Contributions to the Proceedings of

ESRF

ICALEPCS 2011

13th International Conference on Accelerator and Large Experimental Physics Control Systems
10-14th October 2011, WTC Grenoble, France.

Foreword

The 13th International Conference on Accelerator and Large Experimental Control Systems (ICALEPCS 2011) conference was held from the 10th October to the 14th October at the World Trade Center (WTC) in Grenoble, France. It was hosted by the European Synchrotron Radiation Facility (ESRF). The conference was endorsed by the European Physics Society/Experimental Physics Control Systems (EPS/EPCS), the Institute of Electrical and Electronics Engineers (IEEE), Nuclear and Plasma Sciences Society (NPSS), the French Society of Physics (SFP Interdivision Physique des Accélérateurs et Technologies Associées), Physical Society of Japan (JPS), Particle Accelerator Society of Japan (PASJ), and the Association of Asia Pacific Physical Societies (AAPPS). The conference's Local Organising Committee was advised by two committees made up of members from the three regions – the International Scientific Advisory Committee (ISAC) and the Programme Committee (PC). The ISAC was comprised of 47 members and chaired by Roland Mueller of HZB. The PC was made up of 39 members and chaired by Jean-Michel Chaize of the ESRF.

ICALEPCS 2011 had a record attendance. In total 625 registered. Of these 415 were delegates, 54 were 1 or 2 day only attendees, 38 were students or retirees, 18 were sponsors or VIPs, 21 were accompanying persons, 31 were editors or assistants. CERN was the most represented institute followed by the ESRF. The breakdown of attendees by region is as follows: 53 for Asia and Oceania, 451 For Europe, Middle East and Africa, 99 for North and South America.

A total of 573 abstracts were submitted of which 171 were withdrawn. Out of the remaining 402 abstracts 112 were awarded oral status (this includes the keynote and invited talks) and 290 were posters. Mini-orals were introduced for the first time at ICALEPCS. During the mini-oral the speaker was given 3 minutes to present their poster. 31 posters were presented as mini-orals.

ICALEPCS 2011 put strong emphasis on having a high number of quality keynote speakers. For the first time 7 specialists from outside the community presented keynote talks. The feedback on the keynotes from the attendees was very positive proving they clearly contributed to the success of the conference in terms of the quality of the conference and attracting attendees.

The conference themes were chosen by the ISAC. The scientific programme was drawn up by the PC. Both committees did an excellent job choosing topics and talks and encouraging experts to present their work. A number of institutes were represented at ICALEPCS for the first time. Parallel sessions were reintroduced. Out of a total of 20 sessions, 7 were parallel.

There were 6 pre-conference workshops held on the Sunday before the conference. The workshop themes were: Open Hardware Initiative, Cyber-Security, TANGO, jddd, and CDM (Common data model). The attendance of the pre-conference workshops was again very high. Over 200 people attended the workshops.

Tutorials were reintroduced at ICALEPCS 2011. Two tutorials were given: Control Theory and Application to Accelerators and Fusion Reactors by Stefan Simrock and **Implementing DSLs with Xtext and MPS** by Markus Völter. The tutorials were very well attended and much appreciated by the attendeees. A round table discussion was held with some keynote speakers on *When and How to mix Languages. If not why not?*

For the second time the ICALEPCS Lifetime Achievement Award (LAA) was given. The ICALEPCS 2011 award was presented to: Emmanuel Taurel (ESRF), Nicolas Leclerq (SOLEIL), and Pascal Verdier (ESRF) on behalf of and for their contribution to the TANGO collaboration over the last 10 years.

For the first time a selection of the ICALEPCS papers will be published in a peer reviewed journal: Physical Review Special Topics Accelerators and Beams (PRST-AB). A special edition of the journal will be published in mid 2012. All papers accepted and presented at ICALEPCS 2011 are eligible to submit for publication in the peer reviewed journal.

The local organisation of the conference was under the responsibility of the Local Organising Committee (LOC). The LOC was comprised of 9 people and was chaired by Anne-Françoise Maydew. The LOC put emphasis on complementing the high quality scientific programme with an excellent social programme. The conference started with a welcome cocktail in the modern art museum hosted by the city of Grenoble. On the second evening conference attendees were treated to typical French culinary specialties (cheese and wine) and dancing (including the famous French can-can!). An outing was organised during the conference to the Château de Vizille (an important event happened there during the French Revolution). The gala evening was organised in an unusual venue – the Grenoble ice rink - where attendees were treated to a world class French magician show. The post conference tour was a trip to Chamonix and a ride with the cable car up to the Aiguille de Midi to marvel at the spectacular scenery of the Mont Blanc mountain range from up-close.

The ISAC accepted the bid for ICALEPCS 2015 to be held in Melbourne (Australia) hosted jointly by the Australian Synchrotron and the Australian Nuclear Science and Technology Organisation (ANSTO).

As chairman I would like to thank everyone who contributed to make ICALEPCS 2011 a successful and memorable event. The conference was the result of many people's work and support both financial and moral. It all started in 2007 in Knoxville when the ISAC of ICALEPCS 2007 accepted the ESRF bid to host ICALEPCS 2011 in Grenoble. It continued with ICALEPCS 2009 who decided to sponsor ICALEPCS 2011 with the earnings that remained over from ICALEPCS 2009. I thank all the sponsors and exhibitors who helped finance the conference. The ISAC chair and committee did a great job advising the LOC during the 2 years leading up to the conference. The PC

did an excellent job shaping the scientific programme. The editors did a huge and excellent job editing the many abstracts and papers to ensure that the papers were of high quality. The delegates made the conference a success by participating with high quality talks and questions. The city of Grenoble, the WTC and the event organisers (Insight Outside) made a special effort to help make ICALEPCS a success and make the delegates feel welcome. A big thanks to the ESRF, the host institute, and all the colleagues who helped and provided support for ICALEPCS 2011.

Finally I would like to especially thank (1) the proceedings editor, Marie Robichon, for setting up and maintaining the SPMS and ensure that the Proceedings were ready on time, and (2) the LOC chair, Anne-Françoise Maydew, both of whom went far above their normal call of duty, and (3) all the LOC members who worked very hard to ensure ICALEPCS 2011 was a success!

I look forward to seeing everyone in San Francisco in 2013 and in Melbourne in 2015!

Acknowledgments

ICALEPCS 2011 could not have been possible without the help and support of many people. We would like to acknowledge the following people and organisations:

ESRF for hosting the conference and providing the resources to organise it.

The members of the ISAC for choosing the session topics and providing valuable advice.

The members of the PC for setting up an interesting programme.

The proceedings editors – Cindy Cassady (LLNL), Carl Finlay (CLS), Lynda Graham (ESRF), Michaela Marx (DESY), Raphael Müller (GSI), Maria Power (ANL), Marie Robichon (ESRF), Volker RW Schaa (GSI), Thomas Thuillier (LPSC), Emmanuelle Vernay (LPSC).

The author receptionists: Debbie Davison (ESRF), Kirstin Colvin (ESRF)

Volker RW Schaa for preparing the abstracts for the conference guide and for assisting in the preparation of the proceedings.

The helpers who assisted the speakers during the conference.

The numerous ESRF staff who helped with the conference directly and indirectly.

The following learned societies for endorsing the conference – European Physical Society / Experimental Physics Control Systems (EPS/EPCS), Institute of Electrical & Electronics Engineers (IEEE), Nuclear & Plasma Science Society (NPSS), French Society of Physics (SFP Interdivision Physique des Accélérateurs et Technologies Associées), Physical Society of Japan (JPS), Association of Asia Pacific Physical Societies (AAPPS).

The following sponsors for providing financial support to the conference:
Platinum sponsors: SPRING8, Ville de Grenoble;
Gold sponsors: Grenoble-Alpes Métropole, Région Rhône-Alpes, National Instruments, NetApp, SOLEIL;
Image sponsors: Codaralp, Sodexo, Ricoh;
Delegates' bags: Cosylab, National Instruments;
Exhibitors: Aerotech Ltd, Beckhoff Automation GmbH, Caen, Delta Tau UK Limited, Diamond Detectors Ltd, DSoFt Solutions Ltd, D-Tacq Solutions, Friatec AG, FuG Elektronik GmbH, Heason Technology Ltd, Incaa Computers, Instrumentation Technologies, Magenta Systems for Agilent, Micro Controle Spectra Physics, Nexeya, Physical Instruments, Serviware, Struck Innovative Systeme GmbH.

The Grenoble Bureau des Congrès and Tourist Office for their support and help while preparing the conference and during the conference.

NEWS FROM ITER CONTROLS – A STATUS REPORT

Abstract

Construction of ITER has started at the Cadarache site in southern France. The first buildings are taking shape and more than 60 % of the in-kind procurement has been committed by the seven ITER member states (China, Europe, India, Japan, Korea, Russia and United States). The design and manufacturing of the main components of the machine is now underway all over the world. Each of these components comes with a local control system, which must be integrated in the central control system. The control group at ITER has developed two products to facilitate this; the plant control design handbook (PCDH) and the control, data access and communication (CODAC) core system. PCDH is a document which prescribes the technologies and methods to be used in developing local control systems and sets the rules applicable to the in-kind procurements. CODAC core system is a software package, distributed to all in-kind procurement developers, which implements the PCDH and facilitates the compliance of the local control system. In parallel, the ITER control group is proceeding with the design of the central control system to allow fully integrated and automated operation of ITER. In this paper we report on the progress of the design and technology choices and we discuss justifications of those choices. We also report on the results of some pilot projects aimed at validating the design and technologies.

INTRODUCTION

The first concrete was poured in the ITER tokamak seismic pit in August 2011. Construction of the first two buildings is expected to be completed next year and the control building in 2015. In other words, the civil construction of ITER is in full swing. At the same time, more than 60 % of the value of in-kind procurements has been committed by the seven member states and design and construction of ITER components have started all over the world. These components of ITER, procured in-kind, come with their local control systems.

The main challenge for ITER control system is to integrate all these local control systems and enable integrated and automatic operation of the complete ITER facility. Since the ITER schedule is driven by specifications of in-kind procurements the priority of the ITER control group has been to establish the standards and technologies affecting the local control systems as well as facilitating future integration. Two evolving products have been developed to allow this: a set of documents, called the Plant Control Design Handbook (PCDH), defining the standards and a control system framework, called CODAC (Control, Data Access and Communication) Core System, implementing those standards and providing a development environment for local control systems. In parallel, the design of the central system is proceeding with the preliminary design review scheduled for late 2011.

Plant Control Design Handbook

The PCDH is a set of documents that defines mandatory rules, recommended guidelines, methodologies and catalogues of supported products. It is a living document with the latest release issued in February 2011. The PCDH specifies the design methodology for development of local control systems including deliverables. The product catalogue includes Siemens Simatic S7 PLC, IEI PICMG 1.3 PC, National Instrument multipurpose PXI6259 I/O board, Sarel cubicles and more.

The PCDH is contractually binding in all in-kind procurements, which include local control systems. It has been subjected to thorough review by representatives of all ITER member states. The ITER control group is actively promoting PCDH by organizing presentations and training in the member states as well as developing pilot cases for proof of concept. PCDH is available at [1].

CODAC Core System

CODAC Core System (CCS) is a control system framework that implements the standards defined in the PCDH and guarantees that the local control systems can be integrated into the central control system [2]. It runs on all computers within the ITER architecture, both locally and centrally. The most important feature is the use of EPICS [3], which guarantees communication using the channel access protocol. Major releases of CCS are made on a yearly basis. ITER contributions on top of EPICS are publicly available at [1].

Organizations contributing to the ITER project, in particular developers of local control systems can become registered users. A registered user is provided with support, such as software distribution, help desk and access to the development environment.

Before starting to discuss the chosen technologies and the reason for those choices, we briefly describe the overall architecture of the ITER control system. A more detailed description of the architecture is available in [4].

ARCHITECTURE

The architecture of the ITER control system is illustrated in Fig. 1. The main principles are maintained from the conceptual design [5], segregation in three vertical tiers; conventional control, interlock and safety and two horizontal layers; central and local. The local layer is procured in-kind, while the central layer is developed by the host, ITER Organization in France.

The current estimate is that there will be 220 local systems, grouped together and organized into 18 ITER subsystems. These local systems consist of a set of controllers, interfacing the actuators and sensors, and connected together via network switches to the plant operation network (PON). A similar architecture is applied for interlocks (CIN) and safety (CSN). Coordination and orchestration at the central level are first done at the subsystem level and then at the central supervision level. The human machine interface is provided by dedicated CODAC terminals located in the control room or close to the equipment for commissioning and troubleshooting purposes. For the safety system there is a dedicated safety desk in the main and backup control rooms.

In addition, a number of dedicated networks are used; TCN for time distribution and synchronization, SDN for real-time feedback and asynchronous events, ARCN for scientific data archiving and AVN for video transmission.

Table 1: ITER Controls Main Parameters

Parameter	Value
Total number of computers	1.000
Total number of signals (wires)	100.000
Total number of process variables	1.000.000
Total number of active operator screens	100
Update rate per screen (200 PVs)	5 Hz
Maximum sustained data flow on PON	50 MB/s
Total engineering archive rate	5 MB/s
Total scientific archive rate (initial)	1 GB/s
Total scientific archive rate (final)	20 GB/s
Total scientific archive capacity	Few PB/year
Accuracy of time synchronization	50 ns RMS
Number of nodes on SDN	100
Maximum latency asynchronous events	1 ms
Maximum latency sensor to actuator (SDN)	500 µs
Maximum jitter sensor to actuator (SDN)	50 µs
Maximum sustained data flow on SDN	25 MB/s

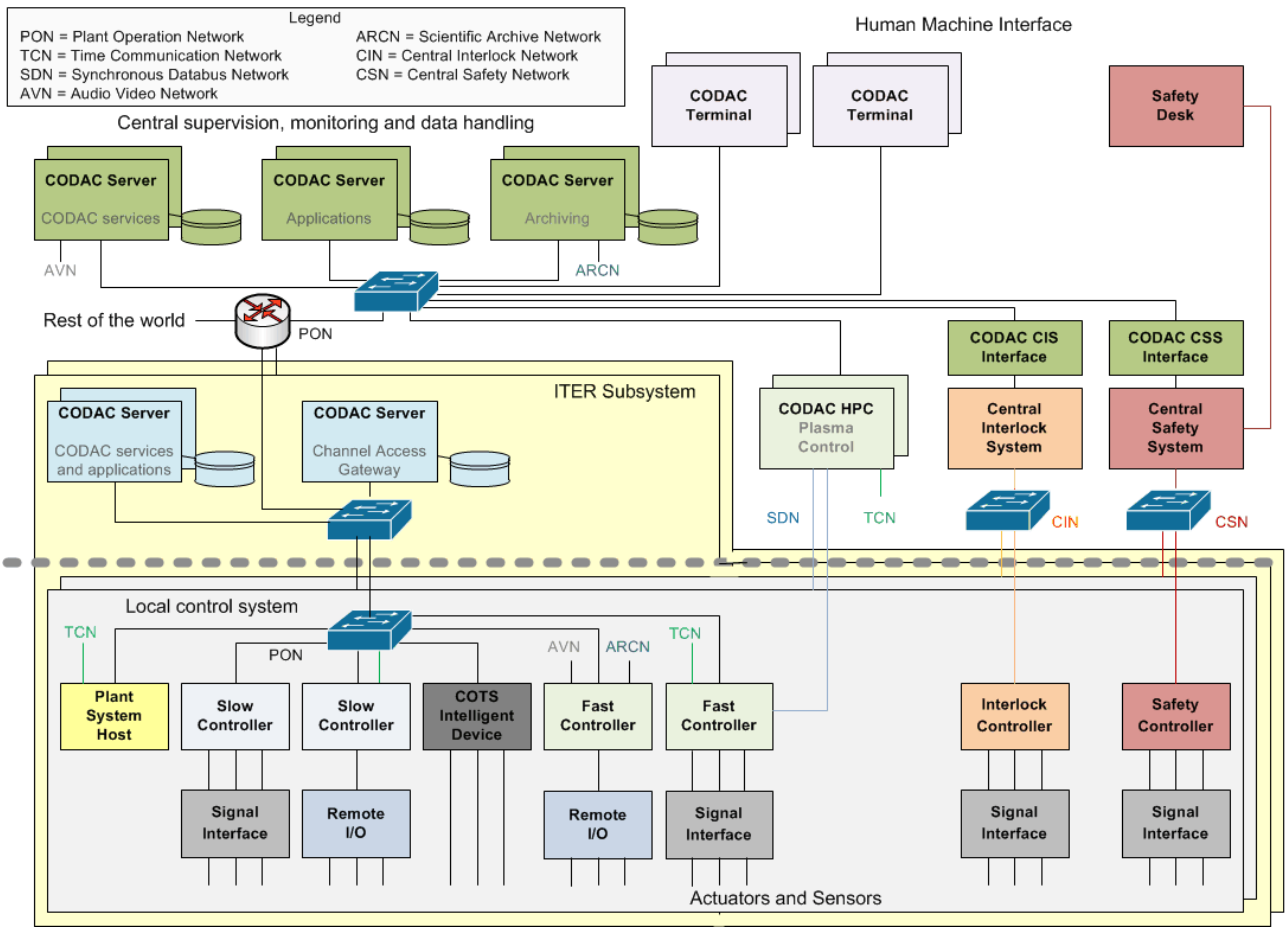

Figure 1: Physical architecture of ITER control system.

SELECTED TECHNOLOGIES

EPICS

A key technology decision was taken in 2009 with the adoption of the EPICS toolkit. This decision gave a head start to the development of CODAC Core System because all key requirements, such as robust communication and "live database", are solved by EPICS. In the preceding evaluation, open source solutions took preference over commercial ones because of longevity requirements. Of the open source alternatives EPICS was the clear winner because of its proven track record of reliability and scalability and the fact that it has been successfully deployed in almost all ITER member states, including on tokamaks in Korea (KSTAR) and the US (NSTX). CODAC Core System v2 comes with EPICS core v 3.14.12 and a selection of additional EPICS packages.

Linux

A second important decision was to adopt Linux as the base operating system. It is an obvious choice considering the selection of EPICS and the general market of large experimental facilities in the world. An evaluation was carried out of the three major commercial providers of Linux: Ubuntu, Red Hat and SUSE. Red Hat was selected for being the market leader and providing the longest support of major releases. CODAC Core System v2 comes with Red Hat Enterprise Linux (RHEL) v5.5 x86_64. It is planned to upgrade to v6.1 in the next major release due in early 2012.

It is estimated that more than 80 % of systems present in the entire control system are non-real-time or soft real-time. The remaining 20 % require real-time features not provided by RHEL. After an evaluation and benchmark of alternatives we have selected MRG-R from Red Hat.

Control System Studio

Control System Studio (CSS), developed by DESY, ORNL and Brookhaven, is an Eclipse-based collection of tools running on top of EPICS to monitor and operate large scale control systems. An evaluation was carried out to address both the functionality and performance of the product and match the requirements, mainly on the presentation layer, of CODAC. Many of these tools rely on a relational database (RDB), typically Oracle or MySQL. However, due to the uncertainty of MySQL's future as open source ITER has selected PostgreSQL as RDB. The evaluation therefore also included compatibility tests with PostgreSQL. The result was to adopt BOY (Best ever Operating interface Yet), BEAST (Best Ever Alarm System Toolkit), BEAUTY (Best Ever Archive UTility, Yet) and SNL Editor (State Notation Language Editor) in CODAC Core System.

Configuration

To address concerns related to the development of local control systems in all member states, an in-house development in unifying configurations has been undertaken. The basic idea is to capture configuration data like definition of process variables, input/output configuration, alarm definitions etc. in a relational database. These data are then used to auto-generate configuration files such as EPICS db files, BEAST and BEAUTY configuration files, BOY engineering screens, driver configurations etc. Further details of this project, called self-description data and using Hibernate, Spring and Eclipse technologies, are given in [6].

Development Environment and Distribution

The distributed nature of the ITER control system development (Fig. 2) requires high quality, both on the product (CODAC Core System) and the software distribution. To achieve quality and be cost effective unifying processes and technologies are essential. Major investments have been made in this area. Subversion has been selected as the version control tool, Apache Maven as the build tool, RPM (Red Hat package management) for packaging and for managing dependencies, Bugzilla as the issue tracking system, Jenkins for continuous integration and automated test execution and Red Hat Network Satellite Server for software distribution [7].

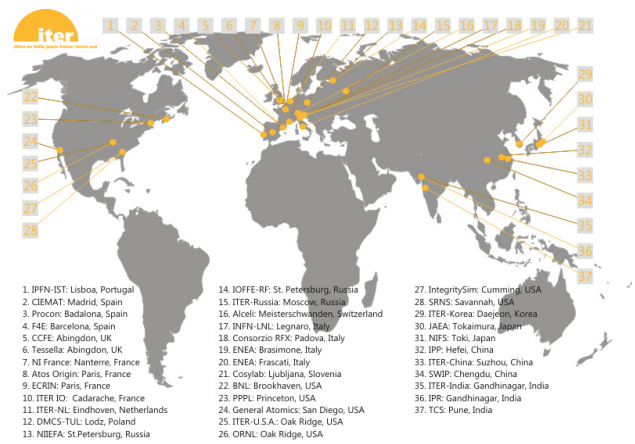

Figure 2: Registered organizations using CCS.

PTPv2 (IEEE 1588-2008)

The driving requirement for synchronizing ITER computers is the off-line correlation of different diagnostics data using absolute time stamps. The requirement has been set to 50 ns RMS. Requirements for pre-programmed triggers are much more relaxed (1 ms RMS). These requirements are matched closely by the precision time protocol (IEEE 1588-2008) now widely supported by many vendors. We have implemented the CODAC TCN network based on a PTPv2 using Meinberg and Symmetricom grand master clocks, IEEE 1588-2008 compatible industrial switches (Cisco IE3000 and Hirschman MAR1040) and NI PXI 6682 timing receivers as host nodes and confirmed the performance.

10 GbE Multicast UDP

The most important requirement for the real-time network SDN is to support control loops with a cycle times of 500 µs, which includes acquisition, computation,

communication and actuation. Assuming a two hop configuration and that communication can use a maximum of 10 % of the available time budget yields an upper limit for latency between two nodes of 25 µs with a maximum jitter of 10 %. Such requirements are traditionally solved by reflective memory technologies. However, with the emergence of 10 Gb Ethernet, cut-through switches and wide support of multicast, switched Ethernet provides an alternative. We commissioned a benchmark with a major switch supplier confirming that switch latency for a cut-through switch is below 2 µs independent of package size. Using 10GbE NIC cards with protocol stack accelerators (Solarflare, Chelsio, Mellanox) we performed additional tests to measure latency including the UDP stack and the API. The results confirm that performance is comparable to reflective memory technology (Fig. 3). Considering technology evolution of Ethernet we have therefore selected 10GbE UDP multicast as our solution for the real-time network.

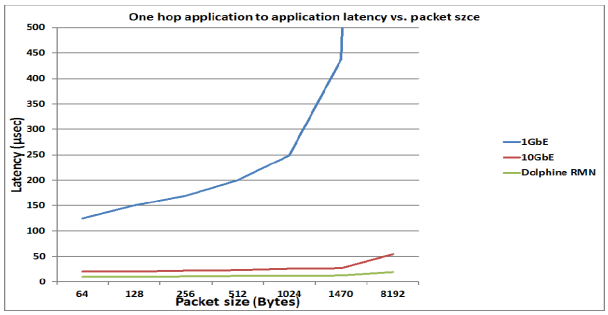

Figure 3. Measured latency 1GbE, 10GbE and RMN.

CURRENT R&D

The two biggest areas of technology selection not yet addressed are scientific archiving and plasma feedback control. A preliminary study of scientific data format has been carried out resulting in indications that HDF5 is the preferred option. This will be followed by the implementation of an archive prototype in 2012. Different options for high performance file systems are also being benchmarked, the main candidates being NFS4, HDFS and pNFS.

A major world-wide effort task with a consortium of experts in plasma control has been initiated. This task aims to detail the requirements and build engineering models of plasma control for ITER. In parallel an evaluation of existing real-time frameworks is underway. This framework, together with the real-time network, will make up the plasma control infrastructure. A primary candidate at this time is MARTe or some derivate of that.

A third area of active R&D concerns fast controllers, particular xTCA and FPGA technologies targeting diagnostics. A number of prototypes are being implemented with the aim of bringing such products into the PCDH catalogue of standard components.

PILOT PROJECTS

A number of pilot projects have been initiated to confirm the technology selections, prove the feasibility of implementing ITER controls using the selected approaches and identify any weak points to be addressed.

The ITER construction site and office buildings are currently powered by a 15kV substation. Applying the methodology and standard components defined in the PCDH, this substation has been successfully interfaced to ITER CODAC using two Siemens S7 PLCs, PSH, CODAC servers and CODAC Core System to monitor, archive and handle alarms for 400 process variables.

The neutral beam test bed facility in RFX Padova, Italy, will be used to test and commission the neutral beam injectors for ITER. The first system to be implemented will be an ion source and RFX has decided to apply CODAC Core System in this project. An initial evaluation has not shown any show-stoppers. The project is expected to be completed in 2015.

The Frascati Tokamak Upgrade (FSU) in Italy decided to upgrade the control for their flywheel generator using PCDH and CCS. This has been accomplished and an interface to the legacy control system has been implemented. Commissioning of the system during tokamak operation is planned in the autumn.

The control system of KSTAR (Korea Superconducting Tokamak Advanced Research) is based on EPICS and therefore a perfect candidate for testing ITER CODAC concepts. A collaboration project is underway to convert the hydrogen fuelling system to ITER standards and to implement closed-loop density control. The conclusion of the first phase is scheduled for late 2011 and of the second phase for late 2012.

CONCLUSIONS

The design and implementation of the ITER control system is progressing according to plan. Many technology decisions have been taken during the last year. The success or failure of the project will be determined by the acceptance of this work by the ITER member states responsible for providing in-kind local control systems.

The views and opinions expressed herein do not necessarily reflect those of the ITER Organization.

Abstract

The ATLAS experiment is one of the multi-purpose experiments at the Large Hadron Collider (LHC), constructed to study elementary particle interactions in collisions of high-energy proton beams. Twelve different sub-detectors as well as the common experimental infrastructure are supervised by the Detector Control System (DCS). The DCS enables equipment supervision of all ATLAS sub-detectors by using a system of >130 server machines running the industrial SCADA product PVSS. This highly distributed system reads, processes and archives of the order of 10^6 operational parameters. Higher level control system layers allow for automatic control procedures, efficient error recognition and handling, and manage the communication with external systems such as the LHC. This contribution firstly describes the status of the ATLAS DCS and the experience gained during the LHC commissioning and the first physics data taking operation period. Secondly, the future evolution and maintenance constraints for the coming years and the LHC high luminosity upgrades are outlined.

INTRODUCTION

The ATLAS experiment [1] at the LHC aims to study the physics of high energy particle interactions in a previously unexplored energy domain. The detector elements are distributed over a cylindrical volume of 25 m diameter and 50 m length. More than 4000 people of 176 institutions in 40 countries contribute to the project.

The DCS has the task to permit coherent and safe operation of ATLAS and to serve as a homogeneous interface to all sub-detectors and the technical infrastructure of the experiment. The DCS must bring the detector into any desired operational state, continuously monitor and archive the operational parameters, signal any abnormal behavior. A more detailed description of the complete ATLAS DCS and specific sub-detector control system hardware and software can be found in [1, 2] and references therein.

OVERALL SYSTEM DESIGN

The DCS was designed and implemented within the frame of the Joint Controls Project (JCOP) [3], a collaboration of the CERN controls group and DCS teams of the LHC experiments. Standards for DCS hardware and software were established together with implementation guidelines both, commonly for JCOP and specifically for ATLAS.

The Front-End (FE) equipment consists of purpose-built electronics and their associated services such as power supplies or cooling circuits. For the implementation of the

DCS Back-End (BE), the industrial Supervisory Controls And Data Acquisition (SCADA) product *PVSS* serves as base software. On top of PVSS, the JCOP Framework facilitates the integration of standard hardware devices and the implementation of homogeneous controls applications. The BE is organized in three layers (see Fig. 1): process control of subsystems, a single control station for a sub-detector allowing stand-alone operation, and global stations with service applications and operator interfaces.

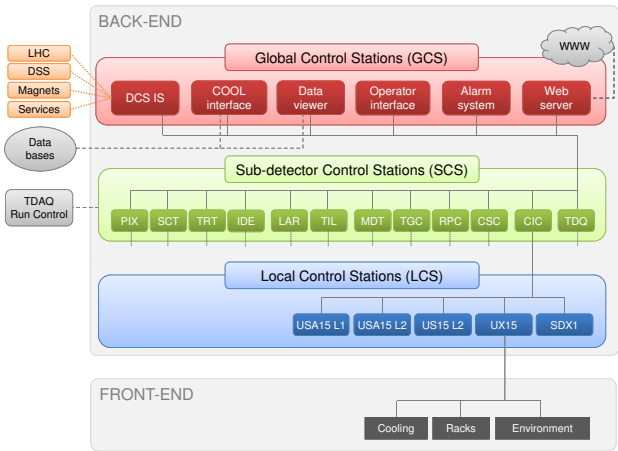

Figure 1: ATLAS DCS architecture.

SYSTEM STANDARD BUILDING BLOCKS

Front-End

The DCS FE equipment had to meet common requirements such as low cost, low power consumption, and high I/O channel density. For equipment interconnection, the CAN industrial field-bus and the CANopen protocol is used wherever possible and appropriate. Electronics in the detector cavern had to allow for remote firmware upgrades, be insensitive to magnetic fields, and be tolerant to radiation exposure expected during the experiment lifetime.

ELMB: A low-cost custom-built I/O concentrator, the Embedded Local Monitoring Board (ELMB) [4] was developed as common solution for interfacing custom designs to the DCS. The ELMB board ($50 \times 67\,\mathrm{mm}^2$) features a 8-bit 4 MHz micro-controller with 64 analog and 32 digital channels and a CAN bus interface. The board is tolerant to strong magnetic fields and radiation hard for integrated doses up to 50 Gy. Further, the ELMB can be embedded within custom designs and has a modular, remotely extendable firmware with a general purpose CANopen I/O application. More than 10000 ELMBs are in use within all LHC experiments, over 5000 alone within ATLAS.

Standardized Commercial Equipment: The industrial standard VME is used to house electronics. For all crates, monitoring is implemented for temperature and general status information as well as power and reset control. The detector components are powered by different types of industrial power supplies featuring control of voltages/currents, over-voltage/current protection, and thermal supervision.

Back-End

DCS Control Station PC: The hardware platform for the BE system are industrial, rack-mounted server machines. Two different standard machine types, one for applications requiring good I/O capability, a second for processing-intensive applications with I/O via Ethernet connectivity. Both models feature redundant, hot-swappable power supplies and disk shadowing.

PVSS: The SCADA package *PVSS* (re-branded to *SIMATIC WinCC OA*) is the main framework for the BE applications. Four main concepts of PVSS make it suitable for a large scale control system implementation:

- Generic types of control process templates may be used depending upon the type of the required application avoiding unnecessary overhead.
- Each PVSS application uses a local database for the storage of control parameters providing synchronized access for all connected processes. Data processing is performed with an event-based approach and data is made persistent by archiving selected DCS parameters to an external Oracle database.
- Different control systems can be connected via LAN to form a *Distributed System* allowing for highly scalable remote data access and event notification.
- A generic Application Programming Interface (API) allows to further extend the functionality of control applications.

Front-end interface software: For interfacing the front-end devices with PVSS, the industry standard OPC was chosen. Commercial equipment manufacturers as well as developers of custom devices provide the *OPC servers* for which PVSS provides an OPC client. For the ELMB CAN bus readout and control, a dedicated CANopen OPC server has been developed. Device types for which OPC could not be used due to maintenance or platform constraints (OPC is limited to MS Windows$^{\mathrm{TM}}$), custom readout applications were interfaced to PVSS using the CERN standard middle-ware *DIM* [5]. PLCs are interfaced to PVSS via Mod-Bus.

The Finite State Machine Toolkit: The JCOP FSM [6] provides a generic, platform-independent, and object-oriented implementation of a state machine toolkit for a highly distributed environment, interfaced to a PVSS control application. The attributes of an FSM object instance are made persistent within the associated PVSS application database. This allows for archiving of the FSM states and transitions, and integration of the FSM functionality into PVSS user interfaces.

INTEGRATION AND OPERATION

Control Hierarchy, Error Handling, Operation

The complete DCS BE is mapped onto a hierarchy of Finite State Machine (FSM) elements using the FSM toolkit. State changes are propagated upwards and commands downwards in the hierarchy allowing for the operation of the complete detector by means of a single

FSM object at the top level. A fixed state model (see Fig. 2) has been applied, reflecting detector conditions for which physics data taking is optimal (READY) or compromised (NOT_READY), or the detector has been turned off (SHUTDOWN). A special STANDBY state is reserved for detectors with intermittent stage for unstable beam conditions. The state UNKNOWN is used when the actual condition cannot be verified. TRANSITION signals a transient state, e.g. ongoing voltage ramps. The actual state of these logical objects is determined by the states of the associated lower level objects (children) via state rules. The lower level objects may follow a more sub-system-specific state model for which guidelines exist.

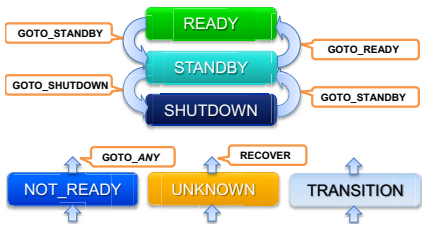

Figure 2: State model for high level objects.

For each critical parameter, alarms can be configured and are classified into one of the severity *Warning*, *Error*, or *Fatal*. To avoid the accumulation of a large number of alarms on the user interface, a masking functionality has been added to hide past occurrences e.g. after a follow-up has been initiated.

Each FSM object in the lowest hierarchy level has an attribute called *Status* which assumes the highest severity of alarms active for the respective device. The Status is then propagated up in the FSM hierarchy and thus allows for error recognition within the top layers of the detector tree and permits to identify problematic devices by following the propagation path downwards.

The DCS is operated from two primary, remotely accessible user interfaces – the FSM Screen for operation of the detector Finite State Machine hierarchy (see Fig. 3) and the Alarm Screen for alarm recognition and acknowledgment. Static status monitoring is provided by web pages on a dedicated web server allowing to quickly visualize all high level FSM user interface panels world-wide and without additional load of BE control stations.

Sub-Systems and LHC Interaction

The DCS of 9 main ATLAS sub-detectors, 3 forward detectors and common services have been integrated into a big distributed system with more than 10^7 individual parameters and subsequently condensed into approximately 10^5 state machine objects (see Table 1).

The data exchange between the ATLAS DCS and external control systems is handled via a dedicated, DIM-based data exchange protocol. All external control systems are homogeneously interfaced to the ATLAS DCS using dedicated DCS Information Servers. A generic data integrity monitoring has been implemented signaling any error condition related to the data quality and availability for the more than 20 different providers.

Table 1: Detector Sub-system Statistics. For each detector component, the # of server control stations and associated PVSS applications, the # of archived parameters, the total # of PVSS parameters, and the # of FSM objects are shown.

System	Component	#Servers (Appl.)	#Archived PVSS Parameters	#Total Parameters	#FSM Objects

Total		131(139)	809k	12.3M	91.2k

The interaction with the operational states of the LHC machine introduces a dynamic element into the operational model. During unstable beams phases (injection, ramp, etc.), the Silicon tracker and Muon detectors must remain at reduced voltage levels. This and additional beam-safety constraints require a hand-shake procedure with the LHC operators. Almost all beam-related actions – ramping the detector voltages depending on beam states with previous cross-checks on detector state and background rates – have been automated within DCS. This leaves DCS the full control over the LHC fill cycle, just requiring operator confirmation for beam injection and beam adjustments after stable beam periods. Finally, DCS is used for continuous monitoring of beam background rates and luminosity information during LHC fills. Figure 4 shows the evolution of typical LHC related parameters at the start of a fill such as beam energy and intensity, luminosity, and the change of voltage levels for two selected channels.

MAINTENANCE AND UPGRADES

Long-Term Maintenance and Organization

The DCS undergoes continuous consolidation, mostly driven by operational requirements, e.g. increasing automation for recurring problems such as power supply trip recovery or readout re-initialization after failures. As for the initial developments, common approaches are used as much as possible in order to limit the amount of potential implementation flaws and ease further maintenance. Some weak points requiring major effort during the future maintenance and consolidation include:

DCS control station upgrade: The usual life cycle of server machines of a maximum of 5 years requires hardware and operating system upgrades. A particular weakness is the choice of hardware I/O modules (e.g. CAN in-

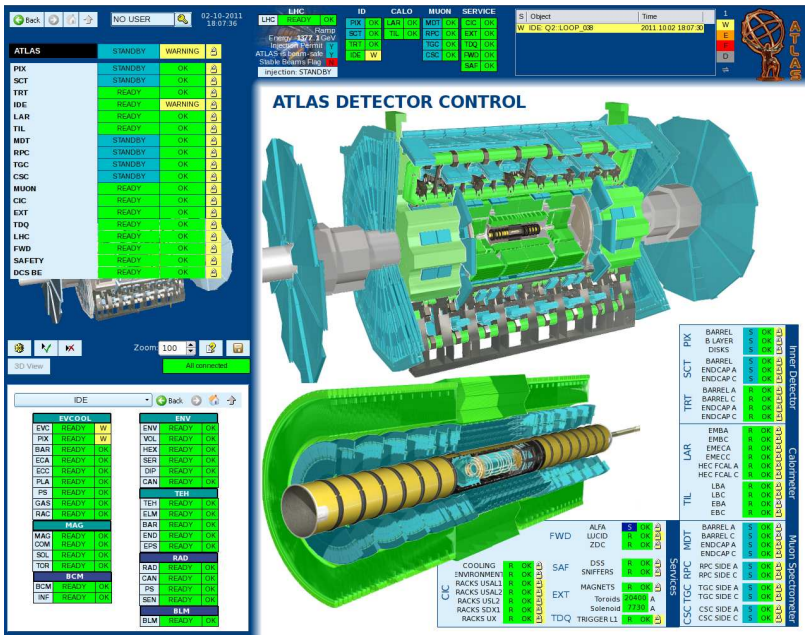

Figure 3: Operator interface (FSM Screen) showing the detector in *STANDBY* configuration during LHC ramp-up. The top hierarchy level object is shown together with its children objects (top left) and the associated main panel (bottom right). The UI allows the navigation to any FSM object and associated panel within the whole ATLAS DCS hierarchy. On the top right, a list of objects with non-OK Status allow shortcut navigation to problems.

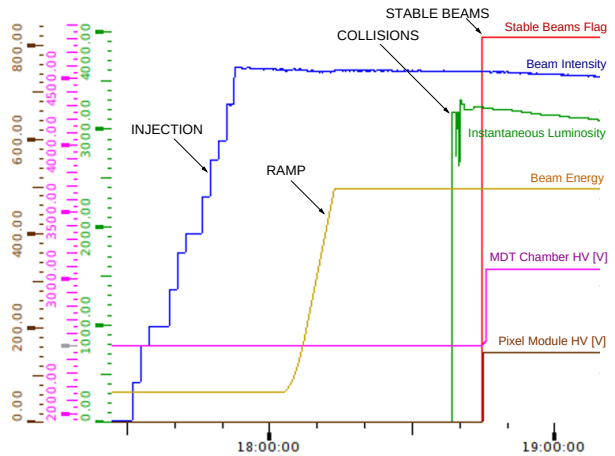

Figure 4: Initial phase of a LHC fill displayed using DCS parameters. The DCS response to the stable-beams signal received from the LHC is illustrated by two selected high voltage channels which are ramped to nominal values.

terface cards) using the PCI bus which have a short life cycle. In the future, USB and/or Ethernet interface adapters will be used which at the same time allow to increase the amount of bus connections per server machine. This enables the use of fewer cost-effective high-performance machines with a high number of cores running multiple DCS applications, or multiple virtual hosts.

Front-end interface software: The use of OPC allowed some degree of standardization of the FE interface software. However, it remains restricted to the Windows platform and lacks security mechanisms. Development activity has started to use OPC Unified Architecture (UA) – a platform independent successor of OPC with greatly increased flexibility, built-in security mechanisms, and the possibility to embed servers into electronics devices.

Future Upgrades

In the upcoming years, the LHC will undergo luminosity upgrades in several stages. Within the next 20 years, the maximum instantaneous luminosity will increase by a factor of 10 and the accumulated dose by a factor of 100 compared to the initial LHC design. This introduces more stringent requirements for DCS on-detector components such as the ELMB. A successor board has been proposed – the ELMB++ [7] – with improved radiation hardness and board flexibility, and removing previous weaknesses.

The ATLAS detector will undergo several upgrade stages for which new DCS components have to be designed and implemented. The first of these new projects is the DCS for an additional innermost barrel layer of the Pixel detector [8] which will be installed during the upcoming long shutdown in 2013/14.

Abstract

This paper presents the architecture and design of the MedAustron accelerator control system. This ion therapy and research facility is currently under construction in Wr. Neustadt, Austria. The accelerator and its control system are designed at CERN. This class of machine is characterized by rich sets of configuration data, real-time reconfiguration needs and high stability requirements. The machine is operated according to a pulse-to-pulse modulation scheme. Each beam cycle is described in terms of ion type, energy, beam dimensions, intensity and spill length. The control system is based on a multi-tier architecture with the aim to achieve a clear separation between front-end devices and their controllers. In-house developments cover a main timing system, a light-weight layer to standardize operation and communication of front-end controllers, fast and slow control of power converters and a procedure programming framework for automating high-level control and data analysis tasks.

INTRODUCTION

The MedAustron particle accelerator [1] is intended to deliver beams of various light ions for research and ion particle therapy. It features multiple ion sources, a Linac, a synchrotron and five beam lines including a proton-gantry (see Fig. 1). Upon request, virtual accelerators that represent beam paths from an ion source to an irradiation room supply beam cycles with pre-configured characteristics. A client system requests beam cycles with certain characteristics and the accelerator control system timely re-configures the front-end components. A request for a next beam cycle is issued while a cycle is generated (pipelined operation), requiring that the control system operates in soft real-time to keep dead-times between beam cycles low. Accelerator subsystems provide pulse-to-pulse modulation operation on a best effort basis, requiring a requesting client system to verify the characteristics of the delivered beam cycles.

Key features of the MedAustron control system are:

- Possibility to partition the accelerator into multiple, independent virtual accelerators and working sets to allow tuning of machine components and servicing concurrently with beam commissioning and operation.
- Optimized operation for pipelined pulse-to-pulse modulation supporting several hundreds of thousands of beam cycle configurations, being able to switch configuration in soft real-time without dead-time for cycle durations down to one second.
- High density remote power converter controller with sub-microsecond timing precision and value precision up to 24 bits operating at up to 50 KHz.
- Highly accurate and flexible real-time event distribution network as main timing system with 100 nanosecond GPS timestamping capabilities.
- Possibility to operate multiple machine partitions concurrently, supporting several modes and operation security levels.
- Role-based authentication and authorization.
- An RDBMS based system to store and organize configuration data and to create and trace versions of configuration data for operation.

This article gives an overview of the accelerator control system architecture and design decisions that govern its implementation.

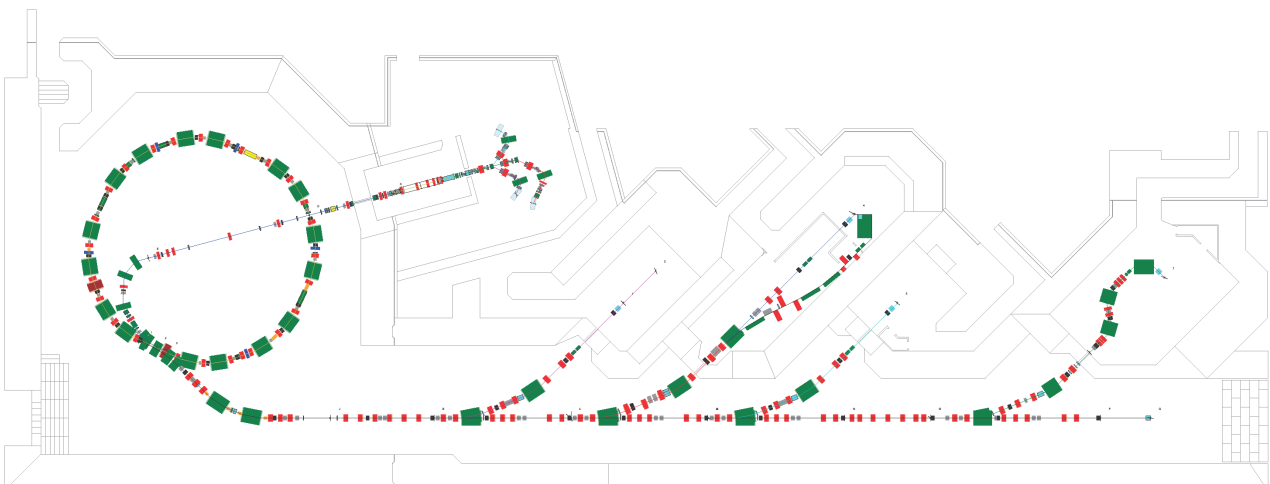

Figure 1: Layout of the MedAustron particle accelerator. Gantry beamline is indicated in bottom right part.

