENGES

Both systems are offering a complete C++ API which compiles each separately with gcc 4.x compilers. But the standard makefiles claim different compiler options and libraries. Additionally the WinCC OA is limited to 32bit.

Due to incompatible header requirements a direct exchange of data types or classes doesn't work. Dedicated data exchange classes were developed which are connecting the WinCC OA and TANGO part by a bidirectional data queue and granting the thread safe access to the exchanged data. There are different approaches for the TANGO server and for the TANGO client.

A major problem of combining a TANGO server and a WinCC OA manager is that both are claiming to define the int main() originally. Even if the source is available and the name conflict might be resolved it turned out that at first the TANGO server needs to start up and the WinCC OA manager template part is possible to run in a separate thread with a renamed and modified main() function. As a third argument the address of the data exchange is passed for a separately compiled library which contains the complete WinCC OA manager.

For compatibility reasons of the by POGO generated TANGO server the WinCC OA part parameters had to be defined as TANGO server property and are forwarded to the WinCC OA thread. To handle the TANGO server as a 'normal' WinCC OA manager, it was wrapped by a script which overcomes the difficulty of setting natively unknown command line TANGO parameters to a WinCC OA application by its management tools.

The combination of TANGO clients and WinCC OA drivers shows smaller difficulties. The program was developed as a standard WinCC OA driver project. The TANGO client properties are provided by the standard TANGO class and operated in an own thread. The same queue classes of the manager are used to create a thread safe data flow. Due to its original WinCC-OA nature the driver is also managed by the WinCC OA management.

ACTUAL STATE

The server (manager) as well as the client (driver) are in production state and hosted on a VMware ESX server as a small 32bit SuSE Linux 1GB RAM virtual machine.

The server gives a response of less than 1ms request to a request of a previously 'connected' value. Scalars of the type bool, int, double, and string are implemented in the current version. Other types will be implemented on request.

The client operates as a native WinCC OA TANGO driver and permits a standard WinCC OA data integration with the only constraint that it is currently not possible to browse the existing tango attributes of a device server.

CONCLUSION

The combination of the SCADA system WinCC OA and TANGO is fruitful for both sides. The TANGO world gains a well-engineered alarming and logging and a bridge to industrial protocols. Many industrial devices are now available to TANGO without any extra driver development. Due to caching any WinCC OA data can be accessed without any time loss in the timescale of the typical TANGO measurement processes. On the other side WinCC OA application range with its easy and straight forward to develop GUI is significantly extended for scientific applications by the huge number of already developed TANGO device servers and it's attributes and simple commands. And last but not least the WinCC OA TANGO driver allows automation engineers a seamless access to TANGO servers without special TANGO knowledge and general software development skills. The load of GUI development for standard automation tasks is shifted from software developers to engineers and therefore reduces the overall engineering costs and frees resources for more complex software tasks.

The solution is in productive state at ANKA.

UNICOS CPC NEW DOMAINS OF APPLICATION: VACUUM AND COOLING & VENTILATION

D.Willeman, E. Blanco, B. Bradu, J. Ortola, CERN, Geneva, Switzerland

Abstract

The UNICOS (**UN**ified **I**ndustrial **CO**ntrol **S**ystem) framework, and concretely the CPC (Continuous Process Control) package, has been extensively used in the domain of continuous processes (e.g. cryogenics, gas flows) and also in others specific to the LHC machine as the collimators environmental measurements interlock system. The application of the UNICOS-CPC to other kind of processes: vacuum and the cooling and ventilation cases are depicted here.

One of the major challenges was to figure out whether the model and devices created so far were also adapted for other type of processes (e.g. Vacuum). To illustrate this challenge two domain use cases will be shown: ISOLDE vacuum control system and the RFQ4 and STP18 (cooling & ventilation) control systems. Both scenarios will be illustrated emphasizing the adaptability of the UNICOS CPC package to create those applications and highlighting the discovered needed features to include in a future version of the UNICOS CPC package.

This paper will also introduce the mechanisms used to optimize the commissioning time, the so-called virtual commissioning. In most of the cases, either the process is not yet accessible or the process is critical and its availability is then reduced, therefore a model of the process is used to validate offline the designed control system.

UNICOS-CPC BASICS

UNICOS (UNified Industrial COntrol System) with its CPC (Continuous Process Control) package is a control framework which was created to design, develop and finally deploy control systems applied mostly to industrial continuous processes [1].

UNICOS-CPC intervenes in the three classical layers of an industrial control system although provides deliverables only for the control and supervision layers. (1) At the field layer, actuators (e.g. valves, pumps...) and sensors (e.g. temperature or pressure measurements) are extensively described in the UNICOS-CPC control system specifications. (2) At the control layer, the framework provides both, a PLC (Programmable Logic Controller) baseline with basic objects and methodology to design the control system.

After an UNICOS unit-oriented design, the process control architecture is defined. A basic structure containing specific devices (e.g. process control units, field objects…) and the interactions between them will be automatically generated. In most of the cases the user introduces the process specific control logic in predefined placeholders keeping the consistency and homogeneity of different applications. (3) At the supervision layer, the so-called SCADA (Supervisory Control and Data Acquisition) layer, the UNICOS-CPC framework will provide also a baseline with all the devices mentioned before and the peer instances already created for the control layer.

Populating those instances, which are automatically generated for the layers of control and supervision, naturally avoids the synchronization problems between them. In addition, the communication resources for the PLCs and the SCADA are also provided and deployed in both layers. Only the control logic, which is process dependent, has to be coded by the control developer.

All plant actuators and sensors are modeled as one or combined in several UNICOS types. The idea of UNICOS-CPC has always been to keep the devices as generic as possible willing to homogenize both design and operation. As a practical example, motors, pumps and digital valves are modeled with a basic type called *OnOff*.

Other UNICOS-CPC strength is the plant operator capability to intervene any time and any place in the plant through its control components. To achieve this, all field objects (e.g. valves, pumps, heaters…) never have direct access to the I/O of the PLCs but through appropriate I/O types. A general view of the UNICOS-CPC objects can be seen in Fig. 1. There are four types of objects: (1) I/O objects (e.g. Analog Input) which link the sensors cabled on a particular channel to the control system, (2) the plant actuators are then modeled by field objects (e.g. OnOff for discrete and Analog for analog actuators). (3) The control objects (e.g. Process Control Object) drive a group of field objects. The controller object (PID) is used for feedback control, and finally the (4) the interface objects used to parameterize alarm thresholds or showing basic plant status.

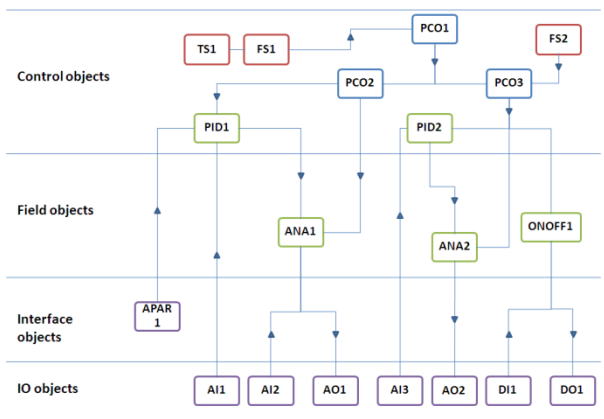

Figure 1: UNICOS-CPC objects hierarchy.

The advantage of a high granularity of types, which gives the framework a great versatility to combine objects to model new needs, could also be judged as an overload in new domain devices where an integration to create more complex devices is likely advisable.

The UNICOS framework was born in 1998 and was firstly used in the LHC cryogenic system. After some evolution and application to other processes (gas flows, interlocks…), we face another challenge: validate the approach in other different domains close to the continuous processes but still with additional requirements.

When CERN decided to replace the out-phased vacuum control system in ISOLDE, we had to check the validity of the UNICOS-CPC in a completely different domain: the vacuum. ISOLDE is a physics facility dedicated to the production of a large variety of radioactive ion beams for a large number of experiments. The vacuum was essential and a high critical component of the installation.

A new challenge started when CERN decided that the control systems of all CERN cooling and ventilation plants had to be done using the UNICOS-CPC framework. More than 150 installations, new and existing, will be deployed using the framework. A brief report of the first installations is provided in this paper.

UNICOS-CPC APPLIED TO VACUUM CONTROL

In large physic experiments, vacuum systems are vital to keep a beam of particles alive and also compulsory in employing cryogenic systems and superconducting magnets. Vacuum can, depending on the experiment, be more or less critical and then the choice of actuators and sensors employed will highly depend on these needs. Other characteristics of the vacuum process are the high repeatability of the control system together with the absence of feedback regulation and predominance of discrete systems.

Vacuum systems are mostly composed by a set of different kind of pumps (e.g. primary, turbomolecular...), and different kind of pneumatic or electrical valves. The measurements are mostly focused on pressure sensors with different ranges of validity.

Most of these devices are usually found in different domains, concretely in the continuous process industry. This is one of the reasons why we believed that the UNICOS-CPC framework was adequate to vacuum installations. The existing UNICOS-CPC types library easily fitted the vacuum requirements.

The ISOLDE vacuum control system was the first vacuum system built with the UNICOS-CPC framework [2]. The vacuum of ISOLDE contains 19 vacuum sectors, 13 pumping stations, 2 venting systems and 1 exhaust facility; see the Fig. 2 where a plant schema is represented. All these subsystems are composed of the devices depicted in Table 1.

Table1: ISOLDE Equipment

Equipment	Number
Valves	180
Turbomolecular pumps	30
Primary pumps	20
Pirani gauges	80
Penning gauges	20

All the penning and Pirani gauges are connected to TPG300 controllers. These controllers are then connected to the PLC via Profibus, an industrial fieldbus.

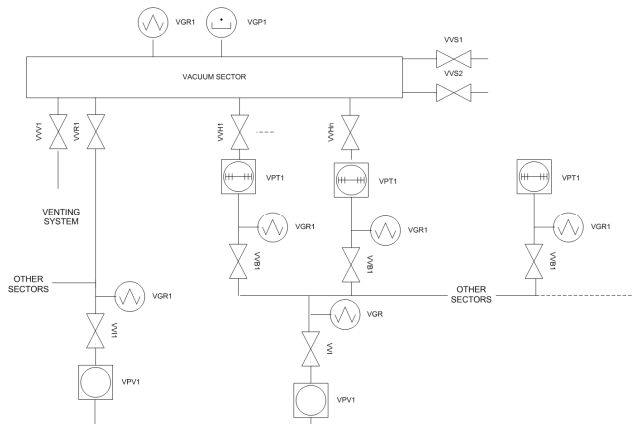

Figure 2: Plant schema of an ISOLDE vacuum sector.

This type of process is highly repeatable. All the vacuum sectors are very similar in ISOLDE and only the number of turbomolecular pumps and its attached valves varies. The goal with installations of this type is to create a set of templates to generate automatically the associated logic only depending in a parameterization. (See Fig. 3). These parameters are the only interaction with the process expert. Once that information is in the UNICOS-CPC spreadsheet specification, the control system logic is automatically generated without a single line of code typed by the developer. This approach considerably saved time for the control system development and for the subsequent upgrades.

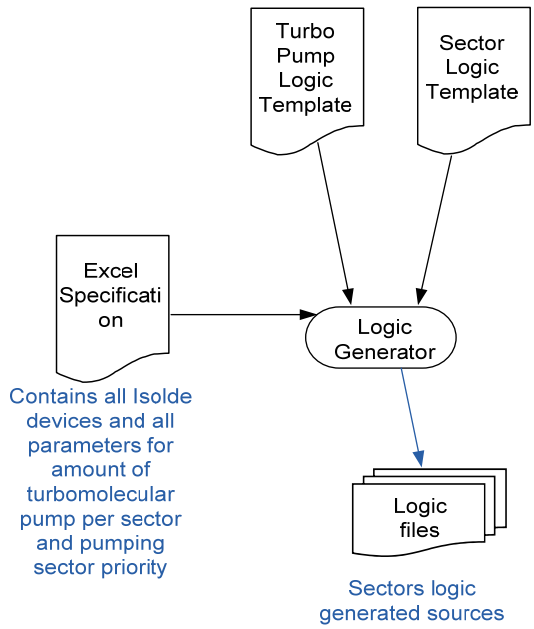

Figure 3: Principle of automatic logic generation.

Following the same philosophy, the operation synoptics were described as templates and with only a few parameters introduced, all the supervision synoptics were automatically created. Again a precious time saved for both, development and maintenance.

The ISOLDE control requirements were challenging. Pumping sector priority management, possibility to manage vacuum level sector by sector and the criticality of the exhaust facility to avoid an undesired release of the irradiated gases contained in ISOLDE, were easily managed with UNICOS-CPC by only parameterization in the control specification.

As an example of matching vacuum devices to UNICOS-CPC objects, the case of the TPG300 vacuum device measuring the pressure combining Pirani and Penning gauges could be analyzed. The final solution combined several basic UNICOS-CPC types to keep the minimum functionality required: only the analogue values and statuses were extracted from the devices and placed in appropriate based UNICOS-CPC objects.

The extraction of all of the information coming from such devices will end up in combining several I/O and interface basic objects. This was one of the motivations to make evolve the UNICOS-CPC framework: to cope with the need of being more flexible in the creation of new types when required. The new UNICOS-CPC v6 package provides the tools to create easily new types in a standard way [3]. This increases the flexibility of UNICOS-CPC to produce new control functionalities and to fulfil operators and process engineers requirements.

UNICOS APPLIED TO COOLING & VENTILATION CONTROL SYSTEMS

Cooling and Ventilation (CV) systems embed very large types of processes. Cooling systems allow the production of cold water by means of chillers or refrigeration towers. They are mainly composed by industrial devices like valves, heat exchangers, compressors, pumps and fans. This kind of processes can be classified as continuous. Then, the HVAC (Heating, Ventilation and Air Conditioning) are performed by air handling units ensuring the control of the indoor air quality (temperature, humidity, oxygen, cleanness). In the scope of accelerators and large experimental physics, the ventilation must be ensured inside tunnels, experimental caverns, experimental halls or computing centers. HVAC systems are also composed by industrial equipments (e.g. heat exchangers, heaters, fans, dampers, valves, filters…).

The control of a refrigeration cooling plant, called STP18 (See Fig. 4), and the cooling of the radiofrequency quadrupole for the future CERN LINAC (RFQ4) were deployed using the UNICOS-CPC package. Once more the framework showed its nature of adaptation to new process domains.

Concerning air handling units, the first control projects are starting up using UNICOS-CPC. Due to the nature of such processes and to handle the new requirements imposed by HVAC systems, the UNICOS-CPC basic package has been enriched with new operation widgets (equipment representation) in a first stage.

The UNICOS-CPC v6 includes the needs in terms of new types and requirements coming from its application to this new domain. These include a new library of HVAC widgets, a color library to show flows of different fluids (e.g. water, gas,…) and additional features such a more secured interlock handling system on some field equipments and automatic integration of regulation structures (e.g.: cascade control).

Moreover, due to different operation needs in Cooling and HVAC systems, where control rooms are not necessarily present and where operation is done via industrial local panels, UNICOS-CPC has been embedded in industrial touch panels in order to ensure local operation at any time.

In the next years, most of Cooling and Ventilation systems at CERN will be progressively upgraded using the UNICOS-CPC framework.

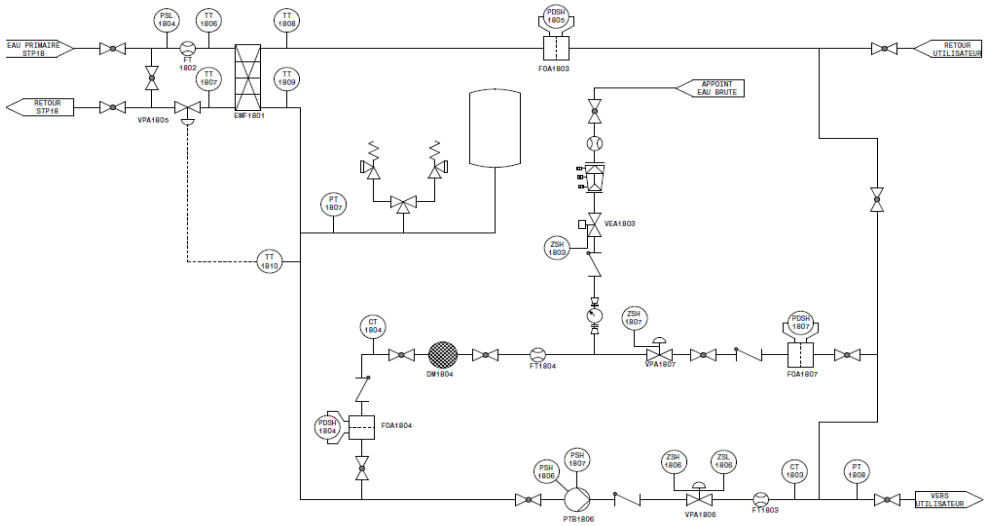

Figure 4: Plant schema of the STP18 cooling plant.

VIRTUAL COMMISSIONING

A cryogenic process simulator able to be plugged to UNICOS-CPC control system has been developed in the last years [4]. This simulator reproduces the process dynamic behaviours based on a set of DAE (Differential Algebraic Equations) describing the physics of the processes. The model of the process is connected to the real control system, reading the PLC outputs (actuators) and simulating the PLC inputs (sensors) in real-time.

The setup of such a simulator allows the development of virtual commissioning platforms in order to make a commissioning of the control system (PLC program and supervision) in advance. Virtual commissioning is a very powerful tool in case of control system upgrades when the commissioning time has to be reduced to minimize the shutdown time of a critical process. In addition to this, the virtual commissioning allows a faster and safer check of the PLC control program where all functional sequences can be tested with the simulator without any risk.

The current process simulator used at CERN for cryogenics has been extended and also supports water cooling simulations. The two systems STP18 and RFQ4 were successfully simulated ensuring an efficient commissioning. Due to the critical nature of some ventilation installations, a dedicated library for HVAC systems will be developed.

CONCLUSION

The ISOLDE control application for vacuum systems, RFQ4 and STP18 for cooling systems were successfully implemented using UNICOS-CPC framework. For all projects, the UNICOS principles applied during the operation and the SCADA features were quickly understood by the operators. The UNICOS-CPC application architecture has been assimilated by vacuum control experts, and since the first implementation, they are autonomous and able to develop and maintain their own control projects. This generic way of control system programming shows its high versatility and its easy learning in different domains of engineering.

The UNICOS-CPC v6 framework will cover missing functionalities identified during the development of both, vacuum and HVAC, control systems. Moreover, the new framework reinforces the local operation by using appropriate industrial devices. It also provides new tools able to create new types and a generic interface to perform virtual commissioning using a simulator.

SUPERVISION APPLICATION FOR THE NEW POWER SUPPLY OF THE CERN PS (POPS)

H. Milcent, X. Genillon, M. Gonzalez-Berges, A. Voitier, CERN, Geneva, Switzerland.

Abstract

The power supply system for the magnets of the CERN PS has been recently upgraded to a new system called POPS (POwer for PS). The old mechanical machine has been replaced by a system based on capacitors. The equipment as well as the low level controls have been provided by an external company (CONVERTEAM). The supervision application has been developed at CERN reusing the technologies and tools used for the LHC Accelerator and Experiments (UNICOS and JCOP frameworks, SIMATIC WinCC Open Architecture SCADA tool). The paper describes the full architecture of the control application, and the challenges faced for the integration with an outsourced system. The benefits of reusing the CERN industrial control frameworks and the required adaptations will be discussed. Finally, the initial operational experience will be presented.

THE NEW POWER SUPPLY OF THE CERN PS

The Proton-Synchrotron (PS) accelerator at CERN is supplied by a new power system (see Fig. 1). This new power system called POPS (Power for PS) [1] replaces the existing power system (including a 90MVA rotating machine), which feeds the main magnets of the PS accelerator. The PS magnets require a maximum DC current of 6kA with a maximum DC voltage of ±10kV. The new power system is based on three-level converters with capacitive energy storages and is rated at 60MW peak power. POPS will supply the PS magnet without drawing all the power from the network. The maximum stored energy in the magnets is 14MJ. The capacitor banks supply this energy. DC/DC converters control this exchange of energy between the capacitor banks and the load. The system is connected to the electrical network by two AC/DC converters (Active Front End). These converters charge the capacitor banks and supply the losses of the load and of the converters.

The POPS control is made up of two different structures that interact to provide the required performances; these are the Function Generator/Controller (FGC) and the CONVERTEAM [2] (CVT) control system. The FGC generates the reference voltage (V_{ref}) for the POPS output voltage and the CVT control system is in charge of producing and maintaining it. The CVT control software has been developed in a proprietary environment called P80i. Once the V_{ref} is set by the FGC the CVT control has to divide it into as many components as the number of DC/DC converters connected in series. This operation called "Voltage Dispatching" is done by assigning coefficients proportional to the amount of energy stored in the capacitors (based on the maximum and minimum voltage for the capacitors that is different depending on whether the capacitor is of floating or charger type). As a general indication the voltage dispatching is done by allowing the floating capacitors to take only part of the inductive contribution to the V_{ref}, leaving all the rest to the chargers.

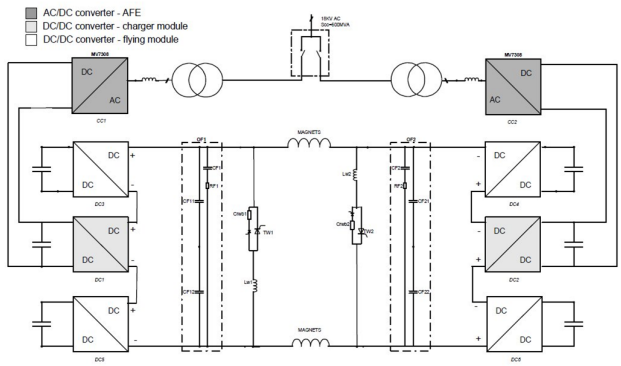

Figure 1: Topology of the power system.

CONTROL ARCHITECTURE

The POPS control system architecture (see Fig. 2) is a three layer control system composed of:

- Field layer with remote input/output module connected to the control layer. This layer is composed of WAGO modules interfaced with the control layer via the PROFIBUS fieldbus.
- Control layer with CONVERTEAM hardware and software based on VME cards, holding the closed control loops and the voltage and capacitors control. The CONVERTEAM control system is distributed over four CPUs and remote IO modules. Each CPU is monitoring the link with the Supervision layer; the interruption of the communication stops the powering of the system.
- Supervision layer. In this layer, process views are provided for the monitoring and the control/command interface of the control system. Other typical functions (e.g. archiving, trending, alarm handling) are also provided by this layer.

The application is usually supplied as a complete turnkey system by CONVERTEAM. However in the context of CERN, tools for the Supervision layer already exist, allowing a smooth integration into the CERN control complex. The Field and Control layer were provided by the company manufacturing the power system. The Supervision layer was developed at CERN. Furthermore, with the usage of CERN tools the interface to the FGCs and the integration of data from the cooling and ventilation subsystem via DIP (Data Interchange

Protocol) [4] was very straightforward. This information is made available in the POPS process view and it is very useful for the operation.

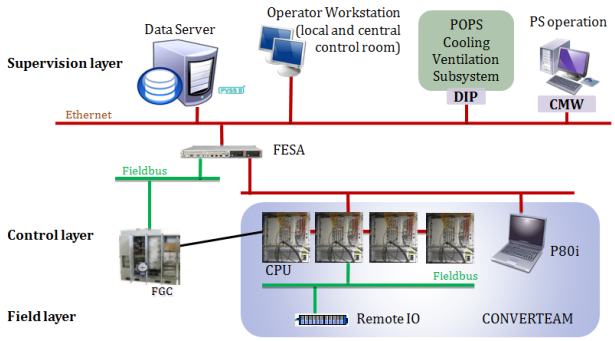

Figure 2: POPS control hardware architecture.

PUTTING IT ALL TOGETHER

Interfaces

Two solutions were used for the interface to the CONVERTEAM control layer: OPC (OLE for Process Control) [3] and a proprietary protocol based on TCP/IP. The first deployment of the supervision application was done with the OPC interface. Later a dedicated front-end program based on the FESA framework [5] was developed to interface with the proprietary protocol.

All the devices defined in the control layer are listed in an Excel spread sheet, which is used by CONVERTEAM to configure their system with the P80i programming console. A dedicated tool (see Fig 3) was developed to extract from this Excel spread sheet all the information for the supervision layer: list of devices, definition, configuration, etc.

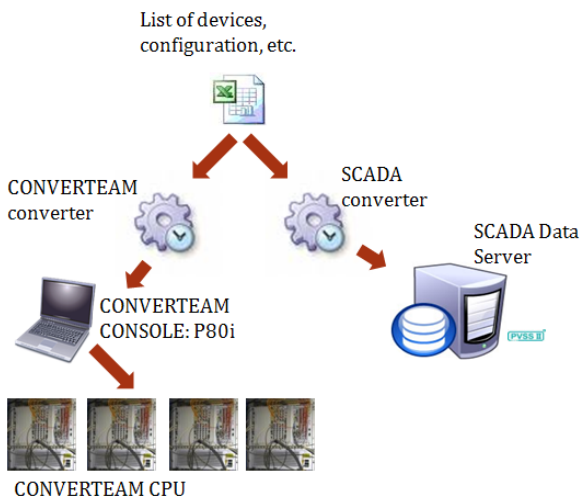

Figure 3: System configuration workflow.

SCADA Framework

The supervision layer of POPS was based on the UNICOS framework [6] developed at CERN. This framework is used to develop control applications. It provides the developers with the means to rapidly develop full control or monitoring applications and provides the operators with ways to interact with all the items of the process from the most simple (e.g. I/O channels) to the high level composite devices. In addition, UNICOS offers tools to diagnose problems in the process, the control system and to access and operate the devices without specific development. It is based on SIMATIC WinCC Open Architecture ® [7] (WinCC OA previously released under the name of PVSS) and it offers at the supervision level, in both Linux and Windows operating systems, functionalities such as: interface to include additional packages, device and file access control, interface to the LHC software suite, a homogenous user interface entirely customizable with features such as navigation capabilities between panels and trends (WWW browser like, contextual buttons, pop-up navigation), access to the devices without creating a specific view (Tree Device Overview), process alarm and event list. A device includes some libraries of code, a set of widgets (summarized view of the device status), a faceplate (detailed view of the device) and the device actions interface. A tool is provided to import the device configuration into the supervision layer. A developer of a UNICOS supervision application does not need any deep WinCC OA knowledge (e.g. scripting). He just needs to import the instances of the process devices; to create the application specific process views using the provided catalogue of devices and to configure the required trends.

Development

The use of the UNICOS framework allowed us to develop the supervision in two phases:

- Phase I: with low-level dedicated devices interfaced via OPC to the control layer. During this phase the equipment and the feedback control loops were validated.
- Phase II: using the FESA interface instead of OPC. High level device widgets encapsulating the low-level devices were added to the Phase I devices. These widgets were developed using the UNICOS widget interface in which a widget can be attached to a hardware device or to a generic device. These widgets were used directly by the operators and the control experts to create the process views.

Both the low-level and high-level device widgets present the device data and the communication link state to the CONVERTEAM CPU. Dedicated 32 bit devices for alarm, interlock and default status were created. Analog input and 32 bit status devices were re-used from other packages without any new development.

INITIAL OPERATIONAL EXPERIENCE

The supervision layer was successfully used during the commissioning and the operation of POPS. Thanks to the UNICOS flexible configuration, the graphical interface (see Fig 4) was customized and divided in three main areas:

- A header: showing the global state of the control system: communication alarm link, shortcut for fast access to the views, user login.
- A status area: presenting the most important state information of the equipment.
- A bottom area: for the most important commands, these commands are protected depending on which user is logged in.
- A central area: where the detailed views for the operators are displayed. About 35 different views were developed for the operation and diagnostic: detail view on the AC/DC, DC/DC, output connections, cooling, interlocks, etc. An expert having no deep knowledge of WinCC OA made the views with the high level widgets.

During the commissioning, each input/output was tested in order to check the complete control chain, from the sensor up to the supervision with the Tree Device Overview, a UNICOS built in feature. Later on, the POPS complete graphical interface was released and commissioned. The event list, another built in utility, was also used to understand the sequence of faults in case of the powering failure of POPS. This event list is based on a sequential list of 32 bit state words. The individual bits for the statuses, the alarms and default states are extracted and ordered by time. As the timestamp of these events comes from the control layer, one can diagnose the exact sequence of faults.

The navigation features provided by the UNICOS framework were also very useful to go directly from one view to another one without having to search within the list of all the views.

Multiple instance of the POPS supervision graphical interface can be started from many places, for instance from local control room, during commissioning or development time, from central control room for the daily operation. This interface in the central control room is very useful for the operators to make a first diagnostic before calling the experts.

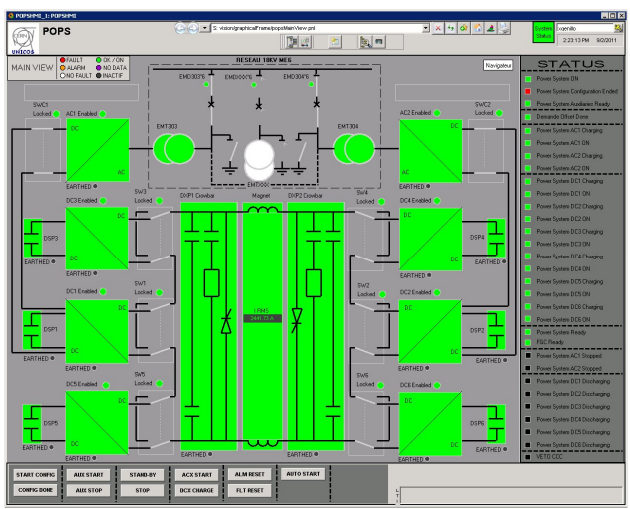

Figure 4: POPS graphical interface.

Later a dedicated interface to the PS operation tool was provided by using the server middleware interface [8] of the LHC Software suite built in UNICOS. This interface publishes the states of devices and a set of commands to act directly on the control layer: stop, start, etc. New states and commands can be easily added by reconfiguring this interface without any development.

CONCLUSION

The control systems of the LHC and the experiments have been running successfully for the last years. This success goes beyond the original scope, the same tools which had been used for their development were used to build new applications like POPS.

The reuse has only been possible because at an early stage of the different LHC projects it was decided to base the developments for industrial controls in a common generic frameworks and components. This choice implied a certain overhead which today is paying off when facing new projects.

The controls for POPS have been developed in a short time frame and with a small team. In addition, it has seamlessly integrated in the CERN controls infrastructure. Any future maintenance and upgrades will also be simplified.

THE ELBE CONTROL SYSTEM – 10 YEARS OF EXPERIENCE WITH COMMERCIAL CONTROL, SCADA AND DAQ ENVIRONMENTS

M. Justus, F. Herbrand, R. Jainsch, N. Kretzschmar, K.-W. Leege, P. Michel, A. Schamlott
Helmholtz-Zentrum Dresden-Rossendorf, Radiation Source ELBE, Germany

Abstract

The electron accelerator facility ELBE is the central experimental site of the Helmholtz-Zentrum Dresden-Rossendorf, Germany. Experiments with Bremsstrahlung started in 2001 and since that, through a series of expansions and modifications, ELBE has evolved to a 24/7 user facility running a total of seven secondary sources including two IR FELs. As its control system, ELBE uses WinCC on top of a networked PLC architecture. For data acquisition with high temporal resolution, PXI and PC based systems are in use, applying National Instruments hardware and LabVIEW application software. Machine protection systems are based on in-house built digital and analogue hardware. An overview of the system is given, along with an experience report on maintenance, reliability and efforts to keep track with ongoing IT, OS and security developments. Limits of application and new demands imposed by the forthcoming facility upgrade as a centre for high intensity beams (in conjunction with TW/PW femtosecond lasers) are discussed.

THE ELBE ACCELERATOR FACILITY

The electron accelerator ELBE is a multiple user facility (see fig. 1) that delivers an electron beam between 5.5 and 33 MeV (pc) with a broad range of temporal schemes, ranging from single sub-pC bunches to a 1 mA cw beams with 13 Mhz repetition rate. Electrons are produced by a 250 kV thermionic d.c. gun and accelerated by two cryomodules, each comprising two 9-cell TESLA-cavities at 1.3 GHz. Until September 2011, the electron beam was alternately delivered to a bremsstrahlung facility, two IR FELs (5…280 µm), a site for channelling X-rays, cell irradiation and detector analysis, a neutron time-of-flight source, a position source and a preliminary electron-laser interaction. Additionally, a well noted superconducting RF gun making progress towards delivering bunch charges of up to 1 nC with significantly decreased transverse emittance. Thus, ELBE is able to address a wide range of scientific disciplines and programs within the Helmholtz community and above.

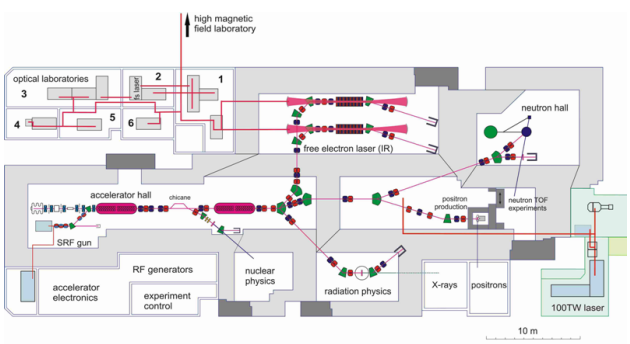

Figure 1: ELBE facility overview.

THE ELBE CONTROL SYSTEM

The ELBE project started in 1999, where the decision was made to use commercial industrial control technology as its control system (CS). Due to its project size, ELBE was sort of a pilot project in electron accelerator technology at the former Forschungszentrum Rossendorf. So this decision was in parts the result of balancing in-house expertise in industrial control systems versus the advantages of systems specifically developed for accelerators. As a multifunctional facility, ELBE has not been built all at once (or better: within few years), but rather grew proportionally with the installed beam lines and user labs.

Looking at the system architecture (fig. 3), the ELBE CS is a mostly straight-forward implementation of the automation pyramid as known from IEC 62264 [1] and depicted in fig. 2. On layers 0…2 we find different branches addressing specific needs of accelerator control: machine control and supervision, machine protection system and data acquisition. On layers 3 & 4 there are web based applications with no direct integration into the ELBE control system.

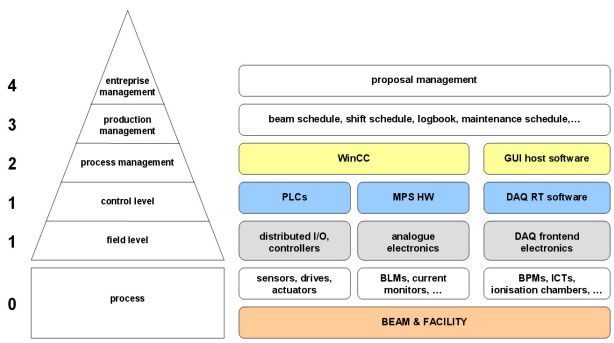

Figure 2: ELBE control system classification.

Machine Control and Supervision

At field level, we use distributed I/O systems interconnected by Profibus DP [2], such as Beckhoff field bus terminals [3], Simatic ET200 [2], or Profibus supporting field devices. “Intelligent slaves” are embedded here to source out specific control tasks from control level.

Control level is represented by Simatic PLCs [2], distinguished by their major areas of functionality, such as personal safety system (PSS), beam generation & beam

control, vacuum & media control, beam dump control and cryogenics. This separation was chosen to achieve an optimum match between tasks and technology of the central hardware and firmware. The software is developed in-house using IEC 61131 languages within the Step7 environment [2]. The CPUs are interconnected by Profibus communication to share main machine parameters. Most of them are within one single project.

For supervisory data acquisition and control (SCADA), we use WinCC, a Windows based system [2], in the form of a server-client architecture. Graphical user interface, alarm handling, data logging & trend display and management of machine settings are implemented. For specific systems, additional standalone WinCC stations or operator panels are available to ensure access independently from the main server. WinCC client stations communicate via LAN with the server.

DAQ Systems

Data acquisition for beam diagnostics, demanding fast triggering and high temporal resolution are realized with National Instruments PXI crates and PC DAQ components [10]. Application software programmed using LabVIEW or LabWindows™/CVI [4], running real time or Windows systems. They mainly use shared network variables for data exchange between host applications and acquisition systems. To interface PXI, PCs or user systems (NIM, VME) with the PLC world, we use OPC [5], specifically the Simatic Net OPC server [2], with defined access rights. Different data engines translate OPC item access into shared variables or telegram based TCP/IP communication, where OPC implementation is not available or inconvenient.

Machine Protection System

The MPS consists of a fast and a slow signal chain. The fast chain is realized with hardware electronics, including beam loss detection, vacuum inrush detection & prevention and the RF system interlock with a total reaction time below 2 milliseconds, using PLC interrupt techniques. Hard-wired data exchange with the main PLC enables altering the MPS functionality according to the current beam option, as well as a diagnostics interface. The slower branch of the MPS is spread all over the PLC code units, ensuring beam shutoff within 2 seconds due to technical failure or operational mistakes.

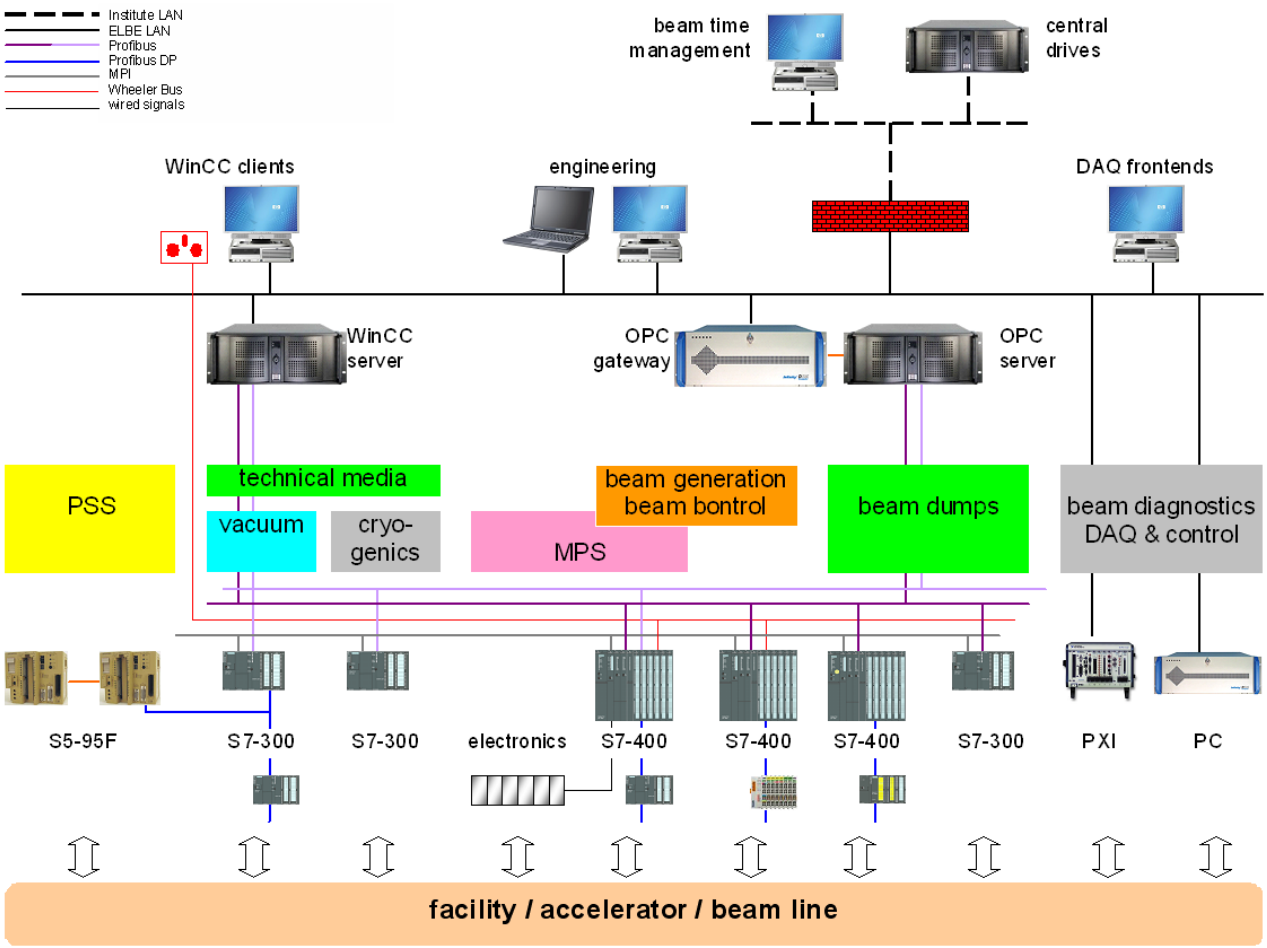

Figure 3: ELBE control system architecture.

Operational Management

ELBE operation is organized by a web based infrastructure like beam time schedule, shift schedules, a logbook with features like failure tracking and user response and a WIKI supporting the operator staff. The overlying administration of experimental proposals is a centralized service of the Helmholtz-Zentrum Dresden-Rossendorf. Integration of these tools into the machine control system is not yet available.

System Key Figures

As all pictures show only exemplarily the system characteristics, a few key number are given in the below table:

Table 1: ELBE Control System Key Figures (Rounded)

PLC CPUs	12
PLC data points	4500
PLC plain machine code	1.5 MB
PLC development software	Step7 V5.5
MPS fast channels	80
WinCC process tags	7000
WinCC client PCs	25
WinCC software	V7.0
OPC items	250
LabVIEW development software	2009
PC / PXI DAQ systems	10
PC / PXI DAQ applications	15
MPS fast hardware channels	80

OPERATIONAL EXPERIENCE AND SYSTEM MANAGEMENT

System Availability and Stability

As a measure for system availability, one can simply monitor the failure or unavailability rate of servers, PLC units, communications and other systems. As ELBE is a single beam linear machine, at least downstream the accelerator subsystems are not permanently needed to deliver beam. In fact, it is a special advantage that for beam time statistics, a critical failure scenario can often be compensated by changing the schedule. Thus, availability is more a result of managing infrastructure, system maintenance and implementing a proper failure monitoring to be one step beyond.

Hardware Management

Usual failure scenarios with few recurrences a year involving CS components are:

- PLC hardware failure, really rare if operational conditions are maintained as specified (this is in terms of radiation exposure not always possible)
- field bus components failure, can occur under hard EMC conditions
- PC & PXI system hardware failure, likely for standard PCs

To meet hardware and communication difficulties, a monitoring system has been established during the last three years to permanently check hardware, field devices (i.e. magnet power supplies, drives), field bus communication, serial connections, as well as CPU operation by means of PLC alarm handling and software diagnostics. Malfunctions are reported to WinCC, enabling statistical analysis within its alarm system. This often helped to detect sub system failure well before the specific components are needed for beam delivery. Commercial PLC technology has been experienced as ideal for implementation of simpler control functionality with a high demand on availability and physical robustness. The advantage of commercial hardware in general is that staff does not have worry about electronics design, availability of parts or firmware compliance, if good manufacturer support is provided.

Software Management

More often, due to permanent modification of the facility during the last years, we experience several types of software problems:

- programming errors in PLC code, WinCC scripts and other software that appear in unlikely and unforeseen system states
- WinCC server failures, i.e. due to project modification during system runtime or communication errors
- communication problems between DAQ components and applications
- malfunction of application software

Dealing with these problems requires (beyond the pure code verification) software and IT management measures. To become independent from overall IT policies (which are usually forced on any system that connects to the general IT infrastructure), the ELBE control system has been segregated from the overall IT network by an own domain behind a firewall (see fig. 3). Dedicated access rights and trusted relations for accounts and groups enable access to central services and drives.

For NI or Siemens application and development software, compatibility of operating systems, development software, hardware components and IT policies has to be checked carefully. Proven and tested configurations are made in-house standards. WinCC itself already offers log files for its own components, such as compiler, script monitoring, runtime software or connection management.

While PLC code usually has a durability of 10 years plus and is nearly independent from the development suite version and the OS, this is not necessarily the case for higher level programming, including LabVIEW. Therefore, we limit the changeover of releases to what is absolutely necessary. Further, software projects are managed using professional versioning tools running on

central IT resources, in combination with routine backup copies.

To give some numbers, table 2 shows renewal and upgrade rate we have experienced or can expect in all conscience:

Table 2: Renewal and Upgrade Rates

PLC hardware	> 10 yrs *
PLC application software	~ 10 yrs *
PLC development software	~ 3 yrs
WinCC server and client PCs	~ 5 yrs
WinCC application software	> 5 yrs **
WinCC development software	~ 3 yrs
NI hardware (PC)	~ 5 yrs
NI hardware (PXI)	> 5 yrs ***
NI application software	~ 2 yrs
NI development software	~ 3 yrs

* few PLC systems have been completely replaced by now, they run between 3 and 10 years

** driven by new software options, WinCC applications were reworked in parts

*** PXI system are involved for about 5 years, no complete replacements so far

OUTLOOK: FUTURE CENTRE FOR HIGH INTENSITY BEAMS

From October 2011 on, parts of the ELBE beam lines and user facilities are being dismantled to give room for new installations addressing the scientific needs of our users or improvement of their experimental sites. Including a building extension, we will install a new THz source and laboratory, the revised neutron production target and the revised interaction chamber for high brightness laser beams with ELBE electrons.

For the ELBE CS, this is an ideal opportunity to keep track with recent and already proven developments:

- The aged out S5 system of the PSS is currently replaced by S7 technology. This system will be expanded to the ne building, including interfaces to personnel access management.
- New beam lines will be equipped with newer PLCs, including extensive re-engineering of the PLC software towards better object orientation and efficiency.
- Profibus Technology will be partly replaced by ProfiNET (an industrial Ethernet standard) to provide more convenient data connections between PLCs and the PC/PXI world based on TCP/IP, as well as to improve the coupling performance of the WinCC system.
- As an in-house pilot project, an optical beam line will equipped with EPICS control. Interfaces to WinCC are realized with TCP/IP communication via PLCs.
- The machine protection system fast chain will be completely redesigned in-house, applying pure hardware logics with PLC interface. The overall reaction time will be decreased below 1 ms, according to the demands of the beam power upgrade (64 kW maximum). PLC interrupt handling is limited to about 1.5 ms and will not be involved in this system anymore

SUMMARY

When looking at implementation time and maintenance, the ELBE control system with its mainly commercial components and in-hose developed software is a good choice for a facility of this size with around 25 staff members running in full 24/7 user operation. The price of this is a large variety of interfaces and system constraints to be managed, and the lack of tools specifically designed for accelerator physics. The aimed future role of ELBE as a facility with > 50 % external users demands more system openness and data availability than we can provide by now, and will more and more involve industrial and office IT.

Abstract

F3RP61 is an embedded PLC CPU module developed by Yokogawa, Japan. It is based on PowerPC 8347 platform. Linux and EPICS can run on it. We do some tests on this device, including CPU performance, network performance, CA access time and scan time stability of EPICS. We also compare F3RP61 with MVME5100, which is most used IOC in BEPCII and BESIII. After this tests and comparison, the performance and capability and role of F3RP61 in CSNS (China Spallation Neutron Source) experimental control system is clear. It can be used as communication nodes between device control layer and global layer. And in some cases, F3RP61 also has the capability to exert more functions such as control tasks.

INTRODUCTION TO TARGET AND INSTRUMENTS OF CSNS

Neutron scattering is a powerful method to probe the structure of the microscopic world, becoming a complementary technique to x-ray in the advanced researches in physics, chemistry, biology, life science, material science, new energy, as well as in other applications. To meet the increasing demands from user community, China decided to build a world-class spallation neutron source, called CSNS. It can provide users a neutron scattering platform with high flux, wide wavelength range and high efficiency. The pulsed-beam feature allows studies not only on the static structure but also the dynamic mechanisms of the microscopic world.

CSNS mainly consists of an H- linac and a proton rapid cycling synchrotron. It is designed to accelerate proton beam pulses to 1.6 GeV kinetic energy at 25 Hz repetition rate. Proton pulses strike a solid metal target to produce spallation neutrons.

The high-energy proton beam extracted from the accelerator bombards on the target to generate neutrons through spallation reaction.

INTRODUCTION TO CONTROL SYSTEM OF TARGET AND INSTRUMENTS

The control system of Target and Instruments provides global control and monitor to all sub-system in Target and Instruments division.

The control system is divided into 3 layers, including front control layer, local control layer and global control layer. Global control layer and local control layer are based on EPICS software. In CSNS Experimental Control System, YOKOGAWA PLC will be adopted as controller in device control layer. EPICS is a SCADA software widely used in large scale physical experiment and accelerator.

Traditionally, device controller in front control layer is a ladder PLC. Control logic is running in this ladder PLC. A soft IOC based on industrial PC is used to connect global control layer based on EPICS and ladder PLC in front control layer. This soft IOC exchanges information only. Because of using two cascaded controller, this system structure decreases the system reliability and costs a lot. A nature idea that these two controllers are combined into one is coming out.

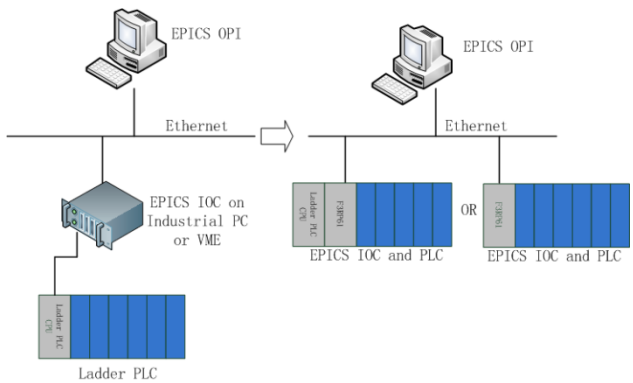

Figure 1: Simplify the path from front control to global control. After Simplifying, reliability increase while cost much fewer.

Now, a new PLC (Programmable Logic Controller) CPU module based on linux OS from YOKOGAWA, F3RP61 [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11], began to be applied in larger physics plant. F3RP61 can be used as EPICS IOC with traditionally ladder PLC CPU in the same framework or even replace the ladder CPU. In way of F3RP61 running in same framework of ladder PLC CPU, the cost of switch and linking cable is saved. In case of F3RP61 replacing ladder CPU, the control logic is running in F3RP61. It can use almost all F3 I/O module directly.This saves the cost of ladder PLC CPU further.

F3RP61 will be used as information exchange and control node in CSNS Experimental Control System. The performance of F3RP61 is the important to design the whole control system.

INTRODUCTION TO RP61 PLC MODULE AND TEST ENVIRONMENT

F3RP61

F3RP61 [14][15] from YOKOGAWA is based on POWERPC MPC8347 533MHz processor. MPC8347 is an E300 core Soc from Freescale Inc. MPC8347 integrates DDR controller, two 100BaseT Ethernet, USB, serial, and mini PCI interface.

Test Environment

All the tests are done on Yokogawa F3RP61-21. The os is linux-2.6.24.3; c compiler is gcc-3.4.3, and libc is libc-2.3.4. RootFs is on Scandisk 2G CF card in the F3RP61. A Dell PC running scientific linux CERN 4.7 is connect to F3RP61 with Cisco 3750 switch. This Dell PC is used as consol host and communication pair of F3RP61.

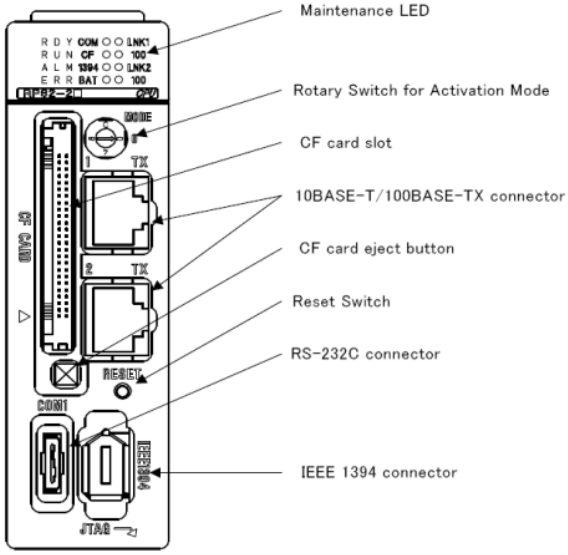

Figure 2: The Front-View of F3RP61.

THE CPU PERFORMANCE TEST

Nbench [12] benchmark is used in performance test to known RP61 CPU well. Nbench is a CPU and memory benchmark program set to test single core CPU, including NUMERIC SORT，STRING SORT，BITFIELD，FP EMULATION，FOURIER，ASSIGNMENT，IDEA，HUFFMAN，LU DECOMPOSITON test program. MEM, INT and FP Performance Index will be obtained by comparing to AMD K6-233 performance after Nbench running. MEM index is for processor bus, cache efficiency and memory performance. INT is integer computing capability of processor. FP is double float performance of CPU. All these expose the theoretical upper limit of the CPU.

The results of Nbench on RP61 are showed in figure 3. These results show that, comparing to AMD K6/233, computing intensive kind of program gain more accelerating.

Figure 4 shows the performance between RP61 and MVME5100, a widely used single border computer in physics experiment and accelerator. Nbench test shows, for CPU capability, performance of F3RP61 is closed to the MVME5100. This means that F3RP61 in compute-intensive applications have certain advantages. Comparing to traditional ladder CPU, RP61, with good operational performance, can do some more complex computing, such as advantage PID algorithm.

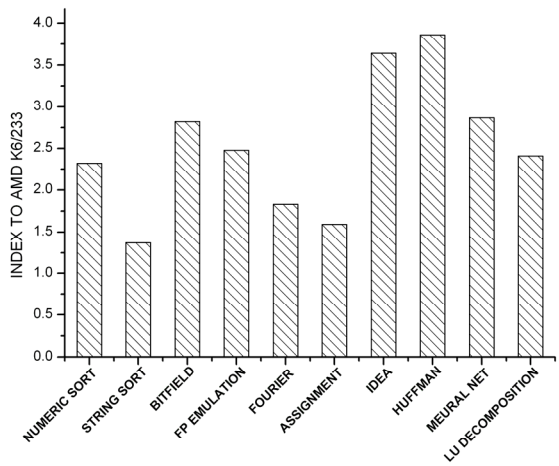

Figure 3: Ten reference program performance Index of Nbench Program Set.

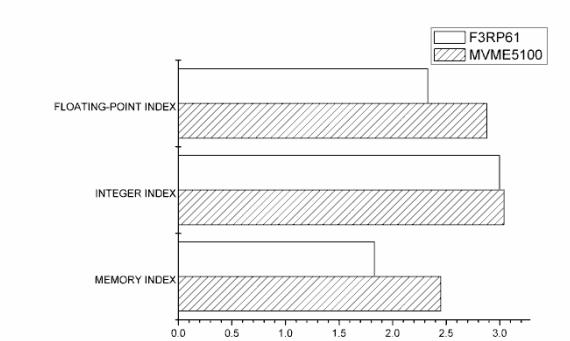

Figure 4: Performance Index Comparison. F3RP61 vs MVME5100.

NET PERFORMANCE TEST

In CSNS Experimental Control System, an important role of RP61 is information exchange node between device control layer and front control layer. So the net throughout performance and CPU utilization is an important index of performance.

Netperf [13] is a standard tool based on TCP and UDP protocol to evaluate net performance. In different test case, Netperf can do bulk data transfer or request/response test. In bulk data transfer test mode, the

result reflects how fast a system can send or receive data to/from another system.

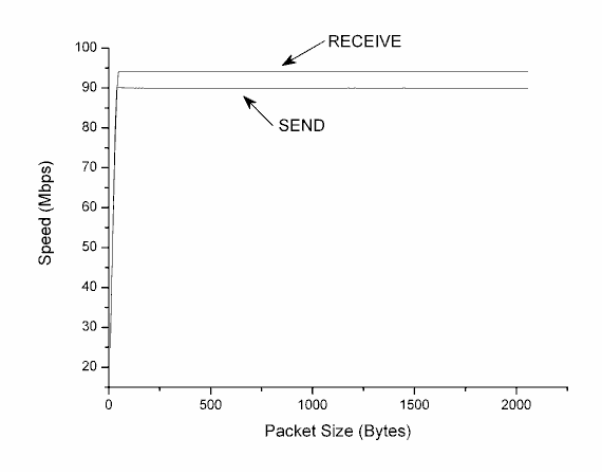

Figure 5: The net speed of F3RP61.

Figure 5 shows the send and receive speed vs. packet size of RP61 to a DELL PC. From about 100 byte, the send and receive speed can close to 100M line speed.

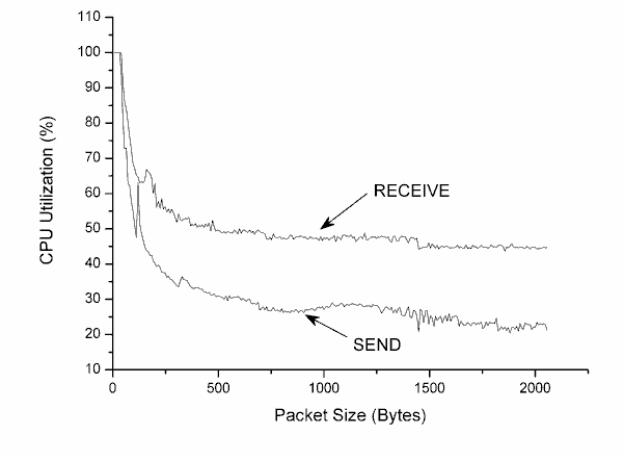

Figure 6: CPU Utilization of sending and receiving.

Figure 6 illustrate the CPU occupation with packet size. In this figure, the speed of net increases with the packet size increasing, while the CPU occupation decrease. This effect is caused by the different packing and depacking cost in TCP/IP stack in different packet size. In control system, the small size packet is dominated, so the net send task should acquire more CPU time. And also from figure 6, as more interruption happens, receive task costs more CPU time than send task. NAPI feature in the linux kernel will reduce CPU utilization obviously.

This CPU utilization of F3RP61 is much larger than MVME5100. This means, the net capability of F3RP61 is not so good.

THE PERFORMANCE ON EPICS

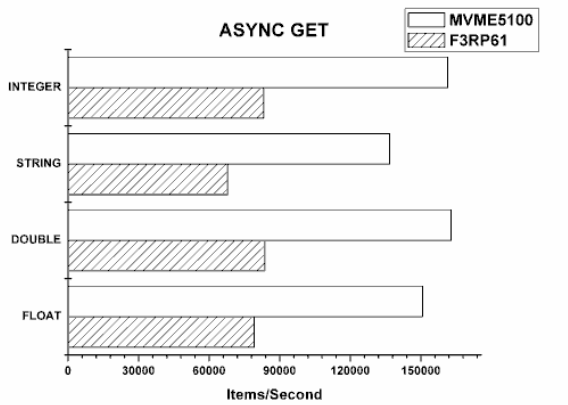

Figure 7: Asynchronous read performance comparison, MVME5100 vs. F3RP61.

In the target and instruments control system of CSNS, F3RP61 is used as information exchange node between device control layer and global control layer, providing PV service and control information exchanging. Besides this, F3RP61 can provide some control functions within epics framework. So how to evaluate and balance these two functions is the problem in front of target and instruments control system.

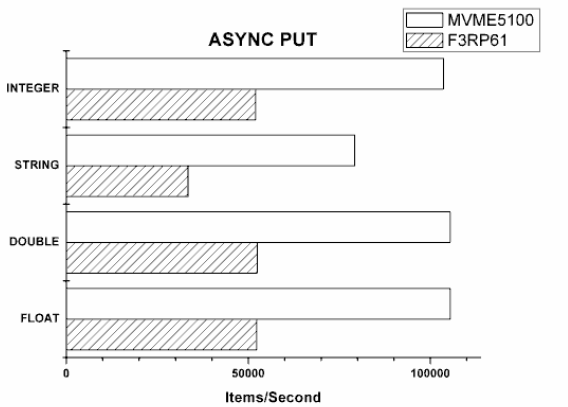

Figure 8: Asynchronous Write performance comparison, MVME5100 vs. F3RP61.

The main tasks of EPICS are providing periodic scan for control and PV access from Ethernet. We can estimate the maximum PV access the F3RP61 can provide through the test to provide design roof for the system design.

EPICS IOC performance on F3RP61 can be estimated through PV access speed test. Figure 7, 8, 9 shows F3RP61 PV access speed comparing to MVME5100. In this test, F3RP61 and Dell PC are connected in the same CISCO 3750 switch. F3RP61 can provide about one half PV access of MVME5100 in case of full CPU occupation. Considering real-time information exchange and reliable PV access service, 20% CPU time can be used to PV

service on information exchange dominant node. More less CPU time, about 5% to 10%, can be allocate to PV access in hybrid node of information exchange and control.

Synchronous read speed is much slower than asynchronous access speed. The reason much time is cost in waiting the response on net.

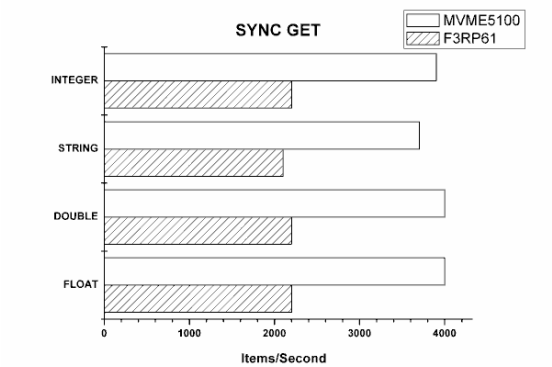

Figure 9: Synchronous read performance comparison, MVME5100 vs. F3RP61.

For control task, the stability of scan period is most important. Figure 10 depicts the output of IOC period scan on F3RP61. The scan period in this chart is 5ms. The period of output is 10ms. The default EPICS configuration was used. After more than 190,000 samples, the Std. Dev. of scan period is about 26us. The Max-min jitter is about 600us. For the general control task, the typical period is about tens of millisecond. This deviation can be accepted.

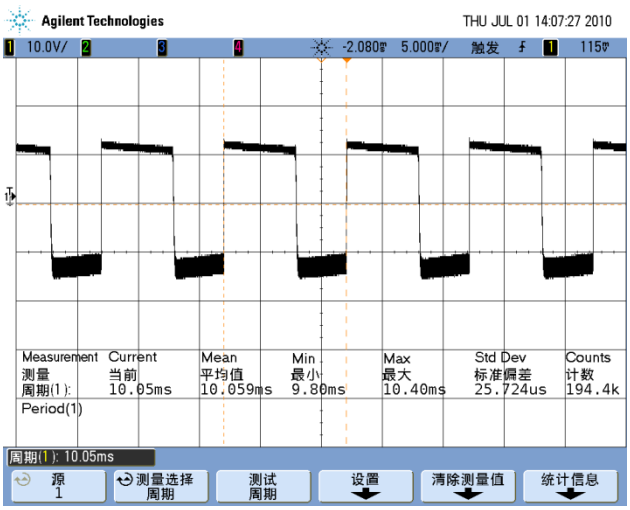

Figure 10: Jitter of 10ms period.

CONCLUSION

Through all the tests in this paper, the conclusion that F3RP61 can be used as information exchange and control node in the target and instruments control system of CSNS can be drawn. Comparing to traditional ladder CPU, F3RP61 is able to do more computing，to run EPICS and to provide more information exchanging.

AGILE DEVELOPMENT AND DEPENDENCY MANAGEMENT FOR INDUSTRIAL CONTROL SYSTEMS

B. Copy, M. Mettälä, CERN, Geneva, Switzerland

Abstract

The production and exploitation of industrial control systems differ substantially from traditional information systems; this is in part due to constraints on the availability and change life-cycle of production systems, as well as their reliance on proprietary protocols and software packages with little support for open development standards [1]. The application of agile software development methods therefore represents a challenge which requires the adoption of existing change and build management tools and approaches that can help bridging the gap and reap the benefits of managed development when dealing with industrial control systems. This paper will consider how agile development tools such as Apache Maven for build management, Hudson for continuous integration or Sonatype Nexus for the operation of "definite media libraries" were leveraged to manage the development life-cyle of the CERN UAB framework [2], as well as other crucial building blocks of the CERN accelerator infrastructure, such as the CERN Common Middleware or the FESA project.

INTRODUCTION

Agile software development methodology characterizes any development method that emphasizes incremental deliveries, working software and fast response to change. It emerged in the 1990s as a response to so-called heavyweight methods, relying on long running project plans, waterfall models and micromanagement.

Agile methods such as SCRUM or Extreme Programming rely on the old maxim “a problem shared is a problem halved”, by encouraging the collaboration of small but cohesive development teams performing fast evolving deliveries. Teams collaborating on a large project will therefore continuously contribute project deliverables to a “common pot”, from which a best-of-breed product release can be composed at any time.

While agile methods emphasize the importance of human interactions over automated processes and customer collaboration over contract negotiations, it is not surprising that software tooling quickly emerged to support operating in such dynamic and fast-paced environments.

Agile Tooling

It would be misleading to consider that agile development can be effective solely with good will, highly motivated independent teams and supporting customers and stakeholders. Agile software tooling aims at freeing software developers from repetitive tasks, while providing immediate and up-to-the-minute feedback on the status of their team's efforts. Developers can therefore confidently test software changes, share their latest progress with their fellow team members without any manual intervention and in the end focus on providing fast updates and concentrating on fulfilling customer requirements.

Agile tooling is necessarily based on software development processes that in most part, originated with heavyweight project management approaches.

SOFTWARE DEVELOPMENT PROCESSES

In order for agile teams to collaborate in a streamlined and manageable manner, well-known project management processes such as :

- Issue management
- Change management
- Dependency management
- Release management

must constantly collaborate and exchange information.

A short summary of each will help us understand their importance, and provide examples of software packages used at CERN to fulfil such demands.

Issue Management

This process focuses on collecting, prioritizing and refining customer demands and internal product quality feedback. Whether use cases, requests for new features or defects identified in existing products, such inputs must be classified and scheduled so as to reduce the risk of unwanted side effects and ensure timely release delivery. Change brought to a product must always take for reference a prior request for such change (once again, to reduce the risk of unidentified and unwanted modifications that could break a working product).

Change Management

This process ensures that changes can be audited, and grouped into coherent set of modifications. Sets of modifications will eventually compose a release. Change management is often seen as a burden by software developers, but becomes a key activity when it is coupled with release management – for instance, once a product version is out in the wild, it is essential to know exactly what differentiates this version from the one that worked better a few weeks or months ago.

Dependency Management

As agile teams happily release ever improving deliverables, being able to orchestrate dependencies among these deliverables becomes an increasingly difficult task. Establishing clear policies and allowing the definition of dependency ranges (*e.g.* by specifying that

Project A can tolerate any of the latest version of Project B, starting from version 1.5 up to version 2.0 and anything in between) becomes a very important aspect of software project management. Considering that software project increasingly rely on third-party open source dependencies, it also becomes important to state and monitor the provenance of such dependencies (*i.e.* if two versions of the same library are available on the internet, one from an untrusted source and one from the official provider of the library, it is naturally preferable to obtain it from the official provider).

Release Management

In order to facilitate software reuse (one of the cornerstones of agile development), software artifacts must be made available in a readily consumable form, so that no time needs to be spent rebuilding such artifacts using the original source (which, if change and dependency management are kept consistent through an established release policy, should of course always be possible). In ITIL v3 [3], a library of best practices in software infrastructure management, a repository used to store readily consumable artifacts is referred to as a **Definite Media Library** (DML). A DML acts as a reference for all artifacts maintained by an organization, and supports features such a search indexes, structured navigation and queries, metadata management and access rights policies enforcement.

Release management also becomes relevant in order to deliver automatic updates to software end-users. Auto-update capabilities have become a common feature of modern operating systems and software packages aimed at the general public.

As an example, the UAB toolset [5] (a development suite for the generation of industrial control systems) offers a Bootstrap utility, illustrated in Fig. 1, which upon startup verifies whether any new versions of the UAB components (such as new device type libraries, new generation plugins etc...) have become available in a central repository.

If new UAB components have been released, end users are offered the possibility to download these components and use them for the generation of their application.

Sonatype Nexus, a commercial DML implementation that acts as an Eclipse P2 repository and a Maven repository, offers a programmatic API (named Aether) which allows to query and download repository contents. The UAB Bootstrap component for instance relies on the Aether API to determine whether new UAB components (in effect, Maven artifacts deployed in Nexus) are available and to download them.

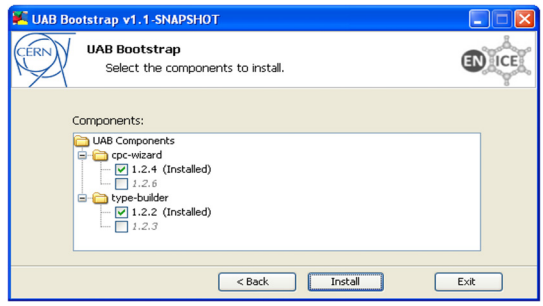

Figure 1: The UAB Bootstrap (using the Aether API).

Continuous Integration

Continuous integration is a quality process that provides constant feedback on changes performed by developers. Coupled with change management, it allows at any point to ensure that developers are informed of regressions (or build breakage) they might introduce in their project.

PROCESSES INTEGRATION

In the context of the UAB project and the LHC Accelerator complex, CERN employs a variety of software packages that support the previously enumerated processes, including :

- **Atlassian JIRA** for issue management
- **Subversion** (SVN) for change management
- **Apache Maven** build for dependency management
- **Sonatype Nexus** as a *definite media library* and release repository for Maven and Eclipse dependencies.
- **Hudson / Atlassian Bamboo** for continuous integration

This best-of-breed selection mixing open-source software with commercial tools operating under various licenses poses necessarily some integration issues. Navigating from one information source is obviously quite possible, as each tool provides navigation links of some sort to its peer processes – but happens to be quite cumbersome when investigating regression issues, plain bugs or releases of insufficient quality due to failure in change or issue management processes.

The CSAR project therefore defines a data format and offers tools that greatly simplify data extraction, navigation and visualization of engineering process related information (when investigating the cause for the introduction of a regression or the presence of a new bug).

Resource Description Framework (RDF)

RDF is a meta-model introduced by the W3C to unify data and meta-data in web-based documents. RDF relies on subject-object-predicate expressions to embed meta-meaning in ordinary data, allowing the data to be processed and leverage by a machine.

RDF acts as an ideal *lingua franca* between our various engineering process support tools, allowing us to harvest all our information and collate it in a navigable way.

Data Visualizations and the Exhibit Framework

Data visualizations represent large amounts of information in an immediately understandable form. Maps, pie charts or tables are traditional visualizations, but others such as heat maps or sparklines can also deliver great expressiveness. In any case, visualizations are decoupled from the data they represent.

The MIT Exhibit framework offer a generic way to represent, query, filter and visualize RDF data. The CSAR project leverages Exhibit and integrates a new visualization yet not supported by the framework for the representation of dependency trees.

Exhibit Reports Build Integration

The CSAR project provides an Apache Maven site plugin – which seamlessly integrates engineering process information into a web-based Maven documentation site [4].

This is particularly useful for continuous integration software packages that support Maven but would not necessarily understand RDF or be able to handle the Exhibit framework.

Fig. 2 presents an example of a Maven generated documentation site integrating an Exhibit report. Once RDF data is provided to Exhibit, the framework automatically generates the required user interfaces elements such as filters and navigation links.

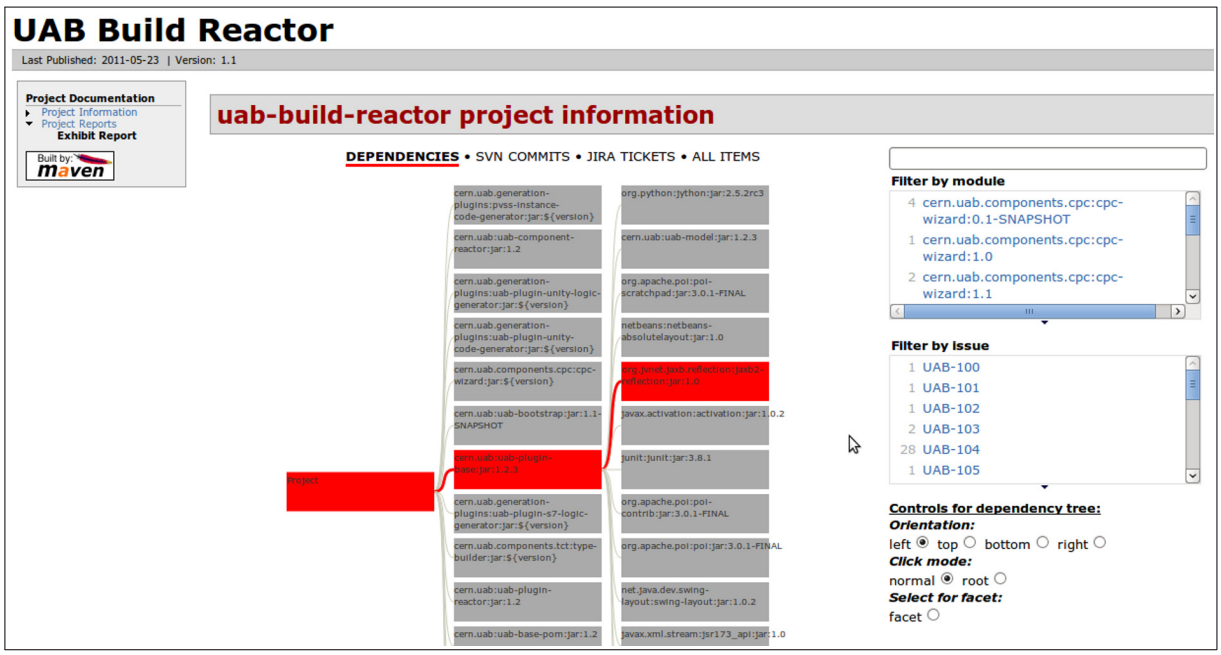

Figure 2: Web-based Maven-generated documentation site with interactive dependency tree and filter fields.

The Exhibit framework also introduces new visualization concepts such as the Timeline visualization, a Javascript widget that allows to browse time-based events, making it particularly suitable for reviewing SVN commit activity or JIRA activity.

Fig. 3 and 4 provide examples of Timeline visualizations as generated by Exhibit according to the RDF data collected by the CSAR collection plugins.

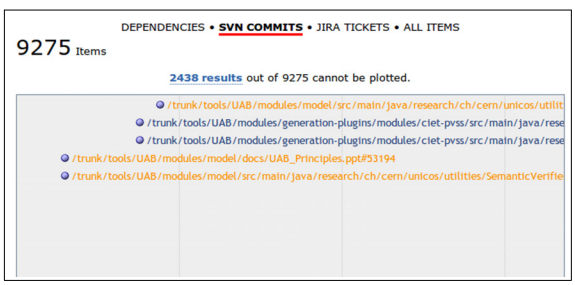

Figure 3: Timeline visualization of SVN activity.

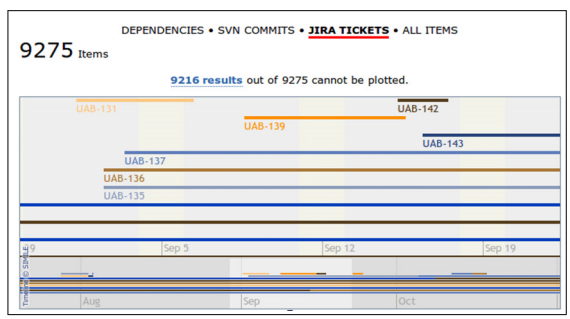

Figure 4: Timeline visualization of JIRA activity.

Timeline visualizations in the Exhibit framework provide navigation links and popup windows which are automatically derived from RDF data.

DATA INTEGRATION

The CSAR project provides Java executables that can be integrated as part of a build process (using their respective Maven plugin wrappers) and extract RDF

information from our various engineering process support systems (JIRA, Maven metadata, Nexus, Subversion).

Once in a unified RDF format, data integration is a matter of collating files together and transforming them to web-friendly RDF dialects (known as Exhibit JSON).

The generation of Exhibit user interface and navigation links is then simply a matter of configuration.

CONCLUSIONS

Integrating software engineering process data sources is useful in order to obtain a global vision of development and release activities. While most engineering process deliver access to structured data, integrating and correlating this information is currently a non-trivial task.

While our usage of RDF as a common data format has certainly proven a workable approach, certain limitations subsist in the current support of RDF. The Exhibit framework for instance was designed highly interactve representation of low volumes of information. A sample extraction of the UAB project activity over the course of 14 months, totalling about 600K lines of code, yielded a 5 megabytes Exhibit JSON input file containing 9275 records, which the Exhibit framework handles with difficulty (requiring a 20 seconds initial startup time and delivering occasional sluggish data filtering performances).

A complete rewrite of the Exhibit framework (Exhibit v3) is interestingly under way in order to ease the integration of third party visualizations and make it able to cope with datasets gathering more than 5 millions of records.

QUICK EXAFS EXPERIMENTS USING A NEW GDA ECLIPSE RCP GUI WITH EPICS HARDWARE CONTROL

R. J. Woolliscroft, C. Coles, M. Gerring, M. Pearson, Diamond Light Source, Oxfordshire, UK

Abstract

The Generic Data Acquisition (GDA) framework [1] is an open source, Java and Eclipse RCP [2] based, data acquisition software framework for synchrotron and neutron facilities. A new implementation of the GDA on the B18 X-ray beamline at the Diamond synchrotron will be discussed. This beamline performs energy scanning X-ray Absorption Spectroscopy (XAS) experiments. It includes a continuous-scan mode of the monochromator synchronised with various detectors for Quick EXAFS (QEXAFS) experiments. XAS energy scans may now be performed in 30s, where the equivalent step scans take approximately 40 minutes.

A new generic perspective for the GDA client has been developed in which graphical editors are used to write XML files which hold experimental parameters. The XML files are marshalled by the GDA server to create Java beans used by Jython scripts which run on the GDA server. Underlying this, a new generic continuous scanning mechanism for the GDA has been developed. The new Eclipse RCP UI, the new continuous scanning mechanism, new hardware development and integration between the two systems shall be covered.

INTRODUCTION

XAS is a mature X-ray technique, with a wide range of applications across scientific disciplines. As a result, there is a need at modern synchrotrons to provide robust and highly automated XAS beamlines, designed to be used by both experienced and occasional users.

B18 is a general purpose XAS photon beamline, complimentary to other XAS beamlines at Diamond. A new quick scanning mode has been developed in which EXAFS data can be collected with a continuous move of the monochromator.

The experimental hutch has two sample positions; an in-vacuum position for 2-4keV (soft X-ray) and an in air position for 4-36keV (hard X-ray). The hard X-ray position has a large experimental area for a range of sample environments (Fig. 1).

DETECTOR

Fluorescence data for EXAFS studies is collected using a 9 element XSPRESS Ge detector [3]. This detector can collect at high count rates whilst being placed close to the sample to maximise the fluorescence yield.

The detector is controlled by a Time Frame Generator (TFG2) [3] card which has a number of programmable input and output signals. The TFG2 card is used to receive and fan-out signals from the monochromator Bragg motor during a quick scanning data collection (Quick EXAFS or QEXAFS). It can be used to drive other detectors which may be used during the experiment. For the QEXAFS experiments, most commonly used are the ion chambers which provide a normalisation for the fluorescence yields.

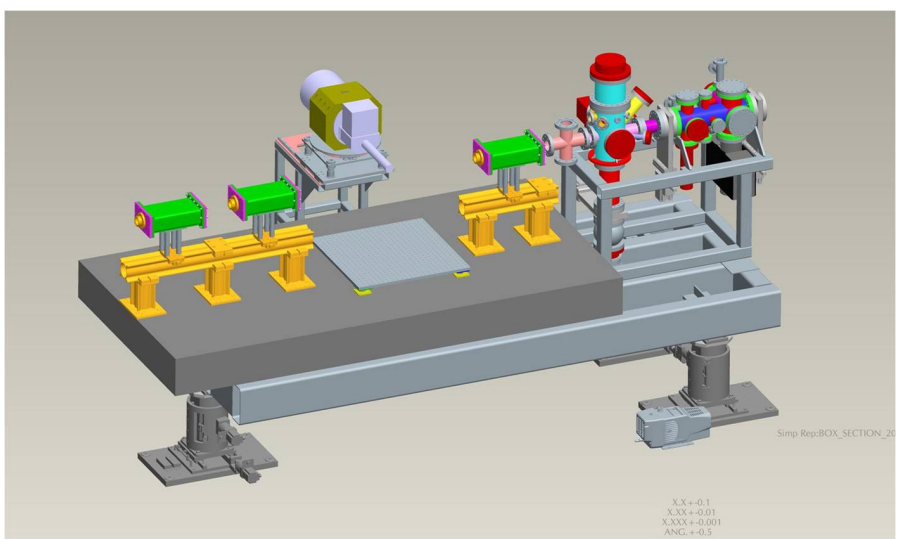

Figure 1: Diagram of the B18 experimental hutch. The in-air sample location is shown. This has a large area for a range of sample environments. The XSPRESS detector for fluorescence and the ion chambers for transmission measurements are shown.

HARDWARE FOR QEXAFS EXPERIMENTS

The monochromator Bragg axis is controlled using a DC brushless in-vacuum motor, with four encoders placed at equal distance around the stage. There is also an encoder on the back of the motor. A Delta Tau Geobrick Low Voltage Integrated Motion System (LV IMS) is used as the motor controller, and this is the Diamond standard controller for beamlines currently being constructed. The Bragg axis and crystal distance axis are controlled together to provide an 'energy' combined axis, and these calculations are performed directly on the controller. This provides us with true synchronised motion of Bragg and crystal distance. Using this control method a very smooth continues motion between two energy points can be achieved, at speeds of up to 1deg/s.

The Experimental Physics and Industrial Control System (EPICS) [4] is used to control and set up the motor controller. Each axis controlled by the Geobrick has an EPICS Motor Record interface, which provides a consistent 'motor' interface for the GDA. The same interface is used for the virtual 'energy' axis, which means the GDA can treat the energy axis as any other axis, and scan it in the same way.

The EPICS Input Output Controller (IOC) is also responsible for setting up the 'position compare' trigger signals for the Bragg axis. These are TTL pulses produced by the Geobrick as the Bragg axis encoders increment in position. The triggers are fed directly into the TFG2 card, which is controlled by the GDA. The readout of the ion chambers is performed using a GE-Fanuc 110BL VME ADC card. This is a 24-bit sigma-delta ADC running at up to 108KHz, which is read out through a new driver used by an IOC running VxWorks.

The trigger signals that are fed into the TFG2 card are used to provide a 'gate' signal. This signal is read into one of the ADC channels, and is used to provide a means by which the IOC can calculate mean and standard deviation of the samples collected during the gate period. Gates as long as several seconds and as short as 1ms are used. Buffering of this data is provided by the EPICS IOC in arrays, so that they can be read out asynchronously by the GDA. However, if required, raw ADC count data is also provided by the EPICS IOC.

NEW CONTINUOUS SCAN

The GDA has a flexible and powerful step scan mechanism which has been applied to the full range of techniques used at the Diamond synchrotron. A new generic continuous scan mechanism was developed for implementation on the B18 beamline, but which could easily be applied to other beamlines with suitable hardware.

Existing Scanning Mechanism

The generic scanning mechanism is available through the *scan* command in the GDA Jython environment. Behind this command is a single class (*ConcurrentScan*) which operates both hardware and detectors in n-dimensional step scans. This operates the hardware through two high-level interfaces: *Scannable* and *Detector*.

The Scannable interface enables the scanning mechanism to operate those objects to be incremented during the scan, and to know what information is supplied by that object at each point. Scannables can represent a wide variety of objects; simple motors, compound motions or even offline data processes which return the results of their calculations asynchronously.

The Detector interface is an extension to the Scannable interface. At each point in the scan Detector objects are used to collect data after the Scannable objects have completed their step movement.

Working with the ConcurrentScan class is a system to broadcast the data from each step in the scan to parts of the UI for live data display to the user and to file writers to record the data in various data formats. The performance of this system is fast enough to cope with large and frequent data points at the speed expected in B18 QEXAFS scans.

Extension to the Scanning Mechanism

The new continuous scan mechanism is designed to work within the existing step scan mechanism. It incorporates many aspects of that system to maximise code reuse. Its design has analogous interfaces: ContinuouslyScannable and BufferedDetector, which are extensions of the Scannable and Detector interfaces respectively.

There is a new single generic continuous scan class (ContinuousScan) which uses those generic interfaces. This class extends the ConcurrentScan class so the continuous scan may be used as the innermost dimension of an n-dimensional step scan. For example, from a single command, the user may loop over a series of samples in an automated changer and perform a QEXAFS scan on each one.

B18 implementation

An implementation of the ContinuouslyScannable interface was written for B18 which operates the Bragg motor via EPICS and controls the position compare parameters. The XSPRESS detector is operated by an implementation of the BufferedDetector interface from which the amount of data stored and the data itself can be retrieved asynchronously by the scan class.

In the B18 QEXAFS scan, the ContinuousScan class is given the experimental parameters and references to the Bragg ContinuouslyScannable and XSPRESS BufferedDetector objects. The hardware is prepared for the scan, and once the Bragg motor motion has been started the scan class polls the XSPRESS BufferedDetector for new data. As new data becomes available, then the existing step scan's mechanism for recording and visualizing the data is used.

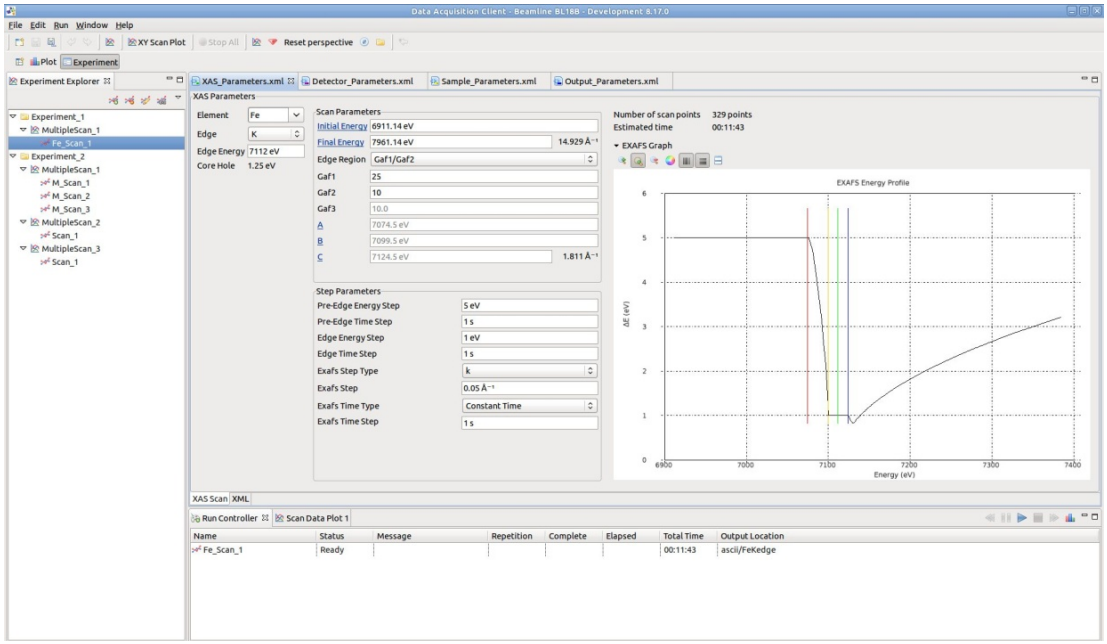

Figure 2: New Experiment perspective for users to design experiments. In B18's implementation four graphical editors are used to write the four XML files which define each experiment. The visible editor is the EXAFS step scan editor.

NEW RCP UI

B18 was the first newly commissioned Diamond beamline to use a GDA client based on the Eclipse RCP platform. A range of generic perspectives have been developed for tasks such as visualisation of data files and Jython scripting.

A new generic perspective, shown in Fig. 2, was written which uses graphical editors to allow users to edit XML files holding the experimental parameters. The perspective has views to manage the XML files and to run a single or a group of experiments (*multiscans*). Multiscans allow several experiments to run sequentially. Multiscans may be stored in different file system folders to keep the files organised. The UI provides a tree view of the multiscans and functionality such as drag and drop to move individual experiments between multiscans. There is a view to run the selected multiscans and display progress.

The perspective is configured using Eclipse extension points and may be applied to other beamlines which could use XML files to define each experiment.

For B18 there are four XML files to describe each experiment. These hold the scan parameters, detector options, sample environment setup and readout options. There are three different editors which write scan parameters to reflect the different experiments run on the beamline: EXAFS, XANES and QEXAFS (detail shown in Fig. 3).

Design

To collect data the UI unmarshalls the XML files into Java beans. These beans are used in a Jython script running on the GDA server which uses the information in those beans to set up the hardware and run appropriate scan commands.

Data is returned to the UI for display and analysis in the same manner whether the scan is a quick or regular EXAFS.

A custom perspective has been written to view experiments in progress, as shown in Fig. 4. This contains views to display the current experiment progress; XSPRESS count rates; visualisation of the data as it becomes available and online data analysis. Graphs show standard XAS analyses: background subtraction, first derivative of the data and the Fourier transform.

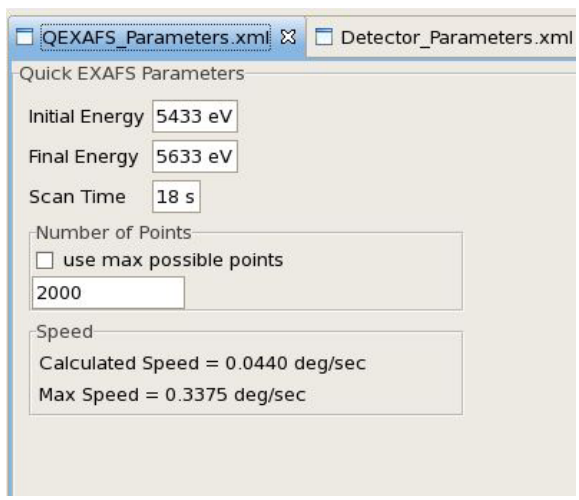

Figure 3: Detail of the Experiment perspective showing the QEXAFS editor.

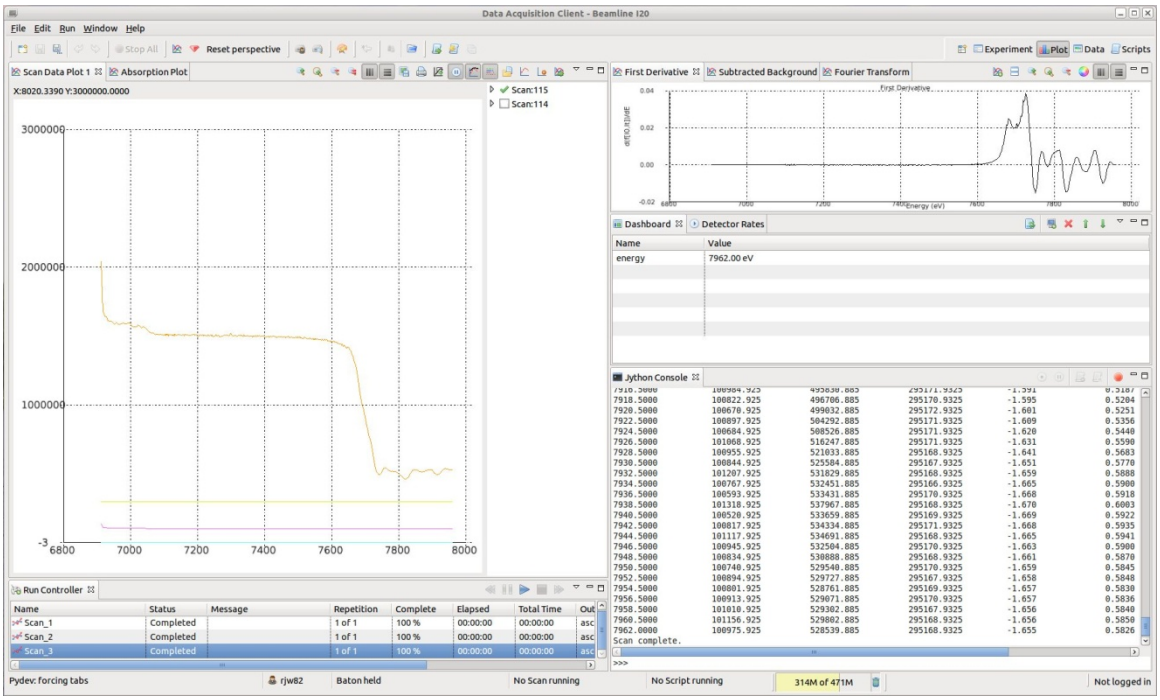

Figure 4: The Plot perspective for Diamond XAS beamlines. This shows data from the experiment in progress. Live plots of the absorption, first derivative of the data after background subtraction, the subtracted background and FFT are shown in other views. The Run Controller view from the Experiment perspective is also shown so experiments may be started from within this perspective.

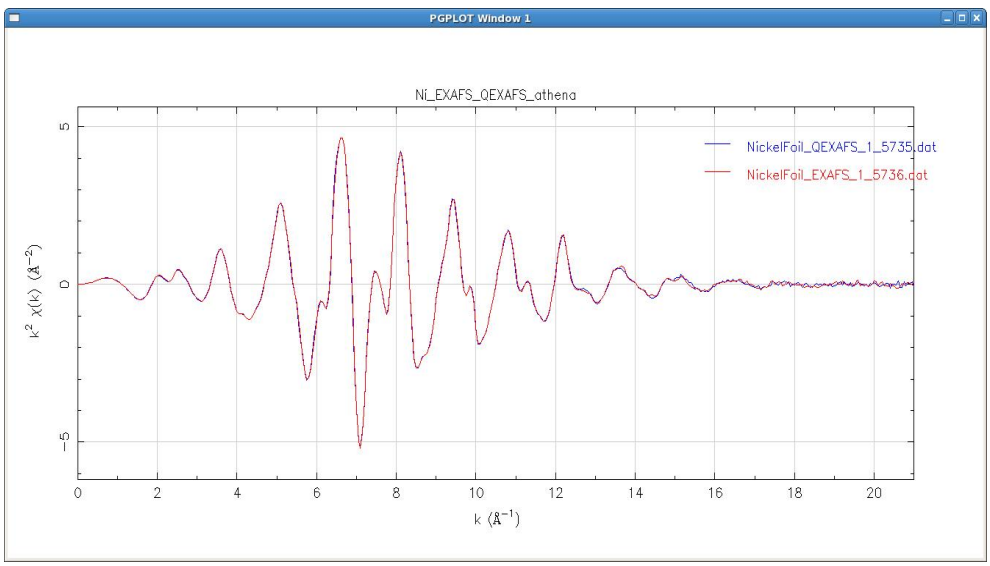

Figure 5: Figure shows the first Quick EXAFS spectrum taken in 60s (25ms per point) (red curve), compared to a step scan running for 50 minutes (1-5s per point) (blue curve).

PERFORMANCE

A typical time for a QEXAFS scan is about 30s where typical step scans take 20 to 40 minutes. The QEXAFS results have been shown to be comparable to step scan data (see Fig. 5).

The QEXAFS mode has been available since Spring 2011 and is currently requested by about a third of proposals to the beamline.

AN OBJECT ORIENTED FRAMEWORK OF EPICS FOR MICROTCA BASED CONTROL SYSTEM

Z. Geng#, SLAC, Menlo Park, California, U.S.A.

Abstract

EPICS (Experimental Physics and Industrial Control System) is a distributed control system platform which has been widely used for large scientific devices control like particle accelerators and fusion plant. EPICS has introduced object oriented (C++) interfaces to most of the core services. But the major part of EPICS, the run-time database, only provides C interfaces, which is hard to involve the EPICS record concerned data and routines in the object oriented architecture of the software. This paper presents an object oriented framework which contains some abstract classes to encapsulate the EPICS record concerned data and routines in C++ classes so that full OOA (Objected Oriented Analysis) and OOD (Object Oriented Design) methodologies can be used for EPCIS IOC design. We also present a dynamic device management scheme for the hot swap capability of the MicroTCA based control system.

INTRODUCTION

Object oriented analysis and design method has become more and more popular in software engineering field, especially after the appearance of UML (Unified Modelling Language) [1] and MDA (Model Driven Architecture) [2].

EPICS has introduced object oriented (C++) interfaces to most of the core services including the operating system abstraction layer. But the major part of EPICS, the run-time database, only provides C interfaces, which is hard to involve the EPICS record concerned data and routines in the object oriented architecture of the software.

The Object Oriented framework for EPICS (OOEPICS) provides several base classes to encapsulate the details of the record processing. The EPICS records and the devices are designed as objects which enable the direct translation of the UML model into EPICS applications. The framework hides most of the details of the EPICS which enable the user to develop his EPICS device driver without knowing much of EPICS.

The OOEPICS framework was originally designed for a MicroTCA based control system which requires dynamic objects creation and deletion to support the hot swap capability of the system. The EPICS base was extended to be able to load the EPICS records dynamically during run time.

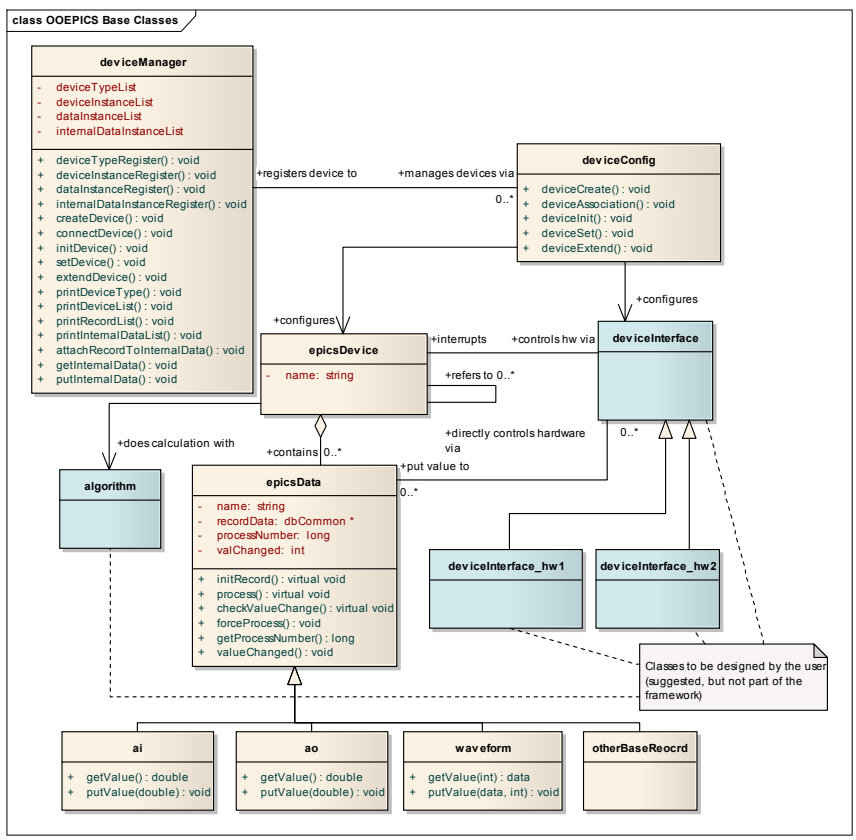

Figure 1: Base classes of OOEPICS framework.