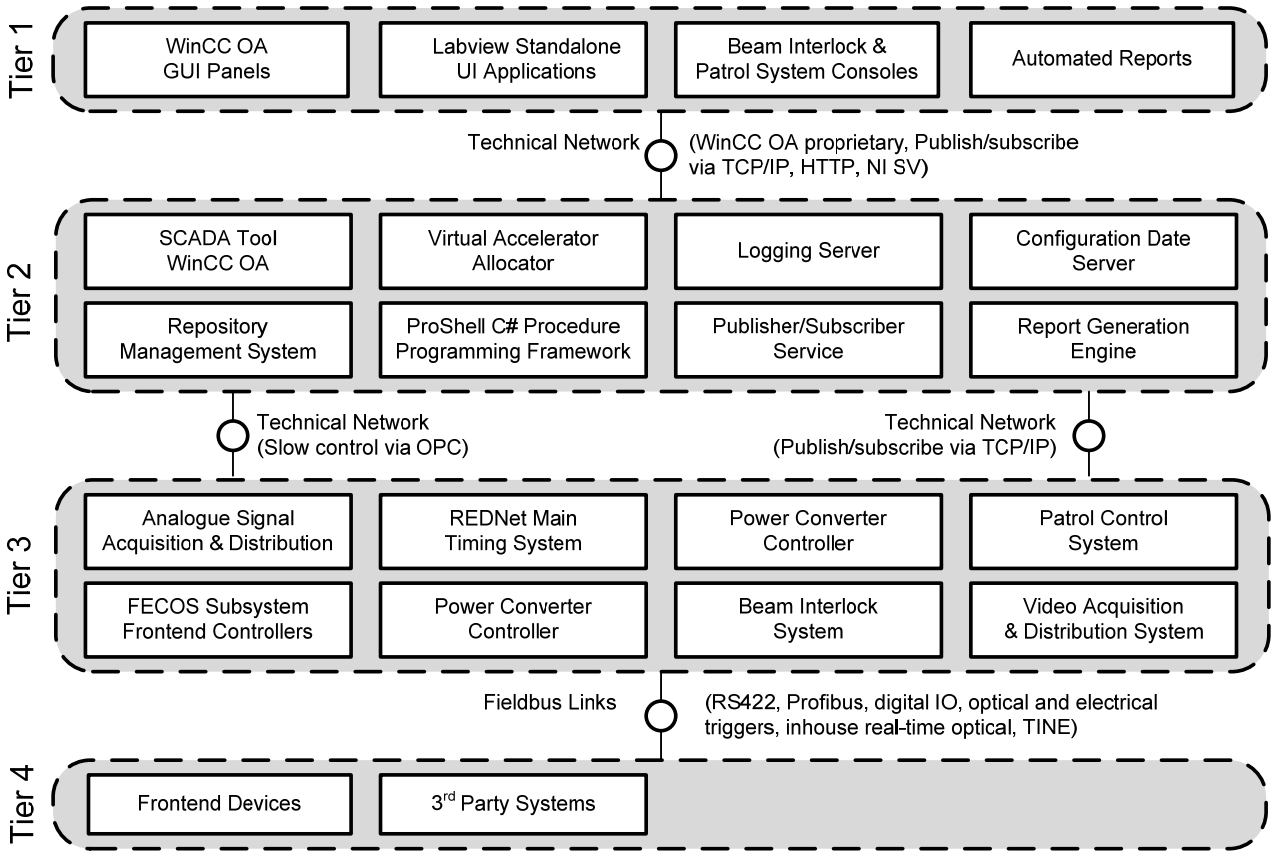

Figure 2: 4-tier accelerator control system architecture. Tier 4 comprises low-level front-end devices or third party control systems that must be integrated via a proxy front-end controller at tier 3. A single physical technical network permits communication among tiers in a secured network environment. Applications at tier 1 and 2 are virtualized.

ARCHITECTURE

Overview

The architecture (see Fig. 2) extends the industry best practice, 3-tier model [2,4] in accordance with [3]: (1) *presentation* tier, (2) *processing* tier, (3) *equipment* tier and (4) *frontend* tier. Components in separate tiers that are distributed over a number of processing devices communicate with each other through a dedicated Ethernet network. Communication between equipment tier and frontend tier may also be achieved through dedicated field-bus and custom links, depending on the imposed constraints. Subsequent sections describe each tier, starting with the frontend tier that is closest to the equipment under control.

Frontend Tier (T-4)

Front-end devices that control the actual accelerator hardware are categorized according to the project's work package organization:

The ion source supplier provides low-level API libraries for a COTS real-time computing platform. They serve implementing a front-end controller (FEC) at tier three that autonomously operates a single ion source. That system is replicated for each of the foreseen ion sources.

Conventional magnet temperature sensors open a circuit to indicate an over-temperature condition. A single PLC using the Siemens Safety Matrix tool [5] drives the circuits of all 262 magnets. This system interfaces also directly to all power converters to deliver machine protection interlock functions. Special magnets feature a separate, in-house developed, Siemens PLC based positioning and cooling monitoring system that interfaces directly to tier 2 via the S7 protocol over TCP/IP.

Power converters come in 2 different flavours: The first family is digitally controlled via RS422 lines and a purpose defined, UART based protocol for current control, slow controls and monitoring. All other power converters are treated as voltage sources that are controlled by in-house designed, analogue regulation boards. Slow controls for status monitoring and state changes are again performed via the specified RS422 line protocol. Each power converter features a trigger input to acquire measurements at dedicated points in time, synchronized within one microsecond. Hence, for slow-controls a fully homogeneous design has been achieved, including the power converters of special magnets.

Injector and synchrotron RF amplifiers feature supplier-provided Siemens PLCs for status monitoring. They interface directly to the SCADA tool at tier-2.

The injector low-level RF system features an embedded, supplier-provided computing device with few modifications to ease pulse-to-pulse modulation operation and cycle-based tagging of measurement data. This Tine-based system is interfaced via the Tine [6] TCP/IP application-level protocol and a custom-built real-time bus for generating stability and duty pulses.

The synchrotron low-level RF system is currently under development at CERN. Its communication interface remains yet to be defined.

Vacuum equipment controllers are self-contained, autonomously operating devices that feature serial interfaces and few digital IO points. They are directly interfaced to the SCADA tool at tier-2 via an OPC server that connects to several terminal servers and a few serial/Ethernet remote IO devices. The same concept applies to the beam interception devices.

Beam diagnostics devices are characterised by a rich set of different front-end electronics and interfaces. A description of the system at tier-4 goes beyond the scope of this article.

Equipment Tier (T-3)

This tier serves two purposes: first, it generates a uniform view of the diverse devices at tier-4 by introducing autonomously working front-end controllers (FEC) that all follow one design pattern. Secondly, the front-end controllers locally keep all configuration data for timely applying configuration changes to achieve efficient pulse-to-pulse modulation operation. Tier-4 devices are virtually represented at this tier either in physical FECs or directly in the SCADA tool at tier-2. FECs are National Instruments PXIe systems running the MS-Windows or Labview-RT operating systems, depending on subsystem specific constraints. FECs are programmed with Labview, using a light-weight layer called Front End Controller Operation System (FECOS) that shields programmers from dealing with communication details, providing design patterns for achieving efficient pulse-to-pulse modulation operation, standard commanding and configuration mechanisms.

Physical FECs communicate with a SCADA system at tier-2 via the OPC protocol. Direct graphical user interfaces for service purposes interface directly to FECs via the NI Shared Variable engine. For high-rate/high-bandwidth measurement data distribution, FECs use an application-level publisher/subscriber protocol based on NI's STM over TCP/IP. FECs may communicate with each other via that protocol to implement non real-time distributed applications or via dedicated low-level signals for real-time synchronization.

Notable physical FECs are the Power Converter Controller (PCC), the REDNet Main Timing System Generator (MTG), the ion source FEC, the injector and synchrotron LLRF FECs to interface to the respective low-level RF control systems.

The main timing system called REDNet [7] distributes events in real-time to synchronize the actions of the FECs. It processes "runs" consisting of lists of pre-defined beam cycles. A beam cycle is represented by a 64bit wide data structure that encodes possible beam characteristics. The MTG acts as single service access point via an application-level TCP/IP protocol for clients that have already successfully allocated a machine partition and that possess a universally unique session identifier (UUID) for this allocation. Before a cycle can be started, the cycle identifier is broadcast to all FECs via the MTG. Once a client has requested the start of a cycle, individual events are broadcast either via a dedicated, optical real-time network and/or the publisher/subscriber mechanism to the frontend applications. Timing system receiver cards generate real-time responses directly to devices via PXI/PXIe real-time bus lines or dedicated hardware interfaces using MRF's Universal IO [8].

The PCC is a PXIe based embedded systems hosting numerous FlexRIO FPGA cards. Each FPGA card can drive up to 6 power converters via an in-house developed, optical real-time link adapter for the NI FlexRIO platform (see Fig. 3). such high-density real-time control of all 260 power converters can be achieved.

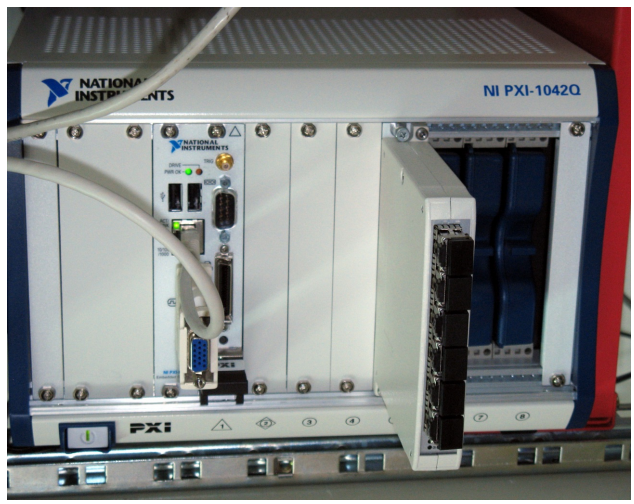

Figure 3: PCC test setup with 1 FlexRIO FPGA board and mounted 6-way optical real-time link adapter.

Finally, this tier hosts also an analogue signals acquisition and distribution system (SADS) that acts as a virtual oscilloscope for up to two concurrent users for about 100 analogue signals. This system is integrated with the MTS so that operators can easily correlate signal over time displays with distributed timing events.

Processing Tier (T-2)

The processing tier (T-2) configures and supervises equipment and frontend tiers. The tier runs supervisory procedures that include machine quality assurance and performance tuning programs. The following list summarizes functions that are located in this tier:

- virtualization of all physical devices as data point structures including a single, uniform state machine for each device that requires state-driven operation,

- creation of a uniform system image by representing all machine partitions, devices, and software components as data points,
- enforcing of role based authentication and access control,
- configuration of front-end controllers via OPC, HTTP and FTP protocols,
- persistent storage of system configuration and device parameters via an RDBMS,
- synchronization and regulation of access to shared resources,
- alarm and error handling, collection of log messages,
- distribution of on-line acquired process data,
- operation data logging and report generation,
- automated execution of supervisory control procedures to acquire machine and beam-related data, to perform quality assurance and performance tuning tasks and to generate new configuration data.

The core system at this tier is a distributed WinCC OA system from ETM. It is the only path to interact with devices during operation periods. Device configuration data may include simple or complex values. They may be static or cycle dependent. A cycle dependent configuration value is assigned a cycle mask and filter, (two 64bit key values). If a software component at FEC level receives the request for a beam cycle, the FECOS framework will look up configuration values based on the cycle mask and filter and provide them to the front-end application. At any time, configuration values can be inspected and modified via WinCC OA. Configuration data are either directly provided to FECs via the OPC protocol or are made available via a dedicated WEB server from which the FECOS executive picks the data.

A particular software component called Virtual Accelerator Allocator (VAA), written entirely in C# is the single entity that accepts requests for machine partition allocations and requests to start a run. This software component interacts solely with the WinCC OA system to achieve its task. Clients issue requests for machine partitions with QoS parameters such as required timing system precision, priority, run mode (medical, medical physics, machine physics or service), name of desired virtual accelerator or working set. If a request cannot be satisfied immediately, the VAA keeps it queued until the client either renews the request or the request times out. All applications in this tier art virtualized using the VMWare server virtualization infrastructure.

Presentation Tier (T-1)

User interfaces are implemented with WinCC OA panels. Enriched user experience such as accelerator synoptics and on-line presentation of measurement data are achieved via re-usable, in-house developed Qt widgets embedded in WinCC OA panels. Data obtained from MAPS can be directly processed these widgets. A panel navigator has been created to allow hierarchical organization of user interface panels, to perform panel-level access control for the defined user roles and to ensure that critical panels cannot be opened multiple times by multiple users at different locations. The CERN/JCOP defined security component [9] is used for implementing fine-grained role based access within panels. A colour and visual language optimized for low-ambient control room use has been devised from best practices in industry and EU norms. A claim mechanism implemented in cooperation between GUI panels and FECOS allows standalone expert user interfaces such as Labview panel applications to be used concurrently with WinCC OA panels to gain direct access to FECs for service purposes without jeopardizing operation safety.

SUMMARY

This article presented the architecture and selected architectural significant components of the MedAustron accelerator control system. This system is based on a 4-tier architecture with the aim to cleanly separate user interfaces, configuration, monitoring and system state processing services, real-time processing and proprietary and third-party supplied accelerator control devices. This control system is an evolution of the CNAO accelerator control system that has recently entered operation. A full vertical column of the system including user interfaces, the main timing system, the configuration repository and the power converter controller has been demonstrated and has proven the validity of the approach. Hence, this architecture may serve as a blueprint for future particle accelerators with comparable operation requirements.

Abstract

For the past twelve years experiments at the Relativistic Heavy Ion Collider (RHIC) have recorded data from collisions of heavy ions and polarized protons, leading to important discoveries in nuclear physics and the spin dynamics of quarks and gluons. BNL is the site of one of the first and still operating alternating gradient synchrotrons, the AGS, which first operated in 1960. The accelerator controls systems for these instruments span multiple generations of technologies. In this report we will describe the current status of the Collider-Accelerator Department controls systems, which are used to control seven different accelerator facilities and multiple science programs (high energy nuclear physics, high energy polarized proton physics, NASA programs, isotope production, and multiple accelerator research and development projects). We will describe the status of current projects, such as the just completed Electron Beam Ion Source (EBIS), our R&D programs in superconducting RF and an Energy Recovery LINAC (ERL), innovations in feedback systems and bunched beam stochastic cooling at RHIC, and plans for future controls system developments.

INTRODUCTION

The BNL Collider Accelerator Department (C-AD) facilities are shown in Fig. 1. The Tandem Van de Graaff (TVDG) accelerators provide heavy ion beams. The 200 MeV LINAC is the source of high-intensity and polarized protons. The Booster synchrotron acts as the second stage of acceleration for beams from both the TVDG and the LINAC. In 2011 EBIS was commissioned and used to provide ion beams to the NASA Space Radiation Laboratory (NSRL) that operates on a beam line off the Booster. Starting in 2012 EBIS will replace the TVDG as the source of ions to RHIC. The AGS acts as a third stage of acceleration before beams are delivered to RHIC. RHIC consists of two accelerators, with counter-rotating beams that can be put into collisions at six intersection points. For normal operations, beams are collided at the STAR and PHENIX experiments. In 2011 a third experiment (AnDY) began tests in the 2 o'clock interaction region. The 4 o'clock region contains the acceleration and storage RF systems for both rings. The 10 o'clock region contains the abort kickers and the beam dumps. The 12 o'clock region contains the polarimeters and hydrogen jet used for polarization measurement and calibration.

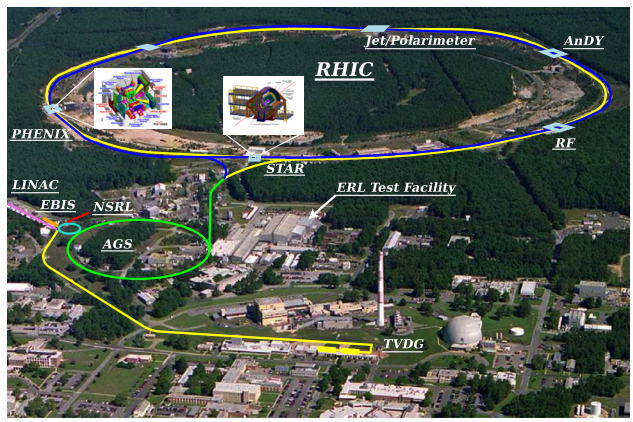

Figure 1: Accelerators at C-AD.

Since the pilot run in 1999 and through to 2011, RHIC has had 6 operating periods (runs) with Au+Au collisions [1, 2, 3]. The Au+Au runs alternated with a d+Au run in 2003 [4], a Cu+Cu run in 2005 [5], and another d+Au run in 2007/08 [6]. We also have run polarized protons, with the first run in 2001. Every year, with the exception of 2007 and 2010 we have had a polarized proton run [7, 8].

RHIC is the first accelerator capable of colliding ions as heavy as gold. As a result, the experiments at RHIC have made significant discoveries, setting the stage for developing a deeper understanding of the quark-gluon plasma (QGP) and the nature of the strong force [9]. The most significant discovery is a new state of hot, dense matter, composed of quarks and gluons, called a "perfect liquid". The properties of this matter can be described by the equations of hydrodynamics when the viscosity is nearly zero. The QGP has been seen to have unusual properties. Symmetry-altering bubbles have been observed, offering hints on the evolution of the early universe. The heaviest antimatter nucleus (an anti-helium-4 nucleus) was discovered at RHIC. RHIC is the world's only accelerator capable of colliding polarized proton beams. The RHIC polarized proton program aims to investigate the missing spin of the proton.

* Work performed under Contract Number DE-AC02-98CH10886 with the auspices of the US Department of Energy.
† kbrown@bnl.gov

In some cases, the spins of the proton's constituent quarks (and antiquarks) only accounts for 30% of its total spin. RHIC experiments are the first to study the spin of gluons and the spin substructure of the proton.

The future of RHIC involves exploring the QGP. RHICs unique capabilities allow a detailed search for the quark matter critical point (the onset of deconfinement), collisions of deuterons or protons on heavy nuclei (so called cold colliding nuclei), collisions of highly deformed nuclei (U+U collisions, so called hot matter) and the exploration of chiral symmetry and thermalization studies. Further into the future is eRHIC, which will collide high energy, high intensity electron beams with ions, polarized protons, and polarized He-3. Such a collider will allow precision imaging of the QGP, determining the spin, flavor, and spatial structure of the nucleon. It will also allow probing more deeply into the nature of the strong force, something still poorly understood, and the properties of gluons, the particles that mediate the strong force.

Controls Systems at C-AD

The C-AD Controls Systems have evolved many times since first installing computer controls in the AGS back in the early 1970's. Today our systems consist of more than 13,000 modules, chassis, fiber optic components, PLCs, and specialty items. Together they combine to provide on the order of ∼1 million setting and measurement control points. The primary Controls hardware platform is the VMEbus chassis, with 315 of these online throughout the facility. Each chassis contains a powerful processor card, and on average contains an additional 10 to 20 custom and commercial VME modules, providing a wide variety of functions and utilities. Some of the types of VME modules include Function Generators, Analog I/O boards, Digital I/O boards, Scalars, Motion Controllers, and specialty Timing boards. A detailed description of the C-AD controls for RHIC is given in ref. [10], although this reference dates back about ten years. Today's system is not much different, although we have many more chassis in the field and have upgraded the performance and bandwidth of our systems. Table 1 shows some of the system parameters for our controls.

The C-AD controls are distributed systems, as shown in Fig. 2. A C++ Accelerator Device Object (ADO) runs on a VME Front-End Computer (FEC) providing access to a power supply or device interface, along with timing and other links (e.g., a real time data link provides basic machine data, such a the main dipole ramp function, directly to FEC level software [11]). Data management consists of a number of servers that together manage data archiving, data logging, process control, and all the various interfaces needed in the main control room (MCR) - alarm managers, controls scripting, system support services, etc.

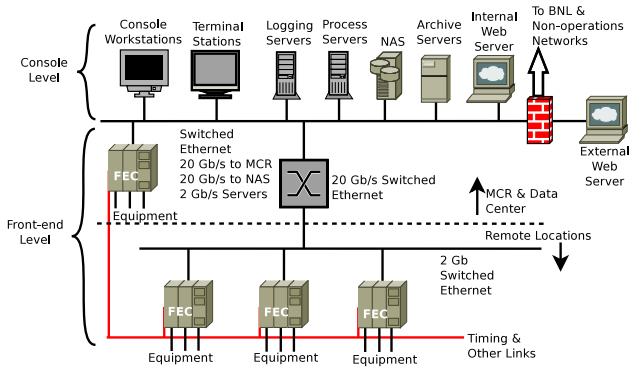

Figure 2: RHIC System Hardware Architecture, 2010.

IMPROVING RHIC LUMINOSITY

Improving the RHIC luminosity is a continuous process. Although RHIC was designed to meet a specific set of parameters, the needs of the experiments are always changing. We now operate RHIC well over an order of magnitude higher than its design. Improvements in the past include methods to make smaller beams through optics manipulations, avoiding processes that tend to increase the beam size, such as intra-beam scattering (IBS), increasing the source intensity, and reducing electron cloud buildup. We also focus on improving integrated luminosity by improving the uptime performance and reducing the time to perform various setup manipulations during the RHIC energy ramp and early part of storing the colliding beams. In the past couple of years we have seen significant increases in the luminosity through the development of bunched beam stochastic cooling. Other improvements include the development of tune, coupling, orbit, and chromaticity feedback [12, 13], correction of 10 Hz orbit oscillations using fast feedback [14], and the development of an all digital low level RF control system in RHIC [15, 16].

EBIS

EBIS consists of a set of external ion sources that inject beam into a solenoid with an ion trap. An electron beam is injected into the solenoid, stripping off electrons bound to the ions. After providing enough time to build up the desired charge states the trap is opened and the ion beam transports to an RFQ and LINAC. The advantages of EBIS include the capability to produce any kind of ion beam (including noble gases and very heavy elements). This will allow RHIC to operate with Uranium beams as well as polarized He-3 [17, 18]. To date, EBIS has reliably provided $He^{+}, He^{2+}, Ne^{5+}, Ne^{8+}, Ar^{11+}, Ti^{18+}$, and Fe^{20+} to NSRL. In 2012 EBIS will provide Uranium and possibly Gold beam to RHIC.

Feedback in RHIC

The development of reliable feedback systems has improved the efficiency of ramp development and the repro-

Table 1: C-AD Controls Systems Parameters, Characterizing the Scale and Performance of our Systems

	2011
Number of front-end VME chassis	315
Number of read/write parameters (settings)	403,000

Number of name server entries (devices & servers)	52,600
Total archive capacity	75 GB/day
Number of Named Items Archived	260,000

ducibility of the accelerator conditions. The added performance improvement has allowed RHIC to operate under more extreme conditions, helping to increase luminosities and beam polarization. For example, the tighter tune control that is accomplished allows operation close to resonances that would normally destroy the beam. Full descriptions of the various feedback systems can be found in ref.'s [12, 13, 14].

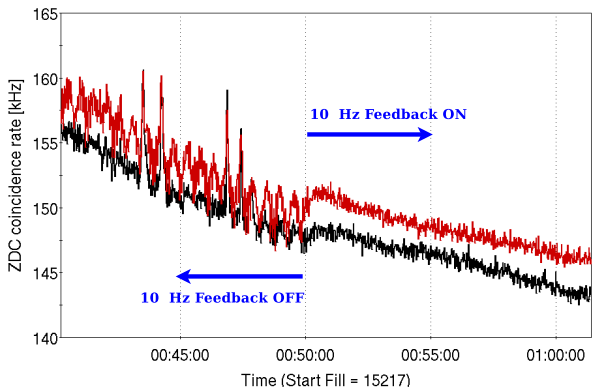

Figure 3: 10 Hz feedback improving the Luminosity at the Experiments. The ZDCs are the zero degree calorimeters used as luminosity monitors.

Stochastic Cooling

The most significant improvement to the heavy ion luminosity in RHIC has been the development of bunched beam stochastic cooling [19]. As can be seen in Fig. 4 the transverse emittance during a store can be reduced, making a smaller beam and maintaining high luminosity during the store. In the 2011 Au+Au run beam was cooled both transversely and longitudinally. This resulted in achieving average store luminosities of $30 \times 10^{26}\ cm^{-2}s^{-1}$ [20], well above the previous record of $20 \times 10^{26}\ cm^{-2}s^{-1}$ from the 2010 run, which included limited cooling, and over a factor of two beyond the $12 \times 10^{26}\ cm^{-2}s^{-1}$, achieved with no cooling in the 2007 run.

Electron Lens

The luminosity of polarized protons in RHIC is limited by head-on beam-beam effects. Beam interactions at the collision points can influence the betatron tunes and tune

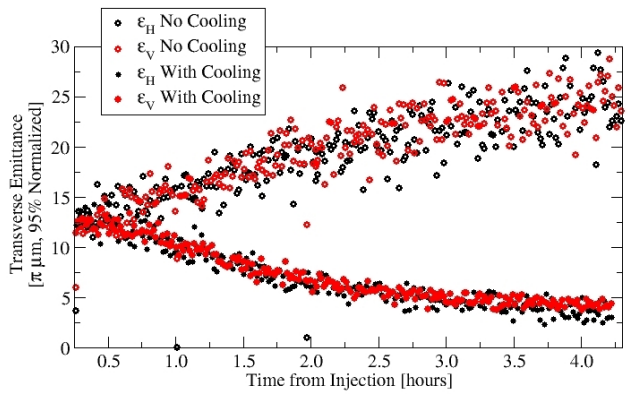

Figure 4: Horizontal and vertical emittances during two different physics stores. The open set of points show the normal increase due to IBS during a store. The solid points show decreasing emittances from transverse cooling. Measured using the RHIC IPM [21]

spreads of the beams. Beam-beam effects can be partially cancelled out by adding a third interaction between the proton beams and an electron beam. A set of electron lenses are being installed in RHIC next year and will be commissioned during the run in 2013. These systems, in combination with an upgrade of the polarized ion source, are expected to improve the polarized proton luminosity by a factor of two [22].

R&D Programs

The C-AD R&D Division was formed at BNL in order to highlight and consolidate the significant accelerator R&D efforts occurring at C-AD. The R&D Division is focused on programs to perform accelerator-based experiments at BNL and to design and construct new facilities.

The main areas of R&D are in superconducting RF systems (SRF), the development of energy recovery LINACs (ERL), the design and construction of eRHIC [23], the development of electron beam sources (high quantum efficiency photocathodes), and to develop coherent electron cooling (CEC) in RHIC [24]. The R&D Division also is closely associated with Stony Brook University's Center for Accelerator Science Education.

The R&D division gets support from the C-AD systems groups, including the Controls Systems groups. The ERL facility is currently being constructed and the controls for

the facility are being developed using the standard C-AD tools and systems (VME based with ADO interfaces).

FUTURE PLANS

Physics Programs

As outlined above, the future of RHIC is the electron-ion collider, adding electron beams, ERLs, and Coherent Electron Cooling to the systems in RHIC. There are three periods of upgrades in the RHIC long term planning. On the short-term (2011-2016) there will be ongoing upgrades to RHIC Luminosity, while the RHIC experiments focus on a well-defined program addressing key open questions in Nuclear Physics, dense matter and the spin structure of the nucleon. On a medium-term (2017-2022), the experiments plan further upgrades to focus on a quantitative pursuit of long-term questions on both cold and hot matter, the strong force, and spin dynamics. On the long-term ($>$ 2022) we enter the eRHIC era adding a 5 GeV (upgradable to 30 GeV) electron accelerator composed of Energy Recovery Linacs inside the RHIC tunnel to facilitate e+Ion, e+p (3He) studies of gluon-dominated cold matter.

Controls Systems

There are many areas in the Controls Systems where we see a need for growth and improvements. These improvements are largely driven by improvements in technologies, but also by improvements in techniques and instrumentation.

Cyber Security is always a concern. The threats are becoming much more sophisticated. New cyber threats reach deeper into the controls hardware with attacks now aimed at PLC and VME level systems. We are actively engaged in instituting measures to protect our systems from these threats.

At C-AD we have a new MCR that is all digital. There are no oscilloscopes or multiplexed signals routed into the new MCR. This puts a greater demand on the software systems. For example, we have built interfaces to remote oscilloscopes that have local signal multiplexing and allow for remote scope control.

Machine protection is a major area of focus. New accelerator systems are coming into operation and new systems are being designed. In addition, there is always a desire to improve reliability and accelerator performance. With these things in mind, we are now working on developing detailed reliability analysis and looking at ways to improve our machine protection systems. We also have new energy sources that can damage components, such as high power synchrotron radiation and high power electron beams.

Accelerator physics online models are improving significantly, which translates into greater computation demands. We also are doing more online analysis (and automatic analysis) which leads to greater data volumes and bandwidth utilization. Techniques such as orbit response matrix measurements (ORM analysis) and online optics measurements are now being done in routine operations, also increasing the computation demands. As we are starting to see today, in the future we expect more physics based controls with parametric interfaces, auto-corrections, and model based corrections. For example, in RHIC, with 10 Hz orbit feedback, we use model derived transfer functions to determine the correct BPM to corrector gains.

More of our systems have all digital controls, such as the new LLRF and new instrumentation systems for feedback. This leads to more information and diagnostics, demanding greater data volumes and bandwidth utilization.

With new feedback systems coming online, we now see new controls paradigms developing. There is an evolution occurring from tuning knobs to adjusting gains, filters, and offsets. Auto-tuning systems are more prevalent as well as automatic parameter corrections. In RHIC we now have the ability to do automatic β^* squeezing during store, while beams are being cooled, to keep the luminosity as high as possible.

Abstract

SuperKEKB electron-positron asymmetric collider is being constructed after a decade of successful operation at KEKB for B physics research. KEKB completed all of the technical milestones, and had offered important insights into the flavor structure of elementary particles, especially the CP violation. The accelerator control system was led by the combination of scripting languages at the operation layer and EPICS at the equipment layer to a successful performance. The new control system in SuperKEKB will continue to employ those major features of KEKB, with additional technologies for the reliability and flexibility. The major structure will be maintained especially the online linkage to the simulation code and slow controls. However, as the design luminosity is 40-times higher than that of KEKB, several orders of magnitude higher performance will be required at certain area. At the same time more controllers with embedded technology will be installed to meet the limited resources.

INTRODUCTION

KEKB B-Factory was designed as an asymmetric electron/positron collider in order to study the violation of CP symmetry in B-meson system. It consisted of double storage rings of 8-GeV electron (HER) and 3.5-GeV positron (LER) with a diameter of 1 km, and a full energy injector linac of 600 m. It achieved twice as the design luminosity and led to the Nobel Prize of Kobayashi and Maskawa for the theory of quarks and the CP symmetry violation.

After a decade of successful operation at KEKB a new electron/positron collider, SuperKEKB, is being constructed to commission in 2014. It aims at a luminosity of $8 \times 10^{35} cm^{-2} s^{-1}$, 40-times higher than that of KEKB, in order to study the flavor physics of elementary particles further, by mainly squeezing the beams at the collision point. The control system should be utilized to the utmost for the goal.

KEKB was constructed and operated almost the same time as PEP-II at SLAC with the same scientific goal. It provided a friendly competition between these two machines and brought many collaborative efforts. New projects SuperKEKB at KEK and Super B at INFN will be constructed in parallel again. It is hoped to exchange ideas between these projects.

* <kazuro.furukawa@kek.jp>

LESSONS AT KEKB CONTROLS

Success of the high performance operation of KEKB owed much to the control system. It was designed more than 15 years ago and had started the beam operation in 1998. While it inherited a part of resources from the previous project TRISTAN, it restructured most of the software and hardware components. It employed the EPICS (experimental physics and industrial control system) toolkit for the low-level control mechanism and scripting languages for high-level operational applications. The combination provided the flexible and robust operational environment.

Lower-level Controls with EPICS

Before KEKB, projects in the institute repeated the development of its own control system. As technologies such as Unix, VME and TCP/IP became de-facto standards at the end of 1980s, it was considered to share control systems among projects. After the Superconducting Super Collider chose EPICS as the main control toolkit, EPICS became a candidate for future controls at KEK [1]. It was decided to employ EPICS for the KEKB ring controls and the previous software resources were not employed. On the other hand EPICS gateways were constructed for the linac injector to make a bridge from the existent control system [2]. The main reason for that was the ring could shutdown the accelerator completely for 4 years, but the linac had to continue the operation for light sources even during the upgrade construction towards KEKB.

The KEKB ring employed several fieldbuses such as VME, VXI, CAMAC, GPIB and ARCNET depending on the purposes. Approximately 100 VME systems with VxWorks operating system served as EPICS I/O controllers (IOCs) for all the hardware devices including 200 VXI mainframes, 50 CAMAC crates and 200 ARCNET segments [3].

At the linac most of the devices employed IP-network-based controllers. Before the KEKB project network-based PLCs and CAMAC crate controllers, and VMEs were managed by middle-layer software on Unix servers. During the upgrade construction for KEKB, those network-based controllers were shared between old control software and EPICS gateways. Gateways were implemented with portable channel access server (PCAS) at the beginning, and were eventually replaced by soft IOCs as EPICS started to support Unix IOCs [4].

Number of EPICS process variables was approximately 300 thousand, and that of archived ones was 150 thousand. They were distributed over 150 VME-based and Linux-based EPICS IOCs.

High-level Application with Scripting Languages

At the linac Tcl/Tk scripting language was effectively employed for its commissioning [5] after the language had been utilized for testing tools for long time. Later for the both the ring and linac Python was employed as it had more strong points [6]. Many of the device control software were written in those two languages, as well as MEDM.

For the beam operation SAD (Strategic Accelerator Design Program) was extended to have an interpreter, SADscript, which emulated most part of Mathematica language [7]. It provides most of the functionalities which is required by accelerator operation such as linear beam optics, symplectic beam tracking, many of non-linear analysis, optimization, list processing, numerical manipulation, EPICS channel access, and graphical user interface.

During the normal operation it is required to measure the beam response on certain parameter changes, and then to optimize those parameters. Such a process can be interactively carried by SADscript, and then turned into a graphical user interface that is performed routinely. New ideas for luminosity optimization were often proposed in the morning meeting, and corresponding operational tools were realized within a day or two. Some of the ideas turned out to be favorable, and the tool became utilized routinely. As many ideas were proposed, rapid tool development was crucial and SADscript played a significant role. Actually it was difficult to name a single mechanism that enabled the high performance of KEKB, however, for example hundred of rapid one-percent improvements provided twice the performance.

Rejuvenation During a Project

As an upgrade of a control system needs considerable effort, it is preferable to maintain the same environment during a project. However, an accelerator project can span more than ten years, and related software, hardware, persons, companies, and their policies may change substantially during that period. It is necessary to introduce advanced technologies to improve the machine even during the project. On the other hand existent components are often found to be difficult to accommodate new technologies. If a component is modified to accept them, others may have to be modified.

Actually, during the KEKB project new operation schemes were introduced almost every year. As most components in the control system were kept the same, it was rather difficult to catch up with the requirements at the later period. One modification might trigger another, and several modifications had to be performed at the same time. Because the shutdown period in a year is limited, if the extent of modifications exceeded the limit, it became very hard.

Thus, we should be prepared to accommodate small upgrades each year not only for application programs but also for control system infrastructure including base software and hardware components in order to manage a project for a long period.

SUPERKEKB CONTROL SYSTEM

The next project SuperKEKB should follow the existent KEKB control system, which featured with EPICS and scripting languages. It is planned to incorporate new technologies to rejuvenate hardware and software components, which do not change the architecture much. However, two new concepts are considered promising, namely channel access everywhere and dual-layered control system that are described below.

Channel Access Everywhere

The accelerator control architecture in KEK evolved in several steps in the past. Some time ago several control systems were standardized with a combination of several fieldbuses, VME field computers, and Unix computers. In order to consolidate the efforts on the development and maintenance some of the fieldbuses were gradually removed and many controllers were directly attached on to IP networks.

At the same time EPICS control software framework was employed at several control systems at KEK. Eventually, many controllers evolved to embed the same EPICS IOC software as on VME field computers as illustrated in Fig. 1. Common IOC software communicates with others using a common protocol called Channel Access (CA), which realizes unified application development environment from the top to the bottom. We call this embedded EPICS framework as “CA Everywhere”, and it enabled the both rapid development and smooth maintenance [4, 8].

Different kinds of controllers have been developed in the framework of CA Everywhere, and they greatly reduced the control efforts and improved the reliability. They include following controllers. Many of them were re-

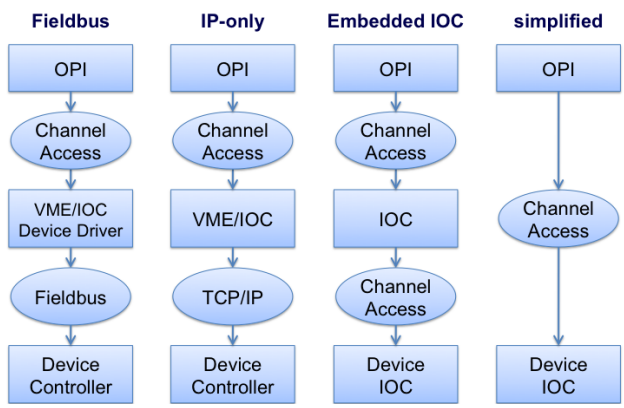

Figure 1: Evolution of device controllers from a fieldbus device towards CA everywhere with embedded IOC.

alized employing FPGA (Field Programmable Gate Array) [9, 10].

- MicroTCA LLRF controller with FPGA and Linux
- Yokogawa FAM3 PLC with Realtime Linux
- Oscilloscope for 50-Hz measurement with Windows
- Timing TDC with Linux
- Microwave power modulator with FPGA and Linux
- Libera BPM readout at 50 Hz with FPGA and Realtime Linux
- NI Compact-RIO with CAS and FPGA

Dual-layered Control System

For higher experimental performance at KEKB and the light sources, it was favorable to inject beams in top-up mode into all the storage rings. In the Photon Factory (PF), a stable beam current would provide precise experimental results. In KEKB, a stable beam current was desired for a sensitive beam collision tuning to increase luminosity.

To that end, simultaneous top-up injection had been established for three storage rings at the KEKB HER and LER, and PF since 2009. Electron and positron beams with very different characteristics, charged from 0.1 nC to 8 nC and with energies of between 2.5 GeV and 8 GeV, were exchanged at a rate of 50 Hz (20 ms). As a result, stored beam stabilities of 0.05 % (1 mA) at the KEKB HER and LER, and 0.01 % (0.05 mA) at PF, were achieved, improving the quality of experiments.

Global and fast controls have been established for such a beam modulation. As the existing control system, based on decade-old hardware and conventional software, was inadequate for controlling the beam within 20 ms, a new event-based control system, capable of regulating over a hundred parameters at 50 Hz, was installed. This system covered the controls of the low-level RF, high-power RF, pulsed magnets, an electron gun, injection systems, and beam instrumentation, whose devices were spread over a 1-km length. While the event-based control system was supervised by the EPICS control software, it had a dedicated communication link for fast, global, and robust controls [11, 12].

An event generator sends timing signals and control data to 17 event receiver stations arranged in a star-like topology. Each link between the event generator and a receiver is carried over a single optical fiber. It provides both synchronized timing signals, with approximately 10 ps precision, and synchronized controls through a realtime software mechanism, at about 10 μs precision. Recent technological advances in FPGA and SFP (Small Form factor Pluggable) enabled reliable controls in this configuration.

The same dual-layered control system with a conventional EPICS control and an event-based control will be essential in SuperKEKB as well. Simultaneous injection will be maintained, as the beam lifetime will be more limited at the SuperKEKB HER and LER. Many more parameters have to be managed precisely in order to realize lower-emittance beams for higher luminosity.

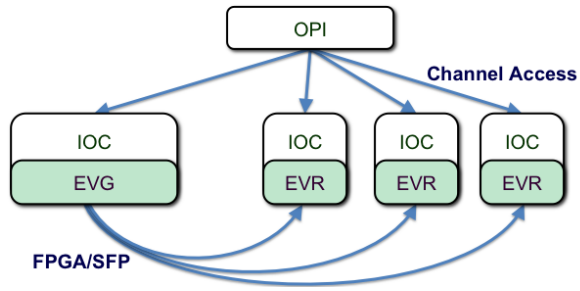

Figure 2: Dual layer controls with EPICS channel access at the top and fast event synchronized control at the bottom.

The event-based control layer manages global, fast controls in the pico- to microsecond range. The EPICS control layer covers slower parameter controls as well as existing conventional controls. Such a layered control system is optimal for the next generation of accelerator systems as depicted in Fig. 2.

CONCLUSION

The design of SuperKEKB controls is being finalized based on the achievement in the KEKB project and the discussion with each sub-group. Control components are constructed preserving EPICS and scripting languages from KEKB and enforcing two additional concepts of "channel access everywhere" and "dual-layer controls".

Abstract

LHCb is a large experiment at the LHC accelerator. The experiment control system is in charge of the configuration, control and monitoring of the different sub-detectors and of all areas of the online system. The building blocks of the control system are based on the PVSS SCADA System complemented by a control Framework developed in common for the 4 LHC experiments. This framework includes an "expert system" like tool called SMI++ which is used for the system automation. The experiment's operations are now almost completely automated, driven by a top-level object called Big-Brother, which pilots all the experiment's standard procedures and the most common error-recovery procedures. The architecture, tools and mechanisms used for the implementation as well as some operational examples will be described.

INTRODUCTION

LHCb [1] is one of the four experiments at the Large Hadron Collider (LHC) at CERN. LHCb's Experiment Control System (ECS) handles the configuration, monitoring and operation of all experimental equipment in all areas of the Online System:

- The Data Acquisition System (DAQ): front-end electronics, readout network, storage etc.
- The Timing and Fast Control System (TFC): timing and trigger distribution electronics.
- The L0 Trigger (L0): the hardware trigger components.
- The High Level Trigger (HLT) Farm: thousands of trigger algorithms running on a large CPU farm.
- The Monitoring Farm: A smaller farm running monitoring tasks to produce histograms for checking online the quality of the data being acquired
- The Detector Control System (DCS): gases, high voltages, low voltages, temperatures, etc
- The Experiment's Infrastructure: magnet, cooling, electricity distribution, detector safety, etc
- Interaction with the outside world: LHC Accelerator, CERN safety system, CERN technical services, etc.

The relationship between the ECS and the other online components of the experiment is shown schematically in Fig. 1. This figure shows that the ECS provides the unique interface between the users and all experimental equipment.

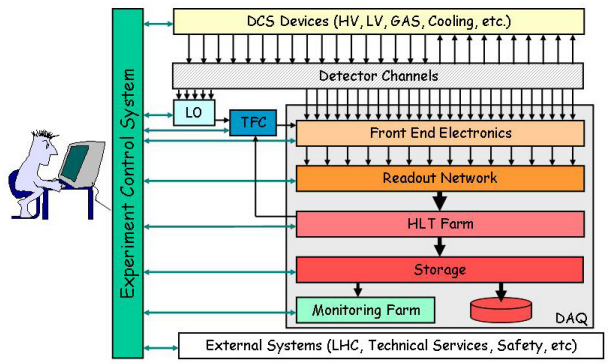

Figure 1: Scope of the Experiment Control System.

In order to achieve an integrated and coherent control system throughout all areas of the online system, a common approach was taken in the design of the complete system and the same tools and components were used for the implementation of the various parts of the system.

A common project, the Joint Controls Project (JCOP) [2], was setup between the four LHC experiments and a Controls group at CERN, to define a common architecture and a framework to be used by the experiments in order to build their detector control systems. LHCb extended the concept, and used these tools for the implementation not only of the DCS, but of all areas of control in the experiment.

SYSTEM ARCHITECTURE

The size and complexity of the LHC experiment's control systems have driven the choice of the system's architecture.

JCOP adopted a hierarchical, highly distributed, tree-like, structure to represent the structure of sub-detectors, sub-systems and hardware components. This hierarchy allows a high degree of independence between components, for concurrent use during integration, test or calibration phases, but it also allows integrated control, both automated and user-driven, during physics data-taking.

The building blocks of this tree can be of two types: "Device Units", the tree leaves, which are capable of "driving" the equipment to which they correspond and "Control Units" (CUs) which correspond to logical sub-systems and can monitor and control the sub-tree below them. Figure 2 shows a simplified version of LHCb's control system architecture.

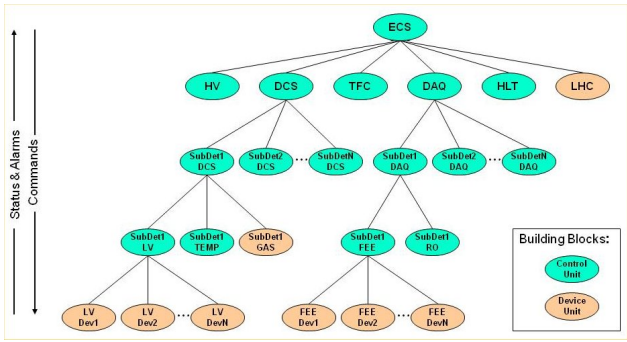

Figure 2: LHCb Simplified Architecture.

THE FRAMEWORK

The JCOP Framework [3] provides for the integration of the various components (devices) in a coherent and uniform manner. JCOP defines the framework as:
"An integrated set of guidelines and software tools used by detector developers to realize their specific control system application. The framework will include, as far as possible all templates, standard elements and functions required to achieve a homogeneous control system and to reduce the development effort as much as possible for the developers".

The JCOP Framework was implemented based on a SCADA (Supervisory Control And Data Acquisition) system called PVSSII [4]. While PVSSII offers most of the needed features to implement a large control system, the "Control Units" described above are abstract objects and are better implemented using a modeling tool. For this purpose SMI++ [5] was integrated into the framework.

SMI++ is a toolkit for designing and implementing distributed control systems, its methodology combines three concepts: object orientation, Finite State Machines (FSM) and rule-based reasoning.

The framework offers tools to implement a hierarchical control system, as described in the architecture chapter, in particular a graphical user interface, shown in Fig. 3, which allows the configuration of object types, declaration of states, actions, rules, etc. as well as the definition and operation of the hierarchical control tree composed of the two types of nodes below.

Device Units

Device Units provide access to "real" devices. In LHCb a device is basically any hardware or software entity that needs to be controlled and/or monitored, it can range from a simple temperature probe to a very complex electronics board or to a trigger process in a large HLT farm. Device Units are mostly implemented using standard PVSS tools.

PVSS provides drivers for different types of commercial hardware and a publish/subscribe protocol (DIM [6]) was interfaced to PVSS to access any non-commercial hardware or software devices. The interface to a device unit is defined as a Finite State Machine. I.e. a device is always in a well-defined state and can receive commands depending on its state.

Control Units

Control Units are logical sub-systems and perform as local decision units. They can take decisions and act on their children, i.e. send them commands, based on their states. Any Control Unit and the associated sub-tree can be a self-contained entity. The logical behavior of a Control Unit is expressed in terms of Finite State Machines. State transitions can be triggered by command reception, either from its parent or from an operator or by State changes of its children. State transitions cause the evaluation of logical conditions (rules) and possibly commands to be sent to the children. This mechanism can be used to propagate actions down the tree, to automate operations and to recover from error situations. The behavior of the Control Units is described and implemented using the SML language which is part of the SMI++ toolkit.