#gengzq@slac.stanford.edu

OOEPICS FRAMEWORK

The OOEPICS framework consists of several base classes and a tool for source code generation which provides a template for the user application.

Base Classes

Figure 1 shows the base classes of the OOEPICS framework.

The base classes setup the basic architecture of the software. Any EPICS applications using the OOEPICS framework can be designed by inheriting the base classes for specific devices.

- epicsData is the base class for EPICS records and device support routines, which realizes some common functionality such as creating EPICS database when the object is created. From that, child classes are derived for all basic EPICS records, such as ao, ai, waveform and so on.
- epicsDevice is the base class for the devices to be controlled which may contains epicsData objects as interfaces to the Channel Access clients.
- deviceConfig realizes common interfaces to configure a device, including registering the device type, creating instances of the device objects and initializing the devices like starting up the threads for the device control.
- deviceManager manages all devices and provides IOC shell commands for device management.

EPICS Records

The key part of the OOEPICS framework is to define an object for each record. The EPICS records were designed more or less based on the object oriented concepts. Table 1 compares the EPICS records and the C++ classes.

Table 1: EPICS Records and C++ Classes

EPICS Records	C++ Classes
Fields	Attributes
Record Support	Methods (platform independent)
Device Support	Methods (platform dependent)

The class of epicsData is defined for the EPICS record. They are linked together by the record name. The object of the class will load the record and obtain the address of the record data during creation and the record will get the address of the object and use its methods as device support.

EPICS Devices

The epicsDevice class is an empty class where the user codes need to be implemented for the control of specific devices.

The epicsDevice class may contain of:

- epicsData objects for uplink control and monitoring.
- Special logic to perform the device control, probably state dependent.
- Algorithms to do signal processing, calibration, optimization and so on.
- Common logical interfaces to interact with physical device.

Device Manager and Configuration

The deviceManager and deviceConfig provide a common way to create, associate, initialize and set up a device control module in user IOC.

The deviceManager class also provides the EPICS API that can be called in the IOC shell. In principle, the user does not need to create any IOC shell commands.

The deviceConfig class should be realized by the developer for specific devices.

Code Generation

The tool of "epics_driver_template" is designed to generate the source code template from the EPICS database file.

The tool will compile the database file into C strings and then use them to initialize the epicsData objects. A derived device class will be generated with the epicsData objects as attributes. A derived deviceConfig class will be generated which allows to define the procedure to create, initialize and setup the device objects.

Development Procedure

Figure 2 shows the procedure for developing EPICS device driver modules with the OOEPICS framework.

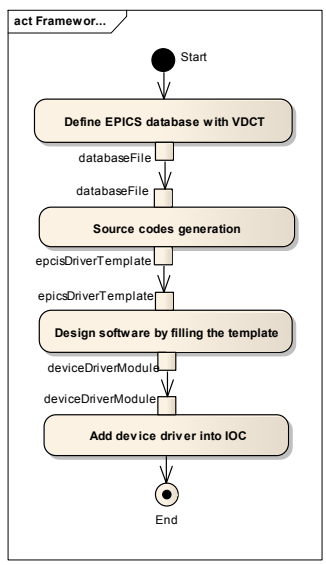

Figure 2: Design procedure with OOEPICS.

DYNAMIC RECORDS LOADING

MicroTCA is hot swappable which allows plugging in new boards without rebooting the crate. The EPICS IOC needs to support such features, which means, loading the device drivers for the new boards without rebooting the IOC software.

The existing EPICS base does not support dynamic record loading. All records must be loaded before executing the iocInit() command. In order to support loading records after iocInit(), the EPICS base needs to be extended.

EPICS Base Extension

Figure 3 shows the architecture of part of the EPICS base concern to the records.

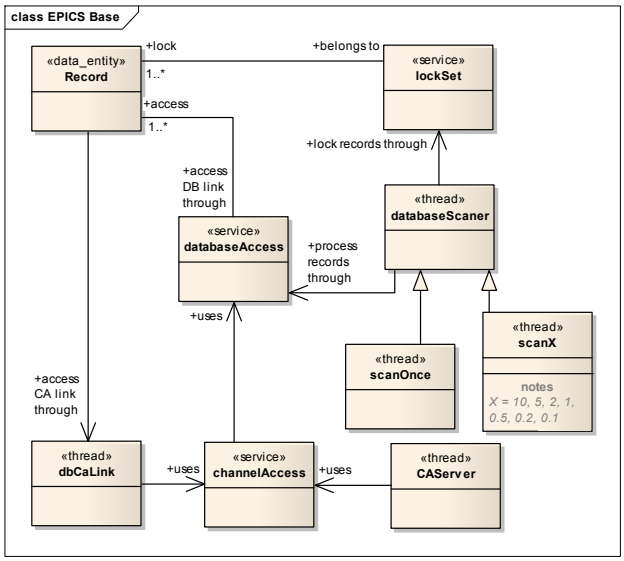

Figure 3: EPICS base modules acting on the records.

Several challenges need to be resolved to load a record during run time:

- Setup the locksets for the newly loaded records. If the new records have no links, simply create new lockset for each of them. If the new records have links with existing records within the same lockset, add the new records to the lockset. And if the new records have links with existing records within different locksets, merge the locksets and add the new records to it.
- Convert PV links to DB link or CA link during record initialization. When converting the PV links, the destination records may have not been loaded yet, so, when a new record is loaded, the record instances loaded previously need to be reconsidered to finish the link conversion.
- Modify the links of existing records. When a new record is loaded, the existing records may want to change their link to point to the new record. In this case, the lockset of the record to be modified should be split firstly and then merged with the lockset of the new link destination.

For solving the problems listed above, a new source file (dbRecordDynamic.c) is added to the EPICS base [3].

The OOEPICS framework and the dynamic records loading functions have been successfully tested in a soft IOC controlling a Newport motion control stage.

CONCLUSION

The OOEPICS framework provides a way to fully access the EPICS records from the user code. The object oriented technology can directly map to EPICS design. It also provides a common way to create, initialize and setup the device driver from the IOC shell. It also enables the user to do EPICS development without knowing much of EPICS, avoiding the long learning curve of EPICS.

The dynamic records loading development provides a good support for hot-swappable system control which enables a complete EPICS based solution for MicroTCA system in the following projects at SLAC.

ISAC EPICS ON LINUX: THE MARCH OF THE PENGUINS

J. Richards, R. Nussbaumer, S. Rapaz, and G. Waters,
TRIUMF, Vancouver, B.C., Canada

Abstract

The DC linear accelerators of the ISAC radioactive beam facility at TRIUMF do not impose rigorous timing constraints on the control system. Therefore a real-time operating system is not essential for device control. The ISAC Control System is completing a move to the use of the Linux operating system for hosting all EPICS IOCs. The IOC platforms include GE-Fanuc VME based CPUs for control of most optics and diagnostics, rack mounted servers for supervising PLCs, small desktop PCs for GPIB and RS232 instruments, as well as embedded ARM processors controlling CAN-bus devices that provide a suitcase sized control system. This article focuses on the experience of creating a customized Linux distribution for front-end IOC deployment. Rationale, a roadmap of the process, and efficiency advantages in personnel training and system management realized by using a single OS will be discussed.

INTRODUCTION - HISTORY

The ISAC control system, implemented using the EPICS toolkit, is completing a migration to use only the Linux operating system for both channel access clients and IOCS. This differs significantly from the original system concept of 1997 in which all IOCS were Motorola VME CPUs running VxWorks, SUN/Solaris was used for the development and production servers, and operator console displays ran on Windows PCs acting as X-terminals [1].

To solve reliability problems, Redhat Linux desktop distributions replaced Windows as the operating system on the operator consoles as early as 2003. Also in 2003, the first i486 processors in the PC104 form-factor and running VxWorks were deployed as IOCs that interfaced with PLCs using TCP/IP [2]. VxWorks boot parameters were installed into the PC104 BIOS via the JTAG interface, which required legacy parallel port hardware and Windows software. To replace or re-function a unit required a new JTAG download via a dongle. By 2005, more powerful Pentium III-based VME CPUs (GMS Mariner – 64 MB RAM) running VxWorks were introduced as replacements for selected MV162 (16 MB RAM) installations.

At that time it became apparent that the maintenance and knowledge support for three different operating systems (Windows,Solaris,VxWorks) was putting too much strain on the resources of the small controls group. As EPICS provided operating system independence for IOCs with release 3.14, a long-term goal was formulated to use Linux as the only operating system in the ISAC control system. Linux is feasible because ISAC is essentially a DC machine which does not demand hard real-time performance from the control system.

Experience using Linux as the operating system on servers, consoles, and developer desktops proved that this single operating system could meet most control needs. Over the period 2004-2010 all the SUN/Solaris hardware was retired and replaced with rack mounted servers running Scientific Linux. Virtualization technology on servers allowed services to be split into single-function servers (database, web, file, dns, ldap) with precise access control. Linux also reduced annual licensing and hardware costs.

The final frontier for Linux deployment was the IOC. Problems with instability on the PC104's VxWorks 5.4 network stack led to replacement with rack-mounted servers running Scientific Linux (SL) which host multiple IOCs. This architecture/OS model met the IOC criteria for stability, reliability, and extensibility. Deployment of single-purpose IOCs on PCs running Redhat desktop distributions began in 2005 [3]. These Linux PCs were used to both develop the IOC application and to deploy it in the field. This "unclean" combination of development and production machine led to the necessity of having "hot spares" available. The PC towers were also prone to hardware failures of hard drives, fans, as well as other problems encountered in the sub-optimal accelerator-laboratory floor environment. As the number of these PC installations grew, so did the effort of Linux administration.

A PROTOTYPE IOC RUNNING LINUX

The need for a small form-factor, low power, no-moving-parts IOC host was identified, and the TS-7350 [*] ARM-based Single Board Computer (PC104 form factor) was chosen as an evaluation platform. Methods for performing software development and field deployment were developed, tested, and deemed acceptable

A project that required a small and highly portable control system for 4 power supplies and 2 vacuum gauges required a microprocessor that was robust, with no fans or spinning media. The ARM units met these criteria. Technologic Systems provide a development kit with a customized Debian Linux distribution and proprietary drivers. A daughter board, TS-CAN1, enabled connectivity to a CAN-bus network using the open-source Ocera-lincan [†] driver, and in-house EPICS device support modelled after existing CAN-bus support. The result was a very small system, with the ARM IOC booting from SD flash within 40 seconds, connected to 5 CAN-bus-attached microcontrollers. A laptop hosting EPICS

[*] http://www.embeddedarm.com/products/board-detail.php?product=TS-7350

[†] http://www.ocera.org/download/components/WP7/lincan-0.3.3.html

channel access extensions serves as an operator console and boot host. This “Control System in a Suitcase” could be deployed for acceptance tests on factory floors. It provided the background experience for identifying the way we want all fieldbus-connected Linux IOCs to work.

EMBEDDED X86 IOC REQUIREMENTS

From the experience gained with the installations mentioned above the following requirements for a generic embedded Linux-x86 IOC were defined (rationale in parentheses):

- No moving parts (increase reliability)
- Network boot – no dongles (simplify maintenance)
  - Reboot time < 40 s (derived from ARM)
- Application agnostic hardware. The target computer does not associate with an application until booted. (eliminates a dedicated "hot spare" per IOC)
- A Linux distribution tailored to ISAC Controls IOC needs (i.e. **Isaclinux**).
  - known kernel composition with all functionality understood
  - kernel to include only services required for our IOC objectives
  - must use standard kernel source distributions
  - root file system must be minimal in size, exposing minimal utilities (reduce security risks, fast boot time)
- Replace the functionality of currently installed VxWorks IOCs
- Separation between application development and production environment – analogous to the VxWorks model where products are created by a cross-compiler on a development host and deployed to different target at run time

METHODS

- The hardware selection for the VME bus was VMIC 7648(Pentium III, 1260 MHz, 512K cache, 128 MB RAM) which we acquired at discount pricing. For RS232/RS485 and GPIB buses we selected a mini ITX motherboard (Atom N270, 1.6 GHz, 512 K cache, 1 GB RAM). These units have low power consumption, low heat load and solid state drives which should translate to high reliability. The ITX provides 2 exposed serial ports, plus an addition 4 on the motherboard. It also provides 2 PCI slots for expansion cards for such buses as GPIB and CAN. This product was considered to have a reasonably long product future and hence a high availability of supply.

- Both hardware architectures selected allow for network boot via their BIOS setups. The industry standard Preboot Execution Environment (PXE) protocol is implemented with pxelinux[‡] and TFTP for diskless, network-only, booting, The VMIC boot time averages 36 seconds. The ITX/Atom pxelinux boot is much slower, 140 seconds. However, by using the enhanced utility, gpxelinux, the ITX/Atom boots in approximately 40.
- Agnosticism was achieved by using a centralized boot system and common root file system. Kernel command line arguments are exposed to the /proc file system and can be accessed by user space applications. A single user space script file "/etc/init.d/rcS" associates kernel command line keywords with functionality. This script is easy to customize, easy to understand, and well structured. Custom keywords are used to identify scripts to run prior to launching an IOC application, such as GPIB or Ethernet private network setups. Other keywords identify the IOC application boot directory and start-up script.
- Customization of an existing Scientific Linux distribution was attempted but abandoned when the difficulties of obtaining kernel sources was apparent. Rather than paring down a bloated desktop release, a very compact Linux distribution was selected as a starting point. Micro Core Linux[§] is a 6MB text-mode distribution of Tiny Core Linux, boots very quickly, uses a Linux 2.6 kernel, and utilizes Busybox[**] for core utilities. The entire Micro Core Linux file system was converted, in-house, to an initrd format. On-going customization of the initrd as well as tools and methods for testing and deployment have rendered the existing incarnation fully disconnected from its ancestry.
  The Micro Core kernel was further pared from 2.2 to 1.8 MB and rebranded as the Isaclinux kernel. Root file system customizations have added 4 MB to the Micro Core starting size, resulting in an Isaclinux file system of 10 MB. The main customization was to the rcS script for launching applications. Other additions for Isaclinux include: ssh server (Dropbear), GNU screen (used to provide a sharable IOC console), C-Kermit (useful troubleshooting tool for serial I/O), EPICS libraries and utilities (e.g. camonitor, caRepeater), and dependency libraries (e.g. libreadline, libncurses, libpcre).
- EPICS OSI library routines for VME are only available for VxWorks and RTEMS. Thus, a

[‡] http://www.syslinux.org
[§] http://distro.ibiblio.org/tinycorelinux
[**] http://busybox.net/

port of a number of EPICS drivers from VxWorks to Linux was undertaken. For the VMIC7648 IOC target, the GE-Fanuc VME_UNIVERSE kernel driver is available[††]. Using the driver's API library a support library for EPICS applications was created that includes a set of access routines that create access windows to the VME bus and convert bus addresses to local addresses for specific VME devices (e.g. sysMapVmeMaster and sysBusToLocalAdrs), interrupt connect routines, and OSI wrappers for VME access. The use of OSI wrappers minimized the software changes required when porting VxWorks device drivers to Linux. Since the VME bus is a Big-endian bus and x86 CPUs such as the VMIC7648 are Little-endian, it was necessary to add byte swapping macros to all VME access operations.

A number of VME device support software changes were also required. For the CAN-bus TEWS Tip810 driver connected via TVME200 VME-bus industry pack carriers, the message receive task was throttled to prevent CPU hogging. The OMS58 receives commands via a 256 byte circular input buffer. On the Pentium based VMIC7648, command acceptance time-outs made it necessary to throttle the send_mess() function in the OMS58 driver code using the POSIX standard function nanoSleep().

- Separation of development and production environments is clearly met by the Isaclinux deployment model. The system is designed to run from a RAM copy created at boot time. Besides being fast, this protects system files from changes and ensures a pristine system on every reboot. This is analogous to the VxWorks model where the VxWorks OS is loaded over the network at boot time. Isaclinux changes can only be introduced via the initrd file system produced on the development server. A Debian development host having the same kernel vintage (2.6.33) as Isaclinux is used to produce the EPICS applications. Using the same C Library and compiler ensures compatibility between run-time environment and EPICS applications

RESULTS – LESSONS LEARNED

One of the primary goals for the Isaclinux project was to standardize deployed systems and stop the proliferation of different hardware architectures, operating system distributions and versions, thereby minimizing system administration overhead. This has been achieved. The development process also offered an opportunity for all authors to become familiar with the internals of the Linux operating system.

The need to customize kernels led to the conviction that a Debian distribution provides a better development platform for embedded systems than Redhat type distributions since access to kernel sources is more standard. The Debian project has official support for embedded systems, including support for the ARM microprocessor. Debian distributions include more up-to-date software related to software development (compilers, libraries, etc.). On the rack-mounted IOC servers that require only TCP/IP to connect to PLCsScientific Linux is still used as the operating system.

We still have some dependency between what we build and where we build it – that is, we have not achieved a cross-native compiling. It would be nice to have a toolchain that creates the target kernel, libraries and apps that could be deployed on any Linux server but our project time ran out. Further enhancements that we are developing include a deployment infrastructure. This consists of packaging the root file system in initrd, version control (legacy/stable/test) of each kernel and root file system, benchmark and regression testing on development hardware and a standardized deployment procedure for production. A configuration tool that provides for event logging of changes to dhcp, pxe, kernel, and initrd is under development.

The VMIC deployments have some issues with certain hardware models. Joerger VSC16 scalers occasionally generate “uninitialized interrupt messages”. VxWorks handles these gracefully and performance is not affected. However on Linux these result in the scaler locking on vector 255. A non-elegant stop gap measure that limits us to one scaler only in any VME crate is to always use vector 255. The CAN-bus interrupt handler works well on 1260 MHz VMICs but blocks erratically on 928.1 MHz clock models.

To date we have Isaclinux deployed in a single VME crate and are awaiting a shutdown period to allow replacement of more VxWorks installations. A number of ITX/Atoms that use StreamDevice for GPIB, RS485, and Ethernet fieldbuses have been installed in the control system. We are evaluating their suitability as digital power supply controllers. For the Atoms, we have also implemented Wake-On-LAN to allow remote restart.

The utility of the ARM with its smaller form-factor is still being explored. Although it is not network-boot enabled (uses boot flash), it loads its applications from an NFS mount. We also have found it to serve well as a serial console for other IOCs, and as a CAN-bus loop packet sniffer.

CONCLUSIONS

The ISAC Control System has a response rate requirement of only 10 Hz. This can be met by an operating system such as GNU/Linux that is not classified as real-time. To minimize IOC application pre-emptions, it is advisable to have the IOC Linux host run only essential services. Isaclinux is a small footprint,

[††] Customizations by TRIUMF DAQ Group.

customized version of a 2.6 Linux distribution. It provides minimal services such as SSH, NTP, DHCP, and NFS needed for a network booted IOC. Its use on such platforms as the GE-Fanuc and Atom allow control of devices on fieldbuses such as VME, GPIB, RS232, and Ethernet.

Linux is now used in all tiers of the ISAC Controls task model including servers, operator consoles, and IOCs. One operating system, understood by all controls personnel, allows a small group of control engineers to share maintenance and development duties easily. This strategy facilitates a sharing of administration duties, concentrates on one platform only for device drivers, and has already proven invaluable in troubleshooting situations.

STATE MACHINE FRAMEWORK AND ITS USE FOR DRIVING LHC OPERATIONAL STATES

M. Misiowiec, V. Baggiolini, M. Solfaroli Camillocci, CERN, Geneva, Switzerland

Abstract

The LHC follows a complex operational cycle with 12 major phases that include equipment tests, preparation, beam injection, ramping and squeezing, finally followed by the physics phase. This cycle is modelled and enforced with a state machine, whereby each operational phase is represented by a state. On each transition, before entering the next state, a series of conditions is verified to make sure the LHC is ready to move on. The State Machine framework was developed to cater for building independent or embedded state machines. They safely drive between the states executing tasks bound to transitions and broadcast related information to interested parties. The framework encourages users to program their own actions. Simple configuration management allows the operators to define and maintain complex models themselves. An emphasis was also put on easy interaction with the remote state machine instances through standard communication protocols. On top of its core functionality, the framework offers a transparent integration with other crucial tools used to operate LHC, such as the LHC Sequencer. LHC Operational States has been in production for a year and was seamlessly adopted by the operators. Further extensions to the framework and its application in operations are under way.

RUNNING LHC

Introduction

A ***state machine*** is a model used in computing. It is composed of states connected by transitions and associated with actions. State machine holds a status where an active state is its most essential attribute.

LHC

During the first period of LHC run it was decided to introduce a state machine with the scope of increasing the operational performance and ensuring control of the LHC operations.

The *LHC Operational States* state machine has a threefold aim of:

- minimizing the risk of errors and mistakes,
- lowering human risk factor,
- increasing machine efficiency by reducing time losses and creating more rigid structure for the LHC nominal cycle.

Meeting such goals has a natural consequence in form of diminished flexibility for the operations, the trade-off all have agreed upon. Moreover, although *Operational States* helps maintaining a high level of equipment safety, it is not a safety but an operational tool.

In order to have a reliable convenient tool, able to cope with the large number of different situations faced by the LHC operations, the state machine had to be carefully studied and prepared. Twelve states were identified, as shown in Table 1. Each LHC machine state is a condition in which the LHC can be found during its lifecycle. In any state, the execution of certain tasks has been restricted (i.e. while the state machine is in "preparation" and there is no beam it is not possible to declare "stable beams" mode) to ensure that no wrong action is performed in critical operational phases.

Table 1: Description of LHC Operational States

state	description
PREPARATION	LHC is prepared to inject beam. All devices are prepared, magnets set to injection current.
INJECTION PROBE	The probe beam is injected and the beam parameters (tune, chromaticity, etc) are checked before injecting nominal beam.
FILLING	Nominal bunches are injected filling the machine.
PREPARE RAMP	Orbit correction and device preparation for ramp is performed.
RAMP	Energy ramp from injection (450 GeV) to nominal.
SQUEEZE	Squeeze beam to nominal value.
ADJUST	Beams are set in collision.
STABLE BEAMS	Experiments can move in their reading devices.
BEAM DUMP	A programmable or unplanned beam dump has happened.
TEST	Used during Stop to test software changes. No limitations applied.
STOP	LHC is not operational (cryo stop, device repair, technical stop).
INJECT DUMP	Special test with operational configuration: beams are injected then dumped immediately after.

STATE MACHINES

Basic Terms

State machine diagram, a ***layout***, is composed of ***states*** and ***transitions***. Each transition is directed, linking precisely two states, hence the whole diagram constitutes a directed cyclic graph. States and transitions are uniquely named, as well as the state machine itself, the ***instance***. Exactly one state is qualified ***initial***, while the others can be assumed ***final***, from which nothing else can be

reached. The current state of the instance is marked ***active***. In principle, there may be only one initial and one active state, being the same at the start of the instance lifetime.

Moving from state A to state B is feasible only if A is *active* and there exists a *transition* from A to B. Moreover, a set of ***actions*** can be assigned to the layout and required to be successfully performed while moving between states. Performing an *action* may relate to any additional operation executed by an *instance* and yield a success or failure. If an action is identified ***fail-forward***, failure is considered neutral to the *move*, otherwise the new *active* state must be decided.

An *action* can be placed in one of three ***locations*** with regard to a single transition or state:

Table 2: Location of Actions

(1)	***on exit***	while *leaving* state A; all transitions from A
(2)	***on transition***	while *moving* from A to B; transition A->B
(3)	***on entry***	while *entering* state B; all transition towards B

Assigning action locations helps to organize the layout and order the actions on the transitions. The actions are performed in natural order of sets: (1), (2) and (3). Those sets can be further sorted if necessary, so that it is known prior to the move in which order actions are called.

Actions are logically divided into two types: ***tasks*** and ***conditions***. *Task* is an operation which holds a significant impact on the environment, changing the state of external entities. An example would be an archiver, logging information to the database, or a publisher which broadcasts messages upon calling. Performing the *task* may end up in failure, although it should not be considered harmful to the *move*. Conversely, *condition* has little impact on the environment, yet it checks its particular quality. Calling the condition results in a boolean value, but should bring no side effects. Failing condition check should inhibit the *move*.

Concepts Omitted

Due to the complexity of the notion, *State Machine Framework* does not support any action rollback mechanism. Each action as a separate entity, unrelated to others, should clean itself up in case of its failure.

Some other reoccurring state machine concepts have proven superfluous in our environment. Hence lack of support for sub-states, nested states, parallel transitions or synchronization blocks that can be found on the state machine library market [2].

LHC OPERATIONAL STATES

State Machine Instance

LHC Operational States is a production instance of *State Machine Framework* based on the specific LHC configuration and dedicated action implementations. The instance follows classic 3-tier architecture with a clear separation of concerns. The middle-tier server runs on a Linux server in CERN computing centre. Configured with twelve states, it manages walking through over twenty transitions. Each transition is equipped with a series of checks that need to be satisfied in order to successfully move forward. They are triggered by a dedicated state machine action, but performed on a remote machine as Sequencer tasks. The results of the checks are communicated back to the core of *Operational States* server where the decisions about the new active state are taken and published further to interested parties. Those being all the listening clients, the database storage and local logging files. The primary clients are Sequencer GUIs, State Machine GUIs and any application using SM client API, although only the first two are authorized to perform state changes.

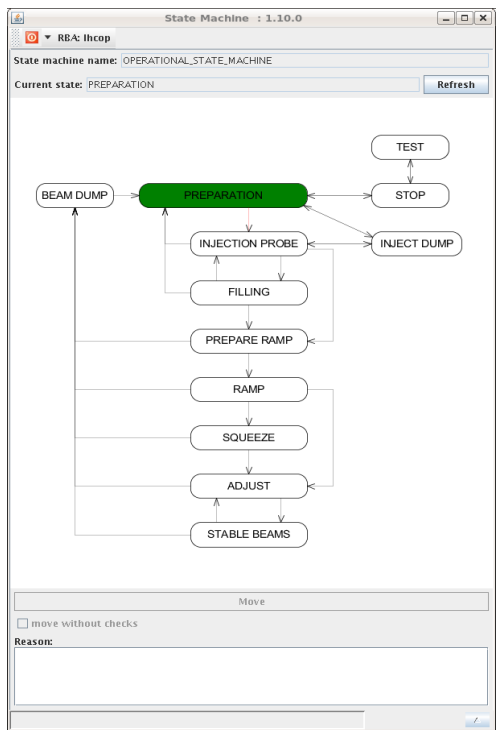

Figure 1: LHC Operational States diagram in SM GUI.

Sequencer

LHC Sequencer [3] is a crucial operators tool. It allows for executing preconfigured, ordered series of operations, i.e. *sequences*. They exemplify the steps taken in order to move the machine along its operational lifecycle. Thus, Sequencer naturally employs the state machine concepts, becoming both its client and executor. Each transition of *Operational States* is requested from a certain Sequencer task. *Operational States* server reacts to the request, among others, by executing its action which in turn launches another Sequencer task.

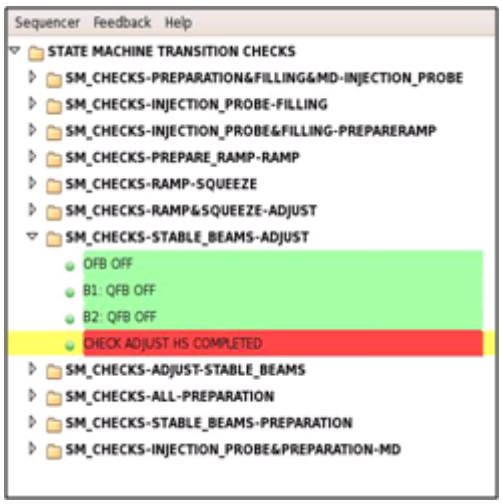

Figure 2: Sequencer checks for transition in SM Checklist.

Those tasks (checks) examine the actual context of the LHC machine, e.g. the external subsystems must meet certain conditions to safely allow to progress to the next stage. In case the check is successful, new active state is decided and returned back to the Sequencer. Otherwise, the operators must take necessary measures so that the conditions are met while the request is repeated.

SM GUI and SM Checklist

To help the operators in visualizing the states diagram two graphical applications were developed. *State Machine GUI* presents the layout indicating the active state, the undergoing transition and the messages issued from the Operational States server. It lets test the transitions outside the Sequencer tasks to ease up their preparation. It also permits to skip certain checks. Such tool proves indispensable in the early development or debugging stages. *State Machine Checklist* is an easy means of presenting the Sequencer checks associated with the transitions. Both tools are extensions to the LHC Sequencer, used on a daily basis in CERN Control Centre.

STATE MACHINE FRAMEWORK

Library

State Machine Framework (SMF) as most of CERN accelerator controls software is created in Java using the Spring framework [4]. Communication between client and server layers of the classic 3-tier architecture is realized with RMI and JMS protocols, employing high level concepts and infrastructure of JAPC [5]. Applications connect to the server through a dedicated client API that allows for performing state changes in both, synchronous and asynchronous ways. In addition to sending the response to the transition requests, server publishes the results through asynchronous channels of JMS. Any client application interested in following state changes, including failed attempts, can become a listener.

SM instance is identified by a unique name that is announced along with the addressing details to the Directory Service [6]. Client library looks up the Directory Service to discover that information. Using an intermediate publishing service greatly improves the flexibility of the SM instance deployment.

By default, SM instance stores its lifecycle data, including state changes, in several resources. Database archive and local log files are the major ones. The current status of the state machine is always preserved between the restarts of the server which provides for smooth upgrades.

Configuration

Configuration of a SM instance can be supplied either through an XML file or a database. In each case, template schema is provided to verify the syntax. Seemingly easier way is to define the layout as an XML document, more readable and simpler to edit. That was also the choice for LHC Operational States, letting operators manage the configuration fully on their own. It has proven an excellent opportunity for stimulating the ultimate users to actively participate in creation and maintenance of the software.

Deployment

SMF source code is split into several packages. Client and server libraries are clearly divided, while actions are shipped in another package. It lets action developers, often outside the state machine team, to contribute their implementations without interfering with main course of *SMF* development. It also alleviates the testing process.

Actions package is combined at the level of deployment of the state machine instance. Lacking an action class results in calling a default one, hence does not break a running server. SM instances are always bundled into a separate product, loosely coupled with the framework packages.

Actions Interface

Actions are generally developed to the dedicated API outside the *SMF* core. They are placed in the instance layout simply through editing its XML/DB configuration. There it is decided if an action falls into a task or a condition logical category. In the action main call, *perform()* method, a variety of information is provided by the SM server, including remote client token and a full SM context from the time of the call. In case of a problem it can throw an exception indicating a non-recoverable error. Otherwise, the action is considered to have completed successfully.

Request Lifecycle

SM instance accepts client calls (RMI) and based on the supplied arguments decides if a state change is possible at the moment. The feasibility of the move is also verified against the SM layout before the call is executed, at the client level. Each request holds additional data, a *payload* that identifies the client application. It can also contain a user provided map of properties. Payload is made available to each action performed on the requested transition, thus client data can be processed at that stage.

Once verified, the request is translated into a series of conditions and tasks that are performed on the transition. The result is then returned to the client, published asynchronously and persisted. Exception or warning messages thrown by the actions are disseminated too. While a single request is handled, all the other incoming requests are put on hold by the server.

Concurrency

One of the key benefits of *SMF* is the soundness of the concurrent model employed. State machines open to a parallel use of many clients are prone to a variety of errors, typically hard to detect at the testing stage. Hence a diligent effort was taken to design and implement a flawless concurrency engine based on Java monitors. As clients are rightly handled also in case of heightened number of requests, the *SMF* proves an accurate solution for fast-changing environments. Over a year of intensive use of *SMF* has confirmed a bug-free environment in that respect too.

Safety

Unlimited access to the SM instance could pose a serious threat to the LHC environment, even if the Sequencer checks have no impact on the probed environment. Role based access model *(RBAC)* was employed to handle the issue, a common solution in CERN controls systems [7]. Each client request's payload is equipped with RBAC token that holds verified credentials of the user. Server decides upon its contents whether the request can be authorized. In case of *LHC Operational States* the access to the SM instance is narrowed solely to the LHC operators.

Embedded Mode

SMF supports not only 3-tier architecture with its separation of clients, server and resources, but also an embedded use within another application. The instance is then accommodated into the scope of controlling application using Spring context, whereby all the client calls are executed locally, between Java threads. Embedded mode is achieved by an appropriate configuration of the instance. No remote calls or auxiliary resources, e.g. Directory Service, are required.

Considering its simplicity and concurrency soundness, such a solution is advised in case a state machine is needed within a more complex application.

CONCLUSIONS

State Machine Framework and its first instance have been operationally used for almost a year now. Over the period they have become an integral constituent of LHC controls software architecture, running impeccably throughout. LHC Operational States instance has reliably intertwined with the existing infrastructure, whereby the LHC Sequencer plays the essential part. The collaboration with other software teams helped to improve the functionality *SMF* offers, while the feedback of the LHC operators have been continuously integrated. Open architecture promoted their active participation in the development of the library. It has also raised several subjects that are being considered for new requirements, thus more work is anticipated in the near future.

State Machine Framework is a general purpose library aimed at both standalone or embedded use wherever state machine concepts need putting in place. Minimal dependency on the accelerator controls infrastructure makes it a comfortable choice for any project seeking a similar tool.

Abstract

The UNICOS (UNified Industrial COntrol System) framework was created back in 1998. Since then a noticeable number of applications in different domains have used this framework. Furthermore UNICOS has been formalized and its supervision layer has been reused in other kinds of applications (e.g. monitoring or supervisory tasks) where a control layer is not necessarily UNICOS oriented. The process control package has been reformulated as the UNICOS CPC package (Continuous Process Control) and a reengineering process has been followed. The drive behind these noticeable changes was (1) being able to upgrade to the new more performing IT technologies in the automatic code generation, (2) being flexible enough to create new additional device types to cope with other needs (e.g. Vacuum or Cooling and Ventilation applications) without major impact on the framework or the PLC code baselines and (3) enhance the framework with new functionalities (e.g. recipes). This publication addresses the motivation, changes, new functionalities and results obtained. It introduces in an overall view the technologies used and changes followed, emphasizing what has been gained for the developer and the final user. Finally some of the new domains where UNICOS CPC has been used will be illustrated.

INTRODUCTION

UNICOS (UNified Industrial Control System) was born more than a decade ago for the development of the LHC cryogenics control system. Since the first application deployed in mid 2001 the enrichment of functionalities and upgrades followed one after the other [1].

Initially, the UNICOS aim was the automation of an industrial process covering the layers of supervision and control. SCADA (Supervisory Control and Data Acquisition) and PLCs (Programmable Logic Controllers) were respectively the components used in those layers. For the first implementation, PCVue32® as SCADA and Schneider PLCs for the PLC layer were the choices. The addition of the Siemens S7 PLCs and the replacement of the SCADA by PVSS (nowadays called WinCC Open Architecture) was the natural evolution as they became recommended CERN components for an industrial control system.

The UNICOS conceptualization in a framework created not only a well defined set of objects but also: (a) an approach to model a process in units (IEC-61512), (b) a generic environment to develop the application specific control logic and (c) a unified way of operating an industrial plant [2].

During the last years the UNICOS framework has been not only successfully applied to the LHC cryogenics but also to many other applications (e.g. gas flow, collimator temperatures, equipment cooling, etc.) and lately to other different domains like ventilation and vacuum installations [3].

The maturity of the framework has induced an evolution towards even a more reusable and open model where the components provided by the framework are not only restricted to PLCs in the control layer [4]. In this way, UNICOS has been also applied to supervision and monitoring applications as the QPS (LHC Quench protection systems), SURVEY (alignment of the focusing LHC low beta magnets) or the PIC (Powering Interlocks controllers) among others.

The process control package has been reformulated as the UNICOS-CPC package (Continuous Process Control) and a sound reengineering process has been followed to finally create the UNICOS-CPC v6.

THE REENGINEERING APPROACH

After more than 10 years of usage of the framework in different domains, process and automation engineers together with plant operators have naturally identified several potential improvements and new requests.

The LHC detectors Gas Control project created additional objects to cope with missing framework functionalities (i.e. parameterization, simple status and analog alarms) which were not initially included in the basic package.

One of the framework features is the use of tools to automatically generate the code; those tools (based on Microsoft Access) although very valuable were unnecessarily rigid for the creation of new object types and rather inefficient when dealing with large projects.

The application dependent control logic is composed of a set of templates that combine together PLC code and a meta-language to make use of advanced features during the code generation (e.g. code reusability, user parameterization, etc.). Users regularly reported difficulties in understanding those logic templates.

All these facts were the driving force behind the vigorous reengineering process of the UNICOS-CPC package.

NEW FEATURES

Some of the package enhancements are: (1) new improved functionalities in almost all its objects as well as new objects, (2) extended flexibility to ease the creation of new objects, (3) the new tooling suite for the automatic generation of the applications, (4) improvement readability and usage of logic templates, (5) local operation enabled, (6) the change of the Siemens PLC

application architecture, (7) dynamic recipes and, finally (8) HMI improvements.

Basic objects improvements

There has been a rationalisation of the existing CPC objects trying to keep their generic characteristic yet. This task has ended by the removal of redundant objects (e.g. Digital Input Calculated is integrated in the Digital Input), deletion of non used objects (e.g. Computed) and creation of new objects (e.g. AnaDO). AnaDO holds an Analog and Onoff objects hybrid behaviour and it is found in most of the industrial pumps in fields like vacuum, cooling and HVAC.

A detailed list of the basic objects together with their category is presented in the Table 1.

Table 1: UNICOS-CPC Basic Objects

Name	Function	Category
xI	x=Analog/Digital Input	I/O
xO	x=Analog/Digital Output	I/O
AIR	Analog Input Real	I/O
AOR	Analog Ouput Real	I/O
xPar	x=Analog/Word/Digital parameter	Interface
xStatus	x=Analog/Word/Digital status	Interface
Analog	Valves, Heaters,...	Field
OnOff	Motors, Pumps,...	Field
AnaDig	PWM, slide valves	Field
Local	Local hand valves	Field
AnaDO	Pumps, Frequency Variators	Field
xAlarm	x=Analog/Digital alarm	Control
Controller	PID feedback control	Control
PCO	Process Control Unit	Control

Among all the modifications in the objects, important changes to mention are:

- Full stop functionality in the field objects. Up to now the PCOs could restart once the interlock was acknowledged and their cause had disappeared. In the new version, the control engineer may specify that the device in full stop mode must be explicitly allowed to restart by the operator. This decouples the interlock acknowledge from the operator explicit restart action.
- Controller mode of operation compliant with the UNICOS modes and standardized working states (regulation, output positioning and tracking). The engineer can work with normalized or with physical units. The cascade controller structures can be now generated from specifications.
- Double inverted output in the OnOff objects.
- Addition of a real PWM (Pulse Width Modulation) functionality inside the AnaDig object.
- Alarms on the Local objects expected positions (e.g. a hand valve expected to be closed but its low end-switch is not active)
- Analog alarms thresholds can be parameterized or imposed by the logic code dynamically.

New Objects Creation by the use of a Meta-model

One of the reengineering process tasks was the polishing of existing objects. There were several inconsistencies between the objects in terms of their internal functionalities, interfaces and naming homogeneity. The proper way to homogenize them was the creation of a UNICOS model.

The model is supported by a meta-model describing the properties of the model [5]. The model describes families which are used by the different objects (e.g. *FEDeviceParameters* to define the object parameters). Having such model has both allowed the refinement of the objects and also allowed the framework to create new objects. To support the creation of the objects a specialized tool was developed: the TCT (Type Creation Tool) which permits a drag-and-drop based mechanism to build new objecs and create the device type definition based on XML (eXtended Markup Language).

UAB: Factory Automation Tools

The previous version of the UNICOS-CPC relied on the automatic generation tools based on Microsft Access. Two different generators were used for each PLC supplier (Schneider and Siemens). The code generated by the tool was somehow attached to the generator itself and the project versioning was difficult.

The importance of appropriate flexible and scalable tools is more visible when dealing with large control systems. Control engineers require them to develop such large systems within a reasonable time. A clear example of this is the LHC cryogenics control where some PLCs are configured using thousands of source code files. Using appropriate factory automation tools optimize the time of application development and increase the engineer performance. Note that one such PLC could deal with more than 2500 I/O channels and 700 field objects (e.g control valves, heaters, etc.).

The need of a more modern and flexible tool dealing with the previous mentioned shortcomings lead to the creation of the UAB (UNICOS Application Builder).

The UAB is formed by different components each one having a specific functionality (See Fig. 1). For example a Siemens S7 plug-in will create the S7 PLC application source code while the SCADA WinCC OA plug-in will be in charge of generating the needed information for the SCADA configuration. A special plug-in, the so-called CPC Wizard, orchestrates the plug-ins involved in creating the control application and shows the control engineer a friendly vision of all the steps to create the process control application [6].

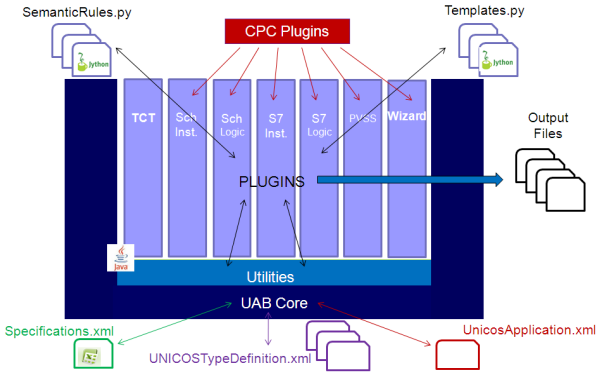

Figure 1: UAB plug-ins.

Another remarkable feature of the UAB architecture is the possibility to include others plug-ins profiting from the already developed core functionalities. This is the case of CoDeSys (Controller Development System), a new plug-in presently being developped which will include a new common IEC-61131-3 based PLC platform.

Control Fogic: Functionality and Femplates

The control logic templates have been rationalized both, by grouping functionalities which were spread out in several templates and also homogenizing them between the two PLC platforms. Table 2 shows the existing standard control logic templates specifying those which are fully generated by the UAB tool.

Table 2: UNICOS-CPC Standard Logic Templates

Name	Function	User edition
BL	Basic logic	No need
CL	Configuration logic	Yes
IL	Interlock logic	Yes
CDOL	Common Dependent Objet logic	No need
GL	Global logic	Yes
DL	Dependent logic	Yes
SL	Sequencer logic (optional)	Yes
TL	Transition logic (optional)	Yes

The format of the logic templates, where the control engineer fills in the process specific logic, has changed. Previously they were text-like files where PLC programming code was explicitly written together with a special language based on Visual Basic to exploit parameterization. Now, with CPC v6, the templates are Python oriented and naturally exploit the benefits of using a scripting language to generate the final PLC code. The advantage: an effortless way to exploit the parameterization included in the control specifications.

Local operation: large vs. small scale projects

Both large and small industrial facilities have different requirements with respect to their automation and operation. When dealing with large projects, the requirements for operation and/or development are quite restrictive and, usually, operation requires centralized control rooms. On the other hand, often, the operation of medium or small projects is not realized 24/7 in front of dedicated HMIs, rather, a subset of information is communicated permanently to a multi-purpose control room where operators, following a multitude of general services, get this information from various processes (e.g. electricity, cooling, ventilation, etc.). Usually that information is a, reduced but still meaningful, set of alarms which should trigger the attention of the operators who, in turn, ask the experts to deal with a problem in case of need. Following this triggering event, the expert connects to the SCADA to check the details of the problem.

There are also cases where domain experts need to command industrial installations locally, and hence, the need of a local interface: the industrial operation touch panels answer that requirement. Availability is also an issue, because the classical SCADA operation relies on Ethernet networks that provide the supervision servers access to the PLCs. Local panels connect naturally to the PLCs with native industrial fieldbuses (e.g. MPI, Profibus, etc.) and exhibit the needed robustness for use in an industrial environment. The new version of UNICOS CPC includes a new mode of operation called *local*. This mode is activated once the object is taken by means of the local panels deployed in the field. The package incorporates a library of objects (faceplates and widgets) to build applications in local touch panels in the same way of what has been offered in the classical SCADA.

Siemens PLC New Architecture

The experience gained with the SIEMENS PLCs in the UNICOS-CPC environment presented a noticeable drawback. In fact, the creation of a new object in the package imposed large modifications to the PLC application architecture. The goals, during the reengineering phase, were to remove this constraint and also to eliminate any required user parameterization once the application is generated.

The usage of the UNICOS model imposed the standardization of the existing and future objects. This, in turn, allows an optimal integration of new objects and an optimal usage of the SIEMENS S7 PLC resources.

Operation using Flexible Recipes

An important feature of a large control system is the ability to apply the appropriate set of parameters at the time they are pertinent. The previous version of the package already included the capability of defining recipes but with a disadvantage: the need of a priori definition of the recipe components.

A flexible recipe mechanism has been developed in the new package version. Flexible recipe management is recognized as a highly desired capability during operation where the plant operators need to tweak the recipes and adapt their components and values to their requirements without rebuilding the control application. The designed recipes can run in multiple PLCs and still be synchronized in its triggering.

The mechanism is PLC platform independent and it is designed in an open and reusable basics, thus becoming in a SCADA component.

HMI Improvements

There have been many modifications concerning visualization in widgets and faceplates: without enumerating the all, there are some new features which deserve attention.

First, because there is a recognized need today to show on the same screens many different control systems (e.g. cooling, HVAC, vacuum, etc.), the colours employed in the HMI had to be redefined. There are no standards in this field, so the engineers must be judicious in their choice. The result is a decrease in the number of employed colours to 4 base colours (green=ok, red=alarm, orange=warning and yellow=force values) and 2 additional error indications (cyan=communication and purple=no data).

Second, the devices can be referred to both with the control name and the expert name. This new feature allows the different experts to have their own project dependant nomenclature in naming their devices.

Third, the alarms representation incorporates the level concept. Following the recommendations of the ANSI/ISA-18.2 standard, a new field on the alarms explicitly characterizes the type of alarm. The four levels employed are fully compatible with the classification of the CERN alarm system.

And four, the objects incorporate two additional navigation options, their positions within the control hierarchy and also the state of the interlocks affecting them in the case of the field and PCO objects.

CONCLUSIONS AND FUTURE PROSPECTS

A large reengineering process has been carried out on the UNICOS CPC package. As a result, CPC v6 provides a better tool suite to automatically create their industrial control applications and also a framework where they can easily extend the objects library in a standard way. The package is already being used in the CERN cooling and HVAC processes.

Following this large reengineering phase, the UNICOS CPC v6 package accepts new capabilities. There are 4 main axes where the tool could develop: auto tuning of controllers, advanced control, redundancy and finally safety systems (see Fig. 2).

Control systems performance depends largely on the correct behaviour of controllers. Most of them are PID (Proportional, Integral and Derivative) and the task of tuning such controllers is widely recognized as a hard job. The package plans to offer automatic tuning mechanisms to the operators.

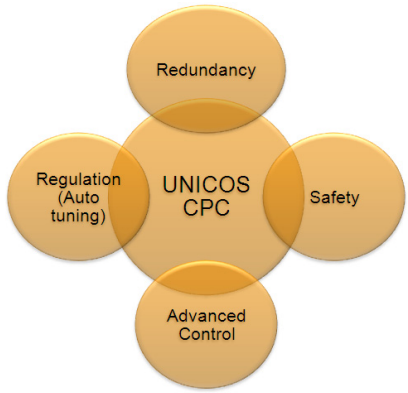

Figure 2: Future work lines.

Some processes show strong nonlinear behaviour and then are intrinsically difficult to regulate. Advanced control solutions are developed to cope with such processes and to help operators. Basic modern control includes a portfolio of solutions from feed-forward, override, cascade to other more sophisticated as Smith predictors and model based predictive control. Some of these solutions are already in the UNICOS CPC v6 (e.g. override, cascade), others will be integrated in the following versions.

Redundancy at the control layer ensures increased availability in the control system. Some processes impose redundancy because of their large downtime in case of PLC failure. UNICOS-CPC will ensure the integration of such components for both Schneider and SIEMENS PLCs.

Finally, safety systems are more often required by the control engineers in processes where safety (personnel and/or equipment) is an issue. Plans for the creation of a similar framework for safety systems are being prepared.

RULES-BASED ANALYSIS WITH JBOSS DROOLS : ADDING INTELLIGENCE TO AUTOMATION

E. De Ley, D. Jacobs, iSencia Belgium, Ghent, Belgium

Abstract

Rules engines are less-known as software technology than the traditional procedural, object-oriented, scripting or dynamic development languages. This is a pity, as their usage may offer an important enrichment to a development toolbox.

JBoss Drools is an open-source rules engine that can easily be embedded in any Java application. Through an integration in our Passerelle process automation suite, we have been able to provide advanced solutions for intelligent process automation, complex event processing, system monitoring and alarming, automated repair etc.

This platform has been proven for many years as an automated diagnosis and repair engine for Belgium's largest telecom provider, and it is being piloted at Synchrotron Soleil for device monitoring and alarming. After an introduction to rules engines in general and JBoss Drools in particular, we will present its integration in a solution platform, some important principles and a practical use case..

PHYSICAL SCIENCES AND INTELLIGENT PROCESS AUTOMATION

General Vision

In today's world of physical scientific research, the usage of and the dependency on advanced technology has become crucial. As the boundaries of research shift, the requirements on tools for exploration, experimentation and verification become ever more complex and extreme.

The required investments, both in costs and in time, are typically huge and can no longer be duplicated by all parties involved in related research domains. Collaboration in the design and usage of advanced “centralized” or “shared” research infrastructure, like synchrotrons, becomes mandatory.

The institutes offering such infrastructure then effectively become service providers for all the parties involved in related research disciplines, both for internal scientists and for visiting researchers (or groups).

Offering complex infrastructure as a service also implies extensive support organizations and processes, like project approval procedures, safety and security regulations, HR, IT support, resource planning, repair workshops, vendor management etc.

Which in turn implies, maybe a bit paradoxically, that the more advanced and exotic the technological requirements for executing scientific research, the more the organizational aspects get closer to traditional requirements for professional service providers in non-scientific domains. But with a clear long-term advantage, compared to many professional organisations : scientific institutes have a single long-term goal - *offer the best-possible infrastructure and support for advancing science*. This clear goal can drive the complete organisation to operate in a transparent and collaborative way.

It is our vision that a *common open software platform for intelligent process automation* can be of tremendous value to assist an organisation in achieving this goal, across the majority of its activities by removing administrative duplication, reducing risk for errors in each step, removing the need for continuous on-site presence and combining advanced security with consistency and transparency where needed.

Such a platform can be used for supporting, automating and orchestrating a wide range of processes, from traditional workflows (such as project approval) to advanced algorithms for resource allocation (e.g. beamlines, guest rooms, login accounts etc.), from automated machine monitoring of the accelerators and control sequences for beamlines, to offering secured access to experiments' results.

Concretely for Synchrotrons

Automation in synchrotrons is typically associated with device drivers, sensors, control buses and other technical components, driven by scripts and hard-coded programs. But the scope for automation can become much larger by increasing the level of abstraction. This in turn allows adding advanced features like automated analysis, diagnosis and decision management through the integration of e.g. a rules engine, which is the scope of this paper.

AUTOMATED ANALYSIS AND DECISIONS

Some example uses of enriching automated processes with analysis and decision logic are:

- *What to do next?* Complex and/or dynamic routing or filtering logic based on previously obtained information
- *Is what we did OK?* automated analysis or validation of results obtained in previous steps
- *Just wake me up when you need me.* Intelligent monitoring systems, integrated in the same platform to automate basic control processes and business processes
- *Wait a moment, how did we get in this mess?* Correlating acquired data and elementary

analysis results to obtain a final diagnosis on a problem situation
- *Oops, how can we get this resolved?* Automated advises for corrective actions in case of problems
- *Don't bother me any more for this.* Automating simple recurring decision processes

Automated diagnosis or decision management can be decomposed in the following stages :

- Autonomous monitoring or discovery
  Continuously track some important performance indicators and generate an alarm when a value becomes suspect.
- Context-sensitive analysis of raised alarms
  Typically involves looking at many different datasets and measurements.
  Uses thresholding, trending etc. to identify exceptions (e.g. taking your fever)
- Consolidation of obtained information and analysis results towards a diagnosis or decision (e.g. "you've got a simple flue"). This may optionally include advises for problem resolution or repair.

RULE ENGINES

To cater for the above needs, the software system must be able to handle large volumes of data and to apply complex reasoning logic on it. An easy-to-understand reasoning approach uses conditional actions, also known as "if-then" logic. Such constructs are frequently used in traditional programming, but for representing complex context-dependent logic they quickly become a nightmare to understand or maintain since :

- it quickly becomes tricky to correctly represent all combinatorial possibilities of the conditions with nested if-then-else statements
- the logic is spread out across different parts of the code base
- the result becomes more and more fragile with each incremental adaptation

Rule engines are specialized software systems for applying conditional actions (if/then rules) on data. The use of a rule engine brings following benefits :

- business logic, expressed as rules, can be externalized from the application code. The business logic can then be maintained in a centralized way with dedicated tools.
- rules can be defined in human-readable form in text files, spreadsheets etc.
- rules are often defined in a declarative way. Starting from facts that you know are true, the desired outcome or action is defined.
- rule engines are optimized to evaluate large rule bases, find matching conditions and trigger the corresponding rules.

The term "rule engine" is used in different ways. The ones which interest us are also known as "production rule systems". The central part of such a system is an inference engine that is able to match rules against facts or data to infer conclusions which result in new facts or in actions. Through optimized matching algorithms such engines are able to scale to high volumes of rules and facts.

INTRODUCING JBOSS DROOLS

Drools[1] is the leading open-source rules engine written in Java. It was started in 2001 and became a prominent Java rules engine with its 2.0 release. In 2005 the Drools project became part of the JBoss group and since then Drools also became known as JBoss Rules. In 2006 JBoss was acquired by Red Hat. Besides funding the core development team, they provide professional services like support and training. The current stable version is Drools v5.2.

The Drools suite contains several modules that together form their *Business Logic Integration Platform,* of which the following ones are of interest for our purposes :

- Drools Expert : the actual rule engine
- Drools Fusion : an integrated engine extension to support event processing and temporal reasoning
- Drools Planning : automated resource planning

Drools Engine

The core of the Drools suite is an advanced Inference Engine using an improved Rete algorithm[2] for pattern matching, adapted for object oriented systems, and for Java in particular. Rules are stored in the production memory, while facts are maintained in the working memory.

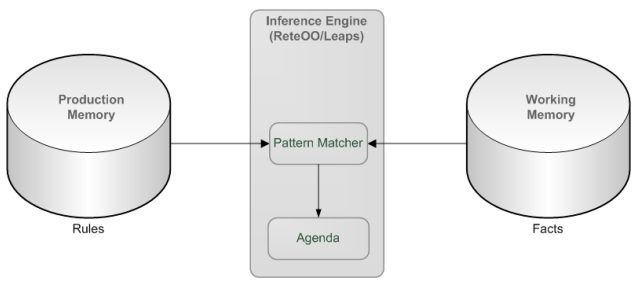

Figure 1 : The main parts of a rule engine.

The production memory remains unchanged during an analysis session, i.e. no rules are added or removed or changed. The contents of the working memory on the other hand can change. Facts may be modified, removed or added, by executing rules or from external sources. After a change in the working memory, the inference engine is triggered and it determines which rules become "true" for the given facts. If there are multiple selected rules, their execution order will be managed via the Agenda, using a conflict resolution strategy.

When a selected rule has been executed, and one or more changes were done in the working memory, the inference engine goes to work again, adapting the agenda and executing the rule that has now reached the highest priority. This iterative process continues until the agenda is empty. Then the analysis session terminates and results can be queried from the working memory or through the usage of global variables.

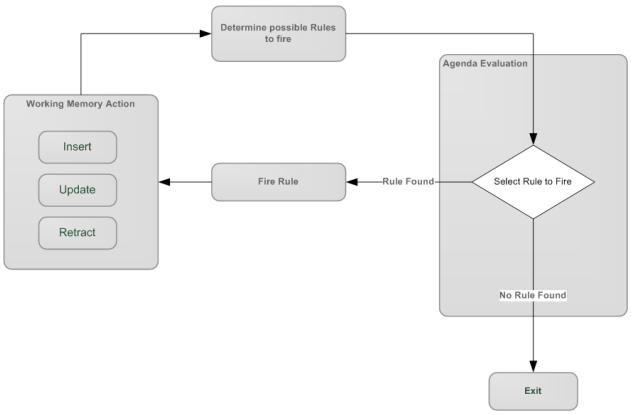

Figure 2 : Iterative inferencing.

Options for Rules Definitions

Drools offers different ways to define rules. The native rules language will feel familiar for Java developers, with the addition of advanced expressions for specifying conditions. For example :

```
rule "Raise prio if 3 pending alarms"
when
    $system : System()
    $alarms : ArrayList( size >= 3 )
      from collect( Alarm( system == $system,
        status == 'pending' ) )
then
    # Raise priority, because $system has
    # 3 or more alarms pending.
   # The pending alarms are in $alarms.
end
```

When repetitive rule patterns occur, one can set-up more readable approaches to define the rules. One way is to create a rule language dedicated to the problem domain, so-called DSL rules.

Rules can then be expressed like :

```
when
  There is a Cheese with
  - age is less than 42
  - type is 'stilton
then
  Taste It
```

which gets translated at runtime in the technical rule language, based on the defined DSL mapping.

A third interesting approach to define rules is to use spreadsheets. This offers a familiar entry tool for non-IT persons to easily define large rules sets as long as they fit in a-priori defined rule templates.

INTRODUCING PASSERELLE

Within Passerelle [3], all processes are defined in graphical models that are executable by one of the available executors. In "real" production environments, the Passerelle Manager, our web-based process automation server platform[4], is the preferred execution engine. It offers a complete solution for process definition, maintenance, execution and follow-up.

In the Passerelle process engine, a process (a.k.a. sequence) is defined by a graphical assembly of actors that each perform a step of the complete process. Assemblies are stored in XML files. Actors get single well-defined responsibilities and are unaware of their surrounding "colleagues". They are only able to communicate via messages sent across channels between the sender's output port and the receivers' input port(s).This strong decoupling improves reusability and maintainability.

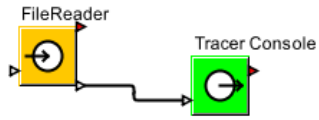

Figure 3 : Reading a file in Passerelle.

In the figure above, the FileReader actor will read a text file from a configurable location, and will send a message for each line to the next actor. In this simple model, this one just dumps the text content of each received message to a Console view.

There are actors available to control Tango devices, to make routing decisions in the process flow, to query databases, send e-mail or SMS etc.

INTEGRATING DROOLS

Drools is easy to integrate in any Java application via :

- Standard JSR-94 Java Rule Engine API
- Drools' own "Knowledge API" with more advanced capabilities, for example to be able to use the Fusion and Planning modules. Passerelle uses the Drools Knowledge API.

One can distinguish the following major API features, required for integration in a production-ready solution:

1. Build a binary version of a knowledgebase packages, from the different types of source
2. Select a knowledgebase package for execution
3. Start an analysis session
4. Feed facts into the working memory
5. Start the inference engine
6. Obtain the results
7. Release session resources when appropriate

Rules and Processes as Versioned Assets

For integration features (1) and (2), Passerelle includes a specialized repository service to maintain *process models*, and *rules assets,* grouped in *project* assets. The service offers a.o. version management, knowledgebase building and packaging, a simple API to retrieve pre-built binary knowledgebase packages and import/export to migrate project assets between test and production environments.

Actors with Intelligence?

Passerelle has specialized actor libraries to integrate the usage of the Drools rule engine in an automated process. These actors utilize the Drools API features (3)-(7) as described above. By configuring the actors with a

reference to the desired rules package, a limited number of actor implementations can be reused in many different processes, each time with the matching rules-based logic.

In this way it is possible to apply rules to analyse the results of the work done in the previous steps of the process, and act on the obtained analysis results, all within a common paradigm of sequences and actors.

Support Tools

Passerelle Manager stores all analysis results, including timed task execution traces, in a relational database. The web UI includes rich views on this data, to aid with application support and with control and improvement of the analysis quality.

EXAMPLE : DIAGNOSIS OF TELECOM LINE - AND SERVICE QUALITY

For the largest Belgian telecommunications provider, a solution has been implemented and is operational since approximately 5 years. To reduce the waiting times for the customers that are contacting the support help-desk, there was a need to be able to automatically trigger a number of tests and measurements on the impacted telephone line and associated services. This should happen even before the customer gets in contact with a help-desk operator, i.e. while still in the waiting queue. Then the operator already has all detailed test results available about the condition of the telephone line, ADSL services etc, when the customer is passed through. Also field technicians, working on-site at their customers can use this automated Diagnosis And Repair Engine.

Each day, approximately 35000 diagnoses are performed for about 700 help-desk operators and 2500 technicians, with dedicated rules for different customer segments, line technologies etc. The result is a dramatic reduction in error rates and a significant increase of “first-time-right” indicators.

EXAMPLE: MONITORING BEAMLINE SOURCE POSITIONS

In this scenario, the goal is to continuously compare beamline source positions to reference values, and to check for slow drift. When the measured position starts drifting, or deviates from the reference position by more than a given threshold, a number of possible root causes must be evaluated (like temperature circuits, insertion device changes etc), and a diagnosis on the plausible cause(s) must be produced.

This requires analysing a stream of position measurement events to :

- compare them against reference values obtained from a snapshot
- check measurement values for drift within a certain time window

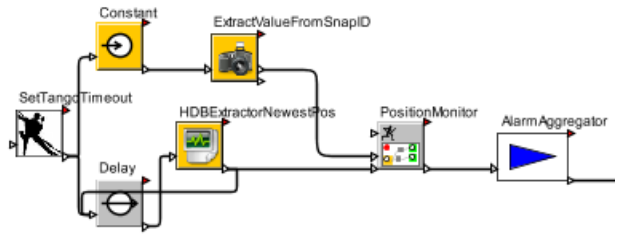

Figure 4 : A fragment of the monitoring sequence.

The monitoring sequence includes an actor to read the reference values from a snapshot and to feed them via an event stream input to the PositionMonitor actor. The HDBExtractorNewestPos actor periodically reads the latest position measurements from the archive and sends these as events to the PositionMonitor. This one can then compare the measurements with the snapshot and also check for drift in measured positions in a time window of e.g. 15 seconds. The below presents an example of using a Java domain model in rules :

```
rule " BLSrcPosition drift > 0.01 within 15 s"
  when
    bl1 : BLSrcPosition($blName1 : beamLine,
        $blPos1 : position )
        from entry-point "BL SrcPos Stream"

    bl2 : BLSrcPosition($blName2 : beamLine,
        beamLine == $blName1,
        this after [0s,15s] bl1,
        eval(position.distanceTo($blPos1)>0.01))
        from entry-point "BL SrcPos Stream"
  then
    // raise an alarm...
end
```

CONCLUSIONS

We have presented the concepts and the added value of integrating a rule engine in a software platform for intelligent process automation. Drools offers many advanced features that are of interest. Besides using standard production rules, it is also possible to perform temporal event-based reasoning and resource planning.

The resulting solution platform can be applied in many different domains, ranging from automated diagnosis and repair in telecommunications customer support to monitoring synchrotron infrastructures to automating beamline experimental sequences.

INTEGRATING GIGABIT ETHERNET CAMERAS INTO EPICS AT DIAMOND LIGHT SOURCE

T. Cobb, Diamond Light Source, Oxfordshire, UK

Abstract

At Diamond Light Source we have selected Gigabit Ethernet cameras supporting GigE Vision for our new photon beamlines. GigE Vision is an interface standard for high speed Ethernet cameras which encourages interoperability between manufacturers. This paper describes the challenges encountered while integrating GigE Vision cameras from a range of vendors into EPICS[1].

INTRODUCTION

Diamond Light Source is a 3 GeV third-generation light source with a 561 m storage ring (SR), a full-energy booster (BR) and a 100 MeV pre-injector Linac[2]. The photon output is optimised for high brightness from undulators and high flux from multi-pole wigglers. The current operational state includes 19 photon beamlines, with a further three beamlines in an advanced stages of design and construction. A further phase of photon beamlines is now confirmed, detailed design and construction of these 10 beamlines started earlier this year.

A range of cameras are used to provide images for diagnostic purposes in both the accelerator and photon beamlines. The accelerator and existing beamlines use Point Grey Flea and Flea2 Firewire cameras. The disadvantage of Firewire is that it requires complex cabling with multiple repeaters chained together. Diamond has used both a licensed Firewire stack running under vxWorks and an open source Firewire stack running on Linux, but both implementations have been somewhat unreliable. This means that the bus occasionally needs to be power cycled, especially when running at 800Mbit/s over 10m cables.

For the next phase of photon beamlines a better solution was needed, so the decision was made to evaluate Gigabit Ethernet cameras. This would allow up to 100m data transfer lengths, with greatly simplified cabling.

INITIAL TESTS

Selecting a Camera

The most suitable replacement camera was the Prosilica GC1020[3], Fig. 1, as it uses the same sensor as the existing Flea2 cameras, and already had EPICS support in the areaDetector[4] module.

Figure 1: Prosilica GC1020 Camera.

Configuring EPICS Support

The areaDetector module provides a common interface for all supported 2d detectors. Integrating the camera into areaDetector allows image processing and analysis plug-ins to be chained together at runtime, such as the NDStats plug-in for statistics, or the ffmpegServer[5] plug-in to provide a compressed mjpg stream for visualisation (see Fig. 2).

The PvAPI[6] library is supplied by Prosilica (now part of Allied Vision Technologies) to control their cameras in the form of a software development kit (SDK) that works on Windows, Linux and OS X. The areaDetector Prosilica driver consists of a translation layer on top of the PvAPI library.

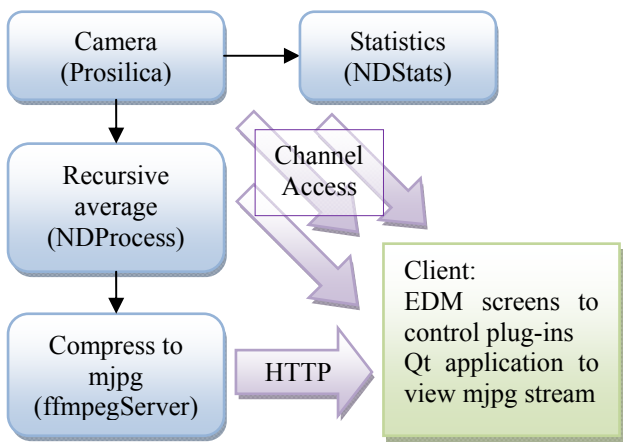

Figure 2: Typical areaDetector plug-in structure.

Conducting a Representative Test

A series of tests was conducted with 10 cameras on a typical beamline network consisting of a Nortel Gigabit Ethernet switch with servers, desktop machines, motor controllers and other Ethernet attached equipment. Different combinations of cameras were tested, and it was noted that the more cameras that were active, the less total bandwidth was achievable without dropped frames. With 3 cameras acquiring, 70MB/s was reliably achievable which was sufficient. Occasionally a camera would hang and stop acquiring, but this was not reproducible later in the lab.

SUPPORTING CAMERAS FROM DIFFERENT VENDORS

All vendors supply an SDK of some form to allow end users to control their cameras, but using one of these SDKs has some disadvantages:

- Most vendors' SDKs are tied to the vendor's cameras, so that you cannot switch to a different vendor without changing SDKs
- Most vendors' SDKs are focussed on the Windows end user, while Diamond uses Linux for control system servers.
- Most vendors' SDKs are closed source, meaning that debugging problems is more difficult, and bugs must be fixed by the vendors.

These factors prompted a search for an open source library that could control any GigE Vision camera, would run on Linux, and could be integrated into EPICS

THE GIGE VISION STANDARD

Most Gigabit Ethernet cameras conform to the GigE Vision[7] standard, which uses the GenICam[8] standard to describe the features supported by the camera. The GenICam standard provides a common interface to many different types of cameras, across different vendors and even across different physical connections types. The camera provides an XML file which describes the features that it supports, and how they map to registers on the device. This means that supporting cameras from different vendors should be simple, as the XML file will describe how the camera should be controlled.

Unfortunately, the licensing conditions of the GigE Vision standard do not allow the licensee to reveal details of the standard. Any licensee wishing to publish software implementing the standard must make the part that is drawn from the standard closed source otherwise they risk breaking the licensing agreement. This would mean that if Diamond used the GigE Vision standard to produce any software implementation, its sources could not be published back to the EPICS community.

In order to be useful to the EPICS community, an open source library was needed, and the only way this library could exist is if it had been reverse engineered. Aravis[9] is one such library.

INTEGRATING ARAVIS INTO EPICS

A typical areaDetector driver consists of a number of parameters, both defined by the base class and specific to this detector, and a mechanism for publishing frames from the detector as NDArrays. As well as the driver, an EPICS database provides access to each of these parameters, and an EDM[10] screen to provide the user interface. The sections below describe the steps taken to wrap the Aravis library in an EPICS module called aravisGigE[11].

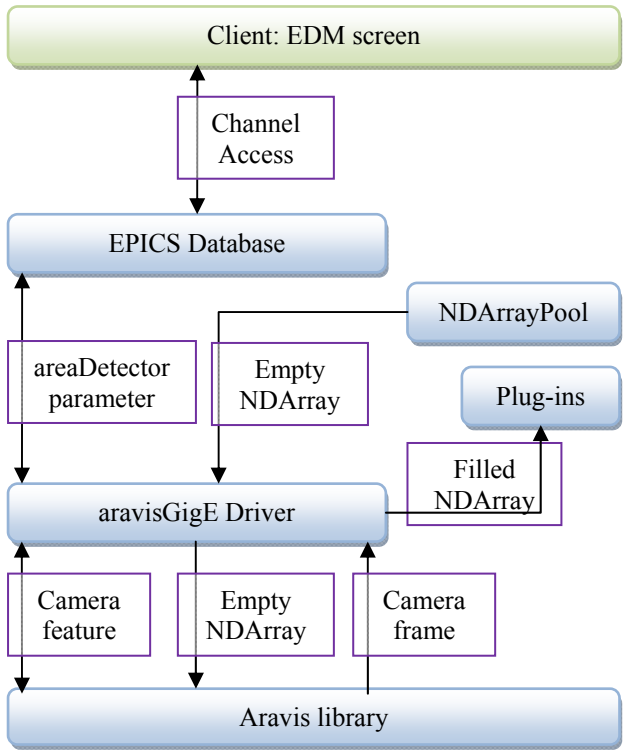

Figure 3: Structure of aravisGigE driver.

The Driver

One of the tasks done by the driver is mapping all the areaDetector common parameters to features supported by the camera. E.g. ADGain is mapped to the "Gain" or "GainRaw" feature. The mapping of areaDetector parameter to camera feature is placed in a hash table. For every other camera feature a new areaDetector parameter is created, and this is also placed in the hash table. When EPICS writes a parameter down to the driver, the corresponding feature is looked up in the hash table, and written to the camera. An update function also periodically updates the readback values of each of the parameters in a similar manner (see Fig. 3).

All memory management of frames in the driver is done using areaDetector's NDArrayPool, which maintain a pool of NDArrays that can be reused when all plug-ins have finished with them. The Aravis library is loaded with a number of NDArrays which it fills in when it gets a new frame.

The driver registers a call-back function with the Aravis library that is called whenever the camera produces a new

frame. This frame is annotated with information like timestamp, colour mode and data type before being published to any connected plug-ins.

Extracting the GenICam XML

Although the driver can query the camera to find out which features it has and create areaDetector parameters on the fly, the EPICS database and EDM screen must be generated at build time. As Aravis parses the GenICam XML from the camera in order to build its list of features, this XML is all that is needed to build a database and screen for the camera. Aravis provides a small utility that will allow the GenICam XML to be written to file.

The EPICS Database and EDM Screen

To parse the XML file, aravisGigE contains a Python script called makeDbAndEdl.py. The script creates a menu structure based on the Category nodes, and a list of feature nodes contained in it.

To create the EPICS database, for each feature node a suitable record is created, using stringin, longin, ai, and mbbi records for StringReg, Integer, Float, and Enumeration nodes respectively. If the field is editable the appropriate output record is created.

To create the EDM screen, a section is drawn for each category, then suitable widgets are created for the records that have been created. A tooltip is added with some suitable text, and a summary screen is created (see Fig. 4).

Figure 4: Section of Prosilica GC summary screen.

DISADVANTAGES OF REVERSE ENGINEERING

The main disadvantage of reverse engineering is that assumptions are made according to the cameras that are available. For instance, the author of Aravis only lists it as being tested on Prosilica and Basler cameras. It is no surprise then that the Prosilica cameras at Diamond work well with Aravis. Different vendors' cameras have been tested with varying degrees of success, the problems mainly being GenICam elements that are not supported in Aravis yet. There have however been some issues with dropped frames on some vendors' cameras that may point to a bug in the packet resend code.

CONCLUSION

The aravisGigE module is being rolled out on new beamlines, and GigE cameras have been retro-fitted on some existing beamlines. So far they have been more reliable than the Firewire cameras, and the simple cabling makes it much easier to move the cameras to different positions. Upcoming power over Ethernet versions of the cameras will reduce the number of cables still further.

It is very useful to have the ability to change manufacturer without the burden of having to write new software. Diamond's standard camera for beamlines is now the Allied Vision Technologies Manta, Fig. 5, but if a particular beamline has requirements that cannot be met by this range of cameras, then one can be sourced from another manufacturer. Aravis does an admirable job of controlling a range of cameras, given its reverse engineered origin.

Figure 5: Allied Vision Technologies Manta Camera.

ARCHITECTURE DESIGN OF THE APPLICATION SOFTWARE FOR THE LOW-LEVEL RF CONTROL SYSTEM OF THE FREE-ELECTRON LASER AT HAMBURG

Z. Geng#, SLAC, Menlo Park, California, U.S.A.
V. Ayvazyan, DESY, Hamburg, Germany
S. Simrock, ITER Organization, St. Paul lez Durance, France

Abstract

The superconducting linear accelerator of the Free-Electron Laser at Hamburg (FLASH) provides high performance electron beams to the lasing system to generate synchrotron radiation to various users. The Low-Level RF (LLRF) system is used to maintain the beam stabilities by stabilizing the RF field in the superconducting cavities with feedback and feed forward algorithms. The LLRF applications are sets of software to perform RF system model identification, control parameters optimization, exception detection and handling, so as to improve the precision, robustness and operability of the LLRF system. In order to implement the LLRF applications in the hardware with multiple distributed processors, an optimized architecture of the software is required for good understandability, maintainability and extendibility. This paper presents the design of the LLRF application software architecture based on the software engineering approach for FLASH.

INTRODUCTION

FLASH is a VUV and soft-X ray free-electron laser machine located at DESY, Hamburg. The layout of FLASH is depicted in Figure 1 [1].

FLASH requires high RF field stabilities up to 0.01 degree in phase (at 1.3 GHz) and 0.01% in amplitude [2]. But various perturbations, such as Lorenz force detuning, microphonics and thermal drift of the cable, will generate amplitude and phase errors on the RF field in the superconducting cavities of FLASH [3].

The LLRF system is introduced to maintain the RF field stabilities with both feedback and feed forward control schemes [4], see Figure 2. The feed forward control is used to control the repetitive perturbations like Lorenz force detuning, beam loading and slow drifts, while the feedback control is used to control the field errors caused by random perturbations like microphonics and charge variations along the bunch train.

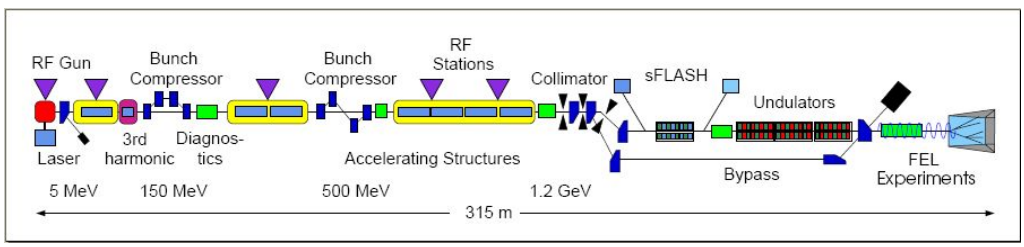

Figure 1: Layout of FLASH.

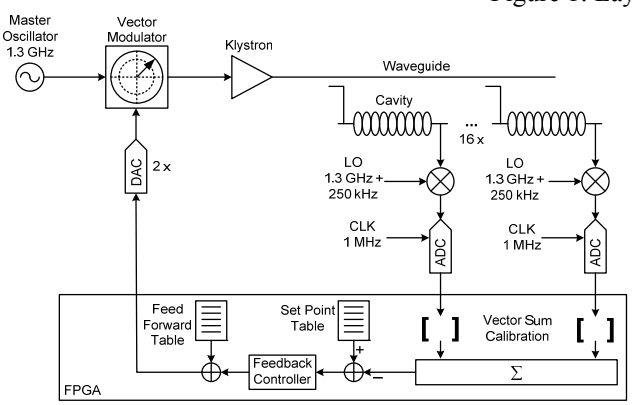

Figure 2: FLASH RF station including LLRF.

There are several great challenges for the LLRF system operation, including precise calibration of the vector sum for multi-cavity operation driven by a single klystron, optimal feedback and feed forward control, exception detection and handling for system robustness and automation for easy operation. So, sophisticated algorithms and application software are required to solve these problems in addition to the basic control loop.

LLRF APPLICATIONS

LLRF applications are sets of software to facilitate the LLRF control loop for better precision, robustness and availability. The main goals of the LLRF applications include

- Improve the RF field stabilities by optimizing the parameters of the RF field controller.
- Improve the robustness and availability of the LLRF system by system diagnostics, exception detection and handling.
- Support automation for easy operation.

The LLRF applications can be divided into several categories and their logical relations are show in Figure 3. Several important applications of each category are listed in Table 1.

#gengzq@slac.stanford.edu

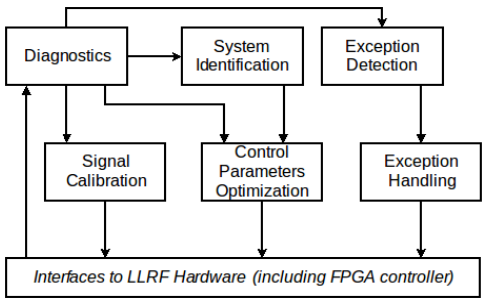

Figure 3: LLRF application categories.

Table 1: LLRF Applications

Category	Applications
Diagnostics	- Beam phase and beam current measurement - Loop phase and loop gain measurement - Cavity incident and reflected waves measurement - Cavity loaded quality factor and detuning measurement
Signal Calibration	- Vector sum calibration - Cavity gradient and phase calibration - Cavity incident and reflected power calibration - RF gun field calibration
System Identification	- RF system dynamic model identification - Cavity model identification - Klystron non-linearity characterization
Control Parameters Optimization	- Adaptive feed forward - Feedback gain scheduling
Exception Detection	- Cavity quench detection - Cavity operational limit exceeded detection - RF system components failure detection
Exception Handling	- Recovery from cavity quench - Adjust cavity gradient

SOFTWARE ARCHITECTURE DESIGN

Software Layers

The architecture of the LLRF applications is designed as several layers, see Figure 4.

The LLRF Algorithm Library will be realized in C language for better performance of the mathematic calculations. It contains most of the LLRF domain knowledge, and is optimized for computation power and memory consumption so that it can be highly reused for both DSP and common CPU programs.

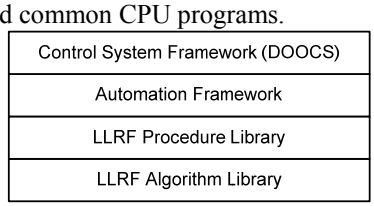

Figure 4: Layers of the LLRF applications architecture.

The LLRF Procedure Library will be realized in C++ language for better extendibility. It realizes the procedures for the tasks (use cases) of the LLRF applications. Sequential or state dependent logics will be used to coordinate the procedures. The platform independent parts of the procedures are designed as abstract classes, which are reusable for different machines with different platforms by derived classes, see Figure 5.

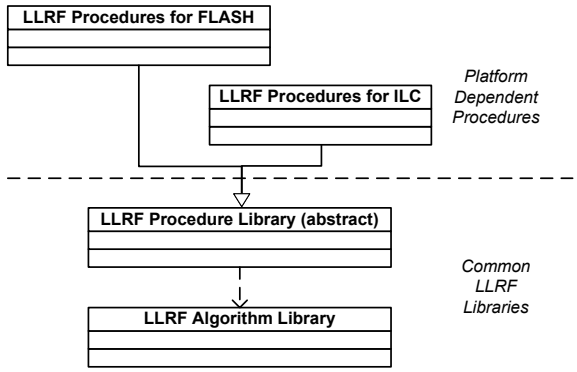

Figure 5: LLRF Libraries.

LLRF Algorithm Library

The aim of this LLRF algorithm library is to share the implementation with FLASH, European XFEL at DESY and even the future ILC.

To be maximum reused by various accelerators, the LLRF algorithm library is designed with C language, which can fit to the popular control systems like DOOCS [5], TINE [6], EPICS [7], and so on. And even can be used for DSP programming.

The library is broken down based on the domains, see Figure 6. The idea is to pack the code for a specified domain (like digital signal processing) so that the whole package can be reused in other applications. Of course, if one domain package has dependencies to other packages, the dependencies should be also considered for reusability.

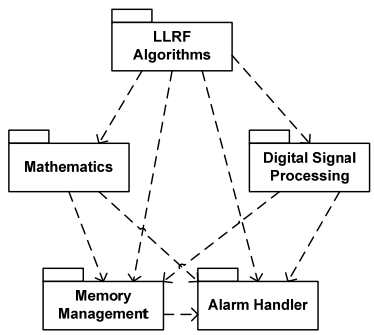

Figure 6: Domain breakdown of the LLRF Algorithm Library.

For each domain package, the codes are divided into three parts: “Available Interface”, “Library Body” and “Required Interface”. The interactions between domain packages are only through the interfaces.

The advantage of this design is that the library body can be upgraded without affecting other domain packages if the interfaces are not changed.

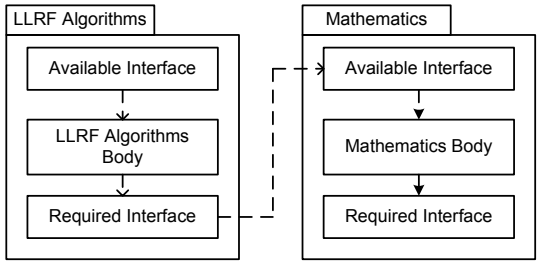

Figure 7: Dependency between packages.

Software Allocations

The LLRF applications at FLASH are realized in the DOOCS control system framework. Different applications are allocated to different DOOCS servers, and they use RPC to communicate with each other through the Ethernet.

The front-end servers are used for front-end hardware control, which will communicate with the LLRF hardware including FPGA controller. Some applications with real-time requirements are also allocated here to avoid the time consumption caused by Ethernet data transfer.

Most other applications for system calibration and optimization are realized in the middle-layer servers for each RF station. The applications that need to adjust more than one RF station are allocated to the middle-layer server for global control. One example is the recovery from quench, from which the cavity gradient of more than one RF stations may be changed.

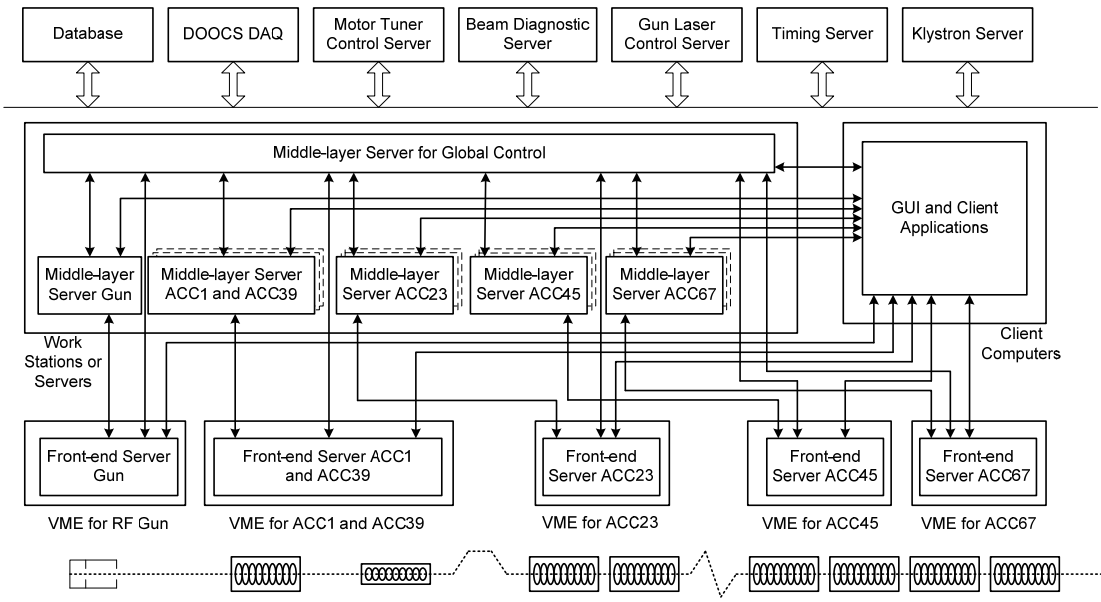

Figure 8: Allocation of the LLRF applications.

CONCLUSION

Software architecture is designed for LLRF applications at FLASH. This is the first time to implement the LLRF applications in a systematic way. The LLRF Algorithm Library has been developed and several applications have been successfully implemented and tested at FLASH [8], including the control table generation, vector sum calibration, RF gun calibration, RF system identification and loop phase and loop gain control. The architecture is proved successful for good understandability, maintainability and extendibility, which will be the reference design for the application software of the LLRF system for the European XFEL project. The experiences gained are also useful for the LLRF system design for other machines like ILC and normal conducting accelerators.

USE OF ITER CODAC CORE SYSTEM IN SPIDER ION SOURCE*

A. Barbalace, M. Breda, R Capobianco, A. Luchetta, G. Manduchi, F. Molon, M. Moressa, P. Simionato, C. Taliercio#, Consorzio RFX, Associazione Euratom-ENEA sulla fusione, Corso Stati Uniti, 4 - 35127 Padova - Italy

Abstract

In February 2011 ITER released a new version (v2) of the CODAC Core System. The SPIDER Ion Source experiment is the first experiment planned in the ITER Neutral Beam Test Facility under construction at Consorzio RFX, Padova, Italy. As the final product of the Test Facility is the ITER Neutral Beam Injector, we decided to adhere from the beginning to the ITER CODAC guidelines. Therefore the EPICS system provided in the CODAC Core System will be used in SPIDER for plant control and supervision and, to some extent, for data acquisition. In this paper we report our experience in the usage of CODAC Core System v2 in the implementation of the control and data acquisition (CODAS) system of SPIDER and, in particular, we analyze the benefits and drawbacks of the Self Description Data (SDD) tools.

INTRODUCTION

The ITER plasma will be heated up to ignition by dedicated additional heating and current drive systems based on the injection of radio frequency power (ion cyclotron, electron cyclotron, lower hybrid) and neutral beams in H or D, which are produced by accelerating negative ions that are successively neutralized. As the performance requirements for the ITER Heating Neutral Beam Injectors (HNB) (beam power 16MW, energy up to 1MeV, beam-on time up to 3600s) are far beyond the parameters of existing injectors [1,2,3], ITER will support the development of the ITER HNBs by an ad-hoc ITER Neutral Beam test facility, to be constructed in Padova, Italy. The first test bed of the facility, referred to as SPIDER, will be used for the development of the ITER full-size ion source.

As the final product of the Test Facility is the ITER Neutral Beam Injector, we decided to adhere from the beginning to the ITER CODAC guidelines. Therefore the EPICS system provided in the CODAC Core System will be used in SPIDER for plant control and supervision and, to some extent, for data acquisition. ITER currently does not provide guidelines neither for the management and the storage of experiment data, nor for the implementation of fast control systems. For this reason, two other frameworks will be integrated in SPIDER: MDSplus and MARTe. MDSplus [4] is a framework for Data Acquisition and management largely used in the fusion community. MARTe [5] is a framework for fast real-time control that has been used in several control applications in JET and other fusion machines in Europe. Interfaces between EPICS, MDSplus and MARTe have been developed to provide seamless integration in a complete Data Acquisition and Control system.

An important concept in ITER CODAC is the Self Description Data (SDD), i.e. is the formal description of all the information related to CODAC. Such information includes the definition of the data items, the used hardware, and the software configuration. XML has been chosen to express self-description data, as it is application-independent and is purely data-centred. Even if in principle all self-description data can be expressed by XML text files, in practice more efficient storage strategies are chosen. In particular, the PostgreSQL relational database has been used in ITER to store SDD information. The current version of CODAC Core System includes also an SDD editor, which provides a user friendly interface for the definition of the data items in SDD. Not all aspects of Self Description are currently implemented because the technology of several CODAC components has not yet been chosen by ITER. Currently the SDD editor allows the definition of the functional breakdown, the signal list, and the variables and commands in controllers.

The information stored in the SDD database is used to generate the EPICS configuration files and the PLC Data blocks for data and command exchange between EPICS Input/Output Controllers (IOCs) and the PLCs. It is also possible to export the SDD in XML, and this feature will be used in SPIDER to add configuration generation tools for MDSplus, with the aim of making SDD the sole repository for the entire system configuration.

In the rest of the paper presents the software frameworks used in SPIDER, in particular those components that have been developed to achieve their integration. The applicability of the SDD approach in SPIDER CODAS will be then discussed, as well as the initial experience in the usage of the SDD editor and, more in general, the implications of the Self Description in the integration of different systems.

USED FRAMEWORKS AND THEIR INTEGRATION

Three open-source software frameworks will be used for the implementation of SPIDER Central CODAS and Plant System CODAS: EPICS, MDSplus and MARTe. The choice of three different frameworks is a consequence of the fact that no framework fully covers the requirements for SPIDER CODAS. EPICS addresses overall coordination and slow control, but does not provide a flexible management for data acquisition, nor is it designed for efficient, fast real-time control.

*This work was set up with financial support by Fusion for Energy.
#cesare.taliercio@igi.cnr.it

Sophisticated data management and storage are instead provided by MDSplus, while MARTe provides the functionality required for the implementation of hard real-time control systems.

EPICS

EPICS is a software framework developed to control particle accelerators and other physics experiments. The core of EPICS consists basically of two components: Process Variables (PV) management and Input/Output Controllers (IOC). Control and monitoring in EPICS is achieved by IOCs, where every IOC runs as an application and runs the operations specified by a set of records defined in one or more EPICS databases (EPICS DB). An EPICS DB defines the required actions for control and monitoring. A set of record types is available and can be used for operations such as reading and writing PLC data blocks. Several other tools are part of the EPICS package, including interactive generation of graphical interfaces, alarm handling and data archiving. These tools are built over Eclipse and form the Control System Studio [6] (CSS), available in the ITER MiniCODAC distribution

MDSplus

MDSplus is a software framework for the management of data and the supervision of data acquisition in fusion experiments. MDSplus is centred on the concept of *pulse file* that is a database containing all information which is pertinent to the experiment, including configuration data and experimental results. A large variety of data types is supported by MDSplus including the Signal data type, which describes the time evolution of signals, normally acquired by Analogue to Digital Converters (ADCs). In addition to data describing the experiment parameters and the experimental results, MDSplus provides the Device data abstraction. A Device in MDSplus is represented by a set of data items describing the current configuration of a given hardware component. Multiple instances of the same kind of hardware device will be reflected in the pulse file by multiple instances of data sets, with the same structure, each describing the current configuration of the associated device instance. A set of methods is associated with every device type, corresponding to a routine reading or writing device data items and interacting with the underlying hardware. A Dispatcher tool supervises the execution of all the required operations in the right order during the experiment sequence.

The foreseen usage of MDSplus in SPIDER CODAS is the management of all the configuration and experimental data, including data storage, data access, graphical visualization of acquired signals, and the supervision of the acquisition of data not coming from PLC. Whilst interaction with PLCs in SPIDER will be by means of EPICS IOCs, the supervision of the other hardware devices, such as ADCs and Camera devices will be handled by MDSplus devices, orchestrated by a set of dispatchers, each supervising the operation of a given control unit.

EPICS-MDSplus Integration

As all data dealt with by SPIDER CODAS resides in MDSplus, it is necessary to export configuration and setup parameters to EPICS. This is achieved by letting MDSplus data be exported as PVs via a Channel Access (CA) server. In SPIDER CODAS all the configuration data items held in the experiment model are exported as PV and therefore they are natively available whenever they are required (e.g. to send configuration data to a PLC via the corresponding PLC interface record in the IOC supervising the associated unit).

Exporting configuration data as PVs allows also the interactive development of graphical interfaces for operator displays, carried out by BOY, a component of the EPICS CSS toolset.

Data which are produced in EPICS IOCs will be stored in MDSplus pulse files, too. Such data will be stored in a pulse file by the EPICS – MDSplus Channel Archiver [6], a tool similar in functionality to the BEAUTY tool of the EPICS CSS. BEAUTY provides the monitoring of a selected set of PVs, storing PV values, acquired either at regular rates or whenever their values change, in a relational Database. The MDSplus Channel Archiver has the same interface towards the selected PVs (both tools are CA clients) but stores PV values in MDSplus pulse files. A PV is associated with every EPICS record, and therefore data values acquired from a given PLC, supervised by the corresponding EPICS records, are mapped onto the associated PV variable, and then automatically changed in the trend pulse file.

As EPICS is used in SPIDER CODAS for the overall coordination during the beam sequence, it is necessary to "trigger" the execution of actions supervised by MDSplus at the right time during the beam sequence. As stated before, the specification of the actions to be executed is embedded in the pulse file. The MDSplus Dispatcher will collect such information and will dispatch the corresponding actions whenever requested to execute a given phase in the beam sequence. Such a request must come from an EPICS IOC running the state machine for the SPIDER beam sequence, and will be sent to MDSplus via a dedicated EPICS record.

MARTe

MARTe is a framework for real-time control. MARTe orchestrates the execution of real-time threads, possibly running on different cores of a multi-core system, and the associated data flow. Every thread carries out the execution of a set of Generic Application Modules (GAMs), handling data acquisition from sensors (normally ADC devices), the computation of some control algorithm, and the generation of the reference signals for the plant. MARTe provides an abstraction of the underlying operating systems and therefore can be run on different platforms. New GAMs can be easily integrated in the system, provided they adhere to a given interface, and the whole system is dynamically configured

by a configuration file, thus providing rapid integration of new control components in the system.

The functionality of MARTe is partially overlapping with EPICS IOCs, as real-time control configuration can defined as one or more EPICS DBs and run by one IOC. However the footprint of MARTe is much more reduced compared with that of EPICS, and MARTe can handle fast control with a number of inputs/outputs well beyond the limits of EPICS [8].

The foreseen usage of MARTe in SPIDER CODAS is the generation of the power supply reference signals, including the management of breakdowns, requiring the interruption of the voltage generation and its subsequent restart with a given dynamics whenever a breakdown is detected.

MARTe integration

The required functionality for real-time control in SPIDER CODAS (initially limited to the generation of the power supply reference signals and the management of breakdowns) will be carried out by a set of GAMs developed for this purpose. These GAMs will acquire in real-time one or more signals carrying information about breakdowns and will produce the reference signals for the power supplies, which have to be turned off and then gradually on in real-time. In addition to the Input/Output signals these GAMs will likely require some configuration parameters and will write some signals (e.g. describing the internal behaviour of the control algorithm) in the pulse file. The required data exchange will be achieved via MDSplus as all data dealt with by the experiment is hosted in MDSplus pulse files

INTEGRATION OF CODAC CORE SYSTEM

The current version (v2) of CODAC Core System basically consists in the EPICS core and CSS components, and the SDD editor.

The SDD editor provides a graphical interface for the definition of the Self Description database, forcing at the same time a set of rules for naming convention in order to adhere to the ITER standards. The current version of the SDD editor covers only a subset of the Self Description Data, represented by those components which are required for the generation of the configuration files for EPICS and the data blocks for the declared PLCs.

The SDD provides Schemas for Plant Systems and Plant Systems I&C. A plant system is an autonomous part of the ITER plant which implements a given technical function. Self Description for Plant Systems will define those physical components which are relevant for Instrumentation and Control (I&C). The list of signals handled by the system is part of this description. Every signal, characterized by a name adhering to the ITER naming conventions, is described by properties describing the component to which it refers, its physical characteristics, such as the physical units, and its I&C characteristics, such as its digital resolution.

Whilst the Plant System description provides a description of the physical organization of the described Plant, a different view is normally required when considering the logical organization of its I&C. Such organization is captured in the Plant System I&C part of the SDD schema. Plant System I&C description includes the I&C components, which may be represented by:

- Slow and fast controllers;
- I/O boards;
- PLCs

In addition, Plant System I&C Self Description includes all the EPICS Process Variables (PVs) which are involved in control and data acquisition.

In order to ease the development of SDD, the SDD editor provides a simplified interface which hides the internal distinction between Plant System and Plant System I&C. Basically, for every plant system, the SDD editor creates three folders:

- *Signals*: defined by a set of components, each containing zero or more signals. Components describe physical parts of the plant system. Signal definitions here refer to the physical description of the input or output systems handled by the component. All information defined under the Signal folder is saved in the Plant System part.
- *Variables & Commands*: describing the Process Variables used to exchange data with the PLCs and the I/O boards as well as the commands to be issued to the controllers. Variables and Commands are organized in functions, which describe the functional breakdown of the Plant I&C. This information is stored in the Plant System I&C part of Self Description.
- *Control Units*: describing the control components (Fast Controllers, I/O modules and PLCs) involved in the Plant System I&C.