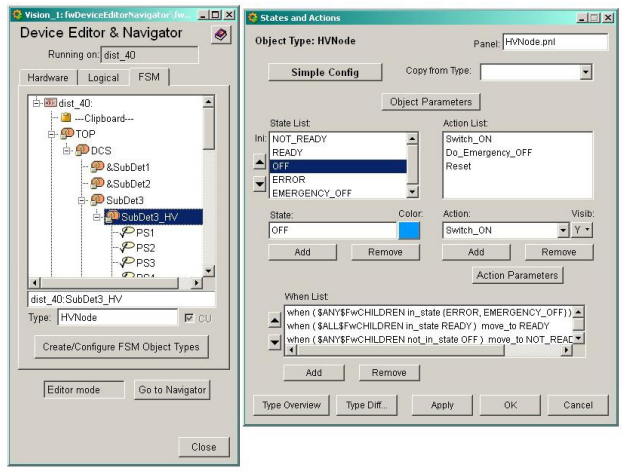

Figure 3: The Framework Device Editor Navigator.

GUIDELINES & TEMPLATES

LHCb is composed of hundreds of sub-systems provided by many different teams from institutes all over the world. The JCOP Framework was distributed to all these teams in order to implement their specific control systems. But in order to make sure to achieve a coherent control system some further guidelines were also specified.

There are various types of equipment being controlled in the various sub-systems, in particular they are normally operated at different times. For example the gas systems should be stable throughout a complete running period, while the high voltages may need to be switched off when the accelerator injects beam. In order to be able to operate all equipment in the correct order three Control Domains have been defined:

- DCS - For the equipment whose operation and stability is normally related to a complete running period. Example: Gas, Cooling, Low Voltages, etc.

- HV - For the equipment whose operation is normally related to the machine state. Example: High Voltages
- DAQ - For the equipment whose operation is related to a "Run". Example: Readout electronics, High Level Trigger processes, etc.

Due to their different characteristics the equipment in the various domains has different states and accepts different actions. For each domain a template implementation of the corresponding Finite State Machine was developed and distributed as a framework component to all sub-detectors. Figure 4 shows the FSM implemented for each domain.

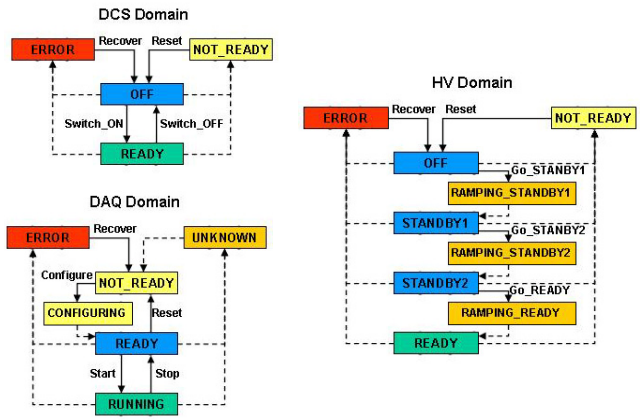

Figure 4: LHCb Finite State Machine Templates

ECS & AUTOMATION

Using the templates described above, the control tree shown in Figure 2 was implemented. The top-level "ECS" node integrates all underlying sub-systems. This node, is, in fact decomposed in three main objects, represented in Fig. 5.

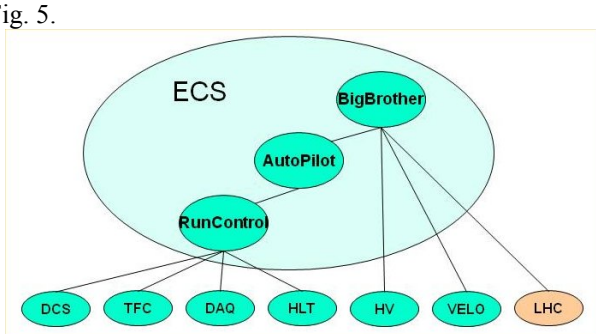

Figure 5: ECS main components

In order to prevent human mistakes and to speed up standard procedures, the system should be, as much as possible, fully automated. Since the same framework, and the same templates are used throughout all sub-systems, the implementation of automation rules within or across sub-systems was a very simple task. Some examples of automated procedures are described below.

High Level Trigger Control

The HLT is performed by a farm of around 1500 PCs, each one running several instances of Trigger processes, in total around 40000 processes are monitored and controlled by the HLT control sub-system.

In such a large system it can happen that not all PCs are operational at a given point, the control system has implemented mechanism to:

1. Automatically exclude misbehaving PCs, either because they take too long to configure, or because they stop responding. If a certain PC misbehaves several times in a row it gets marked as "bad".
2. Consider the farm ready to start a run when a certain percentage of the farm (70% at the moment) is ready, in order to speed up the start-of-run procedure.
3. Once the run is going try to include back the excluded PCs (if not marked as bad). Any PC included at run time, will go automatically through all steps (Configure, Start, etc.) until it is in RUNNING state and processing events like all others.

In general any PC or group of PCs can be transparently excluded or included at run time.

The Run Control

The Run Control provides the main user interface to the Data Acquisition system, it allows operators to include/exclude sub-systems or sub-detectors, to define the current Activity (used in order to configure all sub-systems) and to stop and start runs whenever required. But it also implements some automated actions. In particular it detects problems during the run, for example if sub-detectors are desynchronized, it can by itself issue a "CHANGE_RUN" command, which re-synchronizes all sub-detectors or it can reset and reconfigure the sub-detector responsible for the problem.

These problems are detected by the Run Control itself by checking his own counters, like dead-time or trigger rates, but some problems can only be detected by analysing the event data being acquired. The monitoring tasks while checking the data (since they are integrated in the control system like any other device) also provide flags that can instruct the Run Control to issue automatically a run change or reset a particular sub-detector.

The Auto Pilot

The Auto Pilot's responsibility is to keep the system running. It knows how to sequence operations to get LHCb, and all its sub-systems, running from any state.

Once the system is running, if there is any problem, it will try to recover and get the system back running. Of course it will only try a certain amount of times (5 at the moment), if it doesn't manage it stops and asks for help from the operator.

Big Brother

The, so called, Big Brother control object handles the dependencies between LHCb and the LHC Accelerator. For example, when the accelerator injects beams the sub-detector high-voltages must be kept in a safe state.

Another specificity of LHCb is the Vertex Locator (VELO) sub-detector, which physically moves closer to the beam when the accelerator declares stable beams.

Big Brother's operations are driven by the LHC state, whenever the LHC changes state the appropriate action is sent to the sub-detector's high and low voltage sub-systems, to the VELO and/or to the RunControl through the AutoPilot. For example the sequence of operations when the LHC moves to state "PHYSICS" is the following:

1. Send "Goto_PHYSICS" to all sub-detector's voltages (and in particular the VELO HV)
2. When the beam position is received from a VELO Monitoring task -> Start Closing the VELO
3. When the VELO is closed (centred around the beam position) -> Send a "CHANGE_RUN" to the RunControl in order to cleanly mark the start of physics data taking.

At the moment most LHC State changes need to be confirmed by the operator before the associated actions are sent out to the LHCb sub-systems.

SIZE AND PERFORMANCE

The complete control system, now in production, runs distributed over around 150 PCs, where around 100 are Linux machines and around 50 run Windows.

The Linux machines are mostly used for the control of the HLT farm (50 control PCs) and the data acquisition systems of the sub detectors. While the Windows machines are mostly used for the detector control systems. The whole system is composed of around 2000 control units and more than 50000 device units.

In order to give an idea of the performance of the system: a cold start of the data acquisition system, i.e. the time to completely configure the system and start a run is around four minutes (this includes configuring all sub-detector electronics and starting and configuring around 40000 trigger processes).

In practice a cold start is rarely performed since the run is normally started well before the LHC declares "Stable Beams" and we have implemented a "Fast Run Change" mechanism which allows to stop/start a run in a few seconds (around 5 seconds) whenever the run conditions change, for example when the VELO has moved to nominal position at start of fill, or in order to change trigger settings.

Recently, in particular after the latest addition of automated operations, the Data Acquisition Efficiency is normally around 98 %.

LHCB OPERATIONS

LHCb is now running routinely. For the complete operation of the experiment 2 operators are permanently on shift in the control room: the "Data Manager" responsible for checking the data quality and the "Shift Leader". The Shift Leader's main task is the supervision of the experiment's state and of the data taking activities. For this task he/she uses mainly the Run Control user interface, and the Big Brother user interface, both shown in Fig. 6.

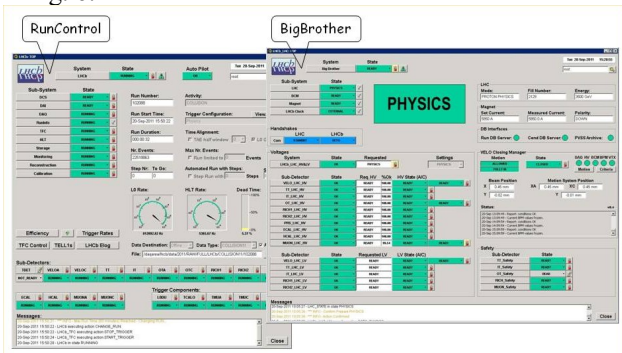

Figure 6: Shift Leader main User Interfaces.

Experience with system operation is very positive, after a short training course any member of the experiment, without previous online experience, is capable of piloting the system.

CONCLUSIONS

LHCb has designed and implemented a coherent and homogeneous control system. The Experiment Control System provides a complete, summarized view of the experiment. It allows to configure, monitor and operate the full experiment either in an integrated, global way for normal physics data taking or to run any combination of sub-detectors in parallel and in standalone.

The system is now being used daily for Physics data taking and for all other global or stand-alone sub-detector activities with very positive results.

Some of the most important features of the ECS, such as the sequencing of operations and the automation and error recovery mechanisms, come from the integration of the SMI++ toolkit within the JCOP PVSS based framework.

LHCb operations are now almost completely automated, which makes the operator task much easier and allowed to greatly improve the overall system efficiency.

MANAGING MAYHEM*

K. S. White, ORNL, Oak Ridge, TN, 37831, U.S.A

Abstract

Research institutes, typically full of excellent scientists and engineers, tend to be very focused on the technical aspects of their work, but reluctant to put much energy into the management functions that enable a healthy, productive organization. This is not really surprising when one considers that scientists and engineers are well trained to measure and evaluate quantitative entities while the management arena is dominated by qualitative concepts. Management is generally considered to include planning, organizing, leading and controlling. This paper discusses the essential management functions and techniques that can be employed to maximize success in a research and development (R&D) organization.

MOTIVATION

Roughly half of all scientific R&D is underwritten by public funding. With ever increasing pressure on governments to reduce spending, it is more important than ever to effectively manage these projects and demonstrate the long term value to the public. For R&D undertaken by private companies, there is even more pressure to demonstrate the investment will lead to profitable products sometimes with very short timelines.

In contrast to most for-profit companies, where goods or services are produced and success is measured almost exclusively by revenue, R&D organizations deal in innovation and measure success in terms knowledge gained. Of course dollars are easy to count but advances in understanding elude quantification.

By its very nature, R&D requires trial and error, creativity, and even failures that lead to rework, to move towards discovery. These critical ingredients are in fact the same variable factors that traditional management techniques strive to eliminate from processes for the sake of consistency and efficiency. The challenge for managers of R&D is how to enable the mayhem needed to fuel innovation while simultaneous assuring the needed progress to keep sponsors satisfied and therefore support future funding.

BACKGROUND

Modern management methods can be traced Frederick Taylor, a mechanical engineer who first published his theories in "The Principles of Scientific Management" in 1911 [1]. It was Taylor's work that first introduced the concept of management as a distinct profession. His work was primarily aimed at the manufacturing industry, which drove the economy during the Industrial Age. Taylor sought to maximize productivity and advocated careful (scientific) study and measurement of each step of the work process to determine the most efficient method. Trained workers should execute these steps without deviation and be paid more for achieving higher productivity.

Taylor's methods proved effective and were widely adopted, laying the groundwork for industrial engineering and quality control. This autocratic approach, with a strong emphasis on the planning, organizing and controlling functions of management, did have a positive impact on productivity and Taylor's influence is still very present in management training and practices today.

Conversely, Taylor's techniques essentially viewed the workers as interchangeable parts of a machine, with pay as their only reward. They had no input into the prescribed processes and were likely to be assigned to perform the same limited function for long periods of time with no consideration of job satisfaction or avenues for skills development. This naturally led to boredom and job dissatisfaction and worker potential remained largely untapped in this system.

Subsequent management studies and theories such as Abraham Maslow's "Hierarchy of Needs", Elton Mayo's "Hawthorne Studies", Frederick Herzberg's "Hygiene and Motivational Factors" and McGregor's "Theory X and Theory Y" introduced elements of human behavior and employee motivation as significant contributors to overall productivity [2].

For R&D managers, one of the most relevant contributors to modern management theory was Peter Drucker who first introduced the term "knowledge worker" in 1957 in his book "The Landmarks of Tomorrow" [3], signaling the future shift from the Industrial Age to the Information Age. In many subsequent publications, Drucker elaborated on how to improve productivity in knowledge work, advocating a high degree of self-management for knowledge workers and viewing knowledge workers as assets rather than costs [4].

WHY IS MANAGEMENT DIFFERENT FOR R&D ORGANIZATIONS?

The primary difference between managing commercial activities and research lies in the inherent uncertainty of the work. By its very nature, research is unpredictable, making it difficult to define desired outcomes, much less forecast each needed step along with associated timelines and costs. Research is nurtured by experimentation and missteps, which are largely excluded by popular management methods, but are vital to discovery.

Another important difference between for-profit companies and scientific entities lies in the typical characteristics of the workforce. Professionals employed by R&D organizations tend to have a higher potential and level of education than the average worker. The best R&D

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy

professionals work well independently and have a strong need for autonomy.

Management of R&D organizations is also complicated by the tendency to place people in management roles primarily because they have demonstrated technical excellence as a scientist or engineer. In this system, a high performing technical person is assigned a management role without any preparation or consideration of characteristics desirable in good manager. This even occurs when the incumbent would prefer to spend the bulk of their time pursing their technical work, but accepts the management role because it is viewed as a way to progress on the career ladder. In this case, it is not uncommon for the newly appointed manager to continue pursuing their research and largely ignore their management duties.

MANAGEMENT FUNCTIONS

The traditional management functions - organizing, planning, controlling and leading - can be overly prescriptive when applied to unpredictable R&D work and demotivating to knowledge workers. Without adjustments for the nature of the work, managers can spend a lot of time on functions that do not help productivity or help the organization meet its goals.

Organizing

The organizing function involves developing a structure and allocating resources to achieve objectives. This implies understanding the required skills mix and recruiting, training, developing and retaining people with the appropriate skills. The organization of a group should take into account how people will be deployed. For example, a group may be organized around projects and this works in the simplest case where people work on only one project at a time. In reality, people are often assigned to more than one project at a time. This leads to the need for more complex structures where people are grouped by skills or functions, and then divide their time between various projects. Given the dynamic nature of R&D, managers should consider organizing in ways that can easily adapt to changing project needs and ensure people can work across organizational boundaries as needed to enable success. The organization structure ultimately influences how people interact and share information.

Planning and Controlling

There are many types of planning, but two important types are strategic planning and work planning. Theoretically, strategic planning begins at the highest level and sets the overall vision and goals of an organization. From strategic plans, sub-organizations set their goals which eventually are divided into group goals and then projects. Work planning typically involves breaking a project down into a series of scheduled tasks along with cost estimates. A typical project plan includes a long list of tasks organized in a timeline along with the resources needed, both labor and materials, to accomplish each task. These plans form a baseline used periodically to assess progress and determine success.

When guided only by traditional management theories and techniques, R&D managers struggle with planning due to limited precedents for their work, the unpredictability of the R&D process and the inability to form clear definitions of successful outcomes. This makes it challenging to generate accurate plans and cost estimates.

Customary management dictates that managers control work by periodically checking project progress versus established goals and objectives detailed in work plans. When progress does not meet expectations, managers are expected to take corrective action to get things back on track.

Too much emphasis on planning and controlling R&D work can lead to great frustration and imply a lack of success when in fact good progress is being made. R&D projects could be better served by reducing the level of detail in plans to reflect the uncertainty of the project. Rather than scheduling strict milestones, managers could define logical points when decisions should be taken about the future path of the research. Plans should build in flexibility and be viewed as a living documents rather than a strict baselines.

Without highly predictable detailed plans, the idea of controlling a project is really futile. For R&D, it is necessary to evaluate progress, but this should be primarily for the purpose of adjusting the plan according to lessons learned. Rather than controlling, an R&D manager should focus on guiding or steering the process in collaboration with key contributors.

Leading

Leadership is perhaps the most important function for R&D managers. First and foremost, leaders establish and communicate their vision for the organization. Articulating an inclusive vision serves to inspire employees and energize them towards accomplishing organizational goals. Leadership also includes establishing an environment that enables success. R&D efforts thrive where people are free to try new methods and openly disseminate the results, even when unsuccessful. Such an environment is key to realizing real innovations, as opposed to the small incremental improvements that otherwise occur.

There are many different leadership styles, often defined by the approach a leader takes to decision making. Because R&D professionals are generally intelligent, educated and value autonomy, effective R&D managers can benefit from engaging key contributors in the decision making process. This is known as the “participative leadership style” and enables better decisions by tapping into the collective intelligence of the organization [5].

OTHER CONSIDERATIONS

Communication

The best managers are good communicators. Many people confuse communication with talking. The best leaders listen more than they talk and engage in active listening, and asking well-placed questions. Good listening not only has the benefit of providing the manager with information, it sends a message to employees saying the manager values their work.

On the other hand, when managers have a message to disseminate, it is useful to remember what marketing experts refer to as the "Rule of Seven". This rule says that people need to hear or see a message at least seven times, preferably in multiple formats, before they will act on it. With the large volume of information that bombards employees today, it makes sense to reinforce your message until it becomes part of the collective consciousness.

Motivation

People generally perform best when given the opportunity to do things they are good at and enjoy. Matching projects to an individual's expertise and interests helps to keep people engaged and interested in their work. Particularly in the world of knowledge workers, giving people a high level of autonomy is considered necessary to fully realize their potential.

Higher productivity can often be achieved by letting capable technical professionals "self-manage" their work to a much higher degree than would be prescribed by traditional management methods. Some studies indicate that productivity can be increased by a factor of two if managers adopt an untraditional leadership style that puts the focus on the ideas of others rather than their own. This strategy is known as the "The Multiplier Effect" and challenges the traditional role of managers as decision makers and advocates using the intelligence of everyone to stimulate the flow of ideas and healthy technical debate that lead to real innovation [6].

In this type of approach, the manager must create an environment of open communication and actively encourage other people to bring forward their ideas. Furthermore, the manager has to adopt a role that is more about facilitating and enabling others than controlling everything personally. This might make some managers insecure about their own value to the organization, However, if one considers the possibilities of tapping more deeply into the intelligence and potential of everyone on staff, not just managers, for good ideas it is easy to see that we might be sitting on a great deal of latent value.

Teamwork

While not every activity requires teamwork, little R&D of any importance can be accomplished by the effort of a single individual working in isolation. Unfortunately, many managers lack the skills to build effective teams. Teamwork depends on a foundation of trust, the ability to openly discuss ideas and commit to a course of action and members who hold each other accountable for results. Patrick Lencioni has written extensively on how to create great teams and effectively lead for success [7].

Conflict

If everyone is encouraged to openly discuss ideas, there is bound to be some disagreement. Managers often spend considerable effort suppressing conflict only to create a superficial outward harmony amongst the staff. When conflict is suppressed, it simply moves underground where it becomes more harmful. It is far better to create a safe environment where all inputs are valued and different viewpoints can be openly discussed. From this type of healthy debate, the best ideas will be strengthened and valuable information emerges leading to better technical decisions. The creativity that leads to innovation is difficult to cultivate without the open discussion of ideas. Rather than smoothing over differences, managers are better served spending their effort to teach employees how to discuss ideas without interpreting critiques as personal affronts.

SUMMARY

Successful management for production oriented businesses tends to rely heavily on the planning, organizing and controlling functions. To be successful in an R&D organization, the manager must be willing to relinquish some control and focus more effort on leading and coordinating the abilities of highly intelligent, educated and autonomous individuals. Good managers invest heavily in developing talented people and creating an environment that lets people do their best work

MANAGING THE DEVELOPMENT OF PLANT SUBSYSTEMS FOR A LARGE INTERNATIONAL PROJECT

Dave Gurd, Vancouver, Canada

Abstract

ITER is an international collaborative project under development by nations representing over one half of the world's population. Major components will be supplied by "Domestic Agencies" representing the various participating countries. While the supervisory control system, known as "CODAC", will be developed "in fund" by the International Organization at the project site in the south of France, the EPICS and PLC-based plant control subsystems are to be developed and tested locally, where the subsystems themselves are being built. This is similar to the model used for the development of the Spallation Neutron Source, which was a US national collaboration. However the much more complex constraints of an international collaboration preclude the use of many specifics of the SNS collaboration approach. Moreover, procedures for final system integration and commissioning at ITER are not yet well defined. This paper will outline the particular issues either inherent in an international collaboration or specific to ITER, and will suggest approaches to mitigate those problems with the goal of assuring a successful and timely integration and commissioning phase.

CONSTRAINTS AND CONSEQUENCES

ITER is too big and expensive an undertaking not to be done as an international collaboration. Without such a collaboration, bringing together the technical and financial resources of most of the developed world, ITER would simply not happen. Members of the partnership have different cultures, different scientific governance, different funding mechanisms, and possibly even different reasons for participating, with the result that political imperatives must inevitably result in some compromises and extra overhead. In addition to addressing very difficult technical challenges, ITER must learn, perhaps often only by trial and error, how best to minimize those inefficiencies and live with certain constraints. With success, ITER should become a model for future large international collaborations, such as the ILC.

As much as possible of the work of building ITER must be shared among the participating countries through their Domestic Agencies (DAs). This was the *sine qua non* of international participation, and it constrains the amount and type of work that is done by the ITER Organization (IO) at Cadarache. The work of IO is primarily to prepare contracts with the DAs, the specifications for these contracts sometimes being "build to print" but more commonly functional specifications. Very little "hands-on" work is done at IO, and much of the design work is accomplished by external contractors.

CODAC, the central common high-level supervisory control system for ITER, is developed "in fund" by IO as opposed to "in kind" by the DAs. The same approach is used for CODAC development as for other IO work, and many of the same constraints apply. Some of the constraints that affect the work and management of the CODAC group are discussed in the paragraphs below.

Staff Size Limitation

In part for reasons of cost containment and in part because of the ITER emphasis on outsourcing, the size of the permanent CODAC staff is severely constrained. The total manpower effort for CODAC design and development at Cadarache is currently set at a level comparable to that used for SNS – a project of about one third the scope. As a consequence, CODAC is required to outsource most of its development work.

Outsourcing

The R&D program has been carried out largely by external contracts, as is (and will be) much of the development of ITER-specific hardware and software. The technical staff is therefore required to spend much of its time writing technical specifications and managing contractors – a task that does not make optimal use of their training and skills. Contractors are located in partner countries all over the world and supervision is impaired by the resulting lack of face-to-face meetings. Although the practice is discouraged by senior management (contracts with well-defined deliverables are preferred), there has been some success with "insourcing," defined here as supplementing staff with external contractors working on site on relatively loose "framework" contracts. More recently, limits have been set on external contractor remuneration that are in some cases below market rates. As a result, some contracts have been suspended, and others cannot be awarded.

Laboratories

For reasons having to do partly with (possibly temporary) space limitations, partly with safety considerations, and partly deriving from the general approach of limited "hands-on" work by IO, the CODAC team currently has only a small "technical area" for prototype testing and development – too small even for a technician's bench. Software developers seldom have the opportunity to turn on a light they can see. As a consequence, they are somewhat disconnected from the concept that what they are doing must eventually relate to real equipment.

Plant System Integration

The most important constraint on the work of the CODAC Group deriving from the ITER agreement is the nature of the interface with the various plant systems – the major components of ITER. It is the role of the ITER Controls Group and CODAC to effect an integration of these components in such a way as to provide to operations a uniform view of an extremely complex system. It is this integration that presents the major challenge for the CODAC Team.

THE INTEGRATION CHALLENGE

The ITER project is broken down into 33 "plant systems." (Magnets, Cryogenics, Cooling Water, Buildings, etc.) These "plants" are to be delivered to the ITER site at Cadarache "in kind" by the participating Domestic Agencies. In many cases, however, the plants are made up of a number of subsystems each with its own specific functional requirements and each to be delivered separately *with its own Instrumentation and Control (I&C) system* by the responsible Domestic Agency. These "stand-alone" I&C systems are referred to as "Plant System I&Cs." There are approximately 220 such Plant I&Cs. (The exact number is a function of design and is subject to change.) All of these plants, plant subsystems and plant system I&Cs are the subjects of contractual arrangements between ITER and the responsible DAs. In some cases more than one DA is responsible for the delivery of a single plant subsystem. In those cases, responsibility for testing and integration remains to be clarified. In any case, it is the responsibility of the CODAC group to do the final integration of these 220 plant system I&Cs with the CODAC infrastructure at Cadarache.

Three important strategies have been adopted to mitigate this difficult integration challenge. Firstly and most obviously, the CODAC group has developed an extensive set of standards that are to be used by plant system developers. They include specific hardware, software, naming convention, development tools, acceptance tests, documentation and procedures. These standards are bound together in the "Plant Control Design Handbook" (PCDH) which is made available to all plant system developers and potential vendors. It is an ITER mandate that they be followed, with enforcement occurring at design reviews.

Secondly, and notwithstanding that it represented an activity clearly not defined within its scope, the CODAC team created an I&C Support activity and dedicated considerable resources to it. They assigned liaisons and created a mechanism to work with the plant teams in the definition of interfaces and functional requirements. They have solicited and collected rack requirements for plant I&Cs. Recently this activity has been recognized in the baseline for the CODAC scope of work.

Thirdly, and from the outset, the proposed architecture envisaged a common interface between plant system I&Cs and CODAC [1]. This was to be effected by the use of a CODAC-supplied "Plant System Host" (PSH) which would front-end each plant system I&C using a mandated common protocol and software interface. The PSH is still a keystone element of the CODAC design, and EPICS channel access is the mandated common protocol [2]. CODAC will also provide developers with a "mini" version of CODAC for testing and development. The adoption of EPICS and Channel Access as the standard supervisory control infrastructure effectively assures a standard interface. The pieces appear to be in place for a seamless integration and commissioning phase.

WHAT COULD GO WRONG?

But here's the thing. There is very little incentive for Domestic Agencies and plant system developers to follow the standards. Rather, because systems are delivered "in kind," there is strong motivation for suppliers to do things as economically as possible; and it is almost always possible to build a specific system more economically – even better – using an optimized selection of hardware and software. Already there have been examples of DAs questioning the standards, or even stating that they do not intend to, or cannot, follow them. "Why do we have to use this over-specified PLC?" "…but we can use an existing design from our last project and save the design costs." "… but we need to spend our money domestically; your standard is only available overseas." "This plant system comes with its own control system – it can't be changed." Hard to argue with any of that.

Even if all the standards were to be followed, it is clear that there would be integration issues. Plant system acceptance tests will not have been done in the same environment as the final configuration. Network issues and conflicts can be anticipated. Use of rack space, already insufficient, can only be optimized centrally. Cable runs and grounding implementations will have to be adapted to the physical situation at Cadarache.

Because of the way procurements have been distributed, some systems have many more distinct I&C systems than is necessary or desirable. It is not clear who will integrate these systems, or where. This is a result of architectural design by "procurement arrangement" rather than by technical considerations. Optimization requires a centralized view.

The current implementation model is referred to as the "black box" model (you have no idea what's inside what you get) or sometimes the "thrown over the wall" model (you might catch it but you're not sure what to do with it.) There will be no trained on-site expertise to commission and maintain these systems. It seems that seamless integration is a pipe dream. Something similar, however, has been managed before.

THE SNS EXPERIENCE

The SNS construction project was a national collaboration of US Department of Energy Laboratories. Each delivered one or more major subsystems (Front End, Linac, Superconducting cavities, Storage Ring, Neutron Target) of the accelerator facility "in kind," and each of these subsystems was delivered with a control system that plugged into the common or "global" services. Like ITER, the Controls Group anticipated integration issues and responded with standardization and the selection of EPICS to be used throughout. But also like ITER, the project Work Breakdown Structure (WBS) placed control of the "plant system I&Cs" (to use ITER language) into the hands of the different partner laboratories, who had many good reasons for going their own way. There was no effective mechanism for enforcing standards, and no effective mechanism for optimizing on-site integration. This was the scenario presented to the SNS Conceptual Design Review (CDR) committee in 1997.

The Committee: "This isn't going to work."
SNS: "But we have standards and we have EPICS."
The Committee: "Good luck with that. Change it."

The SNS WBS was subsequently changed to place the control system at the top level and move both technical and financial responsibility for plant system I&Cs to the central group at Oak Ridge. In practice very little changed – the work was still distributed. Partner lab I&C teams remained at home and worked with local subsystem developers. Only now the funding passed through the central controls office in Oak Ridge, giving it the "clout" to enforce standards. Software was deposited weekly in a central repository at Oak Ridge, and built in that environment. Team leaders at the partner laboratories met frequently in the early days, and reported regularly later. Partner lab teams participated in the integration and commissioning in Oak Ridge, and some funds were set aside for their later intervention if required. Final integration went reasonably well.

APPLYING THE SNS MODEL TO ITER

In the fall of 2010, a proposal was made to ITER management to adopt an approach similar to that which had been successful at SNS. The interface to CODAC would move from a simple Ethernet connection to the PSH to the front panel of the I/O modules that are connected directly to the actuators and sensors of the plant systems. (These would remain the responsibility of the Domestic Agency and their plant system designers.) I&C teams would be formed at each of the Domestic Agencies to oversee and/or implement the plant system I&Cs. These teams would be funded as part of the centralized CODAC activities, and the team leaders would report to the CODAC Division leader at Cadarache. Equipment purchases for plant system I&Cs would be approved and funded centrally. Members of the DA I&C teams would participate in the installation, testing and eventual commissioning of their systems at Cadarache. The CODAC I&C Support team at Cadarache would consider issues related to optimization and integration of subsystems coming from more than one source and facilitate that task.

The cost of the plant system I&Cs (equipment, software and manpower) might be expected to be 50% - 70% of the total cost of the ITER control systems. (It was 60% for SNS.) As that work is not in the current budget for CODAC, a transfer of funds would be needed to finance this increase in scope. The mechanism proposed was a "tax" on each DA requiring I&C, calculated on the basis of anticipated costs of their plant I&Cs according to various "rules-of-thumb."

Although this proposal was put forward primarily as a risk mitigation, citing the risk of both cost and schedule overruns at integration time, it did suggest a potential cost saving to the DAs because of efficiencies that might accrue through bulk purchases and reduced hardware and space requirements. It was unfortunately this rather speculative cost saving, which would not in any case benefit the ITER Organization at Cadarache, that attracted the most attention, particularly as the proposal arrived just as a frenzy of cost containment was initiated at ITER.

The proposal generated considerable interest and discussion both at ITER IO and among the Domestic Agencies. Modified versions were advanced in which more hardware and software would be provided to plant I&C developers, but with no transfer of responsibility or funds. In the end the proposal was rejected for a number of reasons, perhaps most significantly because the "tax" was unacceptable. Worse, some stakeholders seemed to be of the opinion that plant I&Cs were already within the scope of CODAC in any case. That misinformed opinion forebodes an even greater train wreck.

THE PROPOSAL EVOLVES

As noted above, each DA is itself responsible for the design, construction, testing and delivery to Cadarache of a significant number of plant I&C systems. Europe, for example, will deliver the following systems, many extremely complex in themselves, most made up of multiple plant systems and including many plant I&C systems:

Two Cryogenic Plants (LN2 and 80K)
4 Remote Handling Systems
Tritium Plant Systems
Building Management Systems
Electrical Distribution Systems
Waste processing System
Test Blanket
14 Plasma Diagnostic Systems
3 Additional Heating Systems
Standalone Instrumentation
More…

This collection alone is probably comparable in range, cost and complexity to the complete SNS control system. One "additional heating system," for example, is a complete accelerator in itself, with ion source, RF systems, vacuum and cooling systems, beam line components, etc. It becomes immediately apparent that the integration issue presents to the DAs an (only slightly) smaller version of the same concerns that are perceived by CODAC.

For that reason, the controls team at the European DA last spring made a proposal similar to CODAC's for oversight, management and in some cases design and development of the plant I&C systems for which they are responsible. (Figure 1.) Like the CODAC proposal, they have proposed a small team of control system and project management experts to be located at the European DA offices in Barcelona. This team would take responsibility for oversight of all the plant system I&Cs that fall under the European purview. No black boxes. No walls. Like the CODAC proposal, they have appealed to the responsible DA ("Fusion for Energy," or "F4E") for funding to support this activity.

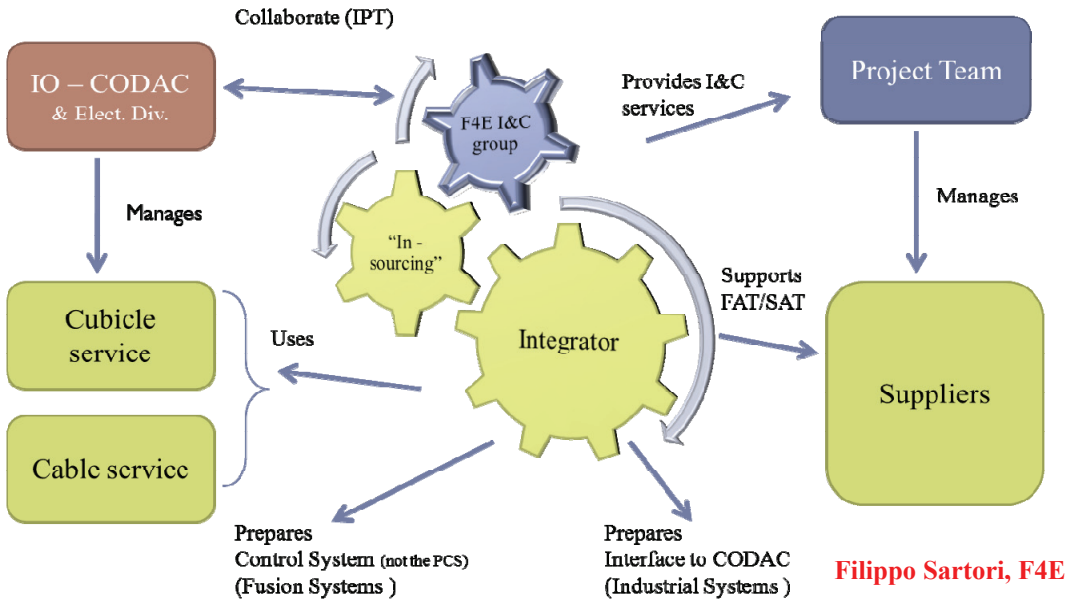

Figure 1. The European Proposal for plant I&C system development.

There are however important differences between the European proposal and the CODAC proposal. In this scenario, the DA controls team would be managed and funded from within the Agency and not through CODAC. Moreover, rather than using a significant number of F4E staff members, the European proposal suggests using a very small staff team and contracting most of the work to two external contractors: one "insourced" to supplement the staff in Barcelona and a second "outsourced" to an integrator that would perform much of its work wherever the subsystems are being built. (The CODAC proposal suggested using ITER staff members.) Formal approval is still required before this proposal becomes the official European approach to delivering plant system controls, but the idea of assigning most work to external contractors is consistent with the general ITER approach, and the proposal seems likelier to receive support for that reason. A meeting of potential integrators has already been held. Because this proposal advocates adherence to CODAC standards and recognizes the importance of a close collaboration with IO, the CODAC team is strong in its support.

CONCLUSIONS

Development of the ITER Control System is taking place in the presence of numerous constraints imposed by the imperatives of an international collaboration. Integration of plant control systems from many different suppliers distributed over the world presents a particularly difficult challenge. Centralizing the development of plant I&C systems was not accepted, however a compromise of centralizing development at the responsible DAs has been proposed by Europe. Learning to work effectively in this environment will be invaluable for future large international collaborations in science and other domains.

SESAME, P.O. Box 7, Amman 19252, Jordan

Abstract

SESAME (Synchrotron-light for Experimental Science and Applications in the Middle East) is a third-generation synchrotron light source under construction near Amman (Jordan), which is expected to become operational in 2015. SESAME will foster scientific and technological excellence in the Middle East and the Mediterranean region, build scientific bridges between neighbouring countries, and foster mutual understanding through international co-operation. The current members of SESAME are Bahrain, Cyprus, Egypt, Iran, Israel, Jordan, Pakistan, the Palestinian Authority and Turkey. An overview about the progress of the facility and the general plan will be given in this paper. We will then focus on the control system by explaining how this aspect is managed: the technical choices, the principal deadlines, the local staff, the international virtual control team, and the first results.

INTRODUCTION

Developed under the auspices of UNESCO and modelled on CERN, SESAME (Synchrotron-light for Experimental Science & Applications in the Middle East) is an international research centre under construction in Jordan [1].

It will enable world-class research by scientists from across the Middle East/Mediterranean region (in subjects ranging from biology and medical sciences through materials and environmental science and physics to archaeology), preventing or reversing the brain drain. It will also build bridges between diverse societies, contributing to a culture of peace through international cooperation in science. It will help foster closer links between people with different traditions, political systems and beliefs. The centrepiece of SESAME is a new 2.5 GeV third-generation light source which will provide very intense light from infra-red to hard X-rays for a wide range of studies. The microtron and the booster constituting the injector section were originally used at the former BESSY I synchrotron but have been greatly upgraded and refurbished. The energy of the microtron is 22.5 MeV whilst the electrons will be accelerated to 800 MeV in the booster. The storage ring will have an emittance of 26 nm.rad and 12 straight sections are available for insertion devices. The phase I scientific program has been finalized and foresees 7 beamlines providing wavelengths from infra-red to hard X-rays. The project is governed by a SESAME Council currently having nine members (Bahrain, Cyprus, Egypt, Iran, Israel, Jordan, Pakistan, the Palestinian Authority, and Turkey), whilst France, Germany, Greece, Italy, Japan, Kuwait, Portugal, Russia, Sweden, Switzerland, the UK, and the USA are observers. The project is benefitting enormously from help and advice provided by various synchrotron laboratories around the world (SOLEIL in France, ALBA in Spain, ELETTRA in Italy, the Swiss Light Source, Diamond in the UK and the Canadian Light Source). The capital funding needed to complete the construction of SESAME is being sought from the members and from various external sources.

Recent progress has included a growth in the number of technical and scientific staff to about 25 people [1]. The radiation shielding wall was completed in April 2011. Extraction of the first beam from the microtron has now been achieved at low energy (10 MeV) [2].

The current progress concerns tests of the booster equipment; the booster will shortly be installed in the tunnel, and preparation is under way for commissioning the booster with beam. In addition all the storage ring equipment has been designed, and the call for tenders is waiting for funding [2].

Figure 1: SESAME radiation shielding wall.

A SPECIAL PROJECT

SESAME is a wonderful project for the idea it conveys, but is very challenging because the budget is not secured in its entirety and arrives in small portions. The technical team is young and inexperienced in accelerator design and construction. The local industry also does not have direct experience in supporting such a project. As a result, the technical management of such a project cannot be conducted in a conventional way. The project leader must have a lot of imagination in order to overcome these challenges.

Thanks mainly to the International Atomic Energy Agency (IAEA) but also to other institutions [1], a programme of training has been underway since 2000. Most members of the SESAME team have spent several months in one of the world's synchrotron radiation facilities and learned about several areas of synchrotron light source construction and operation. Experts from these laboratories have also visited SESAME and this has had a positive impact on the local team. In the case of the control system, a virtual international group has been created.

This has all helped to achieve some important milestones such as the successful commissioning with beam at low energy of the microtron, testing of all of the booster subsystems (RF, vacuum, and cooling systems, diagnostics, and so on), and providing new booster power supplies and new booster dipole vacuum chambers after an international call for tenders. Good news is foreseen concerning the budget. Commitments and offers announced and confirmed by Members in May 2011 look set to provide most of the remaining $35 million needed for the storage ring and the three beamlines that will be in operation from day 1.

TEAM BUILDING

The International Control System Virtual Team

The recruitment of the control system group and its management was particularly difficult. The potential candidates are young and unfamiliar with accelerator control. There is also a limited budget which prevents the hiring of a significant number of staff or the outsourcing of work to specialized companies. SESAME has found very good candidates who have electronics or software skills, but who are new to accelerator or light source control systems. Each newly-hired engineer has therefore been trained in one of the following laboratories: SOLEIL, SLS, CLS, and/or DLS; and coached in order to be operational as soon as possible. Although SESAME, in common with other light sources, has advisory committees which meet once or twice a year, a need for senior experts who can follow the work more closely was essential.

At the end of 2010, the SESAME project leader decided to set up an international "virtual" control system group. This group is composed of experts and managers in the field of accelerator control from the Canadian Light Source (CLS), Diamond Light Source (DLS), the Institute of Research into the Fundamental Laws of the Universe (IRFU) of the CEA, Synchrotron SOLEIL, the Swiss Light Source (SLS), and of course from SESAME itself. The idea is to have close coaching of the SESAME control system team.

A Cross-Over Management

Inside the virtual group management task and responsibilities are defined for better efficiency. The coordination of the virtual group is handled by Pascale Betinelli from SOLEIL. The main reason for this choice is to make the contact between SESAME and the virtual group easier; the part time Technical Director of SESAME (until the end of this year) is the current Director of SOLEIL Sources and Accelerators Division. Moreover Mark Heron, the DLS member of the virtual control group, is present on the Technical Advisory Committee (TAC) of SESAME and on the Computing Advisory Committee (CAC) of SOLEIL. Whilst each local engineer is in charge of a part of the control system, each expert member is responsible for following that part closely and teaching the local engineer particular technical aspects of control.

Figure 2: Members of the SESAME International "Virtual" Control System group.

Recruitment

The coaching starts with recruitment: the members of the virtual group guide SESAME's leaders by finding the right technical skills in the CVs. SESAME's leaders then conduct each job interview and select the person who fits with the technical requirements and the motivation of the project. Today the local control system team is composed of three engineers: Saed Abu Ghannam from Palestine, Ibrahim Saleh from Jordan, Zia-ul-Haque Qazi from Pakistan.

Training

Each engineer had good electronics or software skills but needed to be trained on accelerator control systems. First they went around the world to learn the basics of instrumentation and control: EPICS, VME and Timing System. Saed Abu Ghannam spent one month at CLS, attended the PCaPAC 2010 workshop then spent two months at SLS, one week at SOLEIL and visited IRFU. He was trained in EPICS and discovered the different aspects of a synchrotron radiation facility. Similarly, Ibrahim Saleh has been invited to ICALEPCS 2011 as a member from an industrially emerging nation and will take this opportunity to spend a few weeks at DLS to learn EPICS and interlocks, and at SOLEIL, where he will stay two weeks working on PLC aspects and the installation process. The third member of the SESAME control system group, Zia-ul-Haque Qazi, should soon undertake similar training.

Coaching

Day by day the virtual group guides the control team in the development process. They explain each step to them, providing examples and a work plan. To help the local team, the virtual group has provided a list so that they can easily find who to contact for each type of problem or for advice. On a regular basis the virtual group organizes video conference meetings with all the members, in order to validate technical choices or to review sub-projects such as power supply control, vacuum control, etc. The local engineer who is in charge of a particular task prepare the work with the person responsible for SESAME subsystems and then discuss it with the virtual group in a dedicated video conference meeting. The requirements and the control architecture are then discussed during the review.

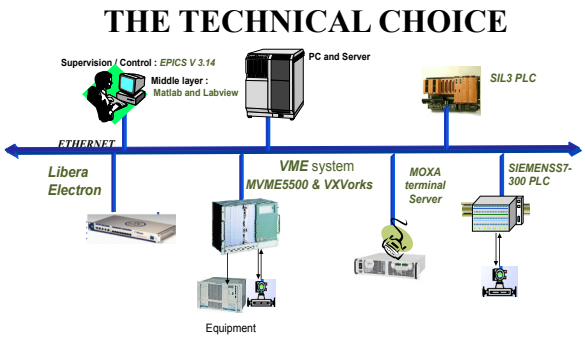

Figure 3: Control Architecture.

SESAME needs to have the most up-to-date control possible, but in doing so needs to consider how the solutions will be supported. It is therefore very important to select items corresponding to the skills of the virtual group. Sometimes SESAME has the chance to receive gifts from the international community. These generous gifts help us to reduce costs but involve some difficult upgrades due to the age of the equipment given or to technology changes. The analysis of the feasibility of integrating old technologies is a process that requires time and special skills

All the time we have to make a compromise between up-to-date technology and pragmatism.

As a result of following these guidelines, the main technical choices are very conventional and tested: EPICS and VME have become established. Figure 3 shows a schematic view of the main architecture.

VME System

We have selected EPICS 3.14 in order to benefit from the latest improvements. For VME systems, we first analyzed the feasibility of integrating old VME 2304 CPUs. Finally we selected the boards currently used at SLS, DLS, and IRFU, namely MVME5500 from Emerson and I/O boards from Hytec Electronics. We would have liked to use the very latest EMERSON CPU technology but during the startup period we cannot accommodate the work load of adopting this new technology. On the VxWorks kernel side, we have chosen to implement version 6.9. This allows us to take advantage of the know-how of IRFU, which is in charge of building the appropriate control system environment (VxWorks kernel with required functionalities, EPICS3.14 base, extensions and development framework).

Because VME technology is expensive and complex to implement and maintain, the international experts encourage the use of stand-alone PLC and Ethernet modules as far as possible.

PLC Systems

SIEMENS PLCs are the de facto standard as SESAME has experience in this field. The local team has already upgraded the control of the Microtron with a CPU312. Furthermore, SOLEIL and DLS have experience with this type of PLC system.

In most cases the machine protection systems will be connected to the PLC from different subsystems (vacuum, cooling, etc.). Part of the power supply and vacuum control will be performed by PLC. In accordance with the SOLEIL specification method, an order has already been placed with SIEMENS' Jordanian supplier. In October SESAME will start to implement booster development with the help of SOLEIL.

Ethernet Standalone Equipment

Serial links are communication interfaces that will have to be managed in large numbers. To reduce cost we have selected a MOXA terminal server with the first items ordered from a local supplier in Dubai. The terminal server was received and an implementation for the corrector power supply of TL1 has already been done. Thanks to the training already received, the implementation required very little help. Figure 4 shows the first EDM interface for the corrector power supply.