An extensive consistency check is carried out by the SDD editor to ensure the consistency of the entered information, including the adherence to the ITER naming convention and the cross references. For example, a Process Variable (defined in Variables & Commands) must be deployed to an existing target (defined in Control Units), and a signal must be associated either with an I/O module channel or with a PLC.

Once the I&C configuration has been entered and saved in PostgreSQL, the required configuration files can be generated. Currently, the EPICS IOC Database description is generated, which defines the EPICS records corresponding to the declared Process Variables, and the CSS configuration files for the alarm interface (BEAST), the Operator Panel (BOY) and the channel archiver (BEAUTY). In addition the data block files for the PLC configuration are generated.

SDD USAGE IN SPIDER

The ITER approach in the definition of the plant I&C via the SDD has proved extremely useful in our

experience, and the availability of a good SDD editor from the very beginning of the system development represents a key factor. Being forced to declare all I&C related information using a single tool simplifies the development process, preventing the scattering of information among different components, and avoids to a large extent errors related to the inconsistent mapping among subsystems. It forces at the same time a strict usage of the naming rules, a very important factor in the development of a large system. Moreover, such an approach allows the automatic generation of a set of useful support tools for system monitoring. As an example, besides the generation of the IOCs based on the current definition of the Process Variables and I/O channels, the CODAC Core system generates also two IOCs for the monitoring of several system parameters such as processor load and the state of the communication link with the PLCs.

We found however two main limits in the current tools for SDD management. The first one is that this approach tends to produce a "flat" model, where a set of records is generated, mapped to the I/O channels (PLCs of other boards) defined in the system. Additional semantics, such as the implementation of specific control in the generated IOCs, or the implementation of synchronizing State Machines can currently be achieved only by manually configuring the EPICS DBs to describe the additional functionality. The drawback of such an approach is that whenever SDD information is changed (e.g. a new signal is added), and the new configuration regenerated, all the additional user-provided configuration information is lost. This is a general problem in the automated generation of software components, which could be solved only by incorporating in the SDD definition also the control semantic. This is however a very ambitious approach because it is very hard to foresee all the possible control approaches, and in practice may lead to a system that is too rigid to be usable in practice.

The second limit is due to the fact that the current version is entirely EPICS centred. While the usage of EPICS has a large consensus for plant supervision and monitoring and, more in general to handle plant (slow) signals, the usage of EPICS for fast control and data acquisition may lead to inefficient solutions. Consider for example the acquisition and the storage in the experiment database of a set of signal acquired by an ADC board with a number of analogue inputs. When supervising data acquisition in EPICS, an Analog Input (ai) record would be defined for the ADC board, whose associated driver handles communication with the ADC hardware. The corresponding PV variable would then be monitored by a BOY Channel Archiver tool, saving every sample in a database. Whenever a new ADC sample is available, the corresponding record will be activated, and the value of the associated PV exported via the Channel Access (CA) protocol over the network and finally received and stored in the experiment database. If the sampling rate is of several kHz and many signals are involved, the system overhead may soon become unsustainable. The approach taken in MDSplus, the Data Acquisition system chosen for SPIDER, is completely different, and a data acquisition thread is created to supervise the acquisition and storage of all the channels of the ADC. Whenever a new set of data samples is available, the thread will directly store the data samples in the pulse file using optimized disk access and network communication, (in the case data access is remote). MDSplus has been in fact designed to handle very high data throughput and is routinely used in fusion experiment where data rates of hundreds of MB/s are achieved.

The SDD approach turns out to be useful even in the implementation of the non-EPICS parts of SPIDER CODAS, and the XML representation of SDD will be used as the source of the structure of the MDSplus pulse files. More in detail, information like the list of signals and the definition of the I/O modules can be retrieved and used to produce a standardized structure of the pulse files. This is achieved by using EXtensible Stylesheet Language [9] (XSL) to define the transformation of the Self Description XML files into the XML files used in MDSplus for the definition of the pulse file structure.

INTUITIONISTIC FUZZY (IF) EVALUATIONS OF MULTIDIMENSIONAL MODEL

Ivanka Valova
Sofia University, Sofia, Bulgaria

Abstract

There are different logical methods for data structuring, but no one is perfect enough. Multidimensional model-MD of data is presentation of data in a form of cube (referred also as infocube or hypercube) with data or in form of "star" type scheme (referred as multidimensional scheme), by use of F-structures (Facts) and set of D-structures (Dimensions), based on the notion of hierarchy of D-structures. The data, being subject of analysis in a specific multidimensional model is located in a Cartesian space, being restricted by D-structures. In fact, the data is either dispersed or „concentrated", therefore the data cells are not distributed evenly within the respective space. The moment of occurrence of any event is difficult to be predicted and the data is concentrated as per time periods, location of performed business event, etc. To process such dispersed or concentrated data, various technical strategies are needed. The basic methods for presentation of such data should be selected. The approaches of data processing and respective calculations are connected with different options for data representation. The use of intuitionistic fuzzy evaluations [1]- IFE provide us new possibilities for alternative presentation and processing of data, subject of analysis in any OLAP application. The use of IFE at the evaluation of multidimensional models will result in the following advantages: analysts will dispose with more complete information for processing and analysis of respective data; benefit for the managers is that the final decisions will be more effective ones; enabling design of more functional multidimensional schemes.

The purpose of this work is to apply intuitionistic fuzzy evaluations of multidimensional model of data.

Key words: On-line Analytic Processing, Intuitionistic Fuzzy Evaluations.

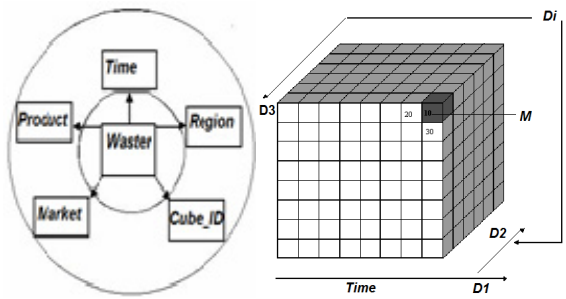
INTRODUCTION

The main task at development of MD model referred as OLAP models is, on the one hand to make the data schemas more understandable for end users and on the other hand to improve the performance in case of queries placed by such users. For such purposes the data schemes are simplified in a manner to contain only most important things (i.e. fact that is to analyzed and respective D-structures, which will be involved in data analysis). These schemas are very close to the concept for performance of data analysis and require the use of specific types of queries, enabling easy adjustment of the system to the needs of users, aiming the obtaining of better response times and producing of result in case of specific query placed.

DESCRIPTION OF THE MODEL

Three different levels of detail have been distinguished in the establishment of a data model, intended for OLAP. On a low level there are measures, which can be grouped into cells if they refer to the same fact (F-structure). The cells further are grouped into different classes, which can be drawn as n-dimensional cubes (on a medium level of detail), owing to which the different dimensions, defining the cube are functionally independent. Eventually, on a high level several cubes representing the same type of fact on different levels of aggregation are grouped into one Fact.

The OLAP model must be able to present a global view of data, including full support for hierarchies of D-structures and multiple hierarchies of data, subject to analysis.



1a) 1b)

Figure 1: Example of OLAP model. 1a) Multidimensional scheme-one F-structure (fact) and several Dimensions (D-structures), 1b) Infocube.

On Fig. 1 is specified example of an OLAP model, where the fact is Wasted product and D-structures are Time, Info Package, Cube_ID, Region, etc. In Fig.1 the Fact is shown in the middle of the scheme, and D-structures (dimensions), being used for analysis of the Fact, are shown around it. The scheme presented in Fig. 1 is also termed "multidimensional scheme" due to the large number of D-structures, which may be involved. The fact in a multidimensional scheme is the object, which contains measures.

Organization of data in a "star" type schema or its representation in form of a cube is very close to the concepts for performance of analysis and facilitates the use of data by end users.

Description of the D-structures

In multidimensional models the information is divided in facts (F-structures) and dimensions (D-structures) [2].

D-structure, (Dimension) – different initial viewpoints at data selection, which will be used during fact analyzing. D-structures contain mainly description attributes.

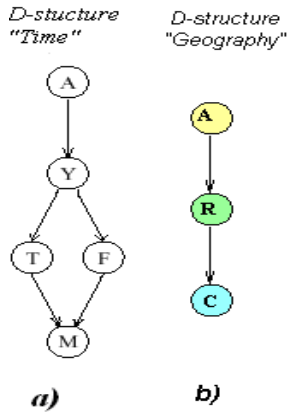


Figure 2: a) D-structure "Time" , A-All, Y- Year, T-three month, F-four month, M –Month b) D- structure "Geography", A-All, R- Region, C-City.

D-structure represents a connected directed graph, provided that each node of the graph corresponds to a given aggregation level, and its arcs reflect "part-whole" relations between the objects within the aggregation levels.

The hierarchy of certain D-structure is linked with determined data consolidation path (Fig. 2). The consolidation path is composed of series of levels or consolidation steps, where each level represents a higher degree of data consolidation. For instance, "business enterprise" may include as consolidation path the levels "business area", "branch", "department", "project", "task" and "employee" [3]. The software product SAP BIW supports 16 D-structures, provided that three of it are mandatory. These are: "Time", "Units", which provide meaning of the values for key indicators and Info packages.

Description of the F-structures

F-structure (Fact) – it represents the data, subject to analysis. The fact contains numerical attributes. The fact in a multidimensional scheme is the object, which contains measures. Measures evaluate attributes of fact [4].

The fact wasted products is evaluated by using the following measures: costs for invested labor, costs for materials used, transportation costs, number of persons involved in the process of wasting and evaluation of the respective products and total costs and other depending on the point of view of the developer and on the endmost needs of analysts and users.

We have evaluated D-structure Product (the degree of preference for whether an article is liked or not), and to make our evaluation more complete it is necessary to consider the Region, where these goods are wasted, the Chain of stores in which the largest quantities have been wasted (and to try to answer whether the wasted goods are a result from poor management), the Vendor who has wasted the goods (if wasted goods are in found in greatest quantity in the same vendor) and if we also consider the Time as a D-structure, we can evaluate in which periods the quantity of wasted goods is the greatest and thus we can evaluate the degree of consumption depending on different seasons.

The subject matter of analysis (fact) is wasted products. Typical D-structures of this application are: product, which is wasted, the store in which it is wasted (e.g. Sofia, Z street) and the date of the respective operation. These D-structures form one hypercube.

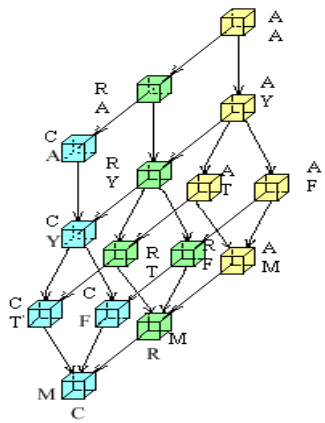

Figure 3: Example of F-structure.

In order to simplify the drawing of model only two D-structures are used – Time Fig. 1a), Geography –Fig. 1b). It is shown on Fig. 3 the structure of Fact, composed of several cubes (boxes). The cubes containing letter C may be used for the purposes of analysis of goods in certain city for different time periods – month, quarter..... year. The cubes containing letter R are used for analysis of goods per regions, again for month, quarter..... year. The box MC shows goods for a month in given city. The cube CT shows certain goods in given city and for time period - quarter. The cube MR reflects the certain goods for a month, but in given region, etc.

If in any F- structure, intended for OLAP, exist All-level and atomic level and the remaining levels are segmented (i.e. contain more than one object or more than one cube), than the graph is a lattice. In the F-structure, intended for OLAP, exists unique level called atomic, which contains elementary objects. Each object at atomic level has one part and this object is called elementary. In D – and F-structures, intended for OLAP, exists a unique level called All- level. This aggregation level has exactly one object.

INTRODUCTION OF IF ASSESSMENTS

We use A_1, A_2,..,.A_n for marking of articles (attributes of certain product). Each symbol may be indicated by lower index for marking of different names from same type.

Each attribute A should be related with definition area dom(A).
Let:
$k(A_i, R_i, T_i)$ – to be the quantity of the objects of the relevant product.
$p(A_i, R_i, T_i)$ – the quantity of the sold articles
$q(A_i, R_i, T_i)$- the quantity of the waste articles.
T_i, R_i – specify time and location of the relevant article

$$\{ \langle A_i, R_i, T_i \rangle, \mu(A_i, R_i, T_i), \nu(A_i, R_i, T_i) \mid \langle A_i, R_i, T_i \rangle \in E \}$$

π - the produced articles, but still remaining unsold, i.e. some of them may be scrapped, therefore there is indefiniteness.
μ - produced and sold articles
V_ν *(All)* - gives the correlation of the waste articles towards the overall production.

$$V_\nu(All) = \frac{\sum_{i=1}^{n} q(A_i, R_i, T_i)}{\sum_{i=1}^{n} k(A_i, R_i, T_i)} \quad (1)$$

$V_\nu(A_i, R_i, T_i)$ - assigns the degree of the waste articles.

$$V_\nu(A_i, R_i, T_i) = \frac{q(A_i, R_i, T_i)}{k(A_i, R_i, T_i)} \quad (2)$$

$V_\mu(All)$ - give preference to the relevant article as a whole

$$V_\mu(All) = \frac{\sum_{i=1}^{n} p(A_i, R_i, T_i)}{\sum_{i=1}^{n} q(A_i, R_i, T_i)} \quad (3)$$

$V_\mu(A_i, r_i, t_i)$ – assigns the degree of preference, whether certain article is preferred or not.

$$V_\mu(A_i, R_i, T_i) = \frac{p(A_i, R_i, T_i)}{k(A_i, R_i, T_i)} \quad (4)$$

From (1) and (3) it follows that

$$V_\mu(All) + V_\nu(All) = \frac{\sum_{i=1}^{n} p(A_i, R_i, T_i) + q(A_i, R_i, T_i)}{\sum_{i=1}^{n} k(A_i, R_i, T_i)} \le \frac{\sum_{i=1}^{n} k(A_i, R_i, T_i)}{\sum_{i=1}^{n} k(A_i, R_i, T_i)} = 1 \quad (5)$$

Therefore $\langle V_\mu(All), V_\nu(All) \rangle$ is an IF estimation.

From (2) and (4) it follows that

$$V_\nu(A_i, R_i, T_i) + V_\mu(A_i, R_i, T_i) = \frac{q(A_i, R_i, T_i) + p(A_i, R_i, T_i)}{k(A_i, R_i, T_i)} \le \frac{k(A_i, R_i, T_i)}{k(A_i, R_i, T_i)} = 1 \quad (6)$$

for each A_i, R_i, T_i.
Therefore $\langle V_\mu(A_i, R_i, T_i), V_\nu(A_i, R_i, T_i) \rangle$ is an IF estimation.

For evaluation of the model we can use Fig. 4. We introduce β, α - Fig. 4. If the aggregate evaluation falls within the trapezoid αODB we have the optimal variant. In case that the respective evaluation falls within the trapezoid αECA, it serves as a sign that the production is ineffective. If the aggregate evaluation falls within the triangle EOD, it means that the production output exceeds the minimum and is sold above the minimum, and on other side the goods become slow-moving ones, which serves as indicator that it is produced more than needed.

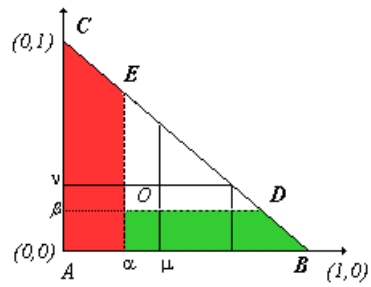

Figure 4: Intuitionistic fuzzy evaluations.

The use of IFE at the evaluation of multidimensional models will result in the following advantages: analysts will dispose with more complete information for processing and analysis of respective data; benefit for the managers is that the final decisions will be more effective ones; enabling design of more functional multidimensional schemes.

CONCLUSIONS

In this paper we represented the use of IFL in assessment of the MD models for analytical data processing.

NOMAD – MORE THAN A SIMPLE SEQUENCER

P. Mutti, F. Cecillon, A. Elaazzouzi, Y. Le Goc, J. Locatelli, H. Ortiz, J. Ratel,
Institut Laue-Langevin, Grenoble, France

Abstract

NOMAD is the new instrument control software of the Institut Laue-Langevin (ILL). A highly sharable code among all the instruments' suite, a user oriented design for tailored functionality and the improvement of the instrument team's autonomy thanks to a uniform and ergonomic user interface are the essential elements guiding the software development. NOMAD implements a client/server approach. The server is the core business containing all the instrument methods and the hardware drivers, while the GUI provides all the necessary functionalities for the interaction between user and hardware. All instruments share the same executable while a set of XML configuration files adapts hardware needs and instrument methods to the specific experimental setup. Thanks to a complete graphical representation of experimental sequences, NOMAD provides an overview of past, present and future operations. Users have the freedom to build their own specific workflows using intuitive drag-and-drop technique. A complete drivers' database to connect and control all possible instrument components has been created, simplifying the inclusion of a new piece of equipment for an experiment. A web application makes available outside the ILL all the relevant information on the status of the experiment. A set of scientific methods facilitates the interaction between users and hardware giving access to instrument control and to complex operations within just one click on the interface.

INTRODUCTION

The Instrument Control Service (SCI) in close collaboration with the ILL's scientists has taken up the challenge to redefine the way experiments are performed. The initial part of the project has been dedicated to an exciting discussion with our scientists and users to define all the use-cases to be included in NOMAD. Such a discussion brought the attention on the following use-case:

UC1: *hardware installation*. Hardware added to the instrument needs to be incorporated into the software control. We have detailed how a new electronic device can be added dynamically to the control software.

UC2: *instrument component setup*. Once a new hardware is added it needs to be configured. This use-case takes into account the different roles that hardware components can have on the instrument control.

UC3: *instrument calibration*. After the hardware is correctly installed and configured, it needs to be calibrated to ensure a correct functioning of the instrument before performing an experiment. This may involve proper PID settings, detector calibration, etc…

UC4: *sample alignment*. In certain cases, a sample needs to be aligned. This is most commonly performed on diffraction-type instruments in which the diffraction pattern depends upon the orientation of the sample with respect to the neutron beam. In other types of instruments this alignment is sometimes known in advance but the instrument still needs to be setup correctly depending on the type of experiment being performed.

UC5: *performing the experiment*. This use-case describes the general steps involved in the execution of an experiment. It starts from the verification of the status of the instrument to continue with the execution of pre-defined list of commands. At the end of a well-defined sequence, data are stored and a detailed report of all the various steps undergone is produced.

All those different use-cases lead to the implementation presented in the current paper.

ARCHITECTURE

The Nomad application is a two-tier client server application [1]. Figure 1 shows a simplified component diagram of the application

Server

The Nomad Server application is the part of the program executing the main tasks required for the control of the instruments. The server written in C++ [2] has three main roles:

- Data provider: to provide the actual values of the variables of the system (e.g. the properties of the instrument).
- Plug-in container: to load, initialize and execute the business logic of the instrument. The state of the instrument is periodically updated by the reading of the connected devices. The business layer is organized into plug-ins separated into drivers (low level layer) and controllers (high-level layer).
- Command sequencer: to process the requests of the client. Those can be complex sequences of instructions onto controllers. A client user can launch batch processing by programming a combination of for loops with parallel execution of commands for the night.

The plug-in libraries are divided into controllers and drivers. These are dynamic libraries loaded by the server. They contain all the business code written for NOMAD including all the available drivers and controllers. Some controllers can be common to each instrument, but some controllers are instrument specific. We also have different levels of abstraction for controllers.

The controller and driver classes loaded by the plug-in libraries describe an object-oriented model of classes. Controller classes interact with controller or driver

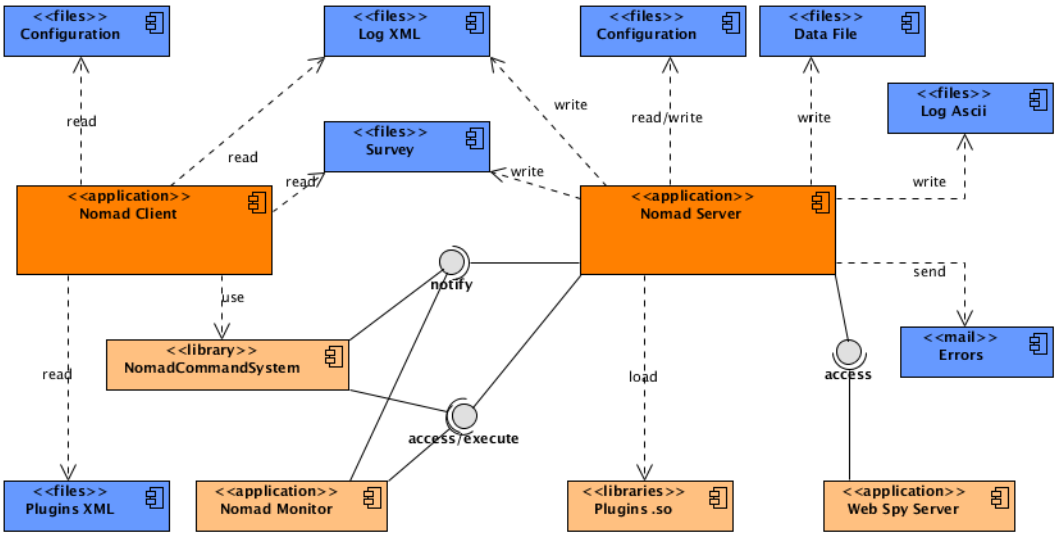

Figure 1: Simplified component diagram for the NOMAD application.

interfaces. We need to describe how we link the different controller and driver objects. These configurations are specific to each instrument. Two main configuration files, the *InstrumentConfig* and *HardwareConfig*, list the controllers and drivers required for a given instrument and how they are linked together. Additional instrument specific configuration files describes acquisition settings or scheduler rules indicating which controllers can execute tasks in parallel and which should be strictly sequential.

The results of the data acquisition are stored into several different file formats. ASCII data files contain all the relevant information organized in a text format following specific rules to be compatible with the existing ILL's data treatment programs. NeXus [3] files contain binary and compressed data. Nexus is a common data format share by neutron, x-ray and muon facilities. It is based on the Hierarchical Data Format (HDF) developed by U.S laboratories and extremely powerful for large data sets. LIST-MODE files are pure binary containing, beside a specific ILL header, the sequence of all detected events and the associate time-stamp to provide a maximum of flexibility to replay the experiment off-line.

NOMAD records all important instrument history information in daily log files. The ASCII version is directly accessible by the user via his favourite text editor. The server includes in this file some additional debugging information that can be helpful for the developers in case of unexpected behaviour. NOMAD is also saving a XML version of the log file. This can be accessed by the NOMAD client application and provides additional features to the user like filtering on specific actions and calendar navigation.

All instrument parameters are permanently monitored and stored into daily Survey XML files. Those data are displayed by the NOMAD client application in a dedicated plot window and the user is able to dynamically select and visualise a specific set of system's variable.

The server automatically notifies to the administrator or to the users all errors occurred during the execution.

Client

The Nomad Client application written in Java [4] SWT is designed to offer a practical Graphical User Interface (GUI) for the user to control the instrument. A dedicated effort has been made to provide an easy-to-use graphical programming of complex sequences of instructions. The NOMAD client application consists of three different graphical views specifically designed to satisfy different needs. The *Hardware* view is intended for the technical support and gives access to all hardware specific parameters like displacement limits, positioning speed, etc… The *Setting* view is mainly devoted to instrument responsible and allows configuring higher-level controllers. Finally the *Launch-Pad* view permits the creation and the execution of a specific workflow.

The *NomadCommandSystem* library is a fundamental component of the client architecture. It is designed as a bridge between the client and the server. It abstracts the way to request the server and it mainly uses Corba proxy objects to communicate with server. It implements some Corba IDL interfaces since it also acts as a server from the Corba point of view.

To minimise the coding work we have designed an XML file format to describe controllers and drivers' GUI without writing any Java SWT code. However, some specific GUI behaviours that cannot be obtained by XML description are directly coded in Java SWT. Some additional configurations files are required by the client application to start. They concern for example label text properties.

Nomad Monitor

We have designed a NOMAD Monitor application written in Java RCP to visualise the actual status of the NOMAD Server system. The application offers the list of the controllers and drivers showing all their property and

the associated values. Controller and driver objects are loaded by requesting the Nomad Server. Nomad Monitor enables debugging controller and driver execution and acts also a configuration manager giving the possibility to dynamically add a new controller or a new driver while the server is running.

Web Spy Server

To provide the user with a maximum of information to promptly react in case of a problem or simply to remotely verify the status of the measurement we have developed a web server that retrieves periodically from NOMAD Server all the actual values of properties. An instrument specific web page is then updated to provide all important information on the instrument (see Fig. 2).

Figure 2: Layout of the web spy for the instrument IN4.

INTER-APPLICATION COMMUNICATION

The CORBA [5] architecture has been chosen to make the connection between the C++ server and the Java client. The CORBA standard offers a flexible interoperability service through the definition of IDL interfaces and its implementations provide good performances in regard of other inter-application communication like, for instance, Web services. However we made the choice to minimize the dependency to CORBA by avoiding the number of CORBA objects for which life cycle is not so easy to manage in C++ and leave them only to the communication layer. For this reason, all our CORBA objects are wrapped into Adapter objects (client and server) that we call *Accessors*. Server and clients use a two-way communication for:

- access/execute: the clients request the server to get or set a value, to execute tasks, etc…
- provider: to provide the actual values of the variables of the system (e.g. the properties of the instrument)
- notify: the server notifies the client when a server variable has changed.

For the client to server requests (on a user request), the client contacts directly the server through the CORBA *Accessor* objects. The server to client request uses the *Observer* pattern to implement an event-handling system.

NOMAD server registers CORBA subscriber objects to dispatch events to them. The server and the clients both use a Producer/Consumer pattern for respectively send and process the event, resulting in an asynchronous event notification. Figure 3 shows a simplified example of server to client forward and backward communication. The Access Data model illustrate the different patterns, synchronous and asynchronous messages from the notification of the server of a value changed to the call of the client for getting the value.

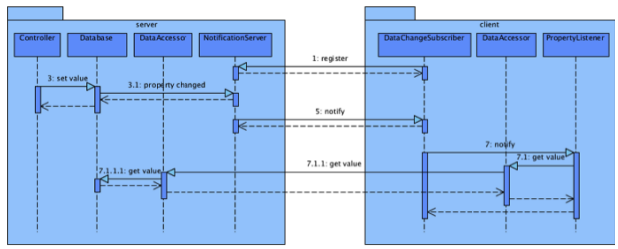

Figure 3: Data Access sequence.

The distributed Publisher/Subscriber objects when the client and the server communicate over a network offers great advantages to refresh the client only when needed and prevent from using client polling, but one drawback is that we can face client firewall port denials.

THE NOMAD SERVER LAYERS

The NOMAD server application is a multi-threaded application designed in three distinct layers.

- Data Provider is the part of the server that stores the data model, e.g. the hierarchy of controllers and drivers with their associated properties. We also store the list of commands accessible from each controller and driver and their current state. This is the data representation of the controllers and drivers running in NOMAD server for a specific instrument (loaded from the configuration files).
- Command can be considered as the business logic layer. It is responsible to execute the requested commands to the controllers and drivers. Each controller or driver accesses its property data from the Data Provider layer. We have designed a framework of classes for controller and drivers to facilitate the business code integration. We have chosen to implement an event-driven programming [6] model to react easily to the real instrument dynamic behaviour (listening to sensors). *AbstractController* is the abstract class to specialize. It contains access methods to associated properties that are bridges to the Data Provider data model. It implements the methods *execute*, *refreshSetValue*, *updateProperty*. The method *execute* contains the execution code of the different registered commands. The most important command is *start*. The *refreshSetValue* is the function implementing how the controller reacts when one of its properties change. This is the way to spread information from the high-level layer (controller) to the low-level layer (driver). The *updateProperty* is the function

describing how the controller reacts to the change of a property of one of its linked controllers or drivers. This is the way to spread information from the low-level layer to the high-level layer. NOMAD has at present about 250 controllers (from the most general to the most instrument specific) and 150 drivers available.

Error management controls the way NOMAD server reacts to the real behaviour of the instrument that can be seen as a complex system depending on many uncontrolled parameters. During the development phase we have rarely access to the real instrument therefore, all the tests performed in the lab cannot be exhaustive. To limit error's occurrence we run logical unitary and functional tests with a basic simulation of the system. A second series of tests aim the verification of the consistency of all instrument configurations. Unexpected behaviours can lead to exceptions, reported in the log files, or to crashes. The last are notified by mail to the developer's team together with the maximum of available information to allow further analysis of the problem. Errors connected to defective behaviour of the instrument generate a series of alarms or warnings that are notify by mail to the instrument responsible.

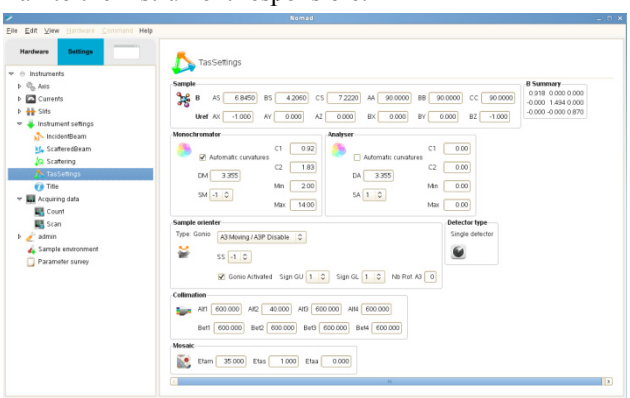

Figure 4: An example of abstract controller.

INSTRUMENT ABSTRACTION

Abstract controllers are used to hide from users the specific underlying hardware or control sequences. It provides an interface relevant to a specific function and then passes user requests to the more specific instances.

The main purpose of the instrument control software renewal is to free human resources and re-uses them to integrate prototyped versions of scientific methods into NOMAD. The main objective is to perform faster and more accurate measurement through intelligent scientific methods and thus increase the efficiency of instruments.

Handling instrument methods complexity, instruments control methods appears at first glance as complex and of large variety. The scientific analysis shows that instrument and scientific methods can be well organized into common elements with specific parameterization.

They are organized in term of primary and secondary spectrometer, sample orienteer, basic scattering and orientation strategies. Presently, the design of the scientific methods shows that only a few set of objects are actually needed. The present complexity and variety comes from the fact that mathematical models are merged into single routines, rigidifying the code. As well, science groups have different notations referring to the same scientific concepts. These will be handled by the GUI, letting the physics concepts behind untouched. Fig. 4 depicts and example of abstract controller that regroup in one single interface all the quantities needed to properly initialise a three-axis spectrometer and prepare it for the experiment. Complex instrument's setup but also alignment and acquisition sequences have been optimized and specifically coded in NOMAD to get the best out of the available beam-time and to facilitate users' tasks.

CONCLUSION

After an initial phase of heavy debugging, NOMAD is meanwhile installed on all ILL's instruments for motors and general hardware setup. So far, more than 20 instruments are fully controlled with it and more are added on a regular base. In addition, 10 installations have been performed to drive technical equipments within the Technical and Project Department. NOMAD includes meanwhile all the hardware devices present at the ILL and all the generic sample environment modules as well as all the instruments' specific ones. It provides the users the freedom to configure dynamically the equipment needed for a specific experiment. The full integration between sequencer, hardware devices and sample environment allows a much better event handling and full synchronization. As well, physical quantities, like energies or wavelength, are compounds of several hardware components. The control of the instrument directly through physical values, those who have a meaning for the user, implied a new way of managing interconnected hardware pieces. Giving control at a more physical than hardware level is in the spirit of opening our instruments suite to a broader audience.

AUTOMATIC CREATION OF LabVIEW NETWORK SHARED VARIABLES

Thomas Kluge, Siemens AG, Erlangen, Germany
Harm Schroeder, ASTRUM IT GmbH, Erlangen, Germany

Abstract

We are in the process of preparing the LabVIEW controlled system components of our Solid State Direct Drive® experiments [1, 2, 3, 4] for the integration into a Supervisory Control And Data Acquisition (SCADA) or distributed control system. The predetermined route to this is the generation of LabVIEW network shared variables that can easily be exported by LabVIEW to the SCADA system using OLE for Process Control (OPC) or other means. Many repetitive tasks are associated with the creation of the shared variables and the required code. We are introducing an efficient and inexpensive procedure that automatically creates shared variable libraries and sets default values for the shared variables. Furthermore, LabVIEW controls are created that are used for managing the connection to the shared variable inside the LabVIEW code operating on the shared variables. The procedure takes as input an XML spreadsheet defining the required input. The procedure utilizes XSLT and LabVIEW scripting. In a later state of the project the code generation can be expanded to also create code and configuration files that will become necessary in order to access the shared variables from the SCADA system of choice.

PROBLEM INTRODUCTION

Using LabVIEW [5] network shared variables [6] makes it easy to connect LabVIEW controlled hardware components to a SCADA or distributed control systems via OPC [8] (see Fig. fig:ExVarDef). You have to provide a set of network shared variables and LabVIEW code that reacts on changes to these variables or updates them. LabVIEW's shared variable engine provides the OPC server.

However, when creating and using shared variable libraries in LabVIEW we've been facing the following tasks that require similar or even identical actions or coding for each variable.

- creating a shared variable library,
- creating a shared variable,
- initializing the value of a new shared variable,
- opening and closing the connection to a shared variable,
- reading and writing shared variable values.

Later, when the connection to a SCADA or distributed control system has to be done, for each library configuration files will have to be written that describe the shared variable libraries for the integration into the system. With multiple instances of the same hardware component the variable creation tasks are multiplied with the number of instances.

The effort for this tasks is significant as it is comparable to the implementation of the real functionality of the code that connects the shared variables with the hardware driver calls.

MATERIALS AND METHODS

Shared Variable Library Description

A shared variable library is identified by a location URL and a name. The library can contain variables of simple types (integer, floating point, boolean, string) and one-dimensional arrays of simple types. Each variable has a unique name inside the library. For each variable we want to define a default value that can be used for initialization of newly created variables.

Required LabVIEW Clusters

For the generic LabVIEW functionality described later we need a set of LabVIEW clusters for each shared variable library. The clusters for each shared variable in the library contain one element named identically to the shared variable in order to store specific information.

- The elements of the "type cluster" have the same type as the shared variable. The "type cluster" can be used for getting information about the data types of the shared variables and for storing values of the shared variables.
- The elements of the "refnum cluster" are LabVIEW's shared variable refnums. They are used for maintaining information about open connections to shared variables.
- The elements of the "access cluster" are booleans. They are used for controlling which shared variables are accessed by generic LabVIEW functionality.

Generic LabVIEW Functionality

Using references to the LabVIEW controls just introduced the following functionality can be provided by generic LabVIEW Virtual Instruments (VI) for all or only a subset of the shared variables inside a library

- creating a variable,
- opening the connection to a variable,
- closing the connection to a variable,
- reading values,
- writing values,
- pre-setting access control cluster.

Shared variable library specific VIs providing this functionality for the clients of the shared variale library just use references to the specific clusters and call these generic VIs.

7						

Figure 1: Example of a shared variable library definition. The XML spreadsheet can be edited with Microsoft's Excel.

Automatic Code Generation

The information about the shared variables and the names of the generated artifacts are stored in an XML file [10] that conforms to the Microsoft XML Spreadsheet [13] schema [12]. This format makes it easy to edit the information and allows us to process it with XSLT stylesheets [11]. The XML file is XSLT-transformed into an XML string that conforms to the LVData XML schema [7] and is then converted into a LabVIEW cluster. This cluster is used by LabVIEW scripting [9] for the generation of all shared variable library specific clusters and VIs.

EXAMPLE

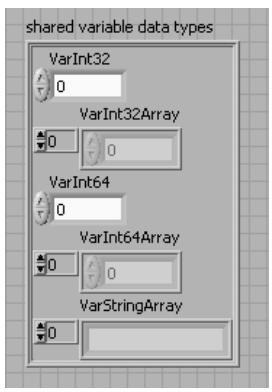

Figure 2: Example of an auto-generated "type cluster".

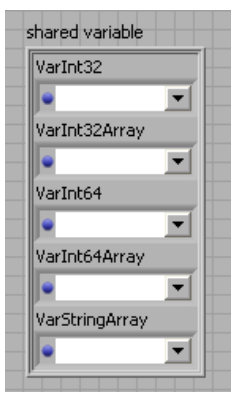

Figure 3: Example of an auto-generated "refnum cluster".

Figure 4: Example of an auto-generated "access cluster".

NEXT STEPS

The tool-chain we have introduced will be used in a next step for decoupling the LabVIEW graphical user interfaces from the underlying hardware control functionality. After this has been done the hardware functionality will be connected to a SCADA system. The tool-chain will be expanded in order to generate the SCADA system specific configuration files for the shared variable libraries.

SUMMARY

LabVIEW scripting has successfully been utilized for LabVIEW code generation allowing significant reduction of recurring work for generating and using LabVIEW shared variable libraries. The LabVIEW-independent XML input information can easily be utilized for further text-base code generation within the build process.

Figure 1 shows a screen-shot of the spreadsheet defining a shared variable library. The auto-generated LabVIEW clusters are shown in Figures 2, 3 and 4. Figure 5 gives you an impression of a generic VI that operates on the auto-generated clusters. The VI shown in Figure 6 is auto-generated and calls the generic VI with references to specific cluster instances. Finally, Figures 7 and 8 illustrate the use of LabVIEW scripting for creation of the cluster shown in Figure 2.

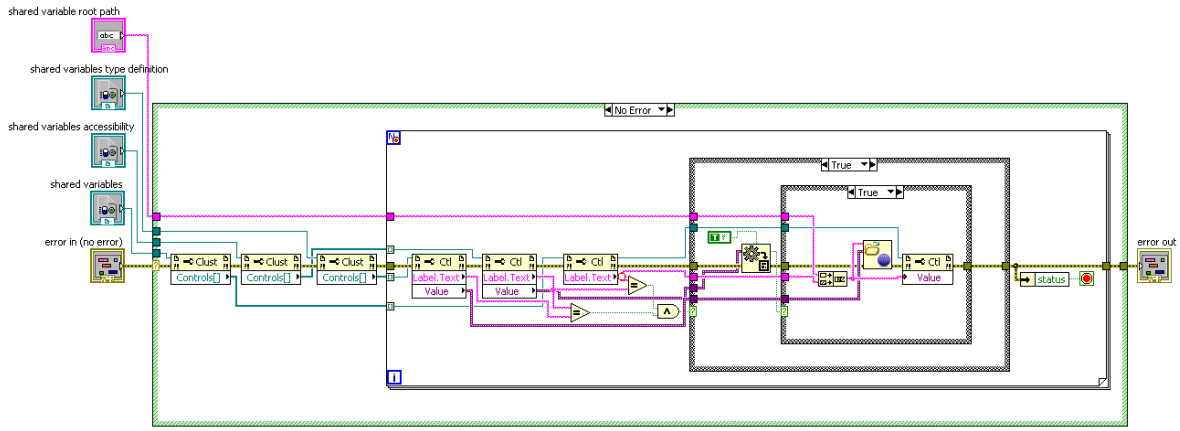

Figure 5: Example of a generic VI. The block diagram shows how shared variables are opened using the auto-generated clusters.

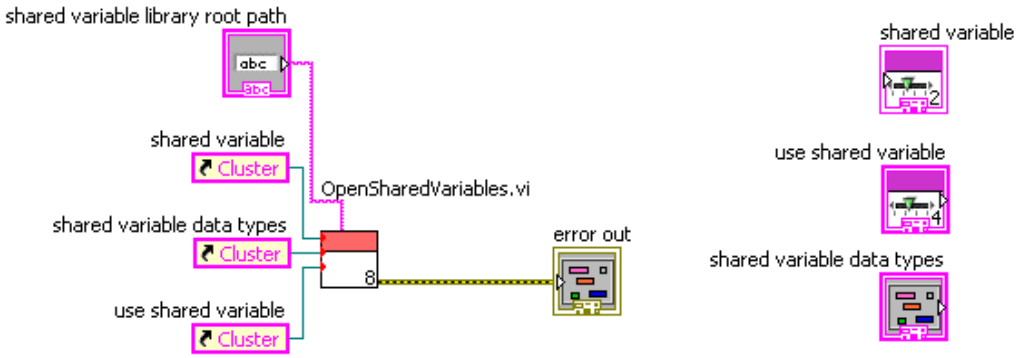

Figure 6: Example of an auto-generated VI that uses the generic VI from Figure 5 for opening shared variables from a specific library.

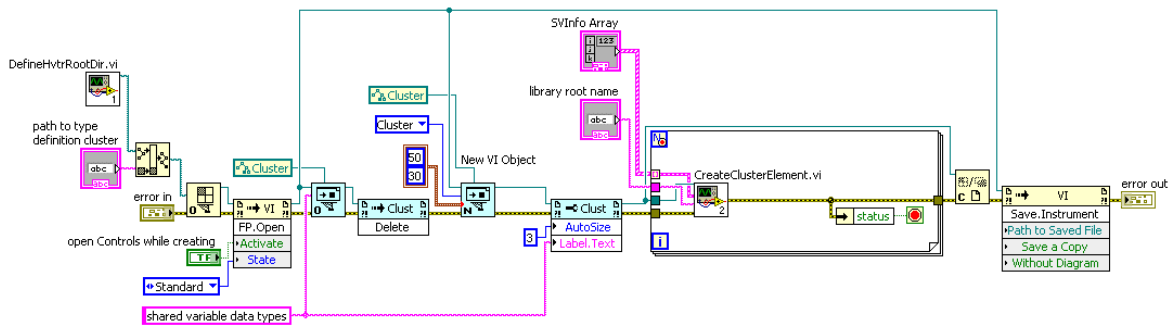

Figure 7: Example of a LabVIEW scripting VI. This VI creates the cluster shown in Figure 2. The sub-VI CreateClusterElement.vi is shown in Figure 8.

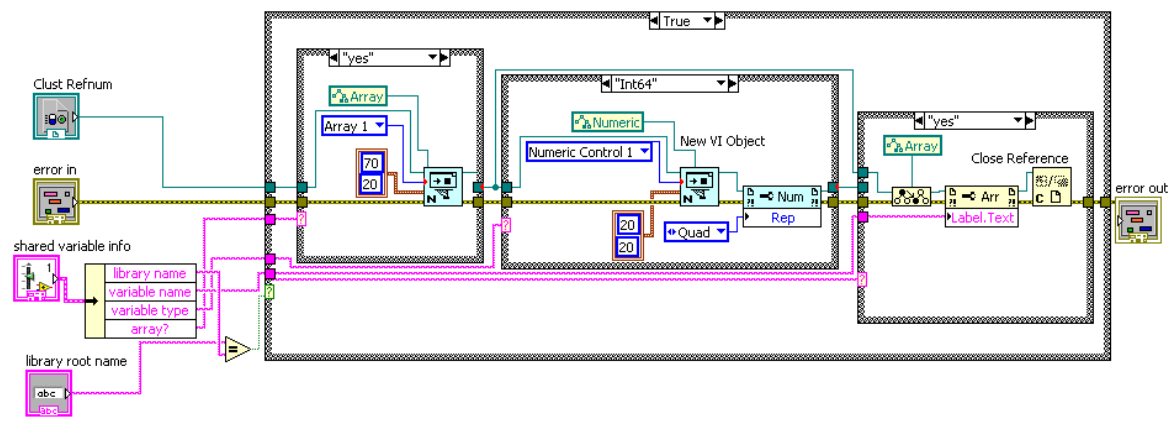

Figure 8: Example of a LabVIEW scripting VI. This VI creates the elements of the cluster shown in Figure 2.

SOFTWARE FOR VIRTUAL ACCELERATOR DESIGNING

N. Kulabukhova, A. Ivanov, V. Korkhov, A. Lazarev, SPbSU, Saint-Petersburg, Russia

Abstract

The article discusses appropriate technologies for software implementation of the Virtual Accelerator. The Virtual Accelerator is considered as a set of services and tools enabling transparent execution of computational software for modeling beam dynamics in accelerators on distributed computing resources. Distributed storage and information processing facilities utilized by the Virtual Accelerator make use of the Service-Oriented Architecture (SOA) according to a cloud computing paradigm. Control system toolkits (such as EPICS, TANGO), computing modules (including high-performance computing), realization of the GUI with existing frameworks and visualization of the data are discussed in the paper. The presented research consists of software analysis for realization of interaction between all levels of the Virtual Accelerator and some samples of middleware implementation. A set of the servers and clusters at St.-Petersburg State University form the infrastructure of the computing environment for Virtual Accelerator design. Usage of component-oriented technology for realization of Virtual Accelerator levels interaction is proposed. The article concludes with an overview and substantiation of a choice of technologies that will be used for design and implementation of the Virtual Accelerator.

INTRODUCTION

The key idea of Virtual Accelerator (VA) concept is beam dynamic modeling by the set of several packages, such as COSY Infinity, MAD, etc., based on distributed computational resources, organized on Grid-technology.

Simulation beam dynamics by different packages with the opportunity to match the results (in case of using different resources for the same task) and the possibility to create the set of tasks when the results of using one package can be sent to the input of another is the main use of VA.

Users will get the access to VA resources by unified interface including GUI on different platforms:

- Web-based application: web-services, web browsers' application (Java Webstar technology, Silverlight, etc.).
- Desktop applications: Windows, Linux.
- Mobile platforms: Android, Windows Phone 7.

Note that the VA is considered as information and calculation environment and does not refer to the real-time control systems. On the other hand this control organization must be provided by connection to the specialized software (e.g. EPICS). Such kind of VA is examined in [1] and [2] where authors emphasize on accelerator control development.

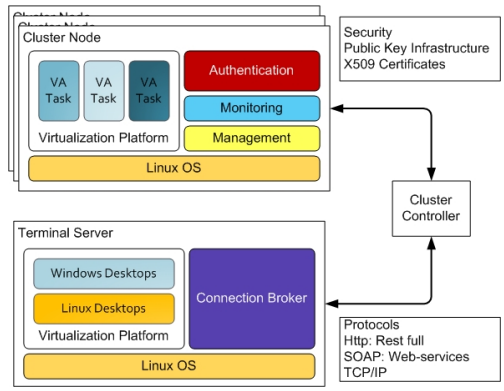

Figure 1: Virtual Accelerator.

In Fig. 1 VA scheme is shown. Cluster controller is a middleware framework developed to interact with calculation programs. This framework provides access by widely used standard protocols such as HTTP, SOAP, TCP/IP.

The same approach to develop a virtual laboratory is discussed in papers [3] and [4] for nuclear physics applications. In article [5] a heterogeneous computing environment and development of the distributed computing systems development are examined.

VIRTUAL ACCELERATOR SCHEME

The usage of VA as a computational resource can be presented as following:

1. Access to the VA resources by the authorization and authentication of users.
2. Specify initial data and settings for calculation:
   - on generalized language for system description (e.g. XML-based),
   - on native package language (COSY Infinity, MAD, OptiM).
3. Choice of the packages and simulation algorithms. Note that user can define the structure on one language (for example, on COSY Infinity notation) and select another program for calculation (e.g. OptiM). In this case conservation of system description will be made by the VA infrastructure invisible for user. And giving the instructions to start the simulation.
4. Monitoring of the task states, data visualization and representation. Access to a logging system with error tracking.

5. Access to the storage of user data that can be represented as simple remote file system with users directories and files. WebDAV protocol can be used for such system.

Security: Access to VA

The VA is available for users as Cloud-service (based on Grid-technology) with standart security features. The authentication techniques are:

- Username and Password
- Public Key Infrastructure and X509 Certificates

Transport level security is provided via SSL encryption. For the prototyping and testing we use OpenSSL program to generate own certificates.

Middleware Implementation: Server Side

Nowadays there exist number of programming languages and technologies. For VA implementation we use Java VM and .NET Framework[1]. Each of these platforms has great built-in capabilities for developing server side software. For example, WCF (Windows Communication Foundations) as a part of .NET Framework provide mapping of business logic in high-level programming languages into web-protocols without any additional effort other than adding declarative information to existing methods.

Client Application

As we mentioned above VA can provide unified access to it services both for web and desktop application. Not

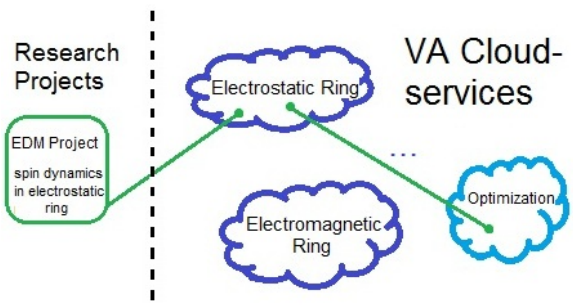

Figure 2: Cloud-services for EDM-project.

all services are required in each case. For example, for EDM-search project[2] it is necessary to include only electrostatic elements, optimization modules and related components (see Fig. 2). Other modules are enabled but available for the research purposes.

An example of the program for EDM project is presented on Fig. 3. It involves electrostatic LEGO objects (elements

[1]Microsoft .NET Framework under Academic Alliance License and Mono as OpenSource platform.

[2]St. Petersburg State University collaborates with Institute for Nuclear Research of Forschungszentrum Jülich, Germany.

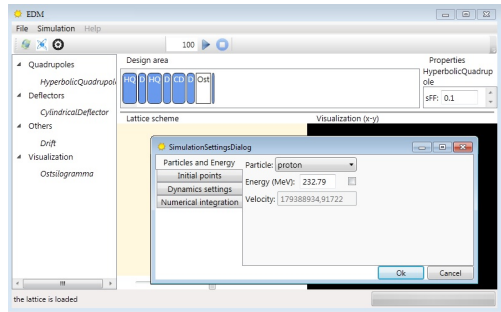

Figure 3: Windows desktop application.

with its parameters, fringe field components), optimization module (e.g. optimization module based on genetic algorithm approach) and visualization tools.

Task Monitoring

For the calculation complex problems (such as long-term beam evaluation) it is important to provide monitoring tools. Researchers at any time can have an opportunity to see progress of the task, restart or cancel it, save obtaining result and etc. VA services must provide real-time interaction with users requests. This requirements provide a complete integrated computing environment for composing,, running, controlling and visualizing applications.

Connection to Physical Equipment

In VA concept it is common interface for simulation model and there should not be differences between access. Both simulation model and equipment adapter (e.g. under the EPICS) must implement the same interfaces. EPICS can be used as a part of the simulation process.

The common user interface of VA allows us to get solutions both in simulation models and in a real machines. This approach provides researcher some mechanism of system identification, parameters optimization and result verification. Such opportunity is impossible without computational models and is a goal aim of the current research.

LEGO PARADIGM IMPLEMENTATION

A LEGO paradigm for VA design is described in [6]. In terms of information technology it corresponds to object oriented design and component programming. Each object represents as independent component with own parameters and behavior. Building the proper class hierarchy allows developer to scale and modify the objects using the already existing solutions. C# and .NET are used for prototyping at the moment. This technology has several advantages compared to Java VM (pointers and memory allocation in the stack, declarative description of the desired functionality, etc.). But in general, these platforms are very similar and the choice depends on the preferences of the development team at all. Note that for implementation of numerical al-

Table 1: Summary of Used Languages

Language	Performance	Web Interfaces	Flexibility
C++	++	--	--
C#	+-	++	++
Java	-+	++	+-

gorithms it will be use C++ as the most powerful language for computing tasks.

A LEGO object is represented as a component object. In object oriented design it means a class with predefined interfaces. Objects has an inheritance hierarchy in that LEGO objects can defined.

LEGO means an ability to choose and change necessary elements without reconstruction of whole structure. For example, in simulation we have a set of integration methods. Of course, each of them mast be used in specific cases that depends on physic problem, mathematical requirements and etc. But for LEGO paradigm they are all one object that knows how to obtain solution and to present it in some form.

SCIENTIFIC VISUALIZATION

Scientific visualization plays an important role in result processing. In the images and animations researcher can diagnose some features associated with the intuitive understanding of the physics of the process rather than they can obtain the same result during statistical data processing.

Visual representation of data help to verify obtaining result and to quickly detect errors that invisible for calculation algorithms but critical to plausibility checking.

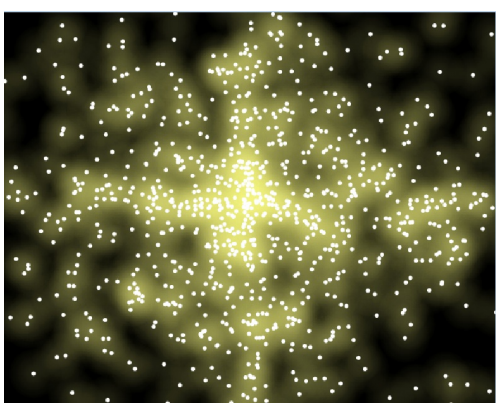

Figure 4: Coordinatewise slice of beam.

In Fig. 4 a coordinatewise ($x - y$ space) slice of beam is shown. In this figure an initial particle distribution is presented. On the picture we can see some clusters of points that may be difficult to find by data mining methods.

CONCLUSION

In the article a scheme of VA organization is described. Data access protocols that will be used are mentioned. Some modules such as global optimization tools, simulation and numerical algorithm are completely developed, other are in a progress. Future plans for this project include extend of the VA tools, implementation of Cloud-service architecture and support developed systems via knowledge base growing, development of methods and approaches in beam dynamics and simulation and validation proposed approach on real machines.

Some approaches that was described above were tested in the distributed computational environment at the faculty of Applied Mathematics and Control Processes on the department of Computer Modelling and Multiprocessor Systems[3].

MSTAPP, A RICH CLIENT CONTROL APPLICATIONS FRAMEWORK AT DESY

Kirsten Hinsch, Winfried Schütte, Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany

Abstract

The control systems for PETRA 3 [1] and its pre accelerators extensively use rich clients for the control room and the servers. Most of them are written with the help of a rich client Java framework: MstApp. They total to 106 different console and 158 individual server applications. MstApp takes care of many common control system application aspects beyond communication. MstApp provides a common look and feel: core menu items, a colour scheme for standard states of hardware components and predefined standardized screen sizes/locations. It interfaces our console application manager (CAM) [2] and displays on demand our communication link diagnostics tools [3], [4]. MstApp supplies an accelerator context for each application; it handles printing, logging, resizing and unexpected application crashes. Due to our standardized deploy process [5] MstApp applications know their individual developers and can even send them – on button press of the users - emails. Further a concept of different operation modes is implemented: view only, operating and expert use [6]. Administration of the corresponding rights is done via web access of a database server. Initialization files on a web server are instantiated as JAVA objects with the help of the Java SE XMLDecoder [7]. Data tables are read with the same mechanism. New MstApp applications can easily be created with in house wizards like the NewProjectWizard [5] or the DeviceServerWizard [8]. MstApp improves the operator experience, application developer productivity and delivered software quality.

INTRODUCTION

As part of the transition of PETRA 2 - an injector for HERA - to PETRA 3 - a dedicated synchrotron machine - an entire new control system was implemented [1], [9]. It is based on Java as a platform independent language, TINE [10] as a communication protocol and MstApp as an application framework.

The control system tasks are implemented with networked rich client JAVA SE 6 applications. We distinguish between console and server applications. And for some complex cases we also have middle layer applications.

Many aspects of these applications are generic. A framework called MstApp was designed to cover the generic aspects not related to the communication protocol. The application developers could then concentrate on the application specific aspects.

LOOK AND FEEL

A common look and feel of all accelerator control client applications eases the task of the operating crew. This is both true on the small level of standard colours for different component states, and on the large level like the layout of the entire application. Printing, protocols, help etc. are always found at the same place.

Standard Colours

There are always a lot of discussions about the best colours for different component states. And once there is an agreement how to find the documentation. The framework MstApp just integrates our agreement on colours as mnemonically named subclasses of the standard Java "Color" class. As an example the colour for error states is defined as a red background with a white foreground (a black foreground would be too difficult to read on a red background).

Standard Sizes and Positions

Applications are not alone on the display but have to live together with many other ones. Well defined application sizes help to use the screen better. MstApp gives predefined sizes and positions. Both can also be saved on a local basis to the hard disc or managed by our console application manager (CAM) [2]. This feature is useful for the control room by having standard work environments. It is also useful for server PCs with many servers. A missing small server display is spotted at a glance.

Standard Menu

Some standard functionality is already provided in the menus. The predefined layout is the following:

- File, containing show logging, printing and exiting
- Machine for the applicable accelerator (optional).
- Options, containing an extensive dialog
- Help, containing an about box, and paths to the most relevant pages of the accelerator control room WIKI

The application developer can add new menus, or in existing menus new menu items. The options dialog is also extensible.

Resizing

A high fraction of our application developers like to design with absolute layout. No layout manager is used. Since the size of our applications is related to the screen size, this works well as long as the size of our display monitors does not change. In reaction to the unavoidable change of display size, a so called ApplicationResizeManager was developed.

An activated ApplicationResizeManager resizes all components of the application top-down. The following properties are resized: position, width, height, font, tables and icons. AWT graphics has to be scaled manually in the paint method. Resizing the font the ApplicationResizeMa-

nager considers both, width and height of the component to calculate the new font size.

Auxiliary Information

A standard MstApp application contains at the bottom a status bar with information about the PC name, date, time, operations and server mode. This is especially helpful for graphical application copies to the logbook [11].

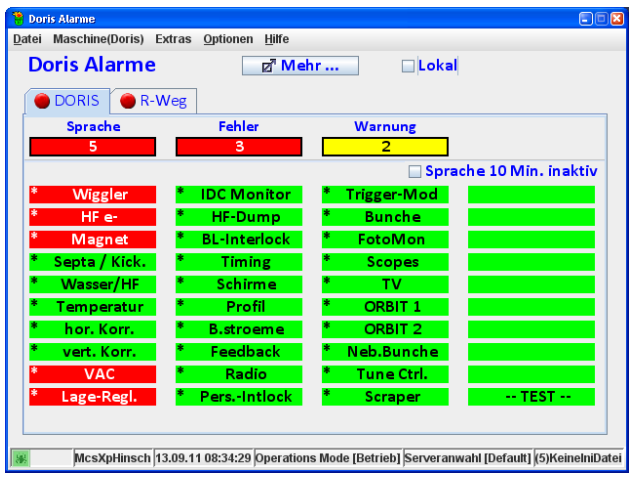

Figure 1: Typical MstApp based client application. The accelerator Doris is chosen. An application developer specific menu “Extras” is added. The status bar at the bottom shows the computer name, date and operations mode. At its left one finds the communication link diagnostic tool Spider.

COMMON TASKS

Operation Modes

Console programs for accelerator control have different users.

Our most important users are the operators in the control room. The operator needs good reading and writing access to the servers running the accelerator hardware.

Then there are users outside the control room interested in current accelerator parameters. They should not be allowed to change the accelerator hardware parameters. Their program use should be restricted to only viewing them.

Finally there are the hardware developer themselves, who need to access their specific devices in an expert way reading and writing to the corresponding servers far in excess of the operators.

Each of these views operating, viewing and expert mode is natively implemented in the framework. Maximum rights are enforced on a basis of user name, pc name and application name via a database table.

We also differentiate between console application accesses to the real hardware server and a simulation server.

These security measures are complementary to the ones inherent to the communication protocol. See for example [12].

Accelerator Context

There are applications so specific that they run only for a single accelerator. Others like the display of the dc current monitor are the same for all circular accelerators. We supply a context for all those accelerators and a standard switch mechanism between them.

Printing to Logbook and Developer E-Mails

The MstApp framework provides an identical print dialog frame for each application. This frame enables the users to print a screenshot to a normal printer as well as to create full logbook entries [11]. The user has a mask for his name, a category and some additional text. A screenshot of the application is added automatically. The user can print this entry to the accelerators logbook (default) and/or sent it as an E-Mail to the developer. To declare his choice he uses two checkboxes.

Help

Help is a very difficult topic. There has to be help at all, it has to be up to date and correct, and the user has to be able to find it. Some users might even want to improve on it.

Due to our common deploy process [5] a minimal up to date help within the application is possible. In this about box style help the user finds the application developers name, telephone number and email address. He finds the version, creation date and location of the application and all its referenced libraries.

If more help seems to be useful, the developer can register a page of our control room wiki. This will be offered by the framework to the user. Still someone has to create and maintain this page.

Console Application Manager (CAM)

For routine accelerator operation it is helpful to have a defined set of applications with defined places for the consoles. Our console application manager [2] does this for us. All MstApp applications are native CAM clients. No developer has to invest here any work.

Communication Link Diagnostics Tools

Network communications is never absolutely reliable. It is therefore mandatory to have some handy analysis tools for an application. The Spider [4] shows all direct TINE [10] links and Tarantula [3] shows the direct links, the links of the linked servers and so on up to a specified depth.

Unhandled Crashes

Obviously applications should never end abnormally (crash). In practice they do crash on some rare occasions. In this case it is important to end the application gracefully and to help the developer to improve on the code.

Our framework tries to ease on this. A Java shutdown hook catches those uncatched errors and tries to display a crash screen. The crash screen allows for printing a screen shot, the about box information and a comment to the accelerator control logbook. Also an email can be sent to the known application developer simple by the press of a button.

Applications do not only die by crashing. Sometimes they just freeze. This is especially bad for server programs. Here a watchdog [2] might stop and restart the server application. A screenshot is put into the TINE protocol server. All those screenshots can be viewed from any framework application.

Initialisation Files

The framework supplies a platform independent way of accessing files from a webserver. Initialisation files, some data tables and the data for allowed operation modes are transported in an xml encoded fashion that can be directly converted to a tree of Java objects with the help of the Java SE XMLDecoder [7].

Technically this works very well though the actual use is a little cumbersome.

Protocols/Logging

Writing protocols for accelerator applications has different objectives than the standard Java logging tools. Therefore a custom logging mechanism for application protocols was introduced. The last 500 (can be configured) entries are kept in main memory and the last seven days are kept on local disc for display directly from the application. Logging from the framework and the application and caught logging from the Java logging mechanism is tagged with a category. Logging of Java exceptions is also supported. By supplying a tag the logging message will be stored in the central TINE logger server [13].

STANDARD SERVER APPLICATIONS

The server framework provides a special JFrame for server applications. It ensures an identical look and feel. So the developers can concentrate on the work without graphical aspects. The server frame inherits from an MstApp client frame and provides all aspects the client has.

A server application has three resize modes. Normally it is small, just a square with the name, the icon and a state like idle or reading data. The small size allows many applications neatly aligned in rows.

Pressing the maximize button the application resizes to medium size. Here additional output shows the start time, the last commands and the last events. The entries to two lists for the commands and the events are done with the MstApp logging commands by using special category tags.

In expert mode the application resizes to the large size. It shows a pane, to which the developer is free to add test buttons and output features, which are interesting for the particular server. Other parts of the frame should not be changed.

The non-graphical work of the server application is coded in classes created by the DeviceServerWizard [8]. The developer adds device specific code in his own custom classes.

Figure 2: A server in small size. It only shows the name, the menu and an icon. The status bar is hidden.

INTEGRATION WITH OTHER FRAMEWORKS AND WIZARDS

Our framework interacts by design well with our other tools: The NewProjectWizard [5], our standard deployment [5] and the DeviceServerWizard [8]. It works with the communication protocols like TINE [10] and DOOCS [14]. Even the combination with jddd [15] is easily possible.

TECHNICAL NOTES

How is it realized in Java? The developer has to supply a special Java class that inherits from a special JFrame: MstFrameMain or in case of a server MstServerFrameMain. MstFrameMain supplies context information and the basic look and feel. Components from the developers are added only to the central user area. The framework creates the MstFrameMain and knows it via a "String" starting parameter. Also parameters for the application name, the accelerator name und application specific parameters can be supplied.

The logging is supplied with a static mechanism.

Standard features like change of operations mode, change of the accelerator and many more are supported by extensive use of the observer pattern [16].

The framework requires only the standard Java libraries. This eases a consistent deployment, since no library can be forgotten by the developer, leading to strange runtime errors. Elements from other libraries - like the Spider - will only be shown, if the hosting library is supplied by the developer (creation by reflection).

CONCLUSION

MstApp improves the operator experience, application developer productivity and delivered software quality. A

common look and feel is achieved and at the same time application developers are relieved from many mundane tasks. Common tasks are only written and tested once. Many changes to the environment can be adapted to in one place only.

ACKNOWLEDGEMENTS

The framework MstApp - as a simple central hook into the control system - has many more authors than this paper. There are major contributions from Reinhard Bacher, Piotr Bartkiewicz, Andreas Labudda, Marcus Walla and Franziska Wedtstein. It is a pleasure for us to thank all mentioned and unmentioned contributors.

DATA ANALYSIS WORKBENCH

A. Götz , M.Gerring, O.Svensson, ESRF, Grenoble, France
S. Brockhauser, EMBL, Grenoble, France.

Abstract

Data Analysis Workbench is a new software tool being developed at the ESRF. Its goal is to provide a tool for both online data analysis which can be used on the beamlines and for offline data analysis which users can use during experiments or take home. The tool includes support for data visualization and workflows. Workflows allow algorithms which exploit parallel architectures to be designed from existing high level modules for data analysis in combination with data collection. The workbench uses Passerelle as the workflow engine and EDNA plugins for data analysis. Actors talking to Tango are used for sending commands to a limited set of hardware to start existing data collection algorithms. A Tango server allows workflows to be executed from existing applications. There are scripting interfaces to Python, Javascript and SPEC. The current state at the ESRF is the workbench is in test on a selected number of beamlines.

INTRODUCTION

The Data Analysis Workbench (DAWB) project has been started to create a platform for integrating data analysis programs. Data analysis programs usually exist as standalone programs. Each program has its own user interface, graphical and/or textual. Each program has its own internal architecture and choice of language and libraries. This makes it extremely difficult if not impossible to share code between programs.

Users are confronted by a myriad of different programs and interfaces to manage. Users generally revert to scripting languages to get around this problem. Scripting languages like Python allow them to provide a level of automation for running analysis programs. However scripts are usually not destined to be shared, documented or distributed. Scripts are also not well adapted to visualisation.

DAWB (see Figure 1) adds a layer on top of scripts to make data analysis and visualisation accessible to everyone and repeatable by introducing the concepts of a workbench, visualisation, scripting, workflows and experiment and data analysis design.

CONCEPTS

The goal of the Data Analysis Workbench is to provide powerful data analysis tools, both for online (synchrotron radiation beamlines) and offline data analysis. The combination in the workbench of a workflow tool (Passerelle, based on Ptolemy II) and a data analysis framework (EDNA) makes it straight-forward to develop advanced but robust data analysis workflows. Prototyping of workflows is facilitated by the workbench data visualisation support which makes it easy to visualise 1D and 2D data. The TANGO framework is used for online data analysis for both integrating beamlines hardware and for remotely controlling the workflow engine from the beamline GUI.

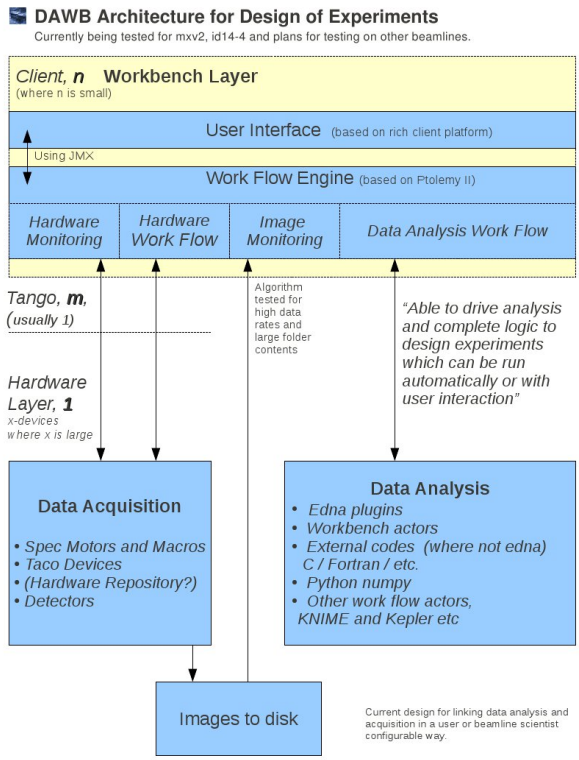

Figure 1: DAWB Architecture.

To achieve these goals the data analysis workbench is based on the following concepts:

Workbench

Data analysis is a sufficiently complex task that a simple approach of a main window with a few buttons is not sufficient. The Eclipse Workbench has been adopted as base platform for the data analysis workbench. The workbench can be best described by quoting the Eclipse documentation*: "*The Workbench aims to achieve seamless tool integration and controlled openness by providing a common paradigm for the creation, management, and navigation of workspace resources. Each Workbench window contains one or more*

* http://help.eclipse.org/indigo/index.jsp

perspectives. Perspectives contain views and editors and control what appears in certain menus and tool bars. More than one Workbench window can exist on the desktop at any given time."

Visualisation

Data analysis is a means to an end. In the initial, intermediate and final steps the raw and analysed data need to be visualised. One of the workbench's main goals is to offer a complete set of visualisation tools in 1D, 2D, 3D and the possibility of following changes as a function of time. Currently 1D and 2D are implemented. The aim is to offer viewers for all types of files typically used in data analysis in a single tool. Users need to learn one set of viewers for all data analysis applications called from the workbench.

Scripting

Scripting is an essential part of data analysis. It allows existing codes to be glued together rapidly and in a flexible manner. The workbench provides support for Python and Javascript as scripting languages. There is basic support for SPEC. Others languages might be added in the future. Python support includes a complete language development environment – PyDev[†]. Scripts can be called as standalone from a terminal or as part of a workflow.

Workflows

Workflows are a convenient way of programming and documenting the flow of data through algorithms. They can also be used to feedback to data acquisition systems when designing experiments. Workflows are naturally parallel and ease the programming of multiple execution threads. DAWB provides strong support for workflows, both online and offline. They are seen as a complement of scripts. Workflows are higher level constructs which assist the beamline scientist and user in building robust pipelines which use scripts.

Features

Import files as links - import large data directories into a project structure as links. This reduces file system overheads.

Open files in various formats - srs, dat, png, jpg, jpeg, tif, tiff, cbf, img, ciff, mccd, edf, pgm, cor, bruker, h5, nxs, pdb, (gz, bz2, zip)

Visualization - able to visualize data in 1D and 2D.

Workflow editing - viewing and editing of workflow data analysis pipelines based on Ptolemy 2.

Running of workflow - able to run workflows in a separate process which is controllable from the GUI and able to run without the user interface.

Eclipse projects - able to keep data in eclipse projects and analyze data further using user interface tools and python.

Drag and Drop - support of drag and drop of data from eclipse projects to Passerelle workflows.

Tango Devices - the monitoring of tango devices and the interaction with them via actors in the workflow.

Image Monitoring - the ability to monitor a directory of images using a thumbnail viewer, even if the directory contents are large and changing quickly.

HDF5 / Nexus - read and write hdf5 including slicing. Plotting of 1D and image datasets and slicing higher dimensions. Supported on a wide range of platforms and in multi-threaded environments. Nexus files in hdf5 also supported.

Data analysis - the support for python actors and EDNA actors natively and connections via system process actors for Fortran, C/C++ and other executable programs. EDNA is the most heavily used framework for integrating arbitrary data analysis to the workbench at the moment.

ECLIPSE/RCP

Eclipse/RCP[‡] is an essential part of DAWB. Eclipse/RCP offers a robust platform for building rich clients. It has many features which are useful for managing a workbench. The fact that it is a commercial quality open source product makes it easy to collaborate with commercial and non-commercial partners. The high quality documentation and large number of resources on the web make it easy to learn. Eclipse/RCP has enabled DAWB to be developed in a way that other institutes who have adopted Eclipse/RCP can use it even if they were not involved in the definition of or aware of DAWB.

WORKFLOWS

Workflows are relatively new in the synchrotron data analysis field. They are however widely used in other scientific fields like biology. They offer a higher level programming language than traditional textual languages e.g. Python, C and Fortran. Their goal is not to replace these languages but to complement them by providing a higher level tool for calling programs in these languages. For this reason workflows should remain high level and not become too fine grained. Too many nodes or graphs in a workflow quickly make it difficult to follow or maintain. Workflows like Passarelle in DAWB should not be confused with programming languages like Labview's graphical programming language G. In the case of the latter the goal is to do as much programming as possible in this language. It is not easy to interface it to scripting

[†] http://pydev.org/

[‡] http://www.eclipse.org/home/categories/rcp.php

languages like C or command line driven programs. DAWB on the other hand encourages users to delegate tasks as much as possible to high level modules (which could be scripts or standalone programs). The workflow is then dedicated to documenting the data flow and adding parallelism to the process. Workflows with the help of appropriate actors make accessing remote sources like web services, batch schedulers and cloud services transparent.

Workflow TANGO Server

The workbench is very good for developing workflows and running them when visualisation is part of the workflow. For some applications however once the workflow has been developed the workbench is not needed anymore. In those cases it is preferable to run the workflow "headless" i.e. without the graphical user interface. A TANGO device server has been written for this purpose. It implements start and abort commands plus the possibility of passing parameters to and from the workflow during its execution. It implements a state machine which reflects the status of the workflow's execution. The device server facilitates the integration of workflows in existing applications like MxCube [4].

MX workflow examples

Experiments performed at macro-molecular crystallography (MX) beamlines can to a large extent be automated [4]. However, the automation of data acquisition (beam delivery, sample changer, centring, mxCuBE) and data analysis (EDNA characterisation [5] and automatic data processing) have up until now been largely decoupled with only few possibilities of data analysis to influence data acquisition. New highly automated beamlines like MASSIF (ESRF upgrade program) will take advantage of advances in beam delivery and automation of sample handling. Together with recent advances in data analysis software packages this creates higher demands in term of overall automation of both data acquisition and data analysis.

The ESRF MX beamlines have successfully used DAWB for developing four workflows which significantly increases the coupling between data analysis and data processing:

Enhanced EDNA characterisation workflow for characterisation of MX crystals. This workflow can automatically re-adjust exposure time, oscillation width and detector distance in case these were not set optimally before collecting the reference images.

Crystal radiation sensitivity measurement workflow for precisely measuring the radiation damage susceptibility of crystals by sacrificing a crystal (or a part of a crystal).

Kappa goniometer re-orientation workflow (see Figure 2) for re-orienting a crystal to the desired orientation, e.g. aligning the principal unit axis along the spindle axis or aligning an even-fold symmetry axis along the spindle axis.

Mesh scan workflow for finding the part of a crystal which gives the best data by scanning in two dimensions a low-intensity beam over the crystal and at the same time evaluate the diffraction intensity.

A paper which describes these workflows in more detail has been submitted [3]. The workflows are planned to go into production later this year.

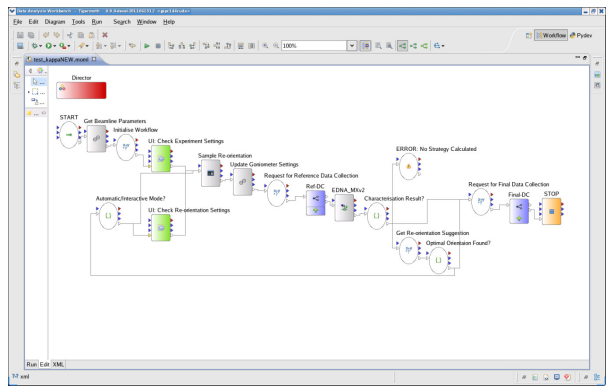

Figure 2: Workbench showing Kappa reorientation workflow for automatic characterisation of MX crystals

EXAFS workflow example

JESF is a Fortran code written for spectroscopy experiments which has been used for obtaining fast, first pass, data analysis at the ESRF. This code can be run online or with "zero dead time" attached to the detector using DAWB. At the ESRF, this works with shared memory. Since JESF uses a file and the speed requirements of the pipeline (2Hz maximum) are not currently large, we decided to write the data to a file and then run JESF on the file. However DAWB allows in memory operation as well. After JESF is run, the result files are opened in real time, so the plots refresh during the run. This pipeline has been tested with a SPEC macro writing to the shared memory currently as the beamline is not yet commissioned. DAWB allows this pipeline to be constructed / modified quickly and delivered to the beamline in a robust way. See Figure 3 for a screenshot of the JESF workflow.

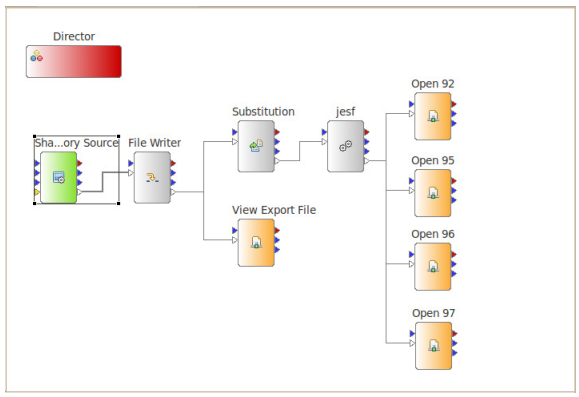

Figure 3: JESF Workflow for EXAFS online data analysis

Future Workflows

The capability of flexibly combining online-data-analysis actors with beamline control actors as well as reusing complete workflows as composite actors in a more complex workflow enables rapid implementations of new experiment protocols. These can include full 3D sample quality characterisation via diffraction tomography, evaluating multiple crystals in a raw sample to find the best diffracting crystal or even the best place and orientation of the best quality crystal. Using the already mentioned couplings of EDNA actors with the Data Collection composite actor, like Radiation Sensitivity Workflow, or Enhanced Characterisation Workflow, even more sophisticated workflows can be built e.g. chaining them one can gain empirically a susceptibility coefficient in the first step and then immediately use it during the characterisation for more precise results. Chaining basic calibration workflows one can automate complete beamline checking protocols. The list of possible workflow programming is endless and comparable to the list of scripts. To gain the most out of workflow design, it is important to keep the structure of the workflows clean and easy-to-understand (comments on the canvas if needed and documentation of course) as well as defining a proper data model to be used all along the communications between the actors, so that the dataflow is kept clean.

COLLABORATION

DAWB is an Open Source program and welcomes collaborators. The source code is on a publicly accessible repository[§]. The source code is released under a modified GPL[**] licence which allows actors developed by third parties not to be under GPL. Workflows developed with DAWB are not bound by the DAWB licence. They can be released under the licence of choice of the developers. Open source licences are encouraged because they allow other developers to study the source code and improve it and or learn from it.

CONCLUSION

DAWB has demonstrated that it is possible to provide a commercial quality workbench for synchrotron data analysis which supports workflows, visualisation and scripting for online and offline data analysis. The first examples of workflows running on MX and EXAFS beamlines are very promising. We think that in the future workflows are going to be an essential part of managing high-level scientific data analysis. DAWB has the features necessary to achieve this. We encourage others who are interested in scientific workflows either as developers or as users to give DAWB a try[††] and if interested to join the DAWB collaboration. We think we should collaborate on the core tool but leave the choice to compete or collaborate on workflows open.

ACKNOWLEDGEMENTS

We would like to acknowledge the following groups: iSencia[‡‡] for providing the Passerelle workflow tool under an open source licence and for doing the Eclipse/RCP version, Soleil for introducing us to Passerelle, Diamond for making parts of GDA and SDA available under an open source licence.

ADDING FLEXIBLE SUBSCRIPTION OPTIONS TO EPICS*

Ralph Lange, Helmholtz-Zentrum Berlin / BESSY II, 12489 Berlin, Germany
Andrew Johnson, Argonne National Laboratory, Argonne, IL 60439, USA
Leo Dalesio, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

The need for a mechanism to control and filter subscriptions to control system variables by the client was described in a paper at the ICALEPCS2009 conference [1]. The implementation follows a plug-in design that allows the insertion of plug-in instances into the event stream on the server side. The client can instantiate and configure these plug-ins when opening a subscription, by adding modifiers to the channel name using JSON notation [2]. This paper describes the design and implementation of a modular server-side plug-in framework for Channel Access, and shows examples for plug-ins as well as their use within an EPICS control system.

MOTIVATION

Over the years, more and more powerful front end computers have lead to increasing data processing rates. Event and timing systems nowadays allow to attach accurate synchronous nanosecond resolution time stamps to data.

Many clients will not need every data update available. Those clients will either want to reduce the update rate for their subscription, or have the updates being correlated to events from the event system, so that they are only getting updates during phases they are specifically interested in.

The EPICS (Experimental Physics and Industrial Control System) toolkit [3] and its network protocol, Channel Access [4], only provide a small set of server-configurable update rates, and only very limited correlation between updates and a timing/event system.

SERVER-SIDE PLUG-IN FRAMEWORK

Considerations

When designing an extension to a widely-used, highly scalable system, a number of considerations have to be taken into account:

- Network compatibility: changing the on-the-wire protocol of Channel Access should be avoided.
- Footprint: the extension should be modular and only add minimal resource use on embedded systems.
- API compatibility: internal APIs should be left intact to avoid breaking externally developed code.

Existing Update Mechanism

The existing update mechanism of the EPICS database has been described in detail in [1] and is shown in Fig. 1. At connection time, a set of per-client tasks and event queues is set up. When the database processes an EPICS record, events are generated from the subscription definitions linked to the record, and put into the event queue. The Channel Access event tasks take events off the queue and ship it to the network.

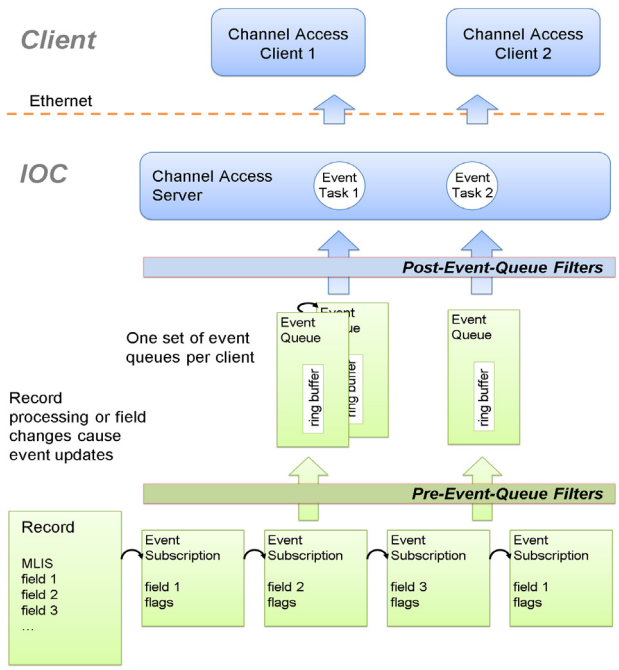

Figure 1: Event Update Mechanism.

Plug-In Framework

The required additional processing of update events is done in plug-ins, that a Channel Access client can request to be inserted into the event stream when the connection is made. These plug-ins have an API that allows for receiving and generating event data, so they can be stacked.

When update events are moving through the plug-in stack, they are handed over to each of the plug-ins. This allows the plug-in to change the event's data as well as the meta data (type, size, time stamp, alarm information etc.) The plug-in may also drop or create additional update events.

Instantiation and configuration of plug-ins is controlled by the client through JSON (JavaScript Object Notation) channel name modifiers, that are transparently forwarded through Channel Access to the IOC [2]. A JSON parser, that has been added to the IOC core software recently, is used for parsing the modifier.

*Work supported by U.S. Department of Energy (under contracts DE-AC02-06CH11357 and DE-AC02-98CH10886), German Bundesministerium für Bildung und Forschung and Land Berlin.

The plug-in framework offers two levels for integration of plug-ins:

A *channel filter* directly implements callbacks for the JSON parser, and thus can use any transmitted JSON structure as configuration.

A *channel filter plug-in* uses a simpler convenience API provided by the framework. Configuration data is restricted to key-value pairs of basic types, but the framework does the parsing for the plug-in, and the simple API allows for easy, efficient, and safe addition of plug-in modules.

The event-related part of both APIs is equivalent.

Adding Plug-Ins to an IOC

All plug-ins have to register themselves with the framework before use, specifying their name (that clients will use for instantiation) and a pointer to their API implementation. The plug-in registration can take place at any time, even after IOC initialization. That would allow plug-in code to be loaded and registered on-demand in a running IOC.

Two Target Layers

The first part of the update mechanism, between record and the event queues (shown *green* in Fig. 1), is done as part of the EPICS database processing, i.e. at high priority. CPU use in this context may keep other records from processing and affect the IOC's real time behavior.

The second part of event generation, between the event queue and the network (shown *blue* in Fig. 1), is done as part of the Channel Access tasks, i.e. at low priority. Database processing will not be affected by CPU usage in this context.

Some plug-in functionality needs to be instantiated on the database side. Plug-ins that reduce the update rate by averaging or limiting should drop surplus events before putting them on the event queue. Plug-ins that correlate updates with an external event system have to do that within the context of record processing.

Other plug-in functionality should be executed in the low priority networking context. Plug-ins that manipulate the data of a single update without relation to other updates, e.g. extracting parts of an array, doing CPU intensive mathematical operations, should avoid affecting the real time database operation, and only do these expensive operations on updates that are actually shipped to the client.

The framework offers instantiation in both layers. Fig. 1 shows the location of the two plug-in layers in the existing update scheme.

PLUG-IN COLLECTION

A number of plug-ins of different complexity have been implemented, to test function and validity of the framework APIs.

ts – Timestamp "Now"

This pre-event-queue plug-in sets the time stamp of the update to "now" (the current time).

Usage: myPV.A{"ts":{}}

When subscribing to a field that does not cause record processing, the data updates are stamped with the time stamp of the record's last processing, which does not show the time the field was updated. This plug-in solves the issue.

dbnd – Deadband Throttling

This pre-event-queue plug-in implements deadband based update throttling, similar to the mechanism in the EPICS records.

Usage: myPV.RVAL{"dbnd":{"m":"rel","d":7.5}}

As a plug-in it is available to any record field, offers per-client configuration, and adds relative deadband specification.

arr – Array Subset

This plug-in inserts itself in the post-event-queue layer. It creates a sub-array with the specified start, increment, and stop index.

Usage: myArray.VAL{"arr"{"s":-5,"i":2}}
myArray.VAL[-5:2:]

The second form is a shorthand notation added for convenience.

sync – Synchronize with Timing System

This pre-event-queue plug-in synchronizes data updates with internal or external timing systems by pushing updates only under certain conditions.

Usage: myPV.VAL{"sync":{"m":"while","s":"red"}}

Synchronization is done with respect to *system state*. This is implemented by means of a small library that offers an API through which named states can be defined and set or reset. Figure 2 shows the effect of the six available synchronization options with respect to a state:

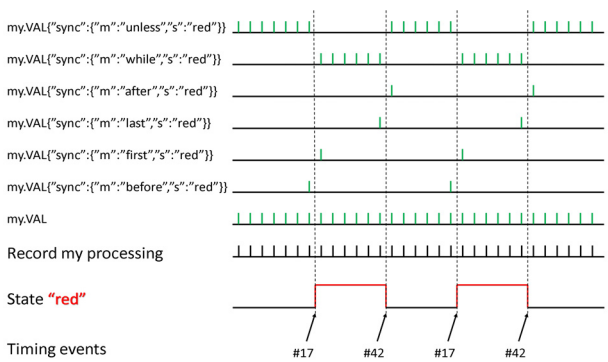

Figure 2: Options of sync Plug-In.

- *unless*: All updates while state is false are being sent.
- *while*: All updates while state is true are being sent.

- *after*: Only the first update after the transition of state from true to false is being sent.
- *last*: Only the last update before the transition of state from true to false is being sent.
- *first*: Only the first update after the transition of state from false to true is being sent.
- *before*: Only the last update before the transition of state from false to true is being sent.

IMPLEMENTATION EXPERIENCES

The major part of the framework implementation was related to reorganization of the subscription definition and data update structures. The subscription structure changes allow per-plug-in and per-plug-in-instance configuration data to be linked to a subscription. The data updates were changed from statical allocation in fixed size lists inside the event queue to heap-allocated structures that use free lists to minimize memory allocation and deallocation at run time.

While implementing the plug-ins described above, the channel filter plug-in API was carefully extended and optimized. In the current state, the individual plug-ins use very little code (40-150 lines of C), and mainly implement the code for their core functionality, i.e. their data update modifications. Thus, implementation of the set of plug-ins described above was fast and uncomplicated.

The two target layer design has proven to be the right approach, as the plug-in designer can freely select the appropriate context for a plug-in.

FOOTPRINT

The framework itself does not add much to the EPICS record structures and code. When no plug-ins are used, the additional memory and computing power consumption is negligible.

Small and embedded EPICS systems will not run into problems because of the plug-in framework.

STATUS

The framework has been developed based on EPICS base version 3.14. The code base is complete and working, unit test code has been written to verify most of the functionality.

Next steps are merging the code into the version 3.15 development trunk, combined with a careful review of the framework's memory allocation techniques and error management – two areas where standards have changed for EPICS base version 3.15.

FURTHER PLANS

Additional plug-ins will allow to throttle data updates by setting the maximum update rate, execute atomic put/get operations, and perform statistical operations on array data.

Records will be able to set default configuration values for certain plug-ins through info tags in the EPICS database.

CONCLUSION

The addition of the server-side plug-in framework to the EPICS toolkit adds valuable functionality to the IOC. It opens yet another way to customize the system, allowing to add exactly the operations needed for a specific installation, and configure them at run time individually for the appropriate connections.

This framework helps to overcome limitations of the existing design, and allows the future addition of new functionality without creating a major impact on performance, memory footprint, or overall complexity.

EPICS V4 IN PYTHON*

Guobao Shen#, Marty Kraimer, Michael Davidsaver, BNL, Upton, NY 11973, U.S.A.

Abstract

Interest in Python as a rapid application development environment continues to grow. Many large experimental scientific facilities have adopted Python for beam commissioning and the operation. The EPICS control system framework has become the de facto standard for the control of large experimental facilities, where it is in use in over 100 facilities. The next version of EPICS (EPICS V4), under active development will extend the support for physics applications, data acquisition, and data analysis. Python support for EPICS V4 will provide an effective framework to address these requirements. This paper presents design, development and status of activities focused on EPICS V4 in Python.

MOTIVATION

As part of the EPICS V4 [1] initiative, there is increased interest in expanding the conventional low level hardware support to include high level applications such as physics applications, data acquisition and data analysis [2]. The support consists of the following main modules: (1) pvData, a memory resident real time database with a predefined data structure; (2) pvAccess, a network protocol for transferring data over wire; (3) pvIOC, a processing engine; (4) pvService, a collection of pvIOC instances implemented as a service.

The high performance/low latency of EPICS V3 for stream data and instrumentation control has been thoroughly demonstrated in many facilities. To implement the proposed extensions to EPICS V4, especially data acquisition, a major concern is its performance. Benchmark tests have been conducted at NSLS-II project to compare the performance of pvAccess with that of Channel Access [3][4]. These benchmarks were performed using pvAccess implemented in Java, and Channel Access implemented in C/C++. The results show that for scalar data, pvAccess has identical performance when processing large numbers channels, and a slightly reduced performance when processing only a few (for example 10) channels. For array processing, pvAccess outperformed Channel Access. More detailed benchmarking results are given in [3]. The benchmark results satisfied the requirements to proceed with the proposed enhancements.

A modular infrastructure based on the client/server model has been designed for NSLS-II for beam commissioning, physics study, and beam operation applications [5][6][7]. In this approach, data flow is separated to 2 parts: (1) acquire data from hardware, and (2) consume data in the application. The 2 flows are implemented with a well-defined API. An advantage of this design is that hardware data flow API is implemented by developers, who have more experience on data and hardware control. The data consumption is handled by physicists who are experts in data analysis.

The client/server implementation is based on EPICS V4, which provides a good technical framework for the infrastructure, the flexibility of data structure design, and satisfactory performance for the physics applications. The 3-tier architecture is shown in Fig. 1. The detailed explanation of this architecture can be found in [8][9].

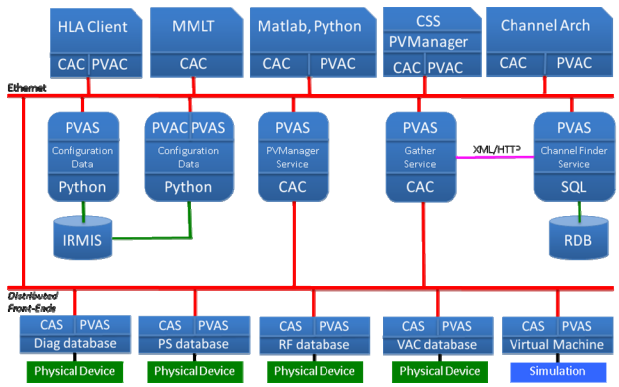

Figure 1: System Architecture.

Figure 1 illustrates the application development environment provided by EPICS V4. Developers have the flexibility to select their favourite technologies to develop back end applications.

At NSLS-II, Python has been selected as the primary development language for physics applications. This motivated us to provide client side Python support. In addition, as shown in Fig. 1, all static data stored in the IRMIS database are served through the V4 server layer. A Python API is under development for access to the IRMIS database. To utilize this API, it is required also to have a Python support on server side.

These 2 factors provided the motivation to have full Python support for EPICS V4. In this paper, we report the results and present current development status for Python support using 3 separate approaches.

PYTHON IMPLEMENTATION

As an interpreted, high-level programming language with dynamic semantics and native support of extensive scientific libraries, Python is very attractive for rapid application development as well as for use as a scripting or glue language. There is a growing interest in the community to use Python as the physics application development platform. At the NSLS-II project, Python has been selected as primary language for physics application development.

EPICS V4 was developed originally in Java, and provides a comprehensive set of features. Later as

*Work supported under auspices of the U.S. Department of Energy under Contract No. DE-AC02-98CH10886 with Brookhaven Science Associates, LLC, and in part by the DOE Contract DE-AC02-76SF00515

#shengb@bnl.gov

requested by the community, a C++ binding was developed and now has full functionality in both the pvData and pvAccess modules, and basic support in the pvIOC and pvService modules. The current language bindings are shown as Table 1.

Table 1: EPICS V4 Language Bindings.

Module	Java	C++	Python
pvData	Y	Y	Y/Limited
pvAccess	Y	Y	Y/Limited
pvIOC	Y	Y/Limited	N
pvService	Y	Y/Limited	N

In this paper, we will focus on the development in Python. For the Python binding, there are several possible solutions: (1) utilizing Python/C API; (2) using existing wrapping tools; and (3) developing a native binding all in Python.

In this section, we will discuss the first two, followed by a discussion of the native binding development the next section.

Python/C

Python/C provides an API for a programmer to build an external module callable in Python. It is a relatively well-understood process to writing an extension module. Most Python/C API functions have one or more arguments as well as a return value of type PyObject*. The returned type is a pointer to an opaque data type, which represents an arbitrary Python object. All Python object types are generally treated the same way in the Python language.

We have to pay attention that all Python objects have a type and a reference count. When exposing an API to Python, the developer must explicitly manage the reference count in the C code. When an object's reference count becomes zero, the object is de-allocated, and collected by garbage collector.

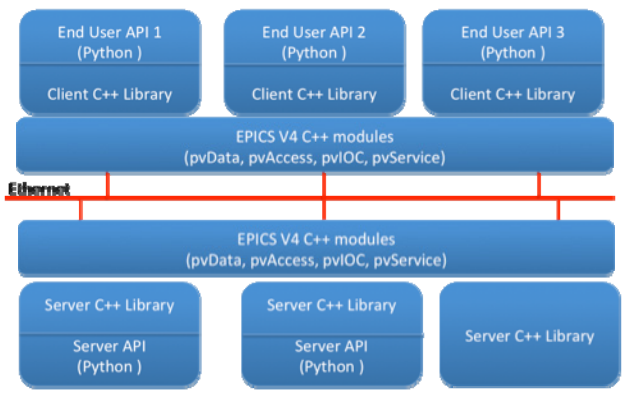

Figure 2: Software Structure Using Python/C.

A realistic approach, shown in Fig. 2, for the end user client interface is to develop a client library in C++, and wrap the C++ library as a Python interface. Each client library is standalone. The benefits are that most codes are in C++, and in general we can gain performance in Python as good as that in C++. However, changes in EPICS V4 C++ modules usually affect the client C++ library. As the project grows, the number of end user client libraries will increase. Long-term maintenance will become an issue.

Wrapping Tools

To minimize the effect to the client library caused by changes of V4 C++ modules, another approach is to wrap each C++ module. This software architecture is as shown in Fig. 3. The end user API is developed in native Python. Any change in the EPICS V4 library affects only the wrapper library, and is transparent to the end API developer/user. Another advantage with this solution is that both client and server can use the same wrapping library.

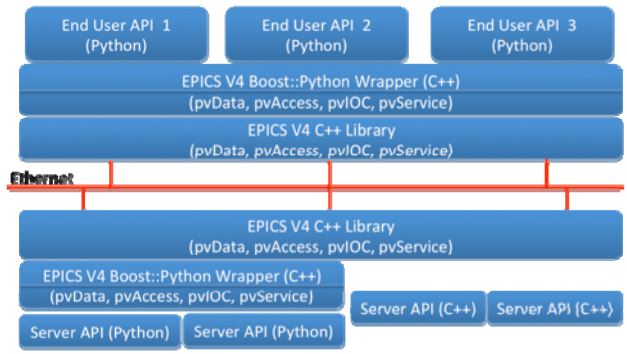

Figure 3: Software Structure by Wrapping V4 Modules.

Tools such as SWIG, SIP, and Boost Python [10] can be used to expose C++ API to Python. Essentially, they are a wrapper for the Python/C API, and provide a more realistic solution to solve many well-known problems. For example, using the Python/C API, the developer has to deal with pointers passed between Python and C++. The developer is responsible for pointer management, particularly when the referenced object has been deleted. Using wrapping tools, those problems are taken care by the tools.

At NSLS II, 2 tools are evaluated, SIP and Boost Python respectively. Because SIP does not support the STD::TR1 smart pointer well, Boost Python was selected in the end. The Boost Python is one member of the Boost C++ library collection, and binds C++ and Python in a mostly-seamless fashion. It also provides a set of policies to track the ownership of an object in both C++ and Python domains. With the Boost Python Library, the developer can quickly and easily export C++ to Python.