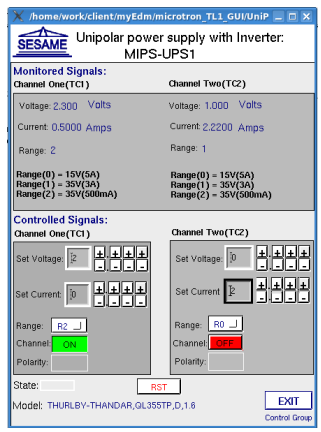

Figure 4: EDM interface for corrector power supply.

The control of diagnostics is supervised by CLS, which has provided a template and advice. Many diagnostics devices come from BESSY I. The three fluorescent screens available around the Booster have been refurbished and the cameras have been replaced by a low-cost Ethernet camera. Current measurement performed by a cavity is still under discussion to understand the

appropriate control mechanism. Whilst there was no tune measurement in the old BESSY I Booster, it is planned to have such a system at SESAME. The BPM read-out electronics is performed by I-Tech Libera Electron modules. SESAME has already received seven Libera Electron modules to be used in its booster ring. A SESAME engineer is in charge of the implementation of the embedded process. Presently EPICS IOC (from DLS) has been installed in one of these modules and the module and driver performance is being analyzed. Performance analysis is being carried out with a 500 MHz signal provided to the Libera Electron inputs through a clock splitter. However the available EPICS IOC is incompatible with latest version of Libera Electron and there is a need for modifications which are currently under way. On the other hand, GUIs have also been obtained from DLS to receive and view information from Libera Electron modules, and these are being used for the performance analysis of the EPICS driver.

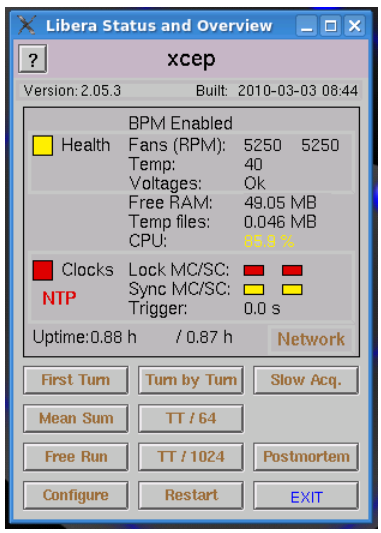

Figure 5: Main GUI for Libera Electron.

Figure 5 shows the main screen from the GUIs for Libera Electron. It shows the health status, the clock status, controls to obtain various types of data from Libera modules such as First Turn, Turn by Turn, etc., as well as controls for Configuration and Restart. Once the performance of EPICS IOC and GUIs is finalized, they will need to be customized by SESAME according to its naming convention.

Booster Timing System

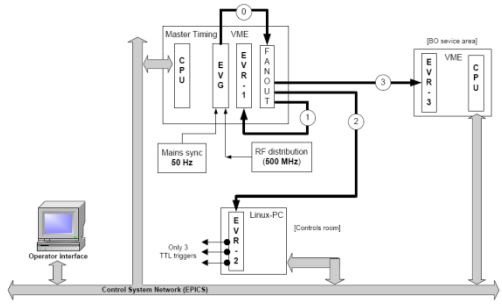

Figure 6: Booster timing system.

SESAME's booster timing system is based on the global event system, widely used in many light source facilities such as APS, SLS, DLS and others. The booster timing system has been designed and developed by SLS, and all the hardware used is from Micro-research Finland. In the SESAME booster timing system, one event generator and three event receivers will be used in order to provide and distribute all the event sequences to operate the booster. Figure 6 shows a schematic of the booster timing system. It will be delivered to the SESAME site at the end of November to be tested before its deployment.

End User Development Environment

The main development environments used are Labview and Matlab. These two software packages are easily interfaced to the EPICS framework and offer a suitable end-user environment. Matlab middle layer physics applications [3] will be used as commissioning tools to and for a few high level control applications from the transfer line to storage ring as in similar facilities. With Labview we can directly integrate the prototype of the Booster RF control, which has already been completed using a CPCI system. In a second step we will upgrade this prototype to run on a VME platform to provide consistency with the rest of the control system.

Network and Server

In SESAME, the control servers are based on virtual machines running Scientific Linux. We currently have around 15 powerful virtual machines. Those machines will be used in making EPICS servers, development consoles, file systems and others.

HOW TO SET UP THE RELATIONSHIP WITH MANUFACTURERS AND SUPPLIERS

Industry in the Middle East has very little experience of Synchrotron light sources. There is also a limited presence of the big companies involved in control systems, and those which are present are reluctant to get involved. From this low point, SESAME has to educate and develop relations with potential suppliers.

International support is again essential: Day by day, through discussion after discussion, companies will come

to understand the approach and objectives. Conversely, SESAME engineers must understand and adjust to the ways in which western companies and people think and work. Once mutual understanding has been established, companies are often willing to help and support the SESAME project. For instance Windriver has offered to let SESAME join their research program.

HOW TO SET UP THE INSTALLATION PROCESS

SESAME engineers have no experience of the requirements and the complexity that they will face during installation. Like all people in similar positions, they need time to understand the necessity for and the strategic requirements of aspects such as a naming convention and a cabling database, and the need to do some tasks in advance. To tell them is not always enough: they need to acquire experience in order to appreciate every detail of the virtual team's advice. Many short discussions are necessary to compensate for the drawbacks of having a virtual team: E-mail and documents are not enough; direct contact is very important to solve problems.

Today, reviews have already been conducted for the power supply, vacuum and diagnostics areas.

OUTCOME AND FUTURE

We should always keep in mind that SESAME is not a standard project and the context and the issues are complex. In 2009 the TAC was worried about the state of the control system. This year, after just one short year of existence of the control system virtual group and the recruitment of local engineers, control system development is going ahead at SESAME. We hope to assemble most of the booster control system by the end of the year. Some control parts like the pulsed magnet control are still critical because of the age of the equipment but we are confident that we can solve the problems.

Unfortunately we note that planning has to be flexible to handle this complex project. The booster assembly will be a true test to demonstrate to the international community the legality and viability of SESAME.

ACKNOWLEDGMENTS

We wish to thank:

- Elder Matias and his team from CLS
- Mark Heron and his team from DLS
- Jean-François Gournay from IFRU
- Babak Kalantari from SLS
- Pascale Betinelli and her team and Laurent S. Nadolski from SOLEIL
- SESAME subsystems responsible for valuable discussions.

They are very involved in this project and always give us good advice and training.

Abstract

The Thirty Meter Telescope (TMT) will be used with Adaptive Optics (AO) systems to allow near diffraction-limited performance in the near-infrared and achieve the main TMT science goals. Adaptive optics systems reduce the effect of the atmospheric distortions by dynamically measuring the distortions with wavefront sensors, performing wavefront reconstruction with a real time controller (RTC), and then compensating for the distortions with deformable mirrors. The requirements for the RTC subsystem of the TMT first light AO system will represent a significant advance over the current generation of astronomical AO control systems. Memory and processing requirements would be at least 2 orders of magnitude greater than the currently most powerful AO systems using conventional approaches, so that innovative wavefront reconstruction algorithms and new hardware approaches will be required. In this paper, we will first present the requirements and challenges for the RTC of the first light AO system, together with the algorithms that have been developed to reduce the memory and processing requirements, and then two possible hardware architectures based on Field Programmable Gate Array (FPGA).

INTRODUCTION

The Thirty Meter Telescope (TMT) Project [1] is designing and building a thirty-meter diameter telescope for research in astronomy at optical and infrared wavelengths. The core of the TMT is a wide field, altitude-azimuth Ritchey-Chretien telescope with a primary mirror consisting of 492 segments. Instruments are located on two large Nasmyth platforms, addressed by an articulated tertiary mirror.

The initial Adaptive Optics (AO) architecture for the TMT is defined to provide near-diffraction-limited wavefront quality and high sky-coverage in the near infra-red (IR) for the first light TMT science instruments IRIS, a near-infrared instrument with parallel imaging and integral-field-spectroscopy support; and IRMS, an imaging, multi-slit near-infrared instrument. The initial AO architecture is a Laser Guide Star (LGS) Multi Conjugate AO (MCAO) architecture consisting of (i) the Narrow Field IR AO System (NFIRAOS) [2], which senses and corrects for wavefront aberrations introduced by the atmospheric turbulence and the telescope itself, and (ii) the Laser Guide Star Facility (LGSF), which generates a constellation of LGS in the mesospheric sodium layer with the brightness, beam quality and geometry required by both NFIRAOS and the future second generation of TMT AO systems [3].

The NFIRAOS system includes two 60x60-order Deformable Mirrors (DM) conjugated at 0km and 11.2km, one fast Tip-Tilt Stage (TTS) serving as a mount for the ground level DM, six 60x60-order LGS Wavefront Sensors (WFS), one high-order Natural Guide Star (NGS) WFS for non-LGS operations, up to three low-order NGS WFS working in the near–infrared and located within each NFIRAOS instrument (also referred as the On-Instrument WFS or OIWFS), and a Real Time Controller (RTC) processing the inputs from the multiple WFS to compute the commands to the deformable mirrors and the tip/tilt stage at sampling frequencies up to 800Hz.

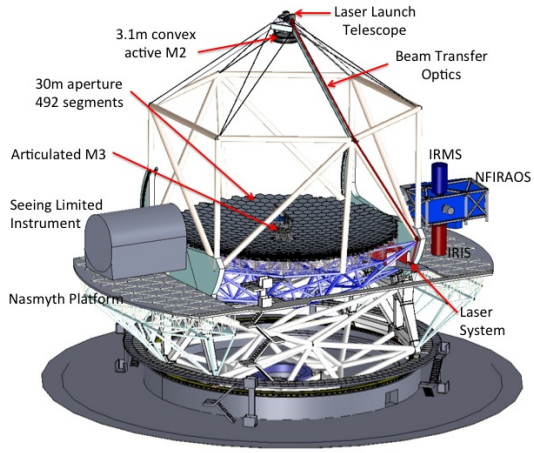

Figure 1: TMT telescope overview and first light instrumentation.

NFIRAOS RTC REQUIREMENTS AND CHALLENGES

The NFIRAOS RTC is one of the most challenging computing components of TMT [4]. It includes several modes of AO operation. The mode that has the most demanding requirements is the LGS AO operation mode. A block diagram of this mode is given in Figure 2.

The RTC requirements in the LGS AO operation mode are split into two categories:

- The *hard real time requirements*, which consist of the LGS wavefront sensor pixel processing, the LGS reference processing, the On-Instrument wavefront sensor pixel processing, the very high-order LGS tomographic wavefront reconstruction using measurements from these multiple wavefront sensors, the On-Instrument wavefront reconstruction

and the calculation of the two deformable mirrors and tip-tilt stage commands. These processes are operated at up to a 800Hz sampling rate, with a 1000µs latency (and a strong goal of 400µs).

- The *background and optimization requirements*, which operate at slower sampling rates to i) optimize in real time the parameters of the hard real time processes as the observing parameters and atmospheric conditions change, ii) estimate the turbulence parameters, iii) offload persistent, low spatial frequency components of the deformable mirrors and tip/tilt stage commands to the telescope, iv) compute the commands for the Fast Steering Mirror located within the Laser Guide Star Facility (LGSF) and, v) acquire the data necessary to reconstruct the AO-compensated science PSF in post-processing (compute AO-compensated science PSF as a goal).

Table 1: RTC Key Numbers

Item	Requirement
Number of LGS WFS	6
Number of pixels per WFS	204,792
Number of gradients per WFS	5792
LGS frame rate	800Hz
Full frame readout time per LGS WFS	500µs
LGS WFS pixel processing latency (performed synchronously with the digitization of the LGS WFS pixel intensities)	10µs
Number of DM actuators	7673
Latency from last gradient to last DM command	1000µs (goal of 400µs)
RTC telemetry storage	90TB (goal of 140TB)
RTC telemetry required data rate	3.5GB/s (goal of 5GB/s)
PSF statistical data required data rate	60MB/s
RTC maximum power dissipation	1500Watts
RTC telemetry storage maximum power dissipation	6000Watts

The RTC works in synchronization with the Reconstructor Parameter Generator (RPG), which sole tasks are to initialize all of the RTC hard real time parameters, and update in real time the wavefront reconstructor parameters and temporal filters based on the RTC inputs. The RPG is also in charge of monitoring the performance of the AO system during observations and providing the tools necessary to calibrate the AO system during day-time calibrations.

Some aspects of this architecture, which have received considerable attention over the last years include the implementation of:

- The LGS WFS and OIWFS "matched filter" gradient estimation algorithms within the LGS WFS and OIWFS pixel processing processes;
- The "split tomography" wavefront reconstruction algorithm, which decomposes the atmospheric turbulence profile into two orthogonal subspaces, which are estimated and controlled separately using the On-Instrument and LGS WFS measurements;
- The real-time estimation of the turbulence profile and atmospheric parameters using slope detection and ranging method (SLODAR);
- The temporal filters and telescope offloads in the deformable mirrors and tip/tilt stage control processes.

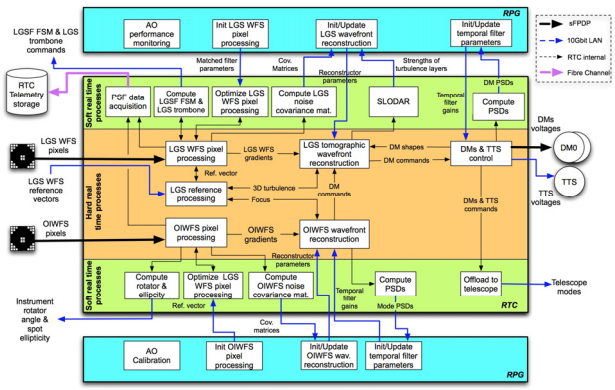

Figure 2: Top-level RTC control block diagram for the LGS AO operation mode. The RTC works in synchronization with the Reconstructor Parameter Generator (RPG – blue boxes). The RTC processes are split into two categories: the hard real time processes (orange) and the background and optimization processes (green). Finally, but not least, the RTC design should be modular to allow the system to be modified or upgraded for the next generation of AO systems.

Wavefront Pixel Processing

The LGS WFS pixels are processed using a constrained matched-filter algorithm. It is a noise optimal algorithm, which allows a reduction in the laser power requirements compared with a classical center-of-gravity algorithm. It consists of a simple matrix-vector multiplication performed synchronously with the digitization of the pixels intensities. The matched filter algorithm is updated in real time at a 1Hz sampling rate (goal of 10Hz) to account for changes in seeing, sodium layer profile and laser beam quality. The optimization is performed by dithering the Laser Guide Star Facility fast steering mirrors.

The On-Instrument WFS pixels are processed using a constrained matched filter algorithm as well. The matched filter algorithm is updated in real time at a 0.1Hz

sampling rate based upon variations in seeing and AO system performance.

Computationally Efficient Wavefront Reconstruction

The NFIRAOS wavefront reconstruction problem requires the computation of over ~7700 DM actuator commands from about ~35,000 LGS WFS measurements at a frame rate of 800 Hz. The standard matrix-vector-multiply (MVM) solution becomes very impractical for systems of this dimensionality, particularly if the control matrix must be updated in real time to account for changes in the atmospheric turbulence profile, rotation of the TMT pupil, or other time-varying effects, which would require the inversion of a very large matrix in real time. Computationally efficient algorithms must be implemented instead. Generally speaking, these algorithms implement close approximations to minimum variance atmospheric tomography. These tomographic algorithms are performed in two steps: estimation of the atmospheric turbulence profile from the LGS WFS measurements, and then projection onto DM locations (least-squares DM fitting). Five low-order modes are computed at lower bandwidth from the On-Instrument WFS wavefront reconstruction using a noise-weighted least-squares reconstruction control matrix. These modes are converted into DM commands and integrated with the DM commands computed from the LGS measurements (split tomography).

Four algorithms have been studied for the tomography step and they all meet the required AO performance in terms of wavefront errors: (i) 30 iterations of Conjugate Gradient without preconditioning (**CG30**), (ii) 3 iterations of Conjugate Gradient with a Fourier Domain Preconditioning Hermitian Matrix (**FD-PCG3**), (iii) Block Gauss-Seidel with 20 iterations of Conjugate Gradient for each layer (**BGS-CG20**) and (iv) Block Gauss-Seidel with Cholesky Back Substitutions for each layer (**BGS-CBS**). Note that closed loop convergence of all these algorithms is accelerated by using warm restart. Finally, the DM fitting step is performed using 5 iterations of Conjugate Gradient. Each proposed algorithm can be expressed as a combination of sparse matrix multiplication, geometrical wavefront propagation through square grids, Fourier transforms, and/or Cholesky back-substitution through triangular sparse matrices.

Finally, the LGS WFS reconstruction parameters are updated in real time at a 0.1Hz sampling rate.

DMs and TTS control

A simple integrator filter with an adjustable gain is applied to the DM error signals computed by the wavefront reconstruction processes. A woofer/tweeter algorithm is implemented for the control of the tip/tilt modes: the TTS commands are obtained by applying an additional proportional-integrator filter to the tip/tilt components of the filtered ground-layer DM commands. The filtered DM and TTS commands are clipped to avoid saturation, and integrator windup is prevented by subtracting such clipping adjustments from the inputs of the temporal filters.

RTC Memory and Computation Requirements

The memory and computation requirements for the LGS WFS pixel processing and the LGS wavefront reconstruction processes are presented in Table 2. These are the most demanding RTC requirements. The LGS wavefront reconstruction memory and computation requirements are presented for the four algorithms described above. Two byte fixed-point arithmetic has been used to estimate the memory requirement for the LGS WFS pixel processing requirements and four byte floating-point arithmetic has been used to estimate the memory for the LGS wavefront reconstruction process. These requirements are useful, but not sufficient to demonstrate that a specific parallel hardware architecture meets the TMT requirements. Data transfer required between the processing elements should be carefully analyzed and minimized when designing the hardware architecture to avoid stall issues.

Table 2: RTC Computation and Memory Requirement

	Memory (MB)	**Nb. of Op. GMAC/s (1000μs latency)**
LGS WFS processing	10	7
LGS wavefront reconstruction		
BGC-CBS	50	80
BGS-CG20	2	280
CG30	2	245
FD3 (2 layers oversampled)	10	140

RTC CONCEPTUAL DESIGN STUDIES

Two RTC conceptual design studies were conducted for TMT in 2009. One study was lead by Dominion Radio Astrophysics Observatory (DRAO) and also included HIA, Lyrtech and the University of Victoria [5]. The second study was performed by the Optical Sciences Company (tOSC) with support from Montana State University. Both groups developed successful designs meeting all performance requirements, and in some cases many goals, for the NFIRAOS RTC. Both studies implemented the processing algorithms specified by TMT in designs based upon existing field programmable gate arrays (FPGAs) and digital signal processors (DSPs), and in electronics packages meeting the requirements for rack space, mass, and power dissipation. The proposed hardware architectures have similarities, but depend greatly upon the choice of tomographic algorithm, which impacts the processing and memory requirements.

DRAO Conceptual Design

A block diagram of the conceptual design proposed by DRAO is given in Figure 3.

The hardware architecture consists of nine custom FPGA boards each including six Xilinx Virtex-5 FPGA, two custom interface boards with thirty-two sFPDP full duplex-links for communication with AO components and RTC telemetry storage system (referred as data recorder in Figure 3) and two general purpose computer boards. The boards are mounted within an Advanced Telecommunications Computing Architecture (ATCA) chassis. The system is highly modular and meets the TMT latency requirement using fixed-point arithmetic and the Block Gauss-Seidel with Cholesky Back Substitutions algorithm. The high-speed WFS pixels are received by the interface boards and then distributed to two FPGA boards, which compute the WFS gradients. The WFS gradients are then forwarded to the wavefront reconstruction engine, which consists of seven FPGA boards and which computes the DM commands. The DM commands are then forwarded to the interface boards, and then applied to the DMs. Scaled down versions of the processes were implemented on Xilinx FPGA to demonstrate the processing time and validate the fixed-point operations.

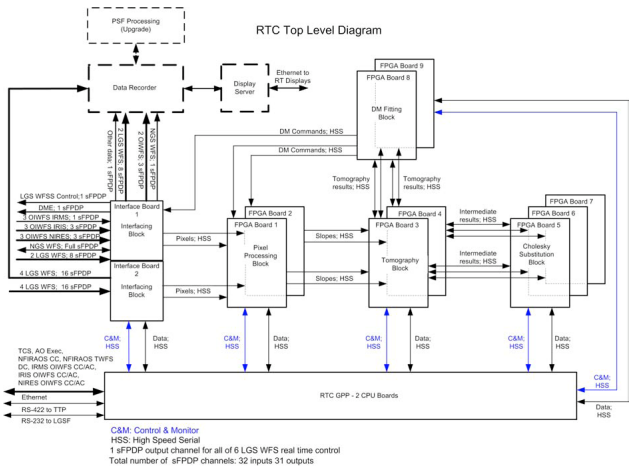

Figure 3: DRAO proposed conceptual design.

tOSC Conceptual Design

A block diagram of the conceptual design proposed by tOSC is given in Figure 4.

The hardware architecture consists of seven TigerSHARC cluster boards, each equipped with eight TigerSHARC DSPs and one Xilinx Virtex-5 FPGA, four FPGA cluster boards each equipped with four Xilinx Virtex-5 FPGA and one TigerSHARC DSP, and one general purpose CPU board. The boards are mounted within an ATCA chassis. The proposed architecture meets the TMT latency goal requirements using floating-point operations and the Conjugate Gradient without preconditioning algorithm. The TigerSHARC boards are used to handle the WFS pixel processing (calibrations, gradient computations and matched filter updates, etc…). The FPGA boards handle the LGS wavefront reconstruction and associated background and optimization tasks. Key functions of the selected algorithm and data transfers were tested on Xilinx FPGA evaluation boards.

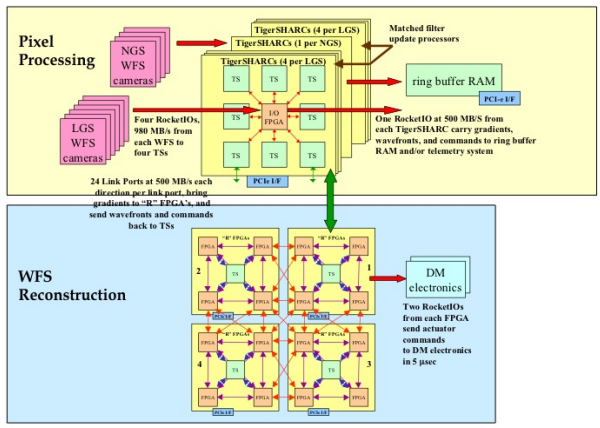

Figure 4: tOSC proposed conceptual design.

CONCLUSION

The TMT NFIRAOS RTC requirements are challenging not only because of the computing and memory requirements, but also because of the complexity of the algorithms to implement, and the number of interfaces to manage. We have demonstrated that the RTC can be implemented via modular and highly parallel hardware architectures, which use existing computing technologies. The next steps for the RTC will be to review the latest generation of multi-processors (Xilinx Virtex-6, Nvidia GPU…), then to define the hardware architecture for a selected algorithm, and finally to prototype and test key components of the RTC hardware architecture.

IMPROVING DATA RETRIEVAL RATES USING REMOTE DATA SERVERS*

Ted D'Ottavio, Bartosz Frak, Seth Nemesure and John Morris, Brookhaven National Laboratory, Upton, NY, U.S.A.

Abstract

The power and scope of modern Control Systems has led to an increased amount of data being collected and stored, including data collected at high (kHz) frequencies. One consequence is that users now routinely make data requests that can cause gigabytes of data to be read and displayed. Given that a users' patience can be measured in seconds, this can be quite a technical challenge. This paper explores one possible solution to this problem - the creation of remote data servers whose performance is optimized to handle context-sensitive data requests. Methods for increasing data delivery performance include the use of high speed network connections between the stored data and the data servers, smart caching of frequently used data, and the culling of data delivered as determined by the context of the data request. This paper describes decisions made when constructing these servers and compares data retrieval performance by clients that use or do not use an intermediate data server.

INTRODUCTION

Can a system be constructed that can read and display tens or hundreds of millions of stored data points to a user in a reasonable period of time (< 10 seconds)? What are the limitations and how can they be addressed? These are the questions that led to the research being reported on here.

The Controls logging system within the Collider-Accelerator Department at Brookhaven National Laboratory collects and stores measurement and setting data for offline analysis. The logging system, in place for about 10 years, uses a combination of user-generated and system-generated requests. These requests are passed to dedicated logger processes, which store the data to disk along with database records indicating how to map the requests to the stored data files. Data is retrieved and displayed by specialized software that allows a user to see what data was logged and to select data to be displayed.

The BNL logging system has become increasingly popular over the years, with the amount of data collected growing by a factor of 10 in the last 5 years, and expected to grow by another factor of 10 over the next 3 years (12 TB of time-series data was stored last year). Much of this increase is coming from requests to store data collected at high frequencies (720Hz to 10 kHz). In rough terms, about 500 MB of data is stored per day for every 1 kHz parameter requested. Retrieving and displaying a days worth of data for just a couple of these parameters means processing about a GB of data contained within files many times that size. For thick client applications that get data directly from the file system, this means transferring all of the data over the network to the client applications, picking out the requested data, and displaying it to the user before his or her patience has been exhausted. This puts a severe strain on both the network (to read the data) and the plotting software (to display it).

The solution reported in this paper uses a data server - a combination hardware/software solution. Its job is to handle user requests for logged data in the most efficient way possible. Its efficiency is a result of two key ideas:

- Read the data quickly – improve network speed to stored data, parallelize reads, and cache data.
- Cull the returned data - send the user only the data that can reasonably be distinguished on the display.

The use of an intermediate data server here follows similar efforts in place within the EPICS community [1] and at the CERN/LHC [2].

SYSTEM DESCRIPTION

The term data server denotes a collection of enterprise grade middleware applications deployed in a virtual cluster of dedicated and adopted process servers. At the core of the system is a single purpose application, whose role is to handle client requests for stored data. These requests are divided into discrete tasks, which are processed in parallel either locally or, in the event the core server cannot complete assigned workload, on one or more satellite servers. Result fragments from all tasks belonging to the same request, are reassembled by the core server and delivered back to the client.

Software Architecture Overview

Java Enterprise Edition 6 (Java EE6) was chosen as a base platform for the entire system. Benefits include a wide array of available web technologies [3] and a scalable business logic platform as well as built-in management features. Glassfish 3.1, which provides a complete open source Java EE6 reference implementation [4], was selected over other EE6 compliant applications servers.

The enterprise applications used to construct the data server are divided into three logical modules (Figure 1):

- Web component, which exposes a RESTful web service API to the remote clients.
- Request dispatch and assembly (RDA) Enterprise Java Beans (EJB) business module responsible for database communication, task scheduling and construction of the response objects.
- Request extract and transform (RET) EJB business module responsible for the data collection, caching and transformation. This component is divided

*Work supported by Brookhaven Science Associates, LLC under contract no. DE-AC02-98CH10886 with the U.S. Department of Energy

furthermore into local and remote sub-modules - the latter deployed on the satellite servers.

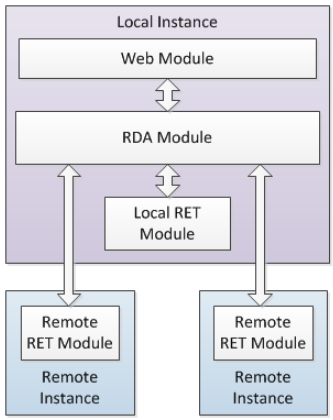

Figure 1: High-level logical system structure.

Request Lifecycle

Every request starts with a RESTful GET call to a designated web service method. The URL used to identify the requested resources has one mandatory path element as well as three mandatory and one optional parameter values – clients consuming this web service are required to specify a name of the request file, start and end times as well as at least one data item name contained in the requested file. The web module submits the request to the RDA component, which queries one or more databases for a list of file paths that fall between the specified start and end time values and match exactly the request file name. At this stage the RDA module attempts to locate each file / resource pairs in either the local or one of the remote caches. Cached file elements are immediately queued on the owning instance for final processing (i.e. culling). The remainder of the file list is sent to a scheduler on a local instance, which attempts to distribute the combined read and process tasks between the clustered RET modules by taking into consideration both performance as well as coherence aspects of the request. The factors, which influence scheduler's decision include:

- The queue length on each cluster instance – the shorter the wait time, the greater the chance that the scheduler will pick that instance.
- Instance spatial location – some cluster member may be physically closer to the stored data than others (i.e. application could be deployed directly on one of the archive server host), which allows them to read stored data at a much higher rate than their networked counterparts.
- Request length – shorter requests, which estimated processing time of under 5 seconds benefit from being scheduled on only one instance.

Regardless of which instance or instances were involved in reading and/or processing the scheduler's request, all intermediate results always make it back to the local instance for final assembly. During this phase of the request lifecycle the results from each processing task are checked for errors. Additionally, if they were processed out of order, they have to be rearranged according to the time index given to them by the scheduler. At this stage the RDA module returns the time sorted, processed results back to the Web component, which can package the processed data in a JAXB compliant wrapper and ship it back to the client.

Spotlight on Culling

Every request that passes through the data server is subjected to the culling algorithm. This algorithm was designed to cut down high volume, time domain datasets to more manageable, lower-density sets. The goal is to return a dataset to the user that is virtually indistinguishable on a scatter plot to the full, un-culled dataset. We have found for typical monitors and resolutions that this occurs when a dataset of about 20k points is returned. The advantage here is that the culled dataset can be transported to the client much more quickly than the full dataset. The disadvantage is that any change in the plot axis limits (for example, a zoom) forces a new data retrieval. Our experience has been that these zoom slowdowns are minimal (< 1 sec) as long as the original data is cached on the data server. The culling algorithm incorporated into the data server uses a parallel processing pipeline, allowing the server to process up to a billion points per second. An enhancement to this algorithm will incorporate user-selected data filters that can be used to further refine the returned datasets.

Hardware

The central EJB container runs in a 64bit environment (Red Hat EL6) on a dedicated rack mounted system. Two 6 core Xeon CPUs, each running at 3.47Ghz, and a total of 144GB of RAM is available to one or more virtual machines - this number depends on garbage collection issues we might encounter once the system is put into production. The SSD caching subsystem is made up of four Intel 250GB solid state drives configured in RAID0 on a 6Gb/s LSI controller. The SSD array is expandable to 3.5TB, and like RAM can be split into multiple partitions. Four 1Gb/s bonded adapters handle the network access to data stores, though only one was used for the results that follow. Satellite servers run in smaller virtual machines on equally powerful CPUs. They have their own in-memory cache, but they lack the disk-store caching, which is available on the core machine. Figure 2 shows the data server's communication diagram.

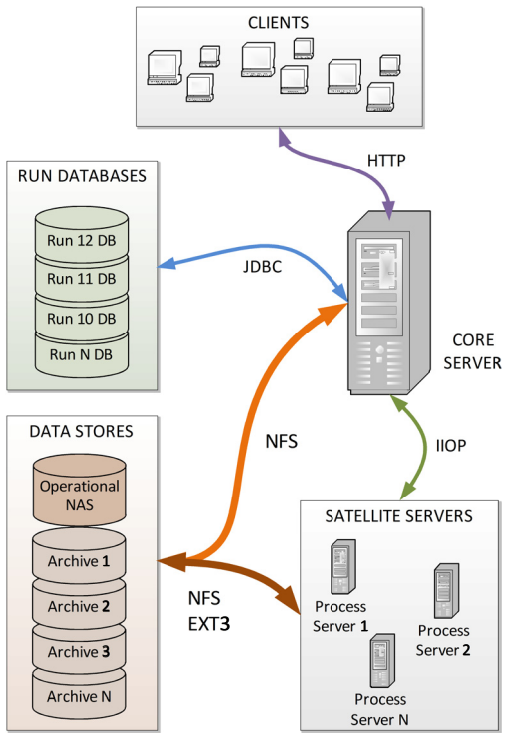

Figure 2: Data server communication diagram.

RESULTS

Data server's parallel processing core is only as fast as the backend, which supplies it the raw data. This is a non-issue for the cached values, however reading from a network store over a 1Gb/s connection can cause a significant bottleneck in the processing pipeline. Before any further development could be done, we had to prove to ourselves that the parallel design could indeed achieve the desired throughput rates. We also wanted to see how the rates scale for both compressed and uncompressed datasets. Figure 3 shows the effective data rates for both types of datasets with varying simultaneous thread count.

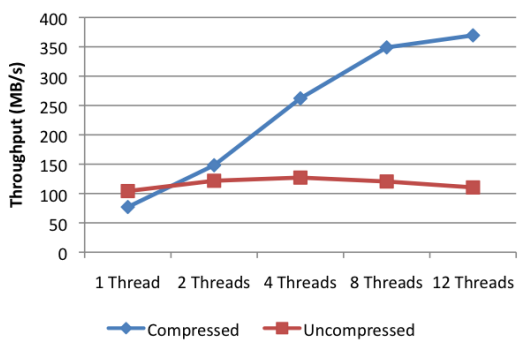

Figure 3: Effective Throughput Read Rates.

The uncompressed data reads over a network are essentially constant around 120MB/s and are unaffected by the additional threads. The same cannot be said for the compressed read scenario. The effective throughput on a 12-core Xeon server increases from 75MB/s to 365MB/s in a fairly linear fashion when moving from 1 to 12 threads. Results for the concurrent compressed scenario were encouraging enough to proceed with the project.

Performance Tests

Our most basic goal for this project was to improve the performance of displaying very large datasets. Our existing software for displaying logged data reads the data directly from disk files and displays the results. Data culling, as described above, is used when necessary to improve display performance. For comparison purposes, this software was modified to allow the option to retrieve data from the data server.

A variety of logged data was tested including very high frequency (10 kHz) and low frequency (1 Hz) data. To eliminate disk-caching issues, a 4 GB dataset was used to flush the cache in between each reading. In addition to having the data server read data from disk files, we also explored the option of reading data from a SSD data cache and from a RAM data cache. The results of these tests are shown in Table 1, which compares the speed at which the displayed data is transported through the various configurations.

Table 1: Data Throughput in Test Configurations

	Throughput	Speedup
Client to Remote Disk-store	5.4 MB/s	-
Client through data server to Remote Disk-store	146 MB/s	27x
Client through data server to SSD cache	245 MB/s	45x
Client through data server to RAM	968 MB/s	180x

The large speed advantage of using the data server (in the worst case, a factor of 27x improvement) is the result of the following:

- Network - the data server has a 1 Gb/s connection to the data file vs. a 100 Mb/s connection for the client.
- Parallel Execution - the data server has up to 12 threads that can individually read and cull data files. The client is single-threaded.
- Hardware - the data server has very fast CPUs with lots of RAM in a 64-bit environment. Clients are typically run on much more modest hardware.

The CPU speed turned out to be more important than we originally realized. This is because the data files are gzip-compressed files and need to be uncompressed before the proper data can be extracted. Fast CPUs significantly increase the speed of data decompression.

The results, while reproducible for a specific set of data, were quite variable across different data requests. In fact, the standard deviation across all of the speed tests within each category was about 50%. We have identified several factors that contribute to this variability:

- Data Density - Data for many items are stored together in files, primarily based on how users have setup logging requests. Extracting one or many from

the same set of files can significantly affect read performance.

- Timestamp Density - For slow data, we store one timestamp per data point. For most fast data we store data as arrays with a single timestamp and an indication of the time between points.
- Data Compression - Some data compresses much better than others. We've seen data compression rates range from 3 to 30 with 5 being a typical value. More highly compressed data can be read faster from disk because it is smaller.

SUMMARY

At this point it appears that our initial goal of decreasing the time it takes to display large datasets by a factor of 10 will easily be met by introducing a data server between client and data. Much of the speed gain has come from a fast network connection between the data server and the data, fast CPUs on the data server that can be run in parallel to process the data, and a culling algorithm that makes it possible to quickly transport data to the client.

There are several items that we have yet had time to explore. First, we would like to increase the network speed between the data server and our data files. Currently, they are connected via a 1 Gb/s network. We are exploring both 4 Gb/s and 10 Gb/s connections. Second, we would like to make a variety of data filters available to our users so that they can more quickly identify their data of interest. Filter types include "only data when the RHIC collider is on its energy ramp", "only data when there is beam in RHIC", and "only data when a measurement is above/below a threshold value". These filter selections will be passed down to the data server and reduce the amount of data that the server needs to process and the associated data that the user will view. Finally, we have plans on making better use of the solid-state drive connected to our data server. Past experiments have shown that users spend about 80% of their time looking at logged data collected within the last week and 90% looking at data collected within the last month. Our plan is to store recent logged data on our 1 TB SSD so that these frequent requests can be delivered more quickly.

THE COMPUTING MODEL OF THE EXPERIMENTS AT PETRA III

Melvin Alfaro, Martin Flemming, Julia Grabitz, Thorsten Kracht*, Birgit Lewendel, Teresa Núñez, Peter van der Reest, André Rothkirch, Frank Schlünzen, Eugen Wintersberger
DESY, Hamburg, Germany

Abstract

The PETRA storage ring at DESY in Hamburg has been refurbished to become a highly brilliant synchrotron radiation source (now named PETRA III [1]). In comparison with the DORIS beamlines, the PETRA III experiments have larger complexity, higher data rates and require an integrated system for data storage and archiving, data processing and data distribution. Tango [2] and Sardana [3] are the main components of our online control system. Tango serves as the backbone to operate all beamline components, certain storage ring devices and equipment from our users. Sardana is an abstraction layer on top of Tango. It standardizes the hardware access, organizes experimental procedures, has a command line interface and provides widgets for graphical user interfaces.

The high brilliance together with the rapid read-out of modern 2D detectors dramatically increase the data rates and volumes. At PETRA III all data are transfered to an online file server which is hosted by the DESY computer center. Near real time analysis and reconstruction steps are executed on a CPU farm. A portal for remote data access is in preparation. Data archiving is done by dCache [4]. An offline file server has been installed for further analysis and inhouse data storage.

INTRODUCTION

By the year 2009 the reconstruction work to turn the storage ring PETRA into a highly-brilliant 3rd generation synchrotron radiation source was completed. The new facility, PETRA III, consists of 14 beamlines which are operated by DESY, the EMBL and HZG. The EMBL stations are independent of DESY as far as IT is concerned. By now, most of the beamlines are in user operation, the rest are currently commissioned.

DESY has a long-lasting experience in the field of synchrotron radiation experiment control which comes from the beamlines at DORIS, FLASH and PETRA. PETRA III creates new challenges. The beamlines have longer extent, consist of more elements and use a greater variety of electronic devices. In addition, the requirements of user interfaces are increasingly demanding. This applies to the scripting language, the command line and the graphical user interfaces. Consequently the online control system had to be newly designed. The original solution of controlling the experiments by a single program, Online [5], was replaced by a distributed client-server system.

The new 2D detectors which are used at PETRA III generate very high data rates. Therefore a concept for data acquisition, data management, reconstruction, analysis and data transfer had to be developed.

This note describes the layout of the computing model which has been implemented to meet the above mentioned requirements.

Figure 1: The PETRA III Hall.

EXPERIMENT CONTROL

The following issues have to be considered when designing an experiment control system:

- **Sustainability** A modular system with defined interfaces for hardware, communication and application layers can be extended and maintained by a group of software developers.
- **Flexibility** An efficient customization of the system is important for the best use of the beamtime. This customization is required due to the frequent change of user groups at the beamlines.
- **Platform independence** Linux and Windows have to be supported. Bindings to scripting and programming languages are mandatory.
- **Performance** An online control system needs sufficient bandwidth to handle motors, counters, timer, etc. However 2D detectors, creating by far the highest data rates, do not use the control system for data transfer but access storage media directly.

An online control system has to be based on a product that is supported by an international community. One reason is to save resources by benefiting from the work of others. At least as important is the communication among the members of the collaboration about new ideas and experiences. And finally, collaborations help to develop common user interfaces.

* Thorsten.Kracht@desy.de

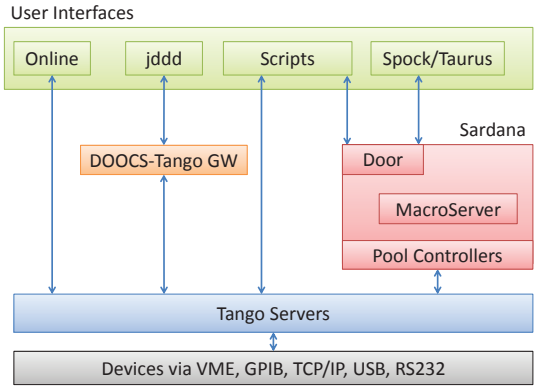

Figure 2: The main components of the experiment control system.

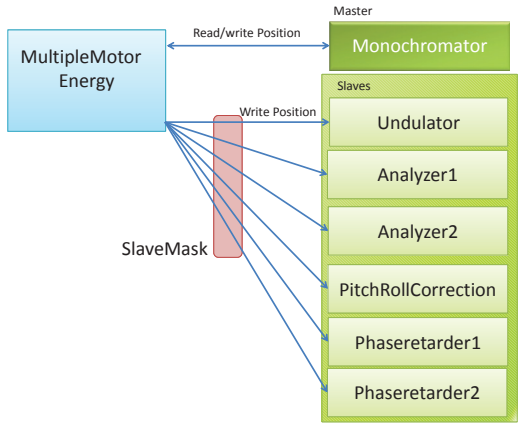

Figure 3: An example for a MultipleMotor server: the beamline energy.

Figure 2 gives a schematic view of the experiment control system. Tango serves as the hardware access layer. Clients can communicate directly to the Tango device servers or make use of the additional functionality that is provided by the Sardana framework.

The Tango Implementation

In order to limit the effect of corrupted database servers at least one Tango instance is installed for every beamline. Another choice was to group devices into classes with identical Tango interfaces. For cameras the LIMA [6] framework has been imported. Currently, area detectors available at PETRA III beamlines are being adopted.

The experiments at PETRA III use a variety of motors with many different parameters. It has been decided to implement a minimal interface in all motor classes, the TANGO_MOTOR. It executes the commands Calibrate, StopMove, ResetMotor and has the attributes Position, UnitLimitMin, UnitLimitMax. At DESY several motor servers of common interest have been developed. All of them implement the TANGO_MOTOR interface:

- **MultipleMotor** This server moves several TANGO_MOTORs concurrently. One of them is assigned to be the master which defines the position of the compound device. The slave motors, which follow the motion of the master, are enabled by a mask attribute, see figure 3.
- **AttributeMotor** A server that converts an attribute of a arbitrary device into a TANGO_MOTOR.
- **TcpIpMotor** This server uses an ASCII protocol via TCP/IP to control arbitraty motors that are temporarily installed by user groups.

Other general purpose servers that have been developed for PETRA III are: the CollisionSensor which avoids hardware damage due to unintentional movements and the ClipBoard server which facilitates a client-client communication by exporting several string attributes.

Tango Clients

These clients are currently used at the PETRA III experiments:

- **Online:** For a long time many DESY beamlines have been operated by this program. It has a command line interface, a binding to Perl and a graphical user interface.
- **Python scripts** Scientists started to write small python applications using PyTango [7] shortly after the PETRA III operation began. PyTango is a python module which exports the complete c++ Tango Api to Python.
- **Diffractometer Server** At PETRA III two beamlines have Eulerian 6-circle diffractometer. The diffractometer server, written by F. Picca of SOLEIL, is used for crystal orientation and direct-reciprocal space transformations imposing certain conditions.
- **jddd** jddd [8] applications exist for every beamline. They display selected variables for a quick overview of the setup, figure 4. jddd has a hierarchical structure with several expansion levels.

Although PETRA III started operation successfully using the above mentioned clients, it was planned to upgrade our user environment. We have chosen the Sardana framework to be the backbone of our future online control system.

Sardana at PETRA III

Sardana was created at ALBA. Important contributions came from the ESRF. Sardana is a framework that structures the domain of experiment control programs and user interfaces. It has several components: the device pool is an additional hardware standardization layer, the MacroServer organizes the execution of procedures that are needed for

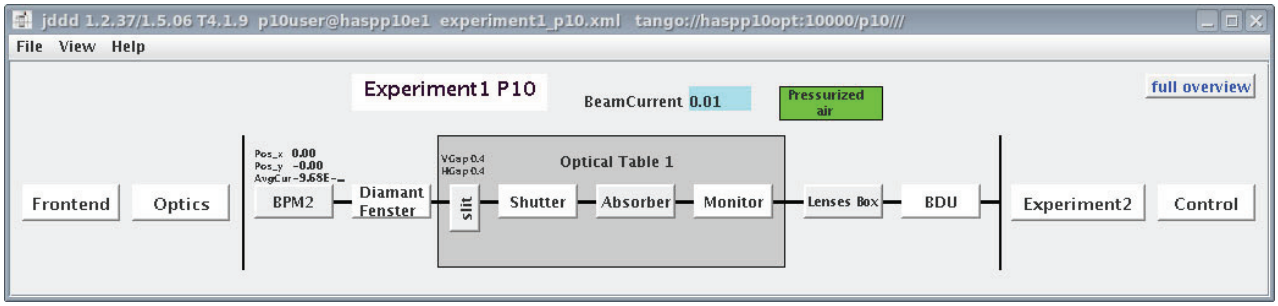

Figure 4: jddd application of a PETRA III beamline, partially expanded.

the measurements, Spock serves as the command line interface and Taurus builds GUIs. These features make Sardana well suited for PETRA III. In the meantime DESY participated in this project by adding some extensions. It has been rolled-out recently to the experiment PCs. First test measurements have been performed.

Data Format

The current practice to produce in a single experiment myriads of small files in a large variety of partially proprietary formats has a bad impact on the performance of the storage and archive system, tremendously increases the complexity of the data management tasks, hinders application development, prevents usage of data across disciplines as well as facilities and makes the long-term preservation of scientific data almost impossible.

To enable users to work with data collected at different beamlines at the same or different facilities, the PNI-HDRI [9] initiative (in close co-operation with the PaN-data project [10]) aims to develop and implement a standard data format, which also permits to aggregate data files from different sources into a performant, portable and self-describing form.

Nexus [11] has been selected as the underlying file format since it's based itself on widely accepted standards (HDF5) and because it has a growing user community in the photon, ion and neutron science world. It is part of the HDRI project to demonstrate experiment specific implementations and to provide guidelines how the application specific information is organized. The experiments at PETRA III will follow the developments of HDRI.

It cannot be expected that the Nexus will generally be accepted by the international photon science community. SOLEIL and ANSTO proposed to add an abstraction layer, CDMA [12], to help application developers to uniformly access files. CDMA uses a dictionary mechanism to translate application notions to data file entities. In order to benefit from these developments, it is planned to write a CDMA plugin for Nexus.

DATA MANAGEMENT

So far it was discussed how an experimental setup is controlled to perform measurements and collect data. This section describes how this data is treated afterwards.

The PETRA III beamlines send their output directly to the online file server. It has the purpose to buffer the data before they are archived and to make them available for near real time analysis, figure 5. All data are copied to the dCache tape pool for archiving. Data to be analyzed is staged to the dCache disk pool. In addition there is an offline file server for storing analysis results and temporary data. These services are provided by the DESY computer center.

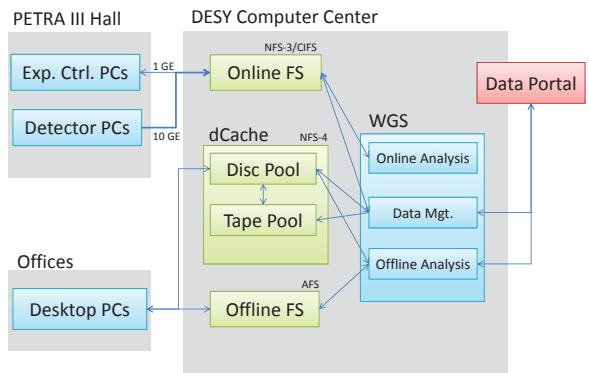

Figure 5: Main data and control flow paths.

Network

Internally the PETRA III experiment hall has a 1 GE Ethernet infrastructure. The hall itself is connected to the DESY computer center by 10 GE Ethernet. Detectors which generate high data rates are connected by 10 GE lines. The effective speed for writing data to disk via the 10 GE lines is about 300 MB/s (from Linux PCs).

File Servers

The online file server storing the data during measurements can be accessed from either Linux or Windows™ systems. Typically, the Linux based experiment PCs and the detector PCs mount this server by NFS

(version 3). It offers CIFS-shares for Windows™ based systems.

The online file server consists of 2 file server systems, each managing 11 drive trays of 14 disks each. It is set up as a raid 6 storage system, has takeover options for the 2 heads in a single system and is operated with snapshot option of 20% of total storage. The total capacity of the online file server is 145 TB for all beamlines (excluding snapshot and spare disks).

If an experiment needs a fast reconstruction step to optimize the measurement, it is done with the data on the online file server.

The offline file server stores analysis results, no raw data. It is accessible from the experiment PCs and the workgroup server via AFS. The capacity of this file server is about 40 TB in a raid 6 setup.

dCache

The dCache is a storage system consisting of a disk pool and a tape pool. It was developed by DESY and FERMILAB for storing high energy physics data. The dCache becomes increasingly important for the photon science department of DESY.

Data are migrated from the online file server to the dCache. During this migration the ownership changes from the beamline account to a user-specific account. The beamline scientists in charge keep full access rights.

Data are directly accessible (via NFS4.1 exports) by analysis programs as long as they are stored on the disk pool. Data that are already on the tape pool need to be staged before they can be read. Data stay on the disk pool for at most 180 days. The residence time in the tape pool is not limited so far.

Data Portal

It is expected that certain guest groups do not have the sufficient IT infrastructure at their home institutes to store and process large data volumes. DESY plans to provide these scientists with storage and compute services. A data portal is currently being prepared that facilities access to the dCache and permits the full remote management of the data, which includes the search for data and meta-data and a user controlled rights management.

Compute Server

Currently PETRA III computing is performed on a blade center which is divided into 16 work group servers (WGS). They have a dual-quad-core cpu with 24 GB RAM and 16 GB swap space running 64bit Scientific Linux. Part of the WGS are organized in a server pool, the remaining ones are addressed directly and can be allocated to specific beamlines. Computing can also be performed on Nvidia™ GPUs. WGS and GPUs are used for reconstruction, analysis and simulation as well as for software compatibility tests or data migration.

CONCLUSIONS

PETRA III computing integrates products that originate from activities of international and national partners: Tango, Sardana, CDMA, dCache. This approach saves resources and enhances the communication on the relevant topics which is crucial for the fast and continous incorporation of new developments. Furthermore, collaborations among synchrotron radiation facilities are the precondition for establishing common user interfaces. A feat that would ease the burden of our scientific users in performing measurements at different sources.

It has been demonstrated that the experiment control system consists of several layers with well defined interfaces making it flexible enough to fulfill the current requirements and to cope with future challenges.

ACKNOWLEDGMENTS

We would like to thank all who made contributions to the Tango control system and our colleagues from ALBA for having created Sardana, in particular T. Coutinho, C. Pascual and J. Klora who gave us so much support. We thank F. Picca for allowing us to use his diffractometer server. We also acknowledge the work of DESY-MCS on jddd.

DATABASE FOUNDATION FOR THE CONFIGURATION MANAGEMENT OF THE CERN ACCELERATOR CONTROLS SYSTEMS

Z. Zaharieva, M. Martin Marquez, M. Peryt, CERN, Geneva, Switzerland

Abstract

The Controls Configuration Database (CCDB) and its interfaces have been developed over the last 25 years in order to become nowadays the basis for the Configuration Management of the Controls System for all accelerators at CERN.

The CCDB contains data for all configuration items and their relationships, required for the correct functioning of the Controls System. The configuration items are quite heterogeneous, depicting different areas of the Controls System – ranging from 3000 Front-End Computers, 75 000 software devices allowing remote control of the accelerators, to valid states of the Accelerators Timing System.

The article will describe the different areas of the CCDB, their interdependencies and the challenges to establish the data model for such a diverse configuration management database, serving a multitude of clients.

The CCDB tracks the life of the configuration items by allowing their clear identification, triggering of change management processes as well as providing status accounting and audits. This necessitated the development and implementation of a combination of tailored processes and tools.

The Controls System is a data-driven one - the data stored in the CCDB is extracted and propagated to the controls hardware in order to configure it remotely. Therefore a special attention is placed on data security and data integrity as an incorrectly configured item can have a direct impact on the operation of the accelerators.

INTRODUCTION

The idea to use a central data storage to describe the components of the Controls System for CERN's Proton Sychrotron (PS) complex was suggested in 1980. Several implementations were made using a variety of database models such as an object oriented one. In 1986 an implementation using a relational database model and in particular using the Oracle® Relational Database Management System (RDBMS) was provided. This marked the birth of the Controls Configuration Database, which has been in service ever since [1]. Throughout its existence it has been constantly evolving, growing in size and in provided functionality in order to cover the increasing complexity of the accelerators Controls System at CERN.

THE NEED FOR CONFIGURATION MANAGEMENT

Configuration Management was established as an important element of Systems Engineering during the 1950s and 1960s. Realizing its importance not only for the hardware configuration of systems, but also for software configuration, was the reason to include it as a component of best practices, formalized by Information Technologies Infrastructure Library (ITIL®) [2].

The amount of technical data, necessary for the control of the CERN accelerator complex is enormous. A common description, in a centralized storage, of all objects needed for the Controls of the accelerators is an essential prerequisite for the correct and coherent functioning of the accelerators.

The CCDB and its interfaces provide configuration management functionalities such as the unique identification and configuration of items, complying with predefined criteria, as well as controlling the configuration changes and status accounting of the configured items. Those functionalities answer the need to establish and maintain the consistency of the Controls System and its components.

SCOPE

The CCDB is the heart of the CERN Accelerators Controls System. Nowadays it covers the need for the configuration of components of the Controls System itself, e.g. the Controls Middleware (CMW), as well as accelerator components as seen by the Controls System, e.g. power converters, for all accelerators: the Large Hadron Collider (LHC), the Super Proton Synchrotron (SPS) Complex, the Proton Synchrotron (PS) Complex, and the CLIC Test Facility (CTF3). The configurations of some components used for the Control Systems for the Technical Infrastructure services at CERN are done in the CCDB too.

Providing the configuration capabilities for such a diverse number of systems and components and representing them in a unified model is quite a challenge. Currently the relational database model of the CCDB comprises of 914 tables, storing over 10GB of current reference data and 50GB of historical versioned data.

CONFIGURATION MANAGEMENT FUNCTIONALITIES, PROVIDED BY THE CCDB AND ASSOCIATED INTERFACES

Configuration of all Components of the Controls System

The data in the CCDB represents components and their properties as seen by the Controls System. It contains data for the complete Controls System topology with some of the main users of the CCDB services being the CMW, the Role Based Access (RBAC), the Accelerator Timing System, the Common Console Manager, etc. (see Fig.1).

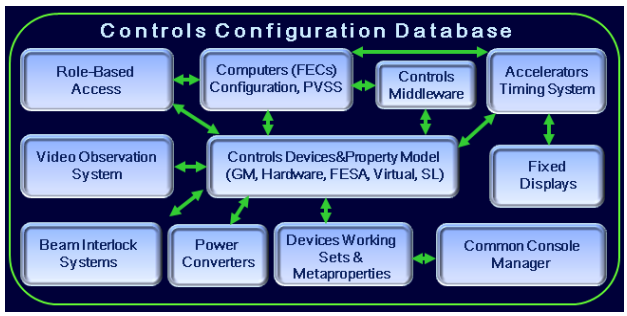

Figure 1: Overview of the different areas of the CCDB.

The Controls devices are the software representations of the accelerator components, controlled by the Controls System, e.g. power converters, radio frequency (RF), beam instrumentation (BI) components, etc. The CCDB currently supports 5 device-property models – General Module (GM), Front-End Software Architecture (FESA), SPS&LEP (SL), Hardware and Virtual. There are more than 1,400 device classes, more than 79,000 devices and more than 2,000,000 properties declared in the CCDB.

The GM and SL legacy frameworks are in the process of being phased-out; they were developed respectively for the PS and SPS complexes.

The FESA framework was introduced 8 years ago. The original data management solution was to store directly XML configuration files in the CCDB, produced by the FESA development tools. This solution presented several shortcomings mainly with the integration of the FESA-related data to the rest of the configuration data in the CCDB. Another problem was tracking of devices and properties changes, contained within the XML files. A major effort to restructure the data management part of the new FESA framework version (3.0) was initiated in 2009 [3]. The main challenge was to implement a structured handling of XML files, which should be used only for data exchange between the FESA end-user tools and the CCDB. The XML files are no longer stored in the CCDB - their contents are extracted on the fly (using a PL/SQL API) and the FESA configuration data is stored into the relational tables. This solution has allowed a complete integration of FESA data into the CCDB relational model and facilitates the handling of common data management tasks.

The Hardware devices framework was developed in 2007 and originally dedicated to the Power Converter Controls [4] devices and PVSS devices for the Machine Protection of LHC (Quench Protection System, Warm Interlock System, Power Interlock System, etc.). Nowadays the scope of this framework has been broadened to a wide variety of physical equipment.

The Virtual devices framework was the last Controls devices framework to be introduced in the CCDB (only 1 year ago) and represents abstract elements that need to be controlled, e.g. signals for the Software Interlock System.

The challenge before the CCDB was to implement as much as possible a unified database model, which suites those 5 diverse Controls devices frameworks [5]. It is the database that provides a layer of abstraction and provides the device-property data in one and the same way to the multiple db clients (e.g. CMW, RBAC).

The CCDB also provides data for the hardware and software configuration (e.g. start-up sequences) of all Front-End computers used by the Controls System. There are more than 3,200 computers declared in the CCDB. Special functionality is available to configure the drivers for the modules, used in the Front-End computers.

The Accelerators Timing System configuration is another important area. At the beginning of 2011 a major renovation of the Timing System was undertaken by the timing experts and this had an impact on the CCDB. The database model was completely reworked in order to introduce high-level timing events and to allow full configuration of low-level timing events. The new model ensures the completeness of the configuration of the Timing System. It allows better integration of the timing data with the rest of the configuration items in CCDB.

It is important to have a complete description of the components, needed for the accelerators Control, stored in a single location such as the CCDB. This provides the possibility to validate configurations against business rules and to establish a coherent picture of all components and their relationships (dependencies between the components).

Extraction of Configurations – Data-Driven Controls System

The CCDB is not merely a storage repository for the configuration of the different components, related to the Controls of the accelerator. The CCDB actively serves to provide real-time configuration data, which is extracted from the database whenever a component needs to be configured. In order to provide the on-line data for the configuration items and their relationships, there are a number of APIs and scripts which have been developed.

Configuration Change Management

For the data-driven Controls System the data in the CCDB describes the Controls components and their properties. Those components need to be upgraded regularly, e.g. Front-End Computers, Device Classes, etc, therefore there is a need for regular data modifications and maintenance in the CCDB.

Each configuration item in CCDB is uniquely identified, which allows the database to trace the history of all operations (data modifications) performed on that item. The users are provided with reports on the current configuration and its evolution over time.

A solution to review potential configuration changes and accept or reject them is under development. The change acceptance process is mainly guided by the status of a given component (operational or not) and whether a change is considered to be backward compatible [6].

On-line Feedback of Deployed Configurations

A recently implemented new feature of the Controls Configuration is the availability of status accounting of the different configuration items. The status data comes in

the form of a feedback from the configured components identifying the currently loaded configuration.

The first configuration items to start sending feedback data are the drivers for the Front-End computer modules and some components from the CMW configurations. This feature of the Controls Configuration Management is extremely important as it solves the years-old problems of discrepancies between the loaded Front-End configurations and the current running configurations, resulting in an unexpected behaviour after a reboot.

It is previewed that this functionality will be extended to cover other areas of the Controls Configuration in the near future, e.g. the software devices configurations deployed on the Front-Ends, etc.

OVERVIEW OF THE CONTROLS CONFIGURATION ENVIRONMENT

Database Complexity

The Controls Configuration database is quite a complex one as it models the Controls System into a relational database. The main challenge for the database model is to maintain data consistency and to enforce the predefined business rules. This is achieved by numerous constraints as well as thousands of lines of PL/SQL code in database triggers or packages. Table 1 provides the exact figures showing the complexity of the CCDB data model.

Table 1: CCDB Statistics

Tables	914
Constraints	2,388
Lines PL/SQL code	42,100
Volume	60GB

Database High Availability

The Controls Configuration services need to be continuously available 24 hours a day, 365 days a year to assure the ability to configure components at any moment in order to operate the various accelerators at CERN as well as to allow configuration changes to be introduced during scheduled accelerator "technical stops". This has been achieved through the use of Oracle cluster technology (RAC) which guarantees not only the hardware but also database software redundancy. This solution ensures no down time even during routine software patching of the database.

Configuration Data Responsibility

There is a diverse user community for the Controls Configuration services, which makes the job of providing tailored user applications challenging. The responsibility to maintain the correctness of the configuration data lies with the relevant equipment experts (BI, RF, etc.), as well as controls experts and accelerator operators.

Data Editing Interfaces

The CCDB Data Editing Interfaces are a suite of web-deployed applications used to modify the stored configuration data. There are currently 12 Configuration Editors, which implement the business logic and processes in the various areas of the CCDB. These applications are based on Oracle's J2EE ADF technology and are used on a daily basis by more than 250 users.

Special attention must be paid to the access rights given to the users of these applications, which need to be tightly controlled due to the sensitive nature of the data and the associated risk of mis-configuration of accelerator components. Strict access control rules are therefore implemented via a custom authorization module. Through the use of the virtual private database feature of Oracle, additional fine grained access control mechanisms are provided within each application.

Data Browsing Interfaces

The CCDB Data Browsing Interfaces comprise of read-only applications (reporting tools), for situations where the configuration data only needs to be consulted. Some 160 reports covering all areas of the CCDB are provided to the user community of roughly 300 people and are built using Oracle APEX technology [7].

APIs and Scripts

Various APIs, written in several languages such as Java (e.g. Java Directory Service, Beam Interlock Systems API), PL/SQL (e.g. Front-Ends Drivers Generation APIs, FESA data extraction API) and some legacy Pro*C scripts (e.g. Front-End configurations), are implemented to extract the configuration data or to generate files to be used by the different components of the Controls System.

Diverse output formats of the components configurations are produced from the CCDB, ranging from text files for drivers generation and hardware and software configuration of computers to XML files and binaries for Controls devices configuration.

DATA SECURITY

Data security is paramount in the CCDB. The CCDB provides specially developed functionality to audit every session opened in the CCDB, allowing monitoring of who changed what data and when.

In order to trace data changes, a custom history framework was developed. All data modifications are recorded and kept on-line since 2005. There is a special web-deployed application – the CCDB History Browser, which gives access to the history logs. This application is used heavily by the Controls Exploitation team.

The history log also serves as a basis for versioning of the configuration data for each configuration item.

QUALITY ASSURANCE – TESTING AND DEVELOPMENT ENVIRONMENTS

The Control of CERN's accelerators is a very dynamic environment with new and changing user requirements coming regularly, directly impacting the database model as well as the different applications and APIs. The best software development style to suit such an environment is

agile programming, facilitating fast prototyping and short time to production to achieve a feature complete solution.

Four environments have been provided for the CCDB, its interfaces and APIs – *Development*, *Test* – used for unit and functional testing, *Next* – used for integration testing and *Production* environments.

The Next environment of the Controls Configuration is part of the Controls TestBed since 2010 [8]. Some changes in the Controls components are so fundamental, e.g. the renovation of the accelerators Timing System in 2011, that it could take more than 1 year before deploying the new functionality to production. The TestBed provides unique opportunities to perform integration and system testing of the new functionalities with all major components of the Controls System being available.

DATA PROPAGATION

The data management for the Control and Operation of CERN's accelerators is implemented as a distributed database environment [9]. Part of the data stored in the CCDB is propagated to other database systems for the needs of the Operation of the accelerators (see Fig.2).

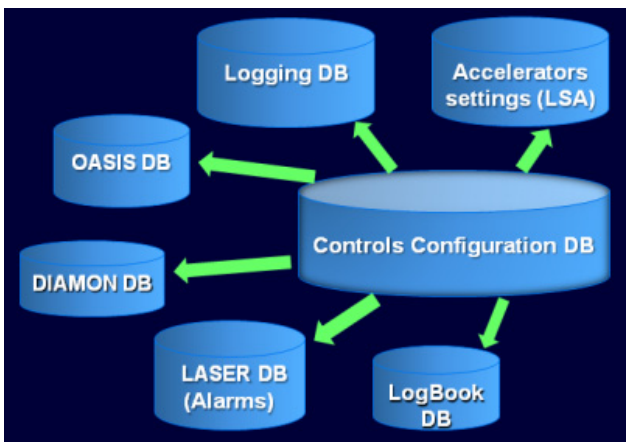

Figure 2: Propagation of data from the CCDB to other databases, used for the Operation of the accelerators.

The alarm definitions (>120,000) for all accelerators devices, are generated and propagated to the Alarms Database [10]. Part of the devices' data is propagated towards the Accelerators Settings (LSA) database, where it is used as a basis for the Operation of the accelerators. The CCDB provides the data for the computers (Front-Ends, consoles, servers, etc.), which need to be monitored by the Diagnostics and Monitoring System (DIAMON).

Safe Propagation of Data Changes

Changes to configuration data in CCDB could have an impact on the related databases. A strategy for smooth data upgrades of the data-driven Controls System has been established with the objective to ensure a coherent set of data throughout all distributed databases. Database procedures are developed in the CCDB to safely propagate data changes, based on knowing the data dependencies between the different systems. The impact of the configuration data changes is analyzed and appropriate actions taken – this process is part of the configuration Change Management functionality provided by the CCDB.

CONCLUSION

The Configuration Management has proven to be an indispensable part of ensuring the correct functioning of any large system.

The Controls Configuration DB, its interfaces and the specific processes implemented around those, are providing the basis for the Configuration Management of the Controls System for all accelerators at CERN. The CCDB ensures conceptual unification and centralization of the diverse configurations of the different items and their relations, thus describing the different components of the Controls System and their dependencies.

Continuous effort is being put into rationalizing, improving, federating and developing new functionality in the existing database and its interfaces.

Abstract

ITER control system will rely on a large number of configuration data, coming from different sources. This information is being created using different tools, stored in various databases and, generally, has different lifecycle. In many cases it is difficult for instrumentation and control (I&C) engineers to have a common view on this information or to check data consistency. The plant system profile database, described in this paper, tries to address these issues by gathering all I&C-specific information in the same database and providing means to analyze these data.

INTRODUCTION

ITER control system, CODAC, has a major challenge of not being created by a single team in a single location, but instead split into different pieces according to the plant systems manufacturing and delivery process. This fact increases substantially the number of people involved in the I&C design, which leads to many different practices and approaches to the implementation of I&C systems. The CODAC team takes preventive measures to reduce diversity by standardizing procedures, hardware and software via its Plant Control Design Handbook (PCDH) and the software product called CODAC Core System (see [1]). The CODAC Core System [2] is a scaled down version of future CODAC, based on EPICS [3], providing essential software support for creating locally of a control system "island" of an arbitrary complexity. These pieces of the control system are called "plant system I&Cs" in ITER terminology.

The configuration data developed with the help of the Core System is conventionally called the "self-description data" (SDD) of particular plant systems, because it allows configuring many elements of the central CODAC by just reading these data (see more on the ITER SDD concept in [4]). The Core System comes with its own relational database, based on PostgreSQL [5], and the tool, called the SDD editor, to create plant system I&C configuration using a top-down approach. This database-enabled solution was initially released in February 2011 and it proven itself being well adapted to I&C engineers' needs. It should be noted that, with the dissemination of Core System installations around the globe, the number of such databases grows, and their content has to be collected and integrated. The workflow to collect these configuration data into the central database is explained in [4].

While the Core System SDD tools are mostly concentrated on the control software configuration part, there are quite a few other areas in the ITER design activities which have impact on I&C configuration. The I&C relies heavily on naming convention for plant components and signals, which is defined and maintained project-wide. The I&C hardware has to be properly allocated in racks and cupboards ("cubicles" in ITER terminology), and those, in turn, have to be assigned to the right locations on the ITER site. The I&C architecture design process is supported with 2-D diagram tool, which has its own database for drawings and I&C objects. The cabling accounting will also be supported by a database solution. Finally, the progress of I&C manufacturing and procurement has to be monitored, and the procured equipment has to be properly registered and accounted. All these tasks are often solved with the help of the tools which are best in their class for functionality, but inevitably bring some diversity with databases and data schemas that accompany them. There is an on-going effort at ITER to unify all engineering data under the umbrella of so-called "engineering database", but the solution has not arrived to production level at the moment and is not yet much I&C-specific.

These circumstances lead to a natural idea of a "syndicated" I&C-specific database which is capable to collect all the I&C-relevant data in a single place and present it in a coherent way. This is what we call a "plant system profile database".

SCOPE AND OBJECTIVES

The main objective was to provide the ITER I&C team with a tool to address immediate needs for configuration data collection and analysis. The scope of the data itself is not always well defined and highly depends on current priorities of work. Thus we opted for a flexible approach, which consists of: 1) providing a solution generic enough to work with any kind of structured data; 2) approaching areas of interest step by step, by determining their properties and implementing them in agreement with the rest of the database.

The most immediate needs at the moment are capturing some top level I&C design decisions and quantitative estimates, as well as tracking the progress of I&C design

and procurement. Consequently, the scope of initial works was to handle the following data:

- breakdown of ITER into plant systems and plant system I&Cs;
- I&C estimates, like estimates of number of cubicles and signals;
- detailed lists of components, signals and I&C variables;
- tracking of procurement arrangements, design reviews, design deliverables, reference documentation.

The objective was attained, even though in many cases the data has not been entered in the database yet or simply does not exist at the moment. Details on the implementation are given in the next section. From this point we are looking forward to address more advanced topics, like:

- support of the remote CODAC Core System databases (a so-called "SDD repository");
- implementation of a workflow between the 2-D diagrams tool and CODAC databases;
- component life cycle management and inventory control;
- support for interlock functional analysis;
- automation of certain routine data imports and data quality checks.

FIRST IMPLEMENTATION

At the design phase, the current ITER infrastructure and CODAC practices have been evaluated, and the following architectural and software decisions have been made:

1) the database backend should be MicroSoft SQL Server [6];
2) the application should have web interface;
3) business logic and the user interface should be written in Java. PrimeFaces [7] should be used for the user interface, Spring [8] for transactional support and Java Hibernate [9] for interaction with the database;
4) data integration tool should be Talend [10].

The task was launched in September 2010; in February 2011 the first version was put in production, and it was gradually introduced into CODAC processes in the following months.

The front page of the application is presented on Fig. 1. It presents an overview of data stored in the database at the moment. The key metrics are number of plant systems and plant system I&Cs ("control islands"), the number of their components and signals, the numbers of I&C controllers and variables handled by them. As one can observe, the population of the database has just started. It is worth noting that the database is not only about technical data – it collects and presents information about administrative aspects of I&C tracking – like procurement arrangements, design review and documentation status. Since the administrative data is available, the database application is able to offer a list of coming milestones right at the front page.

Various aspects of data can be studied using so-called "perspectives" (the names comes from Eclipse perspectives, similar by nature). The perspectives are views of the same data presented from different angles. The main perspectives defined today are:

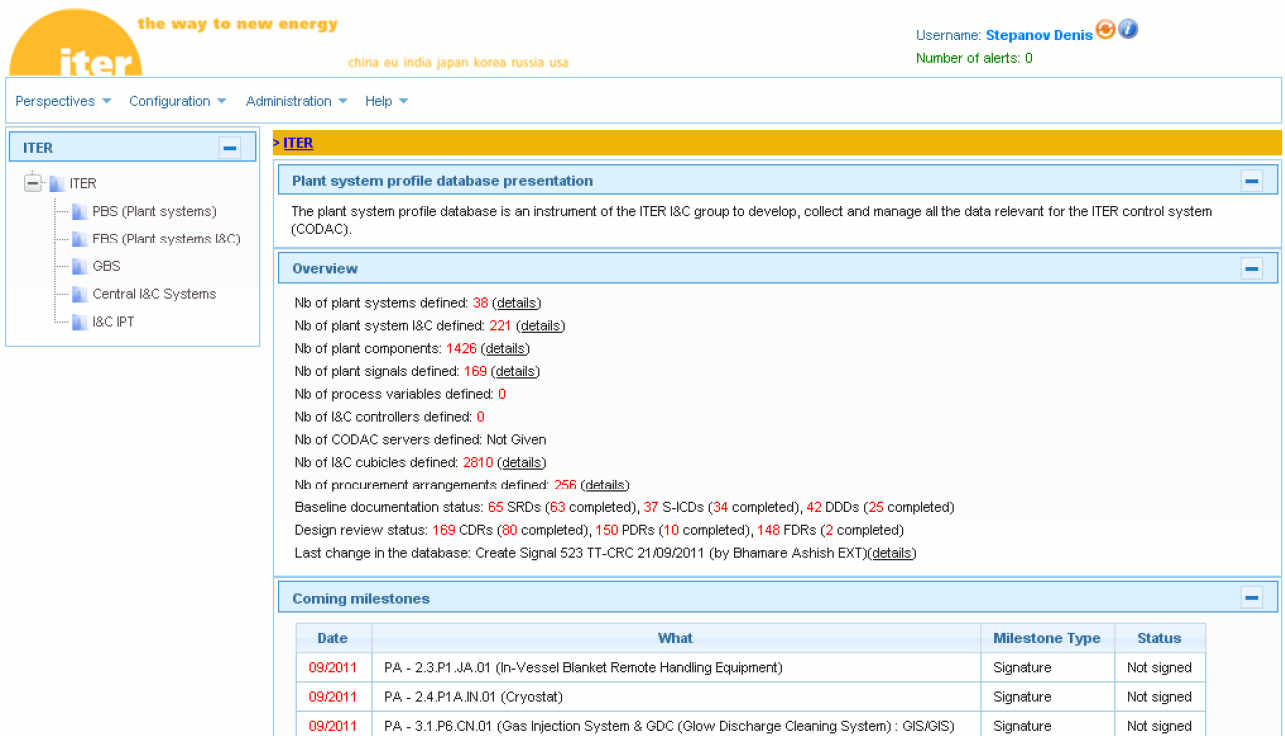

Figure 1: Plant system profile database entry page.

- PBS (Plant Breakdown Structure) perspective – seen from the point of view of plant systems;
- FBS (Functional Breakdown Structure) perspective – seen from the point of view of plant system controls;
- GBS (Geographical Breakdown Structure) perspective – seen from the geographical point of view;
- Central I&C systems perspective – view on configuration of central systems;
- I&C IPT (Integrated Product Team) perspective – organizational and administrative view.

The same object (e.g., a signal or a controller) can appear in various perspectives, with a focus on its properties valuable for that view.

The PBS perspective allows navigating through the list of plant systems and finding out which components, cubicles, signals belong to it and what are the buildings which host the plant system. It also allows entering quantitative estimations, the people responsible for the system and references to the relevant ITER baseline documentation.

The FBS perspective is focused on I&C and presents it as a tree of control functions. It is possible to see the list of functions, control units and variables belonging to a plant system I&C, or enter estimations of those. With the information entered, the database, in principle, can derive a drawing of the I&C architecture. A very simple example, based on the tokamak cooling water system specification, is shown on Fig. 2.

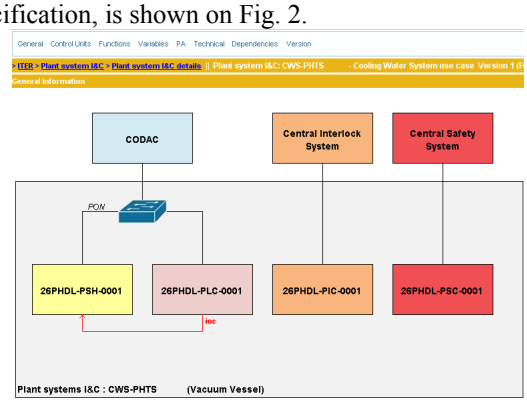

Figure 2: A sketch of a cooling water system I&C, generated by the database web application.

Here one can easily see that the plant system I&C has one slow controller (PLC) which is served by a plant system host running an EPICS Input/Output Controller (IOC). Interlock and safety controllers are equally declared. By clicking on the boxes, one can navigate to the definition of particular controller. The figures like this require zero effort from the end user and are ready to be used in various specification documents, or in presentations. One more advantage is that they use the same styles and PCDH methodology across all ITER systems.

The GBS perspective shows a map of the ITER site and allows going down to individual buildings and rooms and finding out the equipment, such as cubicles, planned to be installed there.

The central I&C systems perspective is focused on configuration of central systems. Currently it only shows the list of CODAC network nodes ("network hutches") which interconnect different buildings. There will be more information added on CODAC special purpose networks, servers, as well as interlock and safety systems.

Finally, the I&C IPT perspective represents an administrative view on the systems. There one can learn the organizational breakdown of people assigned to work on particular systems, information on procurement arrangements, tracking of milestones and documents. One of important activities at the moment is participation of the CODAC team in various design reviews of the ITER plant system systems to make sure that I&C procurement is not forgotten and is designed according to the ITER standards. The reviews are normally structured per procurement packages and pass through different levels of maturity (conceptual, preliminary, or final design). Given the number of procurement arrangements which involve I&C (235 registered in the database at the moment of writing), one can easily understand the amount of work load incurred, which has to be properly planned and accounted. The I&C IPT perspective helps to manage this work by carefully recording all the planned or completed reviews together with the associated documents and remarks from the team.

DATA ANALYSIS AND REPORTS

In many cases it is not sufficient just to collect the I&C data; it is equally important to be able to perform data analysis and present properly certain information of interest. Topics of particular interest for ITER at this moment include:

- Analysis of plant system I&C design in order to understand and have under control the number of key I&C elements – I&C controllers, I/O boards, cubicles and to see if they respond to the envelops defined, such as footprints in rooms and areas designated to host the I&C equipment;
- Analysis of performance requirements and identification of possible bottlenecks in processing data transfer, or response times which may lead to refinement of requirements to the CODAC System or even prompt redesign of some systems;
- Tracking of the I&C design and implementation progress and comparison it with the overall project schedule in order to identify schedule slippages and take preventive measures;
- Estimations of cost of the control system based on average values of key parameters, like a cost of a data acquisition channel.

Here, different implementation approaches could be taken. Key indicators which need to be accessed daily and instantly can be built right into the web application interface, like in the case of dashboard on Fig. 1. More powerful, but less integrated way is to use a reporting services mechanism (MS SQL Server Reporting services in our case), which provides rich presentation layer and

can be created relatively quickly on demand. This is a convenient way of managing reports which need to be accessed regularly. Finally, one can export data of interest into an Excel file and apply processing on his or her own, which enables full presentational power of modern office packages.

Below are some examples of reports created with the help of reporting services. Figure 3 shows a distribution of I&C cubicles among the buildings on the ITER site:

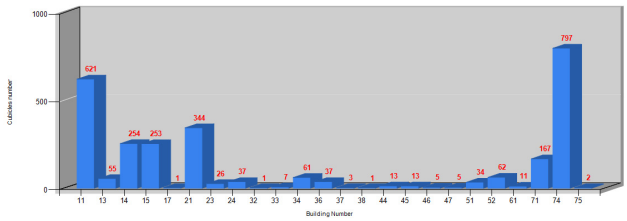

Figure 3: I&C cubicles broken down by buildings.

This graph allows grasping quickly which buildings will be the most I&C-loaded and thus will require particular investment into cabling and network infrastructure.

Another example (Fig. 4) shows a distribution of I&C-related procurement arrangements among the plant systems and the ITER domestic agencies.

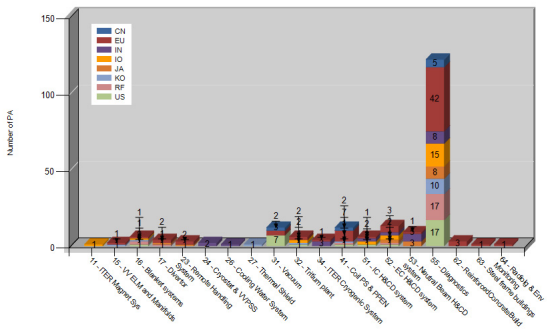

Figure 4: I&C procurement breakdown per plant system.

Finally, to support the I&C progress meetings, where the status of I&C procurement is reviewed and discussed, a specific dashboard was defined. This page, shown on Fig. 5, represents procurement organization, key performance indicators, deliverables and milestones for a given plant system and allows quick understanding whether the I&C procurement is on track and what are the particular issues that have to be resolved. The history of reports can be maintained, e.g., on a weekly basis, so one can go back in time at any given moment, or build a progress graph of key performance indicators evolving with time.

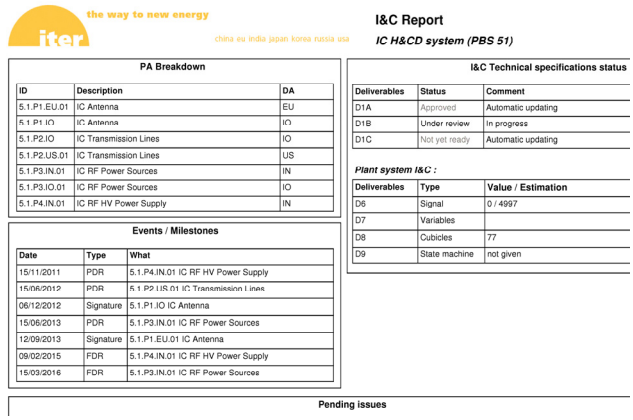

Figure 5: Example of the I&C design and procurement status for the ion-cyclotron heating system.

CONCLUSIONS

The extensive work done by the CODAC team to support the I&C design of the ITER plant systems highlighted the need to supplement this activity with a database application. The plant system profile database, put in production in 2011, has just barely started, but already allows filing the I&C design data in a unified way and calculating useful data metrics. The work is now focused to put the entire information collected so far under the control of the database and to continue integration activities with the CODAC control software and the rest of the ITER databases.

The authors wish to thank the CODAC team and the I&C IPT for their support and suggestions which helped to define and continue to steer the development of the plant system profile database.

The views and opinions expressed herein do not necessarily reflect those of the ITER Organization.

HOW TO MAINTAIN HUNDREDS OF COMPUTERS OFFERING DIFFERENT FUNCTIONALITIES WITH ONLY TWO SYSTEM ADMINISTRATORS

R. Krempaska, A. Bertrand, C. Higgs, R. Kapeller, H. Lutz, M. Provenzano
Paul Scherrer Institute, 5232 Villigen PSI, Switzerland.

Abstract

At the Paul Scherrer Institute, the control systems of our large research facilities are maintained by the Controls section. These facilities include the two proton accelerators, (HIPA and PROSCAN), the two electron accelerators, (SLS and the Injector Test Facility of the future SwissFEL) as well as the control systems of all their related beamlines and test facilities.

This paper describes methods and tools which are used to develop and maintain the challenging computing infrastructure deployed by the Controls section.

CONTROLS COMPUTING INFRASTRUCTURE

The Control system is basically composed of Input Output Controllers (IOCs) running VxWorks operating system on VME hardware using the EPICS (Experimental Physics and Industrial Control System) software. Additionally, there is an increasing number of non VME based IOCs, (so called EPICS soft-IOCs) running mainly on Linux hosts. In total the we are responsible for the installation, configuration and maintenance of up to 400 VME-based IOCs and more than 200 soft-IOCs. There is a remote console interaction with these systems in order to support their development, booting and debugging. Additionally, the control system includes special EPICS servers such as the CCD camera systems that often need dedicated configurations.

Finally, the client part of control system applications requires operator and expert consoles, login clusters and status displays. The Control system configuration and applications software for each facility is stored on independent NFS file servers. The total number of Linux computers and servers is about five hundred. Since only two system administrators are responsible for their installation, configuration and maintenance, we have adopted a well defined solution to face this challenging task:

- Virtualization
- Unified operating system installation and update mechanism
- Automatic configuration by a common tool (puppet)

VIRTUALIZATION

Virtualization allows the system administrators to configure a multitude of "one-task" simple machines such that administrative tasks can run on their own virtual computer. These virtual computers do not require a lot of CPU or memory. This is particularly useful for software upgrades and maintanence. Such systems include boot servers, soft-IOC servers, port server hosts and configuration servers (also called auto-save and restore servers). Computers providing access to private machine networks, such as secure shell (ssh) gateways and Channel Access gateways, are also installed as virtual machines.

Virtualization also enables a rationalization of hardware, operating and energy costs. Our virtual computers run on a VMware cluster (two servers, each with 72Gbytes RAM and SAN storage). Of the 500 Linux computers, about 200 are virtual machines running on the VMware cluster. The remaining systems, (NFS file servers, archiver or development servers) are installed on dedicated hardware blades.

UNIFIED OPERATING SYSTEM INSTALLATION

At PSI the popular Scientific Linux (SL) distribution is used [1]. The PSI Central Computing Division is in charge of distributing and maintaining the SL core and rpm packages [2]. SL is supported by various labs and universities around the world and is based on Red Hat Enterprise, which is recompiled from source and repackaged.

Using the so called "kickstart" mechanism of Red Hat Enterprise, we deploy the base operating system installation which is "tailored" by a software distribution mechanism, called puppet (see next section). The goal is to use the same system management framework for all hosts through their life cycle.

Configuration changes and software updates, (e.g. kernel upgrades) are steered from a central location. Operator consoles in the control room are installed on desktop computers with a standard installation in order to guarantee redundancy and a fast and easy exchange in the case of failure or upgrade.

Thus we are able to achieve an easy and uniform installation on all our systems.

AUTOMATIC CONFIGURATION BY PUPPET

Puppet is an automated administrative software engine for system configuration. It performs administrative tasks, such as adding users, installing packages, and updating server configurations, based on a centralized specification [3].

The Controls system administrators receive daily requests from users for new consoles, servers or office computers. Our existing 500 computers also need to be maintained. Without automated scripts, this would be almost impossible. The SL kickstart and subsequent puppet configuration is central to our automated installation process.

Each facility needs several types of computers, which we call classes. There are about 35 computer classes defined in puppet. The reason is that different classes of computer need different NFS mounts, environmental variables setup, services and cron tasks or additional local user administration and user accounts. A set of puppet configuration files stored in the central PSI repository handle these particular installations issues. Each computer configured by puppet is assigned a class and each class has a hierarchy of configuration files. An example of a configuration file for an IOC boot server configuration can be seen on Fig.1.

```
class class_A_BootPC_VM {

  info "PUPPETSERVERINFO: Configuring host $hostname, role $role, zone $gfaFacility:

  # GFA basics
  include "class_GFA_DesktopBasic"

  # Intranet AFS
  include "class_module_gfa_afs::intranet"
  include "class_module_gfa_files::mkhomedir_skel"
  include class_module_gfa_pam2::setup
  def_module_gfa_pam2::alternative{"GFA-local-noafs-krb5": activate => true, }

  include "class_module_gfa_runlevel::id3"
  include "class_module_gfa_iocLogServer"
  include "class_module_gfa_autoSR"

  # Accounts
  include "class_module_gfa_shellenv::sshkeys"
  include "class_module_gfa_account::ioc"

  include "class_module_gfa_vmware"

  include "class_module_gfa_epics::iocsh"

  # BootPC stuff
  include "class_module_gfa_bootpc"
  include "class_module_gfa_nfs::server"
  include "class_module_gfa_EpicsRecDB"
  include "class_module_gfa_dgrp"

  case $gfaFacility {
    SLS    : {
      def_module_gfa_bootpc::ioc_dir{"/ioc": }
    }
    FIN    : {
      def_module_gfa_bootpc::ioc_dir{"/ioc": mount => "/import_fin/ioc" }
    }
    HIPA   : {
      def_module_gfa_bootpc::ioc_dir{"/ioc": mount => "/import_hipa/ioc" }
    }
    Proscan : {
      def_module_gfa_bootpc::ioc_dir{"/ioc": mount => "/import_proscan/ioc" }
    }
    TRFCB : {
      def_module_gfa_bootpc::ioc_dir{"/ioc": mount => "/import_trfcb/ioc" }
    }
  }
}
```

Figure 1: An example of a puppet configuration file for a boot server virtual computer. The list of include commands in the first part shows the required configuration for this particular computer type. The case statement similar to the C code syntax in the second part shows how special treatment for each facility is done.

The configuration files are used when the puppet update process is scheduled from a cron-job (or manual request). Fig.2 illustrates a schematic flowchart diagram of the puppet deployment which can be factorized into the following steps:

1. The puppet client sends a request for an update. The "client identity", i.e. the computer name, or class is supplied.
2. The puppet server collects configuration information from the hierarchy of configuration files.
3. The puppet server sends packages and executes the update scripts defined in the configuration files.
4. The client gets the yum updates from the yum repository server.
5. The configuration results are stored in the Oracle database.

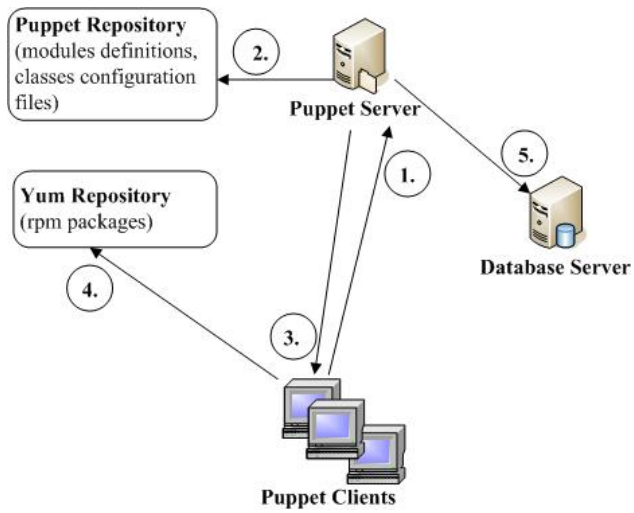

Figure 2: The puppet process configuration of the controls computers.

CONFIGURATION COMPUTERS OVERVIEW

The puppet configuration process is scheduled every 24 hours, typically during the night. Once the puppet configuration process is finished, the results are collected in the Oracle database. At the end of the process a database Web tool called Inventory software [4] integrates complete information about the configured hosts. This is a significant help for the system administrators. Fig.3 shows a database output list of all computers configured by puppet with supplementary information such as last update time, IP-address and Linux version. Finally Fig.4 displays even more detailed information for a host selected from Fig. 3.

Figure 3: List of controls computers configured by puppet.

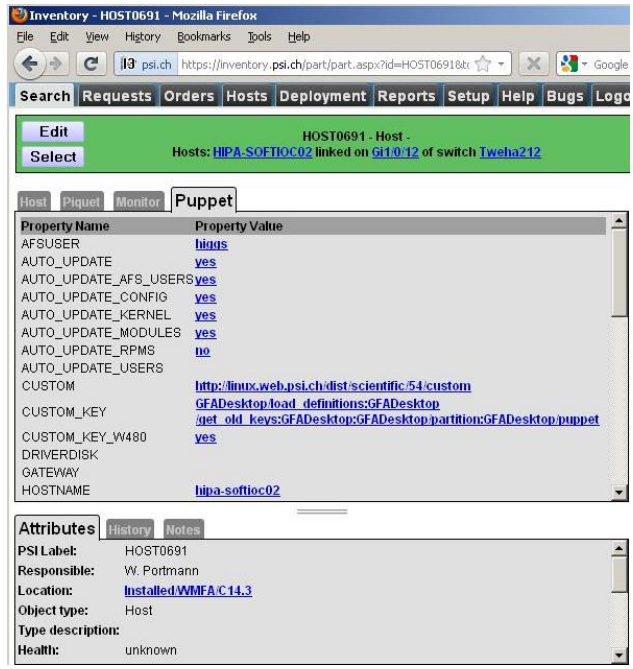

Figure 4: Detailed puppet configuration information for HIPA-SOFTIOC02 selected from Fig.3, visible on the PSI intranet Web.

ACKNOWLEDGMENTS

We want to acknowledge our colleagues M. Gasser, V. Markushin and H. Billich from the PSI AIT group, for their collaboration and for supporting the controls system administration.

INTEGRATED MANAGEMENT TOOL FOR CONTROLS SOFTWARE PROBLEMS, REQUESTS AND PROJECT TASKING AT SLAC

D. Rogind, W. Allen, W. Colocho, G. DeContreras, J. Gordon, P. Pandey, H. Shoaee
SLAC National Accelerator Laboratory, Menlo Park, California, U.S.A.