A disadvantage with Boost Python library is that a boost library must be installed, and care has to be taken to switch between the boost library and the STD library. Moreover, the Boost Python library does not fully support STD::TR1 library, and provides a simulated interface set for STD::TR1.

Native Implementation

Either the Python/C approach or exposing C++ API to Python using wrapping tools is a workable solution.

Although exposing the C++ API allows users to focus their development on native Python, this heavily relies on the Boost Python Library. This library dependency forces all of EPICS V4 to be compiled against the Boost library. Moreover, tracking and passing object ownership to/from between C++ and Python domain is difficult.

Although we believe Boost Python is best approach for exposing the EPICS V4 API to Python, its template meta-programming mechanism pushes compilers to their limits. Often it is necessary to increase template-depth limit settings of the compiler, memory usage can be vast, compile times are long, and error messages are often difficult to decipher.

A new design is under consideration to implement EPICS V4 in native Python to take full advantage of Python. For example EPICS V4 defined an efficient way to describe complex data structures and the data protocol. In the current implementation in either C++ or Java new data structures must be constructed entirely from the primitive data types. Using Python, it is much simpler to map the data structure into a numpy [11] array. The software architecture is shown in Fig. 4.

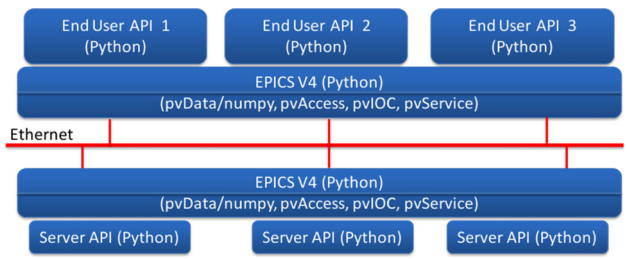

Figure 4: Software Structure in Native Python.

CURRENT STATUS

Python/C

As above described, each library developed in Python/C is a standalone library. In another words, its development relies on each service development. Currently, one library is developed for a service implemented under EPICS V4 in Java, a 'gather' service. The library supports all functions required by clients, and supports all fundamental data manipulation such as get, put, and monitor.

Boost Python Wrapping

With Boost Python library, basic APIs have been implemented in Python for the pvData and pvAccess modules. The end user interface for accessing the gather service is under development. Design and implementation issues related to thread safety and locking have been found and resolved in the C++ modules.

Basic unit tests have been performed for the exposed APIs. More detailed testing is necessary to improve the stability and robustness.

Native Implementation

This is still under design, and the development is at very early stage. Some preliminary code has been developed to verify basic ideas, for example mapping EPICS V4 data structures into numpy arrays.

SUMMARY

This paper presented activities on Python development for EPICS V4. Several different approaches have been conducted at BNL and the status is described.

At the present stage, a workable approach is to utilize Boost Python library. In this approach, there is a trade off solution between performance and flexibility/scripting. Performance benchmarking is necessary.

ACKNOWLEDGEMENT

The authors would like to thank Matej Sekoranja at COSYLAB for his contributions on epics-pvdata development, especially the pvAccess implementations in both Java and C++. They want to give their thanks to Leo Bob Dalesio at BNL for his continuous support and encouragement.

MANGO: AN ONLINE GUI DEVELOPMENT TOOL FOR THE TANGO CONTROL SYSTEM*

G. Strangolino, C. Scafuri, Sincrotrone Trieste, Trieste, Italy

Abstract

Mango is an online tool based on *QTango* [1] that allows easy development of graphical panels ready to run without need to be compiled. Developing with Mango is easy and fast because widgets are dragged from a widget catalogue and dropped into the Mango container. Widgets are then connected to the control system variables by choosing them from a *Tango* [2] device list or by dragging them from any other running application built with the *QTango* library. Mango has also been successfully used during the FERMI@Elettra commissioning both by machine physicists and technicians.

WHAT MANGO IS

Mango is a simple tool to generate online *QTango* panels, that are ready to run without need to be compiled. In this sense, Mango is an interpreter. The interfaces generated with Mango are made up of the simple *QTango* and *Qt4 [3]* widgets, and all the logic of the components and their interaction with each other relies on the intrinsic logic of the widgets themselves.

Whom Mango is Addressed to

- The *Tango* device server programmer, who wants to design a Tango device fully compatible with the *QTango* library and wants to immediately test his work in progress. He might even outline a GUI choosing the most suitable widgets to represent the Tango attributes and commands that are modelled by the device server. The sketch can be saved and submitted to the attention of the GUI developer, who can complete it, improve some human computer interaction aspects and even import the sketch into the *Qt4 designer* to create an executable.
- The GUI developer who wants to rapidly create an interface to a *Tango* device server whose commands and attributes fully support the *QTango* widgets, without needing any additional logic.
- The *end user* of the graphical interface, who can outline a draw of the desired panel and discuss it with GUI developer.
- The control room operator. He might use Mango to create *on the fly* panels, in order to create a summarizing graphical interface gathering *QTango* objects from other real *QTango* executable applications running on the desktop. Actually, the powerful *drag and drop* system exported by the *QTango* library allows dragging a *QTango* widget from an application and dropping it into any Mango container.
- The *QTango* library tester: Mango widgets interacting with the Tango framework are *derived* from the corresponding *QTango* elements and represent valid test objects, both from the stability point of view and from the good design of the elements (the better the widgets are designed, the better possibilities are offered to the Mango tool to manage interoperating *QTango* elements).
- The hardware referent, who commissions the requests to the GUI developer. He may draw a draft of the application containing the relevant controls and widgets and discuss every aspect with the application programmer.

WHAT MANGO IS NOT

Mango is not a tool to design complex control panels, with any other logic than the simple one offered by each *QTango* and *Qt4* widget through the exported *Qt properties* and the *signal/slot* connections. Nevertheless, GUI generation is easy and the work done with Mango is scalable and in no case is wasted: future improvements of the interface and the introduction of complex logic can be started from the *xml* generated with Mango by importing it into a *Qt4 designer* project.

GUI COMPONENTS

The Mango graphical user interface is made up of the following components (see Fig.1).

- An *Object Factory*: a list of *QTango* and *Qt* widgets ready to be used in the *main Mango widget area* by dragging and dropping them from the *Object Factory* widget.
- A *Tango DB Browser*: a tree representing the *Tango* devices exported to the *Tango* database. Attributes and commands of each exported device can be dragged from the *Tango DB Browser* and dropped into the *QTango* widgets populating the *main Mango widget area* component.
- The *main Mango widget area*: a container where *Qt* and *QTango* widgets can be dropped either from the *Object Factory* component or from other *QTango* panels on the desktop. Once the widgets are dropped into this area, they can be *selected, moved and resized* with the mouse, and their properties can be personalized through the *Object Properties* component on the left and by right clicking on them. Multiple selection is possible by pressing the *Control* key while clicking with the mouse.

* This work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3.

Currently, setting widget properties on multiple selections is not supported, but a bunch of actions is available by right clicking over a widget belonging to the multiple selection: move, resize, alignment to grid... Main Mango widget resize events are propagated to children, that resize proportionally, unless the option *Ignore main window resizes* is checked on the *Design Options* component. The *grid* drawn over each Mango container serves as a maths squared exercise book to ease placing the collection of widgets into the main Mango widget area.

- The *Tango Point Information* component: *QTango* widgets use this object to display useful information about their state.
- The *Object Properties* component: allows to click on a property and change its value by either directly editing the property on the tree widget item or by clicking on the custom button that might appear according to the property type. Custom editing dialogues are provided for complex properties like fonts and colours.

DESIGNING A CONTROL PANEL

Composing a graphical control panel with Mango is as easy as dragging an object from the *Object Factory* component and dropping it into the *main Mango widget area.* Once a widget becomes part of the *main Mango widget area*, it can be configured through its properties. For instance, a Tango *source or target* can be associated to a *QTango* widget. To change object properties, one has to first *select* the object with the left button of the mouse. The object is highlighted with a light blue colour and its cyan border is sensible to mouse resize actions. Multiple selection is possible through the *control* key pressed in conjunction with the mouse button. A set of actions is available for multiple selections by right clicking with the mouse over one of the widgets.

Simple Widgets and Containers

Mango widgets can be divided into *simple widgets* and *containers*. Containers are special widgets that can contain both simple widgets and other containers. They propagate the resize events to their children and manage saving their properties. One can populate the interface both with simple widgets and containers without worrying too much about what kind of object she is using. As one can see in Fig.1, the *readers* are connected to *Tango* devices.

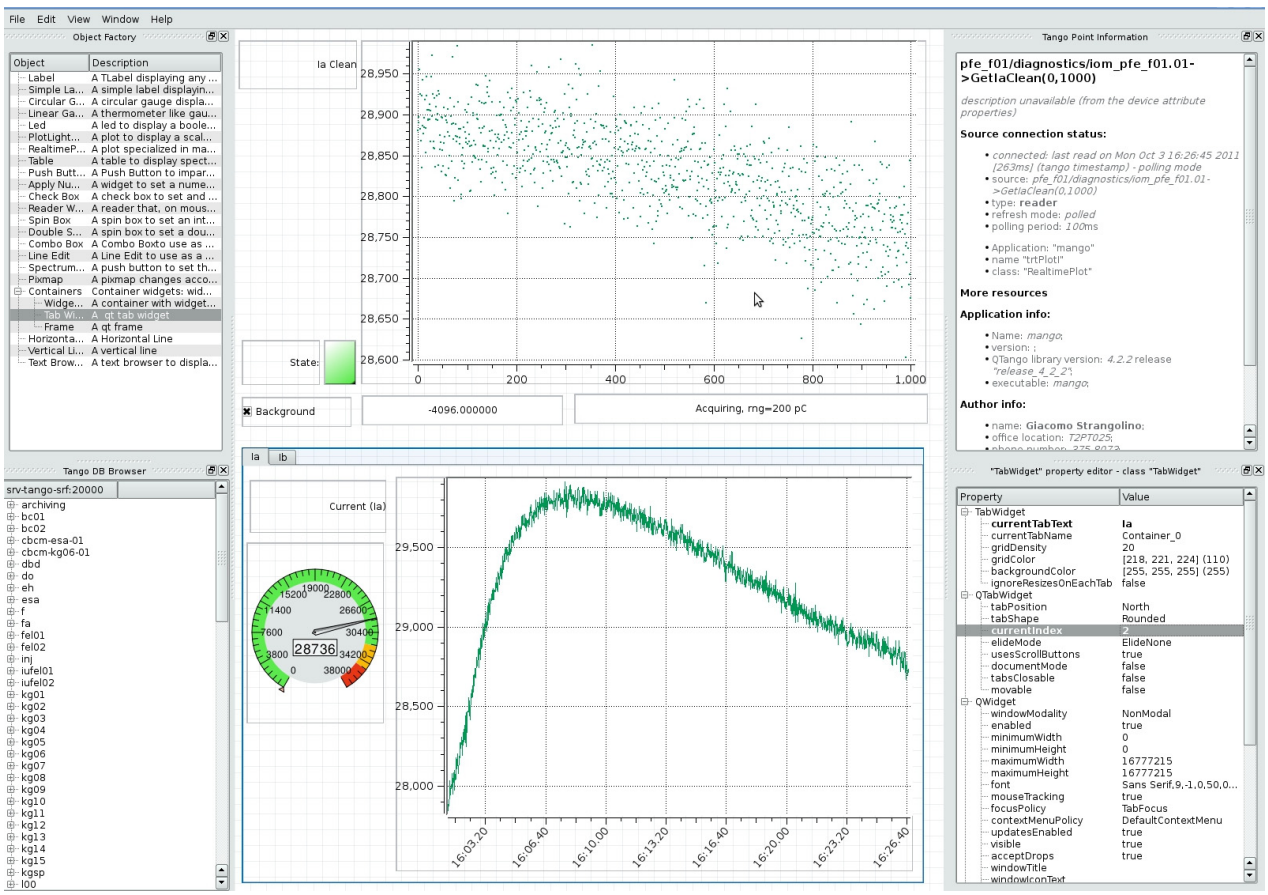

Figure 1: Mango graphical user interface.

In Fig.1 the *tab widget* is currently *selected* and its properties are accessible through the *Object Properties* widget. The *Tango Point Information* component displays the status of the underlying Tango connection that provides data to the plot. *Writers* are partially enabled: they cannot *write* the tango quantity they are connected to when in *design* mode.

EXECUTING A CONTROL PANEL

A Mango project saved as a profile can be loaded in two different ways:

- via the command line;
- launching the Mango application normally, then switching off *design mode* via the *View* menu and loading a profile by triggering the action *Profile Manager...* from the *File* menu.

In the first way you can integrate the Mango panel into a launcher icon or into an application browser. Fig.2 represents the same panel as in Fig.1 in execution mode.

PROFILES

The graphical interfaces realized with Mango can be easily managed via the Mango *profiles*. A profile stores the configuration of a GUI designed with Mango.

CONCLUSIONS

Mango is currently used by GUI and Tango device server programmers to sketch graphical user interfaces and testing purposes. Up to now, Elettra and Fermi@Elettra control room operators have designed and run with Mango about ten control panels.

FURTHER DEVELOPMENTS IN GENERATING TYPE-SAFE MESSAGING

R. Neswold, C. King
FNAL†, Batavia, IL 60510, U.S.A.

Abstract

At ICALEPCS '09, we introduced a source code generator that allows processes to communicate safely using data types native to each host language[1]. In this paper, we discuss further development that has occurred since the conference in Kobe, Japan, including the addition of three more client languages, an optimization in network packet size and the addition of a new protocol data type.

INTRODUCTION

Writing software to support external messaging can be tedious and error-prone. The software author must make sure the required message fields are present, are aligned properly, and follow an agreed upon byte-ordering. If he cuts any corners while implementing the protocol, problems will appear – sometimes weeks or month later. Decoding packets takes extra care since the software must prove the sender's data is well-formed; in addition to byte-ordering and alignment issues, all fields must be validated and range-checked.

The protocol compiler is a command-line utility that generates the source code that safely serializes messages. The compiler takes, as input, a source file that describes the messages found in the protocol and creates the source files that implement it.

The benefits of using the compiler rather than hand-coding the protocol are:

1. Endian issues are handled automatically so the programmer only works with the native data types of their machine.
2. Packing issues are handled automatically so message fields are aligned properly.
3. The messages are implemented in a form that is native to the language (structs in C++, classes in Java, etc.)
4. Messages are completely validated (field values are range-checked, enumerations are validated, all required fields are present.)

Over the past two years, we've used the protocol compiler on many new projects. It has allowed us to focus all our attention on the application design because we know the communication layer just works. Despite it being a very useful tool, we have found a few minor shortcomings. The solutions to which are described in this paper.

```
enum Status { Away, Online };

request SendMessage {
    string text;
}

request UpdateStatus {
    Status newStatus;
}

reply NewMessage {
    string from;
    string text;
}

reply NewStatus {
    string who;
    Status status;
}
```

Figure 1: Protocol source used for examples.

ADDING ENUMERATION TYPES

While designing protocols, we noticed a particular idiom repeatedly being used. We would use an `int16` type to represent a field that could only have a limited set of values (the very use-case that justified adding enumerations to many programming languages.) Emulating these enumerations required us to write our own validation code to make sure the values sent and received were members of the limited set. But type-safety and field validation is exactly what the protocol compiler is supposed to do! So enumerated types were deemed necessary and added as an official data type.

In the generated code of each target language, the underlying integer for each enumeration value is based on a hash value, instead of being sequential, to prevent software from assuming any ordering of the values (and, hence, breaking later if the enumeration is changed.) Programmers are encouraged to ignore the underlying integer values and simply use the symbols provided.

NEW SUPPORTED LANGUAGES

Although the officially supported languages at Fermilab are C++ and Java, there are many groups that use alternate languages to write useful code that isn't meant for the Control Room operators. We've supported these efforts mostly by routing their data requests through Java servlets using the XMLRPC protocol. This approach works, but limits the clients' data rates and adds another "hop" to the return path. If we were to support these additional languages using the protocol compiler, they could request the data directly from the control system.

†Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.

Table 1: Protocol Type to Language Type Mapping

Protocol Type	C++	Java	Python	Erlang	Objective-C
`bool`	`bool`	`bool`	`True` or `False`	atoms 'true' or 'false'	`NSNumber*`
`int16`	`int16_t`	`short`	`int`	integer with restricted range	`NSNumber*`
`int32`	`int32_t`	`int`	`int`	integer with restricted range	`NSNumber*`
`int64`	`int64_t`	`long`	`long`	integer with restricted range	`NSNumber*`
`double`	`double`	`double`	`float`	`float`	`NSNumber*`
`string`	`std::string`	`string`	`str`	`string` (which, in Erlang, is a list of integers)	`NSString*`
`binary`	`std::vector<uint8_t>`	`byte[]`	`bytearray`	`binary`	`NSData*`
`struct T {}`	`struct T {}`	`class T {}`	`class T`	tuple defined with a record specification	Objective-C class
`enum T {}`	`enum T {}`	`enum T {}`	`int` with restricted values	atoms	`enum T {}`
`optional T`	`std::auto_ptr<T>`	nil object references	presence or absence of class attributes	atom 'nil' or actual value	`nil` or actual value
`T[]`	`std::vector<T>`	`T[]`	list of T	list of T	`NSArray*` of objects

Table 1 shows the five currently supported languages and how the protocol data types map to their respective native data types.

The examples given in the following sections assume the protocol input file, `example.proto` (shown in Figure 1), was used.

Python Programming Language

There is a community of Python programmers at Fermilab which lean heavily on the XMLRPC protocol, so it made sense to add Python as target language.

Python's data types are less numerous than there are in C++, so the Python integer type serves several purposes. The generated code makes sure the values are in range before encoding or decoding messages. In addition, Python is a dynamically typed language. So, even though the generated code creates "official" protocol classes to be used for the messages, any class with the correct set of attributes can be used (attributes not defined in the protocol will not be part of the serialization.)

We chose to use the Python iterator interface as the mechanism for marshalling and unmarshalling messages. The unmarshal routines accept and read from a character iterator to decode the message while the marshal routines return an iterator which generates the character stream.

Supporting the example protocol in Figure 1 using Python first requires creating the module that serializes the messages. The following command creates the `example.py` source file:

```
pc -l python example.proto
```

After importing this new module in a Python script, a `SendMessage` message can be marshalled thusly:

```
msg = SendMessage_request()
msg.text = "Hello"
iter = marshal_request(msg)
```

The resulting iterator can be passed to anything that uses an iterator to obtain content: file objects; sockets; and even the bytearray constructor, if simply marshalling to a memory buffer is desired.

Unmarshalling requires a character iterator holding the incoming stream of data:

```
msg = unmarshal_reply(iter)
if isinstance(msg, NewMessage_reply) then:
    print msg.from, ": ", msg.text
```

The resulting message will be stored in `msg`. The specific type of message can be determined using `isinstance()`. If a message cannot be encoded or decoded, a `ProtocolError` exception is raised.

Objective-C

One line of mobile devices uses Java as its preferred development language, which we already support. But there is another line of popular, mobile products we also intend to use, so we added Objective-C as a target. It should be noted that this isn't a generic Objective-C generator; it uses objects defined in the OSX and iOS foundation frameworks and is, therefore, Macintosh- and iOS-specific.

The compiler generates two source files: a `.h` file containing the object interfaces and a `.m` file containing

the implementations. All message fields are represented by pointers to Cocoa objects (`NSNumber*`, `NSString*`, `NSArray*`, etc.), which follows coding conventions used in Macintosh and iOS development. Required fields in a message will always point to a valid Cocoa object and optional fields will either have a valid pointer or be set to `nil`. This generator encodes to and decodes from an `NSData*` object.

Converting the Python example to objective-C results in the following sample for marshalling a request:

```
example_SendMessage_request* msg =
   [[example_SendMessage_request alloc]
init];

msg.text = @"Hello";

NSData* bin = [msg marshal];
```

Since objective-C doesn't have namespaces or a way to nest classes, the names of the protocol messages need to carry enough information to make them unique and end up being quite long. However, objective-C code tends to be verbose, so long names don't stand out as much as they would in other languages.

To unmarshal data, the binary representation is loaded into an `NSData*` object which is then passed via the protocol's unmarshal method:

```
NSData* raw = [[NSData alloc] init];

// ...load the NSData buffer here...

example* msg =
    [[example unmarshal:raw] retain];

if ([msg isKindOfclass:
          [example_NewMessage_reply class]])
{
    example_NewMessage_reply* tmp =
        (example_NewMessage_reply*) msg;

    NSLog(@"%@: %@", [tmp.from],
[tmp.text]);
}
```

If there were any problems decoding the message, an `NSException*` is thrown.

Erlang

Recently, our department has taken an interest in the soft real-time, functional language Erlang[2] and we're looking for ways to use it. Before this can happen, though, Erlang needs to be made a first-class citizen in the control system by enabling it to communicate via ACNET and enabling it send and receive protocol messages. As of 2010, both those requirements were met.

The code generated for Erlang serializes protocol messages to and from Erlang binaries[1]. A binary is read in from a file or a network socket and sent to the unmarshalling function to be converted to an Erlang data type.

Table 2: Sample Integer encodings

Value	Encoding
0	0x00
1	0x01
-1	0xff
127	0x7f
-128	0x80
128	0x00, 0x80
-129	0xff, 0x7f

The Erlang language doesn't have the concept of a pointer so, to represent a missing optional field, its value is set to the atom `nil`.

Reaching back to our example, the Erlang version that encodes a message looks like:

```
Msg =
   #example_sendmessage_request{text="Hello"
},
Bin = example:marshal_request(Msg)
```

The resulting binary can be written to a socket or file. Like objective-C, Erlang doesn't have namespaces so identifiers tend to be verbose to ensure uniqueness.

Retrieving a value from a binary is as easy. In fact, it's so simple, we'll make this code segment do a little more than the previous examples. We'll use Erlang's pattern matching to show how we can decode both request types specified in Figure 1:

```
Bin = … %% obtained from socket, file, etc.
case example:unmarshal_request(Bin) of
 #example_sendmessage_request{text=T} →
   process_message(T);
 #example_updatestatus_request{newstatus=S}
→
   process_status(S)
end
```

OPTIMIZATIONS

Using the compiler has revealed a few opportunities for improvement. This section discusses a few techniques we used to improve both the encoded size and the performance of the encoders.

Packet Size Improvements

The encoded format uses integers to represent integers values, length fields and hashed field names. These integers were typically encoded using four bytes. We found that, most of the time, the length fields of strings and binaries were much smaller than the full range we allowed, resulting in many 0 bytes getting emitted. Integers values, too, didn't always push their range, so many 0 bytes (and FF bytes for negative integers) were emitted.

[1]The actual implementation isn't as symmetric as it sounds because messages are encoded as an Erlang "iolist" which is a binary or a list of binaries.

To reduce the superfluous data, we redefined the way integers are encoded. The current approach treats integers as the minimum number of bytes needed to encode a signed value. Some examples of the new encoding are shown in Table 2.

Unfortunately, the new encoding is incompatible with the older method, so the version of the header was bumped to version 2 (which guarantee messages with different integer encodings will fail when unmarshalling.)

Performance Improvements

When we originally wrote the protocol compiler, we focused on correct behavior before tackling performance issues. Now that we're satisfied with its reliability, we took a step back to see if we could improve the generated code.

It became clear that routines that emit integer values were also being called for integers that were constant (the hash values for message fields, for instance.) We replaced those calls at run-time with code that simply emits the corresponding constant byte sequence.

CONCLUSION

The protocol compiler is continuing to prove itself as an easy and robust way to get applications written in different languages hosted on different computer architectures to communicate. We have two active Erlang projects that are using the protocol compiler to access ACNET data at high data rates. We also used the protocol compiler output to deliver ACNET data to an iPhone/iPad application.

Since it takes an average of two weeks to support a new language, we're willing to expand the protocol compiler to support new languages that our community uses.

CAFE, A MODERN C++ INTERFACE TO THE EPICS CHANNEL ACCESS LIBRARY

J. Chrin, M.C. Sloan, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland

Abstract

CAFE (Channel Access interFacE) is a C++ library that provides a modern, multifaceted interface to the EPICS-based control system. CAFE makes extensive use of templates and containers with multiple STL-compatible access methods to enhance efficiency, flexibility and performance. Stability and robustness are accomplished by ensuring that connectivity to EPICS channels remains in a well defined state in every eventuality, and results of all synchronous and asynchronous operations are captured and reported with integrity. CAFE presents the user with a number of options for writing and retrieving data to and from the control system. In addition to basic read and write operations, a further abstraction layer provides transparency to more intricate functionalities involving logical sets of data; such 'group' objects are easily instantiated through an XML-based configuration mechanism. CAFE's suitability for use in a broad spectrum of applications is demonstrated. These range from high performance Qt GUI (Graphical User Interface) control widgets, to event processing agents that propagate data through the Object Managements Group's Data Distribution Service (OMG-DDS), to script-like frameworks such as MATLAB. The methodology for the modular use of CAFE serves to improve maintainability by enforcing a logical boundary between the channel access components and the programming extensions of the application framework at hand.

CAFE À LA MAISON

The Experimental Physics and Industrial Controls System (EPICS) is an established framework for the development of distributed control systems in the field of particle accelerators and other large-scale experimental endeavours [1]. A dedicated communications protocol, Channel Access (CA), allows for the high throughput of small data packets between the low-level hardware and external programs. Its native client library [2], written in the C programming language, provides remote access to controls data encapsulated in Process Variables (PVs) residing in EPICS Input Output Controllers (IOCs). It is thus the entry point for a number of CA interfaces to various C-based high-level programming languages, including declarative and 4^{th} generation languages such as Python and MATLAB respectively. While each of the resulting CA classes aims to achieve a similar interface and abstract layer, their context is typically confined to the system in which they execute. Another approach would be to enforce a logical boundary between the channel access components and the specifics of a given domain's C/C++ extension framework by providing a single C++ CA library for use across a number of C/C++ based programming languages.

There are several advantages to this library-based approach:

- The inherent simplicity and convenience of maintaining the channel access interface code and the flexibility it offers for library designers.
- New CA functionalities from future EPICS releases [3] need only be integrated in a single repository.
- Bindings to scripting and domain-specific languages are simplified.
- In-house (à la maison) CA expertise ensures a quick response to user needs and problem solving.

CAFE (Channel Access interFacE) is a C++ library that provides a modern, multifaceted interface to EPICS. It is intended to be expressive enough to provide the necessary abstractions in a convenient way and to be flexible enough to act as a host CA interface for other C/C++ based languages.

CAFE provides functionality for synchronous and asynchronous interactions for both individual and groups of channels. Data propagation through channel access is performed exclusively with native data types, although data presented to/by the CAFE interface may be in any meaningful format. This is also true of enumerated types. CAFE makes extensive use of function templates that allow identical code segments to perform a given task for any type of data. These have been used to implement client interfaces, underlying channel access classes, and data type conversions.

Callback functions have been implemented for all operation involving channel access connection handlers, event handlers and access rights handlers. Their invocation triggers their data to be written into a multi-index container provided by the Boost libraries [4]. The container takes ownership of the data object elements, which store all the current details of the associated PV, and provides multiple, distinct interfaces that allow for fast retrieval and modification of the element's data. This is exemplified by an inquiry to the current connection state of a channel which is a factor of $\sim 10^2$ faster compared to the native CA client call. While every gain in efficiency is welcome, it is, however,

the channel access data transfer time (∼ ms) that remains the dominating factor. There is, therefore, some leeway for code optimization within the CAFE Application Programming Interface (API). The most critical issue is to avoid dynamic memory allocation at each channel access transaction as this noticeably impacts performance. The optimal approach is thus for the created PV handle (object reference) to take responsibility for allocating the necessary memory for storing the handle's data set within the element of the container. Memory space is re-allocated whenever the connection event handler is invoked or upon demand.

CAFE aims to hide the low-level technical details of channel access as much as possible. It has thus been preconfigured with a reasonable set of default parameters that allow basic operations to be immediately undertaken without details of CA or other third-party APIs leaking into the application domain. Nevertheless, as users become accustomed to the many CA possibilities, they will wish to optimize connectivity in a manner that best suits the needs of the application, e.g. by influencing certain CA properties such as timeouts, and whether to instigate operations as blocking or non-blocking. Each handle possesses its own set of CA properties that can be easily configured 'on the fly' through designated container access methods. Thus, although the internal mechanics of certain channel access operations may change, the interface gratifyingly remains the same.

CAFE is also equipped with an abstract layer that addresses related data sets as single logical software units. Such data may be retrieved/set with a single method invocation. An XML configuration mechanism is used for the initialization of such CAFE 'group' objects. CAFE thus has its own XML schema for defining collections of related nodes and for constructing groups from collections and individual channels. While such an XML file consisting of collections may be manually instrumented, the practice is to extract nodes of the same type from a master XML accelerator file that defines the topology of the accelerator in Universal Machine Format [5]. A dedicated parser traverses the accelerator XML to identify collection members and to transform their data into the CAFE XML schema. The pre-defined collections are loaded from the generated 'Collections XML file' on initializing CAFE and may be addressed by interfaces through their identifier.

In constructing the channel access interface, effort had been made to follow sound practices presented in [6]. Any remaining errors, however, remain the authors responsibility. The work presented here has been undertaken in a Linux environment and in the context of the Swiss Light Source (SLS) and the 250 MeV SwissFEL Injector Test Facility at the Paul Scherrer Institute (PSI).

SAVEURS DE CAFE

CAFE's suitability for use as a channel access host within different applications is demonstrated with examples ranging from high performance Qt control widgets [7], to Event Processing Agents (EPAs) that propagate data through Object Management Groups's (OMG's) Data Distribution Service (DDS) [8], to script-like frameworks such as MATLAB [9]. Figure 1 illustrates how the CAFE API conceptually extends the different application environments.

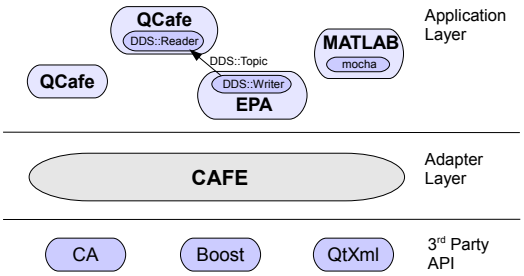

Figure 1: Application objects connecting to CAFE's adapter to channel access.

QCafe

The use of Qt for the development of CAFE-aware GUI (Graphical User Interface) widgets is a natural choice given the commonality in language. Qt offers components for a broad range of customizable widgets that can be readily applied to control system applications, and its graphics canvas and style engine allows modern, sophisticated user interfaces to be created. Qt's low latency coupled with C++'s runtime and memory efficiency further provides for a superior solution for building high performance GUI applications. These aspects could be well exploited for the computation and display of high-volume and high-rate data.

The QCafe package combines the speed, power and flexibility of C++/Qt with CAFE's extensive and robust channel access interface. The QCafe class diagram is shown in Fig. 2. The QCafe widgets are completely decoupled from CAFE as interaction with EPICS PVs is handled solely by QCafe's 'CAFE Interface Class'. EPICS data are then communicated between the interface class and the widgets using Qt's signals and slots mechanism. Some of the control/monitor widgets developed are shown in Fig. 3. The QCafeWheel widget is a customized widget built from other Qt GUI components and exhibits the same behaviour as its counterpart in MEDM (Motif Editor and Display Manager), one of EPICS established GUI builders [10]. Some of the widgets, namely QCafeStripChart, QCafeSlider and QCafeMeter, were developed with Qwt [11], a graphical extension to Qt.

Work is in progress to integrate QCafe widgets into Qt Designer, a tool for designing and building GUIs from Qt components. This will allow EPICS control GUIs to be created in an entirely code-free framework.

EPICS-Qt interfaces have also been developed independently at other facilities [12, 13].

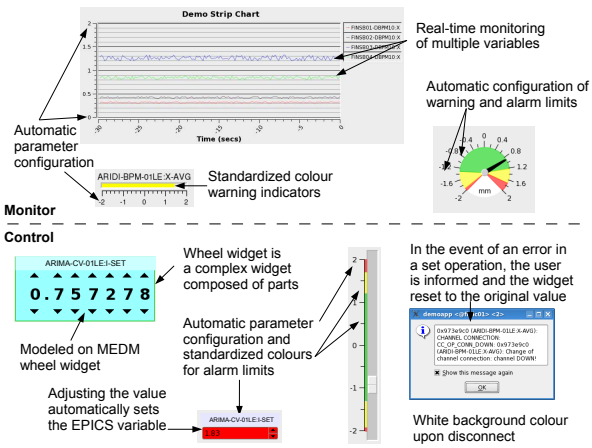

Figure 3: QCafe monitor and control widgets developed with Qt (v. 4.6.3) and Qwt (v. 5.2.1).

CAFE-DDS

High performance messaging middleware is an important component of distributed applications, and one that has been, for many years, an integral part of the high-level applications software infrastructure at the SLS [14, 15]. DDS is a recent OMG standard that supports high performance publish-subscribe messaging with configurable Quality-of-Service (QoS) guarantees. It has been put into good effect at the SwissFEL Injector Test Facility to disseminate summarized results of data acquired from the low-level hardware system. The use of CAFE combined with DDS (OpenSplice Community Edition, v. 5.1 [16]) is exemplified in an EPA that gathers data from the Digital Beam Position Monitors (DBPMs) [17].

The task of the DBPM-EPA is to aggregate, verify and analyze the DBPM data and to publish a summarized data set through a specially designated DDS Topic. The part of CAFE is to provide a simple, intuitive interface to initiate the acquisition of an entire complement of DBPM PVs. This is fulfilled by initiating monitors on the PVs through a single method invocation that includes, as input arguments, a group 'identifier' and a callback function that directs updated values into a designated data container. The DBPM PVs that comprise the group are defined in an XML configuration file by reference to a pre-loaded collection identifier (as described earlier) and the specified device attributes (Listing 1).

On parsing the DBPM-EPA XML configuration file, collections are expanded into their constituent elements and combined with the stated attributes to instantiate a CAFE 'group' object that holds the sequence of required DBPM PVs. The CAFE 'group' object created from Listing 1 is referenced in CAFE methods by its identifier, 'gDBPM'. Static DBPM data (names, positions, etc.) associated with each of the 'gDBPM' group members are extracted from the master SwissFEL XML file, and published to a separate DDS Topic for propagation to GUI clients.

The EPA is thus entirely configurable through XML, and the DDS Topics, which define and identify the data being propagated, provide sufficient information to allow for the dynamic configuration of a GUI client. Changes to the topology of the accelerator may thus be propagated to applications by simple modification to a configuration file, without need to recompile, as demonstrated in [5].

CAFE Mocha

The use of MATLAB in the accelerator community has surged in recent years and is the principal choice of physics application developers at the SwissFEL Injector Test Facility [18]. (The Qt application presented in the previous subsection is one of a few exceptions.) Its increased usage, however, warrants a more extensive interface to the EPICS control system to the presently used mca (MATLAB Channel Access) package [19, 20].

CAFE mocha (MATLAB Objects for CHannel Access) is a MATLAB Executable file (MEX-file) that interfaces CAFE to MATLAB allowing CAFE routines to be called from within MATLAB in the same manner as MATLAB built-in functions. In many respects, the groundwork for MATLAB channel access connectivity had already been laid by mca. CAFE mocha, however, unlike mca, implicitly shelters underlying CA routines from the MEX API. Since the former are designated to the CAFE library, the resulting MEX-file is greatly simplified. Indeed, establishing communication between CAFE methods and the MATLAB workspace, where variables are passed into a function through input and output arguments, is largely re-

duced to mapping MATLAB data types to their equivalent CAFE/C++ data types.

The mocha interface improves on mca by providing support for all MATLAB data types, a richer set of access methods and a further physics oriented abstraction layer. Its use at the SwissFEL Injector Test Facility has been spurred on by the fact that certain tangible benefits became immediately available. Access to MATLAB primitive data types significantly improved performance in the analysis of camera data used in beam profile measurements. The advent of MATLAB's object-oriented programming capabilities has also allowed us to produce mocha-aware classes for specific operations, such as the acquisition of machine snapshots and orbit data (though some computations have been moved to within the MEX-file to enhance performance). Typically these objects, on initialization, extract static data, such as node positions, from CAFE's interface to an XML-based accelerator database (i.e. the master XML accelerator file). Object methods are also invoked to retrieve controls data with one synchronous group call, or to start monitors which cache updated values and, following the convention in mca, may optionally execute a MATLAB script to update a widget value. Widget updates may alternatively be handled through MATLAB's Event and Listener model, which allows a change in an object property to be monitored and a corresponding action to be triggered.

CAFE mocha's compilation on a 64-bit machine has also enabled a first comparison of the injector data with a computationally intensive three-dimensional space-charge simulation model.

A number of mocha mca-like MATLAB scripts [20], which is the usual way in which mca users access the mca MEX-file, have been provided to facilitate transition from mca to mocha for application developers.

HARD ROCK CAFE

Acceptance tests from several external APIs have been performed and give us confidence that CAFE is in a credible, 'Hard as Rock', state and can now be deployed. A short-term objective is to begin the task of replacing CA interfaces that are frozen to deprecated CA functions (as in [21]) with the CAFE API. Developments with QCafe continue with the aim to provide superior, high performance GUI applications, while CAFE-DDS offers a state-of-the-art publish-subscribe mechanism for applications geared towards a reactive form of programming. CAFE's mocha API has demonstrated immediate tangible benefits and work towards its consolidation draws near. The approach of having an extensive and flexible, C++ channel access library to serve as a host API for C/C++ based language extensions will lead to a thoroughly tested code base for other declarative and domain-specific environments, ultimately simplifying maintenance of code. If proved effective, then "Hard Rock Cafe's" mission, "to love all and serve all", is one that may be equally adopted by our very own brand of "Hard Rock CAFE" [22]!

EVALUATION OF SOFTWARE AND ELECTRONICS TECHNOLOGIES FOR THE CONTROL OF THE E-ELT INSTRUMENTS: A CASE STUDY

P. Di Marcantonio#, R. Cirami, I. Coretti, INAF-OATs, via G.B. Tiepolo, 11, I-34143, Trieste, Italy
G. Chiozzi, M. Kiekebusch, ESO, Garching bei Munchen, 85748, Germany

Abstract

In the scope of the evaluation of architecture and technologies for the control system of the E-ELT (European-Extremely Large Telescope) instruments, a collaboration has been set up between the Instrumentation and Control Group of the INAF-OATs and the ESO Directorate of Engineering. The first result of this collaboration is the design and implementation of a prototype of a small but representative control system for an E-ELT instrument that has been setup at the INAF-OATs premises. The electronics has been based on PLCs (Programmable Logical Controller) and Ethernet based fieldbuses from different vendors but using international standards like the IEC 61131-3 and PLCopen Motion Control. The baseline design for the control software follows the architecture of the VLT (Very Large Telescope) Instrumentation application framework but it has been implemented using the ACS (ALMA Common Software), an open source software framework developed for the ALMA project and based on CORBA middleware. The communication among the software components is based on two models: CORBA calls for command/reply using the client/server paradigm and CORBA notification channel for distributing the devices status using the publisher/subscriber paradigm. The communication with the PLCs is based on OPC UA, an international standard for the communication with industrial controllers. The results of this work will contribute to the definition of the architecture of the control system that will be provided to all consortia responsible for the actual implementation of the E-ELT instruments. This paper presents the prototype motivation, its architecture, design and implementation.

INTRODUCTION

The mock-up instrument, to be controlled, is a kind of multi-object (optical) spectrograph composed by the following main subsystems and components:

- One spectrographic arm with an ADC (Atmospheric Dispersion Corrector) and a dedicated CCD;
- One imaging arm with a filter wheel and a dedicated CCD;
- One calibration system equipped with a simple on/off lamp (e.g. Thorium-Argon lamp) and one characterized by a warm-up time required to reach the necessary stability (e.g. Deuterium lamp).

The skeleton of this prototype is based on a real astronomical spectrograph that is being built at INAF-OATs premises and is representative of the components that we expect to be part of a real E-ELT instrument.

#dimarcan@oats.inaf.it

FUNCTIONAL REQUIREMENTS

A detailed set of requirements is a starting point to produce both adequate software and electronic architecture design. For our specific prototype we reused the work done both by ESO and INAF-OATs as part of the studies for the E-ELT Phase A instruments. Dedicated use cases were developed covering aspects like system/instrument start-up, simulation levels, handling of logs and errors, and, typical of an astronomical instrument, handling of the acquisition, observation and calibration phases.

We have reused, moreover, some successful paradigms employed in the VLT software instrumentation framework ([1] and reference therein) applying the experience gained during the software development for the VLT instruments.

Command/ eply

Sub-systems and, in general, devices of the system respond to commands (e.g. *SETUP*) which execute specific actions. Each command is composed by a string made up of one or more keywords (in FITS-like format) and parameters chained together (e.g. *INS.FILT1.NAME U*). Each keyword specifies the subsystem and device the message is addressed to.

State Machine

Devices and components needed to operate the prototype follow the typical VLT state machine. The states implemented are: OFF (not running), LOADED (started-up), STANDBY (software initialized), ONLINE (hardware initialized) [1].

Parallelism

Operations in our prototype are executed in parallel. At the device level this means that all devices are capable of moving in parallel to spare time and minimize initialization procedures. At the higher level (i.e. interaction with the user) it means that the corresponding sub-system does not block upon receiving a request.

SOFTWARE ARCHITECTURE

The baseline design for the prototype Control Software architecture follows a VLT-like approach [1]. Several blocks/packages constitute the overall architecture and could be summarized as follows:

- Low-level control package (identified as **ICS** – the *Instrument Control Software*), responsible for handling the vital part of the prototype (motorized devices and lamps in our case);

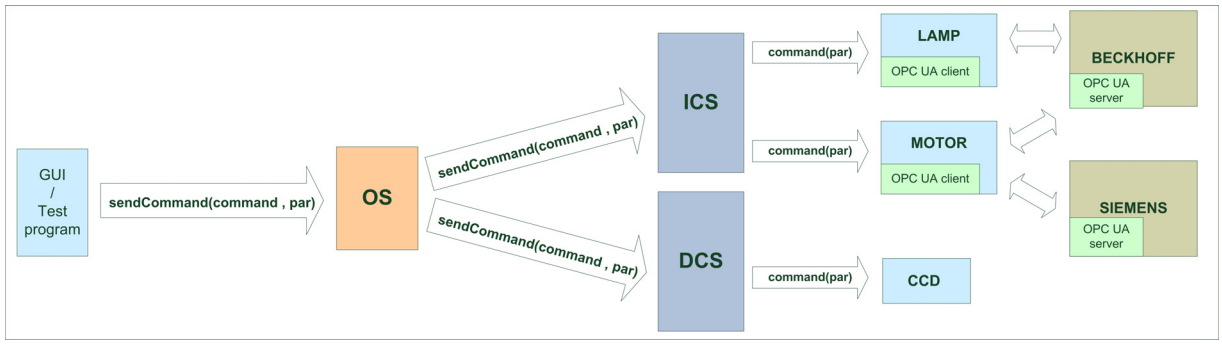

Figure 1: Mock-up prototype software architecture.

- High-level control package (identified as **OS** – the *Observation Software*), responsible for the coordination of activities of the detectors, low-level part and the telescope;
- Detector Control Software (**DCS**), responsible for controlling/handling all detectors.

We decided to use the ALMA ACS framework [2] as the infrastructure software to build our mock-up prototype instrument control software. The reason of this choice is essentially twofold:

- to use a modern, fully fledged, application framework to speed-up the prototype implementation
- to evaluate ALMA ACS complexity (learning curve), completeness, performance and ease-of-integration with other technologies in a view of its possible usage inside the E-ELT project.

The ACS philosophy is to model the system as a set of collaborating components located inside one or more containers contrary to the VLT case where the various software packages are implemented as a set of standalone processes.

Figure 1 shows the final prototype architecture. It is just a schematic picture and does not show all the involved entities (e.g. call-backs, threads). A GUI/test program sends a command to OS, which forwards it to the involved subsystems. Then the subsystem (at present ICS or DCS) sends the command to the appropriate devices. In the case of ICS, the connection between the ACS Components (LAMP or MOTOR) and the hardware (Beckhoff or Siemens PLCs) is realized through the OPC UA technology [3].

In the current version of the prototype the following C++ (ACS) Containers have been configured:

- *OSContainer*
- *ICSContainer*
- *DeviceContainer*, which hosts the LAMP1, LAMP2, FILT1 and ADC1 ACS Characteristic components;
- *DCSContainer*, which hosts the CCDIMAG and CCDSPECTRO ACS Characteristic components.

The motivation of having (so many) different containers even though the system is quite simple is to model it as a highly-distributed system exploiting the great flexibility of the ACS Component/Container model. This will facilitate future modifications. For example, OS and ICS, first implemented in C++, have been in parallel implemented in Java and deployed on a dedicated Java Container, in order to assess the feasibility of using this language for high level coordination tasks.

OS and ICS General Characteristics

In this prototype, the bootstrap of the system uses ACS activation on demand: each component is activated automatically only when requested by another component or by a client. In this way, if there is a need to interact with a specific device it can be just connected to a GUI and the corresponding component will be started up. On the other hand, if there is a request to activate the top-level OS, it will hierarchically activate ICS which in turn will be responsible to activate the needed devices. The ACS configuration database contains the needed deployment information.

The system is designed and implemented to allow executing operations fully in parallel. At the sub-system level (ICS, OS, DCS), command/parameters pairs are received (using a standard SETUP-command syntax implemented via CORBA method invocation) and the corresponding operations executed. Operations are non-blocking i.e. after checking the correctness of the received parameters the involved Component is free to accept new requests. At the OS level this is achieved via call-back mechanism. Before dispatching the incoming command to ICS or DCS, a call-back is instantiated and passed, together with the command, to the appropriate subsystem. In this way, it is responsibility of the involved subsystem to notify when the action has completed allowing OS to handle new requests. Once notified, OS propagates the answer back to the client (see Figure 2).

At the ICS level, a multi-threading paradigm is used instead. Parameters are parsed and sent to the appropriate device using a dedicated thread. Parallel actions are handled by separate threads and a thread join is used as a rendezvous point when all actions are completed (see Figure 2). This allows ICS to receive new commands if required (e.g. an emergency STOP or a SETUP on different devices).

The reason to use the call-back mechanism only at the OS level is due to the fact that OS (in principle) manages a limited number of sub-systems. Call-backs inside ACS are basically CORBA objects. They are therefore somehow "heavy" to activate and this could, at length, lead to some performance penalties.

Adopting these two different paradigms allowed us to compare the two options and to evaluate the easiness of their usage. The final impression is very positive: at the development level both paradigms are fully supported by ACS and also from performance point of view they behave as expected (see final section).

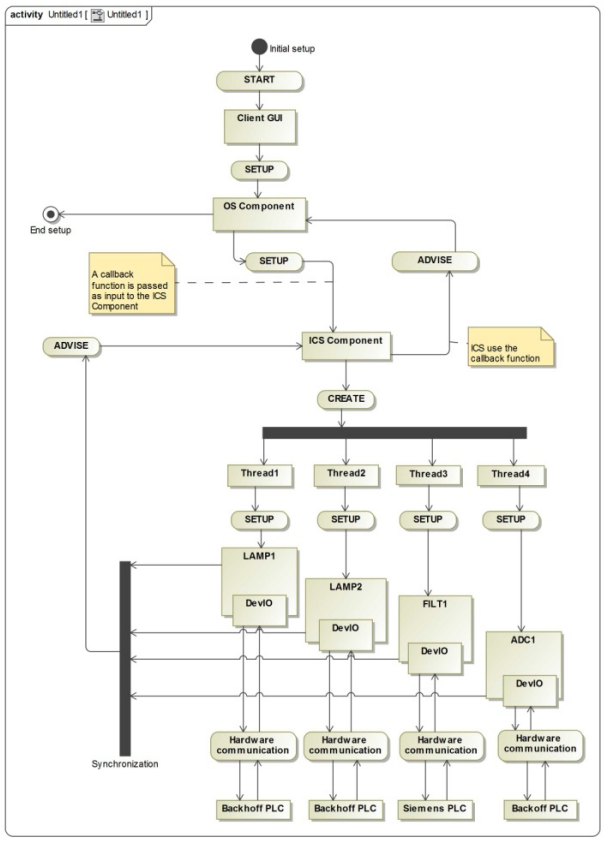

Figure 2: Activity diagram (only ICS part is shown).

The Java implementation for both OS and ICS components has been developed following for both cases the ICS multi-threaded architecture described above. This implementation has demonstrated that Java development is very convenient for these applications and has allowed us to demonstrate also the re-use of other system elements developed for ALMA (like the standard ALMA Master Component state machine or ALMA operator GUIs).

Devices and OPC UA Standard

Both ICS and DCS control hardware devices. Connection to the ICS PLC hardware is handled via OPC UA [3]. The OPC UA is a platform-independent standard through which various kinds of systems and devices can communicate by sending messages between clients and servers over TCP networks. In an OPC UA application we can usually find the following components:

- a "server", usually a thread on the process controller which exposes process data and methods that might run on another node and communicate with the hardware with proprietary protocols. It is supplied (typically) by the hardware manufacturer;
- a "client" that, by means of APIs, implements the OPC UA communication stack and allows the user application to access the data and methods exposed on the "server" side.

In the current prototype version the devices controlled by ICS are:

- LAMP1 – a simple on/off device (mimic a true ThAr lamp) controlled physically by a Beckhoff PLC;
- LAMP2 - a simple on/off device (mimic a true Deuterium lamp), with functionalities similar to Lamp1, but with a warm-up time i.e. the time that the lamp needs to reach full operative mode. Also this lamp is physically controlled by a Beckhoff PLC;
- FILT1 – a filter wheel with certain number of discrete positions controlled physically by a Siemens PLC;
- ADC1 – rotational device physically controlled by a Beckhoff PLC.

DCS controls the following devices:

- CCDImag – implements the interface to a Finger Lakes Instrumentation (FLI) CCD USB Camera.
- CCDSpectro – implemented with dummy responses.

We implemented our own OPC UA client inside the ACS by means of DevIO abstraction layer [2] using the OPC UA client provided by Unified Automation. The OPC UA SDK library is well wrapped inside just two classes: the first one implements all the steps that are necessary to correctly access (i.e. read, write, subscribe) a specific node through a DevIO interface; the second one handles all the connections/disconnections with the PLCs.

Another project based on ACS [4] is now taking this implementation as a starting point for writing a similar implementation on Java. Once this will be done, we will retrofit this prototype with a Java implementation of Device, to verify if also this lower level control part can be implemented conveniently in Java.

ELECTRONIC ARCHITECTURE

One of the aims of the prototype has been to evaluate possible hardware technologies that in terms of performance and cost could be employed in the actual implementation of the E-ELT instruments. Following the description given in the preceding sections (usage of PLCs and communication through OPC UA standard) two complete hardware infrastructures have been set-up to this purpose at our laboratories: one based on Beckhoff TwinCAT SoftPLC platform and the other on Siemens S7-300 PLC platform. Specifically the Beckhoff system is a CX9000 family embedded system equipped with I/O modules (EL1002, EL1014, EL2004) and the AX5201 servo drive able to control the AM3022 brushless synchronous servomotor. The Siemens system is a Compact CPU (CPU 314C-2 DP) equipped with the FM354 Servo Function module able to control a custom made DC drive used in ESO/VLT instruments.

In the Beckhoff case, the PLC software has been derived from the code developed for the ESO/VLT PIONIER instrument and uses the Motion Control (MC)

library conforming to PLCopen IEC 61134-3 as interface to the motors. In the Siemens case, due to the lack of PLCopen compliant libraries (cost and compatibility with our current hardware layout is under evaluation), dedicated code has been developed based on the Siemens FM354_354 block library. Note that the same subset of process variables as the one used in the Beckhoff implementation were exposed making the two platforms fully and transparently interchangeable. This is for sure one of the major achievements of this project: the prototype has shown that thanks to the ACS DevIO abstraction layer and a clever usage of the OPC UA standard, the overall system is unaware of the employed underlying technology/vendor products. By only changing few (ASCII) configuration files, but without having to recompile high-level ACS Components code or changing GUIs, it has been possible to control motors/lamps using platforms of the two different vendors with the possibility to interchange them in a completely seamless way. For the E-ELT instruments this has a quite big impact; it means that it could be possible to change the underlying low-level technology (e.g. due to obsolescence) without affecting the high-level framework or vice-versa in fully transparent way.

Performance

Performance measurement has been done with a mock-up for an ADC connected to the the Beckhoff platform. An ADC is a device able to compensate (counter-balance) the dispersion produced by the terrestrial atmosphere on the incoming starlight, composed by prisms that must be free to rotate. Their position depends on the celestial position of the object to be observed and must be therefore continuously updated.

The performance test that has been carried on is relatively simple: within a thread (spawned by the ACS Component Device associated to the ADC), the new position is calculated (simulating a real astronomical object) and then two calls are made trough OPC UA. The first call updates the target position; the second triggers the actual movement of the motor. To try to reach the real limit of the system, no check is performed on the positioning by the high-level software. In the case the motor is still positioning while a new "move" request is triggered, the target position gets simply updated and the motor continues its movement.

Measurements were made by time stamping, within the ACS code, when a thread is entered, before the first OPC UA call and at the thread exit.

At the PLC level, a physical output was mapped to the "move" flag and then sampled with an oscilloscope. No other tools where accessing the PLC by network when the test was made.

Analysis of these measurements shows that, as expected, most of the time is spent in the OPC UA communication (astronomical computation and thread life cycle management by ACS is negligible compared to the OPC UA calls). With our slow CX9010 system (consider that this is the cheapest Beckhoff CPU family able to run an OPC UA server) and a 10 ms PLC cycle the average time between two consecutive thread call is of the order of 80 ms as confirmed also in Figure 3 by an oscilloscope screen capture.

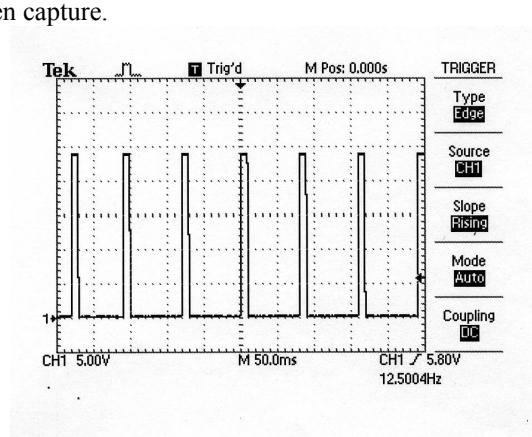

Figure 3: oscilloscope screen capture. Average time between two successive "move" commands is of the order of 80 ms.

Results can be certainly improved using a more performing CPU family (e.g. CX1030), but the actual measurements confirm already now that our (relatively) cheap hardware system connected to the ACS framework through OPC UA is able to sustain cycles of the order of 10 Hz which is well within the requirements asked for our applications.

CONCLUSIONS

The main outcome of our work is that the selected technologies fulfil the imposed requirements and are feasible alternatives to implement instrument control software for the E-ELT. ACS strong points are for sure the Component/Container paradigm, the transparent managing of the Component lifecycles, the DevIO interfaces and the various services offered by the framework which ease implementation (e.g. threads).

The major strength in using OPC UA is the transparent hardware management. Measurements show that performance achieved at the communication level are within specification for most astronomical requirements and therefore OPC UA, in perspective, could be further evaluated as an appealing technology to be employed for the future E-ELT instruments.

A C/C++ BUILD SYSTEM BASED ON MAVEN FOR THE LHC CONTROLS SYSTEM

J. Nguyen Xuan, B. Copy, CERN, Geneva, Switzerland
M. Dönszelmann, Bogazici University, Istanbul, Turkey

Abstract

The CERN accelerator controls system, mainly written in Java and C/C++, consists nowadays of 50 projects and 150 active developers. The controls group has decided to unify the development process and standards (e.g. project layout) using Apache Maven and Sonatype Nexus. Maven is the de-facto build tool for Java, it deals with versioning and dependency management, whereas Nexus is a repository manager. C/C++ developers were struggling to keep their dependencies on other CERN projects, as no versioning was applied, the libraries have to be compiled and available for several platforms and architectures, and finally there was no dependency management mechanism. This results in very complex Makefiles which were difficult to maintain. Even if Maven is primarily designed for Java, a plugin (Maven NAR) adapts the build process for native programming languages for different operating systems and platforms. However C/C++ developers were not keen to abandon their current Makefiles. Hence our approach was to combine the best of the two worlds: NAR/Nexus and Makefiles. Maven NAR manages the dependencies, the versioning and creates a file with the linker and compiler options to include the dependencies. The Makefiles carry the build process to generate the binaries. Finally the resulting artifacts (binaries, header files, metadata) are versioned and stored in a central Nexus repository. Early experiments were conducted in the scope of the controls group's Testbed. Some existing projects have been successfully converted to this solution and some starting projects use this implementation.

MAVEN

Motivation for Maven

The BE/CO group is migrating from an in-house build tool to Maven [1], the industry standards for managing Java projects. This tool is widely used among the Java community by about 60% of developers. More than 100'000 open source projects are available on Maven Central repository, millions of connections happen per year. In addition, Maven can be used seamlessly with many tools for testing, source management, issue tracking, continuous integration, and so on. Since 2003, the BE/CO Java team have been putting a lot of efforts into software quality and reuse of resources in cooperation with other departments [2].

As the C/C++ developers want to improve quality and testing among their projects, the opportunity of unifying the build tools has been taken so they could profit from the same infrastructure, tools and experience from the Java development teams.

Maven Basics

Maven's key features are dependency management and versioning. It tends to enforce standards by providing a uniform build cycle with well defined succinct steps. In short, Maven takes the sources code, resolves and downloads the needed dependencies, builds the files and publishes the output to a repository. The output is called an artifact; it can be a jar, zip, war, etc...

Maven is plugin based and therefore can be easily extended with plugins. The latter can be provided by the Maven core developers, contributors, or one can write its own one. Plugins cover a very wide range of functionalities and have various purposes, such as generating docs, downloading specific artifacts, etc...

As shown in Fig. 1, a project is represented by a XML file called pom.xml (Project Object Model). Its main two parts are project information for the current project and dependencies information.

```
<project>
    <groupId>cern.testbed</groupId>
    <artifactId>testbed</artifactId>
    <version>1.0.0</version>
    <description>...</description>
    <url>http://...</url>

    <dependencies>
        <dependency>
            <groupId>cern.japc</groupId>
            <artifactId>japc-ext-cmwrda</artifactId>
            <version>[2.0.0,3.0.0)</version>
        </dependency>
        <dependency>
            <groupId>cern.japc</groupId>
            <artifactId>japc</artifactId>
            <version>2.11.0</version>
        </dependency>
        <dependency>
            <groupId>junit</groupId>
            <artifactId>junit</artifactId>
            <version>4.8.2</version>
            <scope>test</scope>
        </dependency>
    </dependencies>
</project>
```

Figure 1: Simple pom.xml example.

THE NAR PLUGIN

Motivation, JNI and C Libraries

Maven handles the build steps for Java programs very well. Since Java allows the coupling to C and C++ programs it seems logical to include the step of compilation and linking of JNI (Java Native Interface) [3] modules as part of the Maven build steps. To extend Maven to handle native (C, C++, objective-C, etc...)

languages the NAR (Native ARchive) plugin [4] was written. How this plugin handles the compilation of JNI and other native modules for different platforms as well as their distribution and their usage of Maven's dependency mechanism is explained below. The NAR plugin consists of multiple sub plugins each of which takes part in the NAR lifecycle.

NAR Lifecycle

As mentioned earlier, to build any product Maven runs through a sequence of build steps. These steps are defined as a build lifecycle and directly associated to a packaging definition. By default Maven comes with packagings/lifecycles for jar, war, ear and some more. To enhance the standard build steps in the jar lifecycle with native compilation and linking, extra steps (in bold) where defined in the NAR lifecycle. The packaging for this lifecycle is NAR and a simplified version is given below:

- nar-download
- nar-unpack
- compile, nar-javah, nar-compile
- nar-testCompile
- test, nar-test
- nar-package, jar
- nar-integration-test
- install
- deploy

Native Sources and Headers

Maven assumes standardization for its plugins. The sources and header files for native parts of the code need to be stored in predefined places, which can be redefined if necessary. Header files and c files are not stored in the same location to make it easier to distribute the headers without the sources. These locations are used by the nar-compile plugin but also by the nar-javah plugin which runs the javah compiler. All generated output is stored, as usual in Maven, in subdirectories of the target directory.

AOL and Properties

To distinguish different platforms, operating systems and compiler/linkers the NAR plugin uses an AOL (Architecture Operating system Linker) qualifier. This qualifier looks like "i386-Linux-gcc" on a Linux i386 platform with gcc, but could be further extended in the form i386-Linux63-gcc4.1. The qualifier is used to handle different distributions as well as for selection of options for different compilers. Options and other flags are specified in an aol.properties file which sits next to the pom.xml file. A property file makes more sense than trying to put everything into profiles in the pom.xml as the number of platform/compiler combinations can be fairly large. Properties are stored in the aol.properties file for specific AOLs in dotted notation, for instance:

x86.Windows.msvc.cpp.compiler=msvc
i386.Linux.g++.c.options=-Wall -Wno-long-long

Compilation and Testing

For Java the maven-compiler-plugin handles the flags such as debug, optimization and others. We chose to use the cpptasks library [5] as this library unifies flags, options and linker strategies across different platforms and compilers/linkers. Based on the AOL a compiler, linker and their default flags are retrieved from the aol.properties file. These can be overridden by a project specific aol.properties file. The nar-compile plugin handles the native compilation/linking phase for which the cpptasks library was extended to use multiple cores in parallel to speed up compilation.

The nar-test plugin runs unit tests against the created JNI or standalone library. The test plugin makes sure that all libraries can be found.

The NAR Format and its Attached Artifacts

To package created libraries, executable and object files for re-use by others the NAR plugin uses its own format, the NAR file. A NAR file is no more than a standard jar file containing object files, executables, libraries and or header files. Files are stored in a directory structure that includes the AOL specifier but also reflects if libraries are static or dynamic. In its unpacked form the NAR compiler plugin is able to pick up header files and refer to libraries. This is important if some other package depends on a NAR library.

Three artifacts are produced under normal conditions: a standard NAR containing all Java class files if there are any as part of the project, a *-noarch* NAR file containing all non-architecture (non-AOL) specific files, such as header files and a *-<aol>* NAR file containing AOL specific files such as libraries. The first NAR file contains a property file that refers to the other two, which is used by the nar-download plugin, see below. The two latter NAR files are attached artifacts to the first. As can be seen this set of NAR files is a native equivalent for Java's single jar file.

The NAR files are split up in *-noarch* and multiple *-<aol>* files to make generating them easier and to download only the ones one need for a developer on a particular platform.

Distribution, Install and Deploy

The NAR plugin relies on the standard maven-install and maven-deploy plugins to install and deploy the primary NAR artifact and its attached artifacts. Any mechanism of caching such as the use of Sonatype Nexus [6] works transparently. Any Maven repository server will just store NAR files and their attached artifacts as another type of packaging.

Dependencies on other NAR Libraries

The reason for creating NAR files is so one can make other projects depend on them. These projects need to be also of the NAR packaging type and can then declare NAR dependencies. Any dependency declaration will initiate a download of the primary NAR artifact by Maven

itself. This primary NAR artifact is stored in the local repository.

Downloading and Unpacking Locally

Once a primary artifact of a dependency is downloaded, it is inspected for the above mentioned property file to see what attached artifacts need to be downloaded. In the normal case a *-noarch* and a *-<aol>* artifact will be downloaded by the nar-download plugin and stored in the local repository. As these NAR files as such are no use to any compiler, they will be unpacked by the nar-unpack plugin in a subdirectory of the current projects target directory (the latest version of Maven supports concurrent access to the local repository directory, so unpacking can also be done there in the future, thereby sharing artifacts and gaining space). The unpacked NAR files reveal the header files and libraries of the dependency and can thus be used the nar-compile plugin. Include paths and library paths will be set up automatically.

Cross Talk with other Systems

Other systems exists to build native (and even Java) code. The NAR plugin tries to be open and to integrate with those systems. One can for instance fairly easily call "configure", "autoconf" and "automake" of the GNU build system [7], or just call "make" to build libraries the usual way and use the NAR files purely for distribution and dependencies, as is explained below.

EXTENDING THE NAR PLUGIN

At CERN

At CERN, some projects were successfully converted to Maven NAR, but it resulted in big XML configurations. Indeed to simply add a compilation flag, about fifteen XML lines are needed whereas only one line is required with Makefiles, thus C/C++ developers were not keen to abandon the flexibility of their current Makefiles. In addition to that, CERN projects rely on cross-compilation, which is not covered by Maven NAR out of the box.

Design

Therefore it was essential to modify the NAR plugin according to our needs. A hybrid solution has been favoured: separate the build tasks between Maven NAR and Makefiles. Maven NAR takes care of the dependency management and versioning and Makefiles are in charge of the compilation process. NAR lifecycle has been modified so the goal nar-compile calls a Makefile instead of calling a compiler. Then binaries are expected to be generated and to be published to a binary repository. In our organization we use Sonatype Nexus for Java and decided to reuse it for C/C++ projects.

Finally, in order to support our cross-compilation infrastructure used by our Makefiles, it was necessary to modify cpp-tasks to add our compilers.

Implementation

As shown in Fig. 2, several steps are needed to build a C/C++ project with the customized Maven NAR. The following paragraphs describe each step along with its detailed implementation.

Makefile Generation Phase

The usual nar-download and nar-unpack phases are run, but in addition after those NAR will generate a Makefile with compiler and linker options. This Makefile contains only the dependency information for a specific platform, therefore the chosen naming convention is *Makefile.dep.<aol>*.

Compilation Phase

Maven NAR simply execute the command “make MAVEN_BUILD=true”. By convention, a Makefile needs to be present next to the pom.xml and its default target has to compile the source code. It also needs to include the Makefile.dep previously generated and use the defined macros from it.

The output binaries have to be placed in specific folders. The agreed standard is to put the library in *build/lib/<aol>* and includes in *build/include*. In BE/CO, we tend to enforce platforms independent headers, but some teams required platform specific headers. In this case, these headers go in *build/include/<aol>* and the Makefile generator will add an extra –I flag accordingly.

Packaging Phase

Files will place in the right folders so nar-package can do its job. Thanks to the directory conventions, NAR knows where to pick up what.

Deployment Phase

In Maven terminology, deployment means publishing on a server to make it available to other developers. This phase has not been altered from the official NAR plugin.

Usage Example

At CERN, C/C++ developers are used to define a macro called CPU to define the target platform. Instead of typing the whole target platform, shortcuts such as *L865* or *ppc4* are used. The same shortcuts were kept when invoking Maven commands, but these shortcuts are expanded to the AOL standards as i386-SLC5-gpp.

BENEFITS AND APPLICATION

Benefits

Since the dependencies information is separated and automatically generated, the Makefiles are simplified, the developers do not need to be concerned about dependency management and versioning anymore, and ultimately they can keep their habits with their Makefiles.

The previous implementation using pure Makefiles remains compatible with Maven NAR. Makefiles are called with the flag *MAVEN_BUILD=true* from Maven

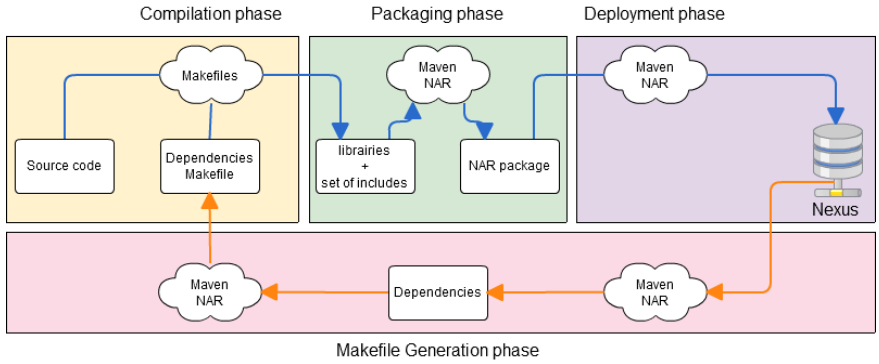

Figure 2: Extension phases.

NAR, thus it is known when a build is processed by Maven or pure Makefiles, some conditions can thus be added in order to include files accordingly.

Standards are also enforced, as explained earlier; Maven NAR needs to know where to pick up the different binaries (executables, libraries, headers). Directories need to have a well-defined structure with standardized names, as well as the files.

In addition of the build tool, the software development/release/deployment process and binary repository are also unified between programming languages. Java developers can easily switch to C/C++ and invoke the same commands through Maven to achieve the same goals. The build lifecycles are almost identical, first the code is compiled, then the unit tests are compiled and run, finally the product gets packaged.

Sharing C/C++ projects across and outside CERN becomes easy with Sonatype Nexus, CERN developers just needs to point to the binary repository and collaborators can proxy it and use the artifacts.

A CI (Continuous Integration) server takes care of building the projects with the bleeding edge source code from our SVN trunk. If a commit breaks a project, it will be immediately spotted.

Applications

The Maven NAR plugin is especially suitable to simplify cross-platform Java C/C++ build processes.

As an example, the build process of the CERN Data Interchange Protocol (DIP), a platform independent middleware protocol, was updated early 2010 to move from two entirely separate build systems relying on a series of manual steps and environment variables configuration into a unified Maven based build.

Because DIP is available both as a C++ and Java API, for three different platforms (Windows 32 bits, Linux SLC5 32 bits and SLC5 64 bits), a grand total of six builds, executed manually, had to be coordinated to assemble a complete distribution release.

Besides reducing the associated maintenance overhead, relying on a Maven build also helped to:

- Integrate more seamlessly the Java and C++ APIs (through JUnit testing)
- xDistribute its various components (Header files, static and dynamic libraries, auto generated documentation, associated development tools).

Since DIP is used by many projects at CERN, distributing it in NAR format also greatly simplified reuse for all CERN Maven based projects.

NEXT STEPS

Unit Tests

There are some improvements which can be done at the test phase. Instead of calling binaries which returns a code exit, we would like to integrate a testing framework to ease the writing of tests. Google C++ Testing Framework is a good candidate [8], to be used with Gcov [9] which offers code coverage. The goal is to generate full reports similar to the JUnit one, which will be displayed in our continuous integration server.

Merge Back with the Official Maven NAR

The CERN Maven NAR version embed functionalities specific to CERN, but most of the used methodology and chosen convention are standards in the C/C++ community. These changes need to be generalized and integrated back into the main version of Maven NAR in order to be able to profit from a community.

JAVA EXPERT GUI FRAMEWORK FOR CERN BEAM INSTRUMENTATION SYSTEMS

S. Bart Pedersen, S. Bozyigit, S. Jackson, CERN, Geneva, Switzerland

Abstract

The CERN Beam Instrumentation Group's software section has recently performed a study of the tools used to produce Java expert GUI applications. This paper will present the analysis that was made to understand the requirements for generic components and the resulting tools including a collection of Java components that have been made available for a wider audience. The paper will also discuss the prospect of using Maven as the deployment tool with its implications for developers and users.

INTRODUCTION

The CERN Beam Instrumentation Group (BI) belongs to the Beams Department (BE). Inside this group, the work of the BI Software Section is to implement real-time servers in C++ that control instruments developed for beam diagnostics located on all CERN accelerators and their transfer lines (LHC, LHC injectors, ISOLDE, LEIR, AD…). The team is composed of around ten physicists, engineers and students with good software skills. The main GUI clients are the hardware specialists in charge of the instruments, along with a few operators and accelerator physicists who use them during special manipulations for additional status and control. Before doing any low level C++ implementation, a design of the instrument is made using a dedicated CERN software architecture called FESA (Front-End Software Architecture) [1] (Figure 1).

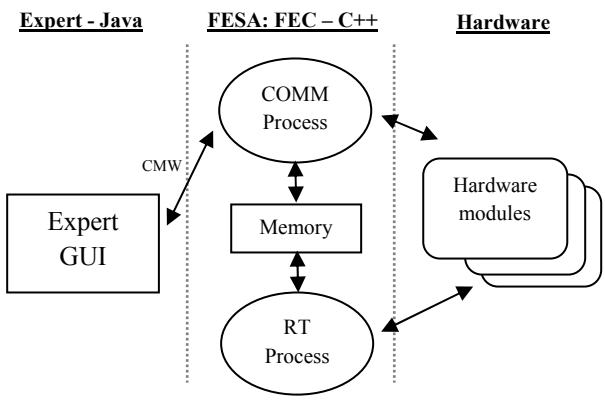

Figure 1: BE Front-End Software Architecture (FESA).

Providing graphical interfaces (GUI) implemented in Java is also part of the section's mandate. Hardware experts need to access their equipments in many different ways for parameter setting, signal visualization, error diagnostics, calibration, data post processing and so on.

Java (JDK1.6) is currently the BE department's development language for all GUIs and the software section's Java developments follow this standard. The low level software architecture, middleware and Java component libraries are provided by the BE Control Group.

PROBLEMATIC

Requests and specifications for new expert GUIs are often very different and depend on the type of instrument, the acquisition electronics and the type of diagnostics to be performed. Therefore, a standardization of a framework's functionalities and a static list of options is insufficient. The software engineer should instead be able to create ad-hoc Java classes and components (graphical or not) to fulfil specific requests.

Nevertheless, since the software requirements, although different, often have a similar overall structure, it made sense to have a common Java framework on top of which everyone could build specific applications. A functionality review of current expert GUIs revealed that a common customizable graphical framework is an efficient way to standardise and facilitate the development of a Java project implementation.

All of CERN's beam instrumentation systems belong to a particular accelerator domain (LHC, SPS, PS…) and are triggered by their own timing events. Each instrument is identified based on a database of devices that links it to a certain device name. The application window should therefore, for example, be able to display the incoming machine cycles and allow easy retrieval of device-names. Another important point is that the number of data types in an acquisition is limited. So, having the same graphical component to input or display a scalar or plot an array using common plot components would be a very efficient solution as it avoids code redundancy and strengthens software quality.

FROM THE OLD TO THE NEW FRAMEWORK

Why Did We Have To Change?

The main purpose of a common expert GUI framework is to provide a skeleton that can easily be built upon, so reducing the need to re-develop large sections of code for new applications and in so doing decreasing the total time spent to create such an expert application.

The old expert GUI framework, in place since 2004, was designed having the same goals in mind, but several issues have appeared over the years. People were therefore using this framework less and less and instead started developing their own applications from scratch. As already mentioned, an internal questionnaire revealed this was mostly due to the rigidity of the framework and the lack of desired functionality. Rigid, because this skeleton was providing a structure in the form of tabs and panels,

which was sufficient at the time when it was designed, but became a constraint as the panels to be shown always needed to be heavily customized. Several missing basic functionalities that were mandatory in terms of beam diagnostic tools also forced programmers to abandon the framework and instead implement their own code.

Besides these concerns, the section was frequently experiencing issues related the dependencies of their applications. All third party libraries coming from other CERN groups were directly obtained at runtime from external repositories and whenever a library lost its backwards compatibility, all the applications depending on it would break.

With the new expert GUI (v2), we tried to address these issues by providing a framework that still has all of the useful functionalities of the old framework, such as the communication and plotting packages, but is also programmatically more flexible (Figure 2). At the same time, we tried to manage the dependency issue by using a specific tool developed to handle this problem. Additionally, other useful components written by members of the section already existed and it was our intention to make these available to all users through the new environment.

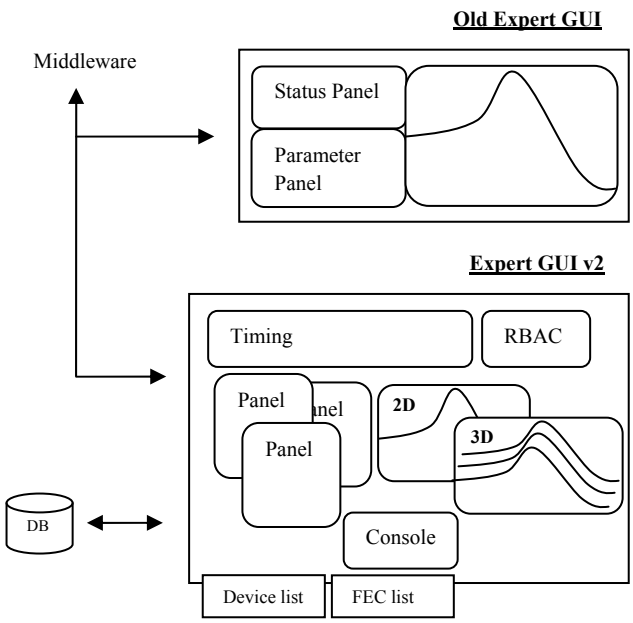

Figure 2: Old and new expert GUI.

What Did We Change?

The expert GUI framework needed a facelift both visually and programmatically. The main transformation was to convert the frame class that always had the same look with fixed tabs and panels to two different classes that inherit an abstract *ExpertGUIFrame*. First there is the *EmptyFrame* that basically provides an empty window where any of the desired components can be included. Second there is the *BasicFrame* which already contains commonly used components such as the RBAC (CERN Role Based Access Control) toolbar and a built-in console at the bottom of the frame.

In order to cover the need for some applications to look like the old expert GUI, a couple of panel classes were included in the new framework (*VintagePanel*, *VintageStylePanel*) that could be easily incorporated into the *BasicFrame*. If other predefined frame classes are desired in the future, they can be easily created with a framework extension.

In the old expert GUI, the very first step to create a program was to create a new main class that inherited properties from the framework main class. While this is still possible in expert GUI v2, by inheriting from the *EmptyFrame* or *BasicFrame* classes, the recommended way to obtain the framework functionality is to fetch a frame instance from a factory class and to use it as a delegate in your main class. This makes sure that the client who is using the provided frames only sees and uses the methods which were meant to be used by the class.

The communication library has basically stayed the same except that there is a new type of communication that deals with database (DB) connections. A new *CommunicationManager* class has been introduced so that the developer need not care about the details of instantiating different kinds of communications (FESA device or DB).

Applications often deal with more than one device, sometimes even with more than one instrument type. To facilitate the initialization of the communication and the handling of those devices, the factory class needs to provide a list of devices and databases. This information is used to create a menu item in the menu bar where all the relevant devices and databases are registered. Additionally, it feeds two manager classes that deal with the actions (button clicks) and the information that accompanies these devices.

Instead of managing the dependencies manually, as is done for applications based on the old expert GUI, we have tried to incorporate a third party tool called Maven, which automatically resolves all dependencies of a project and takes only the specified libraries from a local section repository.

This repository can also be used to share components between the members of the section simply by publishing their libraries into it.

What Are The Benefits?

The expert GUI v2 has become more flexible and it can more easily suit individual needs than its predecessor. For example, if someone wishes to completely write their own application from scratch, they can do so by instantiating the *EmptyFrame* but they wouldn't have to forego the communication library. Or, if someone wants to have an application that looks the same as the old expert GUI, it would also be possible to create it within the same framework. Finally, the new framework offers access to libraries (components) written by others, so everyone can profit from each other's work.

The usage of Maven should simplify the maintenance of the dependencies and generally facilitate the software build lifecycle.

JAVA SOFTWARE PROJECT MANAGEMENT WITH MAVEN

What is Maven?

In short, Maven is a software tool for project management and automation of builds [2], i.e. a build component testing and dependency management tool. Only a subset of the capabilities of Maven has so far been tested within the BE-BI Group.

Maven is not a graphical tool in its own right but a framework that is installed on the system (in an IDE i.e. Eclipse) which assists the development of a project. It is built around the concept of a "build lifecycle". This means that every complete project has to go through all the stages of the cycle which, for example, can contain compilation, testing, packaging (producing a jar), deploying in a local repository, deploying in a remote repository, etc.

The project has to successfully pass all of these stages. In a "traditional" project, these stages would need to be done separately. This manual mode forces the programmer to repeat the same procedure for each stage. Maven attempts to automate these procedures by extracting the pieces of configuration which are needed for every stage (for example: jar name, files to include in the jar, content of the manifest file, deployment location, etc..) and bundles them into a configuration file (Project Object Model) that is specific per project. The most important part of that file in our case is the list of direct dependencies.

Why Do We Need It?

We are not obliged to use Maven, and for us it started more as an experiment to see whether it could fit our needs. We were hoping to profit from the standardisation that comes with Maven as its capability for solving the dependency problem. Its concept of build lifecycle gives many structures almost for free, such as JUnit testing, packaging, JAR signing and generally structured project development. One additional strong argument to study Maven came from the fact that CERN Controls Group was also looking towards using Maven in the future.

Can We Use It?

Our deployment strategy does not implement any versioning of a given application with only a development and operational version at any given time. These two versions used to be deployed by an ANT script into two distinct folders. Each of these folders contains all the Java libraries (JAR) of all the applications, both development and operational versions. Either of these versions can be launched through a program called the *ApplicationLauncher* [3] (Figure 3).

A Maven project can be identified in a repository through three parameters: *GroupId*, *ArtifactId* and *Version*. These three qualifiers determine the folder structure in the local repository where the project is stored. However, if one decides to deploy using Maven, by default it forces you to use the same folder structure. It turns out that our current deployment strategy therefore does not fit well with this Maven approach, requiring some tricks to get rid of the Maven folder structure or significant modification to the *ApplicationLauncher*. In order to stay compatible with the current *ApplicationLauncher* it was therefore decided to opt for an Apache ANT script that copies the deployable JAR files to the desired location.

How Are We Using It?

Maven's dependency management system is declarative, transitive and simple to use. The libraries that a project needs to work properly are declared in its POM (Project XXX YYY) file. The three pre-cited qualifiers are enough for Maven to locate the right library in its repository system. Maven can provide an arbitrary number of repositories where it can obtain the requested libraries. It offers the possibility to specify a local repository which can be used internally in the section and not made public to other developers, allowing the possibility to control and manage changes i.e. updates of external JAR files.

The dependency system's transitivity (inheritance of properties and dependencies) facilitates the development of a project. Only direct dependencies need to be provided to Maven. If the libraries that a project relies on depend on another project, Maven will take care of this. It knows where to fetch the indirect dependencies, since all projects and libraries in the repository come along with a POM file that declares their dependencies.

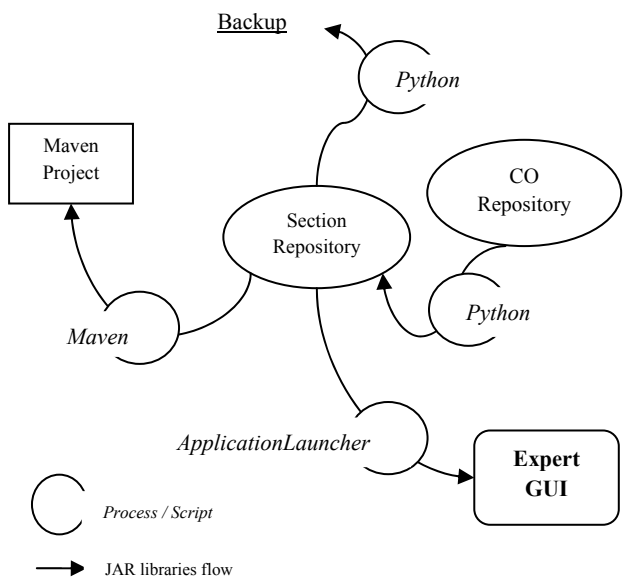

Figure 3: JAR libraries flow.

The inheritance concept, coming from object-oriented programming, is applied to the POM file. Through

inheritance, common settings and properties can be propagated from a "parent" project to projects inheriting from it. This mechanism gives the possibility to define a parent project that contains most of the dependencies and settings that are usually needed in any project. A creator of a new project therefore only needs a POM file to inherit from the parent POM file in order to have all necessary dependencies, to know the location of the keystore for signing JAR files and to have the settings in a manifest file, etc…

In the old expert GUI framework, one needed to check out a template project from the Apache Subversion SVN repository in order to start a new project. Maven also helps in this perspective because it provides a template through a mechanism known as "archetypes". An archetype gives the possibility to steer several properties of a project. It can impose a predefined folder structure on a new project providing opportunity to standardize structure across Java projects. It can also provide additional files such as ANT files or log files and can give a source code template for the entry point of a project.

What Are The Benefits?

It took a rather long time to set-up a generic environment to work with Maven and then to effectively use the tool for development. As it was not possible to deploy our JAR files the way we wanted, we were forced to opt for a hybrid solution using both Maven and ANT. The most comfortable way for us to develop an expert application is to have a simple ANT file that does the cleaning, the compilation, the packing and the final deployment with a simple mouse click as was the case for the old expert GUI. In order to achieve this and spare individual users from unnecessary Maven details, the Maven commands are encapsulated in such an ANT file, with all commands forwarded to the Maven system except for the deployment task which is done directly using ANT commands. To backup files and to retrieve specific JAR files, a Python script is used.

The main advantage of using Maven is the control of the dependency files. In addition the standardization of projects and the use of archetype templates greatly lower the effort required to start a new expert application project.

The incorporation and usage of Maven in our projects is an on-going process and there are still details to be tested. Most of the benefits could probably have been achieved in a different way using different tools. Many of these options, however, would have probably required an unacceptable amount of manual work and would have ended up in a patch work of different components needing to be unified to provide a similar functionality as Maven.

CONCLUSION

The analysis and improvement of our Java software development tools are still on-going. This process is taking time because of several constraints. Keeping backward compatibility with our old applications, sticking to CERN software standards, and covering the needs of all our programmers are just some examples of things to be considered.

The new expert GUI has already given very good results. Users can easily and quickly create a Java project with a pre-defined structure that will allow them to run an application in two mouse clicks. At the same time, they are able to add whatever components they need to libraries that are now common to all. These components have been specified inside our section and therefore already provide most of the functionalities that might be needed in such applications.

The use of Maven is not completed and has led to some integration problems for our Java software architecture. Nevertheless, the handling of the library dependencies and the archetypes are very useful. The CERN Controls group has not yet confirmed that Maven will be one of its standards, but from our experience so far, we will give positive feedback regarding these two interesting features.

Abstract

The integration of web technologies and web services has been, in the recent years, one of the major trends in upgrading and developing control systems for accelerators and large experimental apparatuses. Usually, web technologies have been introduced to complement the control systems with smart add-ons and user friendly services or, for instance, to safely allow access to the control system to users from remote sites.

Despite this still narrow spectrum of employment, some software technologies developed for high performance web services, although originally intended and optimized for these particular applications, deserve some features that would allow their deeper integration in a control system and, eventually, using them to develop some of the control system's core components. In this paper we present the conclusion of the preliminary investigations of a new design for an accelerator control system and associated machine data acquisition system (DAQ), based on a synergic combination of network distributed object caching (DOC) and a non-relational key/value database (KVDB). We investigated these technologies with particular interest on performances, namely speed of data storage and retrieve for the distributed caching, data throughput and queries execution time for the database and, especially, how much this performances can benefit from their inherent scalability.

INTRODUCTION

Two main motivations support the decision to start investigating a new approach in the design and development of CS for particle accelerators.

New developments in this field, similarly to what has happened in recent years, will be basically directed towards improving their functionalities by introducing new services, or improving existing ones, to complement the basic features that are essential for the remote control of the accelerator's components.

These new capabilities rather than being accessorial will be, in many cases, fundamental for the optimal operation of new accelerators that will require careful tuning to achieve the desired performance. An example may be the data acquisition system that is intended to provide machine physicists, but also the experimental groups, with all the information needed to recreate the operational state of the accelerator (set-point of components, information from the beam diagnostic etc.) at any instant during the operations of the machine.

The analysis of recent developments on high-performance software technologies suggests that the design of new accelerator CS may profit from solutions borrowed from cutting-edge Internet services. To fully profit from this new technologies the CS model has to be reconsidered, thus leading to the definition of a new paradigm.

The second strong motivation for this development follow the recent approval, by the Italian Ministry for Education, University and Research (MIUR) of the construction of a new international research centre for fundamental and applied physics to be built in the campus of the University of Rome "Tor Vergata".

It will consist of an innovative very high-luminosity particles collider named SuperB [1] and experimental apparatuses, built by an international collaboration of major scientific institutions under the supervision of Istituto Nazionale di Fisica Nucleare. Clearly, it will offer great opportunities not only for new discovering in particle and applied physics, but also for breakthrough innovation in particle accelerators technologies.

THE !CHAOS FRAMEWORK

A typical example of software technology emerging from developments of Internet services is the class of non-relational databases known as key/value database. They offer an alternative to relational databases (RDMS) that is having a growing success and interest among developers of web services because of their high throughput, scalability and flexibility.

Another example is the object caching, distributed systems that are used to store, in the servers' RAM, frequently requested sets of information in order to both respond faster to requests and distribute the load of the main server to a scalable cluster of cache servers.

These two software technologies, clearly cited on purpose, represent the core components in the design of this new control system we named !CHAOS[2].

In particular, the KVDB is used by DAQ for storing what we call *history data*, while the DOC implements the service for distributing *live data* from the front-end controllers to clients replacing the client/server communication.

Compared to the typical structure of CS, usually represented by the so-called *standard model* [3] of control systems, in the !CHAOS data flow the client (top) and front-end (bottom) layers are not directly connected and, especially, data is not sent by controllers when triggered by

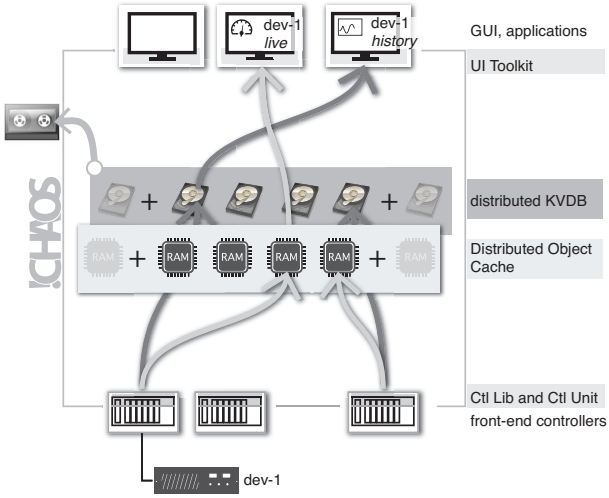

Figure 1: Data flow in the !CHAOS framework.

client request. Instead, alternatively to the typical point to point communication of network distributed systems, in !CHAOS *live data* flow from front-end controllers to the DOC servers, according to the independently adjustable refresh rate, from which datasets can be asynchronously read from any client.

This solution offers a number of advantages.

Firstly, we can use the same strategy, and topology, for both distributing *live data* and storing *history data* as shown in Fig.1. Datasets that need to be updated are identically pushed, by front-end controllers, to both DOC and KVDB servers by issuing *set* commands. It means that data collection mechanism for DAQ is inherently included in the !CHAOS communication framework because both *live* and *history* data are pushed by the data source (the front-end controllers) to similarly distributed caching and storage systems. Moreover, since both DOC and KVDB use key/value data storage, formatting and serialization of datasets can be identical.

Secondly, both the client applications and the front-end controllers are simple clients of the distributed object caching and DAQ. In particular, provided the DOC has an object container for each dataset of the CS, defined by its unique key, a GUI client simply send to the !CHAOS DOC service a *get* request for the object identified by that particular key, i.e. the dataset describing the associated device. On the other side the controller responsible for that device update its dataset, according to the push rate defined for it, by issuing *set* commands to the DOC.

Data refresh rates, as well as other meta-data and global parameters, will be managed by the meta-data server (MDS) that will be described later.

It's worth to underline that in !CHAOS the front-end controllers don't need to run servers for providing data to clients since they themselves are clients of the data distribution and storage services. That improves their robustness, portability and prevents front-end controllers from overload originated by multiple clients' requests.

A fundamental property of both DOCs and KVDBs is their intrinsic scalability that allows distributing a single service over several computers. Moreover, dynamical keys re-distribution allows automatic failover by redirecting to other servers the load of failed one. By taking advantage of this feature !CHAOS can be easily scaled according to both different size of the accelerator infrastructure and the performance required thus avoiding any potential bottleneck that may be expected as the weak link of the star-like communication topology.

In conclusion !CHAOS is a scalable control system infrastructure providing all the services needed for communication, data archiving, timing, etc. to which both front-end controllers and GUI applications plug-in to access and, to some extend, expand its functionalities.

Control Units: The !CHAOS Front-end

Fig.2 shows the logical structure of the software running in a front-end controller. The Control Library (CL) and the Control Unit (CU) are components of the !CHAOS infrastructure while the device management plug-ins (DMPs) are software drivers complementing the !CHAOS framework functionalities by providing the interface to the device. The development of these components is expected either as contribution, or under responsibility, of device experts.

One or more instances of CU can run simultaneously, though completely independent, in a front-end controller. Each of them will be dedicated to a particular device or a family thereof, specialized for that particular components by means of the device management plug-in. The latter are a set of routines implementing five main functionalities: initialization, de-initialization, control loop, dataset update and commands execution.

The Control Library, by means of its *managers*, will provide both the environment for the execution of the Control

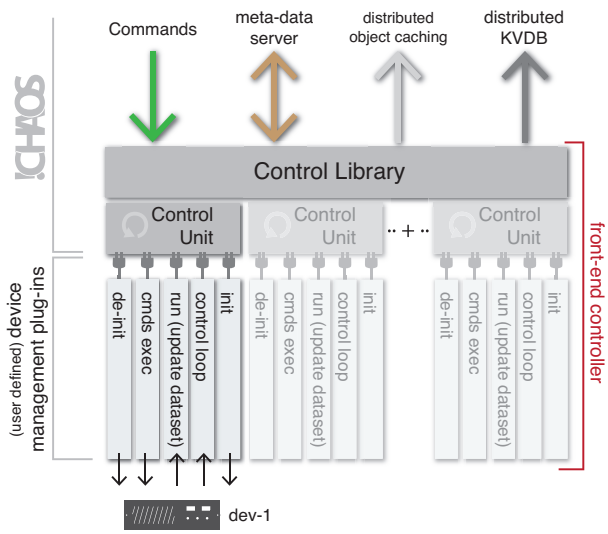

Figure 2: !CHAOS components for the front-end controllers.

Units and the functions needed to access the centralized services (DOC, KVDB, MDS).

Since the CU will control the execution of DMPs, the former will be responsible of invoking the *run* module, according to the refresh rate defined for that device, for reading the device status. The data returned will be used by the CU, via the Control Library, to feed the KVDB and to refresh the value of the correspondent key/value pair in the distributed object caching service.

On the other side, when a command issued by a client application will be received by the CU, the *command* module will be invoked for executing it. Parameters passed to the command's execution plug-in module will specify the action to be taken according to the instructions provided. The use of separated threads assures that requested periodicity of dataset refreshing is preserved even during commands' execution while serialization of parameters passed to the command plug-in allow a common interface for all the commands to be implemented.

Live Data Caching, DAQ and Central Services

Caching of live data, by means of distributed object caching service, and continuous archiving of accelerator data, by using a distributed key/value database, are the main innovations introduced by the !CHAOS paradigm.

DOC service is distributed over many nodes working together to provide clients with a single virtual pool of solid-state memory by sharing a portion of the RAM of each node. Objects are stored in memory as *key/value* pairs and a given object is always stored and always retrieved from the same node in the cluster, unless the number of node changes for any reason.

In !CHAOS a *key* identifies a unique dataset of the control system that is the set of information used to fully describe a real, or virtual, accelerator device.

Each dataset is periodically refreshed by the Control Unit in charge for the corresponding device. In the DOC service, dataset refreshing means overwriting the old data with newer describing the actual state of the device. Refresh rate is set and adjusted independently for each device and typical values span from milliseconds to few seconds.

Similarly, for the DAQ, key/value pairs are pushed to a node of the distributed KVDB to be stored on disks. In this case the *key* contains encoded both the unique dataset indicator and the timestamp. By querying the DAQ for all the datasets corresponding to a given timestamp the status of the accelerator at that particular time can be recovered.

The software opted for implementing the DOC and the KVDB are memcached[4] and mongodb[5] respectively. They demonstrated to offer the needed features and performances and are supported by a large and growing community of users. Nevertheless the abstraction of services provided by the !CHAOS components would allow their replacement, with other implementation of DOC and KVDB, without any modification of both its functionalities and API.

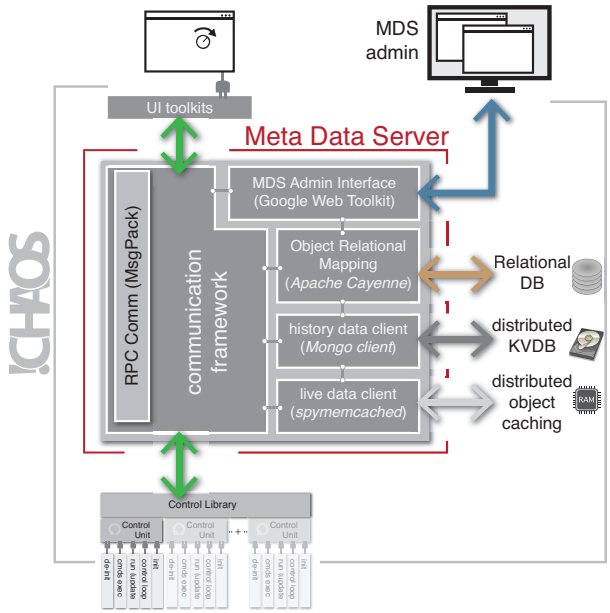

Figure 3: The !CHAOS meta-data server.

A key aspect in the !CHAOS development is the solution used to format data for both storing it, either into DOC or KVDB, and passing it between the different CS components.

Binary serialization is a convenient solution for flattening even complex data structure into a one-dimensional stream of bits suited for transmission through network. It is well suited especially for large binary arrays that are frequently included in datasets of accelerator's components.

What's more, both DOC and KVDB allows binary serialized data. In !CHAOS BSON[6] serialization is used for encoding dataset to be stored both in the *live data* DOC and in the DAQ . BSON serialization is also used by UI toolkit (see next section) for formatting commands sent to front-end Control Units and for passing parameters between CU and device management plug-ins.

Another fundamental component in the !CHAOS framework is the meta-data server (Fig.3). It is designed to store information such as CU configuration, commands list, commands and data semantic, naming service etc.

Object Relational Mapping (ORM) packages will be used to abstract the relational database, used for storing meta-data, by mapping its tables into Java object.

User Interface Toolkit

Client access to !CHAOS services will uniquely allowed through the API provided by the *User Interface toolkit*.

The set of API aiming to abstract and simplify the access of client applications to the !CHAOS service.

Fig.4 shows the logical structure of the UI toolkit layer with the blocks of API to client application and the substrate of API for the abstraction of the !CHAOS services.