Abstract

The Accelerator Directorate (AD) Instrumentation and Controls (ICD) Software (SW) Department at SLAC, with its service center model, continuously receives engineering requests to design, build and support controls for accelerator systems lab-wide. Each customer request can vary in complexity from a small software engineering change to a major enhancement. SLAC's Accelerator Improvement Projects (AIPs), along with DOE Construction projects, also contribute heavily to the work load. The various customer requests and projects, paired with the ongoing operational maintenance and problem reports, place a demand on the department that consistently exceeds the capacity of available resources. A centralized repository - comprised of all requests, project tasks, and problems - available to physicists, operators, managers, and engineers alike, is essential to capture, communicate, prioritize, assign, schedule, track, and finally, commission all work components. The Software Department has recently integrated request / project tasking into SLAC's custom online problem tracking "Comprehensive Accelerator Tool for Enhancing Reliability" (CATER) tool. This paper discusses the newly implemented software request management tool – the workload it helps to track, its structure, features, reports, work-flow and its many usages.

CONTROLS SOFTWARE WORKLOAD

The ICD Software Department, comprised of about 25 engineers, provides complete, long-term, robust, software engineering solutions for control of distributed accelerator systems lab-wide. The department responsibilities include host computing infrastructure, networking, relational databases, real-time embedded (and host-level) device, subsystem, and instrumentation control, process control, engineering/operational GUIs, and service oriented architectures. It also performs user support, upgrade and maintenance activities. The Software Department uses the EPICS (Experimental Physics Industrial Control System) toolkit and its extensions as the basis for most software engineering implementations. The department also fully supports the legacy SLAC Linear Collider (SLC) VMS-based Control system.

ICD Software Department personnel currently spend, on average, 25% of their time in support of LCLS and FACET program operations. All SW (along with other Hardware (HW)) Problems (or trouble reports) newly entered into SLAC's CATER system are discussed at the daily 08:15 maintenance meeting and are usually assigned to a resource by a Lead within hours of creation. One software engineer per week, on a rotational basis, acts as a Controls Deputy (CD) liasion between LCLS Operations and the Software Department. The CD attends the daily meetings, work planning meetings, works and resides within the Control Room, and carefully helps to coordinate the weekly software releases.

For the remaining 75% of the time, software engineers perform development work which can be categorized as either a) customer requests or b) project work. Project work is typically funded and approved by the AIP or DOE (such as the LCLS II Construction Project). Until recently, customer requests were typically delivered verbally or via email to engineers; oftentimes the supervisor or lead remained unaware. Task scheduling and tracking then varied by individual or lead; commonly by a combination of memory, spreadsheets, lists, emails, and disparate project schedules. Both customers and supervisors had limited visibility into work planned, in progress, or accomplished. It remained difficult to assess whether additional resources were justifiable. Furthermore, the work was hard to prioritize and load balance without a centralized list of all department problems, requests, and project tasking

PROBLEM TRACKING TOOL

The CATER Problem Tracking Tool in its current implementation has been in wide use across many organizations at SLAC since 2008. The reports and workflow drive all of the daily LCLS (now joined by FACET) Operations/Maintenance meetings, software and hardware problem and maintenance work tracking, and contribute to the planning of the weekly machine development/access days. CATER is Oracle based, developed with Application Express (APEX), and has one full time developer (outside of ICD) allocated due to ever increasing feature demands.

In order to take advantage of CATER's existing user base, accounts, roles, relational database management, familiar work flow and familiar GUI, SW Requests (and their associated Tasks) were integrated alongside Problems into CATER in June, 2011. SW Requests are of two types: a) Customer, and b) Project Component. Additionally, a SW Job form was implemented which contains all fields required for software release approval and planning. This SW Job feature has proven very valuable for all software release types. Now for the first time, every software engineer has the capability of viewing all of their work – problems, requests, jobs, and project tasking in one place, via the CATER tool. Each user, upon logon, has a personalized dashboard on their home tab which displays all open assignments (Figure 5)

SOFTWARE REQUESTS AND TASKS

LCLS and FACET customers at SLAC are encouraged to login to the familiar CATER trouble reporting system and create a "New Software Request". There is a constant high volume of customer requests that are small in scale, of limited complexity and involve several people tasked separately. The automated Request system has been particulary efficient for tracking these types of entries that might otherwise get forgotten or not receive the proper visibility. Engineers/Leads also create entries to capture customer requests and components of their project based work. Requests use the existing CATER Problems schema and workflow. Fields include: *Title, Description, Status, Request Type ("Customer" or "Project Component"), Work Breakdown Description (funding source), Subsystem, Request Lead, Group (LCLS, FACET,..), Customer Priority, Customer Need Date, Created by, Modified by, Created Date, Modified Date.* There are buttons to *Add Customer*, *Add SW Job*, *Add Task*, and to *Upload* files.

A large Request, such as "Complete LCLS Fast Feedback Project" (Figure 1) may be further broken down into several Tasks, such as "Bunch Charge Feedback" (Figure 2), "Undulator Launch Feedback" etc. Each Task associates with a single resource and more detailed loading and scheduling information. Task fields include: *Title, Assigned to, Effort, Task Priority, Task Skill Set, Start Date, End Date, % Complete, Description, Status, Created by, Created Date*. There is enough information contained in the request /task database such that weekly reports and/or Gantt charts per individual or per project could be generated (future effort).

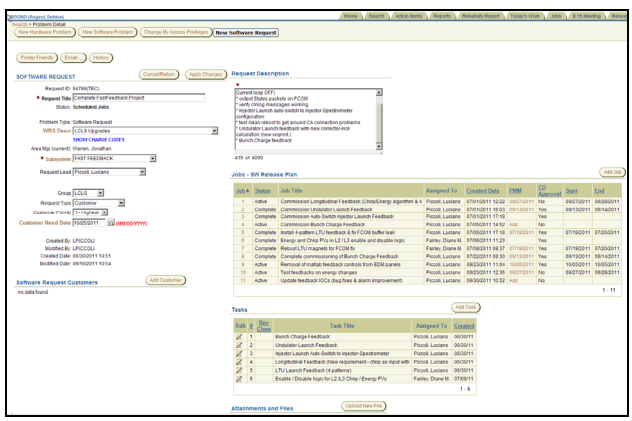

Figure 1: Sample Request Page.

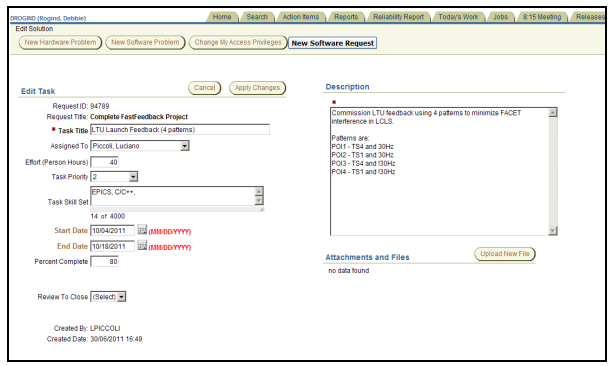

Figure 2: Sample Task Page.

SOFTWARE JOBS

LCLS hardware maintenance / repairs and software releases which require machine access (no beam) are typically scheduled every other week during user runs, while software releases / physicist machine development opportunities requiring an operational machine are scheduled once per week. To help maintain very high LCLS machine availability, all software releases are carefully evaluated for risk / benefit and are detailed in a new SW Job form that includes fields: *Job title, Resource, Time needed, Time Comment, Planned Start/Stop Date/Time, Access Requirements, Beam Requirements, Beam Comment, Invasive (Y/N), Invasive comment, Area, Subsystem, Test Plan, Back out Plan, Systems Required, Systems Affected, Risk/Benefit*. Refer to Figure 3 for a sample SW Job. The SW Jobs submitted each week are reviewed and scheduled in a weekly meeting between the program physicist and Controls Deputy; there are typically 15-20 SW Jobs of varying complexity submitted per week for LCLS. The Controls Deputy plays a pivotal role, especially on release day(s), coordinating the various software engineers along with parallel operational and physicist activities. (Refer to Figure 4, Sample Controls Deputy Report.)

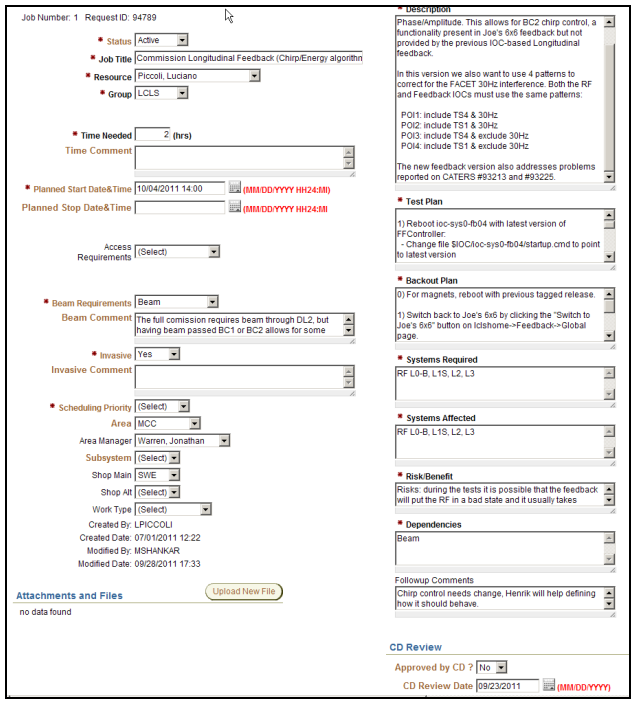

Figure 3: Sample Software Job (Release Plan) Page.

REPORTS

Once logged onto CATER, all users default to their Home tab (dashboard) that summarizes and links to all assigned open "Problems Assigned to Me", "Requests and Tasks Assigned to Me", and "Jobs Assigned to Me" (Figure 5). There are additional views associated with other tabs. The Search tab provides basic and advanced searches plus an interactive report builder to customize report column data and filters, such as All Customer Requests (224 in number) or All Project Requests. The Report tab has many canned reports including the Controls Deputy Report of SW Jobs up for weekly approval (Figure 4), Work Breakdown Structure Names/Priorities, etc. All reports export to MS Excel.

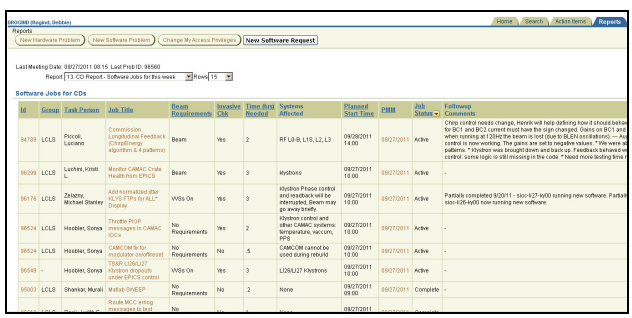

Figure 4: Sample Controls Deputy Report.

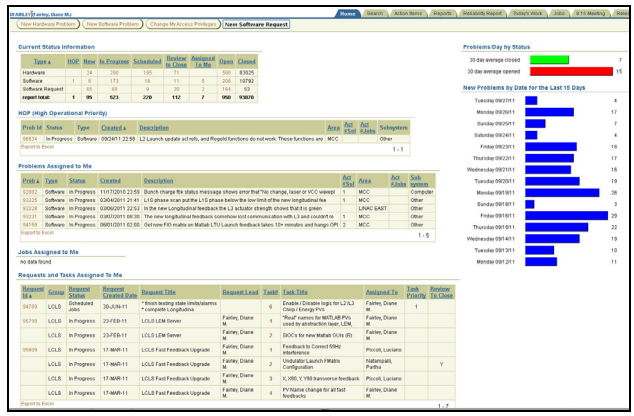

Figure 5: Sample CATER Home Tab (Dashboard).

CATER WORK FLOW

Requests follow the same simple, four state, CATER workflow as Problems because a) it has been proven to work effectively, and b) users are familiar with it. All status transitions in the life of a Request/Problem trigger alerts to email distribution lists which always include software leads. All New Requests/Problems have status=New. Once assigned to a resource, status changes to "In Progress" (or "Scheduled Jobs when SW Jobs are active). When all associated SW Jobs and Tasks (/Solutions for Problems) are complete, the status changes to "Review to Close". The Request/Problem is "Closed" by Leads with the appropriate closure privilege after careful review. The states, associated stakeholder review meetings, necessary reports, and email alerts during the life cycle of a Request/Problem are shown in Figure 6.

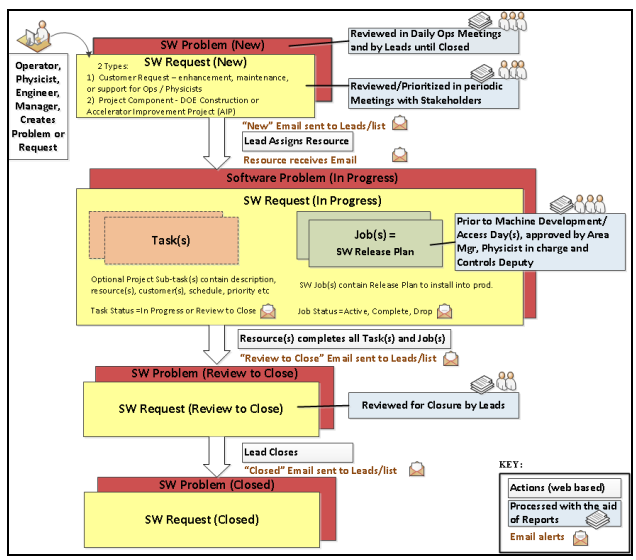

Figure 6: CATER Request/Problem Workflow.

CONCLUSION

Results Achieved

- Customers may view **all** department work to a) direct prioritization; b) better understand why their requests may not have resources allocated, and c) track and aid progress.
- Supervisors/Leads/Staff are informed of all ongoing / upcoming work. Helps to catch potential issues early, prioritize workload, re-task staff, track status, and justify resource decisions

Lessons Learned

- The tool has been particularly useful for tracking the large volume of requests that are small in nature and/or of minor complexity, and require a few hours to a few days of many different resources.
- Integration of Jobs (software test/release plans) for Requests and Problems has been very efficient and well-received for planning and executing machine development days
- Simultaneous development of CATER using Oracle's Application Express (APEX) proves challenging
- Releases for any new Request features are constrained by the normal CATER release cycle

What's next?

- More training and enforcement of data entry
- Roll out to other organizations within ICD; SLAC
- More reporting – weekly reports, Gantt charting

EXTENDING ALARM HANDLING IN TANGO

S. Rubio-Manrique, F. Becheri, D.Fernandez-Carreiras, J.Klora, L.Krause*, A.Milán Otero, Z.Reszela, P.Skorek, CELLS-ALBA Synchrotron, Cerdanyola del Vallès, Spain

Abstract

This paper describes the alarm system developed at Alba Synchrotron, built on Tango Control System. It describes the tools used for configuration and visualization, its integration in user interfaces and its approach to alarm specification; either assigning discrete Alarm/Warning levels or allowing versatile logic rules in Python. This paper also covers the life cycle of the alarm (triggering, logging, notification, explanation and acknowledge) and the automatic control actions that can be triggered by the alarms.

INTRODUCTION

ALBA is the first Synchrotron Light Source built in Spain [1]. Its 3 GeV Storage Ring has been commissioned during 2011 and it's expecting the first beam-line users for beginning 2012. Control of ALBA [2] is based on Tango, a modern control system for scientific facilities developed by the ESRF and maintained by the members of the Tango Collaboration [3]. Tango provides a collection of interfaces for common devices and generic tools for configuration, deployment, archiving and alarms.

The installation and commissioning of ALBA required alarm handling to supervise accelerators conditioning and detect changes in operation conditions. Although two alarm logging systems already existed in Tango, at ALBA we decided to have an alarm system integrated in the existing applications instead of having a separated tool. To do so we combined previous ideas and developments to provide a more flexible alarm handler.

ALARM SYSTEMS IN TANGO

The Tango Alarm System

The Tango Alarm System [4] was developed at Elettra institute (Italy) by Graziano Scalamera and Lorenzo Pivetta. It uses a MySQL alarm database containing sets of rules that are permanently checked by a central daemon, the Tango Alarm Server, which logs alarm changes and triggers actions if needed. The rules are combinations of boolean operators and Tango Attribute values.

Table 1: Tango Alarms Syntax

sr/psch/s1.1/highthr
(({sr/psch/s1.1/stat} & 0x80) && ({sr/psch/s1.1/curr} > 15.0))

*On leave

The Alarm daemon is connected with the control system using CORBA Notification events [4] triggered by the targeted Attribute device; avoiding overhead in the system. The Alarm Server provides logging and is capable to launch commands of other Tango Devices, in which notifications and actions are delegated. All alarms in the system are stored and can be visualized using the graphical log-viewer tool.

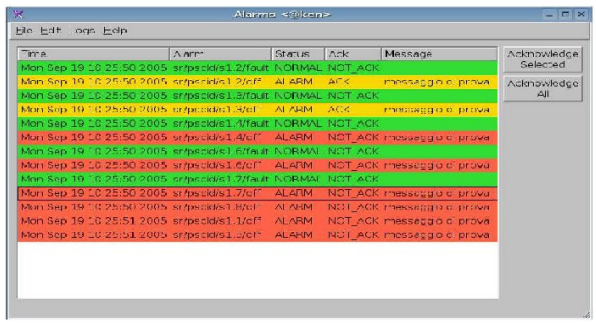

Figure 1: Tango Alarms Logs Viewer.

Soleil Alarm Database

The Alarm Database in operation at Soleil mimics the behaviour of Tango Archiving System [5][6], but it's focused on storing Attribute qualities (Valid, Invalid, Changing, Warning or Alarm) instead of values. The system uses a MySQL database and a pool of Archiver devices that poll periodically the quality of those Tango Attributes previously registered.

The conditions that trigger a change in Attribute Quality are not stored in the Alarm Database but in the Tango Database, using the Alarm/Warning Max/Min Values of each attribute. Configuration and visualization can be done using standard Tango Java tools and Archiving viewer.

ALBA PyAlarm

The PyAlarm device server development started on 2007 during ALBA's construction phase. It was focused on having an small stand-alone alarm system for installation activities (equipment tests, prototype labs, bakeouts, …) in places were database servers or network infrastructure was not fully available or could be interrupted.

Every PyAlarm Tango Device stores its rule sets as device properties, that can be stored in the Tango Database or Tango property files. These files allow the server to be running without Tango database if needed. Access between PyAlarm instances, clients and database have been encapsulated in the Panic API.

Alarm logging is done using Soleil Snapshoting database from the Tango Archiving System[5]. For every

Alarm triggered an Snapshot is recorded containing the Alarm Status and the value of every Attribute involved in the Alarm.

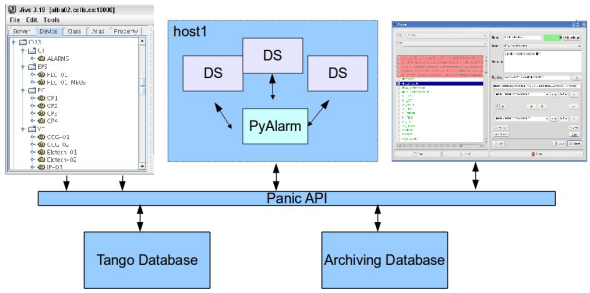

Figure 2: Panic API encapsulates database access and provides alarm setup, validation and visualization.

A Python Alarm System

The PyAlarm rules are inspired in Elettra's rule-sets, with the aim of integrating both systems in the future. But PyAlarm applies python parsing; enabling a richer rule syntax with list comprehensions, regular expressions, string replacement and other functional features.

PyAlarm also creates dynamically [7] new boolean attributes for each new rule set, used to display alarm states from any generic Tango client. The attribute names syntax has been extended to combine conditions on value, quality and time-stamp of attributes.

PyAlarm uses polling when running on top of PyTango, but if Taurus[8] library is available the PyAlarm can use it to switch transparently between polling or events for each attribute.

Table 2: PyAlarm declarations showing syntax for value, host, state, quality and regular expressions.

```
BL_PRESSURE:
                        BL/VC/VGCT-01/P1 > 3e-5
BL_LOST:
              tbl01:10000/BL/CT/DB/State==UNKNOWN
BL_TEMPERATURE:
              BL/EPS/PLC/T1.quality == ATTR_ALARM
ID_TEMPERATURE:
           any(t>85 for t in FIND(ID/*/*/Temp*))
```

THE ALBA ALARM SYSTEM

Although every PyAlarm is an independent process that runs stand-alone, all the Alarm system is coordinated using the Panic python API. This software layer encapsulates the access between servers, clients and the Tango database. The API provides a way to access alarms configuration and modify existing alarm distribution; not allowing to have duplicated alarms in the system.

Once configured, alarm logging and notifications are managed independently by each PyAlarm device. Each PyAlarm device instance manages a collection of alarms distributed by domain/family. Archiving and configuration are centralized in our Tango and Archiving Databases.

Accelerators Alarms Architecture

In Alba Accelerators the PyAlarm instances are dedicated by subsystem (e.g. being Magnets and Vacuum alarm systems are independent processes) and this instances can be decentralized deploying every PyAlarm in the same industrial PC were the monitored system is running.

Alarms can be declared hierarchically to summarize a big amount of alarms in fewer notifications. Alarms can be used as variables within other alarms formulas, that will summarize the state of their primitives when generating reports.

Beam-lines Alarms Architecture

An independent alarm system is running on each of the beam-lines. As the number of devices and subsystems is much smaller it is not needed to distribute the alarm system and it is centralized in a few PyAlarm servers running in the same virtual server were the Tango Database is running.

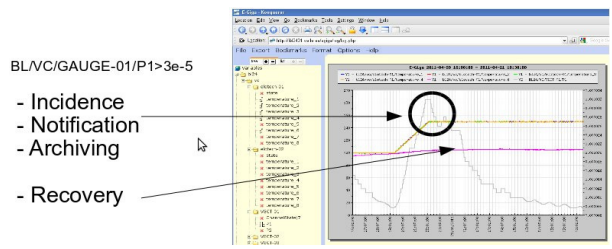

Figure 3: Messages sent during alarm life cycle.

The Alarm life-cycle

Alarms become active when the alarm condition evaluates to a True value, and will require human acknowledge to became inactive again. We added Reminder/Recovered notifications to avoid active and unacknowledged alarms remain unnoticed. Changes in alarm condition value will still trigger email and logging even if the alarm was still active, to make sure that no incidences remain hidden.

Table 3: Types of Messages

Alarm	The alarm condition has been activated.
Recovered	Alarm conditions are now inactive, but alarm state is kept.
Reminder	Condition was active for X period or became active after a Recovered period.
Acknowledge	Alarm has been acknowledged by operator.
Auto-reset	Alarm reset after being in Recovered state for a long time (optional).

Alarm Receivers

PyAlarm started as a notification service, so its main feature is email sending to notify any control incidence. It was initially extended to SMS and soon it was clear that more functionality should be needed. Every new notification feature has been added as a receiver type. In this sense an email address or a tango command are just different kind of receivers, that must be notified in case of incidence.

Every alarm has its own list of receivers, which may contain individual items or tags for groups of receivers. These groups are defined using email addresses, SMS numbers, lists of commands, archiving configurations or groups of them.

Table 4: Types of Receivers

email	Sent for every change in alarm status.
SMS	Sent only for activation.
Html files	To be loaded in the website.
SNAP	Record attribute values in the snapshoting database.
log	Generates a raw log file
COMM	Executes a TangoCommand.

USER INTERFACE

An easier method of global configuration/visualization of alarms helps accelerators and beamlines operators to diagnose incidences during commissioning; as well as modifying alarm conditions if needed.

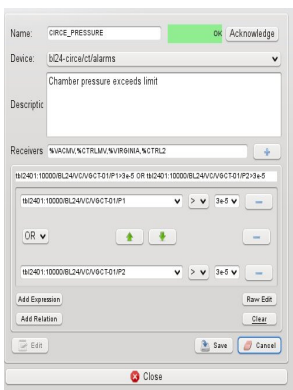

Figure 4: The Alarm editor widget.

An accelerator's alarm system requires an application for configuration, visualization and filtering of alarms usable at operator level; with no need of control system internals background.

The Alarm application allows to filter alarms by subsystem. To integrate alarms in existing applications has been developed an Alarm Toolbar with access to visualization and acknowledgement of alarms. This toolbar is able to filter alarms and status depending on user/application scope.

Alarms can be filtered by subsystem, receivers, attributes targeted and severity. Error, Warning, Info and Debug are the four severities available; which are used to sort the information when summarized in lists or toolbar. To go into detail as much as possible the alarm list provides viewer of attribute values.

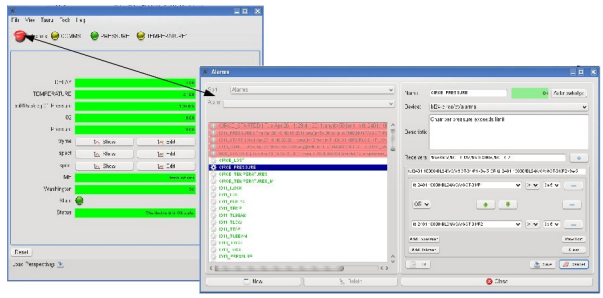

Figure 5: Alarm toolbar and list with filters and editor.

CONCLUSSIONS

We presented the ALBA Alarm System, created for ALBA installation and successfully extended to cover our accelerators and beam-lines. The PyAlarm was used successfully during installation and commissioning of ALBA linac, booster and beam-lines and in certain projects in the ESRF. The early deployment of an alarm system helped to prevent problems and detect irregular behaviours.

But for using it in our storage ring we had to improve the management of hundreds of alarms, adapting the content of messages and adding hierarchies between alarms that reduced the number of notifications sent. Our next objectives are the execution or recommendation of simple actions, linking alarms and low-level troubleshooting.

Unifying Tango alarm systems in a unique solution is still the aim of our development, so we focus next steps on interaction with existing systems; using PyAlarm as notification tool or adapting it to use Elettra Alarms Database as it exists now.

NFC LIKE WIRELESS TECHNOLOGY FOR MONITORING PURPOSES IN SCIENTIFIC/INDUSTRIAL FACILITIES*

I. Badillo#, M. Eguiraun, ESS-Bilbao, Spain
J. Jugo, University of the Basque Country, Spain

Abstract

Wireless technologies are becoming more and more used in large industrial and scientific facilities like particle accelerators for facilitating the monitoring and indeed sensing in these kind of large environments. Cabled equipment means little flexibility in placement and is very expensive in both money and effort whenever reorganization or new installation is needed. So, when cabling is not really needed for performance reasons wireless monitoring and control is a good option, due to the speed of implementation. There are several wireless flavors to choose, as Bluetooth, Zigbee, WiFi, etc. depending on the requirements of each specific application. In this work a wireless monitoring system for EPICS is presented. The desired control system variables are acquired over the network and published in a mobile device, allowing the operator to check process variables everywhere the signal spreads. In this approach, a Python based server will be continuously getting EPICS Process Variables via Channel Access protocol and sending them through a WiFi standard 802.11 network using ICE middleware. ICE is a toolkit oriented to build distributed applications. Finally, the mobile device will read the data and show it to the operator. The security of the communication can be improved by means of a weak wireless signal, following the same idea as in NFC, but for more large distances. With this approach, local monitoring and control applications, as for example a vacuum control system for several pumps, are currently implemented.

INTRODUCTION

Reliable, fast and secure communications must be assured in every place of a large scientific facility, even more when large amount of data is involved due to the rapid development of computing and electronics devices. Cables are often irreplaceable, but when they are not really needed for performance reasons, wireless is a suitable option for monitoring and control due to the numerous advantages it offers: flexibility, mobility, scalability, reduced costs and ease of maintenance.

Different wireless solutions can be found in the market. The most widely used band for industrial and scientific purposes is the ISM band. Inside this, ZigBee [1], Bluetooth [2] and WiFi can be found. The EEE 802.11 standard for WLAN, WiFi, is a very flexible technology, easy to implement, cheap and which provides a wide bandwidth. For these reasons, it has been implemented in large-scale systems, as presented in [3].

*Work funded by ESS Bilbao Consortium
#ibadillo@essbilbao.org

However, the radio waves used in wireless networks create a risk where the network can be hacked, making system vulnerable to threats as denial of service, spoofing or eavesdropping. These issues make mandatory the implementation of security mechanisms to minimize this drawback in industrial uses as SSL/TLS protocols and a proper architecture. In [4] an improved security mechanism is studied.

The goal of the present work is to build a secure and reliable human machine interface system for data monitoring purposes in a large scientific facility, based on a idea similar to Near Field Communication (NFC) but adapted to industrial needs. NFC offers a great security against external attacks since the signal makes physically inaccessible outside the range of transmission, so data exchange can only be made inside a limited radius.

The main disadvantage of this protocol for the present goal, is that the transmission distance, 4 cm or less [5], is insufficient for monitoring and control purposes.

In consequence, the proposed approach uses a limited field communication scheme, with WiFi technology and limiting the signal power to avoid external intrusions depending on the particular characteristics of each application.

In the presented schema, a distributed environment based on a TCP/IP network is considered, where an Experimental and Industrial Control System (EPICS) control network is implemented, [6]. The system sends the desired data over the WiFi network and publishes it in an Android based mobile device, which must be located inside the wireless physical transmission range. Two-way communication will allow not only monitoring, but also changing signal values, for example to turn on/of a certain device.

The idea has been implemented for monitoring the vacuum control system of a negative ion source.

PROPOSED APPROACH

When designing a wireless communication system, security becomes critical, even more when talking about large scientific facilities. In these environments, such as ion sources and particle accelerators, intrusions may result in harmful or even disastrous situations due to the large amount of power involved in equipment consumption. In order to avoid undesired failures or data losses, developers of wireless standards incorporate a large variety of security related features in the protocols. Two of the most commonly used tools is message encryption and node verification. This is used in order to maintain

data integrity, prevent interception of the transmitted data between nodes of the network and avoid spoofing.

Another way to provide security to a wireless network, related to its architecture, is to adjust the transmit-power level to control signal spillage beyond the plant walls. If the radio signal is "invisible" beyond the limits of the facility, it becomes very difficult to steal or intercept the signal. That means a physical security against attacks, independently from the software security mechanism that will be implemented.

This idea is represented in Figure 1, where the mobile device located outside the transmission range cannot reach the wireless signal, therefore it is impossible to access information. It also allows to spread signals only in certain areas of the facility depending on the authorization level. So, a limited field communication approach can lead to a secure installation, limiting the transmission power accordingly to the characteristics of each area.

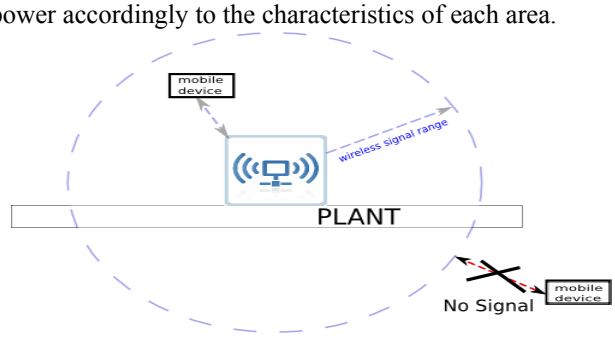

Figure 1: Security based on adjusting transmit-power level.

PROPOSED APPROACH IMPLEMENTATION

Large scientific facilities are complex distributed systems where important amounts of data must be processed and different control devices must be integrated. In this context, as every element might have independent behavior, a middleware distributing messages, commands signals and/or requirements over the net and between elements can be very helpful.

Nowadays, a large number of scientific facilities are being built using EPICS as middleware layer. Its wide usage, makes this solution very scalable. In fact, many vendors incorporate EPICS drivers in their products. Moreover, if a custom device is needed, in house development is also possible. This is the main control system used in the present limited field communication application.

On the other hand, the reduction in production cost of electronic devices and new technologies during last years has open a new market for mobile devices, such as tablets. In a large facility, a small and light computing device, with resources for networking environment, can help the operator in a lot of ways in both the usual operation and maintenance tasks. In this sense, Android based tablet has been chosen as mobile monitoring device, since its popularity and availability of many IDE environments make easy the development of custom applications.

Finally, as no libraries of EPICS for Android are available (unlike for iOS[7]), the use of the ICE middleware [8] is needed to integrate such different environments. It provides libraries for many programming languages, but, in addition to this, network security issues are a key issue of its functionalities.

The main characteristics of these technologies are summarized in the following paragraphs:

- EPICS: It is a control solution based on middleware approach, oriented to distributed control systems. It is used worldwide to create soft real time control systems specially for large scientific facilities as particle accelerators and telescopes. EPICS can be defined as an architecture for building scalable control systems, a collection of tools and codes made collaboratively between major science labs and industry. It is free and reliable and it is being more and more chosen to implement control systems in strategical projects as ITER (International Thermonuclear Experimental Reactor) or ESS (European Spallation Source). That eases feedback between developers in order to improve it. As mentioned before, the proposed networked control system architecture is based on a TCP network due to its advantages in cost and easy integration. But this protocol has non-deterministic characteristics, which makes difficult its use in control systems. The use of EPICS minimizes these disadvantages. Several EPICS controllers (IOCs) are spread along the facility, associated to different devices: sensors, DAQ systems and so on. These IOCs communicate among themselves and share information (Process Variables or PVs) using a protocol called Channel Access (CA) over a TCP/IP standard network. There are several security related mechanisms in EPICS, from among which highlights the EPICS Gateway. It is both a CA server and client and allows to separate the EPICS network from the network it is accessing from.
- ICE (Internet Communications Engine): This is an object-oriented toolkit for building distributed applications, heir of CORBA. It allows to communicate two or more applications of very different nature (operative systems, programming languages...). ICE offers different solutions for security, as encrypted communications and authentication through SSL, which is supported in all of the ICE language bindings.
- Android: Android is a mobile operative system based upon a modified version of the Linux kernel. Since the computing power of the mobile devices is quickly increasing and the price is reducing, its usage is fast spreading in different fields as industrial and scientific facilities [9]. Android is one of the leading OS for this kind of devices and it is updating and

adding services day by day, offering to the developers a huge number of tools to create any types of applications. The monitoring application is developed on an Android platform.

Implemented Architecture

In the implemented schema, a Python based server is used as a "bridge" between EPICS and the Android mobile device. This server program acquires the EPICS Process Variables over the network using the EpicsCA library [10], which provides methods for reading/writing PVs from Python via CA protocol. Moreover, the program organizes the captured PVs in a proper structure to ensure a good throughput and initializes the ICE host application. It creates the ICE object that responds to the client requests.

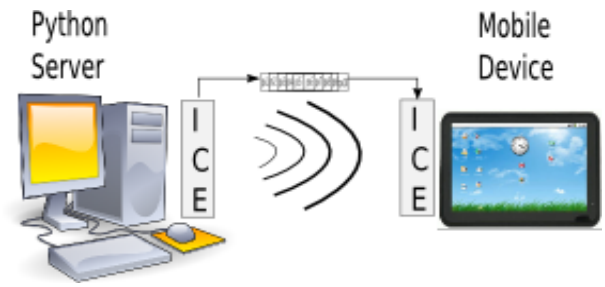

Figure 2: Client/Server communication using the ICE middleware.

Finally, the client is running in an Android mobile device. This application, written in Java, creates a proxy to connect to the object located in the server and invokes the needed operations to request the data. Once the data is obtained, the user interface displays the desired information to the operator. The Figure 2 shows a visual representation of the implemented schema.

SAMPLE APPLICATION: ISHN VACUUM SYSTEM MONITORING AND CONTROL

The presented application is intended to be used on a large scientific facility, to ease the task of the operators during normal operation and in maintenance stages. The main idea is to allow them to control and monitor the main variables of a vacuum system wherever they are inside the spread radius, depending on the transmission power. This fact allows to avoid the dependence of a central computer. Specifically, it has been designed to monitor the vacuum control system of the ISHN (Ion Source Hydrogen Negative) project at ESSBilbao, [11].

ISHN project consists of a Penning type ion source which will deliver up to 65mA of H− beam to a linear accelerator, which finishes generating neutrons by means of spallation process (currently under design). Apart from main devices for managing the ion source, for instance power supplies for plasma generation and hydrogen feed system, the vacuum system in considered a critical system of the project. For the ion source operation, a pressure value in the order of 10^{-6} mbar is required. Any failure could cause dramatic accident, due to the high voltage values needed for operation (several kilovolts), because a vacuum loss could cause high voltage breakdown.

In order to reach the desired vacuum level two mechanical and two turbo pumps are used. Their control system is isolated from the local control of the ion source, except for some interlock and emergency signals. There are managed by a PLC from Schneider, which reads all the signals involved in the operation of the pumps, such as rotation frequency, pressure level, status, etc. A Modbus TCP/IP server publishes all of these variables, and some of them can be accessed in both write and read mode.

An EPICS IOC accesses all of the data by Modbus TCP/IP calls [12], which acts as a wrapper for Twido communication. Even if Modbus communication is present, any call to vacuum system can only be done through EPICS, ensuring that capabilities offered by EPICS are always met.

In such configuration, the devices controlled with EPICS are two mechanical pumps, two turbo pumps, a vacuum sensor and two vacuum gates.

The application for Android has been developed in Eclipse using the ADT (Android Development Tools) and tested on the emulator provided on the Android SDK [13]. The program has been written for the API Level 12 (Android 3.1), compatible with all the newer version and APIs. All the libraries used in the project are provided with the ADT, except the ICE specific ones and those used to build the XY plots. These last were imported from the "androidplot" project [14], which offers a pure Java API for creating dynamic and static charts within Android applications.

The GUI shows a text box where the user must enter the IP to connect to and a "connect" button. Most of the variables are booleans as on/off, alarm status etc., so they will be displayed using a widget that emulates a led, as shown in Figure 3. The analog signals, as rotation frequency of the turbo pumps or temperatures, are represented as a waveform chart which refreshes itself dynamically.

CONCLUSION

In this work, the use of wireless communications for monitoring and sensing in large industrial and scientific facilities has been discussed, proposing a limited field communication approach. In addition, a particular application of this technology has been presented. The advantages of wireless devices make this technology an interesting alternative to common wired and fixed monitoring stations. However, as long as wireless communications are involved, security becomes critical. Adjusting transmission power allows to spread the signal only in the desired radius, avoiding external attacks. A good mechanism limiting the transmission power depending on the application characteristics is also necessary.

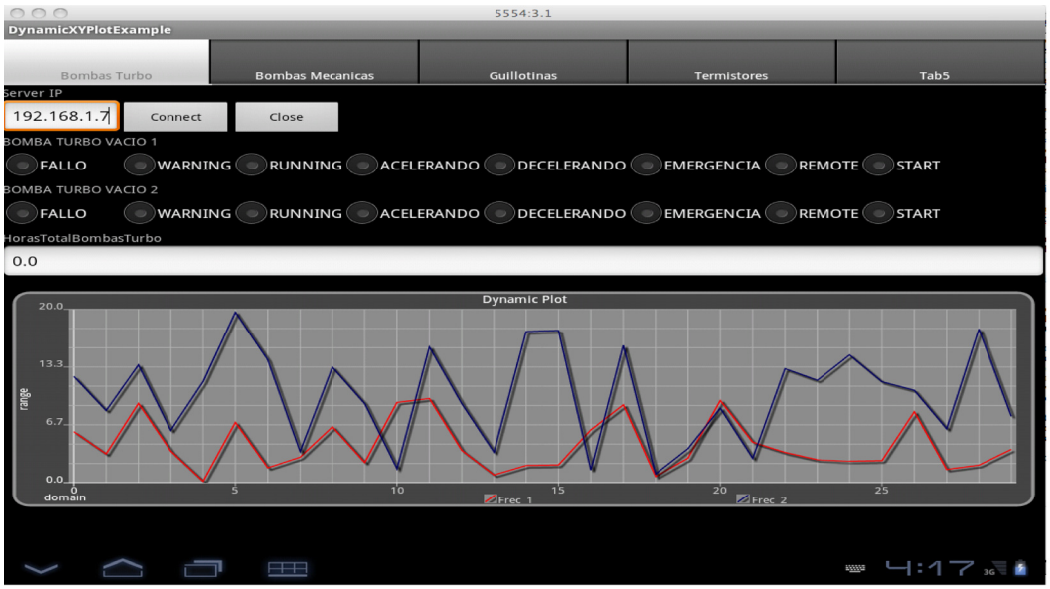

Figure 3: GUI of the Android application.

In particular, EPICS network distributed applications, which involve very heterogeneous environments, take advantage of the simplicity and capabilities of ICE toolkit and the versatility of Android based devices for LFC implementations.

The main purpose of the future work is to implement encrypted communications and authentication through SSL protocol. There is also projected to integrate the EPICS monitor system in a Python based server, to avoid polling in order to improve the overall throughput.

It is worth noting that the presented application will be implemented in the ESS Bilbao project for a real usage and it is intended to extend its monitoring and control tasks to several systems apart from the vacuum control system of ISHN.

APERTURE METER FOR THE LARGE HADRON COLLIDER

G.J. Müller, K. Fuchsberger, S. Redaelli, CERN, Geneva, Switzerland

Abstract

The control of the high intensity beams of the CERN Large Hadron Collider (LHC) is particular challenging and requires a good modeling of the machine and monitoring of various machine parameters. During operation it is crucial to ensure a minimal distance between the beam edge and the aperture of sensitive equipment, e.g. the superconducting magnets, which in all cases must be in the shadow of the collimator's that protect the machine. Possible dangerous situations must be detected as soon as possible. In order to provide the operator with information about the current machine bottlenecks an aperture meter application was developed based on the LHC online modeling toolchain. The calculation of available free aperture takes into account the best available optics and aperture model as well as the relevant beam measurements. This paper describes the design and integration of this application into the control environment and presents results of the usage in daily operation and from validation measurements.

INTRODUCTION

The LHC is running with outstanding performance [1], currently being operated with small emittances and above nominal bunch population (up to 1.4×10^{11} p). Beams with a stored energy of 110 MJ are brought in collision and produce peak luminosities up to 3.3×10^{33} cm^{-1}s^{-1}. This allows to deliver integrated luminosities topping 110 pb^{-1} per fill. Providing very good conditions for the experiments to accumulate collision data, the high energy beams impose a severe danger for the accelerator (especially the superconducting magnets) which has to be protected against beam loss induced damage.

A complex machine protection system is put in place [2], which prevents damage to the accelerator equipment by extracting the beams as soon as any of the safety systems (beam loss monitors, magnet current monitors, quench protection system, collimation system,...) detects potentially unsafe conditions. The knowledge of the available clearance around the circulating beams is of primary importance for machine protection in case of problems related to orbit and optics changes that can bring the beams too close to sensitive equipment. To help the operation team to detect critical conditions early on, an Aperture Meter was conceived and developed to monitor the machine aperture online. After introducing the concept of machine aperture, the design of the LHC Aperture Meter is presented and some first results from standard LHC physics fills and from aperture measurements are shown.

APERTURE DEFINITIONS

The definition of the mechanical aperture of each lattice element seen by the beam is referred to as aperture model of the machine. A continuous model that covers the 27 km of each of the two rings (B1/B2) is available for the LHC.

The concept of available clearance for the circulating beams is however more complex and requires taking into account other relevant machine and beam parameters in addition to the detailed knowledge of the aperture model. The main ingredients to evaluate the aperture in the two planes $z = [x, y]$ at a location s are (see illustration in Fig. 1):

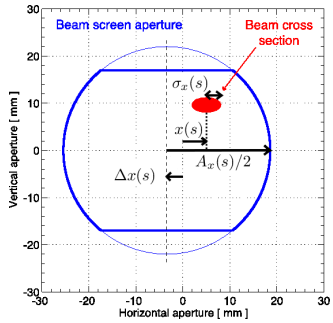

Figure 1: Beam screen aperture with relevant aperture definitions (horizontal plane)

a) mechanical aperture $A_z(s)$ from the design specification or calculated from the movable device positions;
b) offset $\Delta z(s)$ to take into account imperfections like misalignments of magnets (from cold bore measurements before installation) or to include the outcome of beam based alignments of the movable devices that will be described more in detail later on;
c) beam position $z(s)$ and transverse beam size $\sigma_z(s)$.

The minimal beam clearance or available aperture $a_z(s)$ is calculated per plane and defined as

$$a_z(s) = \frac{A_z(s)/2 - |z(s) - \Delta z(s)|}{\sigma_z(s)}$$

For convenience, the aperture is normalized to the transverse beam size $\sigma_z(s) = \sqrt{\beta_z(s)\epsilon_z^{design}}$, where we use the design emittance ϵ_z^{design} for the normalization. Thus the available aperture is expressed in terms of number of available design beam σ. The minimum normalized aperture $a_z^{min} = \min_s a_z(s)$ for each beam and plane is referred to as the aperture bottleneck, e.g. four bottlenecks exist for the LHC.

The method for calculation of the available aperture presented here is a simplified approach to estimate online the clearance for the beams. Information of the nominal machine (optics functions and the design aperture model) are merged with online measurements (movable device positions, beam position, beam energy and the state of the machine with respect to optics and beam trajectory configuration).

DATA PROCESSING

Operational Cycle

During the operation cycle [3] the LHC passes four static states of undefined length to reach physics conditions: i) *Injection* when beams are injected at 450 GeV, ii) *Flat-top* after the beams have been accelerated to the collision energy

of 3.5 TeV, iii) *Betatarget* when the optics have changed so that the β function at the interaction point (IP) is reduced from 11 m to currently 1.0 m β* and iv) *Physics* after the parallel separation at the IPs is collapsed to put the beams in collision. In these static states adjustments to the machine can be performed. Four states with pre-defined time duration exist as the transitions between them: a) the energy *Ramp* to *Flattop*, b) the *Squeeze* to *Betatarget* and c) *Collisions* to reach the *Physics* state. To perform the transition, setting functions with pre-defined length are loaded and executed in the hardware (e.g. power converters, collimator's,...). The `OnlineStateProvider`, provided by the online modeling toolchain (OMT) [4], is used in the aperture meter to determine the current state and time in the setting functions.

Beam Trajectory and Beam Size

The interpolation of beam position data measured by the beam position monitors (BPMs) to all machine elements is done by using the orbit interpolation with transfer matrices implemented in JMad, the JAVA API to MAD-X [4, 5]. A mechanism is provided that allows to define which monitors should be used for the interpolation. This feature is used to exclude BPM data that is flagged as bad reading by the data acquisition or data from BPMs that are excluded by the user. The `JMadOnlineService` of the OMT is used to provide the current machine state's optics functions to be used for the calculation of the transfer matrices. The current machine energy is provided in the service as well. Together with the available nominal β function it allows the calculation of the beam sizes.

Collimator's and Aperture Model

A sophisticated multi-staged collimation system is installed in the LHC for beam cleaning and to provide passive machine protection. Primary (TCP), secondary (TCS) and absorber collimator's (TCLA) are installed in the cleaning insertions of point 3 and 7. Tertiary (TCT) collimator's are installed in the IP regions to complete the collimator hierarchy and protect the triplet magnets. Special collimator's are installed in the injection and dump regions. The collimation hierarchy is defined such that TCPs are the closest to the beam, followed by the TCS, TCLA and TCT. This hierarchy ensures that beam cleaning losses are caught by collimator's only, protecting the superconducting magnets and other equipment. Dangerous conditions that are difficult to observe can develop as a combination of e.g. an orbit bump outside the collimator's and a beam impact at another location. These are not covered by the collimation system and would cause beam losses at the bump location sufficient to create damage – another reason for continuous aperture monitoring.

Collimator's generally have two jaws, controlled by very precise stepping motors, that are aligned around the beam during collimator alignment campaigns. Procedures are established [6] to determine the beam based collimator center. These alignments have to be performed at each static state in the operational cycle to produce the input for the collimator setting generation for the functional states of the operational cycle [7]. Based on these settings, the collimation system then follows the orbit (beam separation and crossing) and optics evolution in the operational cycle. The collimator jaws are aligned around the measured beam centers with the required jaw openings.

The online aperture model provided by the OMT [4] is an extension to the aperture model and calculates the mechanical aperture $A_z(s)$ from the measured collimator jaw positions. The discrepancy between the interpolated orbit in the collimator's during the alignment and the observed beam-based collimator center (the reference for the jaw movement) is taken into account with the offset $\Delta z(s)$. The following procedure is used to determine $\Delta z(s)$ for all collimator's and operational states: i) Establish a default monitor setting for the orbit interpolation module. ii) Interpolate the measured orbit at the time of the collimator alignment to the collimator positions. iii) Store the differences between interpolated orbit and measured beam based centers as $\Delta z(s)$ for the active state. For each alignment campaign performed at the static operational states, step ii) and iii) are repeated. During operation a mechanism is put in place that ensures that the correct offsets are loaded according to the current operational state. If a functional state is active, a linear interpolation to the current time in the setting functions is performed between the offsets of the two adjacent static state.

DESIGN AND FEATURES

The aperture meter application is split in a service and a GUI implementation. As the input data from the various sources is not synchronized, a `DataStore` is implemented in the service and filled independently with: beam sizes, simulated orbit and machine state from the `JMadOnlineService` (currently when triggered and changed data available), aperture data from the online aperture model (when movable device positions change) and measured beam positions (1 Hz) from the Orbit Feedback Service Unit. A `DataSynchronizer` is triggered every 3 s to collect all data from the `DataStore`, perform the orbit interpolation, calculate the available aperture at all elements and determine the five smallest values $a_{z,i}^{min}(s_i)$ of $a_z(s)$ per beam and plane in the machine. The whole data set is then published to all registered listeners like the GUI.

A logging mechanism is implemented, to save the data set to xml files. In playback mode the aperture meter can be used to load either complete aperture meter data sets or to drive the aperture meter with the information from logged orbit data (logging database or file). Additionally the JMad GUI can be started from the aperture meter to perform virtual trims on the knobs that have been imported by the `JMadOnlineService` as well as to change optics.

Various displays are provided in the GUI to visualize the aperture meter data. The main display, conceived as fixed display, is composed out of four minimal aperture evolution views like the one in Fig. 2, one for each beam/plane

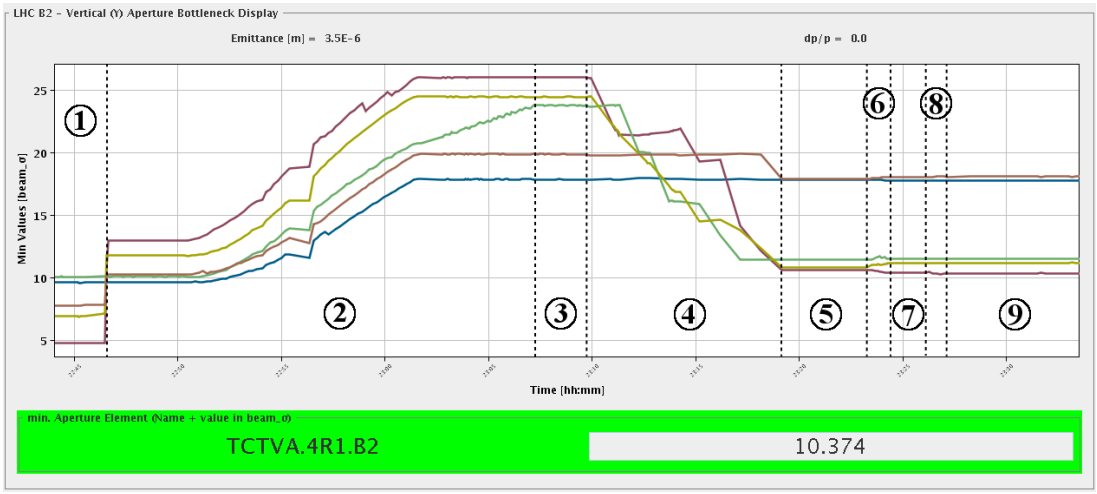

Figure 2: Minimal aperture evolution for beam 2 vertical plane over the operational cycle. The primary and secondary collimator positions are not taken into account.

combination. Each of these views shows the evolution of the available aperture $a_z(s)$ over time for the five locations (containing the bottleneck) in the machine having the smallest values $a_{z,i}^{min}(s_i,t)$ in the assigned beam/plane. Depending on the changes in the machine, the locations of $a_{z,i}^{min}(s_i,t)$ change. To broaden the provided information, only the element with the smallest value per assembly is selected during the minimal aperture determination.

MEASUREMENTS

Two examples for the visualization of the available aperture, calculated in the aperture meter, are presented in the following to demonstrate the functionality of the application.

Full Cycle of the LHC

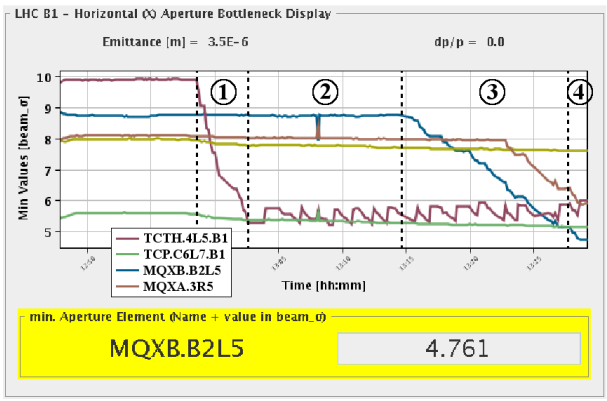
The evolution of $a_{z,i}^{min}(s_i,t)$, calculated by the aperture meter during the operation cycle of the LHC is shown in Fig. 2 for beam 2 in the vertical plane. To visualize the adjustments of the tertiary collimator's (TCT) during the operational cycle the primary (TCP) and secondary (TCS) collimator $a_z(s)$ information have been excluded from the selection of $a_{z,i}^{min}(s_i,t)$, they would be the dominant machine elements as they are the closest to the beam according to the collimator hierarchy. The cycle shown in Fig. 2 brings the beams into collision with no squeeze in IP2, squeeze to 3m in IP8 and to 1.5m in IP1 and IP5. The numbered segments represent the following operational steps: (1) Beam *Injection*, finalized by the retraction of the injection protection devices which can be observed by the step change at the end of the segment. Absorber collimator's (TCLA) in point 3 and 7 and the TCT collimator's in the vertical plane are the $a_{z,i}^{min}(s_i,t)$ locations afterwards. (2) Energy *Ramp* to 3.5 TeV. Caused by *adiabatic damping* the beam size shrinks with increasing beam energy, observable by the increasing $a_{z,i}^{min}(s_i,t)$. The sharp edges might be caused by orbit changes, but have to be investigated further. (3) *Flat-top*, const. $a_{z,i}^{min}(s_i,t)$ and prepare *Squeeze*. (4) *Squeeze*, the β function changes around the IPs and the TCTs are moved closer to the beam. (5) *Betatarget*, const. $a_{z,i}^{min}(s_i,t)$, prepare *Collisions*. (6) *Collisions*, parallel separation closed which can be observed by small changes in $a_{z,i}^{min}(s_i,t)$. In segments 7, 8, and 9 physics conditions are reached. Segment 8 shows marginal changes of $a_{z,i}^{min}(s_i,t)$ caused by luminosity scans. The transitions in the *Squeeze* are not smooth as the adjustment to changed optics takes $\approx 45s$.

Triplet Aperture Measurements

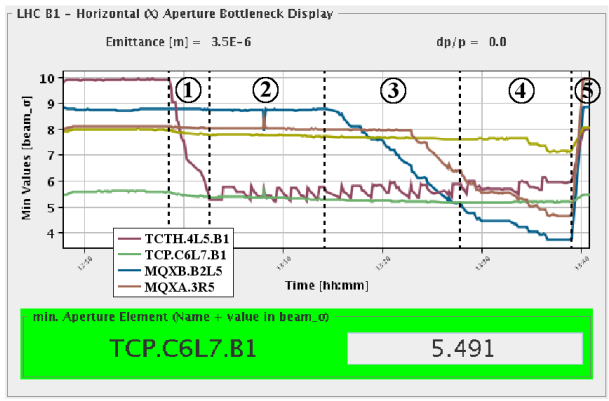
To check and verify the triplet aperture before operating at reduced β* (the extremal β-function in the interaction points) of 1.0 m, scans have been performed in the triplets by using the angle and separation scan knobs created for the luminosity optimization and leveling. These knobs are defined for both beams and have been trimmed simultaneously to create bump shapes comparable to the nominal crossing and separation. The following steps were performed during the scan:

a) increase the bump amplitude until one of the beams touches the corresponding tertiary collimator (TCT), observable by the created beam losses;
b) retract both TCTs left and right from the IR by 0.5 σ;
c) repeat steps (a),(b) until the triplet aperture is exposed, observable by larger loss spikes in the triplet magnets.

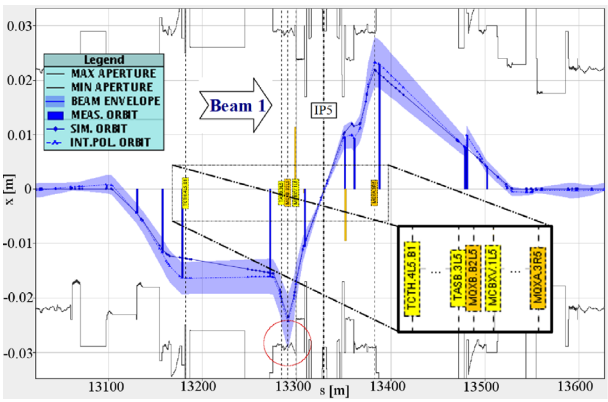
This procedure can be nicely observed by the aperture meter as shown in Fig. 3. The Figures 3a and 3b show the evolution of $a_{z,i}^{min}(s_i,t)$ during the scan. Figure 3a is an example how the bottleneck display notifies about $a_{z,i}^{min}(s_i,t)$ below the warning limits (currently set to 5.0 beam σ). The evolution plots show that under normal conditions the primary collimator (TCP.C6L7.B1) is the bottleneck a_x^{min} in the horizontal plane for beam 1. When the scan is started (1) the TCT is moved towards the beam until it becomes a_x^{min}. The approach of the aperture with the scan according to step (c) can be observed in (2) without any impact on the $a_{z,i}^{min}(s_i,t)$ except for the moving TCT. In (3) the two magnets of the triplets right and left of the IP appear in



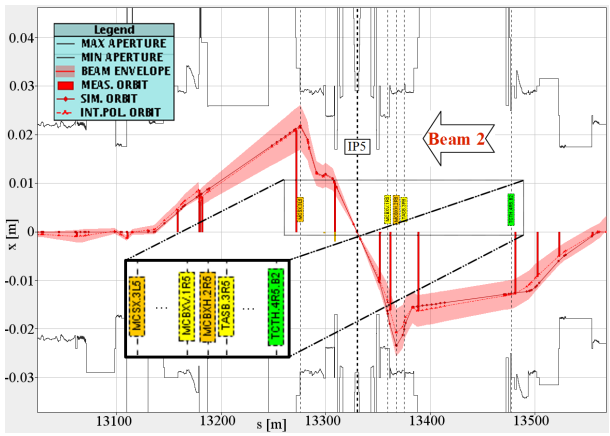
(a) Minimal Aperture Evolution: Triplet Exposed.



(b) Minimal Aperture Evolution: Full Aperture Scan.



(c) Beam 1 display: Max. Hor. Bump.



(d) Beam 2 display: Max. Hor. Bump.

Figure 3: Horizontal triplet aperture scan in IP5 (CMS) at 1.5m β*

$a_{z,i}^{min}(s_i,t)$. The magnet MQXB.B2L5 of the triplet right from the IP becomes a_x^{min} in (4) and the beam is gradually moved closer, reducing a_x^{min}. Finally the triplet is exposed, observed by the created losses. In (5) the collimator's are moved out and the scan knob is trimmed back to zero, to remove the orbit bump and recover nominal operational conditions.

Figures 3c and 3d are the beam views of the aperture meter at the maximum bump excursion achieved during the horizontal scan performed in IP5 (CMS). The simulated, measured and interpolated orbit is plotted in the visualization of the mechanical aperture model. A 3 σ beam envelope is added to the interpolated orbit. The result in the aperture meter (beam envelope touches aperture of MQXB.B2L5 – red circle in Fig. 3c) agrees with the beam loss observations during the scan.

CONCLUSION AND OUTLOOK

The principles for minimal aperture calculation and the design of the aperture meter application have been presented. A first implementation is available for operation and has been especially useful for aperture measurements. Validation is ongoing to determine the accuracy of the calculation results. Further work has to be devoted to optimize the configuration of the system and to improve the visualization and playback features.

STABILIZATION AND POSITIONING OF CLIC QUADRUPOLE MAGNETS WITH SUB-NANOMETRE RESOLUTION*

Stef Janssens†, Kurt Artoos, Christophe Collette, Marco Esposito, Pablo Fernandez Carmona, Michael Guinchard, Claude Hauviller, Andrey Kuzmin, Raphael Leuxe, Raul Moron Ballester, CERN, Geneva, Switzerland

Abstract

To reach the required luminosity at the CLIC interaction point, about 2000 quadrupoles along each linear collider are needed to obtain a vertical beam size of 1 nm at the interaction point. Active mechanical stabilization is required to limit the vibrations of the magnetic axis to the nanometre level in a frequency range from 1 to 100 Hz. The approach of a stiff actuator support was chosen to isolate from ground motion and technical vibrations acting directly on the quadrupoles. The actuators can also reposition the quadrupoles between beam pulses with nanometre resolution. A first conceptual design of the active stabilization and nano positioning based on the stiff support and seismometers was validated in models and experimentally demonstrated on test benches. Lessons learnt from the test benches and information from integrated luminosity simulations using measured stabilization transfer functions lead to improvements of the actuating support, the sensors used and the system controller. The controller electronics were customized to improve performance and to reduce cost, size and power consumption. The outcome of this R&D is implemented in the design of the first prototype of a stabilized CLIC quadrupole magnet.

INTRODUCTION

In CLIC, electrons and positrons are accelerated in two linear accelerators to collide at the interaction point with an energy up to 3 TeV [1]. In order to reach the required luminosity – a measure of collision brightness – the beam size in the interaction point needs to be 1 nm in the vertical plane and 45 nm in the horizontal plane. This small beam size is achieved by focusing the beam with about 4000 Main Beam Quadrupoles (MBQs) in the main beam accelerator. There are 4 types of quadrupoles ranging from Type 1 with a length of 420 mm (100 kg) up to Type 4 with a length of 1915 mm (400 kg). Each quadrupole offset in relation to the beam, causes the beam size to grow at the interaction point, reducing luminosity. Offsets are introduced through quadrupole misalignment, ground motion and external forces on the magnet due to water cooling in the magnet, tunnel ventilation, etc. The static misalignment of the quadrupoles is reduced by an alignment system based on eccentric cams [2]. Two main mitigation techniques are used to reduce the effect of quadrupole vibrations on the luminosity. The first mitigation technique uses beam-based orbit feedback which measures the position of the beam with Beam Position Monitors (BPMs) and redirects it with dipole magnets. An alternate solution would be to reposition some of the quadrupoles between pulses (every 20 ms) to the nanometre level. The beam-based orbit feedback reduces the effect of the quadrupole's vibrations on the luminosity under 1 Hz and at multiples of the repetition rate of the beam (50 Hz).

The second technique reduces the vibrations of the quadrupole locally for each quadrupole by means of an active stabilization system which, along with the nano-positioning, is the subject of this paper. From beam dynamics simulations, a first estimate was made whereby the integrated root mean square (r.m.s.) for the power spectral density of the vibrations should not exceed 1.5 nm at 1 Hz vertically and 5 nm at 1 Hz laterally [3]. A vibration isolation system based on stiff piezo actuators has already been built, using commercial seismometers, reaching the required level [3][4]. This paper presents the existing and improved control systems for stabilization and positioning, their effect on the mechanical system and the influence of the accelerator environment on the global control scheme. Firstly, the configuration of the original stabilization controller based on the seismometer, a new system using an inertial reference mass as well as the controller for the positioning system is explained. Secondly, the constraints on the mechanical design due to the chosen control system are defined. Thirdly, the effect of the accelerator environment on the global control scheme and its lay out are described. Finally, the achievements of the different controller layouts in terms of the stabilization system's transmissibilities are revealed.

VIBRATION ISOLATION AND POSITION CONTROL SYSTEM

A stiff system based on piezo actuators was selected for the stabilization and positioning of the quadrupoles due to the expected external forces on the quadrupole magnet coming from the accelerator environment (tunnel ventilation, water cooling, interconnections of vacuum tubes,etc.). The quadrupole on the piezo actuators is represented as a 1 degree of freedom system (see Fig. 1). The equation of motion in the Laplace domain is given by

$$X(s) = \frac{k}{ms^2+k}W(s) + \frac{1}{ms^2+k}F(s) + \frac{k}{ms^2+k}\Delta(s) \quad (1)$$

with m being the mass of the quadrupole, k the spring stiffness of the active support and F the forces induced on the

* The research leading to these results has received funding from the European Commission under the FP7 Research Infrastructures project EuCARD, grant agreement no.227579

† Stef.marten.johan.janssens@cern.ch

magnet by water cooling and other direct forces. The variable Δ represents the elongation of the actuators depending on the controller used. The different control configurations are described in the following paragraphs.

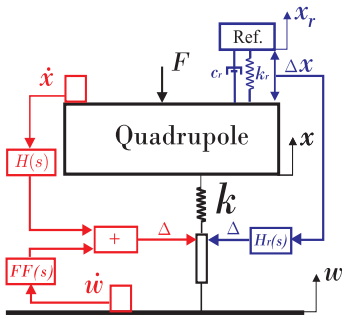

Figure 1: Schematic representation of an active isolation system with a piezo actuator.

Seismometer

The existing vibration isolation system uses commercial seismometers which measure the velocity of a magnetic reference mass with a coil. They have a bandwidth between 33 mHz and 100 Hz limited by several high order filters and are used in a feedforward/feedback configuration to reduce the vibration of the quadrupole. The elongation of the actuators is given by $\Delta = H(s)sX(s) + FF(s)sW(s)$. The feedback controller H(s) includes an integrator, a double lag to limit the bandwidth, a high-pass filter and the sensitivity curve of the seismometer. The feedforward controller FF(s) consists of a high and low-pass filter, an integrator and the seismometer sensitivity. The control system's main limitation is the feedback loop's instability caused by one set of poles coming from a high-order low-pass filter in the seismometer.

Inertial Reference Mass

A new sensor is under development which uses the relative displacement Δx between a reference mass ($X_r(s)$), with a suspension frequency of 1 Hz and a damping ratio $\xi_r = 30$ % achieved by actively damping the system, and the quadrupole position ($X(s)$) (see Fig. 1). This sensor will improve the stability of the controller as the additional poles of the seismometer are removed. Using a capacitive gauge or optical sensor as a measurement device in the inertial reference mass, allows it to be more suitable for an accelerator environment with stray magnetic fields than a seismometer using a coil. The elongation of the actuator for this configuration is given by $\Delta = -H_r(s)(X(s) - X_r(s)) = -H_r(s)X(s)(1 - G_r(s))$ with $G_r(s) = \frac{X_r(s)}{X(s)} = \frac{c_r s + k_r}{m_r s^2 + c_r s + k_r}$. The sensitivity curve looks like an under-damped high-pass filter.

Nano-Position Control

The nano-positioning is performed by a controller using the error ($e(s)$) between the requested quadrupole position ($R(s)$) and the actual relative quadrupole position ($Y(s) = X(s) - W(s)$). The actuator elongation is then given by $\Delta(s) = C(s)e(s)$. The controller $C(s)$ consists of a Proportional-Integral Controller (PI Controller). The limitation of the controller comes from the pole of the first mode of the system. In order to increase stability, a low-pass filter at 40 Hz is added.

MECHANICAL DESIGN CONSTRAINTS

The main limitations for the three different control systems come from instabilities in the feedback loop. The maximum performance of a feedback system is a function of the maximum feedback gain g at which the feedback loop becomes unstable. The margin of the actual gain to this maximum gain is called the Gain Margin (GM). The GM of the system is influenced by the poles related to the first mechanical mode in the system. In order to define the minimal mechanical characteristics of the system, the GM of the controllers with a fixed gain ($g = 10$ for the stabilization and $g = 105$ for the positioning) is set out to a range of first modes ($f_1 = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$) in Fig. 2.

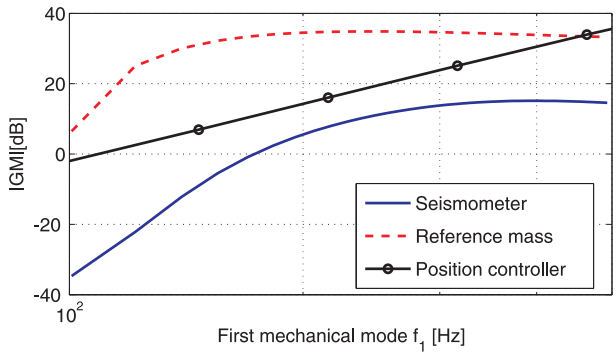

Figure 2: Stability margins for a vibration isolation system with a seismometer, a reference mass and the positioning controller, all with a fixed gain, in function of the first mode of the system.

It shows that the control system with the inertial reference mass has a higher gain margin than the commercial seismometer. Further, for both the inertial mass and the nano-positioning, the first mode should only be higher than 120 Hz in order to have sufficient performance in comparison to 250 Hz for the commercial seismometer. This input from the control system has been taken into account for the mechanical design in the form of an xy-guidance system to increase stiffness in the lateral direction [4] and puts requirements on the design of the alignment system on which the stabilization system will be mounted.

CONSTRAINTS ON GLOBAL THE CONTROL SCHEME

Working in a long linear particle accelerator brings its own set of challenges to the global control scheme for the local stabilization and position controller. The control centre is located kilometres away from the magnets that need

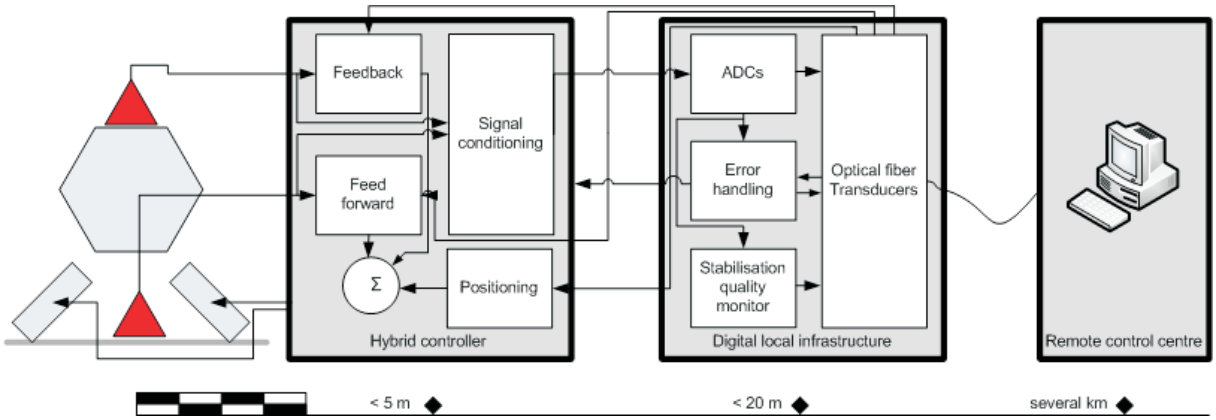

Figure 3: System level description of stabilization controller within CLIC control.

to be stabilized and positioned. It was demonstrated that the phase shift introduced by such a long communication path would be disastrous for the performance of the stabilization controller even when optical fibres are used [6]. To this end, the signals going into and coming out of the global control system are divided between delay critical and best effort delay signals (see Table 1). The signals for the stabilization and positioning controllers are time critical. This limits the distance allowed from the magnet to these controllers. However, the tunnel is an electromagnetically noisy environment and the sensor cables are a weak link. At the same time, putting the electronics closer to the magnet increases the radiation exposure. As a compromise, the stabilization and position controllers are put in a hybrid controller at a distance from the magnet in the order of metres as is shown in Figure 3. The final location will depend on civil engineering constraints. The hybrid mixed-signal electronic board is described in Ref. [5]. It is based on a low noise analogue circuit filtering, shaping, processing and generating the relevant control signals ($\dot{x}$ or Δx,$\dot{w}$ and Δ), and a digital part for the configuration of controller parameters (gain g, filter limits,...). A hybrid solution was chosen over a more classical digital construction using ADCs and DSPs or FPGAs for a number of reasons. ADCs with a resolution of at least 18 bits are required [6], which are not commercially available for radiation environments like CLIC. Latency was also shown critical for the stability and performance of the controller. To achieve the required delay, a very high sampling rate, without buffer, and hardware clock frequency is required. In addition, digital electronics are more sensitive to radiation, especially single events, than analogue electronics. The analogue cumulative errors are worse than those of a digital system but they can be partially compensated by gain corrections. All analogue components are chosen to have low noise and especially a low 1/f corner frequency, as the signal bandwidth of interest starts at 100 mHz (tantalum capacitors, metal thin layer resistors, etc.). Additionally a custom integrated control board has a lower cost, less power consumption, and reduced volume compared to a classic digital platform.

The best-effort delay signals include position, configuration parameters and status. They are processed at a local digital infrastructure which communicates with the remote control centre kilometres away. Only best-effort delay can be expected as these signals need to travel the distance to the remote control centre so a delay is unavoidable which is not a problem as long as the delay is kept constant.

SIMULATIONS AND TEST RESULTS

The effect of the ground vibrations on luminosity depends on the transmissibility of the vibrations from the ground to the quadrupole, the shape of the ground motion at that location and the beam-based orbit feedback, which works only below 1 Hz and at multiples of 50 Hz. Simulations for the transmissibilities of the local vibration controller were performed for a 100 kg mass (Type 1 magnet) on top of two piezo actuators resulting in a natural frequency of around 300 Hz in the vertical direction. Several different local controller configurations were simulated with both commercial seismometers and inertial reference mass (see Fig. 4). These seismometers were used in a feedback and feedback combined with feedforward configuration. The latter was tested on a prototype test bench, using a prototype of the hybrid controller, performing very close to the simulations. The transmissibility of this configuration was included in luminosity simulations [8] which showed that the peak at 80 Hz is undesirable as this is a location where the beam-based orbit feedback does not perform well. Using the reference mass reduces the performance locally at 7 Hz but gives a broader bandwidth as well as re-

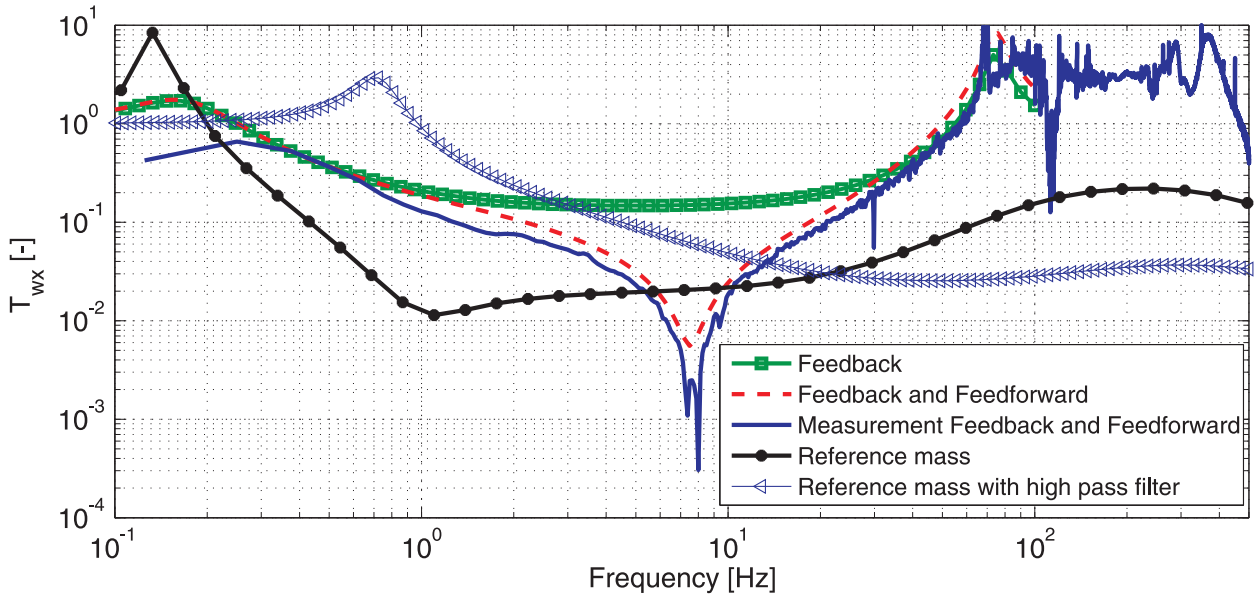

Figure 4: Transmissibilities between ground and quadrupole for the theoretical and measured feedforward combined with feedback system using a seismometer and the feedback using an inertial reference mass.

moving the unwanted peak at around 80 Hz. However, this configuration has a peak at around 0.2 Hz coinciding with the high ground motion due to incoming sea waves known as the micro seismic peak. Including a high-pass filter in order to move the low frequency peak away from the micro seismic peak resolves the problem. The transmissibility for this system also tested in a simulation of the whole accelerator including other mitigation techniques (beam-based feedback, etc.) with a ground motion model corresponding to the vibrations expected in the CLIC tunnel. It was found that the reference mass with the high pass filter gave the best performance reducing the luminosity loss from 68% to only 3 % although it is not the highest performing stabilization system at lower frequencies [7]. This shows that the interaction with the other mitigation techniques and local vibration levels are an important factor in defining the controller for stabilizing CLIC's main beam quadrupoles.

CONCLUSIONS

This paper has shown the effect of the different control systems on the mechanical system and the effect of the global control scheme due to the accelerator environment underlining that the first mechanical mode needs to be above 120 Hz for the position controller and if an inertial mass is used. The commercial geophones need a first mechanical mode higher than 250 Hz to keep it from destabilizing the stabilization controller in feedback configuration. Furthermore, the stabilization and position controller must be placed metres away from the magnet because of a performance drop due to latency and sensitivity to radiation and electromagnetic noise. The choice of a hybrid analogue/digital controller also contributes to reduce the latency. A digital connection was made which communicates with the remote control centre in order to keep some flexibility in the system for local changes in vibration levels and enable monitoring. A list of the interface signals was defined based on the critical delay and best-effort delay requirements. From beam simulations of the whole CLIC accelerator it was revealed that the shape of the stabilization controller is also defined by the interaction with the other mitigation techniques.

UPGRADE OF THE SERVER ARCHITECTURE FOR THE ACCELERATOR CONTROL SYSTEM AT THE HEIDELBERG ION THERAPY CENTER

J.M. Mosthaf*, K. Höppner, S. Hanke, S. Stumpf, A. Peters, T. Haberer
HIT, Heidelberg, Germany

Abstract

The Heidelberg Ion Therapy Center (HIT) is a heavy ion accelerator facility located at the Heidelberg university hospital and intended for cancer treatment with heavy ions and protons. It provides three treatment rooms for therapy of which two using horizontal beam nozzles are in clinical use and the unique gantry with a 360ï¿½ rotating beam port is currently under commissioning. The proprietary accelerator control system runs on several classical server machines, including a main control server, a database server running Oracle, a device settings modeling server (DSM) and several gateway servers for auxiliary system control. As the load on some of the main systems, especially the database and DSM servers, has become very high in terms of CPU and I/O load, a change to a more up to date blade server enclosure with four redundant blades and a 10Gbit internal network architecture has been decided. Due to budgetary reasons, this enclosure will at first only replace the main control, database and DSM servers and consolidate some of the services now running on auxiliary servers. The internal configurable network will improve the communication between servers and database. As all blades in the enclosure are configured identically, one dedicated spare blade is used to provide redundancy in case of hardware failure. Additionally we plan to use virtualization software to further improve redundancy and consolidate the services running on gateways and to make dynamic load balancing available to account for different performance needs e.g. in commissioning or therapy use of the accelerator.

THE HIT ACCELERATOR FACILITY

The Heidelberg Ion Therapy Centre (HIT) is a dedicated hadron accelerator facility for radio-therapeutical treatment of tumor patients [1, 2]. The two horizontally fixed treatment rooms as well as the gantry and experimental area (see Fig. 1) can be served in multiplexed operation with proton and carbon beams with qualified beam parameters (called MEFI, see Table 1), other ions like helium and oxygen have been tested.

The achieved energy range of 88-430 MeV/u for carbon ions and 48-221 MeV/u for protons is sufficient to reach a penetration depth of 20-300 mm in water. Patient treatment in the two horizontal treatment rooms is running at approximately 40 patients a day and the experimental area is used during night shifts. The gantry commissioning is ongoing and expected to finish in early 2012 [3, 4].

Gantry Angle	36	365	365

SERVER ARCHITECTURE OF THE HIT ACCELERATOR CONTROL SYSTEM

The accelerator control system of the HIT facility (Fig. 2) was planned around several classical servers comprising the main ACS servers and the gateway and secondary servers [5, 6]. At the time of conception, this was the most practical way to limit negative influence of secondary systems and DSM calculations on the accelerator cycle.

Original ACS Servers

The original main ACS servers were housed inside two standard 19" racks together with secondary servers and gateways (see Fig. 3). A third 19" rack contains reserve servers and a network attached storage server (NAS) as well as a backup tape library. We used Fujitsu-Siemens TX100S2 and TX200S3 servers with dual core processors and 2 GB of memory running Windows Server 2003 and Oracle 9. This was deemed sufficient for the ACS and ran from 2005 through the commissioning of the facility until 2010 when gantry commissioning began in earnest. With the addition of the gantry angle as parameter for DSM calculations, the database tables for device data were filling rapidly. The addition of a second set of RAM data for de-

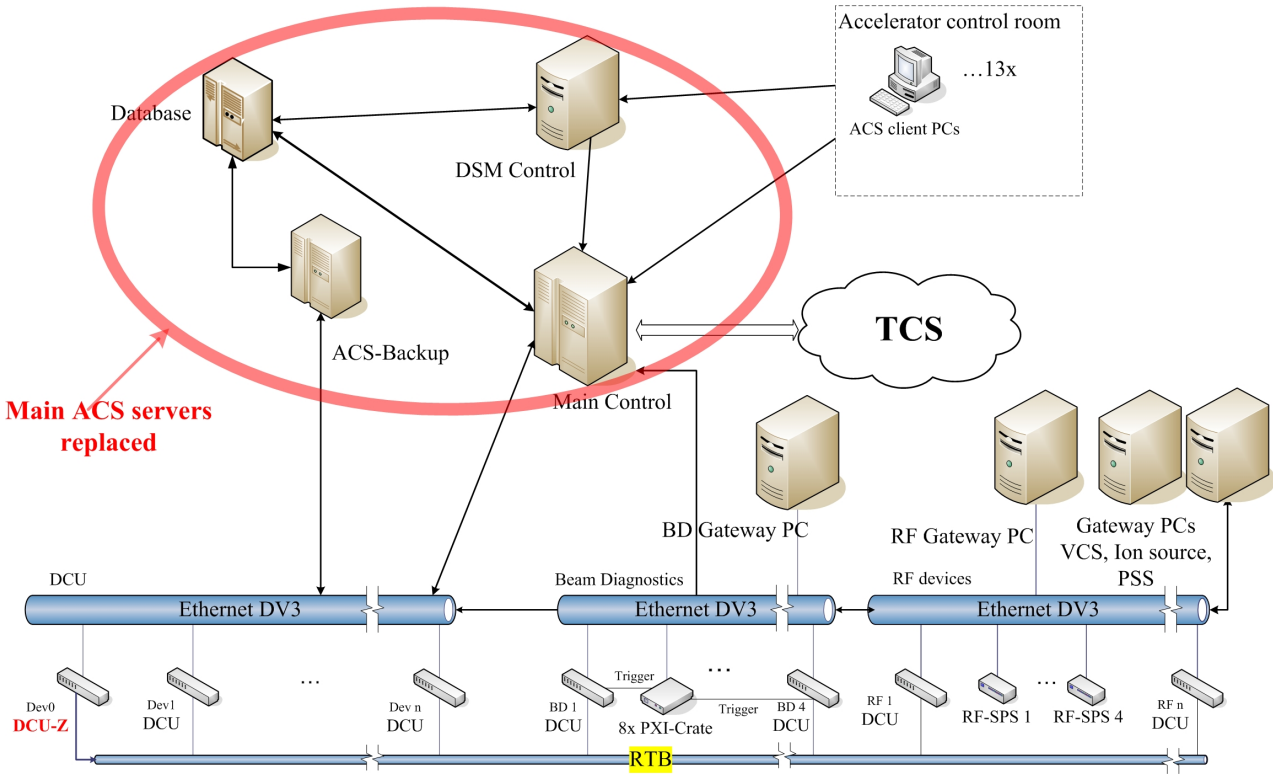

Figure 2: Server architecture and devices of the HIT accelerator control system with replaced servers shown.

vice control units to help in commissioning also strained the database. Underlying flaws in database design and configuration as well as limitations in CPU power, RAM and I/O speed reduced performance of operations and calculations of device settings. Regular statistic optimization and manual pruning were necessary to keep the database from choking.

Figure 3: One of the ACS 19" racks.

One complete interpolation of all gantry devices took between 4 and 6 hours per ion type. Downloading to the device control units (DCU) took more than 38 minutes and flashing took another 30 minutes. Cycle overhead (time between end of one beam cycle and start of a new one) was on average 1000 ms with a high spread. This proved to be an impediment mainly for commissioning of the gantry, but cycle performance was also an important consideration because of its influence on patient throughput. A performance analysis of the database system in cooperation with the industrial supplier of the control system (Eckelmann AG) and the GSI Helmholtzzentrum für Schwerionenforschung revealed issues in the database design as well as installation and configuration problems of the oracle server [7].

New Blade Servers

A part of the solution to these performance problems was a plan to replace the aging server structure with a new, state of the art blade center. Blade centers have several advantages over classical servers.

- High density - more processing power in less space
- Flexibility, modularity, and ease of upgrading - take out and add in server blades while the system is up and running
- Power consumption and power management - consolidation of power supplies and reduction of overall power consumption

- Network and other cabling - simplified cabling requirements and reduced wiring

- Load balancing and failover - blades have simpler and slimmer infrastructure and are designed for this task from the manufacturer

The disadvantages of blade centers are mainly high initial costs for the enclosure and vendor lock-in. To spread the costs over several budgets, it was decided to first replace only the main ACS servers more or less directly with blade servers and also procure the necessary infrastructure for further expansion. We started with one 16-space enclosure with redundant power supplies, management modules and dual Flex-10 10Gb/s Ethernet connections. Four identical blade servers with two 8-core CPUs, 24 GB of RAM and two internal HDDs and one storage blade with four HDDs in a RAID configuration are integrated into the enclosure (Fig. 4. The new database server, running Oracle 11 on Windows Server 2008, is connected to the storage blade and has a completely new configuration according to the tests and recommendations by GSI. All blades are interconnected and share the same power supply, management modules and network connection. After installation and configuration of the blade enclosure and the blade servers, the newest version of oracle 11g was installed on the designated database blade (blade 1 and storage blade) and the HIT ACS on the other servers. As planned, the second blade replaced the maincontrol server, the third blade the DSM and the fourth blade the ACS backup server. The third and fourth blade also double as backup blades in case of hardware failure.

Figure 4: The blade enclosure.

PERFORMANCE IMPROVEMENTS

Following the take-over of the new blade system for the old ACS servers, several measuring shifts were used to determine the performance gains. We compared pre-blade data of cycle times to several testing plans run in patient mode. These testing plans showed an average cycle overhead of 740 ms as opposed to ∼1000 ms. Scatter plots of cycle times before and after the server upgrade are shown in Figures 5 and 6. Red data points show cycles collected with the old servers, while green data points show cycles running with the new blade center. These points show a mix of different accelerator modes and so the decrease in average cycle overhead is not as pronounced.

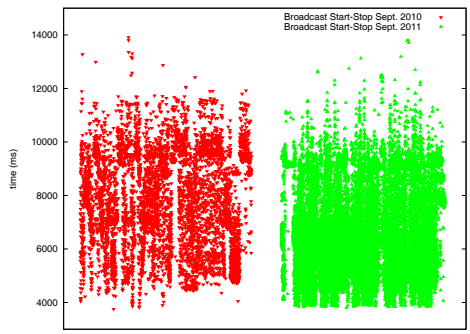

Figure 5: Scatter plot of cycle time.

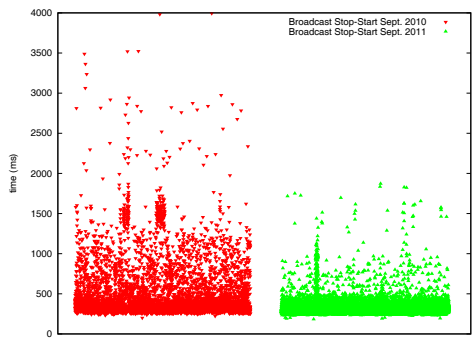

Figure 6: Scatter of cycle overhead.

The spread of the data points is smaller, especially in the cycle overhead graph. The better database performance results in less waiting time during cycle overhead and so reduces average overhead by approximately 30% in test plans. The average overall length of the cycle has been reduced also, while beam time is identical. The improvements in DSM calculation is very significant. As Table 2 shows, the interpolations and download have improved significantly.

Also very noticeable are the improvements in GUI performance. All GUI functions using database queries have been sped up by an appreciable amount. Most responses that took several seconds before, are now instantaneous. Only some functions, like reading and filtering longer log histories or loading data for therapy protocols, still take several seconds.

Table 2: Approximate Improvements with New Blade System

	Original	Blade	Gains
Interpolation (incl. gantry devices)	∼4–6 hrs.	∼1.5 hrs.	>200%
Download (per ion type)	∼40 mins.	∼10 mins.	∼400%
Flash (per ion type)	∼30 mins.	∼8 mins.	>250%
Avg. cycle overhead (with test plans)	∼1000 ms	∼740 ms	∼35%

CONCLUSIONS AND OUTLOOK

The performance gains with the new blade servers are substantial. The Table 2 shows great improvements in DSM computations and gains in operating are also significant. GUI performance is significantly improved and waiting times for database queries are vastly reduced. Even cycle overhead has shortened by a factor of ∼30% and is expected to improve more with new database enhancements. Redundancy is enhanced by the hot spare blade servers which are pre-configured to run all ACS services and by the dual Ethernet connection.

The next step in our upgrade will be to procure more blade servers and incorporate the auxiliary and gateway servers into the blade center. Also planned is a Storage Area Network (SAN) blade that will be connected to all blade servers via internal 10 Gb/s Ethernet and allows saving of server images and fast failover capabilities. More and dedicated hot spare blades will also bring more redundancy. We also plan on using virtualization software to run some of our servers with resource sharing and load balancing to better utilize our server resources to the fullest.

ACKNOWLEDGMENTS

The authors would like to thank Eckelmann AG for their support with the control system migration and testing and measuring of the cycle times as well as the GSI Helmholtzzentrum für Schwerionenforschung for their database performance analysis and their support with the database installation.

A DIGITAL BASE-BAND RF CONTROL SYSTEM*

M. Konrad†, U. Bonnes, C. Burandt, R. Eichhorn,
J. Enders, N. Pietralla, TU Darmstadt, Darmstadt, Germany

Abstract

The analog RF control system of the S-DALINAC has been replaced by a new digital system. The new hardware consists of an RF module and an FPGA board that have been developed in-house. A self-developed CPU implemented in the FPGA executing the control algorithm allows to change the algorithm without time-consuming synthesis. Another micro-controller connects the FPGA board to a standard PC server via CAN bus. This connection is used to adjust control parameters as well as to send commands from the RF control system to the cavity tuner power supplies. The PC runs Linux and an EPICS IOC. The latter is connected to the CAN bus with a device support that uses the SocketCAN network stack included in recent Linux kernels making the IOC independent of the CAN controller hardware. A diagnostic server streams signals from the FPGAs to clients on the network. Clients used for diagnosis include a software oscilloscope as well as a software spectrum analyzer. The parameters of the controllers can be changed with Control System Studio.

We will present the architecture of the RF control system as well as the functionality of its components from a control system developers point of view.

INTRODUCTION

The S-DALINAC is an 130 MeV recirculating electron linac that is operated in CW mode. It uses superconducting niobium cavities at 2 K with a loaded Q of $3 \cdot 10^7$ for acceleration. Their 20 cell design and the high operating frequency of 3 GHz make them very susceptible for microphonics. In addition, superconducting 2 and 5 cell capture cavities, one of them supporting acceleration at velocities $\beta < 1$, are used inside the injector.