In the figure is also introduced the concept of *UI data*

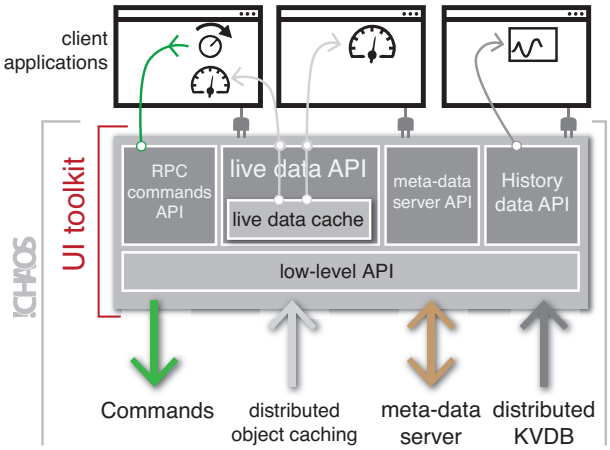

Figure 4: The User Interface toolkit components.

cache we are currently developing to achieve a further improvement of UI toolkit performance.

Practically it consist of a local cache of data and meta-data where UI toolkit APIs may store and share both frequently used meta-data, produced by queries to MDS, and live data read from distributed object cache. Similarly to distributed live data caching, we are considering a solution based on a key/value object caching to store locally this information. Caching of live data will take into account the refresh rate of the particular device dataset for setting its expiration time.

While most of the !CHAOS code is written in C, C++ and Java, development of both client applications and device management plug-ins should include a larger selection of programming languages.

Since at INFN LNF and Roma TV there is a long tradition in developing control and data acquisition systems with National Instruments LabVIEW we already started remodeling of existing front-end software to adapt it to !CHAOS DMP requirements.

On the client side, UI toolkit will provide APIs for most common measurement and analysis software like Matlab and the before mentioned LabVIEW.

CONCLUSION

!CHAOS is a scalable control system infrastructure providing all the services needed for communication, data archiving, timing, etc. in a control system for a particle accelerator or any other large apparatus. Front-end controllers and GUI applications can be seen as plug-ins that access and expand its functionalities.

The innovative communication framework is based on a distributed object caching service while continuous archiving of data is implemented by means of a non-relational distributed key/value database.

The use of the before mentioned software technologies introduces a new paradigm of control system in which the two layers representing the front-end and the client level are complemented by a third intermediate level collecting and distributing the the data produced by the lower front-end controllers.

The control groups at INFN-LNF and INFN-Roma Tor Vergata are committed to finalizing the development of this conceptual design, validating its functionalities and performance, and candidate !CHAOS as the control system for future INFN particle accelerators.

INTEGRATING A WORKFLOW ENGINE WITHIN A COMMERCIAL SCADA TO BUILD END USERS APPLICATIONS IN A SCIENTIFIC ENVIRONMENT

M. Ounsy, S. Pierre-Joseph Zephir, K. Saintin, G. Abeille, Synchrotron Soleil, Gif sur Yvette, France
E. de Ley, Isencia, Gand, Belgium.

Abstract

To build integrated high-level applications, SOLEIL is using an original component-oriented approach based on GlobalSCREEN, an industrial Java SCADA [1]. The aim of this integrated development environment is to give SOLEIL's scientific and technical staff a way to develop GUI applications for external users of beamlines. These GUI applications must address the two following needs: monitoring and supervision of a control system and development and execution of automated processes (as beamline alignment, data collection and on-line data analysis).

The first need is now completely answered through a rich set of Java graphical components based on the COMETE [2] library and providing a high level of service for data logging, scanning and so on. To reach the same quality of service for process automation, a big effort has been made for more seamless integration of PASSERELLE [3], a workflow engine with dedicated user-friendly interfaces for end users, packaged as JavaBeans in GlobalSCREEN components library.

Starting with brief descriptions of software architecture of the PASSERELLE and GlobalSCREEN environments, we will then present the overall system integration design as well as the current status of deployment on SOLEIL beamlines.

INTRODUCTION

GlobalSCREEN is a SCADA supporting the JavaBeans technology. Java beans are reusable graphical unitary components often used in Java GUI software projects (Swing components). GlobalSCREEN provides a user-friendly GUI to implement Java applications by drag-dropping. It also proposes to integrate all developed reusable components in a shared library.

Passerelle is a toolkit provided by Isencia [4] for designing sequences (and more generally data workflows) in a "drag and drop" graphical environment. Its core functionalities are based on the Java technology standards.

To design/develop/program sequences, called models, ISencia provides a graphical IDE (Integrated Development Environment). The IDE offers an execution engine as well as a number of essential framework services.

To use Passerelle models in a non-development environment, another Passerelle execution environment is provided by a GUI (Graphical User Interface) called PasserelleHMI. This GUI is able to display a panel on top of any model, giving access to all its configurable parameters.

This GUI component was the principal tool for the scientific acquisition workflow integration within GlobalSCREEN. That solution was not enough flexible to provide GlobalCREEN application developers with the ability to devise synthetic views where component addressing control/supervision/monitoring can be inter-mixed with elementary Passerelle sequence parameter configurations. There was also the need, behind the scenes, for different sequences to be triggered depending on the different user interaction scenarios with the GlobalSCREEN application.

All these consideration motivated the modification of the overall system integration design.

THE INTEGRATION DESIGN

The basic idea of the system integration design is to use, for the Passerelle environment, the same philosophy used for Tango integration in GlobalSCREEN through the COMETE library and its use of the Tango client API.

Hence the library of graphical components named Passerelle Widgets have been extended to give access to all the Workflow engine features through the use of PasserelleAPI module.

In this new integration design we also took care of the possibility to launch the final end user applications locally or remotely taking benefit from the compatibility of GLOBALSCREEN is compatible with the Java Web Start technology. Java Web Start is a framework developed by Sun Microsystems that allows users to start application software for the Java Platform directly from the Internet using a web browser. This enables SOLEIL users to remotely access the same rich client platform applications they use locally, in daily operation.

To achieve this, all the API Interface libraries needed for client access to each of the services are available with two different implementations, one local and one remote.

For the remote implementation:

- COMETE was adapted to access the control system via an intermediate layer. This layer translates Tango requests to the TangORB API in the local case or to HTTP requests reaching a WebTangORB server for remote access. The WebTangORB server then translates these requests to TangORB API calls to the underlying control system.
- The PasserelleAPI Interface is implemented as HTTP requests addressing a remote server complying with the W3C Webservice standard for

software systems designed to support interoperable machine-to-machine interaction over a network.

APPLICATION EXAMPLE

We will here describe how the use of this new design of Passerelle Workflow engine integration within GlobalSCREEN helped the ANTARES beamline at SOLEIL to provide their users with an integrated graphical user interface with all the needed features to handle their acquisition process.

This beamline (see Fig. 1) was designated for the complete determination of the electronic structure of condensed matter, using the angle resolved photoemission spectroscopy and the photoelectron diffraction (PED), which allows a local characterization of the geometric structure.

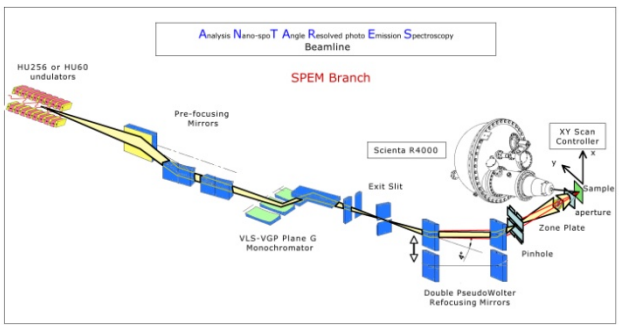

Figure 1: Beamline design.

As shown in the GlobalSCREEN Welcome page (see Fig. 2), the user can access to all the steps needed to drive his experiment: beamline control and supervision, alignment, homing of optical devices, running experiments.

Figure 3 displays the view giving access to all the entry points to all the optics alignments needed before starting the acquisition.

Figure 2: Application welcome page.

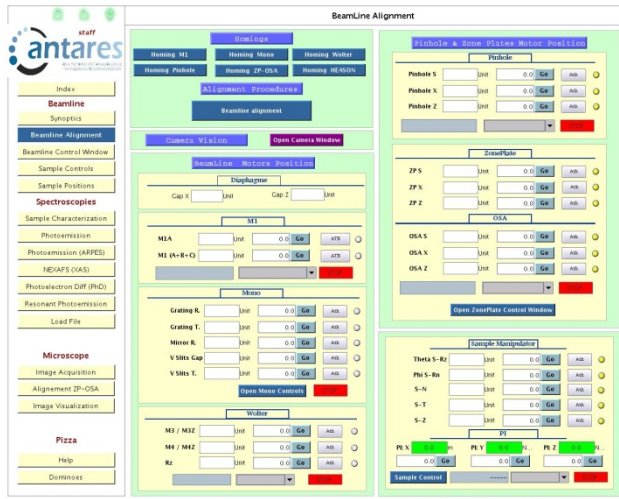

Figure 3: Alignment workflows.

In the Figure 4 below we can see the panel that pops up when we launch the monochromator homing button.

All the buttons entitled “Grating and Mirror”, “Vertical Slits”, “Horizontal Slits” are in fact unitary elementary Passerelle Widgets connected to predefined workflows that can fire Passerelle sequences to be started, resumed or stopped.

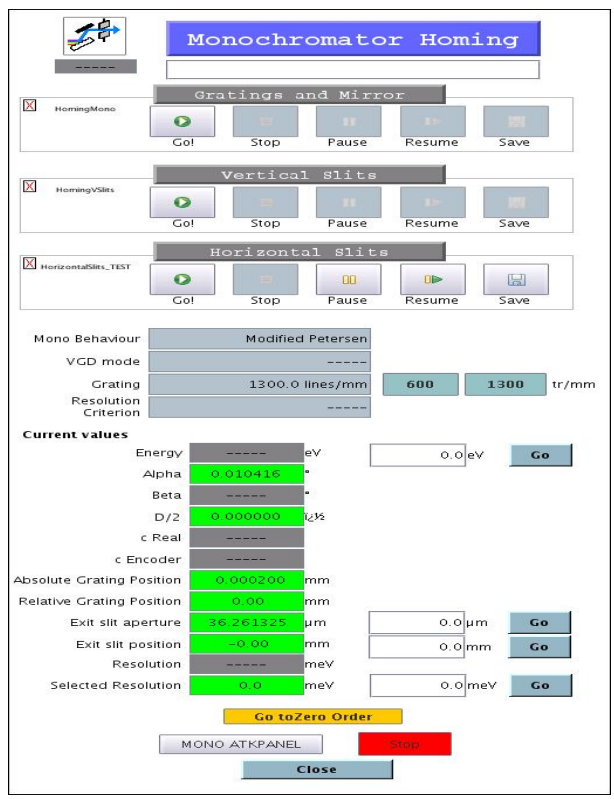

Figure 4: Monochromator alignment.

Figure 5 shows the GUI for performing a photoemission experiment using a Scienta detector. Here again, Passerelle Widgets for the acquisition workflow parameterization, sequence launching are seamlessly intermixed with Comete Widgets for equipments control and data acquisition monitoring (Scienta spectrum and image) giving the user total control of their experimental operation in the same application and hiding all the software layers operating behind the scenes.

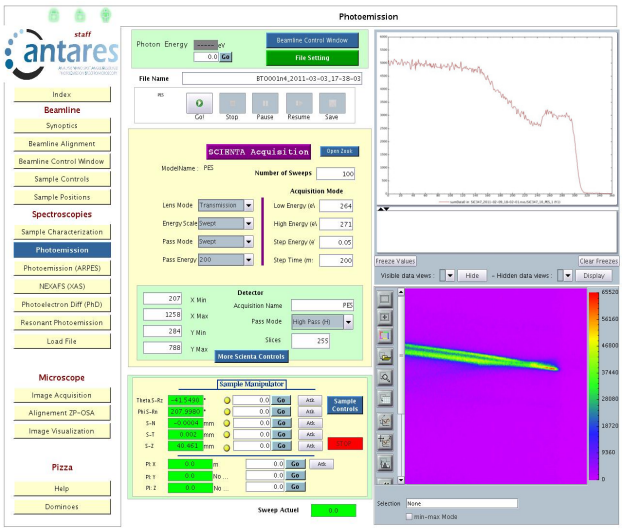

Figure 5: Scienta experiment view.

STATUS OF DEPLOYMENT

The figure below shows that using the Passerelle Workflow engine as a strategic tool for performing experimental acquisition processes in an integrated manner when combined with GlobalScreen is now becoming a reality at SOLEIL. Even if some beamlines are yet to be convinced of the benefit they can obtain from this way of operating beamline, the success obtained on doing it on many beamlines will facilitate this in a near future.

A GENERAL DEVICE DRIVER SIMULATOR TO HELP COMPARE REAL TIME CONTROL SYSTEMS

M.Mohan, European Gravitational Observatory, Cascina (Pisa) , Italy.

Abstract

***S**upervisory **C**ontrol **A**nd **D**ata **A**cquisition systems (**SCADA**) such as *Epics*, *Tango* and *Tine* usually provide small example device driver programs for testing or to help users get started, however they differ between systems making it hard to compare the SCADA. To address this, a small simulator driver was created which emulates signals and errors similar to those received from a hardware device. The simulator driver can return from one to four signals: a ramp signal, a large alarm ramp signal, an error signal and a timeout. The different signals or errors are selected using the associated software device number. The simulator driver performs similar functions to *Epic's* clockApp [1], *Tango's* TangoTest and the *Tine's* sinegenerator but the signals are independent of the SCADA. A command line application, an *Epics* server (IOC), a *Tango* device server, and a *Tine* server (FEC) were created and linked with the simulator driver. In each case the software device numbers were equated to a dummy device. Using the servers it was possible to compare how each SCADA behaved against the same repeatable signals. In addition to comparing and testing the SCADA the finished servers proved useful as templates for real hardware device drivers.

INTRODUCTION

The current vacuum system at EGO [2] is controlled by os9 crates and uses custom software. The software is used to monitor values such as temperature, pressure and displacement. This control system is now being updated for Advanced Virgo. The os9 crates will be replaced by PLCs and a new SCADA will replace the custom software. The SCADA chosen may also be used for other systems at EGO.

Integration of new devices into a SCADA requires the hardware be setup correctly and the protocol (such as modbus) be implemented correctly. Rather than setup a PLC and test different conditions a small library was written to simulate signals. The simulator library generates simple scalar signals and errors similar to those which could be generated by a PLC.

Epics, Tango and Tine SCADA

Epics, tango and tine SCADA were chosen for comparison as they are all stable mature systems which are actively supported and developed. They are all open source projects which run on multiple platforms. The preferred platform at EGO is linux and both epics and tango have been recently packaged for Debian linux using the aptitude [3] package manager which eases installation and updating.

Epics is the most popular and widely supported SCADA followed by tango and then tine. Larger support implies stability [4] and a larger supply of pre-written device servers whereas smaller projects tend to be more flexible and use more advanced techniques.

The architectures of the SCADA investigated are similar and a generalised SCADA view is illustrated in Figure 1. Information from devices such as PLCs D1, D2, D3, and D4 is packaged and put on "software bus" by a Device Server. Different tools under the control of an operator are used to monitor and control the devices. Simulator signals were used in place of signals from D1, D2, D3 and D4.

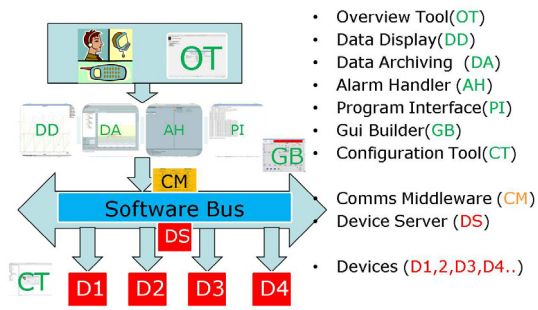

Figure 1: SCADA requirements.

SIMULATOR DEVICE SIGNALS

Four generated signals which are named according to the type of signal returned are shown in Table 1.

Table 1: Simulator Device Names

Device Number	Device Name
1	test/simulator/ramp
2	test/simulator/rampx2
3 (default)	test/simulator/error
4	test/simulator/timeout

The test signal is selected using the Device Number in the same way a modbus value is read using its modbus address. The signals are…

1. ramp: A ramp which rises from 0 to 59.999999 every minute.
2. rampx2: A large ramp which rises from 0 to 119.999998 every minute. Used to test alarms.

3. error: An error signal set at 60. Used to test how the SCADA reacts if the PLC returns a fault (-1).
4. timeout: A timeout signal. Used to emulate when there is no response from a PLC.

The signals are shown in figures 2, 3 and 4 using epics, tango and tine data displays.

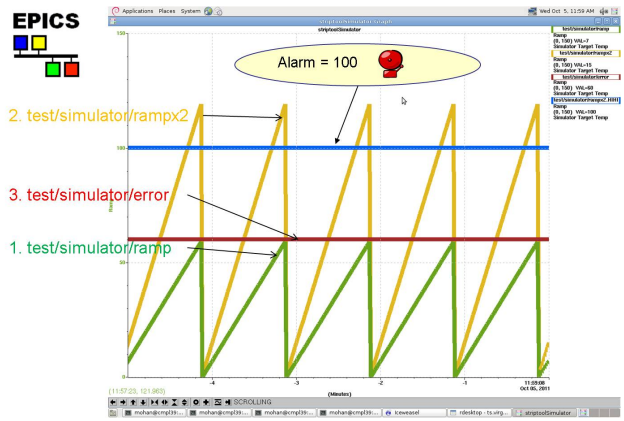

Figure 2: Simulator Signals using epics striptool.

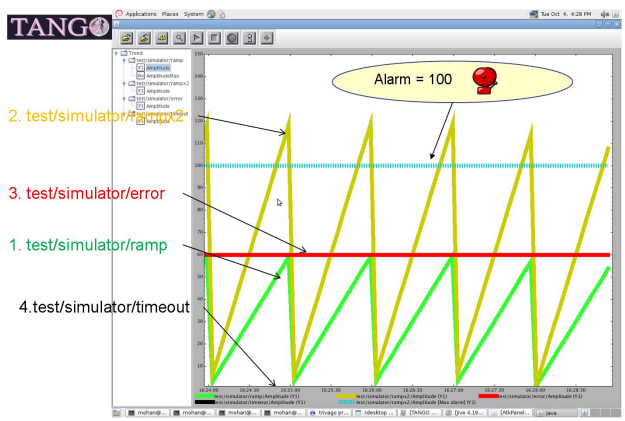

Figure 3: Simulator Signals using tango atkmoni.

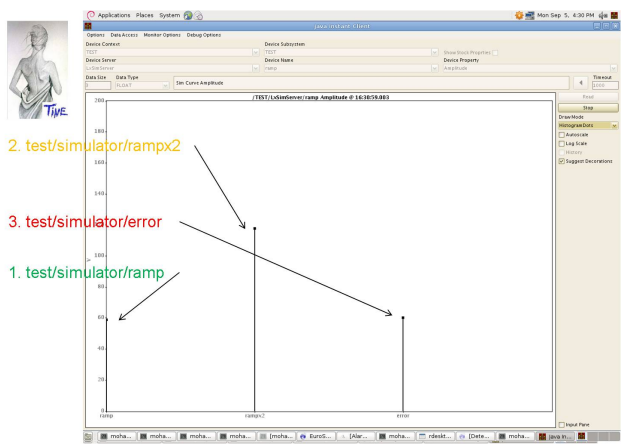

Figure 4: Simulator Signals using tine JClient. "Histogram view". There are several view types in Tine.

How Simulator Signals are Generated

A small c program was used to generate the four signals shown in Figure 2, 3 and 4. The function to generate the signals is shown in Figure 5.

```
…
int GetAmplitude(int DeviceNumber, double *Amplitude)
{
      struct timeval  tv; struct timezone tz;
      struct tm      *tm;
      gettimeofday(&tv, &tz); tm = localtime(&tv.tv_sec);

      // *Amplitude= Seconds time of system clock
      *Amplitude=((double)((1000000*tm-
>tm_sec)+tv.tv_usec)/1000000); //  0-59.999999

      int ErrorValue =0; // default 0=ok

      switch (DeviceNumber)
      {
            case 1: // 0-59.999999 = ramp
                  break;
            case 2: // 0-119.999998 = rampx2
                  *Amplitude=*Amplitude*2;
                  break;
            case 4: // =timeout
                  sleep(99999999);
                  break;
            default: // =error
                  *Amplitude=60;
                  ErrorValue=-1; //  -1 = Error
                  break;
      }
      return ErrorValue; // return 0 or -1
}
…
```

Figure 5: C function to generate Simulator signals.

A library called "libSimulator" was made using the code in Figure 5 and linked with SCADA device servers.

CREATING DEVICE SERVERS

What is a Device?

The concept of the device is at the heart of epics, tango and tine. A device can be considered a container of hardware data and an analogy for this is a shipping container because the devices all look the same although the contents are different. Like devices shipping containers also have unique names [3].

The "device container" in Figure 6 is labelled with static information such as the name of the device, units of measurement and alarm limits. The device is packaged by the device server which updates dynamic information in the device. When the device server is running the device is updated with dynamic content such as Amplitude, state and timestamp. This "device container" is then put on its

respective software bus (epics, tango or tine) where it is identified by its unique name.

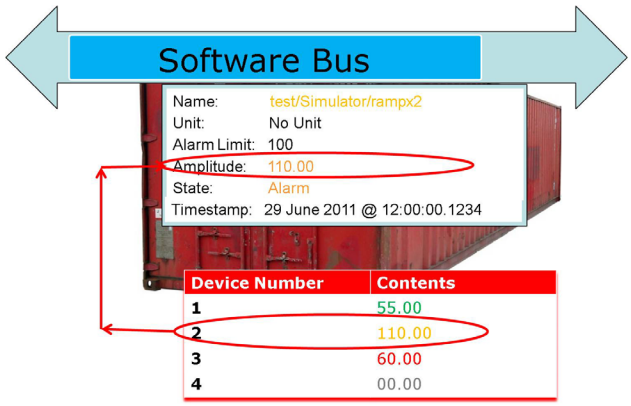

Figure 6: Example: Device test/simulator/rampx2 is updated periodically and results put on software bus.

Integrating Devices in Device Servers

The source code for the software device servers were generated using the template tools makeBaseApp, pogo and srvwizard which are supplied by epics, tango and tine respectively.

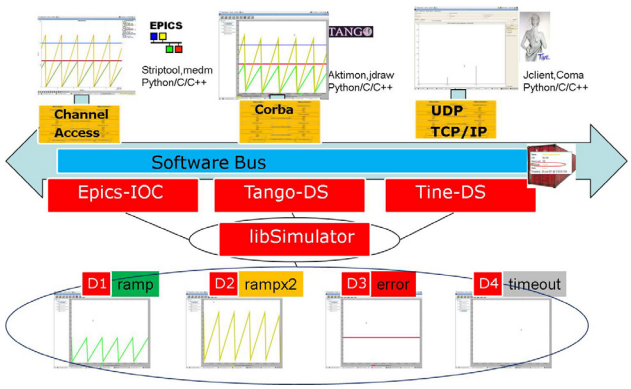

Figure 7: libSimulator test setup.

The device servers were linked to the libSimulator library Figure 7 and device signals generated by calling the function GetAmplitude Figure 5. The code added to device servers to read the devices is similar to the following.

C Command line

```
if(GetAmplitude(DeviceNumber,&Amplitude)==-1)
printf("Error\n");
```

Epics

```
if(GetAmplitude(DeviceNumber,&Amplitude)==-1)
recGblSetSevr(pai,STATE_ALARM,MAJOR_ALARM);
```

Tango

```
if(GetAmplitude(DeviceNumber,&Amplitude)==-1)
set_state(Tango::FAULT);
```

Tine

```
if(GetAmplitude(DeviceNumber,&Amplitude)==-1)
SetAlarm(SIMEQM_TAG,devnr,512,NULL);
```

The codes above read the Amplitude and sets an alarm if an ErrorValue (-1) is returned. This means the SCADA always set an error alarm for device 3 (test/simulator/error).

The default code generated for epics and tine hung on the timeout from device 4 (test/simulator/timeout) because the device server blocks waiting for a reply. Tango however by default sets an alarm state "timeout" and continued to read the other devices if no reply came within 3000 ms. There are several methods to overcome the timeout in epics and tine such as defining each device as thread or using epics async but this involves modifying the default generated code.

For real devices pre-written device servers can be downloaded from the SCADA websites and some hardware devices even come with inbuilt device servers such as the F3RP61 PLC from yokogawa ref [6] which includes an inbuilt epics IOC.

CONFIGURING DEVICES

SCADA configuration tools are used to input static information for devices such as names and alarm thresholds. For the simulator the Device number 1, 2, 3 or 4 must be associated with a unique device name. Epics naming is not compulsory and tango and tine use similar formats so it was possible to use the same Simulator signals names in all SCADA see Table1.

Epics

Configuration information for epics devices are stored in ASCII ".db" files and modified using a text editor. This device information is called a record. In the example in Figure 8 the field HIHI is used to set max alarm threshold to 100.

```
record(ai, "test/simulator/rampx2")
{
      field(DESC, "Signal ramp 0 to 119.999998 per
minute")
      field(INP,"2")
      field(HIHI, "100.0")
..
}
..
```

Figure 8: Epics configuration using .db file

Tango

Configuration information for tango devices are stored in a Mysql database and configured using the tango tool

jive. In the example in Figure 9 Max alarm for "test/simulator/rampx2" is set to 100 for the Amplitude attribute.

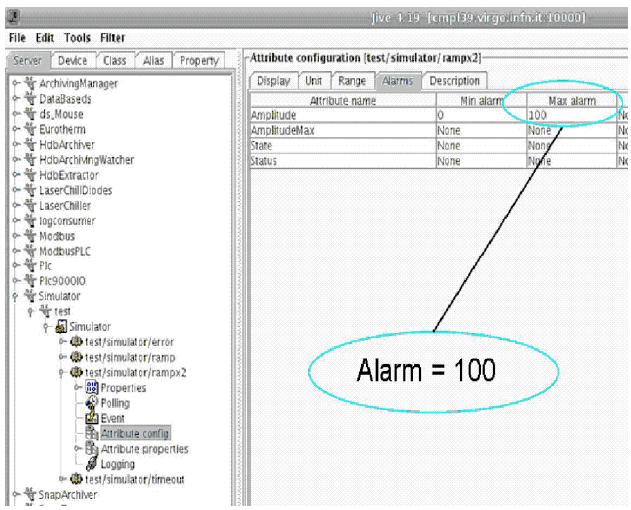

Figure 9: Tango configuration using jive.

Tine

Configuration information for tango devices are stored in a csv files and configured using spreadsheet tools or a text editor. Tine also provides the alternative options of storing configuration information in xml files or in the code.

In the example in Figure 10 High alarm for "test/simulator/rampx2" devices is set to 100.

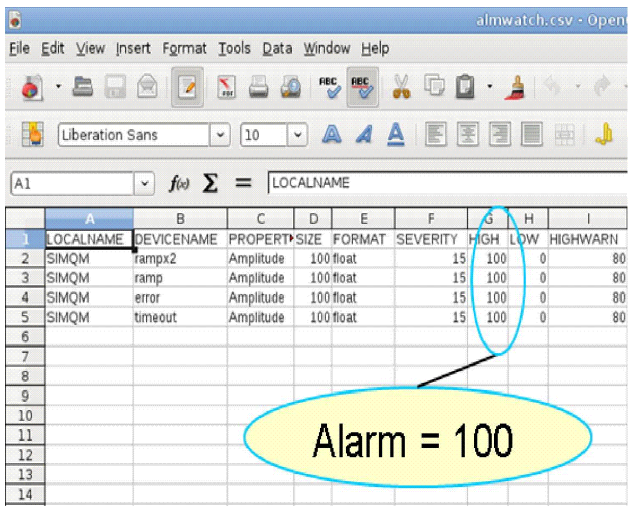

Figure 10: Tine configuration using an excel tool.

In the above configuration cases setting the alarm to 100 successfully caused the SCADA's Alarm handlers (or state handler for tango) to trigger a warning alarm when the property Amplitude exceeded 100 which happened for device rampx2 every 50 seconds.

SCADA TOOLS

After device information had been packaged and configured correctly they are put on the respective "software bus" and made available for the epics, tango or tine tools.

Some tools to view data online in epics, tango and tine are shown in figures 2, 3 and 4. These data display tools are called striptool, atkmoni and JClient respectively.

There are many other monitoring and control tools for epics, tango and tine which perform functions such as Data Display, Alarm Handling, Data Archiving and gui Building (Figure 1). The tools have many similarities and in fact the gui builder tool jddd [7] can be used to build guis for epics, tango and tine. In all cases a unique device name is used to identify the device. Additional tool comparisons can be found in reference [8].

CONCLUSION

Epics, tango and tine are all able to fulfil the requirements for the vacuum control at EGO and more. The learning curve for writing and configuring device servers is high but once mastered devices can be integrated quite quickly. There are many pre-written device servers available especially for the more popular SCADA. These pre-written device servers can be freely downloaded although they must still be configured and tested.

The Simulator is a simple aid to generate repeatable signals independently of the SCADA or hardware. It was useful for learning to write simple device servers for epics, tango and tine and for comparing SCADA tools using known signals.

All the SCADA provide useful tools for monitoring and controlling devices Figure 1. The tools are similar and some tools such as jddd [7] can even be used with all epics, tango and tine.

A UML PROFILE FOR CODE GENERATION OF COMPONENT BASED DISTRIBUTED SYSTEMS

G. Chiozzi, R. Karban, L. Andolfato, ESO, Garching Germany
A. Tejeda, Universidad Católica del Norte, Antofagasta, Chile

Abstract

A consistent and unambiguous implementation of code generation (model to text transformation) from UML must rely on a well defined UML profile, customizing UML for a particular application domain. Such a profile must have a solid foundation in a formally correct ontology, formalizing the concepts and their relations in the specific domain, in order to avoid a maze or set of wildly created stereotypes. The paper describes a generic profile for the code generation of component based distributed systems for control applications, the process to distil the ontology and define the profile, and the strategy followed to implement the code generator. The main steps that take place iteratively include: defining the terms and relations with an ontology, mapping the ontology to the appropriate UML meta-classes, testing the profile by creating modelling examples, and generating the code.

INTRODUCTION

In every phase of a new project, one recurring activity is the assessment of artefacts of previous projects for opportunities of re-use. This might include requirements, architectural principles, design and, eventually, code.

Unfortunately, it becomes often apparent that the documentation is poorly articulated or outdated. The knowledge acquired during implementation and commissioning is just reflected in the code and can be "rediscovered" only by reverse engineering.

The developed code is often tightly linked to a specific infrastructure, which might have become obsolete or cannot be adopted due to project constraints.

To overcome some of those deficiencies, platform dependent information needs to be segregated from the domain specific application, and yet it must be possible to keep the two parts aligned automatically.

This principle can be put into practice, using technology which has become recently mature and, robust, such as Model Driven Development [1].

We want to use this type of development at ESO for new projects and the upgrade of existing systems.

MODEL DRIVEN DEVELOPMENT

The availability of open standards like UML, MOF, CWM (www.omg.org/mda) and open tools, frameworks and transformation languages (www.eclipse.org/emf) is a sign that Model Driven Development technologies are becoming mature and widely adopted [2].

In this approach, the system to be developed is described using a precisely defined domain specific modelling language. The artefacts of the development activity (like documentation and code) are derived from the original model using model to model or model to text transformations. The process can consist of multiple layers, each of them moving from an abstract to a more concrete representation of the system or from domain specific to general purpose languages. At the end of the process, the actual application source code is generated.

Up to a certain level of detail, graphical notations are best suited for system modelling [3]. We have therefore adopted the Unified Modelling Language (UML - www.omg.org/uml) as the general purpose modelling language. By now, UML is accepted by engineers in several fields, also outside the software domain.

Moreover, there are tools available, supporting Model Driven Development based on UML, providing means to define modelling languages and model transformations starting from UML.

It is important to notice that this is a step forward with respect to *Model Based Development*, where models are used just in the early phases of a project and afterwards the code is written by hand. *Model Based Development* suffers from the non formal relation between model and code, which causes obsolescence of the models and misalignment with the code.

THE PROCESS

In order to be able to formally define and implement the Model Transformations that allow going from the model to the final code, it is necessary to have a non-ambiguous description of the specific domain concepts.

UML provides a powerful mechanism to express domain specific concepts: the *Profile*.

A *UML Profile* is a collection of definitions for *stereotypes*, *tags* and *constraints* that customize UML for a domain, redefining the semantics of the modelling language in an additive way. This means that, inside a model, different but compatible UML profiles can be used at the same time to specify different aspects of the system.

We decided to develop a UML Profile to capture the meta-model necessary to describe our typical architecture of a telescope and of its instrumentation.

We started with a comparative analysis of the requirements and architecture of projects developed in the last years. From this analysis a first version of the profile was produced.

Unfortunately, while building the profile we realized that there were very limited possibilities to verify automatically the correctness and un-ambiguity of our models with respect to the meta-model. As a matter of fact the only type of validation allowed is based on the definition and verification of UML constraints, which are still not properly supported by most UML tools.

A proper level of formality can be obtained by defining an *ontology* [4] for the domain, i.e. a formal description of the concepts and of their properties, features, attributes, restrictions and relations.

We created an ontology using UML class diagrams, starting from the ones we used to identify the profile elements (Figure 1). However, those concepts and their relations should be expressed in an *ontology description language* like OWL [4].

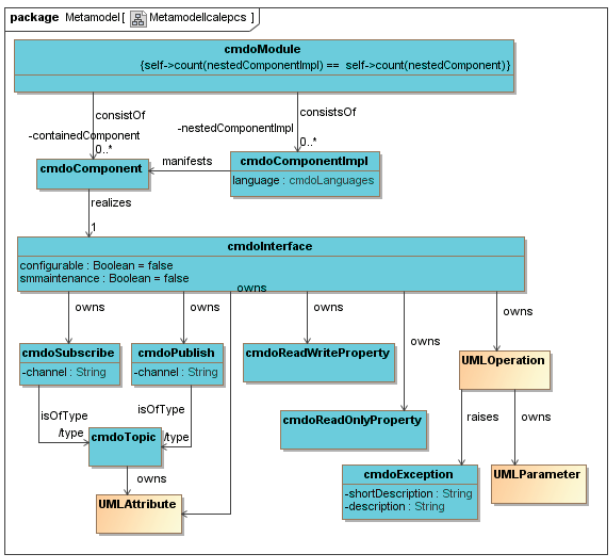

Figure 1: Snippet of the ontology as UML metamodel.

The resulting ontology is heavily affected by our experience and our specific focus, therefore groups with different background might create a different set of concepts to model the same domain.

Depending on the sophistication of the model transformations and of the tools used, we can get different approximations to the real final application.

We have adopted an iterative process consisting of the following steps:

- Analyze and compare parts of real systems we have implemented
- Describe in the *ontology* the common concepts
- Map the ontology to a profile
- Model the system with the new elements
- Implement the transformations
- Compare the generated code with the original code: it must be readable and reliable and it must be possible to add easily hand-crafted code
- Analyze what needs to be modelled and/or refactored at the next iteration

In this work we apply a few basic practical rules:

- An element of the ontology should be mapped in the profile only if it is worthwhile to model, i.e. if it takes less effort to transform the model representation with respect to an handcrafted implementation. The gain should consider parameters like one-to-many transformation scenario, copy&paste errors, or the number of times the element appears in our models.
- If a concept of the ontology applies to all model elements, it should be implemented via an external parameter passed to the transformation engine, while if it applies only to some model elements, it should be a stereotype or a tag.
- If a concept of the ontology applies only to some of the supported platforms, the transformation is ignored for the other platforms.

In the beginning we must expect to add code by hand for substantial parts of the application on top of a simple auto-generated skeleton, but an iterative process of extensions will add more and more automation.

The selection of the transformation language plays an important role in the definition of the profile, because some languages may provide better support for some profile element than others (for example, trading off between using stereotypes or tags favours stereotypes when using the Xpand language). We selected EMF and the Xpand tool set [5] because already used at ESO for some other projects. More details on the code generation process and its implementation are provided in [6].

THE COMODO UML PROFILE

In the overall system model, which includes the representation of hardware components and is typically defined using the System Modelling Language (SysML) profile, our new COMODO (COmponent MODelling for Observatory) profile allows to and model the parts used to generate the code of the real control system.

By keeping the abstract and Platform Independent information separated from the concrete Platform Specific information, we can generate application code for the same system on different platforms by simply replacing the model-to-model transformation for this last layer. A significant effort was spent in separating the Platform Independent Model (PIM) from the Platform Specific Model (PSM).

We will describe here below and in Table 1 some profile elements.

Distributed Components

Telescope control systems fit very well in an architecture based on Distributed Components, i.e. in an architecture where independent entities (called Components) communicate concurrently and asynchronously with each other.

In order to keep a clear distinction between PIM and PSM, we identified three entities in our meta-model:

- **Interface (cmdoInterface - PIM)**
- **Component (cmdoComponent - PIM)**
  In particular, state charts are used to specify behaviour. As described with more details in [6], state charts have been successfully applied at ESO for modelling reactive systems. An extensive usage as a core element of design, supported by code generation, simplifies the development.
- **Component Implementation (cmdoComponentImpl - PSM)**

Table 1: Basic Elements of the Comodo Profile

Name	Base Classifier	Documentation
cmdo Interface	UML Interface	Part of: PIM Public interface that the Component is exposing. Can include: • Operations provided (synchronous invocation paradigm) • Published and subscribed data structures (asynchronous communication paradigm) • Properties, to represent data attributes that can be read/set/monitored • Error handling and exceptions specification • Signals to be used as triggers for the state machine
cmdo Component	UML Class	Part of: PIM Platform independent representation of a Component as it is going to be implemented, realizing the corresponding Interface and optionally specifying the dynamic behavior with a state chart. A design including algorithms or private attributes/operations used in any implementation can be specified here.
cmdo ComponentImpl	UML Artifact	Part of: PSM The Component Implementation is a manifestation of the corresponding cmdoComponent. It represents the actual implementation for a specific platform. If we have multiple implementations for the Component, for example with different programming languages or for different infrastructures, we can model each of them independently without affecting the platform independent representation.
cmdo Topic	UML Signal	Part of: PIM A Topic is a type for (published or subscribed) attributes or parameters. Used as triggers by State Machine.
cmdo Publish	UML Property	Part of: PIM Used to specify whether an attribute in the interface whose type has stereotype cmdoTopic has to be published.
cmdo Subscribe	UML Property	Part of: PIM Used to specify whether an attribute in the interface whose type has stereotype cmdoTopic has to be subscribed.
cmdo Module	UML Package	Part of: PSM This is an organizational unit for specifications of components, interfaces, etc. It identifies a set of deliverables.
cmdo Machine	UML Node	Part of: PSM Machines represent the physical system were one or more containers can run. The deployment of containers is modeled as attributes of machines.
Cmdo Exception	UML Signal	Part of: PIM Exception are used to model errors returned by the interfaces.
Cmdo Container	UML Exe.Env	Part of: PSM Containers are the environments where one or more component implementations can run. The deployment of component implementations is modeled as attributes of containers.

Deployment

The deployment information for the system is part of the PSM, since the same architectural Components can be deployed in different ways depending on the platform.

Moreover, we can have different deployments for the same applications in different phases of the project or for different purposes (testing, commissioning or operation). Deployment is typically a separate responsibility from development and is done by different actors (*system configurators* with respect to *developers*). Our meta-model assumes that Components are deployed in Containers, according to the Component/Container paradigm used by many distributed infrastructures.

A Container provides to Components a set of services (like logging or Component location) that helps shielding the implementation of Components from the specific software infrastructure adopted. In the simplest case of the VLTSW infrastructure the Container is just implemented with a CCS Environment [7], while in the case of ACS a Container is a process that can dynamically load and host multiple Components [8].

E-ELT PROTOTYPE INSTRUMENT

As an example, we show here the model corresponding to a small instrument described in [9], which was developed as a prototype for the evaluation of software and electronics for E-ELT instrumentation (Figure 2).

In this model we define generic interfaces for Subsystems and Devices (Figure 3) which are specialized for a particular application. For example, from the Device we specialize Motors and from that Filter Wheels.

All Devices share a state machine specified in the Device Component platform independent definition.

The model includes the implementation specification for all these components in Java and a test deployment.

With the existing code generator, we can produce from this model a skeleton implementation of this system for the ACS platform, providing sufficient functionality to start-up the system and test interfaces and state machines.

The developer can immediately implement the behaviour code (such as state machine actions and activities) inside the skeletons. With the help of an application framework, a limited knowledge of the

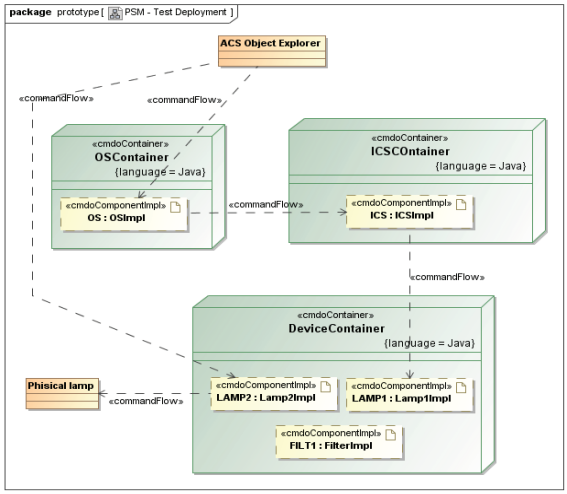

Figure 2: Partial deployment of the instrument.

specific platform is sufficient to complete the development, flattening considerably the learning curve.

In the case of changing platform, all of the PIM of the model would remain the same and probably (depending on the platform) also a big part of the PSM.

Definitions like the ones for Device or Motor are very generic and could therefore become part of the Profile itself or of a domain/project specific extension.

FUTURE DEVELOPMENT

Both, the ontology and the profile need to be extended to cover more domain (telescope and instrumentation) specific aspects of our systems. At the current stage, we have just a generic component/container distributed system model, but we have started to define an architecture framework for telescopes and instruments.

This will be specified through an ontology, with a proper ontology specification language, to allow formal checking.

On the code generation side, we are working on extending the support for ACS to the C++ language. This is also the first step to support the VLT platform, which is essentially based on C++.

CONCLUSIONS

This work is helping us significantly in reaching the objective of modelling our systems in a platform independent way, leaving big parts of the code production to code generators. In this way, the same model can be reused for different infrastructures and, therefore, for different projects and with a longer life span. At the same time, developers are shielded from the details of the specific platform.

This allows us to work now on the modelling of E-ELT TCS and instrumentation without knowing what infrastructure will be finally used, but testing our architecture on the ACS platform (or on the VLT once the transformations will have been implemented).

UNICOS CPC6: AUTOMATED CODE GENERATION FOR PROCESS CONTROL APPLICATIONS*

B. Fernández Adiego, E. Blanco Viñuela, I. Prieto Barreiro, CERN, Geneva, Switzerland

Abstract

The Continuous Process Control package (*CPC*) is one of the components of the CERN Unified Industrial Control System framework (*UNICOS*) [1]. As a part of this framework, UNICOS-CPC provides a well defined library of device types, a methodology and a set of tools to design and implement industrial control applications. The new CPC version uses the software factory UNICOS Application Builder (*UAB*) [2] to develop CPC applications. The CPC component is composed of several platform oriented plug-ins (PLCs and SCADA) describing the structure and the format of the generated code. It uses a resource package where both, the library of device types and the generated file syntax, are defined. The UAB core is the generic part of this software, it discovers and calls dynamically the different plug-ins and provides the required common services. In this paper the UNICOS CPC6 package is introduced. It is composed of several plug-ins: the Instance generator and the Logic generator for both, Siemens and Schneider PLCs, the SCADA generator (based on PVSS) and the CPC wizard as a dedicated plug-in created to provide the user a friendly GUI. A tool called UAB Bootstrap will manage the different UAB components, like CPC, and its dependencies with the resource packages. This tool guides the control system developer during the installation, update and execution of the UAB components.

INTRODUCTION

In this paper, we introduce the UAB CPC6 (*UNICOS Application Builder - Continuous Process Control*) component as a part of the UNICOS (*Unified Industrial Control System*) framework. UNICOS is a control system framework, developed at CERN (*European Organization for Nuclear Research*), designed to implement control system applications. This framework provides a methodology, an object library and a set of tools to generate the control code for these applications. A UNICOS component or package is a part of the UNICOS framework which uses the UNICOS methodology to create a specific type of applications, provides its own object library and uses the UNICOS generation tools to obtain the control code for these applications. Currently there are several UNICOS components, used for different accelerator systems, such as CPC, CIET (*Cryogenics Instrumentation Expert Tool*), QPS (*Quench Protection System*) and SURVEY (Control system for the magnets alignment) [3] (See Fig. 1).

The CPC component has been designed to develop industrial control system applications for continuous processes. It has been used for more than ten years in continuous processes like the LHC (*Large Hadron Collider*) cryogenics system, the gas systems of the LHC experiments, interlock system and lately cooling & ventilation and vacuum systems [4]. The CPC package creates applications focused in the two upper layers of a control system (Supervision and Control) and sets the communication between them automatically. To achieve this, the CPC objects Baselines have been developed at the SCADA (Supervisory Control And Data Acquisition) and the control levels. The control layer is PLC (Programmable Logic Controller) based, currently it has been developed for the Siemens S7 and Schneider platforms and for CoDeSys (Controller Development System) which makes it platform independent, while the SCADA layer has been developed for PVSS, nowadays called WinCC OA (WinCC Open Architecture).

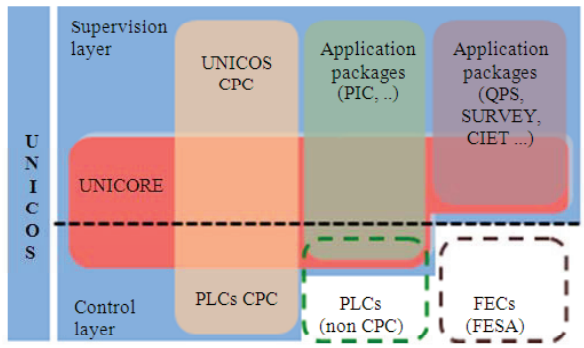

Figure 1: UNICOS Overview.

UNICOS CPC6

The UNICOS-CPC package presents three significant modifications from the previous version: the methodology, the objects and a new generation tool called UAB.

The UNICOS methodology has been improved providing a set of documents and some well-defined steps to develop CPC control applications. Following this methodology, the CPC user will be able to transform the process knowledge into a model based in a hierarchy of CPC objects (See Fig. 2), and implement the control system using that information. These objects have been improved

* Work partially funded by the Spanish Ministry of Science and Innovation

from the previous version, including new functionality and more flexibility for the users and operators [5].

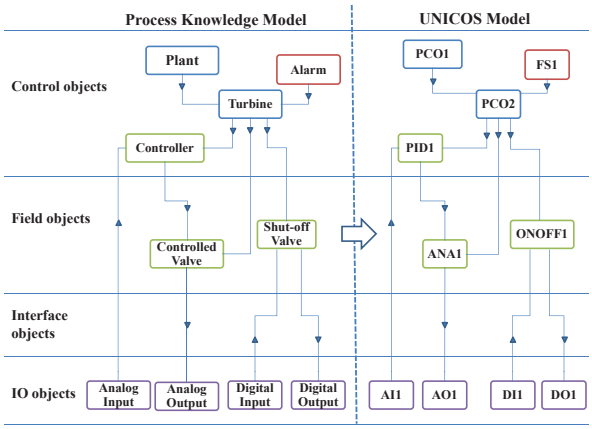

Figure 2: Example of CPC objects hierarchy.

This methodology contains the following steps: (See Fig. 3).

- Functional analysis: the process engineer transfers the process knowledge to the UNICOS Functional Analysis document.
- UNICOS Logic design: the process engineer and the control engineer work together to define the behavior of the process in the UNICOS language.
- Specification file filling: all the UNICOS objects are defined and parametrized using an Excel/XML file.
- Automatic generation: the instance and logic code for the PLC and the configuration file for WinCC OA are generated using the automatic generation tools.
- Logic completion: complete the automatic generation of the logic if necessary, following the UNICOS Logic design.
- Control code compilation.
- Application tests.
- Commissioning.
- Operation.

USING AUTOMATIC GENERATION TOOLS

The use of automatic generation tools allows development of control system applications with a high level of abstraction, decreasing the development, configuration and commissioning time and producing well-structured control code. For this new version, one of the most important requirements was to include a more flexible, extensible, consistent and user-friendly automatic generation tool. As result of these requirements the UAB has been developed. This tool generates the control code extracting information from the UNICOS objects definition and the process knowledge included in the specification file [2].

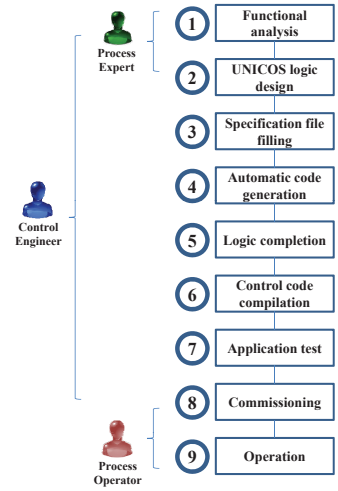

Figure 3: UNICOS-CPC6 methodology.

Architecture

The UAB architecture is composed of three main parts: the UAB core, the UAB plug-ins and the resource package (see Fig. 4). These three parts have different functionalities and life cycles.

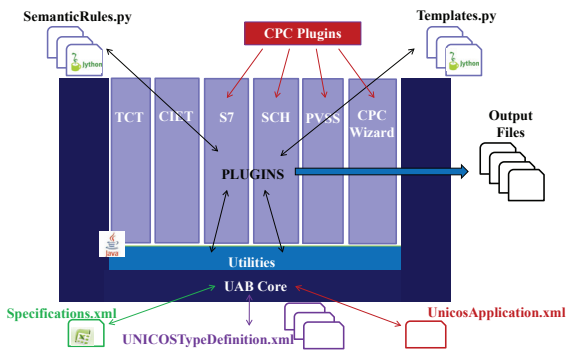

Figure 4: UAB Architecture.

The UAB has been developed in the Java language as well as other technologies like the Jython (Pyhton for Java) scripting language to define the syntax and the contents of the output files. The format for the configuration files is XML (*eXtended Markup Language*) and the technologies used to process these files are JAXB (*Java XML Binding*) and JXPATH (*XML Path Language for Java*). Apache Maven is the selected technology to build and manage the tool.

All the UNICOS objects, as the CPC objects, are defined as XML files (*DeviceTypeDefinitions*), where the

object structure is defined (Inputs, Outputs, Frond-End Parameters, SCADA Parameters, etc.). For this purpose, the so-called *UNICOS Metamodel* has been designed. This Metamodel is an XSD (*XML Schema Definition*) file used to describe and limit the contents of the DeviceTypeDefinitions [6].

UAB Core

The UAB core is the main and generic part of the tool. It is platform independent and provides the common services required by most of the plug-ins (for example User report, logging, etc.). It also has other functionalities, for example dynamically discovering the different plug-ins and asserting their validity, loading the UNICOS Project data information, connecting the plug-ins with the external files, etc.

UAB Plug-ins

A plug-in is the part of UAB where the structure and the format of the generated files are defined. It is platform dependent (i.e. Siemens, Schneider, etc.) and its main function is to generate these files.

Currently, the CPC package contains the following plug-ins:

- Siemens Instance Code Generator: it generates the instance and communication files in SCL (*Structured Control Language*) format and the symbols files containing the address mapping.
- Siemens Logic Code Generator: it generates the control logic files in SCL format.
- Schneider Instance Code Generator: it generates the instance and communication files in XML format.
- Schneider Logic Code Generator: it generates the logic files in XML format.
- WinCC OA Code Generator: it generates the configuration file for WinCC OA in TXT format
- CPC Wizard: it is a dedicated plug-in that provides a friendly GUI to drive the generation of CPC applications. It prompts the user for the mandatory data of the application, validates the user data and triggers the execution of the selected plug-ins with the specified parameters. The wizard's panels can be customized through an XML file and a set of predefined components (like text editors, radio buttons, etc.) (See Fig. 5).

These plug-ins use the services provided by the UAB core to perform the following tasks:

- Read the data from the input sources, like the UNICOS specification file or the DeviceTypeDefinitions.
- Process the semantic check rules to validate the input data.
- Execute the Jython scripts.
- Generate the output files.

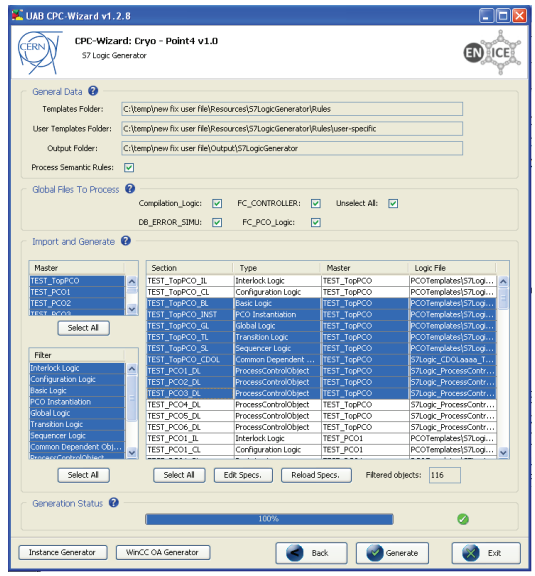

Figure 5: Wizard panel for the Siemens Logic generator.

The plug-ins are completely independent and it is possible to launch them through the wizard or one by one using the XML editor called FESA (*Front-End Software Architecture*) General editor from the FESA framework. Apart form the CPC plug-ins, more plug-ins have been developed in UAB. For example, for the CIET component the instance and WinCC OA configuration plug-ins have been created.

UAB Resources Package

The UAB resources package is the part of the tool where the CPC objects and the contents of the output files are defined, it also contains the semantic check rules used to validate the user inputs during the definition of the project. The CPC resources package contains the following list of elements:

- Generation Templates: these templates, written in Jython scripting language, define the syntax and the contents of the generated control code. There are five types of generation templates: the Siemens instance templates, the Siemens logic templates, the Schneider instance templates, the Schneider logic templates and the WinCC OA templates.
- DeviceTypeDefinitions: the XML files which contain the definition of the CPC objects.
- Baselines: the baseline is the definition of the CPC objects in PLC code and the additional common code necessary to make the application run. It uses the structure defined in the DeviceTypeDefinition and contains the behavior of the objects. Currently the CPC package provides the Siemens and Schneider Baselines and also the UnCPC package which represents the WinCC OA behavior of the CPC objects.
- Semantic Check rules: these are special kinds of

templates used to check the specification file.

- Input/Output Commissioning template: it's a special kind of template designed to generate a IOCommissioning file to help the process and control engineer during the commissioning of the system.

UNICOS MANAGEMENT

The special architecture of UAB, where the software is split in several packages with different life cycles requires an appropriate mechanism to manage the different software versions (for example, while the UAB Core will be very stable, the resource package is susceptible to be modified frequently, changes such as adding new devices, modifying existing devices or modifying the syntax of the output files). For this purpose, the UAB Bootstrap has been created. This tool, developed in Java, is used to manage the different UAB components and its resources packages. The main functionalities of this tool are:

- Upon first installation of UAB, it offers to download the last version of the available UAB components.
- Check for updates of the installed components and its compatible resource packages.
- Download/install new UAB components.
- Unique entry point to execute the UAB components installed.

The different pieces of software that compose UAB (core, plug-ins, resources) are packaged in different artifacts and deployed in a repository manager (Nexus). When the Bootstrap is executed, it queries the repository manager to discover new components, new versions of the installed components and new versions of the resource packages. When a new version is available on the server, it will notify the user and offer to download the new software.

To achieve this, the Bootstrap uses the *Nexus REST API* and the *Aether library*. The repository manager provides the REST API that can be used externally to query Nexus for available artifacts or test if any of the available artifacts has a version number higher than the installed ones. Aether is a general purpose library for interacting with artifact repositories. It provides functionalities to specify the repository locations, dependency resolution between artifacts and artifacts download.

Figure 6 shows the different steps to create an application for a CPC user. The UAB Bootstrap packs the selected CPC component version and the compatible CPC resources package from the Nexus server and installs the UAB software in a local machine. Thus the user will create a CPC application using the CPC wizard installed.

CONCLUSION

The UAB CPC6 component has been developed to add several improvements for developers and users (control system engineers).

The developer, using UAB, will obtain more flexibility and performance, allowing to add new CPC objects easily,

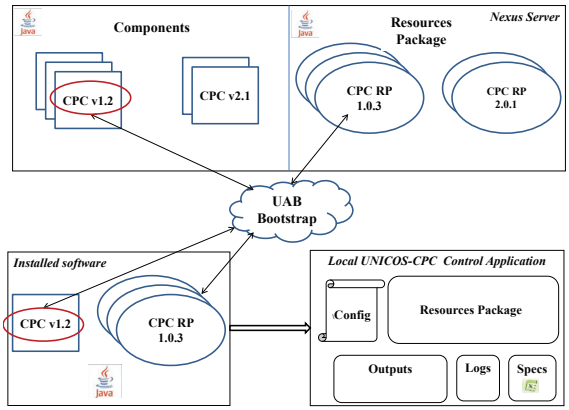

Figure 6: UAB Management.

new plug-ins for new platforms (for example the CIET plug-ins), templates or semantic check rules.

For the user, this new version offers a user-friendly graphic interface to develop CPC applications and a set of services like a powerful version management which guaranties the maintenance of these applications, logging, semantic check verifications, etc. The user can also add new objects, templates or check rules to the resources package.

EXPERIENCE IN USING BASED EMBEDDED CONTROLLERS WITH EPICS ENVIRONMENT FOR BEAM TRANSPORT IN SPES OFF-LINE TARGET PROTOTYPE

M.Montis, M.Giacchini, LNL INFN, Legnaro, Italy

Abstract

EPICS[1] was chosen as general framework to develop the control system of SPES facility under construction at LNL[2]. We report some experience in using some commercial devices based on Debian Linux to control the electrostatic deflectors installed on the beam line at the output of target chamber. We discuss this solution and compare it to other IOC implementations in use in the Target control system.

INTRODUCTION

SPES accelerator, under construction at the Legnaro National Laboratories (LNL), is on ISOL facility (Isotope Separation On-Line) dedicated to the production of radiactive ion beams with high energy and high degree of purity. In a structure like this one, the core of the project are the production target and the ionization ion system, which were carried out a study and design from scratch. This structure is currently in production for execution of experiments from the beginning of 2010.

Analyzing the characteristics required for inspection of this apparatus, it is possible to observe that:

- an heterogeneity of hardware and software solutions are required;
- we have to manage a distribuite control system;
- it is mandatory a real-time processing for every control variable, in order to ensure a robust system.

According to specific requests for software control, optimization of costs that derives from using an opensource software and favouring cooperation between laboratories, EPICS was chosen as control system software for the SPES facility.

The control network architecture created to manage the off-line target prototype is a multi-level structure composed by machines dedicated to network management and all EPICS hosts that implement the real control system environment. For managing all the devices used for the ion beam production, we decided to use PLC solutions in every sub-system in which safety is mandatory and it is necessary to implement fault-tolerant solutions, while particular embedded systems equipped with EPICS software manage all the devices dedicated to the ion beam manipulation (ion beam acceleration and ion beam focus)[3]. Appropriate solutions have been implemented for the integration of PLC subsystem within the EPICS environment, which it will explain in the next section.

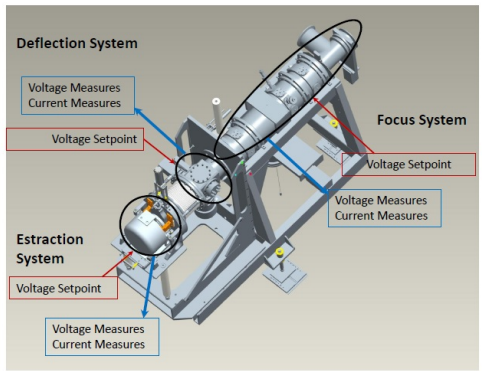

Figure 1: SPES Off-Line Target Prototype: systems and signals managed.

THE CONTROL SYSTEM

System Description

Managing the ion beam geometry, linearity and acceleration is made through the adjustment of the intensity of electrostatic fields generated by appropriate medium voltage power supplies (0-4kV) and high voltage power supplies (0-65kV). Controlling these power supplies it is possible to supervise the ion transport efficiency and optimize the emittance index. For this reason it is necessary to adopt appropriate control strategies to ensure a sufficient level of precision in the voltage settings, and security to all the devices managed.

We decided to base control algorithms on the following strategies:

- *voltage control*: initially we created a closed-loop system with PID regulators for controlling all the power supplies used in the deflection, focus and estraction systems. After this we changed the control strategy and we implemented a new control based in bisection algorithm because during the runs users had to usually change control parameters;
- *current monitoring*: the presence of any current could lead to the establishment of electrical discharges, resulting in the breakdown of components. For this reason we chose to implement a current monitoring strategy, with system shutting down when values exceeded a preset alarm threshold. Because of current values depends on power supplies work condition, we decided to define two different kind of thresholds:

  1. one current threshold for voltage's transitory;

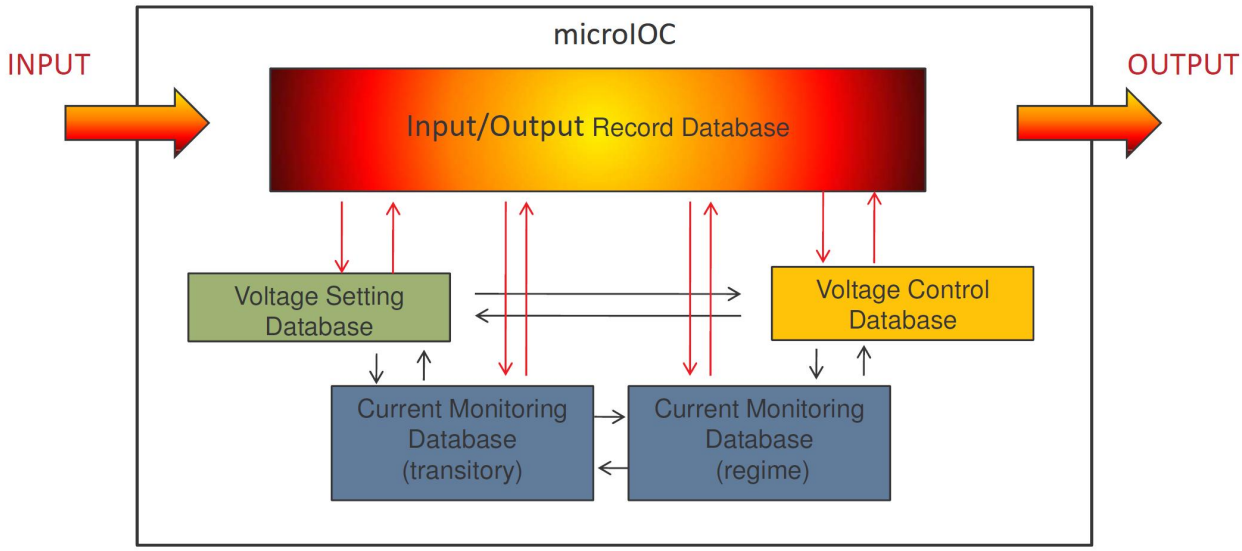

Figure 2: EPICS application developed: it is possible to see the connections between all the Record Istance Files defined and the signals form the field.

2. one current threshold when power supplies work in regime (costant voltage).

Appropriate EPICS Databases these strategy, and all the databases created for the power supplies remote control define the EPICS control system application used to manage the ion beam accelerator and focus systems for the SPES off-line target prototype.

Hardware Solution

While for the others sub-systems that constitute the SPES off-line target prototype we used computer general-purpose to control them, for the accelerator and optic sub-systems we decided to use particular embedded devices equipped with data acquisition cards and the software needed to define an EPICS Input/Output Controller (IOC).

The hardware chosen is an embedded computer (*microIOC*) based on the standard PC/104 and distributed by Cosylab, which allows for a robust and flexible remote control of devices connected to it, thanks to the absence of moving parts (such as hard drives and cooling fans) and a variety of communication interfaces available.

The Channel Access servers, used within the network for systems management of optical beam acceleration, are microIOC with the following characteristics:

- VGA connection;
- two ethernet connections, one in DHCP and one with static IP;
- two USB connestions;
- one RS232 connection;
- one AD I/O board (ADIO 104-AIO12-8) used for data acquisition and signal processing. It is possible to manage:
  - 16 digital input;
  - 16 digital output;
  - 24 analog input (12bit resolution);
  - 12 analog output (12bit resolution).

  Using this kind of boards we can control all the signals desired making an error of $\pm 1V$ for the medium voltage power supplies and $\pm 15V$ for the high voltage power supplies. While in the first case the error is acceptable, for the high voltage power supplies it is mandatory to decrease this value. One possibility suggested is to replace the ADIO board with another board having at least 16bit resolution for the analog input/output.

The operating system (a Debian based GNU/Linux custom distribution) and the EPICS software are stored in a Flash Card memory card. The EPICS environment is configured to initialize an IOC application at boot time. In this way the microIOC, when connected to the network, automatically creates the Channel Access Servers without further configuration by the user. The ADIO board uses a special *EPICS Driver Support* to interact with the control system environment and manage all the digital and analog signals.

During studies made and through the EPICS Community, we analized that the most used way to interface PLC systems with the EPICS environment is using particular hardware called OPC-Servers, that define a layer where the PLC signals are mapped in EPICS Process Variables. To optimize costs and minimize hardware complexity, we decided to implement it with a differet communication interface using the ADIO cards provided by microIOC.

For monitoring the embedded systems and the EPICS environment, we used an appropriate machine equipped with Nagios[4] software; in this way it is possible to control both the hardware and the software status.

Software Solution and Application Developed

During code development we tried to find a database structure which would allow to minimaze the number of Process Variables we have to manage and simplify the software maintenance. In this way it is possible to have a synthetic and readable code for anyone who have to monitor the SPES control system infrastructure. Following the project directives, the control strategy adopted and studies made with other EPICS applications we decided to develop a program structured in five different *Record Instance file*. Analizing Figure 2 shows:

- one Database, using the EPICS Driver Support, defines the interface between the EPICS envoronment and the AD I/O board mounted on the microIOC. This Record Istance File allows to manage all the inputs coming from the field and the outputs used to control the devices desired, such as indicated in Figure 3;
- one Database manages the Records used into the Graphical User Interface for setting all the power supplies's control parameters;
- one Database monitors the currents provided by the power supplies when they work on regime;
- one Database monitors power supplies's currents during voltage transitories;
- one Database realizes the voltage control strategy (PID regulator and bisection algorithm).

Realizing a modular structure for the software allows us to modify it in funcion of the experiment's requests (concerning the control strategies) and the technical requests (for example hardware maintenance) without changing the entire application: for example we modified the control strategy switching between two different databases (as rappresented in Figure 4) keeping unaltered all the other record istance files, except for fews links used to forward the process chain.

From an informatic point of view, Databases are built up with couples of template/substituion files: throught this EPICS environment feature, it is possible to modify all the Process Variables desired (number, type, attributes) and the

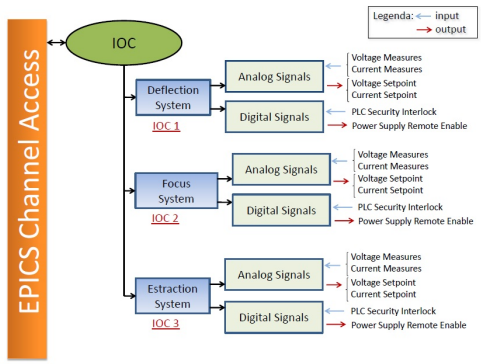

Figure 3: EPICS Control System Structure.

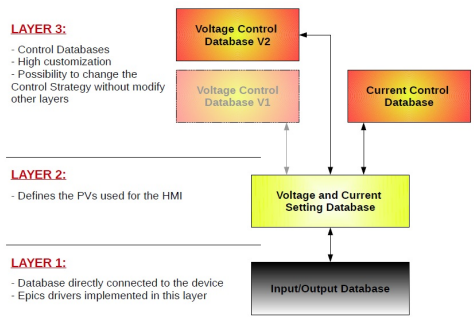

Figure 4: EPICS Application Database - Layers.

database architecture in a fast way editing a little set of text files; at the same time, if someone prefers use graphical editors (such as *VisualDCT*) to edit template files, the database structure will result easier to read and modify, because all the Records needed by the appllication will be instanced only at the IOC boot time. In this way both the debug phase and the maintenance are simplified; in particular this second feature is really important in a project like SPES, where all the works are developed and managed by different people.

For defining Process Variable names, we created a special Naming Convention that provides a descriptive name for every Record and, through it, every user can easy find and modify all the control parameters desired. This Naming Convention will be adopted for the entire facility's control system.

For every EPICS application developed, we created a specific Graphical User Interface (GUI) with Medm, an EPICS tool that provides an complete editor for creating and managing GUIs; an example of Medm GUI is visible in Figure 5. These interfaces are only used by software developers for managing the EPICS control system software, while specific GUIs developed in CSS are used by general users to supervise the SPES off-line target prototype and, in the future, all the SPES facility.

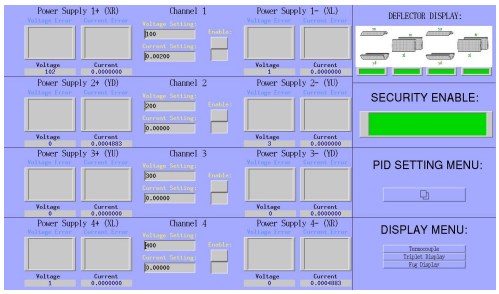

Figure 5: EPICS GUI developed for system maintenance.

CONCLUSION

Particular hardware and software solutions are adopted to design and develop the ion beam accelerator and focus systems in SPES off-line target prototype. On the hardware side, we decided to use specific embedded devices based on the PC/104 standard equipped with all the EPICS tools needed to connect them into the off-line target prototype's control system. During this production period we observed that this hardware solution guatantees good performances. This hardaware allows to create a trasparent layer between PLC systems and EPICS software too, minimizing possible incompatibilities between these two environments.

On the software side, the EPICS application structure adopted permits an easy management by users and a easy reuse of most of the code wrote for others applications and experiments, allowing a minimization of setting times. In general a modular approach for developping EPICS applications is desirable, especially in large and distribuited environment like the SPES facility.

SPIRAL2 CONTROL COMMAND: A STANDARDIZED INTERFACE BETWEEN HIGH LEVEL APPLICATIONS AND EPICS IOCS

C. Haquin, P. Gillette, E. Lemaître, L. Philippe, D. Touchard, Ganil, Caen, France
F. Gougnaud, Y. Lussignol, CEA/DSM/IRFU, Saclay, France.

Abstract

The SPIRAL2 linear accelerator [1] will produce entirely new particle beams enabling exploration of the boundaries of matter. Coupled with the existing GANIL machine this new facility will produce light and heavy exotic nuclei at extremely high intensities. The field deployment of the Control System relies on Linux PCs and servers, VME VxWorks crates and Siemens PLCs; equipment will be addressed either directly or using a Modbus/TCP field bus network. Several laboratories are involved in the software development of the control system. In order to improve efficiency of the collaboration, a special care is taken to the software organization. During the development phase, in a context of tough budget and time constraint, this really makes sense, but also for the exploitation of the new machine, it helps us to design a control system that will require as little effort as possible for maintenance and evolution. The major concepts of this organization are the choice of EPICS, the definition of an EPICS directory tree specific to SPIRAL2, called "topSP2", this is our reference work area for development, integration and exploitation, and the use of version control system (SVN) to store and share our developments independently of the multi-site dimension of the project. The next concept is the definition of a "standardized interface" between high level applications programmed in Java and EPICS databases running in IOCs. This paper relates the rational and objectives of this interface and also its development cycle from specification using UML diagrams to test on the actual equipment.

INTRODUCTION

The Spiral2 Control System is designed with a typical EPICS architecture, relying on OPI Clients and IOC servers communicating using Channel Access (CA) protocol.

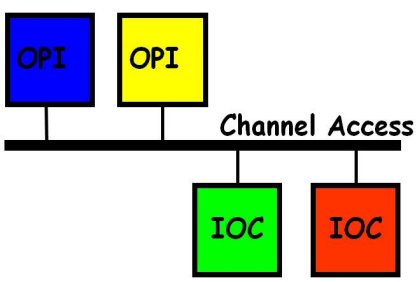

Figure 1: Spiral2 Control System Architecture.

The CA protocol allows OPI to read, write and monitor variables called Process Variables (PV) located in IOC. The CA protocol enable any OPI to access any PV as soon as it knows the PV name, there's no need to know which IOC hosts the PV.

OPI issues CA requests to IOC, which eventually interact with equipment to perform the actual read or write operation. This is the mean by which, over CA, functions are provided to OPI to fulfil its control tasks.

Hence, OPI need to know the names of the PV that correspond to its purposes. This can quickly become a big mess on OPI side since there are many type equipment to be driven and each developer could to adopt its own philosophy on both OPI and IOC sides.

It then appeared obvious that design should be optimized in order to reduce the development effort, but also in the machine exploitation perspective, to be able to face the evolution and maintenance requirements with a small team. Consequently, the decision was made to homogenize the way OPI control the various equipments through PV.

So, starting from the fact that PV names are almost completely determined by the naming convention, which take into account the localisation and the type of equipment [2], and the observation that equipment driving is always achieved through same kind of functions, we started to glimpse the standard interface concept in the sense that the naming convention should be pushed one step further in order to codify the remaining part of the PV name in correlation with the expected function.

This paper explains how the Standard Interface specifies the naming of the PV through which functions are provided to OPI, how it has been implemented on EPICS Data Base side (DB) and the first feedback is presented and next steps are envisaged.

SPECIFICATION OF THE STANDARD INTERFACE

Presentation

- Takes place in CA communication between OPI and IOC.
- Takes advantage of the fact that all equipment are drivable by the same kind of functions.
- Relies on a set of interface PV through which IOC provide the functions needed by OPI.

Goals

- Reduce development effort
- Reduce maintenance effort
- Ease component reuse

Functionalities

We noticed that on OPI side, independently from the equipment type, the following functions are always required:

- Write Consigns
- Write Commands
- Read Back Consign
- Read Measurements
- Read States
- Read Defects

PV Rules

Since functionalities are provided through PV, the name is related to the expected function. The rules are such that OPI can simply deduce the name of the needed PV from the needed functionality.

In the following, "$(CODIF)" refer to the first part of the PV name determined by the project naming convention, "PType" refer to the type of parameter to control (example I for current, V voltage).

Rules for consign related PV

Consign handling consist in write, read back, read actual value operations, each operation being handled by a record.

Table 1: PV Naming Rules for Consign Handling

Operation	PV Name
Write	$(CODIF):*PType*Cons
ReadBack	$(CODIF):*PType*ConsLect
ReadActual	$(CODIF):*PType*Act

In addition, filling of operator display fields is mandatory. In case of *PType*Act PV, alarm fields related to limit and severity are also mandatory.

Rules for measurements related PV

Measurement handling consists only in read actual value operation.

Table 2: PV Naming Rule for Measurement Handling

Operation	PV Name
ReadActual	$(CODIF):*PType*Meas

In addition, filling of operator display fields and alarm fields related to limit and severity is mandatory.

Rules for Commands PV

Commands are orders issued used for example to reset an equipment or to put it "on/off", "in/out" … It basically consists in a write operation, but it is also convenient for OPI to retrieve the list of possible commands, this is achieved with a mbbo record in which possible commands correspond to its ENUM strings. The whole command list can then be retrieved with a caget –d 31 *PVName* and a command can be issued by writing one of the string in the same PV.

Table 3: PV Naming Rule for Command Handling

Operation	PV Name
ReadActual	$(CODIF):Cmd

Rules for status related PV

Status handling consists in read operations related to the states and defects of the system. State and defect words must be analyzed bit per bit, each bit being associated with a string giving its signification. To avoid repetition of the same analysis on OPI side, this analysis is performed on IOC side. The result is provided through the standard interface with a record developed for this purpose. The record is in charge of words analysis and hosts all standard interface compliant PV.

Table 4: PV Hosted by Status Record

Operation	PV Name
Read	$(CODIF):Status.STATE_WORD
Read	$(CODIF):Status.STATE_ON_LIST
Read	$(CODIF):Status.STATE_OFF_LIST
Read	$(CODIF):Status.STATE
Read	$(CODIF):Status.DEFECT_WORD
Read	$(CODIF):Status.DEFECT_LIST
Read	$(CODIF):Status.DEFECT

In the previous table, the xxx_WORD PV contain a word to analyse, xxx_LIST contain a list of strings describing each bit of a word. The STATE PV contains the result of the analysis of the STATE word, when an OFF bit ('0') is found, its corresponding OFF string is copied from the STATE_OFF_LIST, when an ON bit ('1') is found, the string is copied from the STATE_OFF_LIST. The DEFECT PV contains the result of the analysis of the DEFECT word, only ON bits are treated, when an ON bit ('1') is found, its corresponding ON string is copied from the DEFECT_LIST. Each xxx_LIST PV can be retrieved with a caget –d 31 *PVName*

IMPLEMENTATION

This section explains how the standard interface is integrated in EPICS DB.

Consign and Measurements

A read interface PV is handled by an ai or longin record and a written interface PV is handled by an ao or longout record.

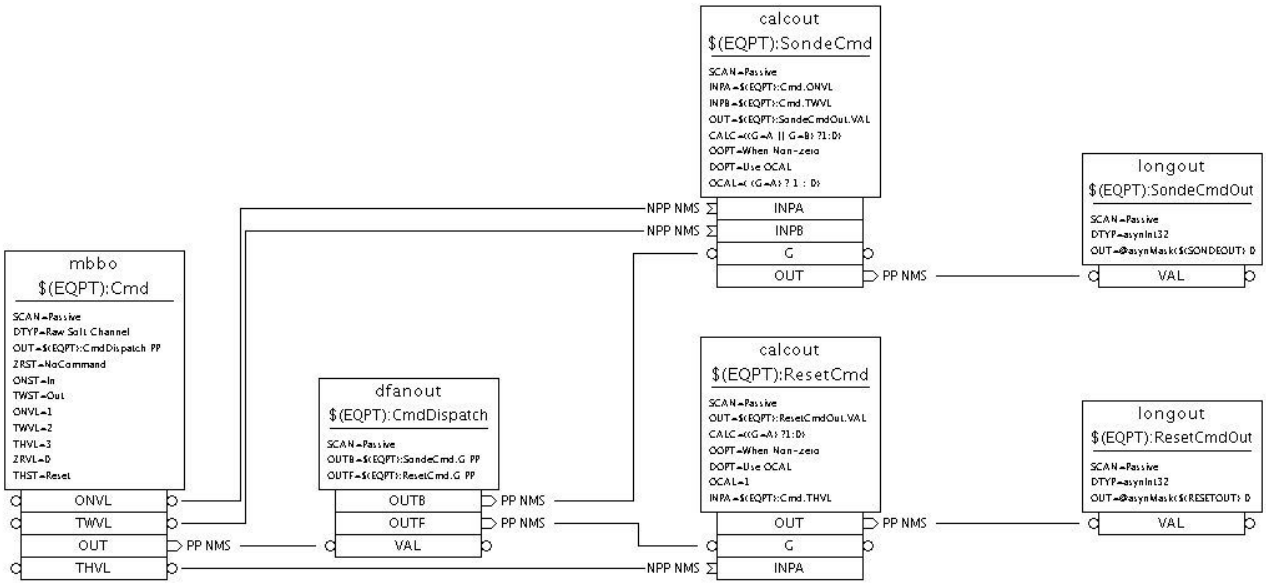

Figure 2: Example of commands handling implementation for an equipment having three commands: "in/out", to be written in the same register and "reset" being written in its own register. When a command is received by the mbbo record, it is transmitted to a dfanout record which dispatches it to two calcout records. The SondeCmd calcout record checks that the command is "in" or "out" if yes the command is actually written via the corresponding longout record, The ResetCmd calcout record checks that the command is "reset" if yes the command is actually written via the corresponding longout record.

Commands

The command interface PV is hosted by a mbbo record, the strings for each individual command are filled in the ZRST, ONST … fields. However, the mbbo record doesn't perform the write operation, this is done by longout record, there are one longout record per command register, depending on the driven equipment. In addition, the path between mbbo record and longout record(s) is secured by calcout record(s) in charge of actually activating or not the longout record(s) and ensuring the validity of what is actually written.

States and Defects

The Status record is in charge of internal state and defect words analysis and interface PV update. The Status record is basically a genSub record in which output fields were renamed and configured in order to comply with the standard interface. The challenging part was to manage each equipment type with its own set of strings through the common to all interface PV. The retained solution consists in defining a version of the Status record specific to each type of equipment, this is simply achieved by creating a copy of the record support structure renamed according to the new equipment and by providing a ".dbd" file in which the equipment strings are defined, in this manner the link between an equipment type and its set of strings is automatically established. Though there are several version of the Status record, they all share the same source code.

At processing time, the record fetches internal state and defect words by dedicated inputs and trigs the processing for each word, if the value has changed. The word analysis process is the same for both state and defect words, a parameter specifying the expected behaviour: "ON" and "OFF" bit values analysis or just "ON" bit value analysis. Strings specified in the ".dbd", basically available in VDCT menus are retrieved with the staticLib functions, and made available to the word analysis process to build the STATUS and DEFECT strings array.

CONCLUSION

We just ended the definition and development of the Standard Interface, so its deployments is still limited to power supply, profiler and faraday cups and the Status Record is not integrated yet. But we used it when setting up and running the control system for deutons source test at Saclay, in a "debug" context it turns out to be really efficient since with the naming convention and the command through mbbo record, driving equipment with simple CA directives in a terminal is a child's play, we can foresee it will ease OPI development. The next step is to integrate the Status record in the power supply, profiler and RF equipments [3]. And soon as possible, all EPICS modules will be made Standard Interface compliant.

COMMERCIAL FPGA BASED MULTIPURPOSE CONTROLLER: IMPLEMENTATION PERSPECTIVE*

I. Arredondo, M. del Campo, P. Echevarria, D. Belver,
L. Muguira, N. Garmendia, H. Hassanzadegan, M. Eguiraun, ESS-Bilbao, Spain
J. Jugo, V. Etxebarria, University of the Basque Country, Leioa, Spain

Abstract

This work presents a fast acquisition multipurpose controller, focussing on its EPICS integration and on its XML based configuration. This controller is based on a Lyrtech VHS-ADC board which encloses an FPGA, connected to a Host PC. This Host acts as local controller and implements an IOC integrating the device in an EPICS network. These tasks have been performed using Java as the main tool to program the PC to make the device fit the desired application. All the process includes the use of different technologies: JNA to handle C functions i.e. FPGA API, JavaIOC to integrate EPICS and XML w3c DOM classes to easily configure the particular application. In order to manage the functions, Java specific tools have been developed: Methods to manage the FPGA (read/write registers, acquire data, ...), methods to create and use the EPICS server (put, get, monitor, ...), mathematical methods to process the data (numeric format conversions, ...) and methods to create/initialize the application structure by means of an XML file (parse elements, build the DOM and the specific application structure). This XML file has some common nodes and tags for all the applications: FPGA registers specifications definition and EPICS variables. This means that the user only has to include a node for the specific application and use the mentioned tools. A main class is in charge of managing the FPGA and EPICS server according to this XML file. This multipurpose controller has been successfully used to implement a BPM and an LLRF application for the ESS-Bilbao facility.

INTRODUCTION

The utilization of the same hardware for the implementation of several applications has some advantages such as, the knowledge of how it works, its limitations, an easier maintenance and development of new tools.

Normally each piece of hardware has its own purpose but with the popularization of FPGAs the hardware has become reconfigurable. The development of an FPGA based hardware could take a long time and, therefore, the utilization of commercial hardware is beneficial. This choice contributes with a fast implementation and reliability, because commercial hardware is, usually, well tested.

In this work the VHS-ADC board of Lyrtech company [1], combined with a PC are used to design a multipurpose controller focusing their function on particle accelerators applications.

* iarredondo@essbilbao.org

In particle accelerators the most of the devices have to be connected to a central network to be controlled or monitored via the facility's standard middleware. Concretely in this paper EPICS [2] is implemented.

On the other hand, and following with the idea of the fast implementation and easy maintenance, it is important to provide some tools to make easier to the programmer the implementation of each application and to allow the user configuring the hardware without the necessity of programming. Therefore, some libraries have been designed to help the programmer and XML language has been chosen to interact with the user.

There are two main processes which are performed in the applications: Monitor and Control. Monitoring process is summarized in read data from the experiment with the hardware, access to this information and publish it on the network. On the other hand, the process of control can be described as a monitoring process with the possibility of interacting with the experiment. This is performed by changing a parameter, sending it through the network to a hardware controller and write it in the hardware.

In the following sections it will be described how to do the implementation of these two processes in a reconfigurable way with a minimal programming by the final user.

SYSTEM OVERVIEW

The main idea of the system is to use a commercial FPGA, the VHS-ADC board of Lyrtech company, to manage different applications related to control and monitor processes and data logging in large facilities. To drive the FPGA, a Host PC is utilized. This PC implements the Hardware Controller (HC) which is the link between the FPGA and the user.

The structure of the system is depicted in Figure 1. The instrument under control is connected to the Lyrtech board which is linked to the Host PC via a cPCI port. The HC reads and writes parameters from and to the FPGA's registers and publishes them over the network by means of an EPICS server. Then, EPICS clients can use the data and change the control parameters.

The structure of the conceptual programming is the following: Acquisition, fast calculations and real-time process are handled by the FPGA while slow or heavy calculations, data logging and EPICS related functions are performed in the HC.

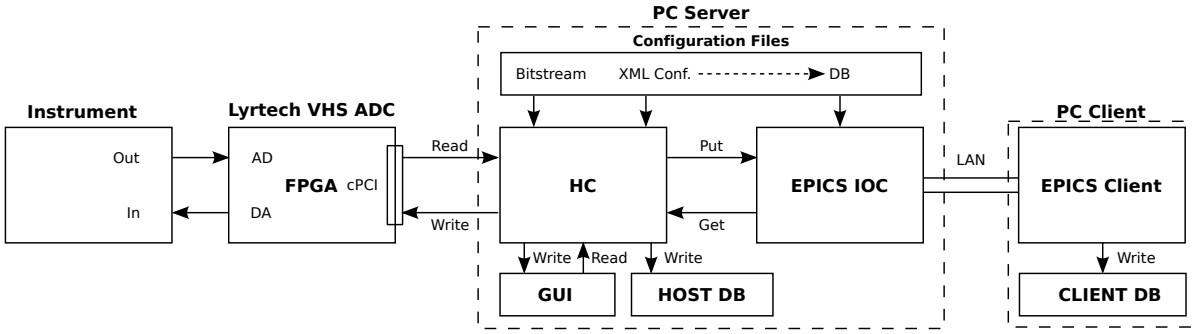

Figure 1: General diagram.

HARDWARE CONTROLLER IMPLEMENTATION

The HC is the core of the system since it is in charge of managing the FPGA, the EPICS server, the EPICS IOC, the DB, the XML configuration files, the local user GUI and of performing some calculations. The integration of all these devices has been carried out utilizing Java language because it is able to handle all of the mentioned needs. Each case is detailed as following:

FPGA: It uses a C programmed API, so JNA [3] is utilized.

EPICS Server and IOC: There is a Java based tool called JavaIOC [4].

DB: It is mainly handled by the java.sql class, because it is implemented in a MySQL database [5].

XML: The configuration file is relatively small and a fast access to the data is required. DOM technology from w3c [6] has been chosen.

GUI: SWT toolkit [7] is used.

The HC program is built with several threads in parallel, to be able to read and write from/to the FPGA, create the EPICS server, update the DB, build the GUI and parse the XML configuration file[1].

However, in order to guarantee versatility and the ease of programming different applications to the final user, some tools, xml rules and instructions have to be provided. These are treated on the following sections.

Managing Tools

In order to provide a set of tools to program the part of the HC which is related with the specific application, some Java classes which fit most common necessities have been designed. These are:

org.essb.mc.epics.db: EPICS Archiver MySQL DB implementation, managing and configuration tools.

org.essb.mc.epics.db.tables: EPICS Archiver MySQL DB formatting utils.

org.essb.mc.epics.utils: EPICS utils to manage a javaIOC: create/destroy context, connect/disconnect channels, caget synchronous/asynchronous, caput synchronous/asynchronous, create/destroy monitor and camonitor.

org.essb.mc.fpga.program: Handle the FPGA: Open/-Close board, program FPGA, program Flash, set FPGA clock, set ADCs status, read ADCs overflow and Read-/Write Registers.

org.essb.mc.fpga.maths: FPGA raw to engineering units conversion and vice versa, and standard numeric conversions.

org.essb.mc.gui.general: Utils to create the GUIs with the most common objects.

org.essb.mc.xml: Tools to acquire the configuration data from an XML document and use it in the main program.

These tools are enough to program a very wide range of applications. Nevertheless once one is set up and working, it is better to have an easy way to reconfigure some parameters depending on the specific device or situation. Here is when the XML configuration file makes the MC more versatile.

XML Based Configuration

With the XML configuration file, the goal is to reconfigure the HC to manage the desired application. Therefore, the first action taken by the HC when it is started is to ask the user for a configuration file. Then it is parsed and dumped in a well defined object in the program. All the necessary tools to perform this issue are in the org.essb.mc.xml class.

The time constraints are, normally, a common characteristic in the accelerators applications, hence, it is important to guarantee a fast access to the data of the configuration file. For this reason, it is better to have this data in the RAM and, therefore, DOM technology is very suitable.

A typical configuration file is like the following one:

```
<!DOCTYPE MCEBC [ <!-- Multipurpose
    Controller Ess Bilbo Configuration-->
  <!ELEMENT MCESSB (Name, Value, FPGA, EPICS,
    BPM)><!-- Multipurpose Controller ESS
    Bilbo-->
  <!ELEMENT Name (#PCDATA)>
```

[1] If more information about the structure of the HC is need, it could be found in [8].

```
<!ELEMENT Value    (#PCDATA)> <!--
    Initial Value -->
<!ELEMENT FPGA   (Used,Bits,Prec,Reg,
    Custom,Custom_ADDR,Signed,RW)>
  <!ELEMENT Used     (#PCDATA)>  <!-- Is
      used in FPGA ?-->
  <!ELEMENT Bits     (#PCDATA)>
  <!ELEMENT Prec     (#PCDATA)>
  <!ELEMENT Reg      (#PCDATA)>
  <!ELEMENT Custom   (#PCDATA)> <!--
      Custom => true or Lyrtech Reg =>
      false -->
  <!ELEMENT Custom_ADDR    (#PCDATA)> <!
      -- Custom register Address -->
  <!ELEMENT Signed   (#PCDATA)> <!--
      Signed => true or No signed =>
      false -->
  <!ELEMENT RW   (#PCDATA)> <!-- Read/
      Write=> 0,1 -->
<!ELEMENT EPICS (Used)>  <!-- EPICS
    config if vble is used in EPICS -->
  <!ELEMENT Used   (#PCDATA)>  <!-- Is
      used in EPICS ?-->
<!ELEMENT BPM (Used,Element,Fit)>  <!--
    BPM config -->
  <!ELEMENT Used   (#PCDATA)>  <!-- Is
      used in BPM ?-->
  <!ELEMENT Element (#PCDATA)> <!--
      Indicate which is the variable in
       BPM application. Left, Right, Up
      , Down (buttons), Amp, Phase, X
      or Y -->
  <!ELEMENT Fit  (#PCDATA)> <!-- BPM
      nonlinear fitting values config
      -->
]>
```

There are five well defined fields into the XML file. The first four ones are compulsory and are repeated for all applications. These are: The name of the variable, its initial value, the FPGA's register configuration and if it is EPICS published or not.

On the other hand, there is the application field which has to be detailed by the user. In the example there is a BPM structure which has fields linking/explaining which button is measuring the variable and some values to fit the electrical delays.

The implemented data structure for the reconfigurability of the HC combines the DOM data calls, with a vectors structure which contains the index of the elements with the same characteristics. For example, in one vector it is stored the index of the elements of the DOM structure which have to be published in EPICS. The implemented structure is in Figure 2. The vectors (Value, FPGA/Read, FPGA/Write and EPICS) contain the index of the DOM node which fits with its function and, on the other hand, there are some structures which will contain the needed information associated with the vector. Conceptually, the working mode is

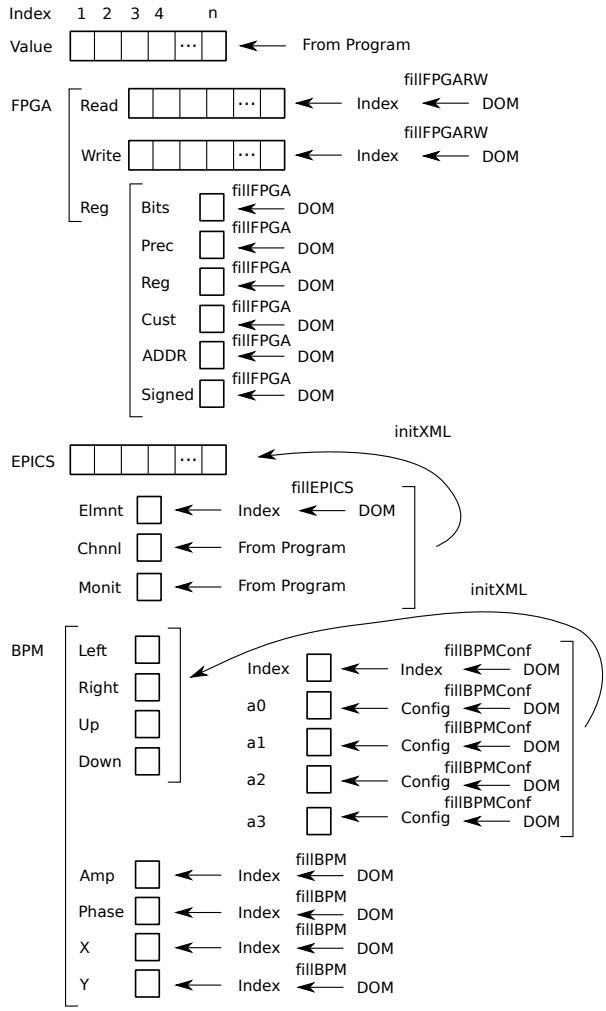

Figure 2: General diagram of communication between the control algorithm and the Host PC.

the following: Firstly the vectors are filled with the corresponding DOM node index. Then, when the program requires some data, it searches inside the vector, fills the corresponding structure with the tags of the node and uses this structure. In Figure 2 it is also detailed the method which is used to handle the data from the DOM.

Implementing a New Application

The steps to implement a new application assuming that the FPGA is suitable for the case (range of signals, ...) are the following:

1. Create the bitfile of the FPGA which fit with the application.
2. Update the configuration file:
   (a) Update the FPGA structures according to the previously designed FPGA bitfile.
   (b) Update the EPICS structures.

(c) Include a new structure for the application in the configuration file.

3. Use the org.essb.mc.xml tools to integrate the new structure into the HC.

4. Use the org.essb.mc.gui.general tools to adequate the GUI to the application. It is only needed to change the application tab, because the FPGA handling one is always the same.

CONCLUSIONS AND FUTURE WORK

In this work, a multipurpose controller based on a commercial FPGA has been presented. It has been designed to fit the large scientific facilities' requirements, using EPICS standard. Therefore, it has to be able to: Perform very fast calculations and precise acquisition, be integrated into the global control network and store the required data. The proposed solution, integrates an FPGA, an EPICS connection and a MySQL database in order to fulfill all of these specifications.

The key idea of this paper has been to explain how this controller has been made versatile, designing programming tools and using XML technology. Concretely, Java tools have been built to ease the labour of the programmer and an XML reconfiguration file has been integrated to make the final user able to configure the device.

Also it has been proposed a method to implement a new application based on the defined tools.

As future work it is foreseen the integration of EPICS database, which is an XML file, into the main XML configuration file. To perform this integration, the use of XLST is expected.

FUNCTION GENERATION AND REGULATION LIBRARIES AND THEIR APPLICATION TO THE CONTROL OF THE NEW MAIN POWER CONVERTER (POPS) AT THE CERN CPS

Q. King, S. T. Page, H. Thiesen, CERN, Geneva, Switzerland
M. Veenstra, EBG MedAustron, Wr. Neustadt, Austria

Abstract

Power converter control for the LHC is based on an embedded control computer called a Function Generator/Controller (FGC). Every converter includes an FGC with responsibility for the generation of the reference current as a function of time and the regulation of the circuit current, as well as control of the converter state [1]. With many new converter controls software classes in development it was decided to generalise several key components of the FGC software in the form of C libraries: function generation in libfg, regulation, limits and simulation in libreg and DCCT, ADC and DAC calibration in libcal. These libraries were first used in the software class dedicated to controlling the new 60MW main power converter (POPS) at the CERN Proton Synchrotron (CPS) where regulation of both magnetic field and circuit current is supported. This paper reports on the functionality provided by each library and in particular libfg and libreg. The libraries are already being used by software classes in development for the next generation FGC for Linac4 converters, as well as the CERN SPS converter controls (MUGEF) and MedAustron converter regulation board.

FUNCTION GENERATION LIBRARY

Calculating a reference value as a function of time is a key requirement for most regulated systems. Libfg is a C library that can generate ten different types of reference function, as listed in Table 1. For each type there are two C structures; one for the configuration of the reference function (config) and the other containing the parameters (pars) needed to generate the reference at a given time. Figure 1 shows how these structures relate to the associated C functions *Init()* and *Gen()*.

To summarise, the *Init* function processes the config structure and calculates the contents of the pars structure. This is then used by the *Gen* function to calculate the reference at the specified time.

Two other structures are concerned: limits and meta. Limits are provided to the *Init* function and allow the absolute, rate of change and acceleration limits to be checked. Meta is produced by the *Init* function with summary information (duration, min/max and start/end reference values). The *Init* function also needs to know the initial time delay and in most cases the initial reference value since most reference functions are relative to an initial reference. Only TABLE and SPLINE define absolutely the entire function and do not need it.

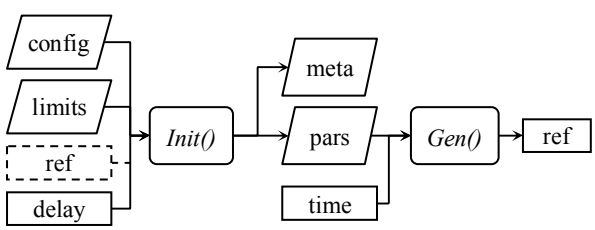

Figure 1: libfg data flow.

Table 1: Libfg Function Types

Name	Function type
PLEP	Single parabola-linear-exponential-parabola segment
PPPL	Multiple parabola-parabola-parabola-linear segments
TABLE	Table interpolated with linear segments
SPLINE	Table interpolated with parabolic splines
LINEAR	Single linear segment in a given time
CUBIC	Single cubic segment in a given time
SINE	Sine with optional window for smooth start/end
COSINE	Cosine with optional window for smooth start/end
SQUARE	Offset square wave
STEPS	Staircase of one or more steps

Reference and Time Units

Libfg does not dictate the interpretation of the reference. For magnet circuit control it might be voltage, current or field, depending upon the regulation mode. Similarly, libfg does not dictate the units of time, though at CERN the units are always seconds.

PLEP

The PLEP function provides a standard way to change the magnet circuit current. The initial and final parabolas provide a smooth start and end, which is vital for super-conducting circuits. The linear section takes over if the rate limit is reached and the exponential section may be needed when ramping down with a 1-quadrant converter. These are unipolar in current and voltage and so the current cannot be ramped down faster than the natural decay rate for the circuit ($T_c = L/R$). Thus when a PLEP is initialised, the result might be a P-P, a P-L-P, a P-E-P or a P-L-E-P depending upon the parameters and the difference between the initial and final reference values.

The PLEP function is special amongst all the functions in libfg because it can be initialised with a non-zero initial rate of change. This can be important if a running

function needs to be aborted smoothly, which is the case in the LHC if cryogenics report an impending problem.

PPPL

The PPPL reference was created for the CPS main magnet controls. The field is ramped up in stages with a series of linear plateaus defined parametrically using seven values. These specify a fast parabolic acceleration followed by a slow parabolic deceleration, then a fast parabolic deceleration and finally a linear section that is not necessarily constant.

TABLE

TABLE provides linear interpolation between points and is the main function type for LHC current references. Linear interpolation is sufficient provided points are close together when the reference is changing rapidly. If the reference should follow a parabola then equation (1) is a useful formula that gives the point spacing t as a function of the maximum acceptable interpolation error ε and the parabolic acceleration a:

$$t = 2\sqrt{(2\varepsilon/a)} \qquad (1)$$

SPLINE

SPLINE offers a way to use fewer points than TABLE by using parabolic splines rather than linear interpolation.

TRIM Functions

Trim functions are useful for small changes in the reference, especially when many circuits must change synchronously, since unlike the PLEP function, the duration for the change is an input parameter. CUBIC trims are essential for super-conducting circuits because they avoid discontinuities in the rate of change which would generate voltage spikes. LINEAR trims can be used for warm circuits but they suffer from undershoot and overshoot and are not used in the LHC.

TEST Functions

The SINE, COSINE, SQUARE and STEPS functions are very useful for converter testing and in some cases for accelerator measurements (e.g. K-modulation).

Definition of Time

Libfg uses single precision floats for time (and all other reference related parameters). The resolution of IEEE 32-bit floating point values is limited by the 23-bit mantissa and will allow 1 µs granularity for up to 10 s, 10 µs granularity up to 100 s and so on. If finer granularity is required then the library can be modified and recompiled to use double precision floats.

REGULATION LIBRARY

Libreg provides all the key components needed to write a program to regulate magnetic field or circuit current.

Magnet Load Model

Figure 2 shows the load model used by libreg. It is based on a magnet with inductance L and resistance R_m (zero for superconducting magnets). This is associated with a parallel damping resistor R_p and a series resistor R_s which corresponds to the cables or bus bars leading to the magnet. In many case multiple magnets are connected in series but for low frequencies their individual impedances can be combined into the four values given in figure 2.

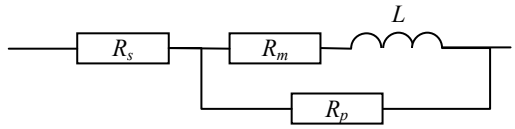

Figure 2: libreg load model.

The gain response of this model is first order and is shown in figure 3.

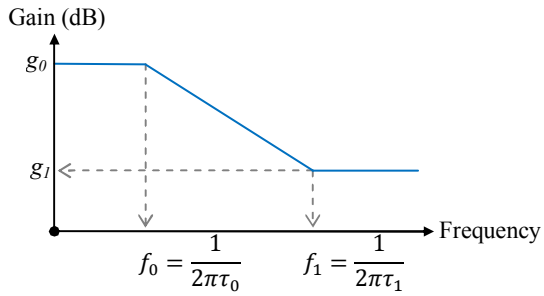

Figure 3: Load model Bode plot.

The pole and zero gains and time constants associated with the break frequencies in the Bode plot are given by:

$$g_0 = \frac{1}{R_s + \frac{R_p R_m}{R_p + R_m}} \qquad g_1 = \frac{1}{R_p + R_s} \qquad (2)$$

$$\tau_0 = \frac{L}{R_m + \frac{R_p R_s}{R_p + R_s}} \qquad \tau_1 = \frac{L}{R_p + R_m} \qquad (3)$$

The gains g_0 and g_1 correspond to the effective load resistance at zero and infinite frequency, while the time constants τ_0 and τ_1 correspond to the effective circuit resistance as seen by the inductance for shorted and open circuits.

Reference and Measurement Limits

Libreg provides functions that implement limits on the current or field and voltage references and the current or field measurement. These have different objectives. The measurement limit is used for protection of the circuit; the converter will be tripped if the limit is exceeded. The reference limits are associated with constraints in the converter and circuit and may cause the reference to be clipped. Normally limits are applied by libfg when initialising a reference function, however if a real-time reference is included then real-time limits are required.

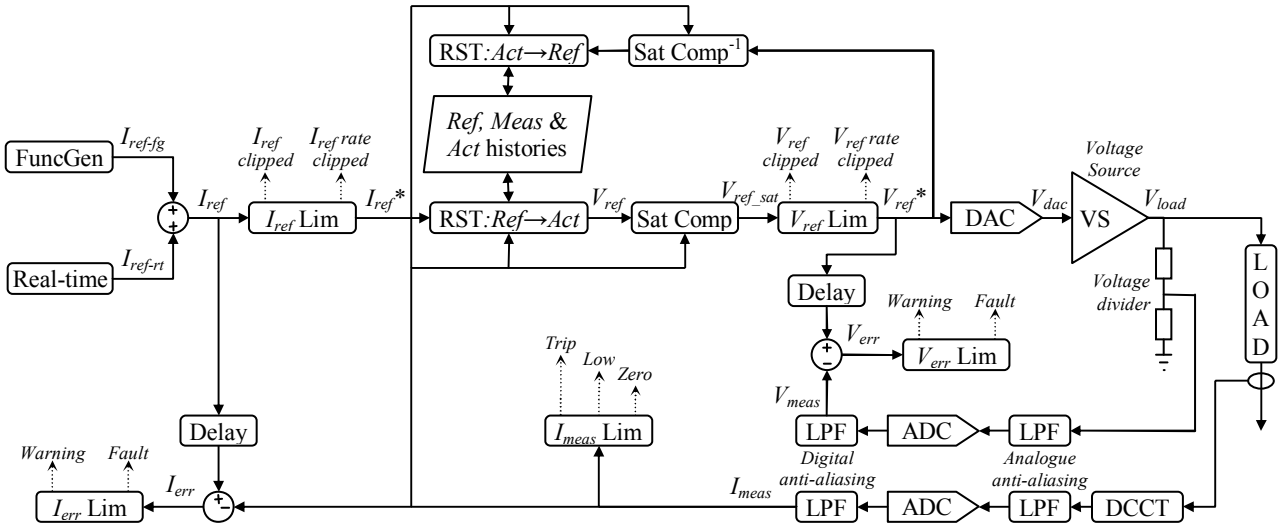

Figure 4: Overview of current regulation of an analogue voltage source.

RST Regulation

Figure 4 presents an overview of the function generation and regulation that can be implemented using libfg and libreg. One of the most flexible ways to implement a linear regulator is with the RST equation:

$$\sum_0^N\{Act_i \cdot S_i\} = \sum_0^N\{Ref_i \cdot T_i\} - \sum_0^N\{Meas_i \cdot R_i\} \qquad (4)$$

Where *i=0* corresponds to the current sample, *i=1* is the previous sample and so on. This notation was proposed by Landau [2], however in many text books the R and S polynomials are exchanged. By keeping the history of the previous *N* samples of the reference, measurement and actuation it is easy to calculate the new actuation if you know the new reference and measurement:

$$Act_0 = \frac{\sum_0^N\{Ref_i \cdot T_i\} - \sum_0^N\{Meas_i \cdot R_i\} - \sum_1^N\{Act_i \cdot S_i\}}{S_0} \qquad (5)$$

Equally, when the actuation is limited or is being driven in open-loop then it is equally easy to back-calculate the reference which, when combined with the new measurement will result in this actuation:

$$Ref_0 = \frac{\sum_0^N\{Act_i \cdot S_i\} + \sum_0^N\{Meas_i \cdot R_i\} - \sum_1^N\{Ref_i \cdot T_i\}}{T_0} \qquad (6)$$

In this way the reference history can be kept coherent with the measurement and actuation histories. This is equivalent to the anti-windup feature of a traditional regulation algorithm.

The benefit of the RST equation is that any linear regulator up to order *N* can be implemented by choosing the appropriate RST polynomial coefficients. Simple PI, PID, or PII controllers can be implemented [3] as well as more complex higher order systems, *without changing the software*. Of course, for complex higher-order systems calculating the coefficients is a challenge.

For a magnet circuit the reference and measurement can either be of the circuit current or magnetic field. The actuation defines the circuit voltage which the voltage source must try to follow.

If the required bandwidth of the current or field regulation is much less than the bandwidth of the voltage source and the bandwidth of the reference is lower still then a deadbeat controller can be used. Since this is exactly the case for the circuits in the LHC the regulation library includes a function to calculate the RST coefficients that will implement a deadbeat PII controller. This works extremely well in the LHC with negligible tracking error.

For applications that require as much bandwidth as possible the transfer function of the voltage source must be accurately modelled and a different approach taken to derive the RST coefficients. Matlab has a powerful toolkit for this, however it does require expert knowledge of automatic control theory.

Magnet Saturation Model

If warm magnets are used beyond about 0.9 teslas, their iron yokes will enter saturation and the inductance drops by as much as 60%. The corresponding change in time constant can destabilise the regulation loop if it is not compensated. Libreg supports compensation of this effect based on the simple linear model of the magnet inductance L_m(I) shown in figure 5. Three parameters are used to characterise the model: L_{sat}, I_{sat_start} and I_{sat_end}.

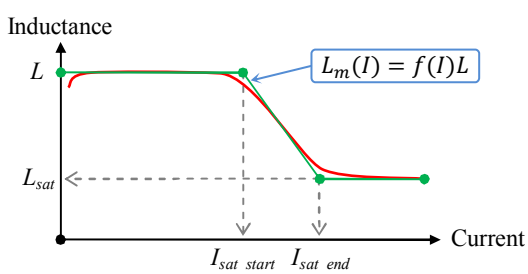

Figure 5: Magnet saturation model.

The saturation model is used to transform V_{ref} in order to hide the saturation effect from the RST algorithm:

$$V_{ref\_sat} = \{1 - f(I)\}IR + f(I)V_{ref} \quad (7)$$

Where $f(I) = L_m(I)/L$ and R is the load resistance associated with magnet load pole:

$$R = R_s + \frac{R_p R_m}{R_p + R_m} \quad (8)$$

As shown in figure 4, equation (7) is used to derive V_{ref_sat} from V_{ref} which is then limited to arrive at V_{ref}*. If clipping occurs then equation (7) is inverted to back-calculate V_{ref} from V_{ref}* and equation (6) is used to back-calculate the reference to keep the RST histories coherent.

Note that when regulating magnetic field, saturation is a second order effect and compensation is not required.

Regulation Error

Figure 4 shows how the regulation error is calculated from the difference between the delayed reference and the measurement. The delay must be set to the tracking delay of the regulator. Libreg includes functions that allow the error to be calculated and limits to be applied.

Simulation of Voltage Source and Load

It is highly desirable to build into converter controls software a simulation mode in which the voltage source, load, and measurements are simulated in software. Libreg includes functions that support a third-order model of the voltage source and simulation of the load model presented above.

FGTEST PROGRAM

A program called fgtest was written under Linux to test libfg and libreg. It is a template for a real-time converter control program, showing how the core elements of the regulation loop presented in figure 4 can be implemented. The program is driven from the command line using parameter files and writes signals to stdout as comma separated values that can be analysed with any suitable tool such as GNUplot, Matlab or Excel.

LIBCAL

Libcal contains functions to support the calibration of voltage dividers, DCCTs, ADCs and DACs, including the option for up to second order temperature compensation for ADCs and DCCTs. More information and the library source files can be downloaded from http://cern.ch/cclibs.

APPLICATIONS

Libfg and libreg were created to support multiple platforms and applications. So far they have been compiled on Linux PCs and TMS320C32 and TMS320C6727 DSPs and from 2012 they will be used in the converter controls software for the CERN LHC, SPS, CPS and PSB accelerators. They will also be used in the new converter controls for the MedAustron accelerator.

For now, only one converter in the CPS accelerator is controlled using the libraries; the new 60 MW POPS converter that drives the main magnets. This is a particularly interesting case since it can regulate magnetic field or circuit current on a cycle by cycle basis. The magnets saturate dramatically above 3.6 kA with a 60% reduction in inductance by the maximum current of 6 kA. This is successfully compensated when regulating current using equation (7).

Figure 6 shows a 1.2 s proton beam cycle with three plateaus. The blue and cyan traces are the field reference and measurement; red shows the current and purple and green show the voltage reference and measurement. The controller runs at 1 kHz, but the regulation acts every 3rd iteration at 333.3 Hz.

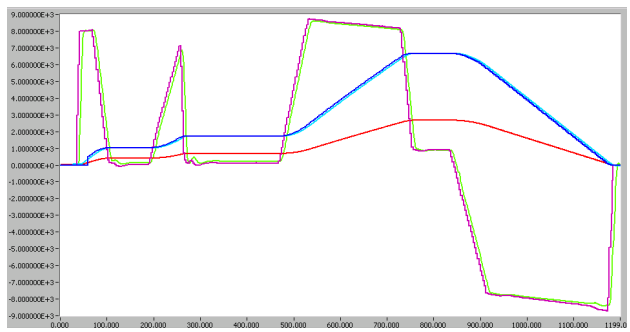

Figure 6: 1.2s cycle with the POPS converter.

AVAILABILITY FOR DOWNLOAD

All the libraries (including libcal) and the fgtest program are freely available under the GNU Lesser General Public License. Visit the website http://cern.ch/cclibs for more information and to download the source. Makefiles for Linux are included.

CONCLUSIONS

These well tested libraries are based on years of operational experience [4] and are a valuable resource for the development of converter regulation software. By centralising these vital components into libraries, the maintenance effort has been reduced and new equipment classes have been developed more quickly.

SIMPLIFIED INSTRUMENT/APPLICATION DEVELOPMENT AND SYSTEM INTEGRATION USING LIBERA BASE SOFTWARE FRAMEWORK

Matej Kenda, Tomaž Beltram, Tomaž Juretič, Borut Repič, Damijan Škvarč, Črt Valentinčič,
Instrumentation Technologies, Solkan, Slovenia

Abstract

Development of many appliances used in scientific environment forces us to face similar challenges, often executed repeatedly. One has to design or integrate hardware components. Support for network and other communications standards needs to be established. Data and signals are processed and dispatched. Interfaces are required to monitor and control the behaviour of the appliances. At Instrumentation Technologies we identified and addressed these issues by creating Libera BASE, which is a framework composed of several reusable building blocks. Libera BASE simplifies some of the tedious tasks and leaves more time to concentrate on real issues of the application. Further more, the end product quality benefits from larger common base of this framework. We present the benefits on examples of instrument implemented on MTCA platform accessible over graphical user interface.

DEVELOPMENT OF ELECTRONIC DEVICES

The need or a vision for a new or improved electronic devices usually emerges from a real-world challenge, issue or a question that needs to be answered.

The device gets defined through the development process in the means of functional (functionality, performance) and non-functional (user experience, scalability, interoperability) requirements. It is then realised through analysis, design implementation, validation and production. This is a day-to-day job in development enterprises all over the world.

For the purpose of accelerator community, the end result of the development is often a measurement instrument, comprising:

- selected hardware architecture (for example Libera hardware architecture A/B, MicroTCA)
- instrument specific electronics, RF
- input signals (analog, digital, timing)
- platform management
- imposed communication protocols
  - PCI, IPMI, Ethernet, SATA, RapidIO
  - Control System protocols, ...
- generic FPGA cores and application specific processing
- application-specific algorithms, parameters, ...

THE ROLE OF SOFTWARE IN RECONFIGURABLE ELECTRONIC DEVICES

The importance of software in electronic devices is increasing. Software is not just an add-on, it became an essential part of electronic devices.

Many of the chips are becoming increasingly integrated and programmable or configurable to some extent. For example FPGA by its nature, ADCs, VCXOs that are controlled over SPI, I2C buses. As a consequence, more software needs to be written to control them.

Software usually acts as the integration layer to make hardware components, application logic and user interfaces to work together. Issues not thought of before the integration need to be resolved then.

Software interfaces are also the points where people communicate with the device. They largely define user experience through graphical, programming and other interfaces. Human behaviour also doesn't comply to standards: any kind of usage of the electronic device needs to be handled in software [1].

REUSABLE SOFTWARE IN MEASUREMENT INSTRUMENTS: SEEING THE PATTERNS

There is a set of concepts that is occurring repeatedly in measurement instruments:

- hardware detection, platform management
- access to functionality implemented in FPGA
- configuration parameters
- notification of changes
- signal acquisition, processing and dispatching
- scaffold for running instrument applications
- supporting standard control system interfaces

Basic Application Support Environment

Powered by Libera BASE

Figure 1: Libera BASE logo.

LIBERA BASE

Libera BASE (Figure 1) is a software framework, developed at Instrumentation Technologies. The design

started in the beginning of 2010 based on many years of previous experience. A common framework was internally needed to develop multiple instruments/applications on the same hardware architecture.

The project's delivery was software framework Libera BASE, which proved itself to be useful widely as initially anticipated [10].

Libera BASE narrows the gap between customer's hardware and the machine's control system. It helps to focus on the application, for which the instrument is designed for with

- software framework for application development and
- intuitive structure and programming interfaces.

Libera BASE simplifies integration into various control systems, however it does not aim to act as a replacement for them.

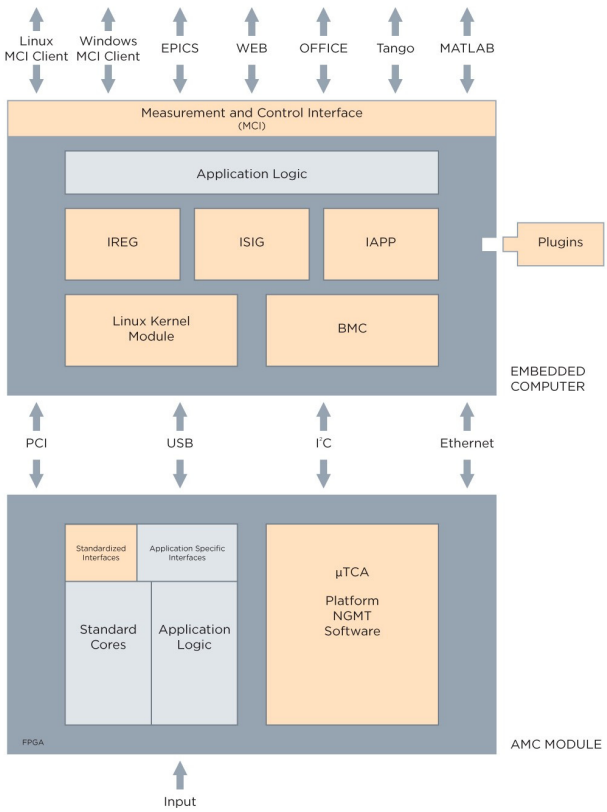

Figure 2: Libera BASE software framework.

Concepts and Building Blocks

Libera BASE consists of several components (Figure 2) that work together in synergy to support applications based on it ([2], [3], [4]).

- **fw**: MicroTCA-compliant platform management
- **bmc**: Hardware abstraction layer (uses IPMI, USB, OpenHPI)
- **lkm**: PCI Linux kernel module relies on a set of standardised FPGA registers
- **ireg**: Application parameters as hierarchical tree
- **isig**: Signal acquisition, processing and dispatching
- **iapp**: Application development framework, plugins
- **mci**: Client programming interface (API) for GNU/Linux and Windows: exposes registry and access to signals
- **tools**: Simple command line tools for automation and scripting
- **adapters**: Matlab and LabView scripts, web, EPICS (EDM, pyEpics) [8], Tango CS [7], FESA [6]

Relation to Libera Instruments

Using Libera BASE to develop instrument application software accelerates development. Measurements of source code size reveal that the share of application-specific software is around 10% of total software; remaining 90% is Libera BASE.

Application software defines the set of user settable parameters, signals, processing and algorithms (Figure 3, Figure 4).

In September 2011, the following instruments use Libera BASE: Libera Brilliance+, Libera Single Pass H, Libera Spectra, Libera LLRF.

Common MCI API is used on all of the instruments which simplifies integration of different instruments into the control system.

Libera BASE is improved incrementally with each new instrument or its new version. Occasionally there are dedicated projects scheduled to develop common functionality.

Improvements of Libera BASE during development of one instrument get incorporated into other instruments on regular basis.

This synergy between the instruments results in better stability and quality of many instruments over time.

Figure 3: Example of parameters in the registry from Libera Brilliance+.

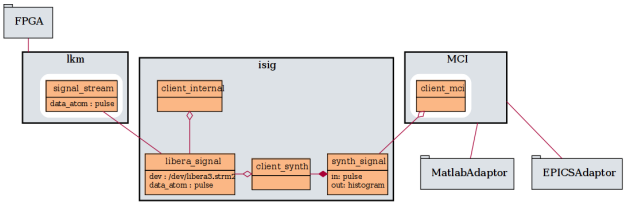

Figure 4: Processing and dispatching a signal.

Libera BASE and Hardware Architectures

Software framework was initially designed to support the modular Libera Hardware Architecture B. Since the coupling between the modules of Libera BASE is low, it is relatively easy to support different hardware architectures with the same software framework. The framework currently supports:

- Libera Hardware Architecture B
- Micro TCA
- Micro TCA for Physics (MTCA.4) [5]

PICMG (PCI Industrial Computer Manufacturers Group [9]) is working on a reference software implementation for applications on MTCA.4. Libera BASE was created sooner and independently from the MTCA.4 reference implementation, because of the market needs.

MTCA.4 reference implementation and Libera BASE share the same mission: help to focus on the application, not the platform.

Libera BASE was presented to PICMG to share ideas and will adapt to the MTCA.4 reference implementation when available.

Libera BASE and Libera Platform A

Instruments based on Libera Platform A provide CSPI API for integration with control systems.

CSPI is only an API, however Libera BASE is a complete framework for application development.

CSPI was designed for a single hardware architecture and instrument. Libera BASE can be adapted to support Libera hardware architecture A, but the opposite would be harder.

Future Plans

Feature set of Libera BASE is becoming rich enough to be able to implement many applications on different hardware architectures.

In the next period it is intended to improve out-of-the box connectivity, abilities to customise/extend the applications and usability.

USAGE SCENARIOS OF LIBERA BASE

Development of New Instruments

Libera BASE software framework provides a productive environment for development of a new instrument.

Integration of Instruments into their Working Environment

The MCI programming interface is designed to be simple, intuitive and powerful. Different instruments expose the same networked API, which can be used from GNU/Linux and Windows clients (Figure 6).

The API is used to implement different client programs (command line, graphical) and adaptors for integration with applications and control systems.

Different instruments have already been accessed from the following clients and adaptors:

- graphical user interface
- command line interface
- Matlab, SCILab
- OpenOffice.org spreadsheet
- mobile devices: iPhone, iPad, Android-based phones (Figure 5)
- web browsers
- EPICS EDM

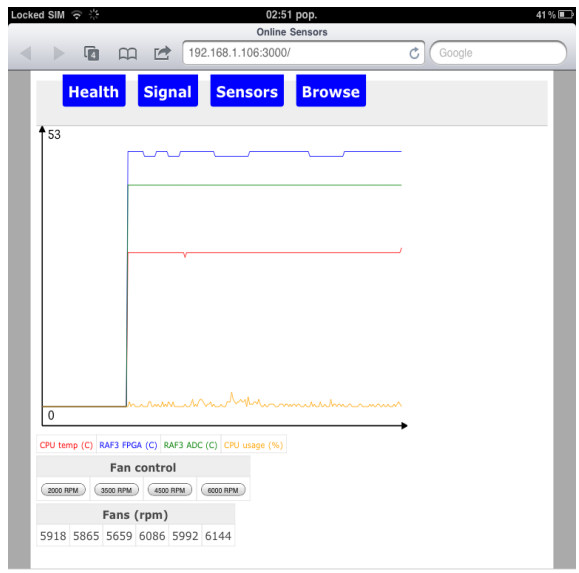

Figure 5: Controlling an instrument from a mobile device.

Customising and Extending an Instrument

Several tools are provided to customise Libera instruments:

- FPGA development kit (FDK)
- FPGA to registry map (no programming needed)
- Software plugins

New parameters and signals implemented when extending the instrument are exported through MCI API in the same way as those originally provided by the instrument.

Source Code Example

```
#include <iostream>
#include "mci/mci.h"
#include "mci/node.h"

int main(int a_argc, char* a_argv[])
{
    mci::Init(a_argc, a_argv);

    auto root = mci::Connect("192.168.1.100", mci::Root::Application);

    //
    // Dump complete tree of registry parameters
    //
    auto nodes = mci::SubTree(root);
    for (auto i(nodes.begin()); i != nodes.end(); ++i) {
        std::cout
            << i->GetFullPath() << " = "
            << i->ToString() << std::endl;
    }

    //
    // Access and modify a parameter
    //
    mci::Path path = mci::Tokenize(
        "boards.raf3.tbt.spike_removal.averaging_window");

    auto n = root.GetNode(path);

    // Read a numeric parameter
    int32_t aw = n;
    std::cout << "Averaging window: " << aw << std::endl;

    // Modify a numeric parameter
    aw = 16;
    n = aw;

    mci::Shutdown();
}
```

Figure 6: Example of C++ source code.

SUMMARY

Libera BASE narrows the gap between your hardware and the machine control system. It simplifies development of instruments and integration into control systems.

Libera BASE provides MCI programming interface that is powerful, easy to learn and use.

The software framework is designed for various hardware technologies.

High level of re-usability increases reliability and quality of instruments.

Supports reconfigurable instruments with its modular structure and extendibility.

CONTROLLING THE EXCALIBUR DETECTOR

J. A. Thompson, I. Horswell, J. Marchal, U. K. Pedersen, Diamond Light Source, Oxfordshire, UK.
S. Burge, J. D. Lipp, T. Nicholls, Science and Technology Facilities Council, Oxfordshire, UK.

Abstract

EXCALIBUR is an advanced photon counting detector being designed and built by a collaboration of Diamond and the STFC. It is based around 48 CERN Medipix3 chips arranged as an 8 x 6 array. The main problem addressed by the design of the hardware and software is the uninterrupted collection and safe storage of image data at rates up to one hundred 2048 x 1536 frames per second. This is achieved by splitting the image into 6 'stripes' and providing a parallel data path for each stripe all the way from the detector chips to the storage. This architecture requires the software to control the configuration of the stripes in a consistent manner and to keep track of the data so that the stripes can be subsequently stitched together into frames.

INTRODUCTION

A 2D position sensitive detector is required for use in a range of imaging experiments at Diamond Light Source. Initially the detector will be applied on photon beam line I13, but the resulting design may be applied on other beam lines and in other applications.

The primary application will be in the technique of Coherent Diffraction Imaging (CDI) [1]. The detector will also find applications in Photon-correlation Spectroscopy (XPCS) [2], full-field microscopy and holo-tomography.

The Medipix3 Device

The Medipix3 device is a 256 x 256 pixel photon counting detector. It has three basic operating modes, single-pixel, charge-summing and colour. The EXCALIBUR instrument will initially support single-pixel and charge-summing modes.

The charge that is collected by a pixel due to an impinging photon is measured and compared to a programmable threshold. Only charge pulses that meet the threshold's requirements are registered by the 12 bit counter. There are two 12 bit counters associated with each pixel. These are normally used so that one is counting photons while the other is being read out, to eliminate dead time between frames.

Targeted Capabilities

Table 1 summarises the capabilities of the EXCALIBUR detector and draws comparison with the Pilatus [3].II and XFS detectors.

Table 1: Specification And Comparison With Competitors

Parameter	EXCALIBUR	Competitors
Frame size	2k x 1.5k pixels	
Maximum frame rate	100Hz, 12 bits continuous 1kHz, 12 bits burst 30kHz, 1 bit histogrammed	Pilatus II < 300Hz Pilatus XFS > 10kHz

Quantum efficiency	~50% at 15keV	~50% at 15keV

HARDWARE ARCHITECTURE

The hardware architecture is shown in Fig. 1. It consists of a sensor array, a number of front-end modules (FEMs) and a cluster of read-out node PCs.

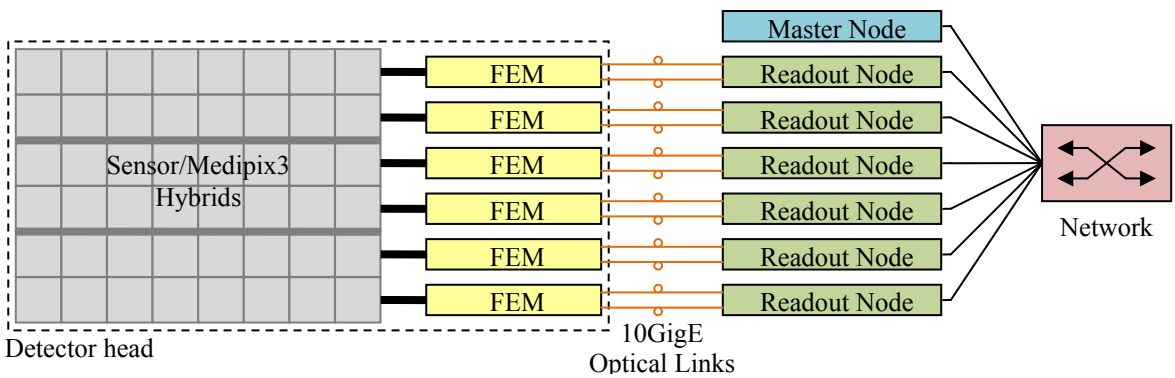

Figure 1: Hardware architecture.

Sensor Assemblies

The sensor assembly consists of three hybrid modules, each containing an 8 by 2 array of sensors and Medipix3 chips. The detector assembly consists of three hybrid modules, each containing a large silicon sensor bonded to an array of 8 x 2 Medipix 3 chips. The gaps between the chips on one module are 3 pixels (the minimum possible); the sensor pixels that cover these gaps are larger, as shown in Fig 5. A 124 pixel wide inactive region is present between modules due to the presence of wire bond pads connecting the chips to their read-out electronics.

Front End Modules

A FEM is provided for each horizontal row of sensors, giving a total of 6 FEMs. Each FEM co-ordinates the acquisition of data by a row of Medipix3 chips and also provides access to most of the registers of the 8 Medipix3 chips for the embedded software. From the point of view of the software, a FEM provides an image 'stripe' that is 2069 by 256 pixels. The seven inter-chip gaps (each of 3 pixels) are included in the output data but do not contain valid data.

Computing Resource

Six read-out nodes and one master node make up the computing cluster for EXCALIBUR. The read-out nodes communicate with the FEMs through 10G Ethernet fibre optic links. Connection to the Diamond Light Source network backbone is then made through six 1G Ethernet links to a switch with a 10G upstream connection.

Data Storage

The primary storage for data captured by EXCALIBUR will be a Lustre [4] distributed file system. Files may also be stored locally on the read-out node's file systems if required.

EMBEDDED SOFTWARE ARCHITECTURE

The embedded software is based on EPICS [5] using the area detector module [6]. Figure 2 shows an overview of the data path software; the classes ADDriver, NDPluginDriver and NDPluginFile are area detector base classes supplied by the module library.

Image Stripe Handling

The AdFem class is responsible for interfacing to the FEM. It receives image stripes, places them into standard area detector buffers and then passes them on for further processing. In addition, it provides EPICS process variables that allow the control of acquisition and the configuration of the Medipix3 and FEM devices.

The pixel arrangement in the stripes is different for each of the pair of FEMs that service a sensor module, due to the rotation of the Medipix3 chips. This is corrected by the AdFemFix class. This function is provided as a separate area detector plug-in to allow it to run on a different core to the FEM readout, keeping the throughput high.

Summary Image Production

The AdSlaves and AdMaster classes together provide the mechanism for transferring at a low rate (configurable

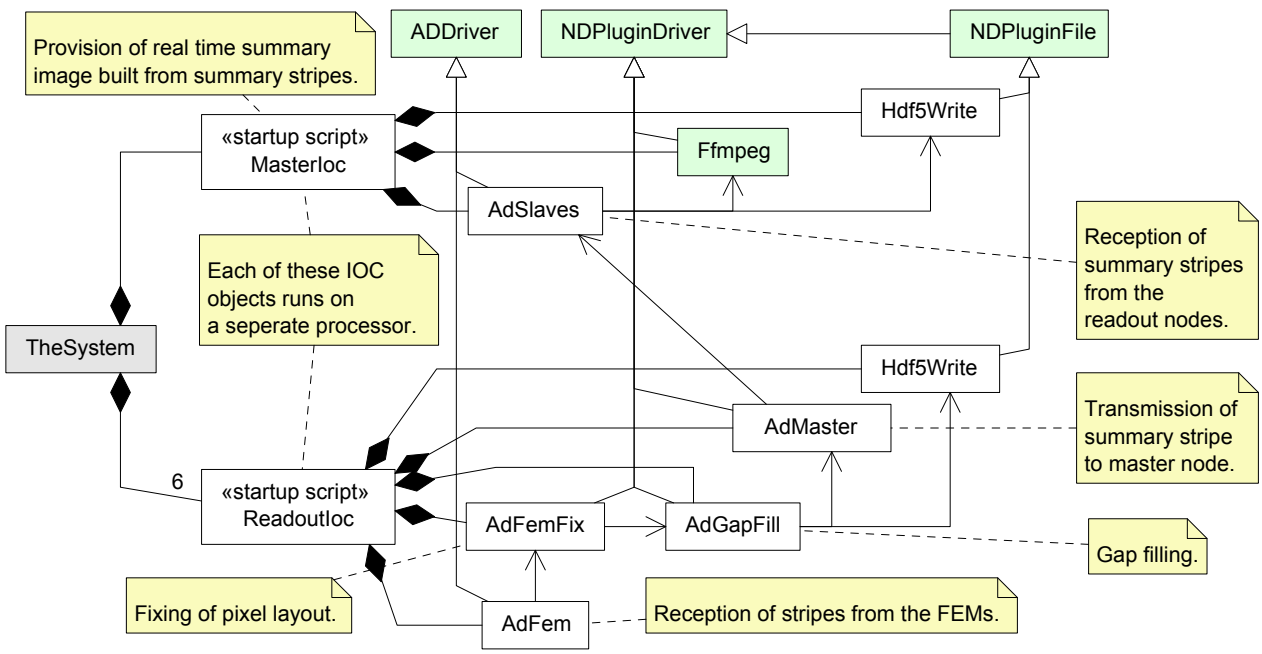

Figure 2: UML class diagram showing a summary of the data path software.

as 1 in N) a summary image stream from the read-out nodes to the master node. A class diagram is shown in Fig. 3.

The AdMaster class transfers every Nth stripe to the AdSlaves class through a TCP socket. The stripes are written into the correct place in a single area detector buffer to stitch them together. Once a stripe is received from each read out node, the complete frame is passed on for further processing on the master node. This will normally include an MPEG streaming plug-in to provide data for a suitable viewer.

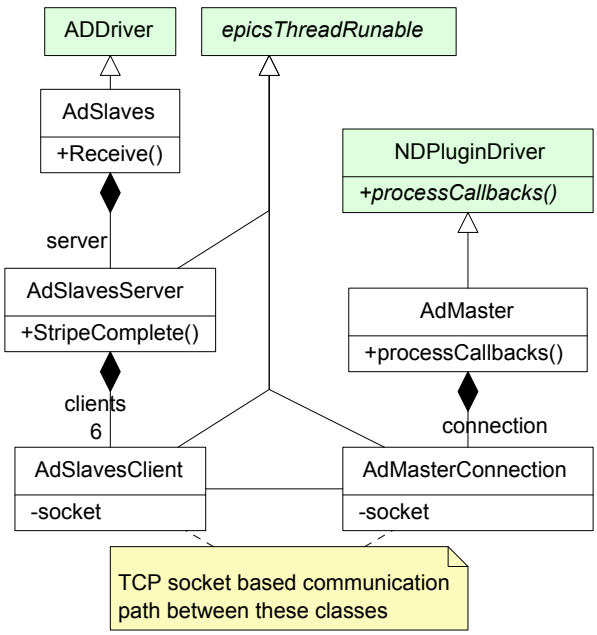

Figure 3: UML class diagram of the summary image processing.

Parallel File Handling

The read-out nodes each open the same file on the Lustre file system and write to the correct part of the file to assemble the stripes into the frame. Not only does this avoid processing by the instrument; it also utilises the multiple parallel write stream capability of Lustre to keep the data rate high.

The files are written in the HDF5 format [7]. The file writing plug-in utilises the version of the HDF5 software that uses the openMPI parallel processing library [8].

Filling the Gaps

The gaps between the adjacent Medipix3 chips are required to be filled, either by a constant value or by interpolation between the pixels surrounding the gap. A class diagram of the plug-in responsible for this task, AdGapFill, is shown in Fig. 4. The chip layout and gap details are shown in Fig. 5.

The large gaps between the modules are always filled with a constant value. The HDF5 file format provides the ability to fill automatically gaps in the recorded data with a constant. Advantage is taken of this feature to fill the large gaps without increasing the data rate of the system.

The small gaps may be filled with a constant value or interpolated, according to configuration. The small vertical gap pixels are already present in the stripe data, so the gap filling plug-in writes the constant or interpolated value as appropriate. The gap filling feature of HDF5 is used again for the horizontal gaps in constant fill mode.

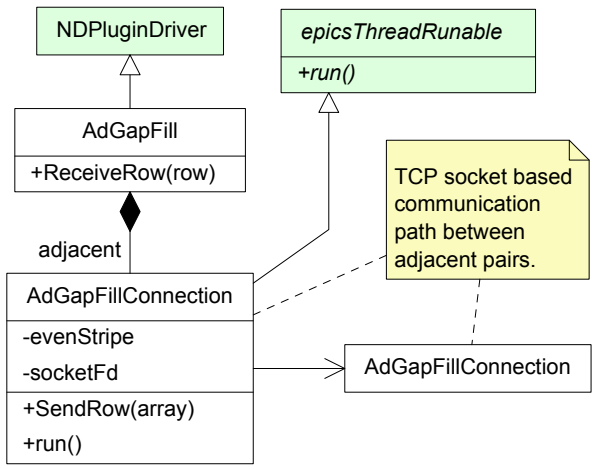

Figure 4: UML class diagram of the gap filling processing.

Interpolating across the small gap between stripes is not straightforward; it requires data communication between the adjacent gap filling plug-ins. The plug-in on the upper side of the gap receives the top row of pixels from the plug-in on the lower side. It then generates extra rows of interpolated pixels which extend the stripe downwards, over the gap.

The sensor areas of the pixels adjacent to the small gaps extend over the gap, as shown in the right of Fig 4. This means that photons landing in the pixel gaps are still captured. Interpolation is therefore concerned with sharing captured photons between the edge pixels and the gap pixels.

Configuration Control

The read-out nodes each provide EPICS process variables that control the operation of a single FEM and its associated Medipix3 chips. These are all available to allow the individual control necessary during many engineering operations, especially during calibration.

For normal user operation, co-ordinated control of the entire instrument is required. This is provided by a separate set of EPICS process variables residing on the master node that model the instrument in a user-oriented manner. These process variables are then expanded and distributed to the read-out nodes by the configuration control state machine. The same entity also monitors the operating state of the whole instrument and audits the distributed configuration.

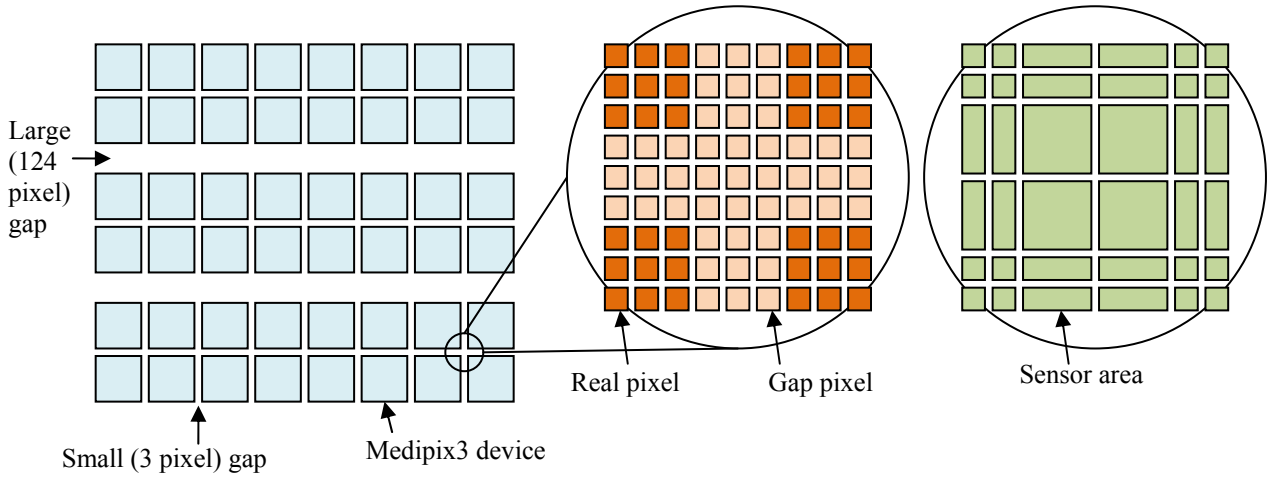

Figure 5. Medipix3 device layout and gap details.

Instrument Calibration

There are many calibration procedures to be undertaken on the instrument to provide the necessary information for correct operation. These include pixel threshold trimming, flat field correction and bad pixel maps. In general, the procedures will be performed by external scripts and will result in calibration files that are loaded onto the instrument and activated at the appropriate time.

SOFTWARE TESTING

The testing of the software was carried out in two phases. The first phase used a software simulation of the hardware with an extensive set of automatic test routines. This provided an automatic record of the testing undertaken and an easy way of repeating the tests at any stage during instrument development.

The second phase was a period of integration and testing with the instrument hardware. This necessarily involved rather more manual intervention and grew as the various parts of the instrument were brought together.

Instrument Simulator

To allow unit testing of the embedded software before the hardware was available, a simulation of the hardware was produced. This consists of three parts, the Medipix3 chip simulation, a FEM simulation and a back door through which the test suite can control the simulation.

The Medipix3 chip simulation is reasonably detailed from a software point of view. It includes the ability to generate pixel data that responds to the settings of the chip's registers in a reasonably appropriate manner.

The FEM simulation is rather simpler. Its main job is getting data into and out of the Medipix3 chips, so many of its functions are invisible to the software.

The simulation connects to the embedded software at a point where the FEM driver library connects to the embedded software proper. This allows the simulation to take the form of a library that is linked in place of the FEM driver library.

Automatic Test Suite

The tests written covered low level Medipix3 register access, configuration management and image frame processing. They were written in Python [9] utilising the PyUnit standard library. Cases are able to control the simulation through its backdoor, allowing both valid and fault conditions to be tested.

CONCLUSIONS

An instrument capable of sustained capture of 2k x 1.5k pixel images at 100 frames per second has been built. This corresponds to a throughput of just over 5Gbps to the Lustre file system in 6 coordinated, parallel data streams.

PC/104 ASYN DRIVERS AT JEFFERSON LAB

J. Yan, T. Allison, S. Witherspoon
Jefferson Lab, Newport News, VA 23606, U.S.A.

Abstract

Asyn Driver was applied for PC/104 IOC serial communication systems at Jefferson Lab. We chose the ines GPIB-PC/104-XL as the GPIB interface module and developed a low lever device driver that is compatible with the asynDriver. Instrument device support was created to provide access to the operating parameters of GPIB devices. A Low level device driver for the serial communication board Model 104-COM-8SM was also developed to run under asynDriver. This serial interface board contains eight independent ports and provides effective RS-485, RS-422 and RS-232 multipoint communication. StreamDevice protocols were applied for the serial communications. The asynDriver in PC/104 IOC applications provides a standard interface between the high level device support and hardware level device drivers. This makes it easy to develop the GPIB and serial communication applications for PC/104 IOCs.

INTRODUCTION

PC/104 embedded IOCs that run RTEMS and EPICS have been applied in many new projects to control all kinds of different devices in Accelerators at Jefferson Lab [1]. Different commercial PC/104 I/O modules on the market such as digital I/O, data acquisition, and communication modules are integrated in our control system. Many devices and instruments are controlled via serial and GPIB communications. With the availability of low cost PC/104 I/O modules, it would be easy to configure these systems. However, device drivers and device support for these new PC/104 I/O modules have to be written under RTEMS and integrated in EPICS system. Solutions that apply EPICS tools and develop the generic drivers for these new modules were researched. asynDriver[2][3] is a general purpose facility for interfacing device specific code to low level communication drivers. It provides a structured environment for developing support for hardware devices both asynchronous and synchronous communications. Since asynDriver provides the EPICS IOC device support, only low-level device drivers for the new I/O modules need to be programmed. This paper presents the selection of PC/104 I/O modules for serial and GPIB communications, the programming of low-level device drivers for these modules, and some samples of applications.

HARDWARE CONFIGURATIONS

The Kontron PC/104 processor board provides two ports, Com1 and Com2, for serial communication. When RTEMS is running, Com1 is configured as the console and Com2 is disabled. Some applications may need RS-232 serial communication, so Com2 can be enabled and configured to provide this function. For some other applications, one PC/104 IOC was required to provide multiple-port serial communications. Therefore, a serial communication board, Model 104-com-8SM, was chosen for this purpose. This serial interface board contains eight independent ports and provides effective RS-485, RS-422 and RS-232 multipoint communication. By setting jumpers on the board, each channel can be configured to any of these modes. A type of XR16L788 octal Universal Asynchronous Receiver and Transmitter (UART) on the board is used as the Asynchronous Communications Element (ACE). A XILINX XCR3256XL Complex Programmable Logic Device (CPLD) is applied to control the XR16L788 chip and communicate with PC/104 ISA bus. Two 40-pin connectors are used for interfacing to communication lines for 8 channels. Figure 1 shows the eight-channel serial communication chassis, where the 104-com-8SM board is stacked on a PC/104 processor module.

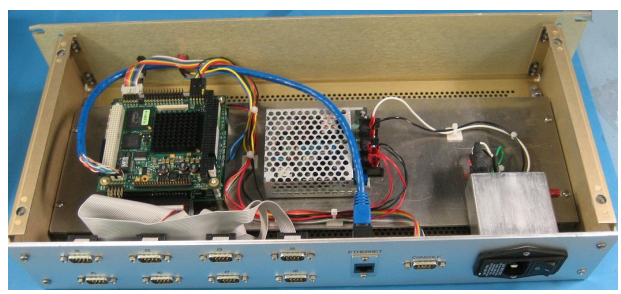

Figure 1: 8-Channel Serial Communication Chassis.

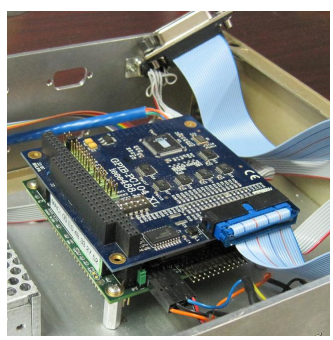

Figure 2: GPIB-PC/104-XL Module Stacked on the PC/104 IOC.

The ines GPIB-PC/104-XL was chosen as the GPIB interface control module for the GIPB communication system. This module has an iGPIB 72110 chip, which provides an interface between a microprocessor system and the GPIB specified in the IEEE Std. 488.1-1087 and 499.2-1987. The iGPIB 72110, a 100-pin TQFP package, is register compatible with NEC uPD7210 in GPIB

Talker/Listener applications. Figure 2 shows the GPIB-PC/104-XL module stacked on a PC/104 processor module through the ISA bus. A 24-pin ribbon cable provides the GPIB interconnects between the interface module and up to 15 GPIB devices.

SOFTWARE DRIVERS

Since the asynDriver provides all components of device support, only the low-level driver needed to be programmed for the new I/O hardware. We wrote drivers for the ines GPIB-PC/104-XL module, 104-com-8SM model, and on-board COM2 port.

On the 104-com-8SM serial module, XR16L788 integrates functions of 8 enhanced 16550 UARTs, a general purpose 16–bit timer/counter and an on-chip oscillator. Device configuration registers include a set of four consecutive interrupt source registers that provides interrupts-status for all 8 UARTs, timer/counter and a sleep wake up indicator. Each UART channel has its own 16550 UART compatible configuration register set for individual channel control, status, and data transfer. The driver was written based on the source code for drvAsynSerialPort.c in the asyn package. However, the register access and interrupt handler are very different between the PC-104/RTEMS and the targeted VME/VxWorks. The structure of the driver can be described as the following:

- Create the structure for ports hardware-specific information.
- Initialize each port.
- Create the IRQ handler for each port
- Create and register asyn port name for each port.
- Set baud rate, parity, bits, stop bit for each serial port.
- Link with higher level routines of asynDriver.

The iGPIB 72110 chip on the GPIB interface module is register-compatible with NEC uPD7210, so the GPIB control interface driver was developed under the specification of uPD7210 registers. The uPD7210 is an intelligent control designed to provide high-level protocol management of the GPIB communication. Control of the uPD7210 is accomplished via 16 internal registers. The driver was programmed based on the file of drvNi1014.c in the asyn package. Here is the structure of the driver:

- Create the port name.
- Set the base I/O address.
- Set the interrupt vector and level.
- Create RTEMS IRQ handler.
- Register the asyn port and connect it with asyn.

All the low-level drivers were compiled as shared library files, so any application can call them.

APPLICATIONS

Most function generators and measurement instrument devices have a GPIB connector. In our new RF control system test stand we have three devices that need to be controlled via GPIB. These devices are CG635 Synthesized clock generator, Agilent E4428C Signal Generator, and Giga-tronics 8540C Universal Power Meter. Figure 3 shows the schematic of the RF control system test stand. For each GPIB device we developed device support according the protocol of asynGpib device support. First of all, we have to determine the set of operations that each device will have to perform. Then we create the device support file for each device and declare the command array. Each command array entry describes the details of a single I/O operation type. Finally, the application database uses the index of the entry in the command array of each file to provide the link between the process variable and the device I/O operation to read or write the value. In this application, CG635 and E4428C mostly require write operation, while 8540C power meters employ reads.

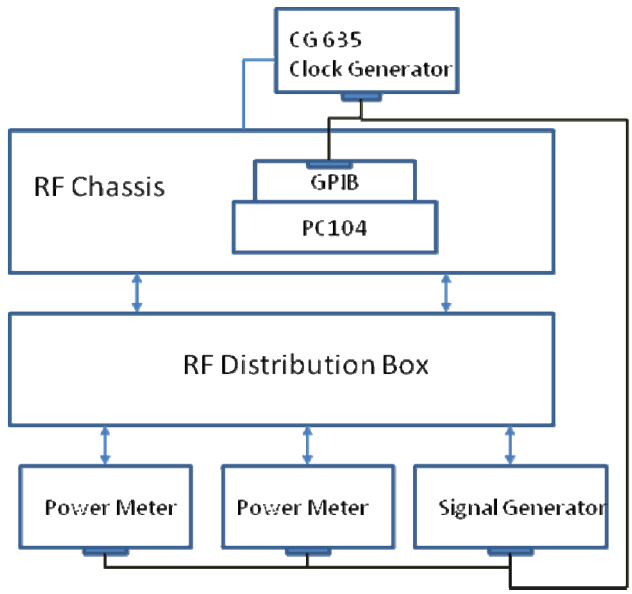

Figure 3: GPIB Communication for RF Control System Test Stand.

Beam Position Monitor (BPM) test stand is a system that calibrates 4-wire BPM cans. This system consists of a 4–channel BPM data acquisition board [4], PC/104 IOC and serial module, two Applied Motion STAC6-Si stepper drives, and a BPM can attached with two HT23-549 stepper motors. The data acquisition board reads the electrical signals from the four (x+, x-, y+, y-) electrodes inside the BPM can. Each stepper motor controls the movement of the BPM can in horizontal (X) or vertical (Y) directions. When the BPM can is moved to a specific position, two serial ports read back the value of the position and the data acquisition board would simultaneously sample the electrical signals from four antennas inside the BPM can. Stepper motors are controlled by writing and reading a set of commands to the stepper drivers. *StreamDevice* [5] is applied as the device support for controlling stepper drivers.

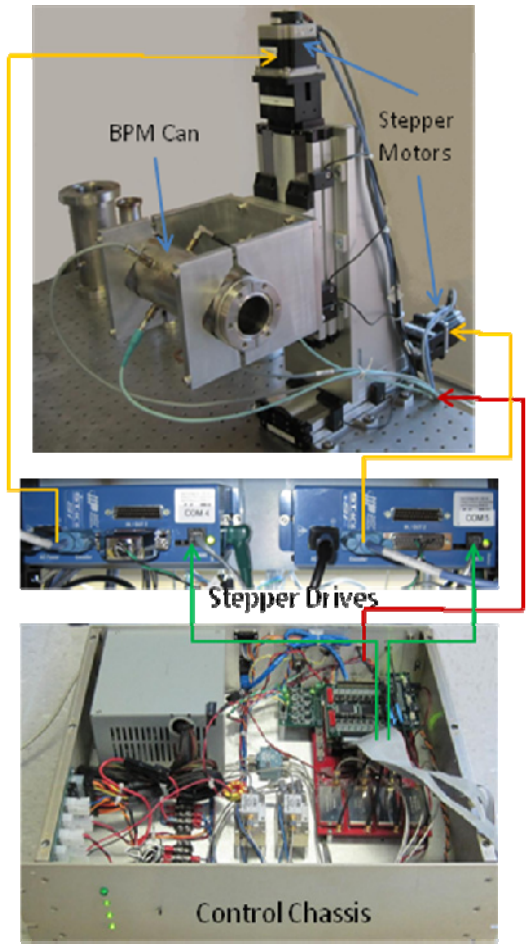

Figure 4: BPM Test Stand Stepper Motor Control System.

StreamDevice is a generic EPICS device support for devices with a "byte stream" based communication interface, such as RS-232, RS-485, GPIB, and telnet-like TCP/IP. It can be configured for any device type with protocol files in plain ASCII text which describes the commands a device understands and the replies it sends. In this application, each stepper drive has one specific protocol file that defines the commands to communicate between the device and database records. Each record with *StreamDevice* support runs a command from the protocol file to read or write its value. The advantages of *StreamDevice* are the ease to configure commands to run devices and the support for all standard record types in EPICS base which have device support.

CONCLUSIONS

Asyn driver has been applied as generic device support for the embedded PC/104 IOCs that run RTEMS and EPICS. The low level drivers for a GPIB interface module and 8-channel serial communication module were developed to be compatible with the asyn toolkit. A number of applications have been written to use the PC/104 asyn driver in our control system at Jefferson Lab. The asyn driver provided an easy integrated solution for PC/104 serial communication applications.

ACKNOWLEDGEMENT

Thanks to the Instrument and Control group and Software group in Jefferson Lab for their technical support.

RECENT DEVELOPMENTS IN SYNCHRONISED MOTION CONTROL AT DIAMOND LIGHT SOURCE

B. Nutter, T. Cobb, M. Pearson, N. Rees, F. Yuan, Diamond Light Source, Oxfordshire, UK

Abstract

At Diamond Light Source the Experimental Physics and Industrial Control System (EPICS) [1] is used with a variety of motion controllers. The use of EPICS ensures a common interface over a range of motorised applications. We have developed a system to enable the use of the same interface for synchronised motion over multiple axes using the Delta Tau Programmable Multi Axis Controller (PMAC). Details of this work will be presented, along with an example and possible future developments.

INTRODUCTION

Diamond Light Source is host to around twenty operational X-ray beamlines, each of which has various motorised devices in order to control and focus X-ray photons. These devices range from simple diagnostics and attenuators, to mirrors and double crystal monochromators, and complex multi-axis diffractometers and hexapod systems. There can be well over one hundred motors on a photon beamline, from simple stepper motors to servo motors, piezo motors and nano motors.

The control of motors is accomplished by using dedicated motor controllers that typically operate a servo control loop and amplifier for each axis. On top of this we have motor control software that sends commands to the controllers and reads back status information. At the highest level we make use of the EPICS control system and the Generic Data Acquisition (GDA) scientific framework [2] to provide a consistent user interface to each type of motor.

In addition to the standard control of each axis we perform synchronised motion on multiple axes. We do this at various levels, such as sending simultaneous move commands from the high level software, or defining a co-ordinate system at the motor controller level (which lets us achieve true synchronised motion).

MOTION CONTROL HARDWARE IN USE AT DIAMOND

Diamond Phase I beamlines use the Delta Tau Turbo PMAC 2 VME Ultralight motor controller. This is a 32-axis controller which sits inside a VME crate alongside a CPU card running VxWorks and EPICS. The Ultralight controller uses a fibre optic communication link to two 16-axis Universal Motion and Automation Controller (UMAC) units, which in turn interface to limit switches, encoders and external amplifier crates.

At the end of Phase I Diamond underwent a tender process for Phase II beamline motion controllers. It was determined that the use of Ethernet-based controllers would be a more flexible and economic alternative than the traditional VME-based controller. The controller we chose was the Delta Tau Geobrick Low Voltage Integrated Motion System (LV IMS). This is a Turbo PMAC 2 controller in a 4U enclosure, with an integrated amplifier board. The amplifier board has 4 or 8 axes of output, each of which can be configured in software to be either a stepper or a servo amplifier. This made it possible not only to control DC stepper motors, with various encoder feedback mechanisms, but also to control brushless and DC servo motors. Step and direction outputs are also available to control pico motors and ultra-high resolution external stepper amplifiers.

The product has suffered somewhat from early design teething troubles, mainly concerning the amplifier firmware. However, all solutions to date have been compatible with the existing hardware platform. We are also seeing an increasing number of very small motors, typically below 500mA, and the current resolution of the Geobrick amplifiers (which are rated at 5A continuous, 15A peak, but have a zero current set point accuracy of nearly 100mA) is becoming an issue.

Diamond has a number of other motor controllers on site. These include the Newport XPS controller, mainly used on Newport diffractometers, and a small number of Aerotech Ensemble controllers, required to take advantage of the smoothness and precision of their inbuilt linear amplifier stages. We also have many piezo stack control devices from Queensgate, PI and Jena, which are controlled by either analogue signals or RS232.

EPICS MOTOR CONTROL SOFTWARE

For each specific motor controller there is a software driver based on the Asyn software framework [3]. Asyn is a low-level driver software abstraction framework, providing synchronous and asynchronous commands and responses. The drivers are either developed in house (normally building on the work of similar drivers) or use is made of drivers developed elsewhere. Above these drivers is a consistent user interface in the form of an EPICS record, called the Motor Record. This provides the user with functions such as *move*, *stop*, *home*, etc., as well as support for modifying the motion properties such as velocity or acceleration. The EPICS Motor Record is documented in full at [4].

The Asyn-based motor driver framework that sits underneath the EPICS motor record has been developed by Diamond and the Advanced Photon Source, and has been previously been presented [5]. The advantages that the driver framework gives us are mainly the ease of adding new drivers for new controllers, the ability to use multiple EPICS records to control a motor and its

parameters and the ability to monitor a motor status asynchronously (by using an event driven polling thread).

GDA SOFTWARE INTERFACE TO EPICS MOTOR SOFTWARE

The GDA is a data acquisition system developed at Diamond to provide a user interface and experiment platform for Diamond beamline users. It has a client-server architecture and includes support for the EPICS channel access protocol. A Java implementation of the EPICS channel access protocol, called Channel Access for Java (CAJ) [6], is used to provide both synchronous and asynchronous communication with EPICS. When configuring the GDA for a beamline, the EPICS motor record name is obtained dynamically from an EPICS-GDA interface XML file, generated during EPICS build and deployment, to ensure consistency between the two systems.

Motor objects in GDA are designed to be in state synchronisation with the underlying EPICS motor record to support the simultaneous use of GDA and EDM (an EPICS-aware Motif-based graphical toolkit called Extensible Display Manager [7]). Access control of EPICS motors is also supported, and can be used to restrict access to particular devices such as insertion devices or front end motors.

Beamline users normally collect data and access EPICS motors using the GDA scan mechanism. This is a very flexible framework capable of capturing a complete data set in experiments, including metadata such as beam conditions and sample environments. It allows users to move motors in multiple dimensions, typically from a start position to an end position in predefined steps, and to collect arbitrary data during a scan.

COORDINATED MOTION SOFTWARE

We have been able to achieve co-ordinated multi axis motion in several ways:

- Sending simultaneous move commands to multiple axes at a high level, using GDA to control multiple motor records. An example of this is slit scanning, where the GDA performs its own calculations for slit gap and centre positions. This is achieved by creating a GDA object to represent the combined motor axes. The object can then be used by the GDA scan mechanism.
- Sending simultaneous move commands to multiple axes at the EPICS level. A set of EPICS records work together to calculate combined motion and send the move commands one-by-one to the motor records. This is similar to the GDA-based mechanism, except in this case the GDA only knows about one EPICS motor record, for example a slit gap 'motor'.
- Using 'deferred moves'. This is a technique that involves the driver queuing up move commands and sending them all at once to the motor controller. This technique is useful if one is attempting to move multiple axes that are 'grouped' together on the motor controller itself. When axes are grouped together, an axis can go into the 'moving' state when we are actually only moving a different axis. This causes an issue when using the EPICS motor record and attempting to drive two axes by sending separate commands, because, to avoid ambiguity, EPICS needs the motor to be idle before the move starts if the client also wants to be notified asynchronously of the move completion. In effect, the motor record does not permit a move to be sent while an axis is already in motion (unless the previous move is stopped first). Deferred moves are a way around this issue, and provide a greater degree of move synchronisation than can be achieved by using high level software alone.
- Making use of the coordinated motion capabilities of the controller, and defining a 'coordinate system' for multiple axes.

We will expand on the 4th option. On the PMAC controller, this method involves setting up the axes in a co-ordinate system, which means defining forward and inverse kinematic calculations and defining a PMAC PLC program to provide combined axis position read-back. An example for a pair of slits is shown in Figure 1.

```
&2
#1->I
#2->I
OPEN FORWARD
CLEAR
Q1=(P1+P2)/2
Q2=P1-P2
CLOSE

OPEN INVERSE
CLEAR
P1=Q1+Q2/2
P2=Q1-Q2/2
CLOSE
```

Figure 1: PMAC forward and inverse kinematics.

In Figure 1 the notation &2 defines co-ordinate system number 2, and the #1->I means that axis 1 will be placed in that co-ordinate system. The Q1 and Q2 variables are from the PMAC 'Q-variable' range on the PMAC which have co-ordinate system scope. Here we are using Q1 and Q2 to represent the combined motion. P1 and P2 are used to represent the real axis position, based on the forward kinematics. We also need to define a PLC program to calculate the real combined motion positions, and this is used for position read-back by the EPICS driver.

```
OPEN PLC 2
CLEAR
Q81= (m162 + m262)/2  ;real center
Q82= (m162 - m262)    ;real gap size
CLOSE
```

Figure 2: Position readback PMAC PLC program.

In Figure 2 we are using Q81 and Q82 to hold the combined motion positions, calculated from the actual motor positions held by the PMAC (which are the mX62 variable, where the X is the axis number). In the above examples we have omitted scale factors, which are required to convert to and from engineering units and PMAC position 'counts'. We need to define a PLC program such as this in order to provide real combined axis position read-back, because the P1 and P2 variables are specific to the kinematic buffer.

Finally, there is also a PMAC motion program, which is executed whenever a combined motion command is sent to the controller. The motion program then makes use of the co-ordinate system, which we defined above.

The EPICS driver for the PMAC has been modified to support the functionality we have described above. There is a coordinate system driver that writes combined motion demand values into Q-variables on the PMAC and executes the motion program on the PMAC. It also reads the Q-variables from the PLC program in order to obtain the position for the combined axes.

This is implemented in the EPICS co-ordinate driver in the motorAxisMove function. It is accomplished by sending three commands to the controller:

- Write new demand values into the appropriate Q-variables for the coordinate system
- Abort the current move (to ensure that the axes are enabled)
- Run the motion program

In the co-ordinate system driver there is a separate thread which polls the actual combined motion axis positions (provided by the PLC program described above). This provides continuous position updates to the motor record, at a configurable rate (typically 10 or 20Hz).

The EPICS coordinate system driver fits into the same asyn motor framework as the existing drivers, and so can be used with the same EPICS motor record code. This means that we have a consistent user interface to both real axes and combined coordinated axes. The PMAC co-ordinate system driver is packaged with the tpmac EPICS support module [8], or is available stand-alone as the pmacAsynCoord module.

DIAMOND STANDARDS FOR DELTA TAU PMAC DEVELOPMENT

The coordinated PMAC driver does make some assumptions about how the PMAC co-ordinate system has been set up. For example, it assumes that the PLC read-back positions will be stored in the variables Q81 to Q89. In order to ensure that PMAC software development is kept in sync with the EPICS driver we developed a set of PMAC programming standards, both for co-ordinate systems and general purpose PMAC PLC programs. These programming guidelines have been written down and we routinely forward them onto equipment suppliers who develop PMAC motion control systems for us. They also serve as a useful guide within the group when we develop new PMAC software. We hope that these standards will be useful to other EPICS sites that are using PMAC controllers, as this will ensure the PMAC co-ordinate system driver will be applicable outside Diamond.

A selection of the standards we have developed is described here. First, we list the reserved PLC program numbers and their intended use in Fig.3.

PLC1	initialization routines
PLC2	motion stop detection
PLC3	amplifier enable routine
PLC4	encoder loss detection
PLC5	CPU use reporting
PLC6	amplifier setup
PLC7	auto amplifier power off

Figure 3: Reserved PLC numbers and their function.

PLCs 8 to 16 are free for application-specific code and PLCs 17 to 31 are reserved for co-ordinate system position reporting (as described in this paper). In order to avoid conflicts PLCxx (where xx is the PLC number) should only use PMAC P-variables (which have global scope) in the Pxx00 to Pxx99 range.

Motion programs and co-ordinate systems should use Q-variables where possible, and only use P-variables in the range P3200 to P4200 (to avoid conflicting with PLC programs). For co-ordinate systems we reserve the following Q-variable ranges:

- Q71 to Q79 – co-ordinate system demand positions.
- Q81 to Q89 – co-ordinate system readback positions (these are the positions calculated by the position reporting PLC program).
- Q400 to Q439 – backlash compensation settings in coordinate systems.

In addition to the above, Delta Tau reserve various variable ranges for their own use. We also document various PMAC programming guidelines, such as best practice for developing a homing PLC program. For example it is bad practice to disable limit switches during a homing program, in case the program fails and therefore fails to re-enable the limit switches.

CONCLUSION AND FUTURE DEVELOPMENTS

Significant progress has been made with the new Delta Tau Geobrick controller on the final Phase II beamlines. On most beamlines we have deployed PMAC co-ordinate systems to drive combined motion systems such as mirrors and slits. We have found this to be very reliable and to provide true synchronised motion at the controller level.

Further work is planned on the EPICS PMAC driver to provide support for trajectory scanning. Eventually we are aiming to have a consistent trajectory scanning interface that is controller- and driver-independent, similar to the existing abstract interface that the motor record provides for standard axis motion.

Abstract

The installation of ITER-relevant materials for the Plasma Facing Components (PFCs) in the Joint European Torus (JET) is expected to have a strong impact on the operation and protection of the experiment. In particular, the use of all-beryllium tiles, which deteriorate at a substantially lower temperature than the formerly installed Carbon Fibre Composite (CFC) tiles, imposes strict thermal restrictions on the PFCs during operation. Prompt and precise responses are therefore required whenever anomalous temperatures are detected.

The new Vessel Thermal Map (VTM) real-time application collects the temperature measurements provided by dedicated pyrometers and Infra-Red (IR) cameras, groups them according to spatial location and probable offending heat source and raises alarms that will trigger appropriate protective responses. In the context of JETs global scheme for the protection of the new wall, the system is required to run on a 10 millisecond cycle communicating with other systems through the Real-Time Data Network (RTDN).

In order to meet these requirements a Commercial Off-The-Shelf (COTS) solution has been adopted based on standard x86 multi-core technology, Linux and the Multi-threaded Application Real-Time executor (MARTe) software framework. This paper presents an overview of the system with particular technical focus on the configuration of its real-time capability and the benefits of the modular development approach and advanced tools provided by the MARTe framework.

INTRODUCTION

As the fusion scientific community steers their efforts towards the operation of the ITER tokamak, JET aims to provide an important contribution as it will operate with similar PFC materials. In particular, demonstrating the predicted reduction of the tritium retention levels when compared with the previous CFC-based wall[1]. JET's new all metal wall surface made of solid beryllium, tungsten and tungsten coated CFC is much less robust than the previous one therefore raising serious challenges in high power operational conditions.

The Protection of the ITER-like Wall (PIW) project was launched with the aim of providing the necessary tools to ensure the integrity of the vessel during JET's scientific campaigns. These include a set of 13 IR cameras and 9 pyrometer diagnostics that, together with their real-time image processing systems[2], provide the temperatures of PFCs.

The VTM collects these temperature measurements, groups them according to spatial location and probable offending heat source, and raises alarms that trigger the appropriate protective responses coordinated by the Real-Time Protection Sequencer[3] (RTPS) system, see Figure 1. RTPS drives the Local Managers (LM) for all of JET's non-inductive heating systems: Lower Hybrid (LH), Radio Frequency (RF) and Neutral Beam (NB), the Plasma Density Local Manager (PDLM) and the Plasma Position and Current Control (PPCC) system.

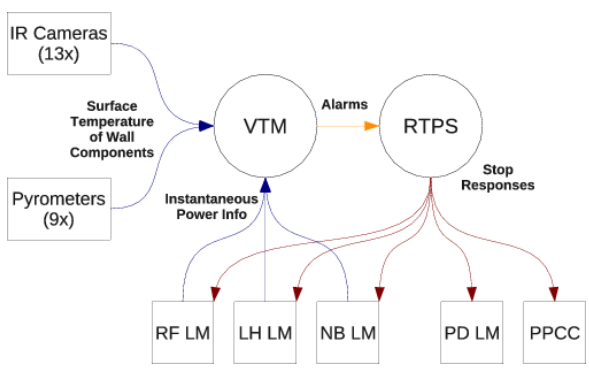

Figure 1: VTM in the context of the PIW project.

VTM FUNCTIONAL OVERVIEW

Temperature measurements of physical tile groups are processed by the VTM in macro sets called Logical Tiles (LTs). These macro sets take advantage of toroidal symmetry to establish the equivalence of temperature measurements that share the same poloidal position although taken at different toroidal locations. This feature allows for different camera views that, although not "looking at" particular physical tiles, monitor "equivalent" ones. Also, in case of measurement loss (e.g. when a camera fails in the middle of an experiment), VTM checks to see if the minimum amount of measurements for each LT is still fulfilled and, if so, the experiment proceeds without significant risk to the machine. After checking the validity of temperature measurements, VTM estimates LT temperatures as the maximum of all temperature measurements within the set.

At a higher level, sets of LTs are grouped into *Wall Segments* (WSs). Similar to the LT estimated temperature, the WS temperature is defined as the maximum of all LT temperatures within the set. Alarm triggering temperature thresholds are placed on WS estimated temperatures. VTM has the capability of processing a maximum number of 60 WSs (30 fixed and 30 user-definable) and more than 400 tiles.

Figure 3 shows part VTM's expert graphical user interface where WS related quantities and the mapping between physical and logical tiles are controlled.

The system was specified to run at 100 Hz, twice the frequency of the real-time image processing units' temperature outputs and its real-time I/O was specified to be performed solely via the ATM-based RTDN[4].

HARDWARE

Because of its technical specifications, and after considering other options such as VxWorks® and VME (VV) or RTAI and ATCA (RA), VTM was chosen to be implemented on a standard 4GB x86 multicore (6 cores) Linux-based PC with a PCI Gb ethernet Network Interface Card (NIC) and a PCI ATM NIC. Despite JET's long history of implementing the VV combination for real-time systems and the recent success of using the RA combination for the new Vertical Stabilisation system, the chosen path proved advantageous in terms of cost, development effort, debugging tools availability and with support within the Linux and MARTe's community.

SOFTWARE

The VTM system was built using the MARTe real-time framework[5] on a multicore vanilla (2.6.35.9) Linux platform. Real-Time performance with a traditionally non real-time operating system is achieved by configuring cpu isolation in terms of processes, threads and Interrupt ReQuest (IRQ) affinities, see Table 1.

The synchronization of the VTM system with JET's central timing is done via the RTDN. Central timing is read by the Real-Time General Services (RTGS) system directly from a VME electronics module and made available to the network. VTM not only time stamps its internal data using this clock but also triggers its own "control" cycle on the arrival of this ATM packet. Preliminary results show that worst case jitters of less than 50 μs on RTGS are propagated to worse case jitters of less than 100 μs on the VTM, see Figure 2.

Table 1: CPU Affinities

CPU #	Task
0	Linux & MARTe services
1	ATM IRQs
2	ATM synch Rx thread
3	ATM Rx threads
4	ATM Rx threads
5	Real-Time thread

Lab tests were performed using the available Linux kernel's real-time patch but those showed no performance improvements when compared to the above mentioned configuration.

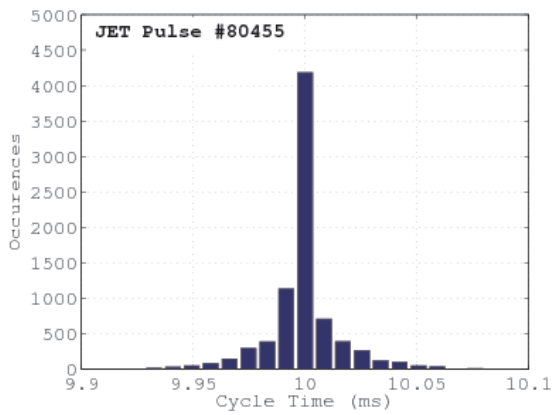

Figure 2: VTM Cycle Time.

Furthermore, the VTM system receives a total of 19 ATM packets in real-time (13 packets from cameras, 2 from pyrometers, 3 from additional heating systems plus the synchronization packet). A standard Linux (kernel module) ATM low-level driver is used together with a (user space) MARTe thread-based high-level driver socket implementation for receiving.

The system has been configured to boot remotely using the *tftp* protocol and mount its file system using NFS. These approaches attempt to make the VTM more resilient to hardware faults.

MARTe is a multi-platform framework for the development and deployment of data-driven, flexible and modular real-time applications. It is based on a real-time oriented C++ library called BaseLib2. It currently supports the VxWorks®, Linux, Linux/RTAI®, Solaris® and Windows® operating systems. Ideally, and assuming the

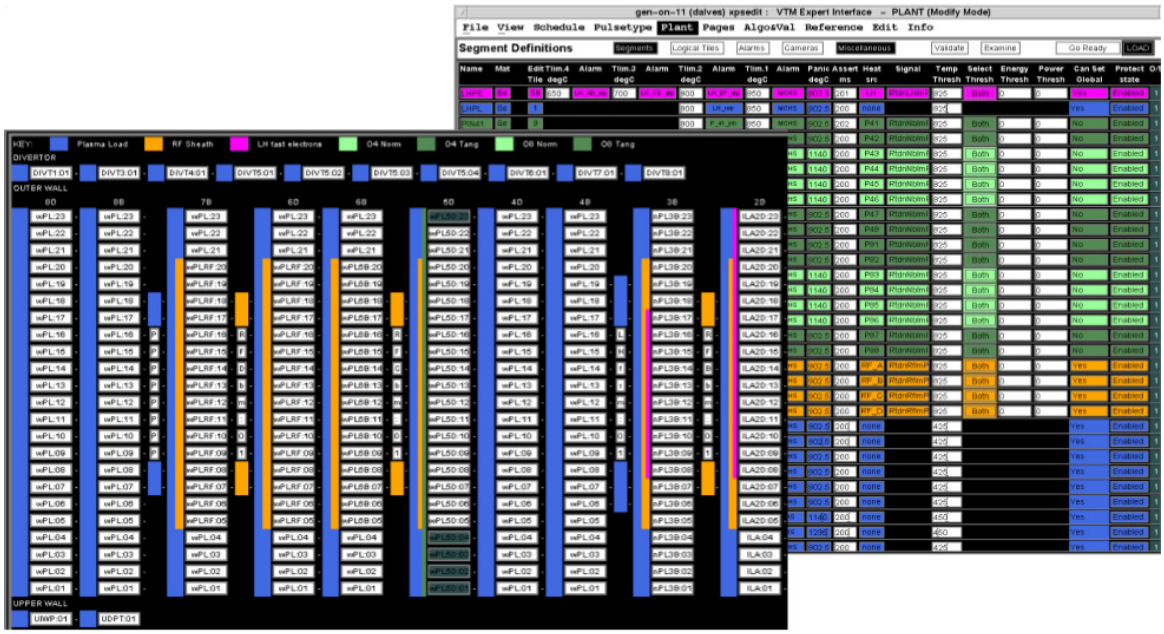

Figure 3: VTM Expert Graphical User Interface.

required hardware components are supported, the developer is only required to write the pieces of software dealing with the logic/algorithmic aspects specific to the control application itself.

MARTe, from the user point of view, is primarily a sequential executor of *Generic Application Modules* (GAMs) in a real-time priority context. MARTe also defines standard high-level interfaces for various activities including driver I/O, http display and messaging. It provides a configurable internal state machine which, in the case of the VTM, is driven remotely by JET's global state machine. According to its current state, the appropriate list of GAMs is executed. Deeply embedded in MARTe's philosophy is the idea that GAMs should not be aware of one another and would perform specific and self-contained tasks communicating with each other exclusively by writing signals to and reading signals from the *Dynamic Data Buffer* (DDB). This buffer is basically a signal pool with a standard access interface. MARTe also contains a driver pool of high-level interfaces for common (and/or maybe less common user implementable) activities, e.g., I/O. Finally, the External Time Triggering Service (ETTS) is the entity that unleashes the execution of the GAMs. It can either be interrupt driven or polling a specific event. Figure 4 shows not only some of MARTe's architecture but also the specific VTM GAMs:

ATM Synch input GAM - is unblocked by the ETTS on the arrival of the ATM synch packet every 10 ms;

ATM input GAMs - make the ATM packets' data available as DDB signals;

Digital Filter GAM - filters DDB signals;

Logical Tile GAM - estimates LT temperatures based on the measurements;

Wall Segment GAM - estimates WS temperatures based on LT temperatures;

Alarm GAM - issues alarms based on WS temperatures and thresholds;

Event GAM - records and displays alarm events;

ATM output GAMs - output the alarms and WS temperatures to the RTDN;

Data Collection GAM - record DDB signals to be collected for posterity;

Web Statistics GAM - http display of DDB signal statistics.

To provide a convenient and intuitive real-time display of the vessel temperature map, an Ajax based http service (see Figure 5) has been developed. Planar images of both JET's inner and outer wall are used as canvas for painting each LTs' temperature using the color code indicated at the bottom of the Figure. This service has been tested with a single browser client polling at 4 Hz and no impact was observed in the system's real-time performance.

PRELIMINARY RESULTS

As a proof of concept, dedicated plasma pulses were performed to test the end-to-end response of PIW's protection apparatus. Simulated camera measurements based on visible light were provided to the VTM and reference pulses were used to place VTM's alarm triggering temperature thresholds at convenient levels. Figure 6 illustrates the achievement of pulse 80455 where a Divertor Hot-Spot (DHS) was detected by the VTM at the bottom of the machine and the correspondent alarm triggered the appropriate predefined PPCC response moving the plasma current's

centroid upwards and reducing the gap between the plasma boundary and the top of the vessel.

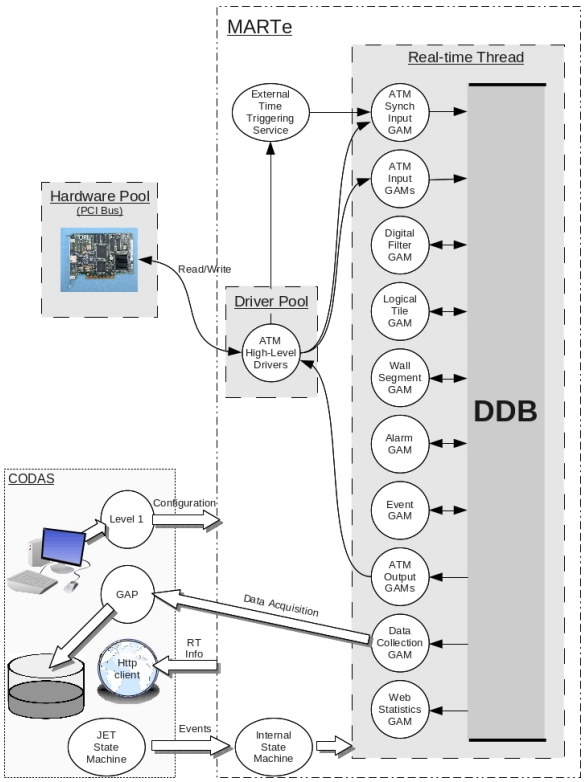

Figure 4: VTM MARTe.

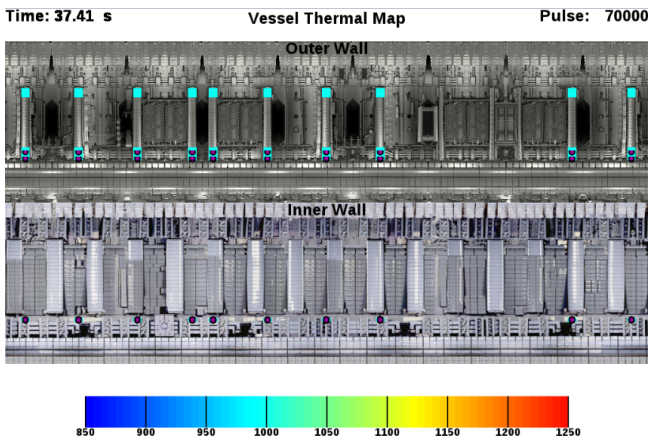

Figure 5: Real-Time temperature map display - http/ajax based polling @ 4 Hz without compromising real-time performance.

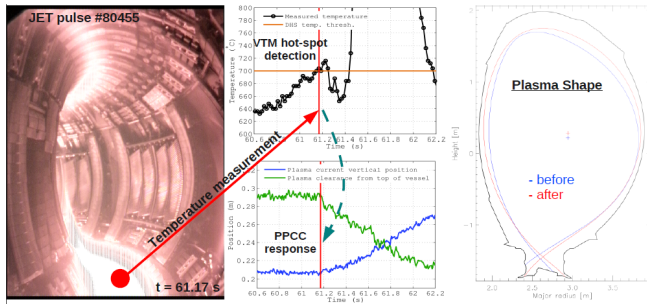

Figure 6: Preliminary results - upon the detection of a thermal event, VTM signaled RTPS, which in turn drove PPCC into a new plasma shape and position.

CONCLUSIONS

The VTM has been demonstrated to perform the role it was designed for in the context of the PIW project. The non traditional configuration of its real-time capability, using a plain Linux vanilla kernel together with the user-space MARTe-based implementation makes it an interesting proof that with little effort it is possible to have an application meeting real-time requirements. Its Ajax-based visual temperature monitoring service with no impact in real-time performance takes this matter to an even higher level demonstrating the potential of the multicore approach.

In the near future this system will be part of the standard machine protection ensemble fundamental to JET operations.

TIMING SYSTEM SOLUTION FOR MEDAUSTRON; REAL-TIME EVENT AND DATA DISTRIBUTION NETWORK

R. Štefanič, R. Tavčar, J. Dedič, Cosylab, Ljubljana, Slovenia
J. Gutleber, CERN, Geneva, Switzerland
R. Moser, EBG MedAustron, Wr. Neustadt, Austri

Abstract

MedAustron is an ion beam research and therapy centre under construction in Wiener Neustadt, Austria. The facility features a synchrotron particle accelerator for light ions. The timing system for this class of accelerators has been developed in close collaboration between MedAustron and Cosylab.

Mitigating economical and technological risks, we have chosen a proven, widely used Micro Research Finland (MRF) timing equipment and redesigned its FPGA firmware, extending its high-logic services above transport layer, as required by machine specifics. We obtained a generic real-time broadcast network for coordinating actions of a compact, pulse-to-pulse modulation based particle accelerator. High-level services include support for virtual accelerators and a rich selection of event response mechanisms. The system uses a combination of a real-time link for downstream events and a non-real-time link for upstream messaging and non time-critical communication. It comes with National Instruments LabVIEW-based software support, ready to be integrated into PXIe based front-end controllers.

This article explains the high level logic services provided by the real-time link, describes the non-real-time interfaces and presents the software configuration mechanisms.

ABOUT MEDAUSTRON

MedAustron [1, 2] is intended for research and clinical therapy applications. Its synchrotron-based accelerator will have 3-5 ion sources (protons, carbon ions and possibly other light ions) and 5 beamlines, one of which is a rotating gantry. It will provide ion beams with energies up to 800MeV to several irradiation stations used for different purposes. Development follows defined processes and quality management standards. Among the development goals is to use commercially available components where possible to minimize the technological and economical risks. The machine will serve as a blueprint for further applications. Accelerator layout is shown in Figure 1.

TECHNOLOGY CHOICE FOR MEDAUSTRON TIMING SYSTEM HW

No out-of-the box timing system solution exists yet for MedAustron's type of accelerators. The key requirements for the timing system are a deterministic network protocol for real-time operation, reliable event/data distribution and fast response times from the timing system master to all (about 300) controlled devices. It must provide 1µs real-time control loop resolution, 100 ns timestamp resolution and support for 250.000 different accelerator cycles.

When approaching timing system design, we examined the possibilities of reusing existing technology and Micro Research Finland (MRF) [3] proved the most suitable. It is designed for more demanding light-source accelerators and satisfies MedAustron synchronization requirements well. What it lacks is the required higher-level logic and a generic accelerator timing system application. We therefore decided to keep MRF's widely used and proven timing transport layer and build the high level logic application on top in its FPGA firmware. As MedAustron Control System (MACS) software will run on National Instruments' PXIe controllers, we will develop MRF cards in PXIe form factor.

An important part of the timing system is the software support which is fully integrated into MedAustron Control System (MACS). The software provides flexible mechanisms for configuration, control and supervision of the timing system. It is implemented within MedAustron's Front End Control System (FECOS) software framework, developed in LabVIEW, also in close collaboration between MedAustron and Cosylab. The framework is compatible with LabVIEW Real-Time operating system, allowing implementation of both non-real-time and real-time device support applications (i.e. FECOS components).

Reusing the MRF timing transport layer for timing system design enabled us to deal with machine specifics and focus more on integration aspects of the design, which is often an underestimated and overlooked part of timing system development.

TIMING SYSTEM OVERVIEW

MedAustron Timing System, called the Real-time Event Distribution Network (REDNET) comprises a real-time and a non-real-time link. The real-time link is based on MRF transport layer and custom logic in FPGA, whereas the non-real-time link is based on Gigabit Ethernet.

The real-time network topology is the same as original MRF: one Event Generator (EVG) and multiple Event Receivers (EVR), connected in tree topology with multiple fanout layers. Each card is located in a PXI crate

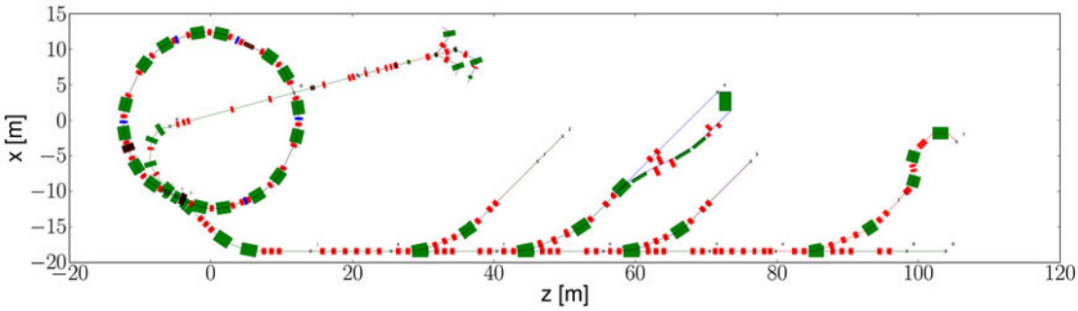

Figure 1: Accelerator layout with injection chain, extraction line and transport lines.

with the PXI controller running support software. The combination of an EVG (or EVR) card with its support software is called the Main Timing Generator (MTG); or Main Timing Receiver (MTR), respectively. The timing system will control about 300 devices, but EVR's sophisticated I/O mechanisms lower the number of required EVRs. Support software provides access to configuration and control to the supervisory control system and triggers transmission of traffic over both the real-time and the non-real-time interface.

The configuration of MTG and MTRs is done by the supervisory control system via a non real-time supervisory interface.

HIGH LEVEL SERVICES OF TIMING SYSTEM REAL-TIME INTERFACE

The following subsections describe the timing system's main services. Richness of logic in communication and event response mechanisms also illustrates specific requirements of MedAustron accelerator class.

Event Response Mechanisms

The timing receiver offers multiple possibilities of controlling its neighbouring cards via numerous hardware connections and via software IRQs. Through LabVIEW API, the user can easily configure the Event Receiver to:

- trigger external devices (via TTL, fibre optic, etc.)
- trigger PXI/PXIe neighbouring cards (via star trigger bus)
- provide neighbouring cards with real-time data (via trigger bus)
- provide SW applications with IRQs and real-time data
- provide delayed, inverted or otherwise "post-shaped" response to timing events (e.g. for fine tuning of synchrotron injection synchronization down to 5 ns resolution)

All types of subscriptions to different events can be used by the same application.

Virtual Accelerator (VAcc) Support

Timing events are scheduled in 5 separate, concurrently usable execution slots (ES), providing concurrently running virtual accelerator functionality. The concept enables users to program individual accelerators as if they were separate, each of them having its own execution configuration. However, timing events of all VAccs are piped through the same serial link (fibre optic), where prioritization takes place in case events are scheduled for emission at the very same moment. Receivers can be linked to any combination of these VAccs and event responses for different ES can be configured separately.

This feature will enable commissioning of different parts of accelerator (e.g. ion sources) at the same time independently, reducing commissioning time immensely. During machine use, it will provide a safe, controllable way of experimenting with new accelerator settings.

Commands

Commands are an extended concept of timing events, also providing data payload, which makes them very useful for distributing near-real-time information. They are implemented using the concept of pipes, additionally abstracting the communication channel to make it even easier to use. Commands have the lowest priority.

Heartbeat Event and Time Service

Along with emission of timing events defined in a sequence, the MTG also provides a unique heartbeat event emitted independently of any other traffic. Its emission range is configurable, ranging from 0.5Hz to 50Hz. Receiver response to the heartbeat event is fully configurable. This functionality is used to operate the injector in temperature stabilized mode.

The time service mechanism provides a transparent way of distributing current time to all receivers.

Real-Time Traffic Prioritization Scheme

Figure 2 explains the prioritization of different real-time traffic and offers an insight into the mechanisms implemented inside EVG FPGA firmware. All emission mechanisms are conveniently configurable through LabVIEW API. The figure shows that among the 5 ES, one has top priority over all other traffic. Next is the heartbeat event, then the other 4 ES, followed by asynchronous user events and commands.

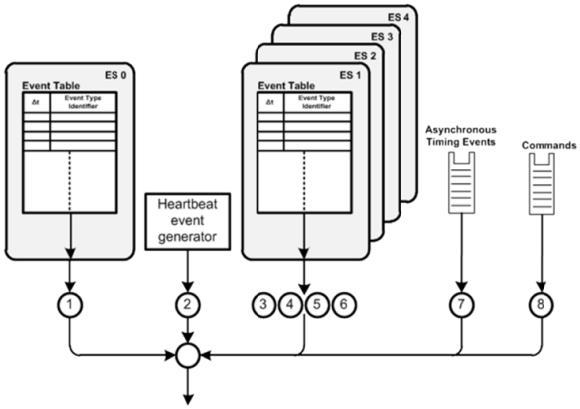

Figure 2: Message prioritization scheme.

Synchronization Parameters

Table 1 shows the timing characteristics of the event emission mechanism.

Timing events can be scheduled with the granularity of 1µs, meaning that every µs, events from all 5 execution slots and the heartbeat event can be scheduled for emission. In such case, fixed prioritization occurs, as shown in Figure 2. At reception, events are time-stamped with 100 ns resolution. These timing characteristics satisfy MedAustron timing system requirements, which strongly guided the system design. The underlying MRF transport layer greatly exceeds this synchronization performance.

Table 1: Timing System Synchronization Parameters

Event Emission Granularity	1µs
Timestamp Resolution	100 ns

NON-REAL-TIME INTERFACE AND SOFTWARE CONFIGURATION

There are two main messaging services implemented for the non-real-time interface. Both are based on National Instruments Simple TCP/IP Messaging (STM), extending its functionality to serve our specific needs.

Simple Messaging Mechanism (SIM)

This is a simple enhancement of STM. It provides the interface to the PVSS-based supervisory control system, which uses it for execution control and configuration of accelerator cycles by issuing requests to the MTG, moving it through the cycle generation process.

Publish- Subscribe Service

Built upon the SIM interface, the Publish-Subscribe Service provides enriched messaging mechanisms for communication between all software support components across the non-real-time network. MTG publishes commands via this interface to all "slow" devices without requirements for deterministic operation. One of the mechanisms based on this service is acknowledgement of commands; for monitoring the system integrity during operation, all commands received by relevant devices via real-time and/or non-real-time interface must be acknowledged via the Publish-Subscribe interface. The MTG denies service if any acknowledgements fail to arrive. The Publish-Subscribe service can freely be used for non-real-time communication between device-specific software components within FECOS.

Configuration of Software Components

Configuration of all FECOS components is provided in XML files, providing startup and operation parameters, process variable locations and any other user-defined information. In fact, all structurally rich information is distributed to and among components in standard XML format. This information includes accelerator sequence definitions used by the MTG and timing event response configurations used by the EVR.

Process variables for online configuration and monitoring of end devices are implemented via LabVIEW's shared variable engine and connected via OLE for Process Control (OPC) to the PVSS-based SCADA server of the supervisory interface.

CONCLUSION

By using the off-the-shelf product from MRF and building the machine specific real-time application on top of its already widely used and stable transmission layer, the overall design time can be greatly reduced. The design effort can thus be strongly focused on specifics of the machine itself and not on the timing distribution layer, which has already been successfully addressed multiple times before. The total time from requirements to the working system was less than 2 years. This design approach is the way to achieve precise, but versatile solutions able to cope with complex use cases of different machines.

The control system software framework provides developers with flexible communication and configuration mechanisms. It also provides a generic component structure which readily integrates into the control system framework and allows the device support developer to focus mainly on the implementation of device-specific application, speeding up the development process.

SYNCHRONOUSLY DRIVEN POWER CONVERTER CONTROLLER SOLUTION FOR MEDAUSTRON

Luka Šepetavc, Jože Dedič, Rok Tavčar, Cosylab, Ljubljana, Slovenia
Johannes Gutleber, CERN, Geneva, Switzerland
Roland Moser, EBG MedAustron, Wr. Neustadt, Austria

Abstract

MedAustron is an ion beam cancer therapy and research centre currently under construction in Wiener Neustadt, Austria. This facility features a synchrotron particle accelerator for light ions. Cosylab is closely working together with MedAustron on the development of a power converter controller (PCC) for the 260 deployed power converters – power supplies.

Power converters deliver power to magnets used for focusing and steering particle beams. We have designed and developed software and hardware which allows integration of different types of power converters into MedAustron's control system (MACS). PCC's role is to synchronously control and monitor connected power converters. Custom real-time fibre optics link and modular front end devices have been designed for this purpose. Modular front end devices make it possible to interface with almost any type of power converter – with or without built in regulation logic. We implemented real-time mechanisms and a dedicated real-time fibre link to satisfy requirements for synchronous control of power converters and data acquisition of their output current measurements.

MEDAUSTRON

MedAustron [1, 2, 3] is a synchrotron based accelerator for cancer treatment with protons and carbon ions. It will be used for clinical and non-clinical research in the fields of medical radiation physics, radiation biology and experimental physics. Synchrotron will deliver proton beams with energies up to 800 MeV. Three irradiation rooms are indented for medical use, one of which with a gantry, and one irradiation room for non-medical use.

INTRODUCTION

PCC is a distributed system of PXIe crates and front end devices that controls power converters. Its purpose is to ensure precise application of desired output values on power converters at precise points in time. Output value on power converters determines the magnetic field in magnets throughout the accelerator. PCC works together with MedAustron's timing system to achieve synchronous operation across all power converters. An important part of PCC is acquisition of measurements and verification of measured values against desired reference values.

POWER CONVERTER CONTROLLER – SYSTEM OVERVIEW

Output current values on power converters are set via set-points. PCC's main role is synchronous generation of set-points and acquisition of measurement results. During normal accelerator operation PCC works autonomously. Its operation is mainly dictated by the timing system. For expert or service use, PCC allows completely manual control of its functions. All of PCC's configuration parameters can be changed during runtime, which greatly simplifies and shortens commissioning and servicing of the machine.

Slow Power Converters

Slower power converters, such as those for magnets in low energy beam transport (LEBT), medium energy beam transport (MEBT) and extraction line, are controlled with single set-point values. Output on these power converters usually changes every few seconds or every few minutes. This change of output value coincides with accelerator cycles. Every accelerator cycle defines a different desired energy level of the beam.

Single set-point values are provided to the PCC in advance as a list of values associated to accelerator cycles. Optionally, when PCC is operated manually, single set-point values can be provided directly over the operator's graphical user interface and can be applied on power converter's output immediately.

PCC can provide single set-point values in different units. For example when the front end device is coupled with a digital signal processor (DSP) board, set-points can be provided as voltage, current or magnetic field. This in-house developed DSP board internally processes the received value and puts an appropriate voltage level on its analog output interface towards the power converter.

Fast Power Converters

Faster power converters, used for scanning magnets and in the main ring, are controlled with set-point sequences. Set-point sequence is a set of multiple single set-point values stored in one file. The execution of a sequence is dictated by the timing system. Graphical representation of a sequence is shown in Fig. 1.

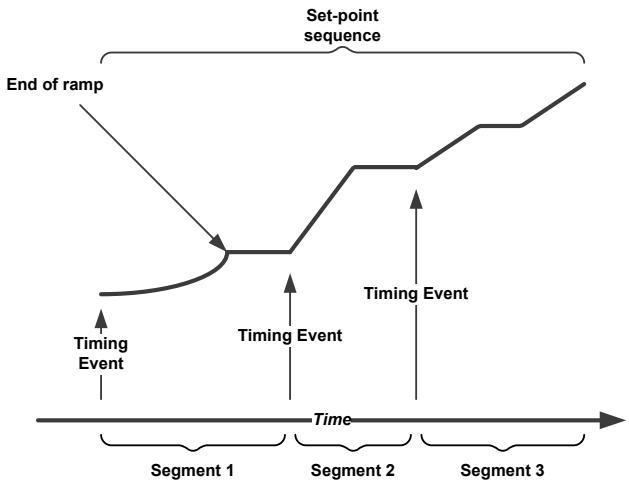

Figure 1: Structure of a set-point sequence used for fast power converters.

Output Waveform Verification

In order to verify the output of power converters against the desired reference values, PCC acquires measurements from connected power converters. Measurements are internally buffered in the PCC and optionally filtered. PCC can perform automatic verification of measured values against reference values or provide measurements to the user for inspection. Acquisition of measurements can be triggered with timing events, thus acquiring results from a specific point in time. For faster power converters, measurements are acquiread and time stamped with an accuracy of 1 microsecond.

Measurements are updated and visualized to the user in real-time, but can also be frozen. Results can be overlaid with a reference waveform from the generated set-point sequence and received timing events. This representation contains a complete set of data for the user to analyse and take advantage of in the process of fine tuning machine parameters.

Flexible Support for New Power Converter Types

Power converters with built-in logic and known set of commands can be easily integrated into the PCC. Minimal effort is required to implement a new driver in PCC application. The role of the driver is to translate power converter's set of commands into a format that is understood by the PCC application. Driver handles power converter's low level functionality and specific initialization procedures. Higher level functionality is handled by the PCC application above the driver. For expert usage and service purposes, PCC can bypass power converter driver and transparently pass commands to the power converter in raw format.

Power converters, which act as regular voltage sources, are integrated into the PCC seamlessly. Such power converters are connected to the DSP board which is attached on the front end device. Driver for the DSP board already exists and allows full configuration of parameters, e.g. for optimization of regulation loop.

TECHNOLOGY BEHIND THE POWER CONVERTER CONTROLLER

To successfully operate power converters in MedAustron's synchrotron, several challenges needed to be overcome. The most important one is synchronicity of PCC's actions. A group of fast power converters has to be synchronously controlled with an accuracy of 1 microsecond or better. Different synchronization mechanisms have to be supported. The main synchronization is dictated by the timing system, from which PCC receives timing events. Other types of synchronization include pulse synchronization and start/stop synchronization. They can be used in combination with respiratory system which is monitoring the patient and can, for example, pause and continue the operation of the PCC.

PCC Application Software

Along with hardware we designed and developed full software support. The main part of the PCC system is based on an off-the-shelf National Instruments PXIe crate, which can be seen in the middle of Fig. 2.

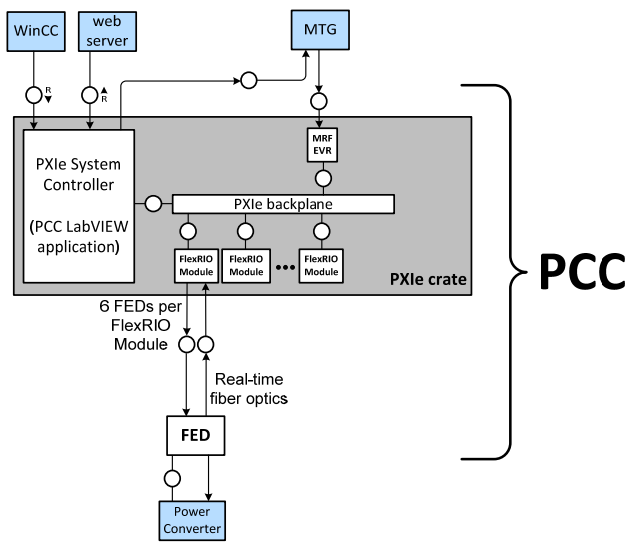

Figure 2: Architecure of PCC and interaction with other systems.

Running on the PXIe system controller are multiple instances of PCC application, integrated into MedAustron's Front End Control System (FECOS) software framework, all developed in LabVIEW. In MedAustron, PCC application is controlled and supervised over SIMATIC WinCC OA SCADA system. For expert use, PCC application can optionally be controlled with a web interface. PCC application is responsible for handling data from supervisory control system, controlled hardware and timing system, as well as specifics of different power converters: translation of

power converter commands, initialization procedures, preparation of set-point values etc. For every power converter there is a dedicated PCC application instance running on the system controller. Every PCC application instance is configured with a configuration XML and configuration shared variables accessible over the network. When more power converters need to be connected, additional PCC applications are instantiated. If all slots in the PXIe crate are full, additional crate(-s) are added.

PCC application communicates with FlexRIO FPGA Modules – FPGA based cards inserted into PXIe crate slots. Firmware on FlexRIO FPGA Modules carries out time critical tasks. These tasks include transmission of data over real-time optical link, reception of timing events from the PXIe timing receiver card, generation of single set-point values and sequences, acquisition and buffering of measurement values etc. Attached onto FlexRIO FPGA Modules are FlexRIO Adapter Modules carrying optical interfaces for communication with front end devices.

FlexRIO Adapter Module with Generic Optical Interfaces

FlexRIO Adapter Module (Fig. 3) is a custom developed adapter board with 6 generic optical connectors that connects up to 6 front end devices. The adapter is completely generic and can be used for any type of application that requires multiple optical interfaces.

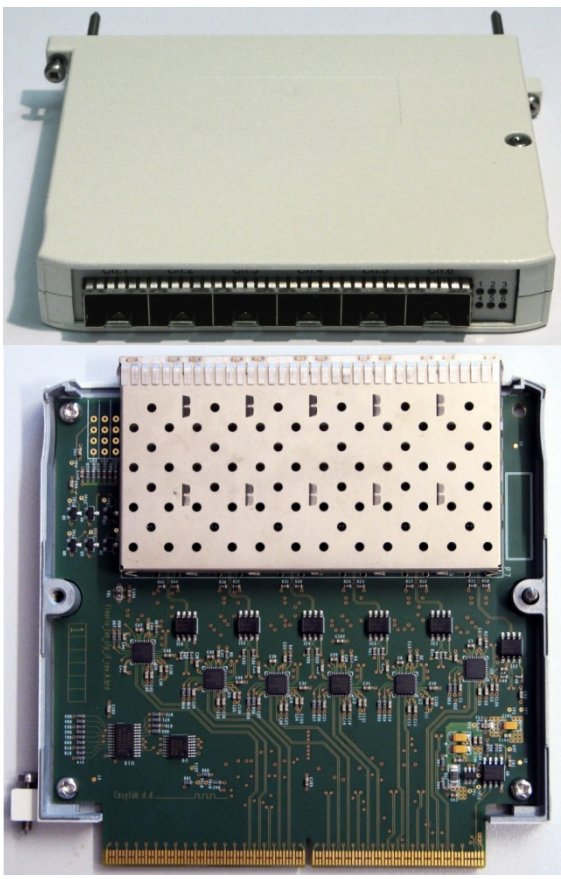

Figure 3: FlexRIO Adapter Module with 6 generic optical connectors (top – encased, bottom – PCB).

FlexRIO Adapter Module attaches onto a FlexRIO FPGA Module which takes control of the optical interfaces.

Front End Device

Front end device (Fig. 4) is an FPGA-based board which connects to a power converter directly through a RS-422 serial interface or indirectly through a DSP board. Front end device acts as a translator between the real-time fibre link and power converter's interface.

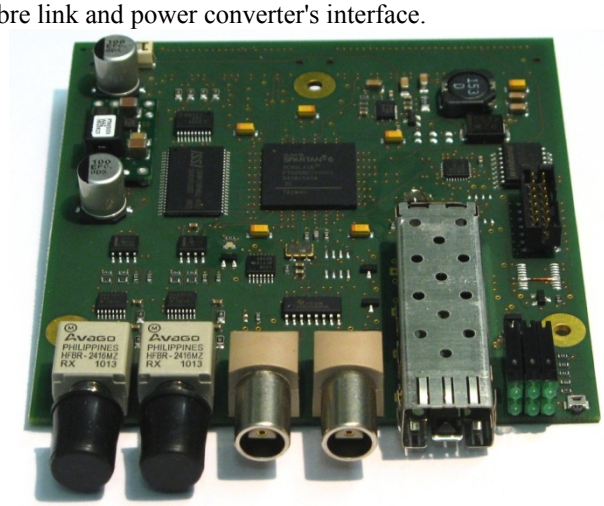

Figure 4: FPGA based front end device board.

FED plugs onto an in-house developed DSP board in case a regular voltage source power converter needs to be controlled. DSP board implements sophisticated regulation logic and regulates the output of the power converter via an analog interface.

Front end device can be located a few hundred meters away from the PXIe crate, near the actual power converter. It plugs onto a baseboard which acts as an expansion board for different I/O connectors (RS422, UHPI, trigger input and output...). Because most of the complex logic is located on the front end device, it makes it easier to design a new baseboard with connectors, if new types of interfaces are required.

Real-Time Fibre Optic Link

A custom real-time fibre optic link protocol has been designed for communication between FlexRIO Adapter Modules and front end devices. Its generic design allows it to be used for different other purposes. Its main feature is logic pipes. Each pipe has an independent interface for transmission and reception of data. Data is prioritized among the pipes by the protocol. One of the pipes has the highest priority and provides completely deterministic performance in terms of latency when data is transmitted and received. This pipe is used for transmission of set-point values (current, voltage...) towards power converters and reception of measurement values from power converters.

All logic pipes and the protocol are designed in a generic way. The protocol can be easily reused for other

application requiring deterministic behaviour, plus non-deterministic transmission of background data.

CONCLUSION

Power converter controller for MedAustron is a distributed system based on off-the-shelf National Instruments PXIe hardware and custom designed modular hardware components. Modular front end device and baseboard design simplify integration with different types of power converters. Adding software support for new types of power converters requires minimal effort. PCC integrates into WinCC SCADA system and is completely configurable during runtime. PCC's operation is dictated by the timing system. Custom designed real-time fibre link protocol guarantees 1 microsecond synchronisation among different power converters. The PCC distributed system allows control of an arbitrary number of power converters of various types, making it suitable for machines of different sizes.

PCI HARDWARE SUPPORT IN LIA-2 CONTROL SYSTEM

D. Bolkhovityanov, P. Cheblakov, BINP, Novosibirsk, Russia.

Abstract

LIA-2 control system is built on cPCI crates with x86-compatible processor boards running Linux. Slow electronics is connected via CAN-bus, while fast electronics (4MHz and 200MHz fast ADCs and 200MHz timers) are implemented as cPCI/PMC modules. Several ways to drive PCI control electronics in Linux were examined. Finally a userspace drivers approach was chosen. These drivers communicate with hardware via a small kernel module, which provides access to PCI BARs and to interrupt handling. This module was named USPCI (User-Space PCI access). This approach dramatically simplifies creation of drivers, as opposed to kernel drivers, and provides high reliability (because only a tiny and thoroughly-debugged piece of code runs in kernel).

LIA-2 accelerator was successfully commissioned, and the solution chosen has proven adequate and very easy to use. Besides, USPCI turned out to be a handy tool for examination and debugging of PCI devices direct from command-line. In this paper available approaches to work with PCI control hardware in Linux are considered, and USPCI architecture is described.

INTRODUCTION

LIA-2 [1] linear induction accelerator is designed in Budker INP as an injector for full scale 20 MeV linear induction accelerator which can be used for X-ray flash radiography with high space resolution. This machine utilizes ultra high vacuum, precise beam optics design based on low temperature dispenser cathode of 190 mm in diameter. The designed value of beam emittance (120 π mm•mrad, not normalized) is achieved at 2 MeV and 2 kA of electron beam energy and current.

LIA-2 control system is based on cPCI crates with x86-compatible CPU boards running Linux (CentOS-5.2 with custom-built 2.6.25 kernel. Slow control electronics (modulator controllers, slow DACs/ADCs) is connected via CAN, while fast hardware – such as 4MHz and 200MHz ADCs and 200MHz timers – are cPCI/PMC boards.

LIA-2 control system software is based on CX [2]. Being highly modular, CX doesn't include CAN and PCI support "out of the box". So, PCI hardware support had to be created from scratch.

Control system hardware drivers differ dramatically from regular OS drivers in many aspects.

- They implement different model: interaction via "channels" or "records" instead of files, char/block semantics, ioctl()s etc.
- Control system hardware itself, such as DACs, ADCs, timers etc., also has very little in common with regular computer hardware, such as NICs, display cards, serial and SCSI/IDE/SATA ports.
- So, timing requirements and model of operation also differ radically.
- Usually what CS drivers do is read and write hardware memory, plus catch IRQs in a simple manner - what we used to do with CAMAC and VME.

But PCI subsystem in Linux kernel doesn't have a simple way to do it - it is oriented on regular hardware driver requirements.

So, we had to make a way to access PCI hardware in the same manner as CAMAC and VME.

ANALYSED SOLUTIONS

The following existing solutions were considered while choosing the most appropriate one for LIA-2.

Loadable Kernel Modules

It is also known as kernel drivers. A module, running in kernel space, has direct access to PCI and various kernel subsystems. Thus, it can support arbitrary complex hardware, and achieve maximum performance. However, this comes at very high price:

- Development of kernel code is an extremely complex task. Kernel programming requires exceptionally high skills, and debugging such code is very cumbersome.
- Kernel modules are closely tied to internal kernel interfaces, which often change between versions. So, any kernel upgrade requires modification and repeated testing of driver code.
- Similarly, any modifications due to changes in control hardware are also labour-intensive.
- Moving to another *nix platform is almost impossible.

UIO: User-Space Drivers

UIO is a framework that allows implementing PCI drivers in userspace [3]. User space drivers eliminate most of disadvantages of kernel drivers. Advantages of userspace drivers are:

- you don't have specific kernel drivers for wide range of similar devices;
- much easier to develop and to port to other *nix operation systems;
- fault tolerance.

A tiny kernel-side driver to handle some basic interrupt routine is needed as part of every UIO driver. UIO is just a simple way to create very simple, non-performance critical drivers, which has probably been merged more with a "merge-and-see-if-it-happens-something-interesting" attitude than anything else. For now UIO doesn't allow to create anything but very simple drivers: no DMA, no network and block drivers [4].

Microdrivers

The Microdrivers [5, 6] architecture was developed at University of Wisconsin-Madison. The main goal of microdrivers is to achieve a better fault tolerance without loose in performance. Microdrivers reduce the amount of driver code running in the kernel by splitting driver functionality between a small kernel-mode component and a larger user-mode component.

Microdrivers seek the middle ground between monolithic kernels and microkernels, and improve reliability while maximizing performance. In a microdriver, the functionality of a device driver is split between a kernel-mode component and a user-mode component. The kernel-mode component contains critical and frequently used functionality, while the user-mode component contains non-critical and infrequently used functionality.

However, this approach is still destined for "usual" devices, not for control system specific hardware. And yet this requires a kernel part for *each* driver.

Hardware Access Layer

Many major hardware manufacturers implement their own, rather complex, infrastructures to access their control hardware. Usually these include a set of kernel drivers and multi-layer user-space libraries.

Examples include NI-KAL from National Instruments [7], IX-PCI, IX-ISA, IX-PIO from ICP-DAS [8]; COMEDI [9] was an open-source attempt to make manufacturer-agnostic implementation of such system.

Those infrastructures are often just components of larger systems, are usually oriented on specific manufacturer's hardware, and in many cases include closed-source parts.

Thus, this approach looks inadequate for our goals.

WinDriver™

The WinDriver™ [10] product line supports any device, regardless of its silicon vendor, and enables you to focus on your driver's added-value functionality, instead of on the operating system internals.

Its advantages are simple development of drivers and their portability between platforms.

But WinDriver is not free and it is closed-source.

USPCI APPROACH

USPCI (User-Space PCI access) implements approach, similar to WinDriver's: drivers run in user-space, and access hardware via a single tiny kernel module, which implements PCI I/O and simple interrupt management.

The main goal was to minimize drivers' complexity and design time. User-space drivers don't need to implement standard low-level interfaces, as regular OS drivers do. Since most control hardware don't require high throughput and ultra-low, real-time-like interrupt response latency, user-space implementation is quite adequate.

This approach has been widely used in Linux.

- Libusb [11] is a good example: it allows implementing user-space drivers for wide class of USB devices.
- X.org's 2D drivers operate in userspace, thus simplifying support of different unix-like OSes.
- CUPS and programs accessing the serial port like pppd are yet another example of userspace programs accessing the devices directly - the kernel doesn't implement any specific LPT printer or serial modem driver, those userspace programs implement the driver that knows how to talk to the printer.

USPCI INTERNALS

USPCI is a small and simple kernel module, implementing following functionality:

- /dev/uspci char device;
- access to address space of PCI-device (I/O ports & memory);
- data read and write in any PCI BAR of selected device (regardless of type – memory and I/O ports are accessed in the same way);
- 8-, 16-, 32-bit I/O support (64-bit is implemented, but yet untested);
- interrupt handling, with shared IRQ support (PCI address and mask+condition are specified for IRQ checking);
- interrupt counting;
- interrupt flags accumulation;
- target PCI device can be chosen by either PCI address (BUS:DEVICE.FUNCTION) or device ID (VENDOR:DEVICE:INSTANCE or VENDOR:DEVICE:SERIAL).

Since USPCI kernel module is simple and short, it was easy to test and is stable.

USPCI API and Workflow

The USPCI module is accessible from user-space via */dev/uspci* char device. Most operations are performed via *ioctl()* interface.

The following steps should be performed first to interact with PCI device:

- Open the */dev/uspci* via *open()* syscall.
- Select target PCI device – either by bus ID, or by vendor:device ID. This is achieved via USPCI_SETPCIID ioctl.
- Optionally specify a method of IRQ checking (required for shared IRQs) and IRQ acknowledgement. USPCI_SET_IRQ does this.
- Optionally specify a list of operations to perform upon close of file descriptor (such as stopping, IRQ masking, etc.) - USPCI_ON_CLOSE.

Than device's resources can be read and written via USPCI_DO_IO ioctl; very similar to how NAF is done in CAMAC or bus I/O is performed in VME. Usually all these *ioctl()*s are wrapped by a more friendly library.

In order to "finish" interrupt processing the USPCI_FGT_IRQ is called, which returns interrupt count

and accumulated interrupt flags; these are reset afterwards.

USPCI implements “poll” interface, which allows using file descriptor, associated with device, in *select()* and *poll()* syscalls.

To finish interaction with device, its file descriptor must be *close()*'d. Since *nix closes all file descriptors upon program termination, this, together with ON_CLOSE specification, enables to leave device in a safe state in all cases, including user-space driver crash.

Uspci_Test

Command-line interface program was developed for the purpose of device debugging. This program provides an access to all USPCI functions and logic. The use of the program allows analysing of device operation at development of userspace drivers.

CONCLUSION

USPCI Linux kernel driver was developed at BINP for access to PCI-devices of LIA-2 control system. This kernel driver allows developing of userspace drivers that is an optimal approach for control system building.

The drivers for following BINP-made devices were developed with the use of USPCI: timer DL 200 ME Fast, timer DL 200 ME Slow and ADC 200 ME. These drivers are successfully implemented in CX control system for LIA-2. The driver for PISO-ENCODER600 of ICP-DAS Co., Ltd production was also developed [12].

PERFORMANCE OF THE STANDARD FAIR EQUIPMENT CONTROLLER PROTOTYPE

Stefan Rauch, Ralph C. Bär, Wolfgang Panschow, Matthias Thieme, GSI, Darmstadt, Germany

Abstract

For the control system of the new FAIR accelerator facility a standard equipment controller, the Scalable Control Unit (SCU), is presently under development. First prototypes have already been tested in real applications [1]. The controller combines an x86 COM Express™ Board and an Altera Arria™ II FPGA. Over a parallel bus interface called the SCU bus, up to 12 slave boards can be controlled. Communication between CPU and FPGA is done by a PCIe link. We discuss the real time behaviour between the Linux OS and the FPGA Hardware. For the test, a Front-End Software Architecture (FESA) class, running under Linux, communicates with the PCIe bridge in the FPGA. Although we are using PCIe only for single 32 bit wide accesses to the FPGA address space, the performance still seems sufficient. The tests showed an average response time to IRQs of 50 μs with a 1.6 GHz Intel Atom CPU. This includes the context change to the FESA user space application and the reply back to the FPGA. Further topics are the bandwidth of the PCIe link for single/burst transfers and the performance of the SCU bus communication.

DESCRIPTION OF THE SCU

- SCUB connections with LVDS and PCIe
  - strict Master/Slave bus
  - 16Bit data bus, 16Bit address bus
  - in addition serial LVDS and PCIe channels
- COM Express™ module Type II with Intel Atom
- 32Mbyte Parallel Flash
- RJ45 Gigabit Ethernet from COM Express™ module
- two SFP connectors
  - Timing (White Rabbit over GbE)
  - AUX LAN (GbE)
- Arria™ II FPGA
- White Rabbit Receiver (FPGA) [2]
- 128Mbyte DDR3 memory
- IO Extension for existing timing system
  - DEV-BUS: GSI fieldbus
  - Event-In: Timing Events
  - both based on MIL-STD-1553
- USB 2.0
- 2x EIA-232

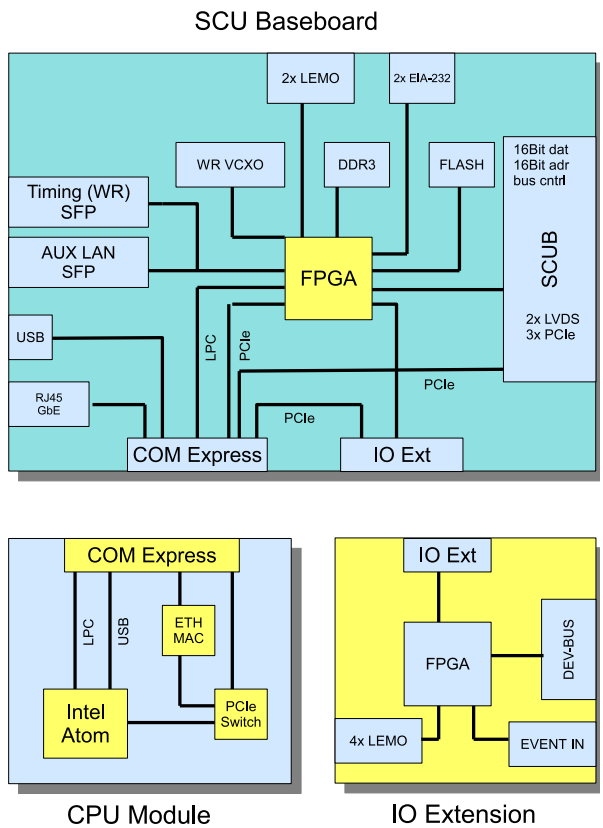

Figure 1: Layout of the SCU Carrier Board.

STATUS REPORT OF THE PROJECT

The prototype should have been ready in July 2011, but to complications during the design phase it came to a delay. The layout for the prototype baseboard is now finished and ready for production (see Figures 1, 2, 3). The first boards are expected to arrive in November 2011.

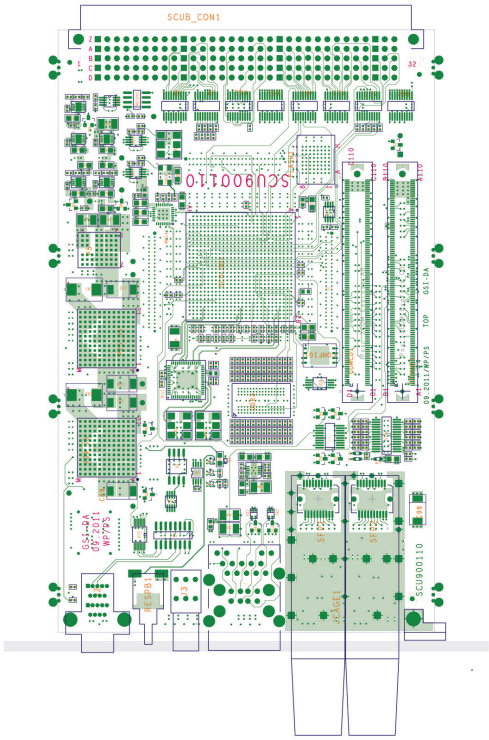

Figure 2: Layout of the SCU Carrier Board.

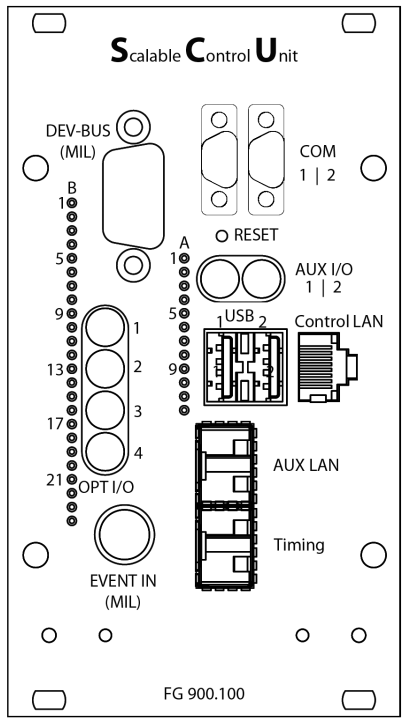

Figure 3: Front Panel of the SCU Cassette.

PROBLEMS DURING DESIGN PHASE

Early during the design phase came the decision for the combination of an FPGA and an COM Express™ module. The connection of the Module requires an FPGA with PCIe capability. The decision fell for the Altera Arria™ II FPGA with high speed serial transceivers. The Arria™ FPGA comes with a hard IP cell for PCIe so no license fees are needed. This FPGA and the design tools were quite new, when the testing of base components of the system like PCIe or DDR3 communication began. We had the possibility to test these technologies in another project and realized some problems with the design tools. In FPGA prototyping you typically implement the design first in the FPGA due to constraints in the pinning of the PCB. In this special case, the design tool allowed the hard IP core to be connected to the transceiver block 1 of the Arria™. The problem is, there is no hardware connection in the FPGA and the PCBs did not run PCIe with the hard macro cell. One possibility to solve this problem was the use of a soft core implementation. This would result in high license fees and unnecessary loss of logic cells in the FPGA. Another temporary solution was the rewiring on the PCB. After patching the PCIe to transceiver block 0 the connection worked perfectly. Altera fixed the issue in the next version of their design tool, but for the final solution a redesign of the PCB was needed.

Another problem worth mentioning was the DDR3 controller. With the first version of the design tool we could not get an reliable system talking to an DDR3 memory. Only after applying several patches the DDR3 accesses were working. But on the PCB we used for testing PCIe, the DDR3 gave us some more trouble. The chip we used is an 16Bit wide DDR3, but only 8Bit wide accesses were successful. This issue could be solved with the newest design software.

LESSONS LEARNED

If we had to do the project again, we would plan more time for testing the new (at least for us) technologies. We were aware of the fact, that their would be problems with a new and complex FPGA like the Arria™ II and this was not the first FPGA project we did. But when dealing with FPGAs like the Arria™ II, there are a lot of constraints in placing the external connections. This is especially true for connecting the pins of the memory controllers. The same applies for the high speed serial transceivers and the clocking of these. You have to be totally sure, how you are going to use use the transceivers, because most changes cannot be done after finishing the PCB. This was a new experience for us as we have only dealt with low scale FPGAs like Altera Cyclon™ or Xilinx Spartan™ before. The vendors are aware of the problem and try to help with wizards for pin placing and constraining. During layout phase this tools can be used again to find optimal routes on the PCB.

IN DETAIL: IMPLEMENTING A LPC UART

- Problem: SuperIO Chip does not fit in Layout
- Solution: extending LPC bus to FPGA, implementing UART functionality in logic
- Low Pin Count Bus, four address/data lines, serial clk, frame signal

The COM Express™ module of the SCU needed an external Winbond SuperIO chip for the UART functionality. This is mainly needed for debugging with a serial console during the boot phase. The BIOS of the module supports up to two UARTs. During the layout phase of the board it came clear, that there is no space left on the base board for the SuperIO chip. This and the fact, that only the UART functionality of the chip is used, lead us to moving the logic into the FPGA. The communication between SuperIO and COM Express™ module uses the LPC bus [3]. This bus is a serialized version of the ISA bus and uses four address/data lines and a serial clock. It runs at 33Mhz and offers bus modes as e.g. IO read/write, MEM read/write. The bus lines are connected to the FPGA instead of the SuperIO. In the FPGA we use logic for decoding the LPC bus accesses to UART transfers. The logic modules are based mainly on existing projects from OpenCore.org: a Whishbone LPC Peripheral bridge [4] and a 16750 compatible UART [5]. If you want to emulate the behaviour of the Winbond SuperIO chip, you have to understand, how the extended addressing of the SuperIO works. The chip is connected to the IO port space of the COM Express™ module. It supports up to 11 logical devices (e.g. UARTs, printer port, MIDI). To access the configuration registers of these devices you have to enter the extended function mode. This is done with two writes of 0x87 to the base address of the SuperIO. Then you select the device number and the configuration register. After reading or updating the register content you send the value 0xAA to the base address. This mechanism has to be implemented in the FPGA to allow the BIOS to configure the logical devices, like setting a base address of the UART. The 8 UART registers of the 16750 compatible core are then mapped to the configured base address. The device can now be accessed by the BIOS code during boot up and by an operating system driver. It is possible to implement further devices in the FPGA like another UART or printer port with this scheme.

NEW DEVELOPMENTS ON TORE SUPRA DATA ACQUISITION UNITS

F. Leroux, G. Caulier, L. Ducobu, M. Goniche
CEA, IRFM, F-13108 Saint-Paul-lez-Durance, France
G. Antar, American University of Beirut, Physics Department, Beirut 1107 2020, Lebanon

Abstract

The Tore Supra data acquisition system (DAS) was designed in the early 1980s and has considerably evolved since then. Three generations of data acquisition units still coexist. As cost and maintenance of different operating systems is expensive, it was decided to explore an alternative solution based on an open source operating system (OS) with a diskless system for the fourth generation. In 2010, Linux distributions for VME bus and PCI bus systems have been evaluated and compared to Lynx OS™ real time OS. The results obtained allowed to choose a version of Linux for VME and PC platform for DAS on Tore Supra. In 2011, the Tore Supra DAS dedicated software was ported on a Linux diskless PCI platform. The new generation was successfully tested during real plasma experiments on one diagnostic, called DCEDRE.

INTRODUCTION

The Tore Supra data acquisition system (DAS) (Fig. 1) was designed in the early 1980s [1] and has considerably evolved since then. Three generations of data acquisition units still coexist. Totalizing now 50 diagnostics and subsystems, the data acquisition units are operated simultaneously. The first generation was based on Multibus systems with an Intel processor and RMX™ operating system. Since 1995, most of these systems have been replaced by VME bus systems equipped with Motorola PowerPC processor boards running a Lynx OS™ real-time OS to obtain a more powerful architecture. The third generation was developed to perform extensive data acquisition for infrared and visible video cameras that produce large amounts of data to handle. It was supported by industrial PC over a Microsoft Windows™ OS.

The first two generations, Multibus and VME bus systems, are diskless with real time OS (RTOS). Diskless systems are desirable for reliability and maintainability as they share common resources like kernel and file system. The advantages of these architectures are:

- a common kernel
- a common file system
- easy updating and backup
- reliability (no hard disk)
- can be installed closest to the detector
- insensitive to the magnetic field
- easy to deploy

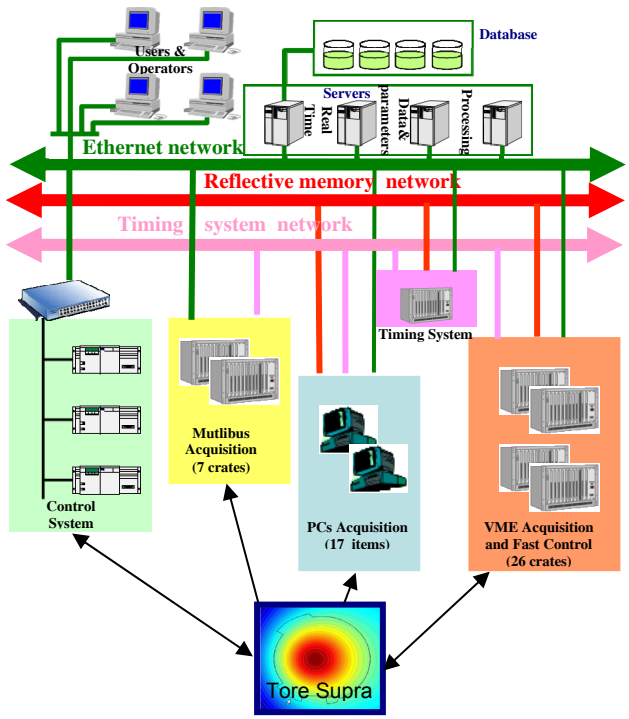

Figure 1: The Tore Supra data acquisition system.

These facilities considerably reduce the maintenance cost. Moreover, open source real-time operating system are now available that may provide free and convenient solutions for DAS. As a result, it was decided to explore an alternative solution based on an open source OS with a diskless system for the fourth generation. Currently, Linux OS is fairly mature to be used on DAS with pre-emptive and real time features on x86 architecture. In 2010, Linux distributions for PCI bus systems have been evaluated and compared to LynxOS real time OS. The latency and time response to any hardware interrupt has been achieved with x86 and x86 multi-core architecture target processors. The results obtained allowed to choose a version of Linux PCI platform for DAS on Tore Supra. These aspects and the new diagnostic DCEDRE are detailed in the following of the paper.

DAS NEEDS ON TORE SUPRA

Two kinds of DAS with different level of determinism are used on Tore Supra, hard real time systems and soft real time systems. The real time plasma control system

(hard real time system) on Tore Supra has a constraint of 2 ms cycle time. For example, one of Tore Supra safety components is provided by a spectrometer measuring the level of copper and iron [2]. The acquisition unit allows heating systems to adapt in real time the injected power into Tore Supra through a feedback on these levels of impurity. The acquisition unit must provide continuous values every 4ms. The data acquisition and computed results must be completed within this interval.

Soft real time systems must meet deadlines with a degree of flexibility. Data acquisitions that do not realize real time control accept missed dead lines like a read on data acquisition board. To solve this problem data are stored in acquisition card memory or directly into the computer memory by a DMA transfer between acquisition card and computer. The time constraint is 4 millisecond cycle time.

Data acquisition system must support Tore Supra standards on both hardware and software, especially the real time plasma control which is based on a reflective memory network with ScramNet card from Curtiss Wright. On software point of view, the message oriented middleware (MOM) RTworks [1], that is the heart of Tore Supra DAS must be supported.

NEW DAS FOR TORE SUPRA

New Hardware

A PCI bus platform has been chosen with CompactPCI (CPCI) standard for the new architecture (Fig. 2).

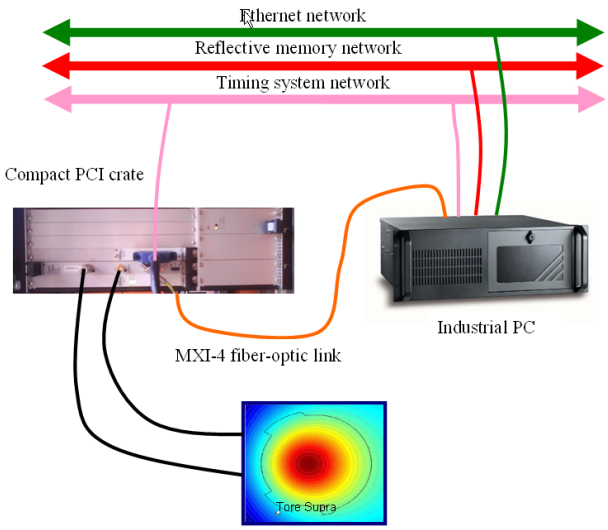

Figure 2: New DAS architecture.

CPCI bypasses the limit of five PCI slots in PC and offers a wide range of CPU and data acquisition boards. It is possible to use directly PXI cards, PCI and PMC (PCI mezzanine card) cards with adapter in a CPCI crate. The processor unit is not included in the CPCI crate. An industrial PC is connected to CPCI crate by a MXI-4 bridge from National Instruments. MXI-4 bridge provides a remote control of CPCI electronics cards from industrial PC through a fully transparent link connected with fiber-optic cabling. The separation of the I/O board from the industrial PC allows having a robust system like VME bus system and a lifespan of more than 10 years. This configuration has the advantage:

- easy upgrading of the calculation power without changing all the data acquisition
- a less noisy environment than for industrial PC for very fast data acquisition (2GHz).

For a reduced DAS development time, electronic cards providers are selected for hardware availability and drivers quality, so the development time is now down to half between design and delivery.

New OS, Linux

The first milestone was to find a Linux distribution. The target system for PCI bus system are x86 multi-core processor with industrial PC. X86 processor is widely used in Linux community which has led us not to use commercial distribution. A custom solution has been developed.

The main challenge will be to develop a diskless system. A diskless system on Tore Supra (named client) starts with Ethernet networks. Client has only memory and its file system is hosted on a server. The client-server architecture is showed on Figure 3. At startup, a client downloads the kernel on the server. The file system is common to all clients to facilitate the management. The user application development is realized on a compiler.

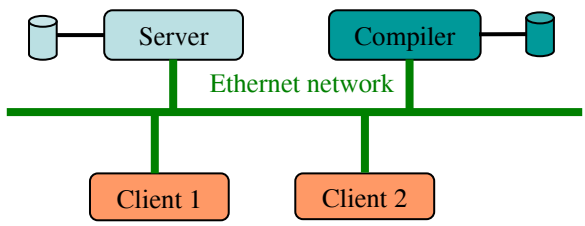

Figure 3: Client-server model on TS.

The target boot is based on PXE (Preboot eXecution Environment) boot. Some unnecessary services such as energy saving, virtual memory are disabled that slowdown the system. A hard RTOS solution will be evaluated in 2012 with Xenomai real time extension for Linux.

TESTS AND RESULTS

Tests were conducted to measure real time performance on few target systems and Linux version. Target systems tested were:

- X86 INTEL processor 2,8GHz.
- X86 INTEL dual core processor 3GHz on an industrial PC.

Different Linux version 2.6 with different preemption option were chosen to be evaluated:

- 2.6.28.10 preemptible kernel (low latency desktop)
- 2.6.26.8-rt16 Complete Preemption (Real-Time)

As referred in DAS needs on Tore Supra section a RTOS must meet deadline. Interrupt response time measurement and polling device can evaluate RTOS performance for a given target. Performance tests were also done with Lynx OS on a VME target system to compare Linux to a commercial RTOS.

The interrupt response time (Fig. 4) is the interval between the time when a hardware interrupt occur and the time when the user task wake up to run. The interrupt response time is the sum of interrupt latency, interrupt processing, context switching and task wake up.

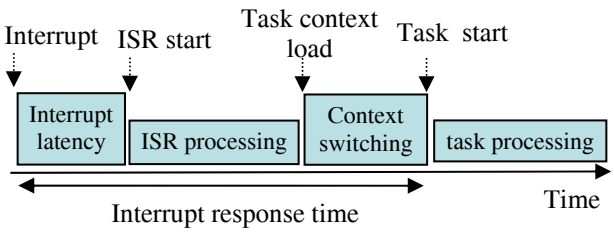

Figure 4: Interrupt response time definition.

For response time tests, user task simulates a processing consuming 100% of processing power to measure the impact on Linux to evaluate RTOS closest to reality. A 500µs interrupt frequency and 400µs processing simulation were used for this test during 1 hour.

Linux 2.6.28.10 on x86 dual core target is not far of hard RTOS Lynx OS (Fig. 5). Linux 2.6.28.10 is better in interrupt management than Linux 2.6.26.8 RT. Linux 2.6.28.1 interrupt time response is 38µs against 50µs for Linux 2.6.26.8 RT.

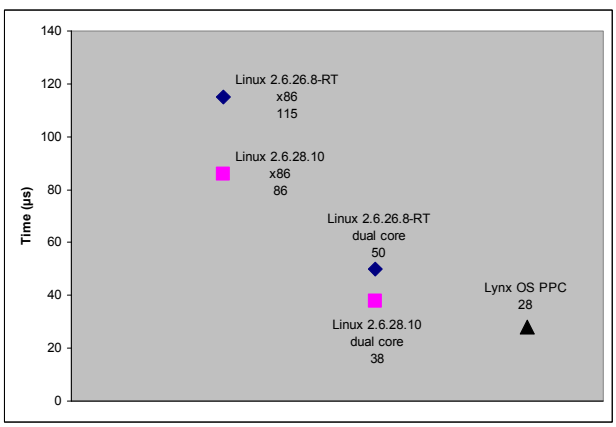

Figure 5: Interrupt time response result.

Some VME I/O (input/output) devices used on Lynx OS target do not generate interrupt to indicate that data are available. I/O devices require the application to generate the necessary request in order to interact with them. The application runs in a periodic loop and makes a request every time through the loop, called polling device. Polling is also a way to consider more quickly an event than interrupt. A test was done to find the polling frequency limit on each target system and Linux version (Fig. 6).

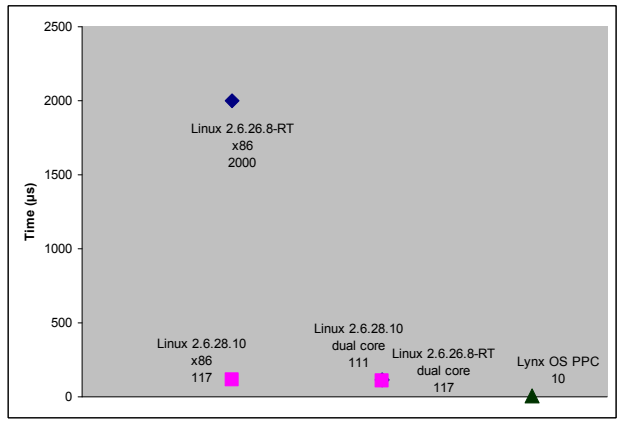

Figure 6: Polling frequency limit.

Lynx OS takes advantage on Linux. Moreover Lynx OS is completely freeze and do not reply to any request unlike to Linux. Linux 2.6.28.10 have a large advantage on x86 while both versions of Linux are equal on dual core. With upper CPU frequency than PPC, x86 dual core is close to hard RTOS performance.

NEW DIAGNOSTICS WITH LINUX

Linux with a system disk has been used successfully on a new diagnostic for the dust detection in 2010. It can count and quantify the dust sucked into a vacuum duct continuously 24/7. In 2011, the Tore Supra DAS custom software was ported on a Linux diskless PCI platform. The new generation was validated on plasma experiment for the so called DCEDRE diagnostic (Fig. 7).

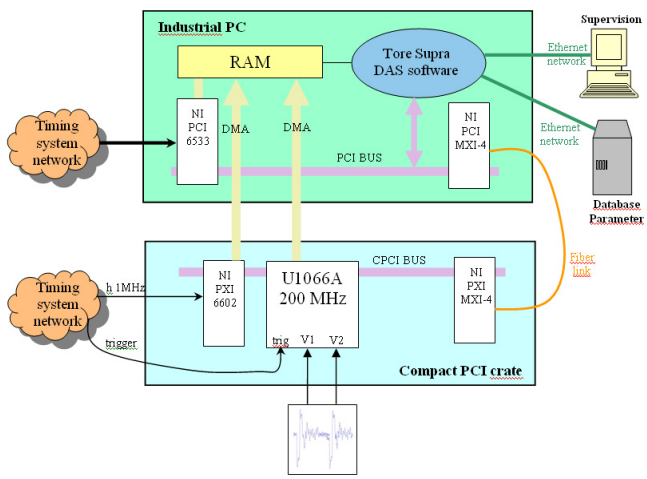

Figure 7: DCEDRE architecture.

This new diagnostic aiming at measuring the full frequency spectrum (0-200MHz) of electrostatic probes signal during high frequency power injection into the plasma gave preliminary results during Ion Cyclotron Range of Frequency (f=57MHz) heating.

Two signals are acquired on an Agilent U1066A, 200 MHz digitizer, 12 bit resolution with a wide bandwidth of 100MHz. An external trigger for timing system network starts data acquisition for 100000 samples at 200MHz samples rate. Data are time stamped with NI PXI 6602 card clocked by 1MHz timing system network.

Spectrum is obtained by Fourier transform of a set of 10^5 measurements (Δt=5ns). When the antenna is powered (P=1MW), peaks are obtained at f but also in some cases at f/2 (Fig. 8), giving some evidence of the complex interaction of the plasma edge, where the probe is located, with the wave.

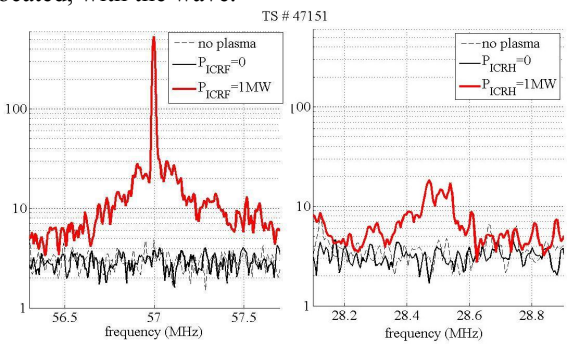

Figure 8: Blow-up of the power spectrum during ICRF heating experiment (acquisition rate: 200MHz).

CONCLUSION

This study showed that real-time Linux solutions can be used for the data acquisition systems of Tore Supra. Linux on PCI bus systems fulfils Tore Supra needs for soft real time application. Linux 2.6.28.10 preemptible kernel (low latency desktop) on x86 dual core is the best solution and obtain equivalent performance to Lynx OS on interrupt time response. PCI platforms will reduce the cost of hardware, development time and operating costs.

New Tore Supra DAS architecture is like ITER recommendation for ITER CODAC control system [3]. New DAS will be used easily for testing plant system controllers for ITER CODAC on Tore Supra experiments.

In 2011, the new diagnostic DCEDRE has validated the new diskless PCI architecture with Linux OS on experiments.

The next steps are:

- Performance tests with Xenomai in 2012.
- New diagnostics for plasma control with Linux 2.6 diskless system in 2012.
- Upgrade data acquisition unit of hybrid heating system on Linux diskless system with real time arc detection algorithm 100µs cycle in 2012.
- For x86 dual core system, to dedicate a core to Linux and the other to Xenomai.

LIA-2 POWER SUPPLY CONTROL SYSTEM

A. Panov, P. Bak, D. Bolkhovityanov
The Budker Institute of Nuclear Physics, Novosibirsk, Russia

Abstract

LIA-2 is an electron Linear Induction Accelerator designed in Budker INP as an injector for full scale 20MeV Linear Induction Acceleratorfor X-ray flash radiography with high space resolution. Inductors get power from 48 modulators, grouped by 6 in 8 racks. Each modulator includes three control sub-devices connected via internal CAN-bus to an embedded modulator controller, which operates under Keil RTX real-time OS control. Each rack includes a cPCI crate equipped with x86-compatible processor board running Linux with CX-server. Modulator controllers are connected to cPCI crate via external CAN-bus and interact with CX-server via extended KOZAK standard. In modulator controller operation many software mechanisms are used e.g. different modes, detection of an internal sub-device offline state, request repost, addressing, system error and other.

LIA-2

LIA-2 is originally an electron linear induction injector for 20MeV Linear Induction Accelerator designed in Budker INP for X-ray flash radiographywith high space resolution. It is a facility producing pulsed electron beam with energy 2MeV, current 1 kA and spot size less than 2mm. Beam quality and reliability of facility are required for radiography experiments. Accelerating section consist of 96 inductors based on the amorphous ferromagnetic laminated cores. Each modulator feeds two inductors, total 48. All modulators grouped by 6 in 8 racks.

Basic LIA-2 parameters are presented in Table 1. The accelerator includes electron beam forming, accelerating and focusing system, high voltage pulsed power system, beam diagnostic system, high vacuum system and control system.

Table 1: LIA-2 Basic Parameters

Parameter (Units)	Value
Maximum electron beam energy (MeV)	2.0
Maximum electron beam current (kA)	2.0
Number of pulses in the burst	2
Cathode heater DC power (kW)	2.5
Time interval between pulses in the burst (μs)	2 - 10
Pulse duration, flat top ±4% (ns)	200
Maximum repetition rate (Hz)	0.1
Min. beam spot size FWHM on the target (mm)	1.5

MODULATOR

Pulsed HV power supply system consists of 48 identical double pulse modulators, two charging units (one for each pulse) and coaxial feeding lines (20 cables for one modulator). Each modulator feeds two inductors in parallel and includes two Pulse Forming Networks (PFN) (one for each pulse), two cold cathode thyratrons TPI 1-10K/50 with a switched current 10 kA and working voltage 50 kV[1], two thyratron starters and a degausser (see Fig.1). Two starters (STR1/2) and degausser (DEG) are driven by Local Control Boards (LCB). In addition, each modulator is equipped by the controller (MC). 48 modulator controller, 144 LCB, 8 cPCI crates with CX-server and main control panel form HV power supply control system.

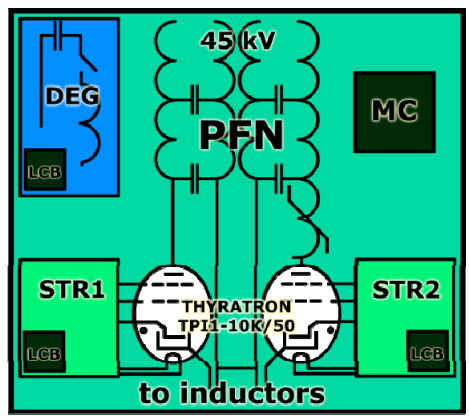

Figure 1: Modulator structure.

Hardware

Modulator controller is based on LPC2119 microcontroller by NXP. This microcontroller includes a 32-bit ARM7TDMI-S CPU with real-time emulation and embedded trace support, together with 128 kB of embedded high-speed flash memory. The LPC2119 contains various 32-bit timers, 4-channel 10-bit ADC, two advanced CAN channels, PWM channels and 46 fast GPIO lines with up to nine external interrupt pins. The microcontroller performs following tasks: communication with external server and internal sub-devices on CAN-bus (125kb/s), slow interlocks gathering (response time less than 60 ms) and processing, parameters calibrations, indicator control (on Serial Peripheral Interface (SPI)), internal sub-devices supply control and other. Modulator controller also includes Programmable Logic Device (PLD) EPM3128 by Altera. This PLD is based on MAX3000A architecture and contains 128 macrocells. The EPM3128 performs fast interlocks gathering and processing with response time less than 1 us. Modulator

controller contains five inputs for fast internal interlocks with optic isolators, three inputs for synchronization pulses and output for final interlock with optic isolator. Inner structure of modulator controller with local control boards are presented on Fig.2.

Local Control Board is based on T89C51CC01 microcontroller by Atmel. This microcontroller implements 8-bit 80C51 CPU. The T89C51CC01 contains 32 KB flash memory and 2KB EEPROM, three 16-bit timers, 8 multiplexed inputs of 10-bit ADC, 5 outputs 8-bit PWM, one CAN channel and 34 digital I/O lines.

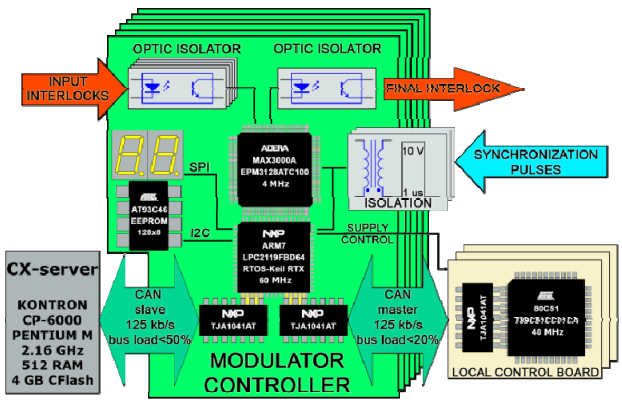

Figure 2: Modulator Controller and Local Control Boards.

Software

The modulator controller works under control of a Real-Time Operating System (RTOS) Keil RTX. The Keil RTX is a royalty-free, deterministic RTOS designed for ARM and Cortex-M devices. It allows creating programs that simultaneously perform multiple functions and helps create applications which are better structured and more easily maintained.

Features

- Royalty-free, deterministic RTOS with source code.
- Flexible Scheduling: round-robin, pre-emptive, and collaborative.
- High-Speed real-time operation with low interrupt latency.
- Small footprint for resource constrained systems.
- Unlimited number of tasks each with 254 priority levels.
- Unlimited number of mailboxes, semaphores, mutexes, and timers.
- Support for multithreading and thread-safe operation.

In the modulator controller Keil RTX is used with following features.

- Main clock 60 MHz
- System clock 1 kHz
- Round-Robin task switching
- Number of concurrent running tasks 20
- Task stack size 200 bytes

Main cycles

- Watchdog check 800 ms
- Interlocks check 50 ms
- Indicator refresh 300 ms
- Settings saving 1 m
- Internal management 45 ms

Modulator controllers are connected to cPCI crate via external CAN-bus and interact with CX-server [2] via extended KOZAK standard [3].

Addressing

Each modulator has unique functional address which sits in CAN connector. Based on this functional address modulator controller identify its network ID and physical address. Network ID is used in communication with CX-server and physical address is continually displayed on the front indicator. Physical address consists of a figure and a character. The figure indicates modulator rack serial number and the character indicates modulator serial number in this rack. All modulators with even character have even network ID. If one wishes to replace a modulator, one just removes old modulator and inserts a new one, than modulator identifies all addresses by itself.

Offline state detection and request age

One of the most important mechanisms is detection of an internal sub-device offline state. There are four counters (three individual and one shared) that define current state of internal sub-devices. Sub-device sits in offline state if counter value is less than minimum value and it sits in online state if counter value is greater than maximum value. Values of these counters are changed when internal communication task running. Counter value is decreased when the sender in a request processing task is recognized. Value of the shared counter will increase when there will be no more messages in a specified time domain (timeout for internal receive). Values of individual counters will increase when individual message will be sent for suitable sub-device. Also multi-request about current sub-devices states is sent if shared counter value is less than maximum level. Knowledge about current states of the internal sub-devices is especially important if sub-device sits in offline state and there are several messages for him. In this case all requests for this sub-device aren't sent but remembered.

All requests have an age counter. Value of the age counter is started to increase only when request is sent for suitable sub-device. Request gets old and then will be added in FIFO for sending if age counter value of this request is greater than maximum level. This mechanism is worked only when internal sub-device is online, but multi-request is sent until all sub-devices get offline.

Modes

Each modulator can be in one of six modes (*Sleep, Experiment, Action, Adjustment, Programming* and *Emergency* - ***SEAAPE***). On the Fig. 3 possible transitions from one mode to another are presented. Essentially one mode differs from another by Mask of Admissible Commands (MAC) which is used at the request reception.

Sleep is an initial modulator mode. All internal sub-devices of the modulator are switched off. In this mode operator can write minor settings (e.g. heating time of a hydrogen thyratron, masks of the enabled internal interlocks etc.). Final interlock is active.

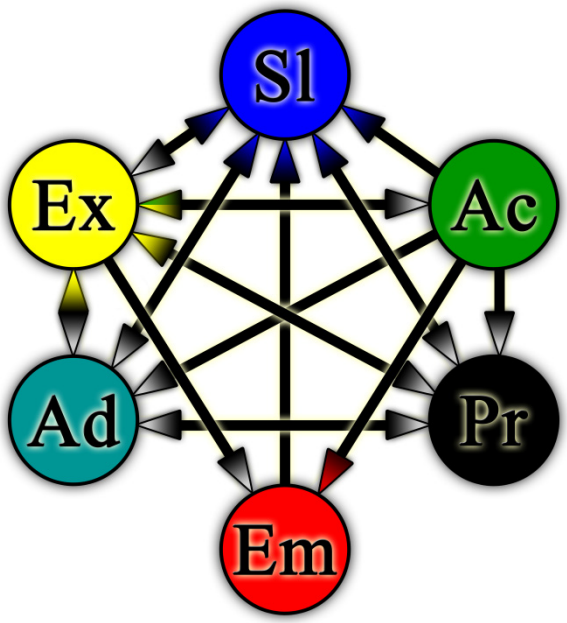

Figure 3: Possible transitions from one mode to another.

Button or power reset
Watchdog timer reset
Main shot
Enabled interlock
Command

Experiment is a basic modulator mode. All internal sub-devices of the modulator are switched on. In this mode operator can write major settings (e.g. heating current of a hydrogen thyratron, discharge arc current, degausser voltage etc.) and minor settings (like in *Sleep* mode). Final interlock is managed by current enabled internal interlocks. This mode is necessary for test LIA-2 shots. It is necessary to perform approximately one hundred shots in order for final main shot to be performed without any problems, because experiment with main shot is very expensive.

Action is a mode of main shot. In this mode operator cannot change any settings. If any enabled internal interlock appears then final interlock would active and modulator would change mode on *Emergency*. After main shot modulator change mode to *Experiment* by itself.

Adjustment is a mode for calibration of measured signals and other auxiliary procedures. Final interlock is active.

Programming is a mode for firmware download to the microcontroller. Final interlock is active.

Emergency is a mode when there is enabled internal interlock. In this mode all internal sub-devices are switched off, interlocks are hold and final interlock is active. Operator should change mode to *Sleep* for exit from this mode or reset microcontroller.

Modes approach makes all system more fail-safe and decrease human factor.

Abstract

This paper describes the development and implementation of the Detector Control System (DCS) of the Tile Calorimeter detector. The DCS must ensure coherent and safe operation of the Detector. It provides control and monitoring of all parameters of the system and gives to the user a comprehensive picture of the detector behaviour.

INTRODUCTION

The Tile Calorimeter [1] is one of the sub-detectors of the ATLAS experiment [2]. It is a sampling calorimeter made of steel plates (absorber) and scintillating tiles (active material). The design, general features and expected performance of the calorimeter are well described in the "ATLAS Tile Calorimeter Technical Design Report" [3]. The Tile Calorimeter consists of one barrel and two extended barrel parts. All the three sections have a cylindrical structure further sub-divided into 64 independent modules. The calorimeter cells are defined by grouping together sets of optical fibbers into bunches leading to photomultiplier tubes (PMTs). The front-end electronics and PMTs are located in the outer side of the Tile Calorimeter modules, in so-called electronics drawers.

The Detector Control System (DCS) is responsible for safe and coherent detector operation. All ATLAS sub-detectors have their own local DCS, which detailed architecture strongly depends on the structure of the general DCS system of the ATLAS experiment [4] and on electronics architecture and mechanical issues of the sub-detector itself. Each local DCS controls and monitors the operation of a sub-detector and related equipment.

Although each sub-detector is responsible for the implementation and for internal organization of the sub-systems, they must fully comply with the requirements defined by ATLAS central DCS [5]. The DCS of the sub-detectors must follow the general ATLAS DCS system architecture as much as possible unless there are special requirements where the sub-detectors need tailored solutions.

The DCS provides control and monitoring of the main systems of the Tile Calorimeter detector, which are the High Voltage distribution system and the Low Voltage Power Supply (LVPS) system. In addition, DCS is also responsible for interactions with detector calibration and data acquisition systems, and monitoring the detector infrastructure related systems: detector water-cooling and rack control.

TILE CALORIMETER DCS

The commercial Supervisory Control and Data Acquisition (SCADA) package PVSS II has been chosen by the Joint COntrols Project (JCOP) at CERN to implement Back End (BE) software for all LHC experiments [6]. The PVSS II is a commercial product, from Austrian company ETM. It is used to connect to hardware devices, acquire data from them, monitor their behaviour and to initialize, configure and operate them. PVSS II has a highly distributed and flexible architecture, and it allows connection of several autonomous systems through the network.

The BE system of the ATLAS experiment is organized hierarchically in three layers or levels as shown in Figure 1. This hierarchy allows the experiment to be divided into independent partitions, which have the ability to operate in standalone or integrated mode.

At the top layer, there are Global Control Stations (GCS), which are in charge of overall operation of the detector. They provide high level monitoring and control of all sub-detectors, while data processing and command execution are handled at the lower levels. The GCS is able to access all stations in the hierarchy.

The Sub-detector Control Station (SCS) represents the middle level of the hierarchy. The Tile Calorimeter, as a sub-detector of ATLAS, has its own SCS, which allows the complete operation of the sub-detector, by means of dedicated graphical interfaces. At this level of hierarchy, the connection with the TDAQ system, calibration systems and detector infrastructure takes place in order to ensure that detector operation and physics data taking are synchronized.

At the bottom level of the hierarchy are the Local Control Stations (LCS), which handles the low level monitoring and control of LV and HV systems of sub-detector. The LCS executes the commands received from the layers above.

In order to implement the BE system of the Tile Calorimeter DCS, five rack-mounted computers are used, located in USA15 racks. As it is shown in Figure 1, four of those are used as LCS stations (each for one Tile Calorimeter partition) and one as the SCS station. The operating system of those computers is Windows XP and they run PVSS II as a system service.

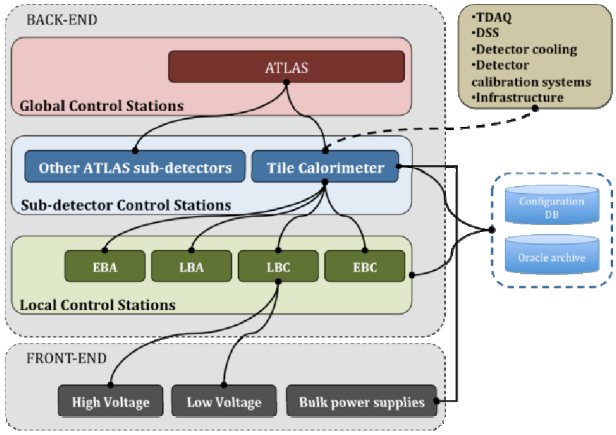

Figure 1: Hierarchy of the DCS of the Tile Calorimeter, as part of the ATLAS control system.

THE LOW VOLTAGE POWER SUPPLIES (LVPS) SYSTEM

The LVPS system is a two stage system: first stage converts 400V AC input into 200V DC output (100 m from the detector in USA15) and then second stage placed on the detector converts 200V DC into 8 independent levels of lower voltages in the range (-15V; +15V). These voltages are used to power the detector Front End (FE) electronics. The Tile Calorimeter FE electronics consists of digital and analog components of the readout system and High Voltage (HV) distributor system. In this section, the hardware entities of LVPS system and their interconnections are briefly described.

The LVPS system is composed by three devices: finger Low Voltage Power Supplies (fLVPS) located at the FE electronics of Tile Calorimeter, auxiliary boards (AUX boards) located in the racks of USA 15 and bulk power supplies providing 200V DC located also in the racks of USA 15.

The fLVPS and AUX board devices make use of Embedded Local Monitoring Board (ELMB) [7], as a general purpose I/O and processing unit for CAN communication [8]. The ELMB fully implements the industry standard of CANbus protocol and it provides minimal functionality of a slave node according to this protocol specifications.

The communication between the fLVPS and the Aux Board devices is made using the ELMB motherboard and the interface of the ELMB with the PVSS is done by an OPC server/client approach [9] where the client is provided by the PVSS manager and the OPC server by a software developed by the ATLAS DCS Central Team, CANopen OPC server. [10]

Figure 2 shows the layout of the ELMB based readout chain, for one Tile Calorimeter partition. In the LVPS system the maximum number of ELMB nodes per CAN branch is 16 and the number of CAN branches per partition is 5. Four of the CAN branches are used for communication with fLVPS devices and one for communication with AUX boards. The CAN Power Supply Unit (CAN PSU) is used to feed the CAN Transceiver part of the ELMB. The length of CAN branches, used to communicate with fLVPS devices is 120-150m and for AUX board devices it is ~10m.

The CAN communication speed for AUX board and fLVPS devices is set to 125KB/sec. Used CAN node addresses are from 1 to 16, as labelled on Figure 2. Branch #0 is used for the communication with AUX board devices and the others (branches #1 - #4) for the fLVPS devices. The numbering of Kvaser card [11] port matches to the branch numbering.

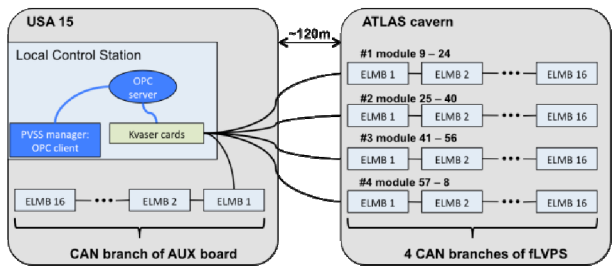

Figure 2: Communication schema with Aux Boards and fLVPS devices, for one Tile Calorimeter partition.

THE HIGH VOLTAGE DISTRIBUTOR SYSTEM

The High Voltage (HV) Distributor system is described in details [1], in the following we provide general information about the system power and communication lines at the ATLAS cavern.

The HV Distribution system consists of two devices: HV Bulk Power Supply (HV Bulk PS) and Super Drawer device. The HV Bulk PS devices are located in the ATLAS electronics cavern, called USA15 and the Super Drawer devices are located at the sub-detector area.

The HV Distributor system uses the HV Bulk PS device channels to provide input high voltage for each Super Drawer device. The HV Bulk PS provides 850 or 930 V, with the maximum DC current of 20mA. To use one input high voltage per Super Drawer, and to distribute and to regulate in-situ voltages of each individual PMT channel, with the precision better than 0.5V. The typical length of supply lines between HV Bulk PS and Super Drawer devices is about 120m.

The communication between the HV Bulk PS that uses ModBus/RTU protocol [12], and the DCS computer running PVSS which can only support ModBus/TCT, is achieved using a Port Server converter [13].

Inside the Super Drawer we have one HV_MICRO card, two HV_OPTO cards, HV internal and external buses, and the Flexible Bus (which links two HV Buses). The HV_MICRO controller card manages the voltages for individual PMTs through the HV_OPTO distributor cards and is used as the I/O and processing unit for CAN

communication providing functionality of the slave node according to the specifications of this protocol, as can be seen on Figure 3.

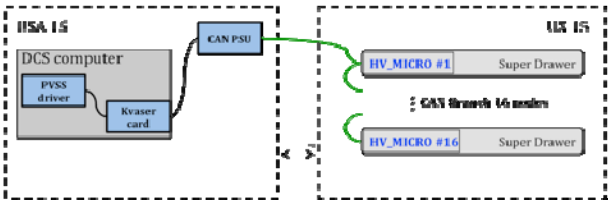

Figure 3: The HVMicro based readout chain.

CONCLUSIONS

The DCS implementation of Tile Calorimeter system follows requirements and suggestions from ATLAS DCS integration guidelines [5]. The DCS of the LVPS system represents comprehensive picture of the system and allows operator to have ability of full control over the system.

This paper provides detailed description of the hardware components of the LVPS system, emphasizes the critical parameters of the system and their monitoring thresholds for ALARM and WARNING. Implemented commands for individual device units of the LVPS system are given in details and time estimates for their execution are provided.

Usage of the Configuration and Conditions DB are also described in this paper. Analysis of the DCS data, from conditions DB showed that daily-recorded data size is in reasonable limit and allows understanding of the LVPS system behaviour. Implementation of the Configuration DB allows storing of the full information about the LVPS system calibration and nominal output voltages.

This paper presents a comprehensive picture of the Tile Calorimeter DCS system, as implemented following the requirements of the ATLAS DCS integration guidelines. The DCS of the LVPS system has been ready on time and proved to be both user-friendly and robust. It was successfully operated in a reliable manner for almost 2 years. A key element in this successful implementation was the correct selection of the building blocks since the beginning of the implementation.

We present the organization of the supervisory level for the LVPS system, information necessary for the operator to have the ability of full control over the system, and a detailed description of the hardware components of the LVPS system with emphasis on the critical parameters of the system and their monitoring thresholds for ALARM and WARNING. Details of the commands implemented for the individual device units of the LVPS system are given as well as time estimates for their execution.

Usage of the Configuration and Conditions DB are also described in this paper. Analysis of the DCS data from the Conditions DB showed that the daily recorded data is reasonable in size and allows understanding of the LVPS system behaviour. Implementation of the Configuration DB allows storing of the full information about the LVPS system calibration and nominal output voltages.

NSLS-II BEAM POSITION MONITOR EMBEDDED PROCESSOR AND CONTROL SYSTEM*

Kiman Ha#, J. De Long, Young Hu, Yuke Tian, Joe Mead, Kurt Vetter and L. R Dalesio BNL
Photon Sciences, Upton, NY 11973, U.S.A.

Abstract

The NSLS-II is a 3 Gev 3rd generation light source that is currently under construction. A sub-micron Digital Beam Position Monitor (DBPM) system consisting of hardware electronics, an embedded software processor and EPICS IOC has been successfully developed and tested in the ALS storage ring and BNL Lab.

INTRODUCTION

The BPM is a key component for the NSLS-II machine, it was designed and development based on digital down conversion and FPGA digital signal processing technology. Performance testing has already shown 200 nm stability under controlled thermal conditions [1]. The Digital Front End (DFE) board utilizes a Virtex-6 FPGA from Xilinx, it provides a Gigabit Ethernet TEMAC core and a Micro-Blaze 32-bit RISC soft core processor for system on a chip embedded applications. Digital signal processing components are designed and implemented using Xilinx System Generator and the Matlab/Simulink tools. The embedded processor was designed using Xilinx EDK for kernel based multi threaded applications. The DBPM uses an EPICS IOC for control and monitoring. The DBPM communicates with the IOC using a simple, robust Ethernet protocol to directly accesses a 1 GB DDR-3 memory space. An Industrial PC running the Linux Operating System (Debian 6) supports waveform monitoring including; ADC raw data waveforms (117 MHz), Turn by Turn (TBT, 378 kHz) waveforms, Fast waveforms (FA, 10 kHz) and slow data (SA, 10 Hz). ADC raw, TBT and FA data is triggered on demand and supports a large 1 million sample history buffer (~ 32 Mbytes) transmitted to host computers (EPICS IOC, Matlab stand alone client computer). The EPICS IOC application program is based on the EPICS Asyn driver for custom TCP/IP protocol communications. It provides very stable communication with the Microblaze core. This paper will describe the NSLS-II new advanced DBPM functionality, embedded software and EPICS for control systems.

HARDWARE

Figure 1 shows the NSLS-II DBPM design for the Injection system. It contains separated DFE and AFE boards. The DFE board includes a Virtex-6 FPGA and Gigabit ethernet PHY chip and 128 Mbyte x 16-bit Flash memory. The AFE board has four individual RF receiver channels and high speed digitizer a PLL, attenuators and a pilot tone RF frequency synthesizer.

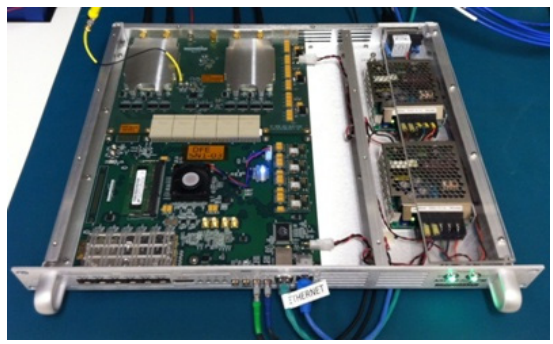

Figure 1: RF BPM for Injection System.

Embedded Event Receiver (EVR)

An embedded EVR with reduced functionality compared to the Micro Research Finland EVR board is implemented on the FPGA. The Embedded EVR synchronizes all of the BPM's data and generates synchronized clocks and trigger signals in addition to time stamps with 8 ns resolution.

Serial Data Interface (SDI)

A Fast Orbit Feedback System (FOFB) will be operational for the storage ring orbit stabilization. The NSLS-II requires a 10 kHz feedback rate. Vertical and horizontal Data is transferred to the cell controller every 100 uS using the Xilinx GTX transceivers at 5Gb/s. All data from all BPMs is collected at the cell controllers in approximately 20us.

RS232 Serial Interface

RS232 serial interface is used as a console port for the MicroBlaze processor. It is very helpful with system monitoring and diagnostics. The Microblaze initial boot information is displayed on the serial console. Boot manager, system reboot command and remote updating are operated using the serial console. This serial port connects with a terminal server (Ethernet to Serial converter box) for remote operation.

Tri-Mode Ethernet Interface

Virtex-6 Microblaze based TCP/IP socket communication performance is 4 Mbytes/sec, the RAW API mode is 3 times faster and the test results show a maximum of 12 MByte/sec. But the RAW API functions

* Work supported by DOE contract No: DE-AC02-98CH10886
#*kha@bnl.gov

have some limitations in that buffer overflow occurs during the multiple frame transmits. The DFE board utilizes onboard Marvel Alaska PHY device (88E1111) for Ethernet communications it supports 10/100/1000 Mbps/sec. The DFE board supports only GMII interface from the FPGA to the PHY chipset. The PHY connection to the EPICS IOC is through an RJ-45 Ethernet connector with built-in magnetics. The FPGA clock generator provides a 25 MHz external clock to PHY clock input.

EMBEDDED SOFTWARE

Figure 2 shows the internal FPGA components of the embedded processor and HDL signal processor. Xilinx provides a flexible embedded software development environment. The DBPM target board embedded software uses Xilinx Kernel mode. The Microblaze has application threads for multiple socket ports communicating with client applications. Multi sockets provide optimized communication speeds for different data structures. For example large waveform array reading (~32 Mb) takes approximately 30 seconds, to allow higher priority data transfers the large waveform thread can be pre-empted. For the embedded firmware development Xilinx software tool versions: XPS/SDK 13.2, Microblaze 8.2a, XilKernel 5.0 and LWIP 3.0 a are used..

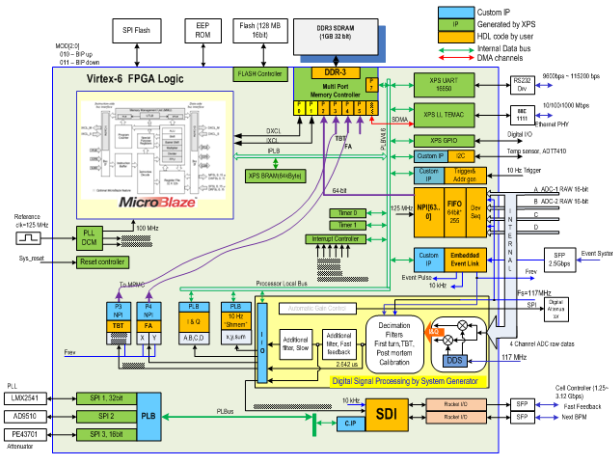

Figure 2: FPGA internal components for control and data processing.

MicroBlaze Soft Processor

The Microblaze core is a 32-bit RISC soft core processor using a Harvard architecture optimized for embedded applications. The Microblaze has a floating point unit, memory management unit, instruction and data caches and many other optimization functions. The EDK tool provides a simplified configuration wizard and it easily configures the BSP for FPGA embedded application. The Microblaze primary bus is the PLB, as master the MicroBlaze connects to slave PLB I/O peripherals. For the Virtex-6 DFE board the Microblaze and PLB are running at 100 MHz.

Lightweight IP (lwIP)

LwIP is an open source TCP/IP network stack for Microcontroller Ethernet applications. Xilinx EDK provides lwIP software customized to run on Xilinx Embedded systems. lwIP provides a TCP/IP socket layer API and raw API layer for applications. lwIP socket API is very similar to the Berkeley/BSD sockets therefore easily implements network programming . The lwIP v3.00.a version library is provided by Xilinx EDK 13.2.

MicroBlaze Processor Local Bus (PLB)

The Microblaze local bus interface is the 32-bit PLB and all I/O peripherals are PLB slaves. The Microblaze Data/Instruction cash bus interface to the multi-port memory controller which connects to the DDR-3 memory. Using external cash increases Microblaze and TCP/IP communication performance.

Multiport Memory Controller (MPMC)

Figure 3 and 4 show DDR write timing and the memory map. The MPMC is a key component for system performance tuning and real time operation. The MPMC physicaly interfaces to the DDR-3 memory and provides eight individual ports for the user bus interfaces. The DFE uses a SODIMM socket type 1GB DDR-3 memory and it is clocked at 400 MHz. It operates at double the rate of the clock and total the transfer rate is 32bits * 800 MHz. MPMC port 0 and port 1 is assigned for Microblaze Data/Instruction cash. Port 2 is a soft DMA port for the Gigabit Ethernet driver. Port 3 is connected to the ADC raw data path and operates at the ADC sampling frequency (117 MHz). Port 4 is assigned to the TBT data bus and Port 5 is assigned to 10 kHz FA data. One million points of ADC raw data and TBT and FA data can be copied to DDR-3 memory on demand or on a repetitive trigger.

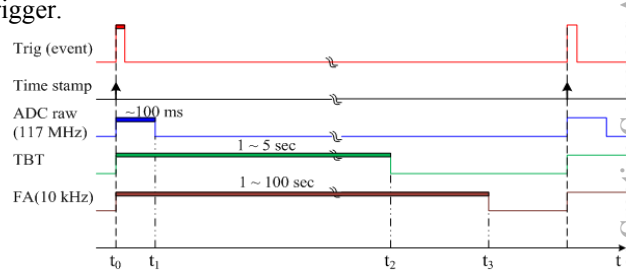

Figure 3: Timing of the waveform transmitter to DDR-3.

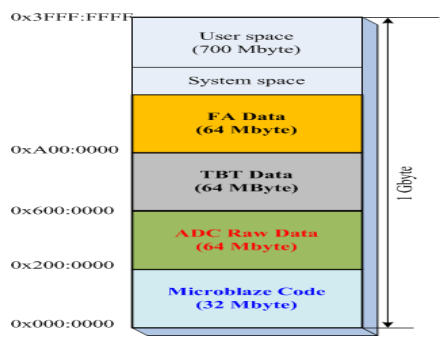

Figure 4: DDR-3 memory map (1 Gbyte).

BPM CONTROL AND IOC

Feedback control and event system links are separated from Ethernet because the global fast orbit feedback rate is 10 kHz and must provide global BPM data to the cell controllers deterministically. Similarly the event system runs at 125 MHz and requires determinism. Figure 5 shows a single cell BPM system configuration. The NSLS-II storage ring is divided into 30 such cells. Each cell has a VME EVR, a Linux IOC for communications and a cell controller for the fast orbit feedback system.

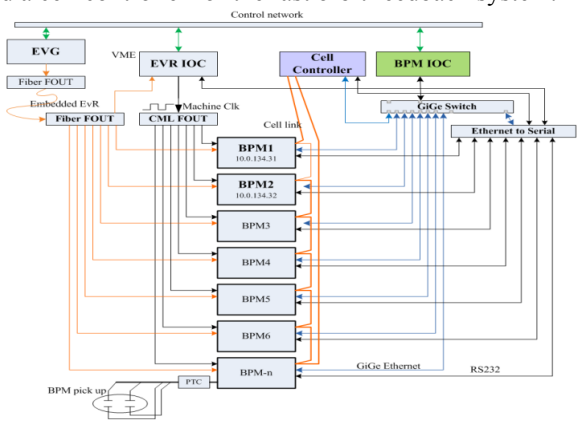

Figure 5: Layout of single cell.

Figure 6 shows embedded BPM software and EPICS IOC connect configurations. The Control System uses the Linux IOC for DBPM signal control and monitoring. IOC and BPM communication ports support Gb Ethernet. This communication uses a simple protocol based on register memory mapping. The DFE main device which is a Virtex-6 provides a hardware TEMAC Ethernet core and Microblaze soft processor that handle TCP/IP communication protocols. The EPICS IOC has three threads running for communication with the DBPM. The SA thread is designed for reading SA data (1024 bytes) and control register reads at the 10 Hz rate. The Microblaze SA server uses the RAW TCP/IP API functions for improved performance. The DDR waveform thread uses the socket TCP/IP API functions for stable communication because waveform data sets can be as long as 32 Mbytes. The DBPM EPICS IOC is an Industrial PC running the Linux Operating System, most communication is based on Ethernet ports.

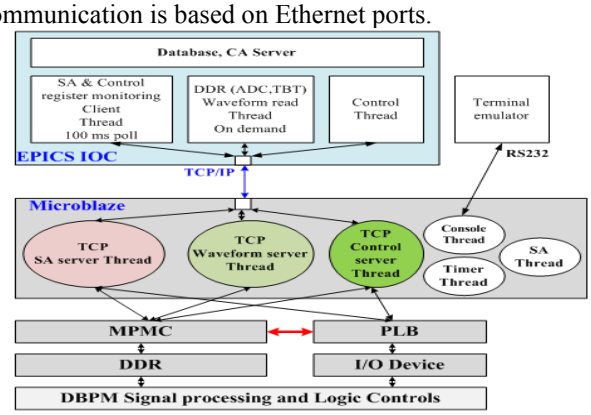

Figure 6: Control systems for BPM.

EPICS EXTENSIONS

Figure 7 shows EDM client examples for BPM controls and data measurements. ADC waveforms include 4 button signals: A, B, C, D and SUM data, the displayed waveform length is 4 k points and a slider PV can control the offset address within the 1Mpoint waveform. TBT waveforms include A, B, C, D, X and Y position, Sum and Q data. The TBT waveform length is 8000 points and a slider PV can control the turn offset within the 1 Million turn waveform. 10 kHz waveforms are the same as TBT waveforms. 10 Hz data is the 10 kHz data averaged over 1000 samples.

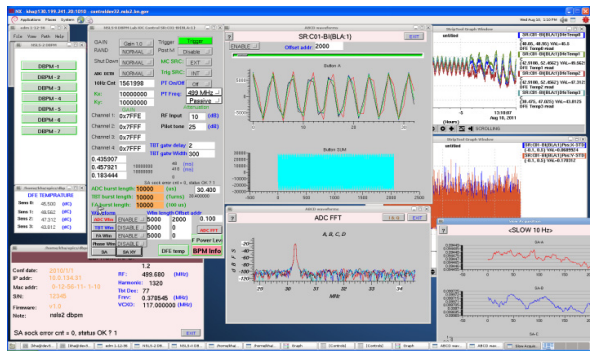

Figure 7: EPICS EDM screen for control and waveform monitoring.

SUMMARY

The development of sub-micron BPMs and their control system for the NSLS-II has been completed and successfully tested in the EPICS environment. FPGA based embedded software provides very reliable and stable operation. This year we will produce BPMs for the Linac and Injection systems, continue developing embedded firmware and EPICS software for the Booster and Storage ring BPMs.

ACKNOWEDGMENT

The authors are grateful and thank the NSLS-II beam diagnostics group. A special thanks to M. Maggipinto, A. Dellapenna Jr., and B. Bacha for their support. Also thanks to Michael Davidsaver and Jayesh Shah for VME event system support, Robert Petkus for BPM IOC and network integration.

A NEW FAST TRIGGERLESS ACQUISITION SYSTEM FOR LARGE DETECTOR ARRAYS

P. Mutti*, M. Jentschel, E. Ruiz-Martinez, J. Ratel, F. Rey, W. Urban,
Institut Laue-Langevin, Grenoble, France

Abstract

Presently a common characteristic trend in low and medium energy nuclear physics is to develop complex detector systems to form multi-detector arrays. The main objective of such an elaborated set-up is to obtain comprehensive information about all reactions. State-of-art γ-ray spectroscopy requires nowadays the use of large arrays of high purity Ge detectors (HPGe) often coupled with anti-Compton active shielding to reduce the ambient background. In view of this complexity, the front-end electronics must provide precise information about amplitude, time, detection position and possibly pulse shape. The large multiplicity of the detection system requires the capability to process the multitude of signals from many detectors, fast processing and very high throughput of more than 10^6 data words/sec. The possibility of handling such a complex system using traditional analogue electronics has shown rapidly its limitation due, first of all, to the non negligible cost per channel and, moreover, to the signal degradation associated with complex analogue path.

Nowadays, digital pulse processing systems are available, with performances, in terms of timing and energy resolution, equal if not better than the corresponding analogue ones for a fraction of the cost per channel. The presented system uses a combination of a 15-bit 100 MS/s digitizer with a PowerPC-based VME single board computer. Real-time processing algorithms have been developed to handle total event rates of more than 1 MHz, providing on-line display for single and coincidence events.

INTRODUCTION

The principle functions of the front end electronics for nuclear physics applications are to acquire the electrical charge pulses generated by a radiation detector, to extract the quantities of interest and to convert them into a digital format. Usually these quantities of interest are the particle energy, the time of arrival and the shape information [1].

In an ideal acquisition system, the analog signal has to be converted into a digital data stream as earliest as possible and then transferred to preserve the information. Today with the modern digitizers the restrictions of the A/D conversion have been reduced because of the increment of the sampling frequency and the resolution in terms of the number of bits. Besides the loss of information due to the A/D conversion error, the major problem of the fully digital approach is the huge amount of data to handle. It is almost impossible to have a system in which the data throughput rate allows the acquisition of all the channels and makes the on-line analysis at the same time, the loss of data it will be dramatic.

In order to reduce the amount of data to be transferred, a Field Programmable Gate Array (FPGA) can be used to perform on-line digital pulse processing and consequently extract and save the relevant quantities [2].

The present paper will start with the description of the chosen digital approach solution to maximize the throughput of the acquisition system. The digital pulse processing algorithm section summarizes the applied techniques to reduce the amount of data and extract the quantities of interest. It will be followed by a description of the on-line acquisition engine implemented at the Institut Laue-Langevin to cover the experimental needs. The achieved performances in a series of real experiments will be discussed followed by the most important conclusions gathered in the development of the project.

DIGITAL APPROACH

In an ideal acquisition system, the analog signal is converted into a digital data stream as earliest as possible and then transferred, without any loss of information, to a computer that can make the analysis and extract the quantities of interest off-line. Thanks to a great variety of hardware available, the end user is able to best match the requirements of the specific experiment concerning the critical phase of the A/D conversion. Applications implementing very fast response detectors or requiring precise time determination will most profit from a reduced number of bits (typically 8 or 10 bit) and a high sample frequency (from 500 MS/s up to 5 GS/s). The opposite is true when high-energy resolution is required but the detector signals are relatively slow. In such a case 14/15 bit digitizers are better suited at a price of a lower sampling (typically 100 MS/s). Besides the loss of information due to the A/D conversion error, the major problem of the fully digital approach is the huge amount of data to readout. It is necessary to restrict the acquisition to some selected parts of the signals.

Like in a common oscilloscope, this happens firstly by means of the trigger defining a certain time window in which the signal has to be recorded (acquisition window). The difference between a common oscilloscope and a digitizer is that the latter has several memory buffers for the triggers and can save subsequent acquisition windows without any dead time between them. Therefore, the acquisition can take place without the loss of any event, no matter what is the frequency and the distribution of them, at least until the readout rate allows the empting of the memory buffers. For the present application we have chosen a CAEN digitizer (mod. V1724 – 8 channels 15

*mutti@ill.eu

bit 100 MS/s). Each channel of the digitizer is equipped with a dedicated FPGA that continuously writes the digital samples coming from the ADC into a circular memory buffer. When it receives the trigger, it keeps saving the post trigger samples, then freezes that buffer (which is made available for the readout) and continues to save the samples into a new buffer. The record length (number of samples in the acquisition window) and the size of the post trigger are both programmable.

The use of the trigger is the first step towards the reduction of the overall data throughput rate. However, in most cases, this is not sufficient because the number of channels, the event rate (i.e. pulses per second) and the event size (record length for each pulse) are such that the total throughput rate exceeds the capability of any type of readout bus. It is hence necessary to apply some data reduction technique.

The simplest approach is to discard the channels or some parts of the records that do not contain any significant information (zero suppression). The ideal would be to apply on-line digital algorithms able to extract from the signal only the quantities of interest (i.e. the time of arrival or the energy of the particle) and save and transfer to the computer only those numbers. Sometimes, the best compromise is to have an intermediate solution in which the digitizer saves part of the waveform together with the quantities calculated on-line.

DIGITAL PULSE PROCESSING ALGORITHM

The purpose of the Digital Pulse Processing (DPP) is to perform on-line signal processing able to transform the row sequence of samples into a compressed data packet that preserves the relevant information. For this purpose, a specific algorithm implemented in each channel's FPGA allows to extract the energy and/or the arrival time of the detected pulses. The pulse conversion starts as soon as a trigger is generated. In our case, this is via a voltage step overtaking a programmable digital threshold rather then comparing the absolute voltage level, as in the case of analog systems.

For an accurate time determination, the traditional approach would make use of a Constant Fraction Discriminator (CFD), where the zero crossing of the sum of the input and the delayed, attenuated and inverted input, delivers the wanted information independently of the amplitude of the pulse. In the digital CFD the FPGA calculate the second derivative of the input signal (the direct output of the detector preamplifier). The input signal can be represented as the sum of two exponential decays being the fast component determined by the time constant of the detector and the slow one by the RC of the preamplifier. A simple calculation demonstrates that the zero crossing of such a second derivate depends only on the two time constants while it does not depend on the pulse amplitude. The zero crossing of the second derivate of the input signal delivers, therefore, an accurate time determination with an uncertainty equivalent to one unit of the sampling time.

A trapezoidal filter is applied to the input signal to derive its amplitude, proportional to energy. This filter can be shortly described as an algorithm able to transform the typical exponential decay signal generated by a charge sensitive preamplifier into a trapezoid [3]. The height difference between the signal baseline and the flat top of the trapezoid is proportional to the amplitude of the initial pulse.

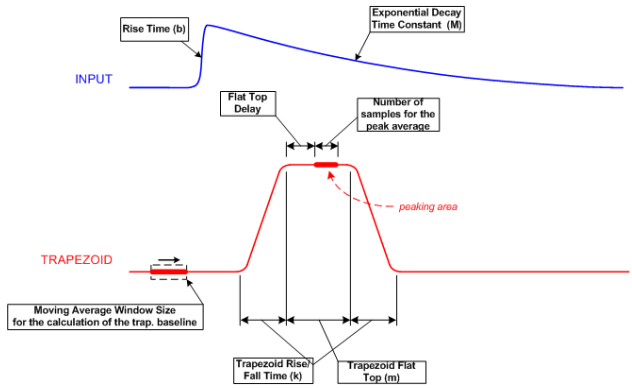

Figure 1: Trapezoidal filter with the relevant parameters.

Figure 1 describes all the relevant parameters necessary for a proper determination of the pulse height. This trapezoid plays more or less the same role of the shaping amplifier in a traditional analog acquisition system. We want to highlight the analogy between the two systems: both have a shaping time constant and must be calibrated for the pole-zero cancellation. For both, a long shaping time gives a better energy resolution but increases the probability of pile-up. Both are AC coupled with respect to the output of the preamplifier whose baseline is hence removed, but both have their own output DC offset, which constitutes another baseline for the peak detection. Setting the parameters of the trapezoidal filter is equivalent to change the shaping time in a classical spectroscopy amplifier.

ON-LINE ACQUISITION ENGINE

Our newly developed acquisition system consist of the following three main elements: a number of digitizers according to the required number of detectors, a processor card providing real-time algorithms and the instrument control software responsible for setting parameters, the real-time display and list-mode storage of data. Figure 2 represent schematically all the elements on the newly developed acquisition engine that will be discussed in further details in the following. The present system has been dimensioned according to the needs for the upcoming γ-spectroscopy campaign of measurements using the EXOGAM [4] high efficiency array of γ-ray detectors. Up to 10 segmented clover detectors will be used in the array. Segmentation is required to provide the optimum performance in terms of efficiency, energy resolution and minimization of multiple-hit events. These

Ge detectors will be surrounded by bismuth germanate BGO suppression shields and will also have passive heavy metal collimators for background reduction purposes.

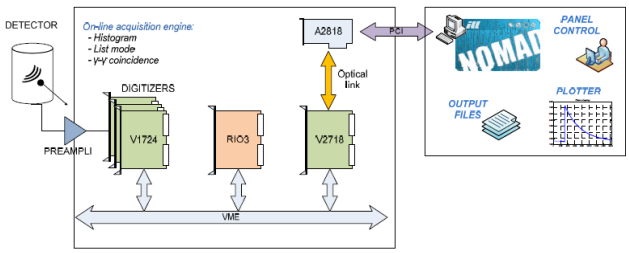

Figure 2: Schematic view of the acquisition engine.

Digitizers

The model used is the CAEN waveform digitizer board V1724. It is a 1-unit wide VME 6U module housing 8 channels 15 bit 100 MS/s flash ADC with threshold auto-trigger capabilities [5]. Trigger signals can be provided via the front panel input as well as via the VME bus, but they can also be generated internally, as soon as a programmable voltage threshold is reached. The individual auto-trigger of one channel can be propagated to the other channels and onto the front panel trigger output. The board features a front panel clock/reference I/O and a PLL circuit for clock synthesis from internal/external references. In this way, several boards can be phase synchronized to an external clock source or to a V1724 clock master board.

The digitizers consist of a common motherboard housing specific mezzanine cards for each channel. The motherboard houses the clock logic management and the readout control FPGA that provides the trigger management and acts as a bridge between the local bus and the different interfaces (VME 64X, Optical link, PCI express, USB 2.0). Mezzanine cards house the input front-ends and the channel FPGA that accounts for the analog-to-digital conversion, the digital pulse processing algorithm and the memory buffers. The readout control FPGA accesses the mezzanine cards through the local bus.

Processor Card

The real-time acquisition engine is implemented in a Power PC based VME board computer equipped with 256 MB of memory. This board does not contain any operating system to optimize real-time performances and prevent any dead time. A specific set of routines has been developed to account for the acquisition and all the functionalities necessary to access the digitizers [6]. We have developed real-time processing algorithms capable to handle total event rates of more than 1 MHz, providing on-line display for singles and coincidence events. The purposes of the processor card are:

- to create the data structures containing the variables and the parameters for the acquisition
- to initialize and program the digitizers
- to read the data from the digitizer, using BLT in the VME bus
- to analyze the acquired data extracting the wanted information and store them in the internal memory
- to generate the histograms for each input and for the coincidences.
- to create the list mode events
- to store list-mode data to the external mass storage.

Instrument Control Software

The instrument control software is acting as interface between the acquisition hardware and the user. It offers a full graphical interface to access all parameters related to the configuration of the digitizers as well as of the acquisition card. It allows real time visualization of all relevant spectra including double and triple coincidences.

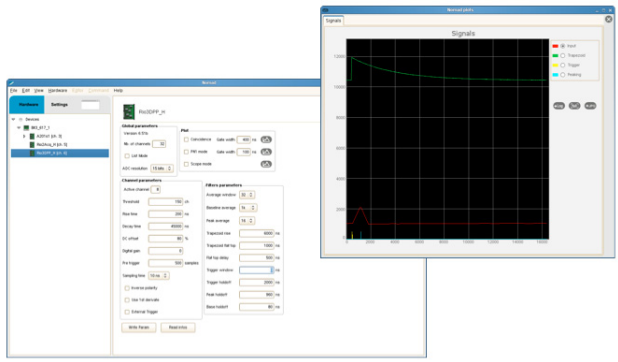

Figure 3: The digitizers setup screen and the oscilloscope live display.

Figure 3 depict the oscilloscope mode display used to tune the sampling parameters for each channel of the digitizer cards. This mode offers the unique advantage to visualize instantaneously the effects of any parameter modification with respect to all signals involved in the acquisition.

RESULTS

The new acquisition engine has been implemented with two different detector setups. The first test has been performed using an array of eight HPGe detectors for γ-spectroscopy studies from (n_{th}, γ) reaction. The goal of this experiment was, amongst others, to verify the beam quality, with respect to background and collimation, as well as the overall performance of the new acquisition in view of the upcoming EXOGAM campaign of measurements.

The detector setup of the second test was more complex, implementing a combination of HPGe and BGO detectors. The scientific goal of the experiment was to measure the e^+e^- pair-production cross-section close to the 1022 keV threshold [7]. We had the possibility to verify the accurate time synchronization amongst several digitizer cards as well as the capability of the system to handle detectors with completely different time response. Figure 4 shows the energy spectrum measured by the HPGe detector from ^{152}Eu radioactive source. We could

obtain an energy resolution of 2.45(5) keV at the 1408 keV γ-line. In the zoom area the doublet at 1085 and 1089 keV is clearly resolved.

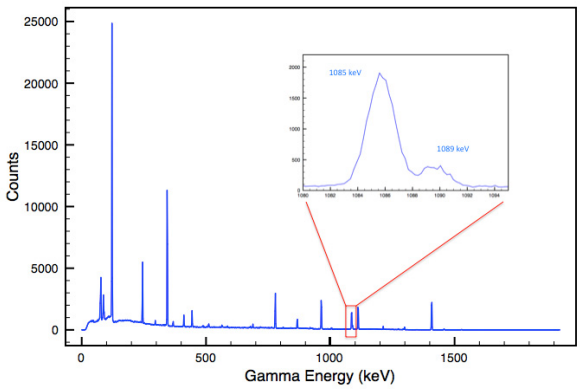

Figure 4: HPGe energy spectrum from the ^{152}Eu radioactive source.

From the analysis of the recorded list-mode data acquired using a ^{22}Na radioactive source in pair spectrometer mode, we could derive the timing properties of the new acquisition. The ^{22}Na source was selected because of the close vicinity of its 1274 keV γ-line with the energy range interesting for the experiment. Figure 5 reports the spectrum of the coincidence between BGOs and Ge detectors. The time difference between γ-detection in any of the BGO detectors and the corresponding detection in the Ge detector is plotted versus time. A single, very clean peak is visible at about 200 ns after the γ-detection in the BGOs.

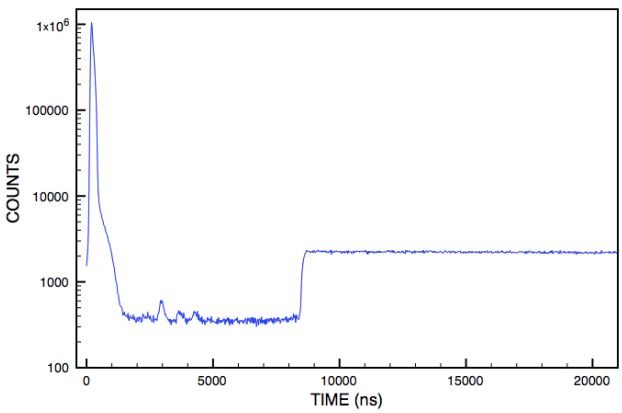

Figure 5: Time between BGO (start) and Ge (stop), measured for ^{22}Na source in pair spectrometer mode.

After about 8 μs the spectrum shows a rather low and extremely constant level of random coincidences. The absence of BGO-Ge coincidences below 8 μs could be explained by the conversion time of the system necessary to derive the energy and the time information. We do not have an evident explanation for the deformation of the main peak toward longer coincidence time. One possibility could be related to a slight misalignment in time on the signals from some of the BGOs.

CONCLUSIONS

The new acquisition system developed at the ILL implements a fully digital approach where the A/D conversion is performed directly on the preamplifier signal. With a reduced cost per channel, with respect to the analog approach, we are able to obtain information on energy, time and pulse shape. A direct comparison between the full digital system with an analog equivalent using the same detector did not show any significant loss in energy resolution.

All the relevant parameters are stored on EPROM for a maximum of flexibility and reproducibility. In the practical implementation using two different detector setups, the system has shown great modularity and the capability to be adapted to different types of signals from different detectors.

One major advantage is the possibility to acquire all signals independently from any trigger condition, reducing the chance of errors in the electronic setup and preserving a maximum of flexibility for the off-line analysis. Despite the large amount of data collected, the system never showed any significant dead time and our laboratory tests showed the possibility to achieve count rates higher that 1 MHz.

The combination of the new hardware and our control software offers the possibility to access a full set of graphical tools for configuration purposes as well as for on-line display of singles and coincidence spectra.

EVOLUTION OF THE CERN POWER CONVERTER FUNCTION GENERATOR/CONTROLLER FOR OPERATION IN FAST CYCLING ACCELERATORS

D. Calcoen, Q. King, P.F. Semanaz, CERN, Geneva, Switzerland

Abstract

Power converters in the LHC are controlled by the second generation of an embedded computer known as a Function Generator/Controller (FGC2). Following the success of this control system, new power converter installations at CERN will be based around an evolution of the design – a third generation called FGC3. The FGC3 will initially be used in the PS Booster and Linac4. This paper compares the hardware of the two generations of FGC and details the decisions made during the design of the FGC3.

FGC ORIGINS

LHC power converters are current sources composed of three elements:

- A *voltage source* consisting of the components needed to convert electrical energy from a given source into the desired voltage on a given load. This includes protections and analogue voltage regulation.
- Calibrated *current measurement* devices to acquire the measurement needed for the current regulation. In some cases these require very high levels of absolute accuracy, stability and very low noise.
- A *Function Generator/Controller (FGC)* which integrates the voltage source and current measurement system to become a current source by providing various services including function generation, current regulation and state control.

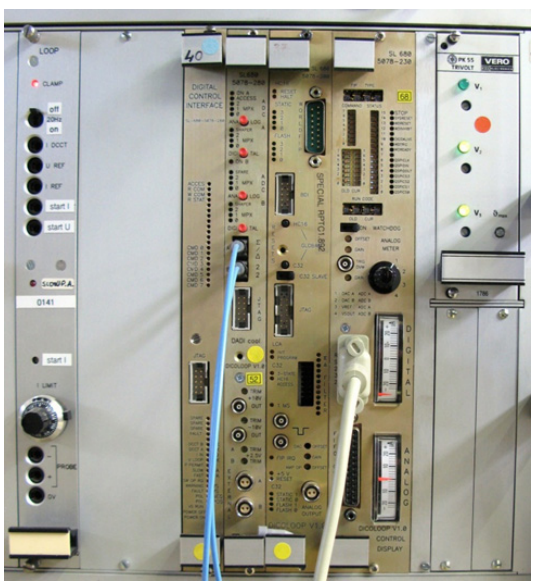

Figure 1: FGC1 developed from 1996-1999.

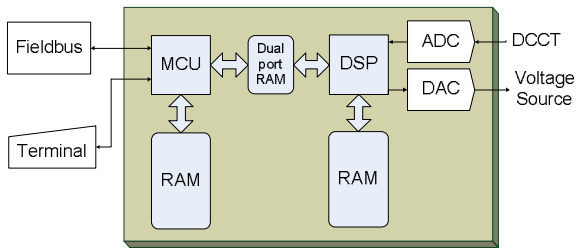

Figure 2: FGC core architecture.

The FGC project was launched in 1996 [1] with a specification that included:

- Resolution and tracking error down to 1 ppm on the current.
- Timing synchronisation to better than 1 ms.
- Radiation tolerance of up to about 2 gray per year with a life expectancy of 20 years.
- Use of WorldFIP as the synchronous fieldbus for remote operation and including support for real-time control at up to 50 Hz for accelerator-level regulation loops (i.e. orbit, tune and chromaticity).
- Mechanical and electronic design by CERN and manufacture of 2000 units by industry.

More specifically the FGC is responsible for:

- Generating the synchronised function of current versus time to be used as the reference, as required by operations at the system (accelerator) level.
- Measurement and regulation of the current.
- Control and monitoring of the power converter state.
- Integration with system level interlocks, in this case the LHC Powering Interlock Controller (PIC).
- Remote (WorldFIP) and local (RS232) communication.
- Collection and reporting of FGC and power converter diagnostics.
- Logging for post mortem analysis.
- Component identification and temperature measurement using Dallas 1-wire devices.

The first milestone for the project was to deliver 75 FGCs by the end of 1999 to run the converters in the LHC magnet test facility [2][3]. This milestone was met with a first non-radiation tolerant version called the FGC1, shown in figure 1. Seventy-five were produced and were operated in various test facilities from 2000 until 2010.

Figure 2 shows the core architecture of the FGC. It is based on an integer microcontroller (MCU) and a floating point DSP. This architecture was kept unchanged in the evolution from the FGC1 to the final design used in the LHC, the FGC2.

Figure 3: FGC2 developed from 2000-2003.

FGC2 OVERVIEW

At the core of both FGC1 and FGC2 is a Motorola M68HC16Z1 integer microcontroller (MCU) clocked at 16 MHz and a Texas TMS320C32 floating point digital signal processor (DSP) clocked at 32 MHz. Both devices date from the early 1990s and are still in production today. Each processor has its own error-corrected 512KB SRAM. Furthermore, 16KB of the MCU's SRAM is visible to the DSP to enable communication between them. Programs are stored in flash memories connected to the MCU.

Aside from the addition of error detection and correction (EDAC) chips on the SRAM, the biggest change in the FGC2 was mechanical. The circuits were reformatted from four 6U x 160 mm cards to six 6U x 80 mm cards which are mounted on a passive motherboard and enclosed inside a metal cassette, as shown in figure 3.

Glue logic was moved from a Spartan FPGA to eleven smaller flash-based Xilinx 95000 series CPLDs, all mapped into the MCU memory space. Being flash-based these CPLDs do not suffer from corruption of their programming under radiation and they were hoped to be sufficiently tolerant to support the radiation anticipated in the LHC. Unfortunately recent tests have shown that they have a small cross section for latch-up in a high-energy particle field and this will become a problem when the LHC reaches nominal intensity. A replacement design is in development for deployment in 2015 for the systems affected by radiation.

The redundant acquisition of the circuit current is performed by two ADS1201 delta-sigma ADCs. These were the first delta-sigma ADCs from Burr Brown and they do not contain a digital filter. This was implemented externally in Spartan 20 FPGAs which are vulnerable to radiation, so a second analogue interface was developed for the FGCs using MAX337CWI SAR ADCs. The noise and linearity are worse than the ADS1201 but the tunnel-based systems require less precision and these ADCs are sufficiently radiation tolerant to operate next to the LHC.

So far, the FGC2 has been a very successful design for the LHC which is currently operating at about 5% of nominal radiation levels [4]. Its strong points are, in particular:

- Use of the robust WorldFIP fieldbus for both data and synchronisation [5].
- Use of the Dallas 1-wire bus allowing identification of components and measurement of the temperature.
- Metal cassette providing a robust mechanical enclosure.

The FGC project delivered 1750 controllers for operation in the LHC in 2007 at a cost of 7 million Swiss Francs and 50 FTE years. Hardware development took six years and the software took 8 years so there was a strong motivation to re-use as much as possible when developing the next generation FGC.

FGC3 DESIGN

An evolution of the FGC2 was the chosen for the control of new power converters in the PS Booster and the new LINAC 4. The primary objective was to improve performance to allow a higher current regulation bandwidth while reducing costs by re-using as much as possible from the FGC2 development. A key choice was to not maintain the radiation-tolerant specification of the FGC2 since the FGC3 will not be deployed in radiation areas; this has a big impact on the cost of development and production.

Mechanics

The specification for the new controls electronics included the requirement that the crate be only 3U high, compared to 6U for the FGC2. Fortunately the increased density of modern components allowed the FGC3 to fit within a cassette that is half the height and width of the FGC2. The length increased from 160 to 220mm so the volume is reduced by a factor of 3. Figure 4 shows an FGC3 inside its cassette. It can run with passive ventilation and dissipates 8W. The rear connector is a

Figure 4: FGC3 developed from 2007-2011.

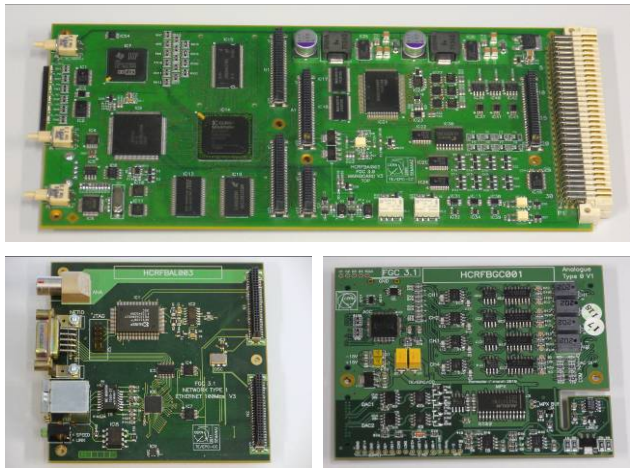

Figure 5: FGC3 motherboard, FGC_Ether and analogue interface daughter boards.

5-row 160-pin DIN connector (as used for VME 64 cards).

The FGC2 structure of a passive motherboard and six daughter boards is replaced by a densely integrated motherboard with two mezzanine daughter boards, as shown in figure 5.

Daughter boards

Anticipating an evolution of the network and analogue interfaces of the FGC3, these functions were moved onto two daughter boards.

When the FGC3 was designed, WorldFIP was the only network choice available, so the first network daughter board provides identical behaviour to the FGC2's WorldFIP interface. Software support for WorldFIP will be maintained indefinitely to allow an FGC3 to operate in the non-radiation areas of the LHC. Alstom stopped developing WorldFIP in 2001 so in 2010 we adopted Ethernet as our future fieldbus (see below). Thus a second variant of the network daughter board now exists (shown in figure 5) and this will be used in all non-LHC installations.

The first use of FGC3s is with small (±10A, ±30V) power converters in the PS Booster. For these an analogue daughter board has been produced with four high precision ADC channels (ADS1274) and two 16-bit DACs (MAX5541). This ADC is a sixth order delta-sigma design with a signal bandwidth up to 50 kHz. We implement our own low-latency digital filters in the FPGA on the motherboard, running at up to 50 ksps. The next application of the FGC3 will be with fast-pulsed converters based on capacitor discharge. These require two higher speed acquisition channels (500 ksps for up to 4 ms) so a second type of analogue daughter board has been designed with two ADS1675 delta-sigma ADCs as well as two slower channels using an ADS1274.

Processors

Modern MCUs or DSPs can easily outperform the combined processing power of the MCU and DSP in the FGC2. However, maintaining the architecture of an MCU and a floating point DSP does not present major disadvantages and allows the re-use of the FGC2 software. The required boost in performance comes from the Renesas RX610 MCU and Texas TMS320C6727b DSP. In the first design in 2007 the little-endian Renesas M32C/87 MCU was selected because of our long experience working with the Renesas M16C and M32C families. This choice required some low-level modifications in the software due to the endian difference with the FGC2's big-endian Motorola M68HC16Z1.

In 2010 the Renesas RX family became available and the Renesas roadmap presented it as the future for the M32C family. As well as having a higher clock rate and a floating point unit, the RX has selectable endianess so we could choose big endian and maintain compatibility with the HC16.

The change in MCU family introduced an eight month delay in the FGC3 project just as we were about to launch pre-series production. But the cost of this short-term delay was considered well worth the benefit given the long-term perspective of the design. More than 1000 units are expected to be produced over the next ten years.

Programmable Logic

The FGC3 logic is concentrated in one Xilinx Spartan 3AN/700 FPGA. Many of the designs were migrated from the FGC2's CPLDs with only minor modifications. This particular FGPA includes an EEPROM to hold its configuration which reduces the chip count by one and is better value than an FPGA plus external EEPROM.

One weakness in the FGC2 design was the inability to reprogram the CPLD logic remotely via the WorldFIP network, since the logic was needed for the processors to run. To avoid this restriction in the FGC3, the MCU and network interface can work without the FPGA. A new logic program can be received via the network and written by the MCU to the EEPROM inside the FPGA.

Synchronisation and communications

Synchronisation is a key requirement for the FGC. Both FGC2 and FGC3 need a 50 Hz sync pulse to discipline a phase-locked loop. In the FGC2 this is a digital PLL based on a fixed quartz oscillator while in the FGC3, clock purity is more important so a VCXO is driven by a 14-bit DAC. Thus the PLL has digital phase detection and a software PI algorithm combined with an analogue oscillator; but it still needs the 50 Hz sync.

When using the WorldFIP network, the sync pulse is simply the IRQ signal from the MicroFIP interface device. This works because WorldFIP is deterministic

Figure 6: Ethernet switch and sync pulse injector.

and the jitter is ±1.5 µs. Ethernet is not deterministic so a separate 50 Hz sync signal is routed to the FGC on a spare pair of wires in the UTP cable carrying the 100 Mbps Ethernet. The jitter on this sync signal is much less than 100 ns. To make this work, a 24-port sync pulse injector box is mounted under each 24-port Ethernet switch and each link is routed via the box. This is shown in figure 6.

The 50 Hz comes from a timing receiver in the gateway PC and is routed on a coax cable running in parallel with the gigabit Ethernet backbone which links the gateway to the switches. The extra cost and space required for this custom designed box is minimal and the reward is considerable: completely standard low-cost Ethernet infrastructure and components can be used. The gateway is a rack-mounted PC with two Ethernet interfaces built-in. The unmanaged switches are cheap commodity items and 100 Mbps LAN chipsets as used in the FGC3 are also widely available from numerous suppliers.

The FGC communication protocols are the same running on WorldFIP packets or raw Ethernet packets. The cycle time remains 50 Hz in both cases. Throughput is far higher with Ethernet because packets are up to 1500 bytes instead of 120 bytes and multiple Ethernet packets can be sent in the same cycle. The gigabit backbone has enough capacity to allow up to 64 FGC3s to be linked to each gateway (instead of 30 over WorldFIP) and for all to communicate at maximum rate simultaneously.

Network address

The network address of an FGC on WorldFIP (1-30) is encoded on a small passive kaptan circuit board soldered into the DB9 connector. Thus FGC cassettes may be changed but the network address (and thus the system's identity to the control system) remains with the connector.

This has proven extremely effective and reliable and to allow a similar solution with Ethernet the bottom byte of the MAC address is coded on a passive circuit board soldered into a DB9 dongle that must be plugged into the front panel of the FGC3 in order to release the system from reset. At boot up, the FGC3 reads the network address (1-64) from the dongle and uses it to form the MAC address that it writes into the SMSC LAN9221 Ethernet interface chip.

SOFTWARE TOOLS

The FGC2 software environment is based on a commercial IDE from RistanCASE GmbH called DAC and two commercial compilers; the HC16 HI-CROSS+ compiler from Hiware and the TMS320C3x/4x C compiler from Texas Instruments. Both were developed for Windows 98 and have been frozen since 1999. So despite being commercial products, neither is supported and compatibility with future versions of Windows is not assured. This is a concern given the anticipated 20 year lifetime for the FGC2.

The FGC3 software environment is based on open source tools. The IDE is Eclipse with Git for version control. The GNU gcc toolchain generates code for the Renesas RX610. It can also generate code for the TMS320C6x family but for the moment we are using a proprietary compiler from Texas.

Some bugs were detected in gcc for the RX and the M32C (when it was being used) but each time the availability of the source code and the large community that supports the gcc toolchain allowed us to fix the bugs and generate a new compiler in less than five days. This experience encourages us to migrate to gcc wherever possible.

We have chosen NewLib as the ANSI C library for the RX because it supports multi-threaded applications and is perfectly suited to small embedded systems.

The real-time OS used on the MCU of both the FGC2 and FGC3 is called NanOS. It is an in-house development derived by simplifying µC/OS-II [6].

CONCLUSIONS

Despite the completely different MCUs, DSPs and fieldbus technologies, the FGC3 is running the software developed for the FGC2. Both programs share a common code base and share about 90% of their source code. By maintaining the core architecture combined with the flexibility given by the programmable logic and the separation of functionality into different modules, both generations of FGC appear almost identical at the conceptual level.

The porting and debugging of the low-level functions to the new FGC3 took about 1 year, while for the higher level functions it took another 6 months. By comparison the development of the current operational FGC2 software took twelve years. By inheriting technology from the FGC2, the project saved an estimated 30 FTE years compared to starting from scratch.

As hardware design tools (PCB and FPGA) become more powerful, it has become clear that it is the software which becomes the hardest and most time consuming part of an embedded converter controller development project.

FAST SCALAR DATA BUFFERING INTERFACE IN LINUX 2.6 KERNEL

A. Homs#, ESRF, Grenoble, France.

Abstract

Key instrumentation devices like counter/timers, analog-to-digital converters and encoders provide scalar data input. Many of them allow fast acquisitions, but do not provide hardware triggering or buffering mechanisms. A Linux 2.4 kernel driver called *Hook* was developed at the ESRF as a generic software-triggered buffering interface. This work presents the portage of the ESRF *Hook* interface to the Linux 2.6 kernel. The interface distinguishes two independent functional groups: trigger event generators and data channels. Devices in the first group create software events, like hardware interrupts generated by timers or external signals. On each event, one or more device channels on the second group are read and stored in kernel buffers. The event generators and data channels to be read are fully configurable before each sequence. Designed for fast acquisitions, the *Hook* implementation is well adapted to multi-CPU systems, where the interrupt latency is notably reduced. On heavily loaded dual-core PCs running standard (non real time) Linux, data can be taken at 1 KHz without losing events. Additional features include full integration into the /sys virtual file-system and hot-plug devices support.

INTRODUCTION

Many scientific experiments carried out at the ESRF beamlines (BL) are based on the *scan* concept, where the evolution in time of one or more magnitudes is measured, typically while scanning the values of one or more parameters. Two modes of scan execution are identified. In "step-by-step mode", scan steps and measurements are performed sequentially (parameter change does not overlap in time with detector integration), starting and stopping the involved hardware at each point. In "continuous mode", both scan and measurement are executed in parallel, increasing the duty cycle of the X-ray beam utilisation, and/or notably reducing the total scan duration. As a drawback, time errors in the synchronisation of the readout of all the involved magnitudes affect the precision of the continuous scan.

Initial support to continuous mode at the ESRF was based on a "soft" synchronisation. In the first versions, a scan loop sequentially read, as fast as possible, motors and counters in a VME crate from a remote control workstation. The next approach read all these scan magnitudes sequentially inside a program running in the VME crate, removing the network from the sources of synchronisation error. A third performance improvement used a combination of hard and soft synchronisations. A hardware event triggered an interrupt request (IRQ), and during its IRQ service routine (ISR) all the scan scalar parameters (implemented as registers in instrumentation boards) were read and stored in a kernel buffer.

This IRQ *Hook* mechanism, originally developed in OS/9, was extended in Linux 2.2 [1] and 2.4 kernels with a flexible configuration interface. A dedicated TACO device server allowed the configuration and reading of the kernel buffer by the BL control program, running on the same PC or on a remote workstation.

In the migration of the VME and PCI instrumentation control at the ESRF to Linux 2.6, the new kernel device abstraction was extensively used [2]. In particular, a robust VME infrastructure was developed for Symmetric-Multi-Processor (SMP) environments, supporting device hot-plug functionality.

HOOK INTERFACE

Device Abstraction

Virtually all the common instrumentation hardware providing scalar parameters can fit in the simple device/channel concept. A hardware unit (VME/PCI board, serial line/GPIB/Ethernet instrument) is considered in this context a device. It groups control registers or commands, and exports one or more scalar channels. In addition, a device can generate events, typically hardware IRQs or operating system (OS) signals. These events are used in the *Hook* structure to trigger the readout of an arbitrary set of channels (belonging to the same and/or other devices), which are recorded in dedicated buffers.

Like its Linux 2.4 predecessor, the *Hook* interface is seen as a "kernel service" that instrumentation drivers register to using their names. This interface has been completely redesigned in Linux 2.6 to explicitly distinguish device, event, and channel structures. The same kernel "device" concept already identified by those drivers by a *major:minor* pair, like a specific PCI board structure associated to a kernel *pci_dev*, can contain an analogue *hook_dev* structure. Each *hook_dev* is the parent of a group of *hook_chan* and/or *hook_event* structures, depending of the board functionality.

Once all *hook_devs*, with their *hook_events* and *hook_chans*, are registered at drivers' start-up, they are ready to be used. The "user" side of the *Hook* "service" configures for an acquisition (*Hook* buffer) the event generator and the data channels to be read at each event. The event setup is performed through the board-specific drivers because of its complex nature. As a result of this setup, the event generator's driver installs the *hook_event* on the specified *Hook* buffer. The data channel setup is performed through the *Hook* driver interface, by using a list of *<drv_name, minor, chan_idx>* triplets that reference the channels to store on the buffer.

#alejandro.homs@esrf.fr

Each *hook_chan* has an associated *hook_chan_functs*; the structure defining the methods that carry out its specific functionality. During buffer channel setup a *prepare* method is called for each selected channel to perform its hardware initialisation. If it succeeds, the board driver module is locked to avoid to be removed from the kernel, and the *hook_chan_functs.lock* method is called to notify the board driver that the channel is in use. On each point the event generator driver calls the *Hook* interface, and the *read* method is called for all the involved *hook_chans* to trigger their readout. In case the channel value is not available immediately (it is called in kernel interrupt context), the *read* method can return a delayed completion request. Two solutions are identified in such a condition: asynchronous response or "read-before-next". In the former, the board driver is responsible of calling an asynchronous buffer write *Hook* function once the value is ready. The latter is requested if the driver does not provide asynchronous events; it can only ensure that the value will ready before the next event. Then, the *read_before_next* method is called to retrieve the previous channel value. Upon acquisition end the *unlock* method is called to release the channel.

A device can have channels of different classes, and hence have different set of methods, which might be the case of a multi-purpose counter/timer, analogue and digital I/O PCI board.

The current *Hook* implementation is Linux 2.6 kernel is limited to VME and PCI boards, which generate hardware IRQs and can be controlled by standard I/O operations. Communication-based devices using serial line, GPIB or Ethernet interfaces are not covered (yet). This limitation is due to both the complexity in accessing these platforms from the kernel interrupt context and the latency normally associated to those instruments. Nevertheless, Linux 2.6 kernels are so flexible and well structured that the support of those interfaces would be, in principle, possible.

Buffer Functionality

As we have seen, a fast acquisition involves an event generator, a set of data channels and a kernel buffer. Multiple acquisitions, each with its own buffer, can be performed in parallel on the same PC; they might share data channels if the *prepare* and *lock* methods' implementations allow it. The *Hook* driver creates 5 buffers by default, but this can be changed at module load time.

Two buffer filling modes are implemented: linear, where the acquisition stops once the buffer is full; and circular, where a ring buffer is implemented and data must be read continuously to not get overwritten. Data overrun is not considered a fatal error, but it is always reported.

In addition to kernel memory allocation and management, each *Hook* buffer is in turn a *hook_dev*. In this sense it exports two *hook_chans*: the point index and elapsed time in microseconds, both measured since the beginning of the acquisition. These two values are very important to determine if an event has been lost, either by the kernel (elapsed time between adjacent points higher than expected) or by the user-space program reading buffers (discontinuity in point index). Each buffer also exports a *hook_event*: a Linux software timer, whose period can be set with a time resolution given by the kernel HZ timer frequency (HZ=1000 in RedHat EL 4: 1 ms resolution).

A simple user-space library allows to configure the kernel interface and to read the buffer contents in an efficient way. As mentioned before, a TACO server on top of the library allows clients like SPEC [3], the central BL control application, to retrieve the data on the buffers. For ring-buffer acquisitions with intervals below 1 ms, the readout must be performed continuously due to the limited length of kernel buffers. For these fast acquisitions, the TACO server provides a bigger, user-space buffer and an auxiliary thread to empty the kernel buffer accordingly. This relaxes the time constrains of the remote SPEC main acquisition loop.

Virtual sysfs Support

The Linux 2.6 */sys* virtual file-system gives a useful user-space visibility of kernel structures. The *class* interface is used in the *Hook* to export information about the registered elements, replicating its tree structure of *hook_drv*, *hook_dev*, *hook_chan* and *hook_event*. In this direction, additional *read_desc* methods in *hook_chan* and *hook_event* are foreseen to provide a human-readable description through */sys* interface.

The *Hook* driver allows code tracing and debugging through messages on the standard kernel *syslog* interface. However, this is far from optimal for very fast acquisitions. In order to provide real time status to user space, the */sys* interface also publishes the instantaneous buffer information. It includes buffer setup (size, filling mode, list of channels) and buffer state (total number of events, number of points to be read and elapsed time since start).

IMPLEMENTATION

Supported Hardware

The standard ESRF BL instrumentation PCI and VME boards used for fast acquisition has been ported to the Linux 2.6 Hook structure:

- ESRF PCI P201 Counter/Timer
- ESRF VME VCT6 Counter/Timer
- Compcontrol CC133 Incremental Encoder
- ADAS ICV150 Analog-to-Digital Converter (ADC)

The first two boards implement both data channels and event generators; the last two only export data channels.

SMP and VME Issues

Linux 2.6 gives an improved support to hot-plug dynamics, that is, devices that can appear and disappear without system control. This is the case of VME devices connected to PCI/VME bus couplers; if the remote crate is disconnected the corresponding VME devices no longer exist on the system. It becomes an important issue in SMP

systems, because one or more CPU/cores could be referring to one device while another is trying to delete it. Such situation is even more critical in the *Hook* environment, which works on interrupt context and the system can immediately hang on invalid operations. Special care has been taken to protect all the data structures against these different situations.

Nevertheless, some crashes or conflicts are unavoidable if performance must be kept as first design priority. One example is found on scans with a PCI IRQ-based event generator that reads channels in VME boards. The conflict arises if the remote VME bus access (channel *read)* is done while another CPU/core is performing an Interrupt-Acknowledge cycle on the same VME bus. This condition is forbidden by the PCI/VME bus coupler, and implementing additional protection mechanisms would sacrifice the performance of fast acquisitions.

PERFORMANCE

Measurement Details

The current ESRF standard instrumentation control computer is based on 4U industrial PCs with Intel Core 2 Duo E6400 @ 2.13 GHz. The OS is RedHat EL 4 [Update 6]; the official Linux kernel 2.6.9-67.ELsmp has not been modified. Measurements have been performed on that system with two PCI counter/timer boards, and one SBS Bit-3 PCI/VME bus coupler with all the supported VME boards mentioned before. The event generator is either a PCI and/or VME timer programmed in free-run (cyclic counting), with end-of-count (EOC) IRQ activated. Another counter of the same board is set to count microseconds, and to latch its value on timer EOC. By reading the running counter value as first data channel and then its EOC-latched value, it is possible to calculate the effective IRQ latency. Moreover, by specifying the running counter value twice consecutively in the channel list, the channel access time is obtained, quantifying the systematic component of the synchronisation error.

Single Acquisitions

For the first tests the VCT6 channel 1 was configured as free-run timer for event generation and channel 2 as a microseconds counter, as explained before. The *Hook* buffer was setup to store 10 channels:

- VCT6 channel 2 running counter (read 4 times)
- VCT6 channel 2 latch counter
- *Hook* buffer 0 point index
- *Hook* buffer 0 time stamp (read twice)
- ICV150 channels 1 & 2

The measurement results for a timer event frequency of 5 KHz are shown in Table 1. Trying to measure at higher event frequencies resulted in data point lost.

A common conclusion for all the measured magnitudes is their small standard deviation (SD), showing that, in most of the time, the Linux SMP kernel is very regular in scheduling. The notable difference in VCT6 and P201 average IRQ latencies comes from the delay added by the PCI/VME bus coupler hardware and software layers.

Table 1: VCT6 IRQ Latency and Read Delays (µs)

Magnitude	Min.	Ave.	Max.	SD
VCT6 IRQ latency	15	24	126	0.8
VCT6 channel read delay	0	2.5	150	0.8
Hook channel read delay	2	3.1	22	0.7

The results for the same measurements using the P201 are shown in Table 2. Again, 5 KHz is the maximum readout frequency for stable acquisitions.

Table 2: P201 IRQ Latency and Read Delays (µs)

Magnitude	Min.	Ave.	Max.	SD
P201 IRQ latency	3	4.2	105	0.6
P201 channel read delay	0	0.9	7	0.25
Hook channel read delay	2	3.1	26	0.7

When analysing the maximum IRQ latency values, it should be noted that these conditions are close to the data sampling reliability limits. As it will be seen in the next section, lower sample frequencies give smaller differences between min./max. values. Indeed, the higher sample frequency, the larger amount of data per unit time must be transferred from kernel to user-space, and then to the TACO client via the Ethernet device, reducing the total idle times of CPUs, chipset and hardware busses.

In this sense, IRQs shared with active devices like network and disk controllers are a proven source of instabilities. The limited number of 4 available PCI IRQs in standard systems makes sharing difficult to avoid. It is better then to choose inactive devices like embedded USB or graphics controllers, unused in most of our applications.

It should be noted that jitter in ISR scheduling is important if the channels to be read are not hard synchronised with the event generator. This is the case of many encoders and ADCs. If, on the contrary, the boards allow data latching on hardware events, like VCT6 and P201 counters, this jitter does not contribute to the measurement error, and it is only important to guarantee that no point is lost by the kernel.

Parallel Acquisitions

It was explained before that the *Hook* has been designed to support parallel acquisitions. This can be useful when a monitoring process turns in the "background" during fast scans, or when devices with different speed capabilities are brought together on the same measurement.

We have performed both uncorrelated and correlated parallel acquisitions with the VCT6 and the P201 reading VME and PCI channels, respectively. In the uncorrelated case, both timers generate IRQs at the same frequency but

with unlinked phase, creating both coincidence and anti-coincidence conditions during very long scans due to the independence of their internal oscillators. In the second case, the VCT6 is the master timer and two P201 boards have been chained as slaves, so the VME and PCI IRQs synchronisation is at a sub-microsecond level.

Unlike previous measurements, where the acquisition was the only running task in the system, the parallel uncorrelated scans have been performed under heavy system load. Besides the fast acquisition, the system was executing:

- RedHat kernel recompilation using rpmbuild
- Intensive network data transfer with *iperf*-like program
- Linux root (/) partition imaging in a file on a user partition using basic OS tools.

Each of these tasks was continuously executed in *bash* with the basic loop *while true; do …; done*. The OS load ranged from 2.5 – 4.5, with an average of 3.5. The uncorrelated statistics under these conditions are shown in Table 3.

Table 3: IRQ Latencies (µs) in Uncorrelated Parallel Scans @ 1 KHz on Heavily Loaded System

Magnitude	Min.	Ave.	Max.	SD
VCT6 IRQ latency	14	26	80	3.0
P201 IRQ latency	3	6	110	8.5

Like in the previous cases, the tests ran for 24 hours, and no scan point is missing. Again, no specific tuning, or kernel patching has been applied; the default RedHat configuration with the *CONFIG_PREEMPT=no* kernel option has been kept.

The correlated measurements were performed on an unloaded system to double the scan rate. Table 4 shows the corresponding results.

Table 4: IRQ Latencies (µs) in Correlated Parallel Scans @ 2 KHz on Unloaded System (2x P201)

Magnitude	Min.	Ave.	Max.	SD
VCT6 IRQ latency	14	25	70	1.6
2nd P201 IRQ latency	45	50	104	2.0

The shift in the P201 IRQ latency comes from the fact that it is measured on the second board, on a different PCI slot that shares IRQ with a larger number of devices.

DEPLOYMENT AT THE ESRF

The Linux 2.6 *Hook* interface has been in production on ID31 Powder Diffraction ESRF BL for more than one year. It is the core of the BL experiments, which are normally carried out between 60 – 300 Hz sample rates (3 – 15 ms). System instabilities have been completely fixed during this time, including vulnerabilities against crashes of the remote BL control workstation. It is planned to be deployed to the other of ESRF BLs that use fast scans during the next long shutdown, in the framework of a global SuSE 7.2 → RedHat EL 4 migration campaign.

CONCLUSIONS

A generic kernel *Hook* interface, providing fast software trigger and scalar data buffering, has been ported to Linux 2.6. Good performance results are obtained with standard (non real time) RedHat EL 4 kernels running on mid-level dual-core CPUs. Up to two parallel, uncorrelated acquisitions can be performed at 1 KHz on heavily loaded systems without data lost. Support to */sys* virtual file-system provides useful information for *Hook* configuration, monitoring and debugging. The new module has been in production at the ESRF for more than one year; its deployment to the rest of ESRF BLs is foreseen soon.

Abstract

We have developed a data acquisition system for X-ray and optical imaging devices at SACLA (SPring-8 Angstrom Compact free electron LAser). The frontends with the Camera Link interface transfer the data to data-handling servers, which buffer and distribute the data to on-line monitors and a high-speed storage. The system is partly operational for SACLA beam commissioning since March 2011. The full system for X-ray 2D detector experiments will be released in November 2011.

INTRODUCTION

The X-ray free electron laser (XFEL) facility, SACLA, has been constructed at the SPring-8 site. The XFEL has unprecedented characteristics such as high peak brightness, ultra-short pulses, and full spatial coherence. These features are believed to open new opportunities in a variety of scientific fields. The facility has started to accelerate electron beams up to 8 GeV in February 2011, and the first X-ray laser was observed in June 2011.

In order to meet the requirements of proposed experiments to be performed at SACLA, Multi-Port Charge-Coupled Device (MPCCD) detector has been developed. The MPCCD sensor has 0.5 M pixels with 50 um square pixels. It is packaged in a 4-side buttable arrangement in order to enable large area detector by forming tiled array [1]. In the first experimental runs starting from March 2012, two arrayed detectors with 8 and 4 sensors in tandem will be the operation with maximum data rate reaching 5.8 Gbps. Each sensor is driven by a readout board, which transmits the digitized data through a Camera Link base configuration interface. The resulting data is processed on the VME Camera Link board, and transferred to a data-handling server via TCP/IP socket communication on 1 Gbps Ethernet. The data are pipeline buffered on the server, and sent to the on-line data visualization terminals, and a data file server connected to the high-speed data storage. The data acquisition is carried out completely in parallel so to ensure the scalability for detectors with arrayed sensors.

FRONTEND

We have developed the image data-handling scheme using the event-synchronized data-acquisition system [2]. We selected the Camera Link standard to achieve real-time triggering and high-speed data transfer. We have made available a VME Camera Link board for base configuration cameras in addition to the off-the-shelf PCI-express Camera Link board (AVALDATA APX-3318) for medium and full configuration devices. The former board has been developed in order to achieve on-the-fly lossless compression.

VME Camera Link Board

The VME Camera Link board is composed of a Camera Link base configuration interface and a processor PMC (PrPMC) mezzanine cards onto a carrier VME board with a FPGA [3]. Figure 1 shows VME Camera Link board. The data is first acquired via the Camera Link interface card and sent to the FPGA, Virtex-5 FXT (XC5VFX70T), and buffered to a DDR2 memory. Buffered data are compressed by a lossless range-coder algorithm within the FPGA, and transmitted to the buffer in the SDRAM on the PrPMC card. On the PrPMC card, TCP/IP socket server process is running on Freescale Semiconductor embedded Linux. A client process on the data-handling server receives the data through a Gigabit Ethernet interface. The achieved overall data rate in this scheme was 760 Mbps, which outperforms the required bandwidth of 480 Mbps. The carrier board has another Gigabit Ethernet interface. The Linux hard core on the FPGA has another TCP/IP socket server process on the TimeSys Linux, which can deliver the uncompressed data at the reduced frame rate for on-line monitoring. The measured data rate was 200-300 Mbps. Currently we have implemented MPCCD detector and a VGA camera for the screen monitors of the beamline.

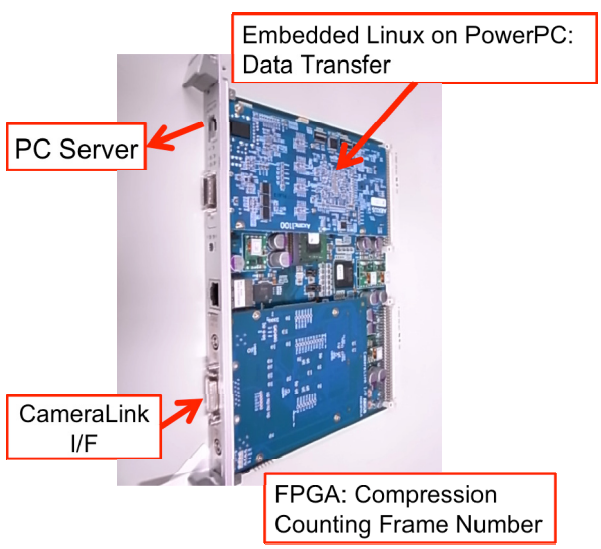

Figure 1: VME Camera Link board.

* kiyomichi@spring8.or.jp
# hatsui@spring8.or.jp

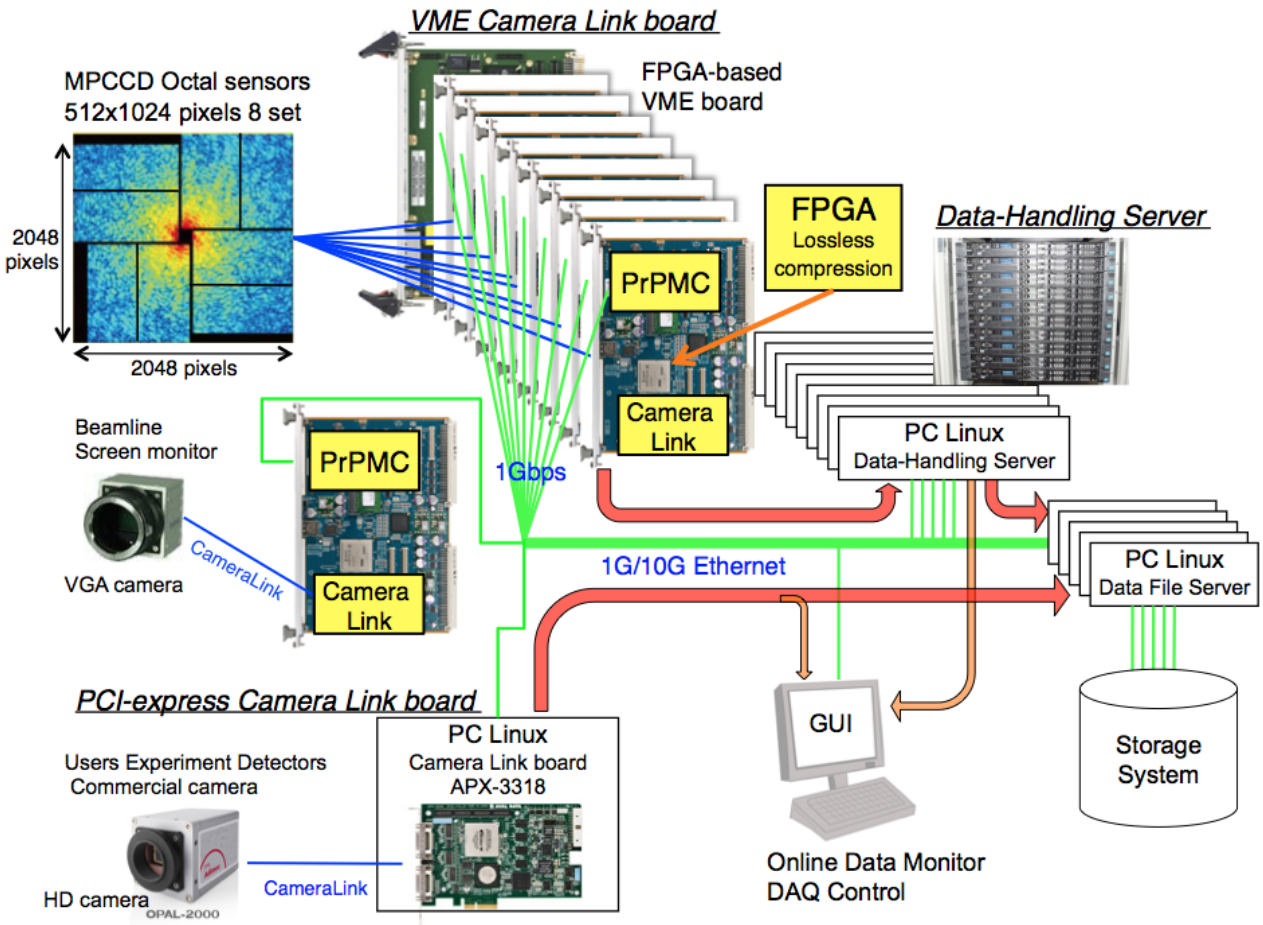

Figure 2: Schematic view and data flow of the image data-acquisition system (VME and PC).

Off-the-Shelf PCI-Express Camera Link Board

The PCI express Camera Link board (AVALDATA APX-3318) is employed on the operating system CentOS 5.4 for the sensor calibrations of MPCCD detectors. Long-term stability of the data transfer performance with this board in conjunction with high-definition (1920x1080 pixel) CCD cameras (Adimec OPAL 2000) has been successfully examined under the SACLA DAQ system. The stability verification with scientific CMOS camera (pco.edge PCO AG, 2560x2160 pixel) is now in progress. The current status of the VME-based and the PC-based Camera Link data acquisition are summarized in Table 1.

DATA-HANDLING SERVER

Figure 2 shows the schematic view and data flow of the VME-based and the PC-based image data acquisition systems. The data-handling server receives the data from the VME Camera Link board by TCP/IP socket connection. Each sensor data is transferred to the corresponding data-handling server, and stored temporally to a ring buffer in the server memory after formatting the data structure. Another process on the data-handling server reads the data from the ring buffer and provides a TCP/IP data transport service. A client process on a data file server receives the data and writes them to the connected high speed storage comprising of StoreNext single file system on the DDN (Data Direct Network) S2A9900 Storage. Total data throughput with 12 MPCCD sensors reaches 5.8 Gbps was achieved without any loss of the data.

Table 1: Current Status of VME-based and PC-based Camera Link Data Acquisition

	VME system	PC system
No. of support cameras	2	>100
Supported Camera Link configuration	base only	Base, medium full
Camera clock	< 80MHz	< 85MHz
Loss-less compression	Yes	No
MADOCA control	Yes	Yes

Another server process on the data-handling server offers data transmission service to the on-line data monitors. The process can provide basic analysis features such as averaging, region-of-interest statistical analysis, line profile calculation etc. User can also implement their own analysis code on the data-handling server to monitor

their experimental conditions. All these client-server processes as well as the board configuration control processes are controlled by the MADOCA framework [4] in order to achieve rapid implementation in the distributed SACLA DAQ system.

BEAM COMMISSIONING

The electron beam commissioning at SACLA started in February 2011, and the first light was observed in March. After three months of beam tuning, the first X-ray laser was observed in June. In the course of the commissioning, the DAQ system has been employed extensively for X-monitoring the spontaneous X-ray from the undulators, and X-ray laser characteristics.

SUMMARY

The image data acquisition system has been developed for the X-ray 2D detector and optical cameras at SACLA. We have developed a VME Camera Link board. We demonstrated that the data transfer from the MPCCD detectors to the high-speed data storage at a transfer rate of 5.8 Gbps. The off-the-shelf PCI-express Camera Link board was also implemented in the system in order to support wider range of cameras.

ACKNOWLEDGEMENT

The authors would like to thank Mr. Yu Kirino, Mr. M. Nagasaki, Mr. Y. Yoshioka and other members of ARKUS Corporation for the development of VME Camera Link board.

POWER SUPPLY CONTROL INTERFACE FOR THE TAIWAN PHOTON SOURCE

C.Y. Wu, Jenny Chen, Y.S. Cheng, P.C. Chiu, Demi Lee, C.Y. Liao, K.B. Liu, K.T. Hsu, K.H. Hu, C.H. Kuo,
NSRRC, Hsinchu 30076, Taiwan

Abstract

The Taiwan Photon Source (TPS) is a latest generation synchrotron light source. Stringent power supply specification should be met to achieve design goals of the TPS. High precision power supply is equipped with 20, 18, and 16 bits DAC for the storage ring dipole, quadrupole, and sextupole magnets with Ethernet interface. Control interface include basic functionality and some advanced features which are useful for performance monitoring and transient diagnostics. These power supplies can be access by EPICS IOCs. Corrector power supplies control interface is a special design embedded interface module which will mount at the corrector power supply crate to achieve required performance. The setting reference of the corrector power supply is generated by 20 bits DAC and reading is done by 24 bits ADC. The interface module is embedded with EPICS IOC for slow control. Fast setting ports are also supported by the internal FPGA for orbit feedback.

INTRODUCTION

The TPS is a latest generation of high brightness synchrotron light source which has been under construction at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan since 2010 [1]. It consists of a 150 MeV electron Linac, a 3 GeV booster synchrotron, and a 3 GeV storage ring. The magnets of TPS are important components around strong ring, booster ring and transport lines. These magnets are used to bend electron and keep electron orbit of storing ring and booster ring. In order to achieve these requirements, many types of power supplies will be used for different magnets. The TPS power supplies control interfaces include Ethernet and CPSC (Ethernet). The functionalities, operation interface and preliminary test of power supplies will be shown in this report.

The EPICS (Experimental Physics and Industrial Control System) is a set of open source software tools, libraries and applications developed collaboratively and used to create distributed soft real-time control systems for scientific instruments such as the particle accelerators [2]. Many resources and supports are available as well as numerous applications for accelerator have been developed.

As a result, the EPICS framework was also selected as control system infrastructure for the TPS project. The EPICS platform has been gradually built and tested to control and monitor the subsystems of TPS. Utilizing EPICS channel access mechanism with the specific toolkits, the data can be accessed between the IOCs and the clients.

STORAGE RING POWER SUPPLY CONTROL INTERFACE

TPS power supplies control interface are divided into four categories rather than a unified solution. These four kinds of power supplies will be provided by three different vendors. The reason of this choice is to meet the practical situation from manpower, budget and available vendors.

Table 1: TPS Storage Ring Power Supply Summary

Magnet	Type	Max Current	Stability ppm	Number of PS	Vendor	Control Interface
Dipole	Unipolar	750 A	±10	1	IE Power (Eaton)	Ethernet
Quadrupole	Unipolar	250 A	±10	240	Chroma ATE Inc.	Ethernet
Sextupole	Unipolar	250 A	±50	168	Chroma ATE Inc.	Ethernet
Corrector	Bipolar	± 10 A	±10	HC: 168 VC: 168 Fast HC: 96 Fast VC: 96	ITRI	CPSC Ethernet – EPICS CA SFP – Orbit Feedback
Skew Quadrupole	Bipolar	± 10 A	±10	96	ITRI	CPSC (Ethernet)

ITRI: Industrial Technology Research Institute of Taiwan, R.O.C.

Dipole Magnet Power Supply

The storage ring dipole DC power supply will be equipped with Ethernet interface. Control resolution will be 18 bits effective number, noise and drift will be better than 10 ppm and it had contracted to IE Power [3] (acquired by Eaton Corporation in 2011).

Quadrupole and Sextupole Magnet Power Supply

The intermediate power supply for storage ring quadrupole and sextupole magnet with current rating 250 Amp will be equipped with Ethernet interface as well. The quadrupole magnet power supply is 18bit with higher stability than sextupole magnet with 16 bits. The two kinds of power supplies are both contracted to a local company Chroma ATE Inc. [4] and would have internal data buffer for transient recording capability.

Corrector Power Supply and Skew Quadrupole Power Supply

The small power supply for corrector magnets in the range of ±10 Amp categories will be interfaced to analogue interface directly. The power supply is NSRRC home made and manufactured by Industrial Technology Research Institute of Taiwan, R.O.C. [5]. The controller

interface CPSC (Corrector Power Supply Controller) is dedicated to be designed for both EPICS control system and fast orbit feedback application. Table 1 summarizes the specifications of storage ring power supplies.

Control system for the TPS is based upon EPICS toolkit framework. The EPICS toolkit provides standard tools for display creation, archiving, alarm handling and etc. These toolkits which have various functionalities will be employed to monitor and to control accelerator system.

There are 24 of dedicated cPCI EPICS IOCs are built individually at the 24 cells of storage ring to operate the power supplies respectively. Each IOC is used to control 10 quadrupole magnet power supplies and 7 sextupole magnet power supplies, and one of IOC is appended to control only one dipole magnet power supply.

The cPCI EPICS IOC equipped with the latest generation CPU board will be standardized as ADLINK cPCI-6510 CPU module [6]. The 6U cPCI platform was chosen for the EPICS IOC platform. Local company manufactured crate and CPU module which could provide an economic solution is the major reason. StreamDevice is a feasible tool to build connection between EPICS IOC and power supplies.

The small power supplies applied for both slow/fast correctors and skew quadrupole magnets. There will be 8 power supply modules in one crate and the first slot will be plugged in one CPSC. Besides general control, monitor and configuration, the fast correctors will be also applied for the fast orbit feedback. The CPSC with EPICS IOC is therefore dedicatedly designed and the embedded FPGA will handle fast setting application. Synchronization mechanism and built-in waveform are also supported. Figure 1 shows the overall control of power supplies for each cell of the storage ring.

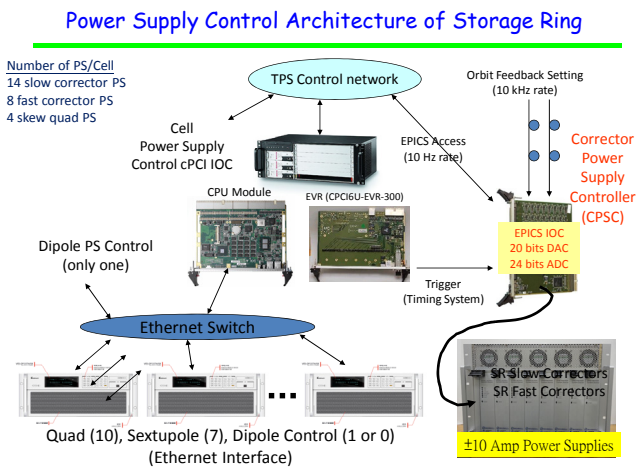

Figure 1: Control infrastructure in one cell of TPS storage ring power supplies.

BOOSTER RING POWER SUPPLY CONTROL INTERFACE

The booster power supplies are composed of one dipole power supply with maximum current 1200 Ampere and four family quadrupole power supplies with maximum current of 130 Ampere. These power supplies will be equipped with the same controller with serial control interface internally. Serial to Ethernet adapter will interface with control system. These power supplies will support external reference input or internal waveform generator for booster power supply ramping. The overall booster ring power supplies control interface is shown in Fig. 2. The most probably booster ramping waveform is sinusoidal wave. Two family of sextupole are driven by two small power supplies. There are 60 horizontal corrector and 36 vertical correctors. Corrector power supplies of the booster will adopt CPSC also. If corrector ramping is necessary, the CPSC has built-in waveform generator which can fulfil this functionality. Table 2 summarizes the specifications of booster ring power supplies.

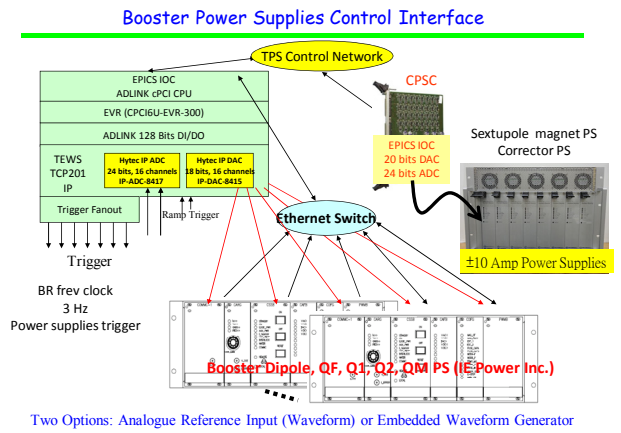

Figure 2: Control infrastructure of TPS booster ring power supplies.

Table 2: TPS booster ring power supply summary

Magnet	Type	Max Current	Stability ppm	Number of PS	Vendor	Control Interface
Dipole	Unipolar	1200 A	±10	1	IE Power (Eaton)	Ethernet*
Quadrupole	Unipolar	130 A	±10	4	IE Power (Eaton)	Ethernet*
Sextupole	Bipolar	± 10 A	±10	2	ITRI	CPSC (Ethernet) with Waveform support in CPSC
Corrector	Bipolar	± 10 A	±10	HC: 60 VC: 36	ITRI	CPSC (Ethernet) with Waveform support in CPSC

TRANSPORT LINES POWER SUPPLY CONTROL INTERFACE

Power supplies for the transport lines includes linac to the booster transport line (LTB) and booster to the storage ring (BTS) dipole magnets, quadrupole magnets and correctors, and DC septa are summarized in Table 3 and Table 4. It was decided that the transport line dipole and quadrupole power supply will adopt the same type power supply as the sextupole power supply of the storage ring to minimize the types of power supply. The rating of the sextupole power supply is 250 Ampere that need parallel two and three sets for the BTS dipole (484 Amp) and DC septa (608 Amp) applications. The power supplies have

the same Ethernet interface with the storage ring sextupole. Despite the corrector for the transport line is much relaxed in the noise specification, the power supply same as the storage ring corrector will be used for this applications to simplify the types of power supply. The corrector power supply for transport line will be controlled by the CPSC module also.

There are two DC septa serve for the booster extraction and storage ring injection to relax the single long pulse septum required due to limited space available for these pulse septa.

Table 3: TPS LTB power supply summary

Magnet	Type	Max Current	Stability ppm	Number of PS	Vendor	Control Interface
Bending	Unipolar	250 A	±10	1	Chroma ATE Inc.	Ethernet

SR extraction DC Septum	Unipolar	750 A	±50	3 (parallel)	Chroma ATE Inc.	Ethernet

POWER SUPPLY CONTROL ENVIRONMENT

To control and monitor power supplies based on EPICS environment via Ethernet, the clients should be installed the specific EPICS base and the graphical OPI (Operation Interface) toolkits, such as EDM (Extensible Display Manager) and MATLAB (channel access via the labCA module) for EPICS channel access.

STORAGE RING POWER SUPPLY OPERATION INTERFACE

The EDM toolkit was chosen to develop the operation interface. The client console can use the specific EDM page to access the data via PV channel access. The preliminary GUI page of storage ring dipole, quadrupole and sextupole magnet power supplies controls should be shown in Fig. 3. Figure 4 shows the GUI page of storage ring vertical corrector, horizontal corrector and skew quadrupole magnet power supplies controls. The macro name method was regularly used to switch each display page. The main control page was shown critical information for observing status easily, and the main operation process functions are also executed from the panel.

The MATLAB toolkit with labCA is adopted to develop the high level application program for commissioning and diverse operation procedures. The application includes the specific overall power on/off control, degauss process, checking power supply status, operation performance analysis, operation statistics and etc. The various operation processes will be developed and tested according to the various operation modes. The detail control page of power supplies with the trend plot for observing is shown in Fig. 5. It shows the current variation during the degauss process executed. The degauss application is also developed with the specific function of batch process to reduce the peak of power consumption for saving energy.

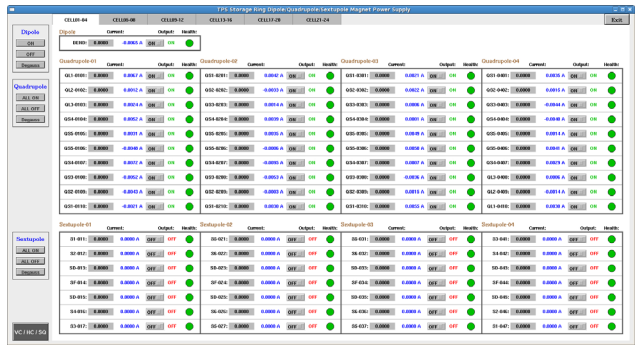

Figure 3: The operation interface of storage ring dipole, quadrupole and sextupole magnet power supplies.

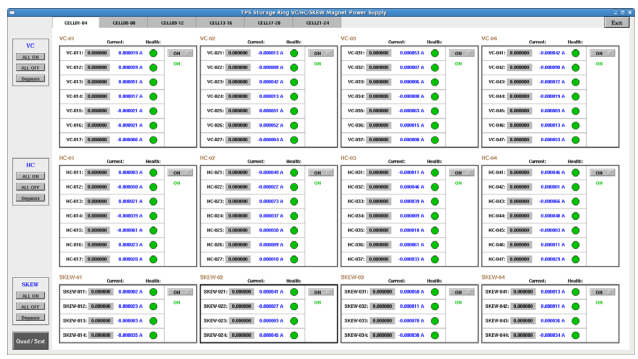

Figure 4: The operation interface of storage ring vertical corrector, horizontal corrector and skew quadrupole magnet power supplies.

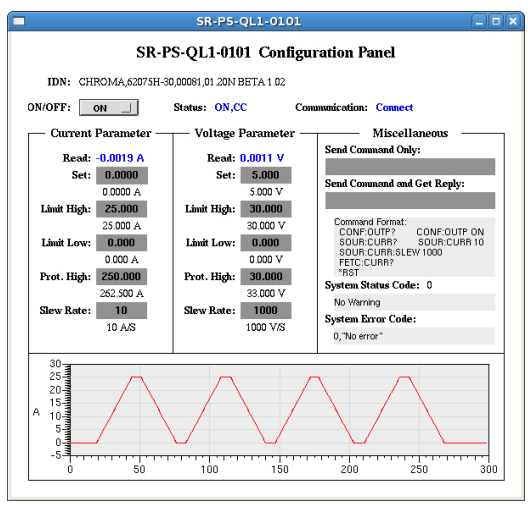

Figure 5: The trend shows current variation of the quadrupole magnet power supply during the simulated degauss process.

PRELIMINARY TEST OF INTERMEDIATE POWER SUPPLY

The several prototype intermediate power supplies for storage ring quadrupole magnet and sextupole magnet have been delivered in NSRRC. These power supplies including 18 bit resolution is used to control quadrupole magnet and 16 bit resolution for sextupole magnet. These power supplies have internal data buffer for transient waveform recorder. The maximum recorder time is 10 seconds with 1k samples/sec and 10000 recorder points. The transient waveform recorder is helpful to analyse behaviours of power supply.

The quadrupole magnet power supply provides sinusoidal wave generator in output DC current of power supply. The frequency and amplitude of sinusoidal wave are adjustable. The sinusoidal wave generator will be used to diagnose power supply and beam physics applications. Figures 6-7 show functionality tests include transient waveform recorder and sinusoidal wave generator for sextupole magnet and quadrupole power supplies. Figure 8 displays current setting resolution test of the prototype sextupole magnet power supply. The resolution is 10 mA with magnet load. The current setting resolution is 5 mA with magnet load for quadrupole magnet power supply is shown in Fig. 9.

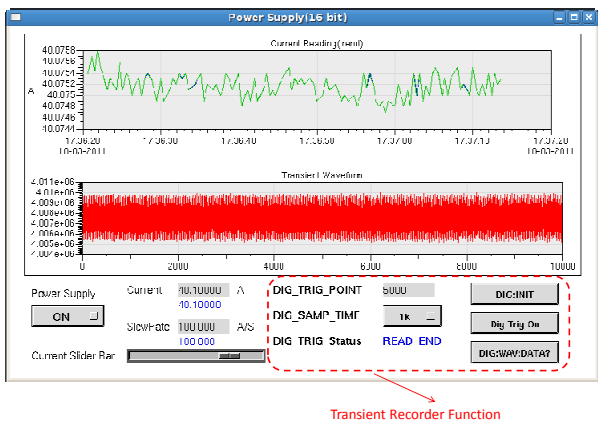

Figure 6: The engineer test EDM screen for functionality of the sextupole magnet power supply.

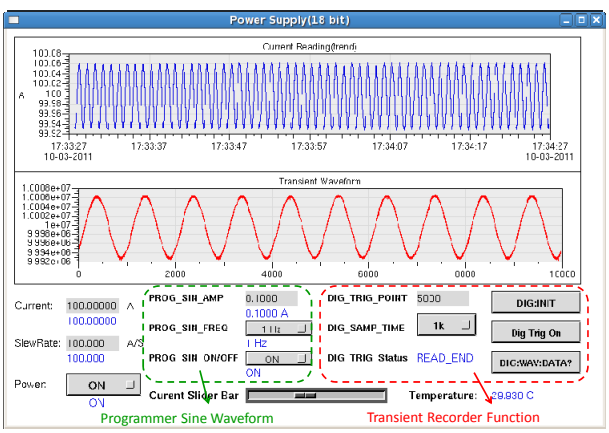

Figure 7: The engineer test EDM screen for functionality of the quadrupole magnet power supply.

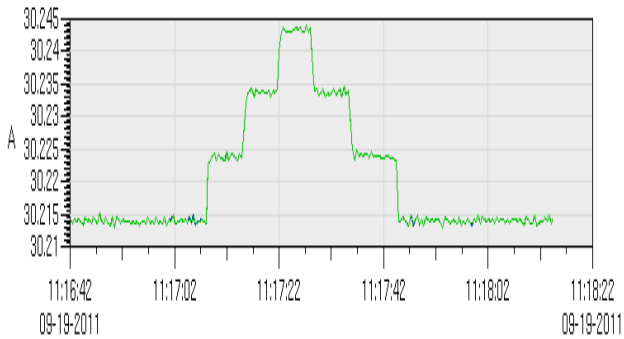

Figure 8: The current setting resolution test of the sextupole magnet power supply.

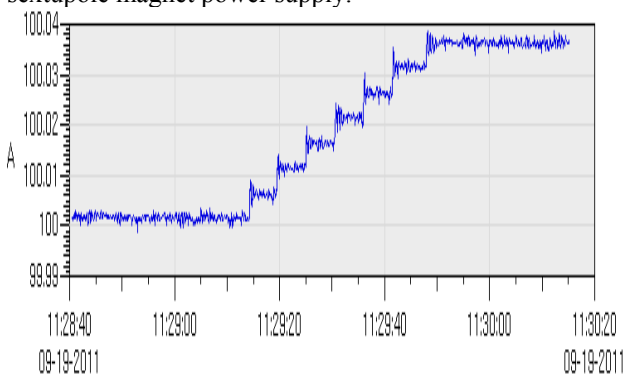

Figure 9: The current setting resolution test of the quadrupole magnet power supply.

SUMMARY

The power supply system of TPS is still in the acquisition phase. Most of power supplies will arrive in 2012. Preparation of the power supply control interface is on going. Prototyping of EPICS support for intermediate power supply of the storage ring, booster ring and transport lines are in proceeding. Plan of the power supply control for main power supply of the storage ring and booster ring is on the way. The CPSC module was contracted to the vendor, detailed design is in proceeding.

Preliminary user interfaces and operation procedures are presented in this report. Before power supplies delivered, the virtual power supply control environment was constantly established for developing the operation applications in advance. The operation applications include the operation interface, power on/off setting and checking, degauss process and etc. The various operation processes will be developed and tested according to the various operation modes. The performance and high level applications of power supplies of TPS will be demonstrated other reports in the future.

DEVELOPMENT OF PATTERN AWARE UNIT (PAU) FOR THE LCLS BEAM BASED FAST FEEDBACK SYSTEM*

K. H. Kim#, S. Allison, D. Fairley, T. M. Himel, P. Krejcik, D. Rogind, E. Williams, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, U.S.A.

Abstract

LCLS is now successfully operating at its design beam repetition rate of 120 Hz, but in order to ensure stable beam operation at this high rate we have developed a new timing pattern aware EPICS controller for beam line actuators. Actuators that are capable of responding at 120 Hz are controlled by the new Pattern Aware Unit (PAU) as part of the beam-based feedback system [1]. The beam at the LCLS is synchronized to the 60 Hz AC power line phase and is subject to electrical noise which differs according to which of the six possible AC phases is chosen from the 3-phase site power line. Beam operation at 120 Hz interleaves two of these 60 Hz phases and the feedback must be able to apply independent corrections to the beam pulse according to which of the 60 Hz timing patterns the pulse is synchronized to. The PAU works together with the LCLS Event Timing system which broadcasts a timing pattern that uniquely identifies each pulse when it is measured and allows the feedback correction to be applied to subsequent pulses belonging to the same timing pattern, or time slot, as it is referred to at SLAC. At 120 Hz operation this effectively provides us with two independent, but interleaved feedback loops. Other beam programs at the SLAC facility such as LCLS-II and FACET will be pulsed on other time slots and the PAUs in those systems will respond to their appropriate timing patterns. This paper describes the details of the PAU development: real-time requirements and achievement, scalability, and consistency. The operational results will also be described.

INTRODUCTION

SLAC timing system generates 360 Hz fiducial which conducts timing events and is synchronized with the 60 Hz AC power line phase[2, 3]. Thus, there are 6 time slots, each of them corresponding to a different AC power line phase. According to the 120 Hz beam repetition, we need to choose 2 different time slots – TS1 and TS4 for the LCLS, then the LCLS beam runs on the two different AC phases. The different AC phase makes different gain or different response on the actuators – magnets and RF power in accelerator. For the stable 120 Hz beam operation on the LCLS, we need to compensate the different response on the actuators. There are other power line variation sources at the SLAC such as the FACET and LCLS-II which are other beam programs, those are pulsed on other time slots and makes different power line variations. Thus, each of the beam programs makes different power line variations, and needs to compensate for these variations for the stable operation. All of the power line variations can be recognized by the timing pattern on the event system. Thus we have developed a new timing pattern aware EPICS controller which is called Pattern Aware Unit (PAU) for the beam line actuators (Fig. 1).

The PAU should be located in the actuator, and receives control values from the beam-based fast feedback or higher level feedback loop. The feedback system has multiple independent feedback loops which correspond to the each timing patterns. The PAU selects a set value from the multiple feedback loops according to the timing pattern, then implement the set value to the actuator.

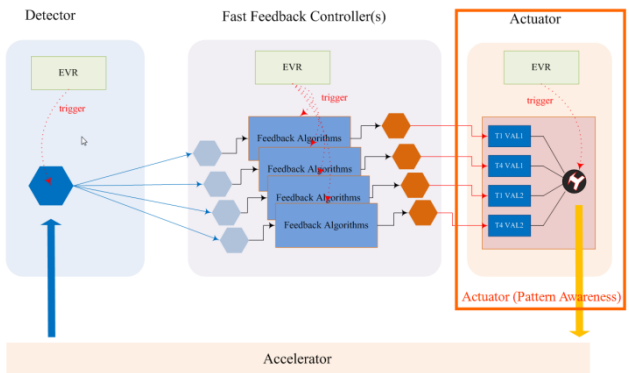

Figure 1: Concept of Pattern Awareness Unit.

REQUIREMENTS

The PAU is a generic software solution for the pattern aware operation. It is required to fit with the SLAC timing system and also required to work with the magnet control system, RF and any other actuator system which requires pattern aware operation.

The PAU is woken up by the fiducial interrupt from the timing system, and performs the pattern matching. The pattern is provided by the event system at every fiducial, and includes the following information: beam code, time slot, and 5 x 32 bits event masks [3].

The PAU performs the pattern matching two times: advanced pattern matching to set the actuator for the next beam pulse, and current pattern matching to get the control data from higher level feedback or to get the beam measurement data from the instruments. For the pattern matching, the PAU utilizes the event pipeline in the event system. This pipeline provides the pattern information two fiducial advanced. That is how the PAU takes action prior to the next beam pulse.

The PAU requires an accurate adjustable time delay due to the various delay times for the data gathering from the high level feedback and the beam measurement

*Work supported by the U.S. DOE Contract DE-AC02-76SF00515
#khkim@SLAC.Stanford.EDU

instrument. Thus, the PAU needs to handle the high-resolution timer on the CPU board. The PAU needs to support various actuators which have very different method to be handled. Thus, the PAU requires an extendability way to handle the different method for different actuators.

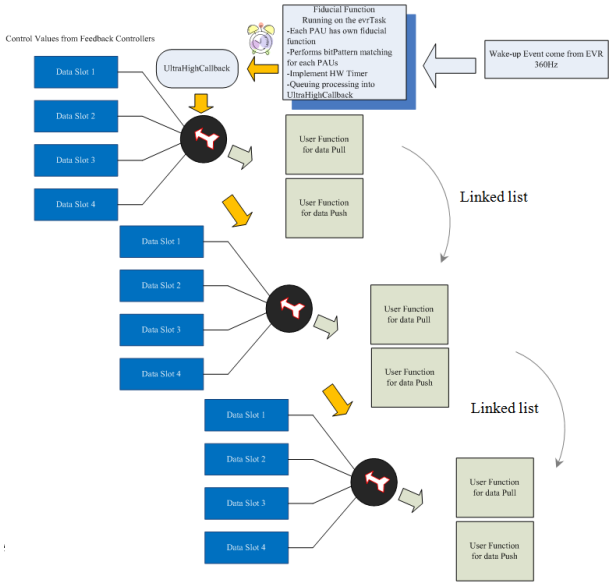

Figure 2: PAU processing for the Multiple Muxes.

IMPLEMENTATIONS

The event system provides a fiducial thread which is woken up by the 360 Hz fiducial interrupts. The PAU utilizes the fiducial thread for the advance/current pattern matching. Actually, the fiducial thread has a hook to register a user function, the PAU registers its hook function as the user function which has the pattern matching codes for the fiducial hook during the initialization. The pattern matching code performs the advance and current pattern matching with the event information from two fiducials ahead, and from the current fiducial, both of which areprovided by the event pipline in the event system.

If the PAU gets the matched pattern, the PAU sets up the high resolution timer on the CPU board which can be adjusted with sub nano-second resolution. The PAU has a user variable which is used for the adjustable time delay. User can configure the PAU delay with this variable. Actually, the delay value is decided by trial experiments to fit into the correct timing for the data gathering.

There is a high priority callback thread, the PAU's own thread called the UltraHighPriority Callback, which is woken up by the high resolution timer. This callback thread has a priority just lower than the fiducial thread and higher than any other EPICS thread. Thus, it can not be blocked by other tasks except the fiducial.

A PAU governs multiple multiplexers, or muxes, each mux corresponds to a physical quantity and a control variable: for example, RF phase, RF amplitude, or strength of corrector magnet. The multiple muxes in the same PAU share the same pattern matching. Thus, the PAU does the pattern matching once instead of the multiple muxes (Fig. 2).

This idea can reduce the pattern matching effort for individual control variable, and improves the real-time performance. This idea also saves the high-resolution timer which is a limited resource: there is finite number of high-resolution timer on the CPU board, in our case it has four. Each PAU occupies one high-resolution timer. Thus, it only allows maximum four PAUs on a CPU board with the high-resolution timer but, the mux idea allows it to handle a larger number of control variables. Actually, the muxes in a PAU has been implemented with the epics linked list (ellList), thus, there is no limit to create multiple instances.

The UltraHighPriority Callback visits each mux in the linked list one by one, and processes the user functions in the muxes. There are two kinds of user function: data pull

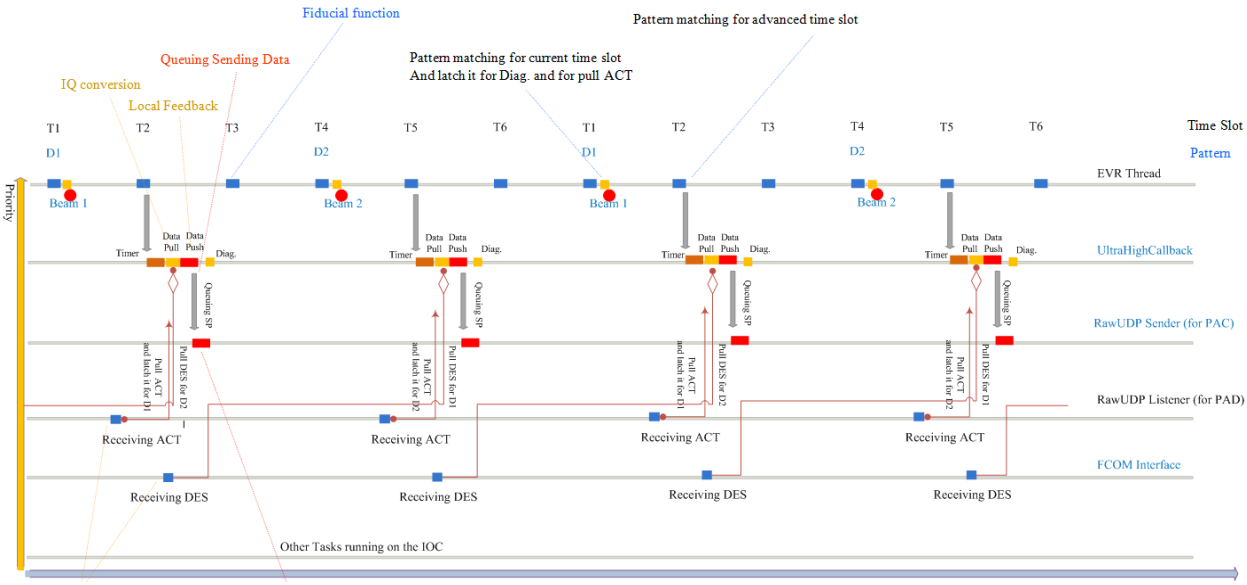

Figure 3: Time line for the 120 Hz Interlaced mode.

function for the current pattern matching, and data push function for the advanced pattern matching. System engineer who is using the PAU software for their system can register those functions for each of muxes.

The data pull function should perform data gathering from the higher level feedback or from the measurement instrument. The incoming data should be moved to the correct data slot which is decided by the current patter matching. The data pull function should perform set data to the actuator, this function brings the data from a correct data slot which is decided by the advanced pattern matching and implements the data into the actuator.

Some systems require more complexity for the data push function. For example, the RF system. This system has local regulation loop for phase and amplitude. The regulation loop requires additional calculations compare to others and also requires both physical quantities: phase and amplitude. Thus, we could not implement both muxes independently for phase and amplitude [4, 5].

The PAU has a concept namely 'Association' to make a relationship between both of the muxes, and we can use an iocsh command to make the association after creating the PAU and the muxes and before the ioc initialization. The concept for the association is not only used for making relation between phase and amplitude, also can be used for the more complex configuration. The local control loop for the LCLS laser RF system, there are three different sources: 2856 MHz oscillator, 119 MHz, and phase cavity. The local feedbacks for each source are related to each other to avoid jumping to a different bucket when switching it to a different source. We also utilize the association for the coupling for these three sources. The PAU has the other callback function namely diag function which has been implemented as a part of PAU software package and is performed very last time of the UltraHighPriority Callback.

After finishing every muxes' user function, the PAU processes a self-diagnostic function. This function does some house keeping work for PAU itself and measures the PAU performance: which data slot has been chosen by the pattern matching, how much time spent by the pattern matching, user functions including the self-diagnostic function itself, and what is the ISR delay for the high-resolution timer. The diag function updates the performance data every time when the PAU is activated by the fiducial, and this information is monitored by EPICS PVs.

Even if the beam based fast feedback supports the pattern aware operation, we still need to consider the non-pattern aware software. There is a longitudinal feedback system which has been written with MATLAB, and controls L2 and L3 section in LCLS, called 6x6 feedback. This 6x6 feedback does not support the pattern aware operation and is still being used for the LCLS. The static offset mode turns this non-pattern aware feedback into a pseudo-pattern aware (Fig. 4). The mux has offset PVs for the each data slot. When the mux implement the set value on the actuator, add up the offset value into the master set value. Thus, the non-pattern aware feedback provides the master set value, and operator or other software can provide pre-defined offset values for each patterns. The pre-defined offset value compensates differences between the different time-slots and patterns. Each mux has a PV to select the fast feedback mode (pattern aware) and static offset mode (pseudo-pattern aware).

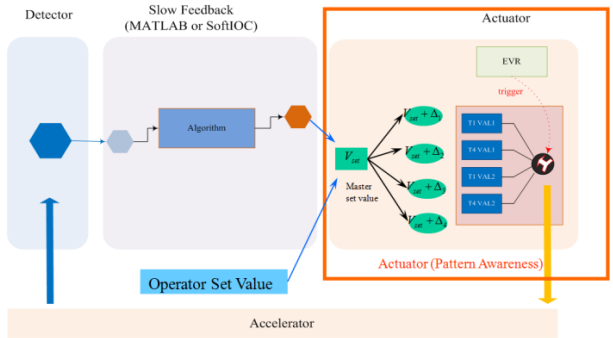

Figure 4: Static offset mode – backward compatibility for the non-pattern aware software.

APPLICATIONS

We have utilized the PAU software package for the RF system and magnets in the LCLS. These systems are controlled by the beam-based fast feedback system. The fast feedback system communicates with the actuator system through FCOM which is a dedicated communication protocol based on UDP/IP-Multicasting. The user pull function cares the FCOM communication with the fast feedback system, and the user push function works for the implement of the actuator set value.

Table 1: PAUs for RF System

PAU	MUXes and Associations	Remarks
PAU0 for Thales Laser System	1 station, 2 associations 3 muxes	2856 MHz PDES 119 MHz PDES Delegate PDES
PAU1for Coherent Laser System	1 station 2 associations 3 muxes	2856 MHz PDES 119 MHz PDES Delegate PDES
PAU2 RF Feedback for IN20	6 stations 6 associations 12 muxes	PDES/ADES for gun, L0A, L0B, TCAV0, L1S, L1X
PAU3 Feedback for LI24	7 stations 9 associations 18 muxes 2 virtual layers (L2/L3 abstraction)	PDES/ADES for L2Ref, TCAV3, KLY24_1, KLY24_2, KLY24_3, S29, S30, L2Abstr, L3Abstr

Especially, the user push function for the RF system is more complicated. It processes the local regulation loop for phase and amplitude, and network communication to the phase&amplitude controller (PAC). RF system has 4

PAUs and each PAU has various number of muxes. We need to use the association concept for the RF system, to make relation among different sources in the laser system, and to make relation between phase and amplitude.

We are using MATLAB based non-pattern aware longitudinal feedback for the L2 and L3 instead of the beam-based fast feedback. The PAU software provides pseudo-pattern aware for this feedback with the static-offset mode. We have implemented an abstraction layer between delegate muxes and individual klystron muxes. The abstraction layer controls the individual muxes to make a collective behaviour on L2 and L3 which reflects the delegate muxes. The non-pattern aware feedback is dealing with the delegate muxes. The abstraction layer has been implemented as the user functions for the muxes.

Table 2: PAUs for Magnet System

PAU	MUXes and Associations	Remarks
PAU0 Corrector in LTU0 area	1 corrector 1 mux	xcor_548
PAU1 Correctors in LTU1 area	3 correctors 3 muxes	xcor_488 xcor_493 xcor_593

PERFORMANCE MEASUREMENTS AND REAL-TIME DEADLINE

The PAU has self-diagnostics which provides accurate measurements for processing time and delay for the every important step. We have utilized this self-diagnostics for the real-time deadline analysis. Table 3 shows the processing time, the worst case is RF system and it takes ~ 105 µsec. According to the Figure 5, PAU wakes up 2 fiducials prior from the next beam. But, PAU need to wait ~ 200 µsec for the communication delay from the beam-based fast feedback or higher level feedback. Some of the actuators require a settling time, worst case is magnet. It requires almost 6 msec. We can consider fiducial interval 2,778 µsec and beam delay from fiducial ~ 1 msec, then the PAU has 251µsec margin from the real-time deadline.

Table 3: Real-Time Performance Measurement

PAU Processing	Processing Time or Delay
Pattern Matching in Fiducial	2 µsec
ISR delay	3 µsec
User Pull Function	25 µsec
User Push Function	60 µsec
Self-diagnostics and house keeping	15 µsec

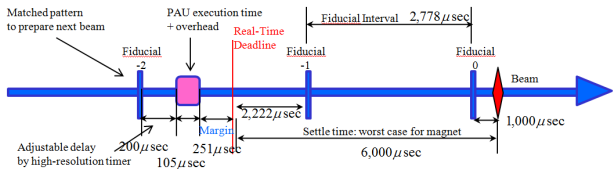

Figure 5: Performance Measurement and Real-Time Deadline.

SUMMARY

The PAU software has been designed as a generic software module for the LCLS beam line actuator. It was implemented to get adaptability to fit into various systems which have particular and unique requirements. We applied PAU software to the RF system, and magnet system, and it contributed for the stable 120 Hz beam-rate operation on LCLS. During this work, we accomplished the followings.

- Integrate with the beam-based fast feedback system for the RF system, and Magnet System
- Achieve the pattern aware operation
- Support non-pattern aware longitudinal feedback for L2 and L3, and make it to pseudo-pattern aware operation
- Implement the various user pull/push functions for the particular/unique requirement: RF local regulation loop, Amplitude/Phase to I and Q conversion, Abstraction Layer for L2 and L3.

YAMS: A STEPPER MOTOR CONTROLLER FOR THE FERMI@Elettra FREE ELECTRON LASER*

A. Abrami, M. De Marco, M. Lonza, D. Vittor, Sincrotrone Trieste, Trieste, Italy.

Abstract

New projects, like FERMI@Elettra, demand for standardization of the systems in order to cut development and maintenance costs. The various motion control applications foreseen in this project required a specific controller able to flexibly adapt to any need while maintaining a common interface to the control system to minimize software development efforts. These reasons led us to design and build "Yet Another Motor Subrack", (YAMS), a 3U chassis containing a commercial stepper motor controller, up to eight motor drivers and all the necessary auxiliary systems. The motors can be controlled locally by means of an operator panel or remotely through an Ethernet interface and a dedicated Tango device server. The paper describes the details of the project and the deployment issues.

INTRODUCTION

The starting point for this project was the history of the ELETTRA storage ring and particularly of its beamlines and experimental chambers where, although the motion problem was central for experimental people, a number of different solutions were used, ranging from “commercial off the shelf” to “entirely home made”. This was the stimulus and the knowledge background from which this stepper controller has been designed.

Project Design Criteria

One of the design goals was to realize a modular and “reasonably” flexible device suitable for the major number of use cases in FERMI@Elettra motion problems. “Reasonably” in the sense that we didn't want to replicate any of the market available controller that claimed to fit with a lot of (all) plants. The reference motor type was fixed as two-phase one.

The initial idea was to assemble the core controller board, a suitable motor power supply and the motor driver boards into a 3U size subrack.

A motor driver board was designed to fit into a DIN41494 Eurocard standard, so a “per motor” modularity could be achieved. It was foreseen to host a small daughter board dedicated to encoder signal conditioning, thus realizing the necessary “encoder flexibility”.

The ELETTRA motion control history led us to use the Galil DMC-21x3 as the core of this project [1]. This family of motor controllers may drive from one to eight axis. In order to assure flexibility, the internal connections between the DMC and the drivers have been split in two groups of four axis each.

An obvious effort was done to standardize the connections to motors and encoders: one connector for the “axis”, i.e. motor phases, limit/home switches (with supply for optical ones), brake control and “emergency stop” signal; and one connector carrying signals both for “digital” and “analog” encoders.

Another design criteria was to be able to re-use this stepper motor controller also in the ELETTRA beamlines, which will anyway require the design of new 3 and 5 phase driver boards.

Software application programs availability, especially in the Tango control framework, was another key point in the enumeration of the criteria used in the design phase.

Figure 1: YAMS chassis (front view).

HARDWARE DESCRIPTION

A 3U subrack contains the power supply for the motor driver circuitry, the DMC controller, the power supply for the DMC and for the other electronics (encoders, etc.), a simple local control panel and the Ethernet connection. In addition, this subrack may be equipped with up to 8 motor driver boards.

Figure 2: YAMS chassis (rear view).

In Fig. 2 a YAMS subrack equipped with six motor driver boards is shown; blind panels are used to close the unused slots (here not shown).

*Work partly supported by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3

YAMS Subrack

Table 1 summarizes the main characteristics of this controller:

Table 1: YAMS Subrack Characteristics

Function	Value
Mains power supply	220V
Motor power supply	24V, 350W max
Electronics power supply	5V, 50W - ±12V, 30W
Core motion controller	DMC family by Galil Inc.
Communication Interface	Ethernet 10BASE-T
Local Interface & Control	Motor, speed (1 out of 2), direction-movement selectors Stop-all-motion pushbutton Power supply leds.
Motor driver boards	up to 8

YAMS Motor Driver Boards

These boards are designed in the DIN41494 Eurocard standard, each carrying the electronics necessary to cope with different motor type and power. From the point of view of the core controller the connecting bus is the same, being its main feature the pulse/direction interface. The power section of the board is realized using the IMxxxH hybrid family produced by IMS (now "Schneider Electric Motion USA") [2].

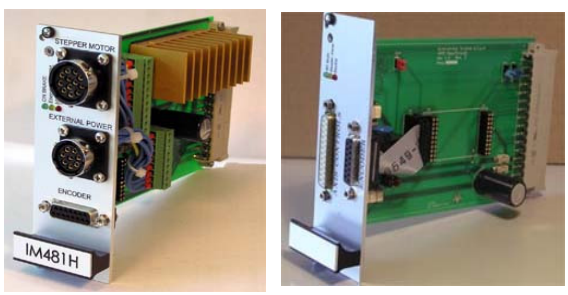

Figure 3: (A, left) Low Power Driver Board IM481H, (B, right) Passthrough Driver Board.

Table 2 shows the main common characteristics of these boards:

Table 2: YAMS Motor Driver Characteristics

Common feature	
Motor power supply	24V
Electronics power supply	5V, ±12V
Motor type	2 phase
Motor run/hold current configuration	via dip switch

As Fig. 3A shows, the board features three connectors. The first (upper in the figure) is dedicated to the axis connections: motor phase, limit/home switches (with power supply for the optical ones), brake and emergency stop signal. The central connector is used for connecting the hybrid power, i.e. the power section of the board, to the internal power supply, or to an external one. In this way multiple high power motors may run at the same time. In the third connector, the sud-D one, there are all the encoder signals, both for digital and analog encoders.

Table 3 summarizes the motor current ranges of the three adopted IMS boards:

Table 3: YAMS Motor Current Ranges

Card Name	IM481H	IM483H	IM805H
IMS hybrid	IM481H	IM483H	IM805H
Motor current (peak)	0.2– 2.1 A	0.5 – 4.2 A	1 – 7.1 A

Besides the driver board that actually may power a stepper motor, a “versatile board” was designed called “Passthrough”, Fig. 3B. This board is equipped with two connectors. One of them carries the motor, switches and brake signals: this is not directly connectable to the phases of a motor, a power stage with the pulse/direction interface must be interposed (for instance motors with power electronic integrated). The other connector is exactly the same sub-D encoder connector of the other boards, and, in fact, this board has the same “encoder conditioning philosophy” and may host the same range of encoder daughter boards.

YAMS Encoder Daughter Boards

The purpose of the encoder boards is to adapt and/or condition the signals coming from the encoder to the inputs accepted by the DMC controller. Up to now we have developed three types of encoder boards, as shown in Fig. 4:

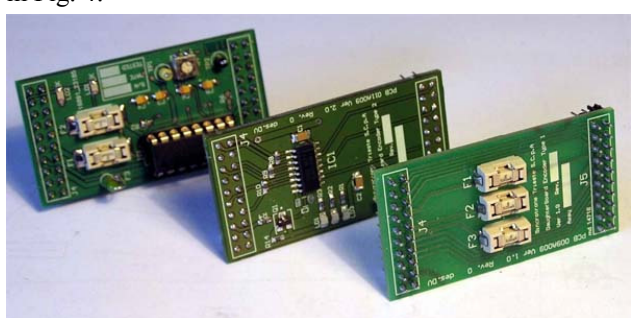

Figure 4: Encoders Boards.

- Type 1 encoder board: it just connects the external encoder connector to the internal signal buses. No conditioning is performed.
- Type 2 encoder board: it converts RS422 level balanced signals from digital sin/cos encoders to unbalanced signals.
- Type 3 encoder board: it accepts a 4-20mA analog signal and converts it to an internal voltage signal.

SOFTWARE DESCRIPTION

The DMC family controllers have their own communication and programming protocol and language, besides a good basic instruction set for motion control. So, if necessary, it is possible to add specific routines into the controller memory to improve the controller functionalities. These routines may be referred as "firmware".

A similar solution for motion control was also adopted by the SOLEIL synchrotron light source, participating with other partners, including Sincrotrone Trieste, to the Tango collaboration. They developed the software architecture and the first releases of the "galilbox-srv" and "galilaxis-srv" Tango device servers (Fig. 5). As a result, the YAMS project has inherited a considerable amount of knowledge and ready to re-use code, thus reducing the overall development time.

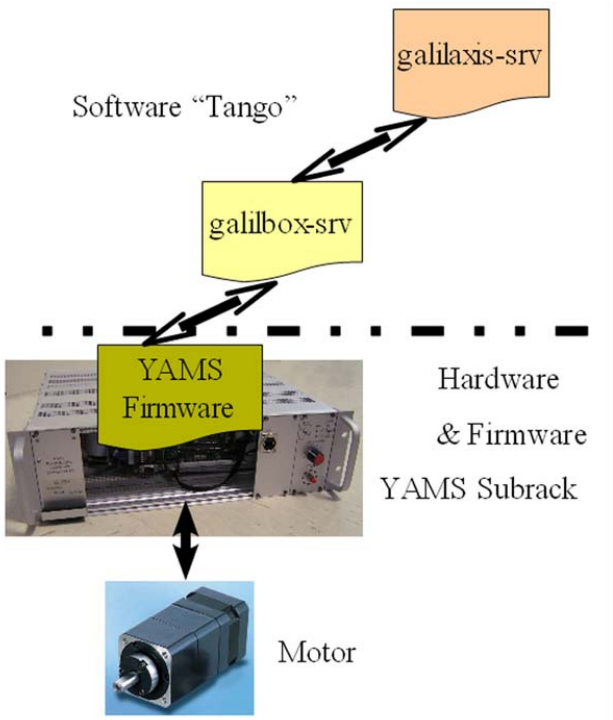

Figure 5: Hardware/Software Architecture.

Differences between SOLEIL and FERMI@Elettra in the modality the stepper controllers are employed, led us to modify both firmware and software from their initial releases. For instance, the FERMI@Elettra version is capable to read a potentiometric encoder, i.e. an analog sensor, and close on it the motion control loop.

FERMI INSTALLATIONS

In the whole facility, more than 400 axes will be eventually controlled by YAMS, using different phase currents, with or without brakes and with different encoder types, RS422 digital, potentiomentric and LVDT. The range of applications span from heavy duty ones (like the "bunch compressor" in Fig. 6), to high precision ones such as the photon spectrometer installed in the photon beam transport area (Fig. 7).

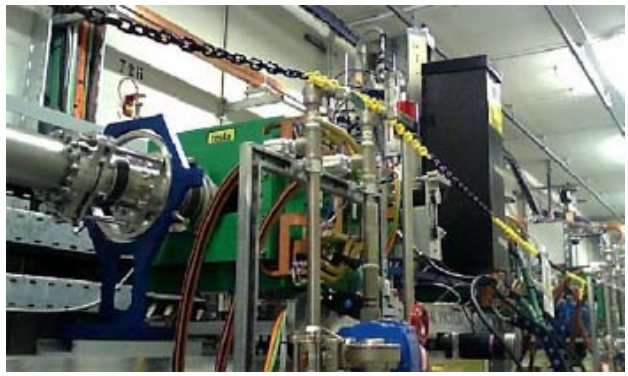

Figure 6: Bunch Compressor, an heavy duty installation.

Figure 7: Photon spectrometer, an high precision installation.

DEVELOPMENT

A new driver board is under development, it will adapt the YAMS bus interface to the old "Berger-Lahr" D450 (5 phase) and D920 (3 phase) stepping motor cards, thus confirming and realizing the "retro-fit" issue for the old installations in ELETTRA.

A piezo motor driver board and a 1Vpp analog encoder daughter board will soon be designed for beamlines and experimental chambers.

CONCLUSIONS

In this project, a significant reduction of the development time has been achieved, meanwhile maintaining costs at a reasonable low level. The "in depth" knowledge of all hardware and software components of this motion system allows to suggest the best solution for each motion request that arose during the design and installation. In the installations carried out up to now, YAMS has proved the good features of modularity and flexibility of this motion approach.

COMPARATIVE ANALYSIS OF EPICS IOC AND MARTe FOR THE DEVELOPMENT OF A HARD REAL-TIME CONTROL APPLICATION*

A. Barbalace†, A. Luchetta, G. Manduchi, C. Taliercio, Consorzio RFX, Padova, Italy

Abstract

EPICS is used worldwide to build distributed control systems for scientific experiments. The EPICS software suite is based around the Channel Access (CA) network protocol that allows the communication of different EPICS clients and servers in a distributed architecture. Servers are called Input/Output Controllers (IOCs) and perform real-world I/O or local control tasks. EPICS IOCs were originally designed for VxWorks to meet the demanding real-time requirements of control algorithms and have lately been ported to different operating systems.

The MARTe framework has recently been adopted to develop an increasing number of hard real-time systems in different fusion experiments. MARTe is a software library that allows the rapid and modular development of stand-alone hard real-time control applications on different operating systems. MARTe has been created to be portable and during the last years it has evolved to follow the multi-core evolution.

In this paper we review several implementation differences between EPICS IOC and MARTe. We dissect their internal data structures and synchronization mechanisms to understand what happens behind the scenes. Differences in the component based approach and in the concurrent model of computation in EPICS IOC and MARTe are explained. Such differences lead to distinct time models in the computational blocks and distinct real-time capabilities of the two frameworks that a developer must be aware of.

INTRODUCTION

Developing a real-time control application is a complex task if it has to be designed from the ground up. Everything must be checked and carefully reviewed to guarantee bug-free code and bounded execution times. Likely there exist many different programming environments to code a real-time control system and many are suited for scientific experiments. In this work the EPICS [1] and the MARTe/BaseLib [2] (in the following referred as MARTe) software frameworks are analyzed.

The EPICS software suite is built around the Channel Access (CA) network protocol that allows the communication of different EPICS clients and servers in a distributed architecture. Servers are called Input/Output Controllers (IOCs) and perform real-world I/O or local control tasks.

MARTe is a software library that allows the rapid and modular development of stand-alone hard real-time control applications on different Operating Systems (OSs).

As far as we know there are no published comparative analyses of software frameworks for the development of control applications, especially involving EPICS and MARTe. This work is intended to complement an earlier paper [3] where we presented a performance comparison of the two software frameworks.

We analyze EPICS version 3.14.11 and MARTe CVS version June 2011. All facts presented here are OS-independent, whereas paper [3] refers to Linux PREEMPT_RT. In this paper we address several implementation differences and similarities of the two software frameworks which are both written in the C/C++ language.

ARCHITECTURAL OVERVIEW

Component Based Approach

Both EPICS IOC and MARTe present a modular architecture where components can be connected to carry out the required control algorithm. Components in EPICS IOC are implemented by *records*, while in MARTe they are implemented by *Generic Application Modules* (GAMs). Records are logically grouped in *databases*, GAMs belong to a *Real Time Thread*.

In EPICS new record types (or *Record Supports*) can be created by providing a set of routines and data structures adhering to a given C prototype; the newly created record will carry out the required computation. For every record type it is possible to define a new *Device Support* that enables the record to interact with an I/O device.

New components in MARTe are created by subclassing the GAM class or any other descendant of the GAM class. By subclassing, all the functionalities required to properly interact with the MARTe environment are inherited by the new component. In MARTe only two special subclasses of the GAM can handle data communication with a device driver: `InputGAM` and `OutputGAM`. Such classes can be associated to an I/O device via a *Generic ACQuisition Module* (GACQM), similar to what is called Device Support in an EPICS IOC.

Configuration Capability

The current configuration of both frameworks, i.e. the sets of component instances and the way they are intercon-

nected, is defined in one or more text files which get parsed to produce the target application.

In an EPICS IOC the records that populate a database are declared in a configuration file. In MARTe a configuration file contains not only the functional blocks (GAMs) of the control algorithm but also instance descriptions of generic C++ classes. Such instance descriptions can be specified to extend the functionality of the target MARTe application. As an example, to monitor the data exchanged by the GAMs in a control loop an instance description of a Web Server class can be included in the configuration file.

In both EPICS and MARTe a control application is described by a configuration file. The way in which such files are used to create the application differs between the two frameworks.

Creating a New Application In EPICS a configuration file is used to generate IOC source code before compilation. Instead, in MARTe, a configuration file is loaded by a running MARTe system.