Furthermore, room-temperature chopper and buncher cavities are operated. A new polarized electron injector has been assembled in the accelerator hall [1]. Its bunching system consists of a chopper cavity and a 3 GHz as well as a 6 GHz harmonic buncher. Therefore the RF control system has to deal with different loaded quality factors (Q_L) ranging from some 5000 to $3 \cdot 10^7$ as well as with different operating frequencies.

The target specification for the stability of the accelerating field is an error in phase of $0.7°$ rms and a relative error in amplitude of $8 \cdot 10^{-5}$ rms. Since the old analog RF control system never achieved these values and became more and more unreliable it has been replaced by the new digital RF control system last year.

* Work supported by DFG through CRC 634.
† konrad@ikp.tu-darmstadt.de

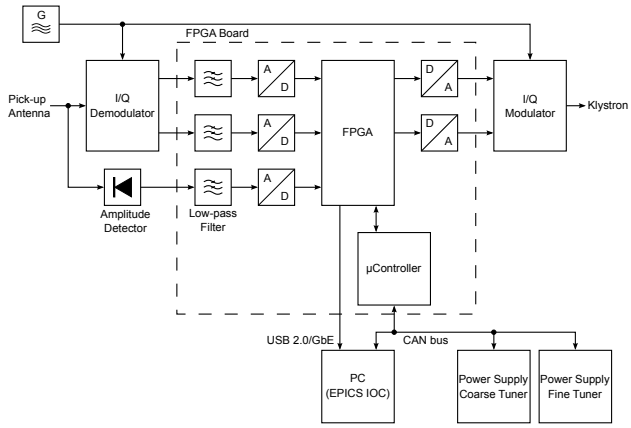

Figure 1: Overview over the hardware components of one channel of the RF control system.

CONTROLLER-BOARD HARDWARE

The RF control system converts the RF signals down to the base band. This allows to split the hardware into two parts: A frequency dependent RF board containing the I/Q (de)modulator and a frequency independent FPGA board processing the signals (see Fig. 1). All hardware components have been developed in-house. A separate power detector located on the RF board improves the accuracy of the magnitude measurement.

The analog signals are low-pass filtered on the FPGA board before they are digitized to avoid aliasing effects. The filters used for this purpose are third-order π filters with an edge frequency of $\approx$ 100 kHz. This filtering step is very important because the $19/20\,\pi$ mode of our 20 cell cavities is only separated by 700 kHz from the π mode used for acceleration. The chosen filter design ensures that the adjacent mode is suppressed by 55 dB while on the other hand the phase shift introduced by the filter is negligible for microphonic frequencies (up to 10 kHz).

High-linearity 18 bit ADCs are used to meet the specification in respect to accuracy. They run at their maximum sampling rate of 1 MS/s to keep the latency low and to allow the system to detect the signal of a detuned cavity operated in self-excited loop mode.

The FPGA used on the controller boards is a Xilinx Spartan 6 (XC6SLX45). Roughly 25% of its resources are used up to now leaving enough room for future extensions of the algorithm.

The requirements concerning the resolution of the DACs are not as high as for the ADCs. The DACs that are used on the FPGA board have a resolution of 16 bits and run with a frequency of 1 MS/s.

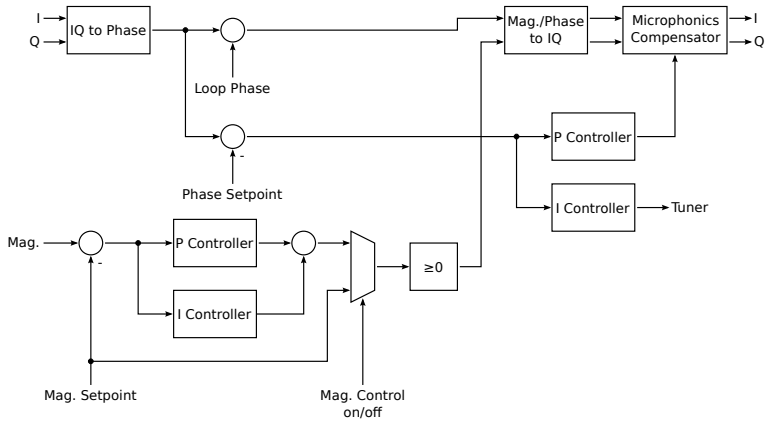

Figure 2: Simplified flow-chart of the self-excited loop control algorithm used with the superconducting cavities.

FPGA AND CONTROL ALGORITHM

The different Q_Ls of our cavities make different control algorithms necessary. The room-temperature copper resonators are operated with a generator-driven resonator (GDR) algorithm whereas for the superconducting cavities a self-excited loop (SEL) algorithm is better suited. Figure 2 shows a simplified flow-chart of the SEL control algorithm. In addition to simple operations like multiplication and adding operations it uses CORDIC blocks to transform from Cartesian coordinates (I and Q) to polar coordinates (magnitude and phase) and back [2]. For a more detailed description of the control algorithms see [3] and [4].

The control algorithm is implemented as a program for a self-developed soft CPU that is placed into the FPGA. The CPU is highly optimized for the implementation of RF control algorithms. Its arithmetic logic unit (ALU) uses 18 bit operands in order to fully exploit the accuracy of the ADCs. To keep things as simple as possible the instruction set is reduced to the operations needed for RF control algorithms. The CPU does not use complex memory access but only variable and parameter registers. Parameter registers are used for control parameters that are adjusted by the operator. They are read-only for the soft CPU but read/write for the micro-controller which connects the controller board to the PC. Variable registers used for intermediary results on the other hand are read-only for the micro-controller but read/write for the soft CPU. This concept together with a two-staged pipeline allows a high clock rate of 80 MHz. Complex operations like the conversion from Cartesian coordinates into polar coordinates and back are based on Xilinx CORDIC IP cores [5] that can be used from the CPU and that are pipelined as well (about 30 stages).

The CPU provides several 36 bit accumulating registers that can be used for the implementation of integral controllers. Only the 18 most significant bits are used for further processing but all 36 bits are considered for the accumulated sum. This allows integral controllers with time constants of roughly 1 s.

To avoid discontinuities all operations are available in a normal and a clipping variant. The latter clips the signal to the maximum/minimum 18 bit value if the result of an operation exceeds the range. The normal variant of the instructions is typically used for phase operations whereas the clipping variant is used for calculations with magnitude or I/Q values.

Using a soft CPU for the control algorithm has advantages in diagnostics because all variables (and thereby all intermediary results) are stored in fixed registers (block RAMs) where they can be read out easily. In particular there is no need for 18 bit data paths and huge multiplexers throughout the whole FPGA that would consume a great deal of the resources. In addition to this the soft CPU approach speeds up the development of the control algorithms. No time consuming synthesis of the Verilog code is necessary after the control algorithm has been changed. On the other hand the serial processing of the data reduces the performance. It turned out that for most practical purposes this penalty is small since the latency between ADC and DAC is determined mainly by the CORDIC blocks. The latency caused by the complete control algorithm is approximately 1 μs.

SLOW CONTROL

The controller boards are connected to a standard PC server via CAN bus. This interface is used to monitor and adjust all slowly varying (e. g. by user interaction) parameters of the control algorithm and the hardware. The micro-controller that connects the FPGA boards to the CAN bus runs Nut/OS, an open source real-time operating system providing cooperative multi-threading [6]. In addition to communicating with the PC it sends commands directly to the fine and coarse tuner power supplies via CAN bus. A three-step controller implemented in the micro-controller activates the motor tuner if the fine tuner approaches its limits.

The PC runs Linux and an EPICS IOC that is hooked up to the CAN bus via a device support that uses the SocketCAN network stack included in recent Linux kernels (since 2.6.25) [7]. SocketCAN provides access to the CAN bus

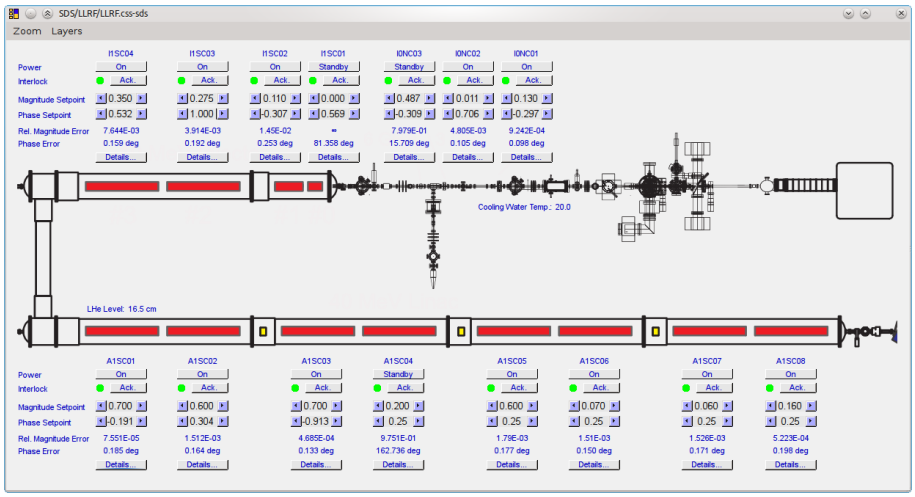

Figure 3: Screenshot of the main display of the RF control system's operator interface. It only provides the most frequently used controls and links to further displays for details.

via network devices (BSD sockets) which can be accessed by multiple applications at the same time (e. g. the IOC and a CAN sniffer). Furthermore it acts as an abstraction layer that makes the device support independent of a specific CAN card or hardware vendor (all CAN cards having a SocketCAN driver are supported).

All together the IOC provides several thousand records for all 16 RF channels. A great deal of them is related to diagnostics.

The operator interface has been implemented with Synoptic Display Studio [8]. Figure 3 shows a screenshot of a display providing an overview over all control loops and their most important controls. Further controls are available on control algorithm specific displays that contain all parameters for the selected controller.

DIAGNOSTICS

The FPGA boards provide fast diagnostic data via USB 2.0. Eight signals with a resolution of 16 bits are continuously transferred into the PC with the full sampling rate of 1 MS/s. The two least significant bits of the full 18 bit result are available as separate channels.

During operation eight controller boards are plugged into a crate together with a concentrator card. The concentrator card uses an FPGA to collect the data from the controller boards and streams the selected signals to the PC over its own USB 2.0 interface (cp. Fig. 4). Two crates can be coupled over a parallel LVDS interface. In this configuration one concentrator module acts as master and the other as slave. Signals from different controller boards and crates can be transferred at the same time.

In addition to the eight channels with full sampling rate the master concentrator card provides a stream of all 64 signals of all 16 controller boards on a second USB 2.0 interface. This data is transferred with a reduced sampling rate of 2 kHz and is intended for monitoring. Both USB data streams end at the PC where the IOC reads the data via a specially developed device support.

The data streams are forwarded by the diagnostic server process to the connected clients via TCP connections. Typical client applications include a software oscilloscope [9] that has been extended with a data source plug-in that reads data over the network from the IOC as well as a software spectrum analyzer [10]. Data recording is possible with standard Unix tools (e. g. netcat).

In addition to forwarding the stream of data the slow data stream is fed into EPICS records by the device support. It provides mean values of all signals every 0.1 s which can be used for monitoring.

Those values can be used to detect if a controller is out of lock but they do not provide precise information about the performance of the cavity and its controller. Even the oscilloscope view of the fast streaming data is not very helpful because it is difficult to see small changes in a noisy signal. A much more meaningful measure for the errors of the field in the cavity are the RMS errors of the magnitude and phase error signals. They could be calculated from the fast streaming data at the PC but this would be possible only for four cavities even if all eight diagnostic channels are sacrificed for this purpose. To cover all cavities while keeping the diagnostic channels free for the operator the RMS calculation has been moved partly into the FPGAs of the controller boards. They have the whole data stream available and can relieve the PC from processing work by carrying out the most time-consuming part of the calculation. The FPGAs calculate the square of the signals for each ADC sample and sum 2^{17} of them up which corresponds to a time of roughly 0.1 s. The result is transferred to the PC via CAN bus. The EPICS IOC calculates the square root of the sums and scales the values to finally get an error in degrees or a relative error in case of the magnitude respectively.

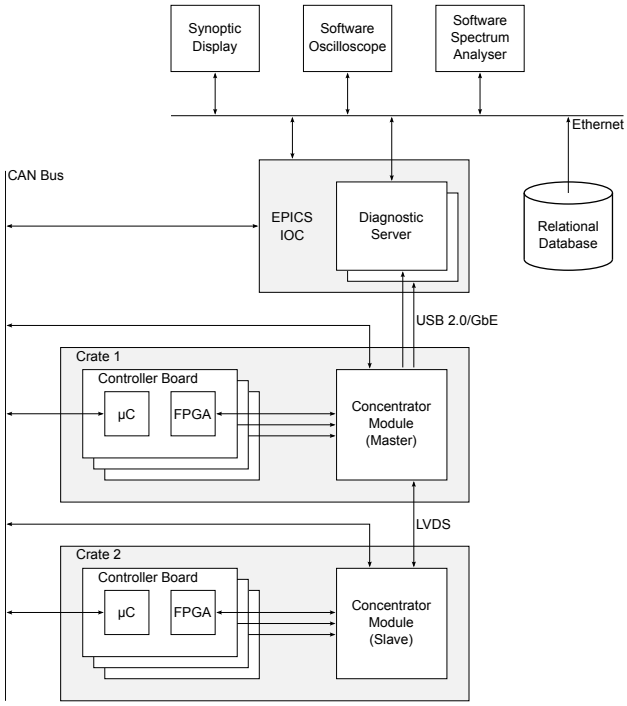

Figure 4: Data flow between controller boards, concentrator modules, diagnostic server and clients.

SOFTWARE AND FIRMWARE DEPLOYMENT

The RF control system has been put into operation as soon as the major components allowed stable operation. A lot of bug fixes and new features have been integrated since then. It turned out that the concept of continuous integration works best for us. It requires to recompile and deploy the software to the PC server and firmware to the microcontrollers and FPGAs frequently and – most important – in a repeatable fashion. This has been achieved by using the Debian Fully Automatic Installation (FAI) [11] to setup the PC server over the network. A virtual machine is used for testing to make sure all packages are installed cleanly before the production machine is reinstalled. To speed up the installation some software components are automatically build by a build server and distributed as Debian packages. This way changes can be deployed to the test or the production system within minutes. A complete installation of the server takes about 10 minutes. This means that downtimes of the accelerator of half an hour can be used to upgrade the complete RF control software. Updates of the IOC are possible even during operation because the controller boards run completely independent of the PC.

The IOC configuration is generated automatically from a relational database and a set of templates during installation. This way we can recover quickly from a broken PC without the need to hold completely installed and configured spare hardware available. Instead one spare machine is sufficient for all PCs running IOCs.

The micro-controller firmware images of the FPGA boards and the tuner power supplies can be updated via CAN bus. A boot loader makes it possible to recover from broken firmware images without physical access to the JTAG chain. The configuration of the FPGAs can be written using the same technique. A multi-boot functionality provides a fall-back to a second "golden" image for the FPGA in case of a broken primary bitstream [12].

These measures together with revision control of all components make a significant contribution to reduce the downtime of the RF control system.

SUMMARY

The digital RF control system is based on in-house developed hardware giving us full control over every detail. The soft CPU that has been implemented in the FPGA allows fast and flexible modification of the control algorithm on one hand and powerful diagnostics on the other hand. The availability of extensive diagnostics has proven to be a considerable precondition for the smooth commissioning of a new RF control system.

A highly automatized deployment of all parts of the software and configuration allows a fast integration of further improvements into the production system.

LHC SUPERTABLE

M. Pereira, T.E. Lahey*, M. Lamont, G.J. Müller, D. D. Teixeira, CERN, Geneva, Switzerland
E.S. McCrory, Fermilab, Batavia, USA

Abstract

LHC operations generate enormous amounts of data. This data is being stored in many different databases. Hence, it is difficult for operators, physicists, engineers and management to have a clear view on the overall accelerator performance. Until recently the logging database, through its desktop interface TIMBER, was the only way of retrieving information on a fill-by-fill basis. The LHC Supertable has been developed to provide a summary of key LHC performance parameters in a clear, consistent and comprehensive format. The columns in this table represent main parameters that describe the collider's operation such as luminosity, beam intensity, emittance, etc. The data is organized in a tabular fill-by-fill manner with different levels of detail. Particular emphasis was placed on data sharing by making data available in various open formats. Typically the contents are calculated for periods of time that map to the accelerator's states or beam modes such as Injection, Stable Beams, etc. Data retrieval and calculation is triggered automatically after the end of each fill. The LHC Supertable project currently publishes 80 columns of data on around 100 fills.

MOTIVATION

Even before the LHC came into operation it was already evident that there would be a need for means of easily obtaining general statistics on the performance of the accelerator. The LHC has been in stable activity for several months now and a large amount of data has already been produced. The increase of accelerator's performance and the thirst of physicists for data highlighted the need for a tool that processes and displays information on performance and other statistics.

Although the data is commonly available and accessible through dedicated tools it is troublesome to create an overall view of the operation of the LHC. One of the main data sources is the LHC Logging Service [1]. This service consists of two databases where data from all LHC devices and parameters is stored. Access to these databases is done through a Java API or through a desktop application called *TIMBER*. While the Java API allows other developers to retrieve data programatically, TIMBER can provide plots and data export into different formats. Although these tools fulfill their intended purpose they are much better at providing data of specific aspects of the LHC than producing the full picture. Another limitation of the available data mining tools available is that their use is typically restricted within CERN.

* On leave from SLAC, Menlo Park, California, USA

As for the Tevatron [2], an application was developed to provide summary data of the performance of the LHC.

THE SUPERTABLE

The supertable is a spreadsheet which provides a summary of LHC key parameters that can be used to assess the accelerators performance [3]. The columns of this table represent beam or accelerator parameters, such as, luminosities, beam intensities, crossing angles, filling scheme, etc. Each row contains the values of these parameters for each fill. The intent of the LHC Supertable is not to provide detailed data on each of these parameters. For that purpose, specialized and dedicated tools have been developed over the years and are used by experts on each of the domains. Instead this application aggregates and formats data in a concise and clear way so that physicists, experts and management alike can be given a general overview of the collider. In summary the LHC Supertable aims at:

- Providing a summary of the key parameters that detail the performance of the LHC.
- Providing a concrete mechanism for determining these key parameters on which everyone can agree (or, at least, through which the parties that disagree can have a basis for their argument).
- Displaying data in easily understandable formats such as web pages and excel sheets.
- Being a small, simple and concise resource.

A similar system has been implemented in Fermilab for the Tevatron accelerator. Fermilab's Supertable has been in operation since 2004 and currently stores data on thousands of fills. In order to profit from Fermilab's experience with their implementation, the LAFS workgroup was called in to give their input and contribution to the project. As a result, CERN's Supertable architecture is greatly inspired on Fermilab's experience [4]. A proposal was made [5] to implement a web application that would gather data from various data sources, process and store in a dedicated database and finally publish the digested data. The solution would profit from Fermilab's experience while the implementation would take in account the specificities of the LHC.

IMPLEMENTATION DETAILS

The LHC Supertable is a web application developed in Java and using the Spring framework. The application is divided in two components: persistence and web.

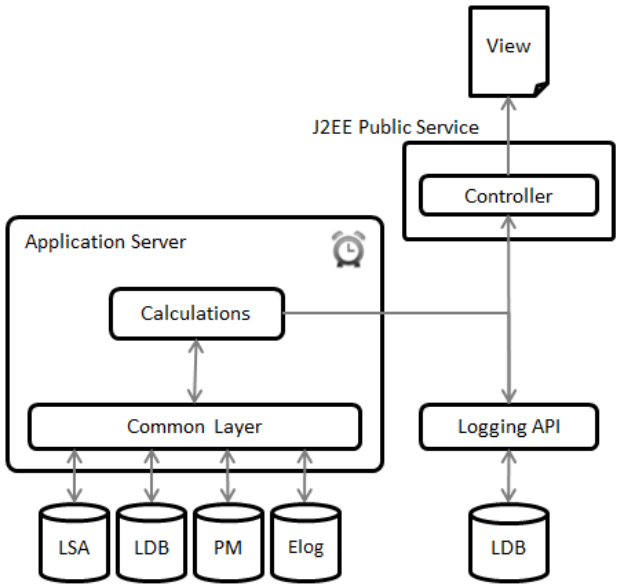

Figure 1: Simplified architecture overview of the LHC Supertable application.

Persistence Module

The persistence module is responsible for gathering data from the various data sources, processing the data and persist it in the database. This process is triggered by a cron job scheduled to run every 30 minutes. When the process is started there is first a verification if there are new fills to be calculated. If so, the *processor* will iterate through the columns of the supertable, calculating them one by one for that particular fill. The algorithms themselves are encapsulated in Java classes called *cells*. Each *cell* in the Java code is responsible for the calculation of one or more supertable cells. In example, the beta star scheme in the supertable is calculated within the *BetaStarSchemeCell* Java class, while luminosities are calculated in the *LuminosityCell*. With this separation of concerns each *cell* becomes an independent unit responsible for processing a set of columns in the table. Figure 1 shows a simplified view of the architecture.

Each attribute in the Supertable has an associate algorithm description and unit. These two elements are of great importance as beam or accelerator parameters may be calculated in different ways. However, the algorithm used to calculate a certain property may change over time. The Supertable offers the possibility to change algorithms inbetween fills or recalculate past fills. The calculation of parameters, i.e. peak ATLAS luminosity, typically involves the retrieval of data from one of the data sources. The Supertable is currently gathering data from the Logging Database, LSA [6], Postmortem [7] and the E-logbook. The current implementation is flexible enough to support the introduction of new data sources. Since one of the primary motivations of the Supertable is for a simple, clean and organized presentation the columns have been classified into one or more specific categories, which we call

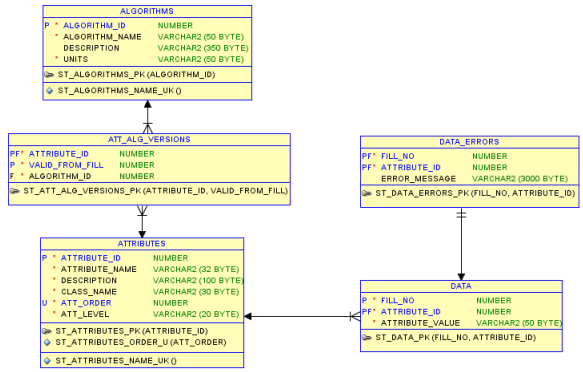

Figure 2: Implemented database schema.

views. The user can select one of these simple views to focus his/her attention on his/her area of interest. For example, the Luminosity view will only show columns concerning luminosity. The organization of columns into *views* provides different levels of detail according to the user's needs.

Data Storage

After all columns have being calculated the data is persisted in the database. For that purpose a schema has been created in the Logging Database. The Logging Database ensures the persistance of the data for the living time of the LHC. Hence, for the sake of consistency and centralization of services, the data of the Supertable was stored in the same environment as the rest of the logging data.

As shown in Figure 2 the database schema is quite simple but provides a lot of flexibility in the supertable. The table ATTRIBUTES is where the columns of the Supertable are defined. It currently holds 87 different attributes and, as mentioned before, each one has a class name field which corresponds to the name of the Java class responsible for calculating the value of the attribute. Additionally, the ordering and level of the columns are also defined in this table allowing to easily change the appearance of the Supertable in the web interface. Add, remove and edit operations on attributes can be performed via a dedicated administration package. This data driven approach makes the structure more flexible making it unnecessary to redeploy the application module responsible for the reads and writes in the database. In the ALGORITHMS table are defined both the algorithm and units per attribute of the Supertable. It was decided not to separate algorithms and units in different tables since they are strongly coupled and the separation wouldn't bring a significant added value in terms on flexibility. Since it is possible to change the algorithm being used in the calculation of a Supertable column without having to recalculate past fills an extra table was needed. The ATT_ALG_VERSIONS table keeps track of which algorithms were used to calculate each attribute throughout the calculated fills. Whenever a new algorithm is added

for the calculation of a column, this table will contain the fill number from which the algorithm went into effect. In case errors occurred at the time of the calculation of a fill these are stored in the data errors table. These errors should be displayed to the user to explain the reason behind eventual missing values for some columns. The choice of the logging database as final location for this scheme brought along an inherent limitation. Due to how the backup process occurs in the logging database, data becomes read only after a undefined period of time. In practice this means the recalculations of fills can only be performed provided that the backup process hasnt handled those particular fills. This schema doesn't currently offer any kind of versioning of data but we believe that this could be one of the solutions to workaround the mentioned constraint. Data from the Supertable can be programatically accessed through the Logging API using the *SupertableController*.

Web Module

The second module of the LHC Supertable is the web interface. The technology chosen was Google Web Toolkit. GWT allowed the creation and maintenance of a powerful Javascript front-end developed 100% in Java. The interface was made clean and as simple as possible but providing enough functionality to be useful. It displays data in tabular form and provides the algorithms used to calculate each parameter as well as the units. Columns are organized in 5 views and by default only a small subset will be displayed. In addition, exports in Excel and JSON are available allowing users to use data as they see fit.

CURRENT STATUS & OUTLOOK

The project as specified has been fully implemented as shown in Figure 3. The LHC Supertable currently publishes 87 columns of data for over 300 fills. Several views are available providing more or less detail according to the users needs. Data can be exported in both excel and JSON [9] formats along with a static html version. Despite the implementation of all planned functionalities the Supertable suffered from a great problem early on: quality of data. For some of the trickiest parameters to calculate algorithms were adopted from Fermilab's Supertable such as emittances, luminosities from emittances, among others. However, some of the implemented algorithms didn't translate well to the LHCs reality. Even though some of those algorithms have been changed, some errors still persist in the calculations. At the same time the LHC Supertable project was being developed another project was under way. The LHC Performance and Statistics although similar in goal started from a different point.

The Statistics application focused at first on creating a repository on ROOT files containing data on a set of key performance parameters of the LHC during the course of a fill. These files are meant to be used by physicists or experts who want to explore in more detail what happened

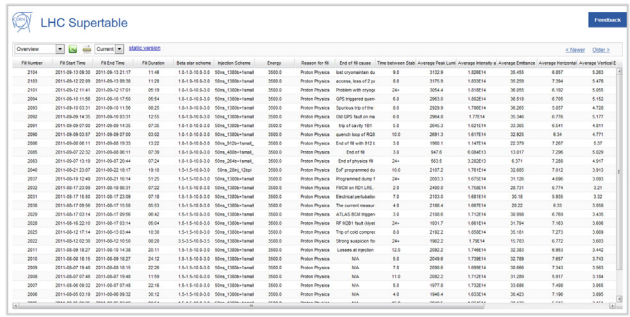

Figure 3: LHC Supertable web interface.

during a particular fill. Additionally, the Statistics application also made available a set of ROOT generated plots and a small table describing a limited subset of parameters also characterized by the Supertable. After some analysis of the functionality and architecture of both applications it was clear that these weren't concurrent systems but rather complementary. Hence a decision was taken to merge the two systems and provide a better service to the users of both applications. At the time of this writing the developer teams of both projects are reviewing the calculation algorithms used for the LHC Supertable which will be later applied in the new application. A system that provides statistics on the operation of the LHC is very much needed and of the utmost importance, however, it is rendered useless if it provides erroneous data.

CONCLUSIONS

The LHC Supertable has been designed, implemented and commissioned to provide a clear and consistent view of LHC operations data to all interested parties in the CERN community. As with any complex project, this product has evolved over its short lifetime to adapt to the environment in which it must exist. While input from the Tevatron Supertable has been invaluable, the LHC calculations often have been subtly different from the comparable Tevatron calculations, leading to some confusion in the customer base. As the user base grows it has become clear that this application is filling a void and providing functionalities that were not available in the existing expert tools. The merge with the LHC Statistics and Performance project is ongoing and should soon go into production. The final product will bring users a new set of functionalities and data for our users.

CONSTRUCTION OF NEW DATA ARCHIVE SYSTEM IN RIKEN RI BEAM FACTORY

M. Komiyama#, N. Fukunishi, RIKEN Nishina Center, Wako, Saitama, Japan
A. Uchiyama, SHI Accelerator Service, Ltd., Shinagawa, Tokyo, Japan

Abstract

RIKEN Radioactive Isotope Beam Factory (RIBF) is a cyclotron-based next-generation radioactive beam facility. RIBF uses two types of control systems; an experimental physics and industrial control system (EPICS)-based system and a group of several non-EPICS-based systems. For each control system there is a corresponding data archiving system in operation, and in order to unify these two data archives, since October 2009 we have been developing a new archiving system. This new data archive system, named RIBF Control Data Archive System (RIBFCAS), is required, at intervals between 1–60 s, to collect and store more than 3000 data generated by EPICS controlled devices through EPICS input/output controllers (IOCs). In addition, RIBFCAS must be able to combine the existing non-EPICS-based systems. To fulfill these requirements, a Java-based platform has been created, and client applications are based on Adobe AIR runtime. The RIBFCAS hardware system, therefore, consists of an application server, a database server and client-PCs. Presently, we have succeeded in stably acquiring approximately 3000 data from 22 IOCs every 10 s. Moreover, incorporation of the non-EPICS-based data archive system into RIBFCAS is now in progress.

OVERVIEW OF RIBF CONTROL SYSTEM

With an aim to explore unknown properties of unstable nuclei, the RIKEN Radioactive Isotope Beam Factory (RIBF) began operation in 2006 as the first of several next-generation RI beam facilities planned worldwide. RIBF is a cyclotron-based in-flight facility, and RIBF accelerators can supply RI beams at energies hundreds of MeV/nucleon over the entire range of atomic masses [1].

As shown in Fig. 1, the RIBF control system has a degree of complexity. The primary components of RIBF accelerators, such as magnet power supplies, beam diagnostic devices and vacuum systems, are controlled by an experimental physics and industrial control system (EPICS)-based system [2]. Additionally, there are several standalone control systems not integrated into the EPICS-based system, for example, those for radio frequency (RF) systems, the cooling water system and various long-standing ion sources. These systems operate independently of the remainder of the RIBF control system.

The EPICS-based system utilizes a number of device controllers, such as a Versa Module European (VME) control board, numerous types of programmable logic controllers (PLCs), general-purpose interface bus (GP-IB) controllers, PIC network interface card kit (PICNIC) [3], computer automated measurement and control (CAMAC) in-house controllers and in-house controllers based on network interfaces,. To integrate these device controllers within the EPICS framework, EPICS input/output controllers (IOCs) running "iocCore" software are necessary. "iocCore" is a set of EPICS routines that define process variables and implement real-time control algorithms. In our system, almost all EPICS driver/device supports for controllers can also be executed on Linux-based IOCs.

CAMAC in-house controllers, Device Interface Modules (DIMs), are managed by using the network crate controller CC/NET, a commercial product of Toyo Corporation [4, 5]. Because CC/NET is a Linux-based single-board computer, we can execute EPICS base software on it, and therefore the CC/NET itself becomes an IOC. In addition to CC/NET, a PLC-CPU module newly developed by Yokogawa Electric Corporation, F3RP61-2L (hereinafter, RP) [6], also works as an IOC; a soft real-time Linux environment. In contrast, the network-based in-house controller, Network-DIM (N-DIM) [7], the GP-IB controllers, PICNIC and the PLCs do not contain general operating systems (OS) on which to execute EPICS base software. To manage these controllers in the EPICS framework, they must be connected to additional IOCs through Ethernet connections to convert the communication protocols between EPICS channel access (CA) and the N-DIM or GP-IB controllers or PICNIC or PLCs. Linux-based IOCs, small single-board computers (ALIX) [8] are used to convert the protocols. The exception to the above is for NIO, a commercial control board from Hitachi Zosen Corporation, which is instead controlled by a device/driver support originating from VxWorks.

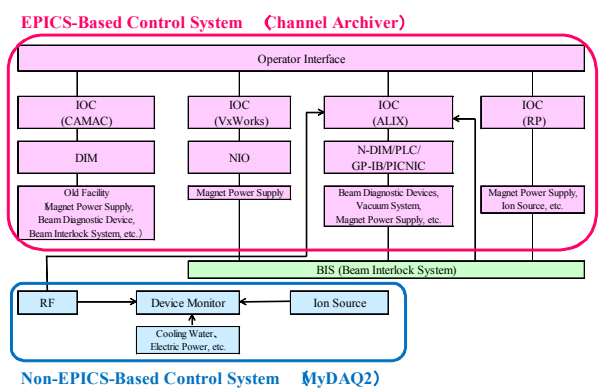

Figure 1: Schematic of RIBF Control System.

misaki@riken.jp

DIMs control approximately 370 magnet power supplies, and 100 beam diagnostic devices and vacuum systems. N-DIMs control around 250 beam diagnostic devices and vacuum systems. NIO boards control about 420 magnet power supplies. RPs control approximately 50 magnet power supplies and newly developed 28 GHz electron cyclotron resonance ion sources [9]. PLCs control the vacuum systems of cyclotrons and certain beam diagnostic devices. Although RIBF has many PLCs, EPICS controls only a proportion of these; Other PLCs have their own control systems and are independent of EPICS.

Two data archive systems have been used to record the various parameters of RIBF during operation. The pair "Channel Archiver" and "Archive Viewer", developed by the EPICS collaboration [10], is used as a data archiver for the EPICS control system. A new version of Channel Archiver, "RDB Channel Archiver", was released in 2010 to store data and configurations in a relational database (RDB); however, our system still uses the old release.

The second achieve system, "MyDAQ2" developed by the SPring-8 control group [11], is used to acquire and store non-EPICS-based systems parameters. Initially, each non-EPICS-based system individually managed their own data, and MyDAQ2 was introduced in order to manage all non-EPICS-based data in a cohesive manner. MyDAQ2 obtains data from each device through an Ethernet and stores them in a MySQL database such that users can retrieve stored data by using an associated Web application.

Although coexistence of two data archives covering different sections of the accelerator system does not cause significant problems in daily use, unifying the two database systems is favored. However, it is difficult to apply Channel Archiver to our non-EPICS-based systems. On the contrary, while it may be technically feasible to apply MyDAQ2 to our EPICS system, handling vast amounts of data is highly demanding. MyDAQ2 was developed for users who perform experiments at one of the SPring-8 beam lines, not the entire Spring-8 control system, and as a result the interface of MyDAQ2 is suitable for handling smaller amounts of data.

A drawback of the coexistence of two data archives is that data processing is necessary to investigate correlations in the stored data. For example, suppose we notice a gradual decrease in beam intensity, we are then required to investigate the correlation between operation parameters, such as temperature of cyclotron magnets and beam intensity. Since beam intensity data are stored in the Channel Archiver and magnet temperature data are stored in MyDAQ2, data processing is needed for comparison between the data. With a unified system, performing correlation analyses becomes easier and may be helpful for a more stable operation of RIBF. Furthermore, if the unified system can be used not only to display retrieved data but also to monitor real-time data, we can immediately fix an observed instability.

For the reasons indicated above, we decided to construct a new data archive system. This new system must meet the following requirements: acquire all parameters essential for the stable operation of RIBF accelerators at the required sampling rates, retrieve stored data and monitor real-time data.

DEVELOPMENT OF NEW DATA ARCHIVE SYSTEM

Outline

Since October 2009, we have been developing a new data archive system, RIBF Control Data Archive System (RIBFCAS), which covers both EPICS-based and non-EPICS-based systems. An outline of RIBFCAS is as follows:

1) Adoption of an open-source database was considered preferable.
2) For the EPICS-based system, a Java-encoded data acquisition program was newly developed to communicate with IOCs.
3) For the non-EPICS-based system, RIBFCAS works together with MyDAQ2 instead of developing new interfaces with the standalone control systems.
4) The client program has an ability to show both past and real-time data.
5) We plan to retain stored data for a minimum of five years. Data from up to two years previously can be searched immediately from client PCs at all times; however, older data are retrieved from a backup.

The RIBFCAS data acquisition system has to be capable of collecting more than 3000 data values at 1–60 s intervals, depending on the device type. System performance is highly reliant on the choice of database. Accounting for query performance, especially for large tables, we concluded that PostgreSQL 8.4.1 satisfied our fundamental requirements, because it supports a basic table partitioning function.

To achieve 2), a CA library must be used in RIBFCAS data acquisition program. The performance of this CA library is also important when storing the large data discussed above. A number of CA libraries were tested in order to find the most suitable for our intended purpose, and the results are discussed in the proceeding section.

For 3), MyDAQ2 data are merged with the data from the EPICS-based system by using a client application. We have created a CGI program to retrieve data from MyDAQ2 and export them in extensible markup language (XML) format to the RIBFCAS client application.

In realizing 4), a client application was developed on Adobe AIR. The advantage of using this platform is that client applications can be executed in multiple Adobe AIR runtime environments regardless of the file format.

Performance Test of CA Libraries

We evaluated data acquisition speeds for three CA libraries: Java Channel Access (JCA), Java Channel Access Light Library (JCAL) and an adapter library for JCA application programming interface (API) (JCAL–JCA). JCA is supported by the EPICS collaboration [12], and JCAL and JCA–JCAL were developed by the J-PARC control group [13]. Performance of the libraries was examined by writing programs with each such that all data could be processed for three chosen IOC types, having approximately 200 parameters apiece. One process of the test programs attempted to obtain data every 1 s and a test was concluded by obtaining five successive failures or successes. The JCA program was implemented for a single thread, whereas the JCAL program was implemented for multiple threads, since JCAL was developed as a thread-safe library in order to improve the stability of JCA when used in multi-thread technology. We measured the data acquisition time during each test and the results are summarized in Table 1.

The JCAL and JCA–JCAL programs successfully processed all data within 1 s, where the average time to acquire a datum was approximately 2 ms. There are no significant differences between the performances of JCAL and JCA–JCAL. When compared with these two programs, a longer data acquisition time was found for the JCA program due to the introduction of a delay time in order to establish a safe connection between the program and an IOC. If the JCA program attempts to process data from any channel of an IOC following a JCA-API call to establish channel connection, the program receives signals indicating an unconnected status and returns a failure message. To avoid this scenario, it was necessary to wait for 40 ms after each connection was established. For the case of the CC/NET IOC, this delay was increased 100 ms. As a consequence, we selected JCAL as the CA library for RIBFCAS.

Table 1: Performance of EPICS Java Library

IOC	Number of Parameters	JCA Execution Time (ms)	JCA Average (ms)		JCA–JCAL Execution Time (ms)	JCA–JCAL Average (ms)		JCAL Execution Time (ms)	JCAL Average (ms)	
CC/NET	187	49830	43	Fail	5102	2	Pass	5035	2	Pass
ALIX	198	46986	42	Pass	5104	2	Pass	5042	2	Pass
VME	192	45540	42	Pass	5101	1	Pass	5037	2	Pass

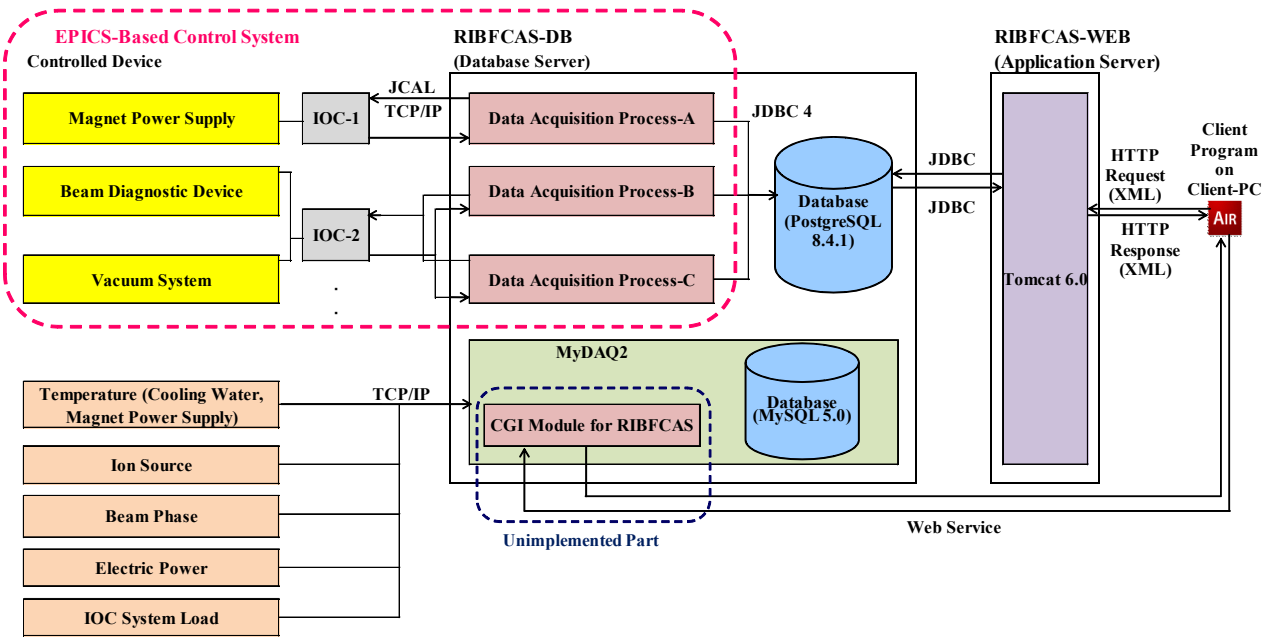

Figure 2: RIBFCAS Schematic Overview.

Structure of RIBFCAS

Figure 2 shows the structure of RIBFCAS. RIBFCAS consists of a database server, an application server, and client PCs. These are all connected to the EPICS local area network. The database server (RIBFCAS-DB) executes a JCAL-based data acquisition program to collect EPICS data. In addition, MyDAQ2 currently runs on RIBFCAS-DB and the MySQL database is also managed on this server. The application server (RIBFCAS-WEB) implements Tomcat version 6.0, which is a Web application server for the Java environment. Tomcat executes tasks in response to requests from client PCs, and returns retrieved data to client PCs in XML format. On client PCs, applications are executed on Adobe AIR runtime.

Table 2 shows the hardware specification of these servers and PCs. However, the performance of the existing database server is not sufficient to fulfill our requirements. Hence, we plan to upgrade the server.

The data acquisition program has the following features:

- The data collection program is divided into several processes and multi-thread technology is used to execute these processes simultaneously. This program structure gives the flexibility to divide

existing processes into segments or to add new threads for devices introduced to RIBF accelerator complex in future upgrades.

- A list containing a large amount of information collected by RIBFCAS is managed within the XML framework in the program, making it easier to change device data.
- The system has an organized multilayer structure; components such as the database, data collection processes and data collection logic in the database server, Web service and client services are isolated from each other.

The main RIBFCAS system was completed in FY2010 and performance tests commenced in FY2011.

Table 2: Hardware Specification of RIBFCAS

	RIBFCAS-DB	RIBFCAS-WEB
CPU	Intel Xeon (Quad Core) 2.33 GHz	Intel Core2Duo 2.20 GHz
Memory	16 GB	1 GB
Hard disk drive	120 GB (RAID10, SAS)	80 GB
OS	CentOS 5.2 (32 bit)	CentOS 5.3 (64 bit)

OPERATIONAL STATUS

A trial for the EPICS-based section of RIBFCAS began on 26 April 2011, according to the operating schedule of RIBF. The program acquires values for approximately 3000 various component parameters of RIBF from 22 IOCs by using nine separate processes. During the test period, RIBFCAS has been storing data of the vacuum systems of cyclotrons and beam transport lines, the magnet power supplies and the beam diagnostic devices, once every 10 s. Although the present data sampling rate of 10 s is sufficient to monitor the stability of the systems, it is also possible to optimize the time interval for acquisition depending on device type.

Thus, we have succeeded in continuous data acquisition without significant problems occurring. The stored data has been constantly growing and reached approximately 76 GB on 13 July. During this period, unexpected system interruptions have transpired on several occasions, with the data collection process terminated due to limitations in memory usage of the 32-bit OS. The cause of this phenomenon might be unresolved small memory leaks in the data acquisition program. To avoid these interruptions resulting from memory usage limitations, we have adopted a practice of restarting the relevant processes routinely and automatically. Note that this phenomenon was not observed for CC/NET.

The client application has also been shown to work well. The client program successfully monitors real-time data and can also retrieve data for any period stored in the database. In both cases, a user can select any amount of any data for viewing. The client program displays data over a 24 h interval for a parameter within 10 s, and data over 1 h within 0.3 s. Even more, only 0.05 s is required to recall 24 h data of a parameter once it has been referred to. Monitored or retrieved data are displayed as a time plot in the client application and obtained plots can also be saved as text or JPEG files.

FUTURE PLAN

Although investigation of the source of the memory leakage in the data acquisition program must be pursued, RIBFCAS has started to collect stably data from the EPICS-based system. As a next step, we plan to develop an additional client application that processes the data stored by MyDAQ2. This is an important stage in unifying the two existing databases. Another problem to be solved is management of the vast amounts of data. As already stated, the EPICS-based section of RIBFCAS collects 76 GB of data every 2.5 months, which corresponds to 400 GB of stored data every year. Selection of appropriate hardware to handle such data is now in progress. We plan to complete the development of RIBFCAS in FY2011.

ACKNOWLEDGMENTS

We would thank to Mr. T. Etoh and Mr. Y. Otaka in Swadok Co., Ltd. for their coding the RIBFCAS programs.

ALGORITHMS AND DATA STRUCTURES FOR THE EPICS CHANNEL ARCHIVER

J. Rowland, M.T. Heron, S.J. Singleton, K. Vijayan, M. Leech,
Diamond Light Source, Oxfordshire, UK

Abstract

Diamond Light Source records 3GB of process data per day and has a 15TB archive on line using the EPICS Channel Archiver. This paper describes recent modifications to the software to improve performance and usability. The file-size limit on the R-Tree index has been removed, allowing all archived data to be searchable from one index. A decimation system works directly on compressed archives from a backup server and produces multi-rate reduced data with minimum and maximum values to support time efficient summary reporting and range queries. The XMLRPC interface has been extended to provide binary data transfer to clients needing large amounts of raw data.

INTRODUCTION

This paper investigates the architecture of the EPICS Channel Archiver and describes the changes made to improve performance and usability at Diamond. Other database designs were also considered as part of the upgrade progress and for intermediate processing of decimated data, and this information is summarized as a reference for future archiver developments. Information about the data structures used in external storage is not always available in user documentation, but it is essential to consider these together with hardware capabilities and query patterns when good performance is required.

Problem Statement

The EPICS Channel Archiver (Archiver) records data from N channels, each producing samples at a different rate. We assume that timestamps are monotonic, and that samples arrive sorted in time but unsorted by channel. The goal of the Archiver is to manage this data and fulfil queries in a timely manner to support operations. The most common query returns samples from M << N channels between times T0 and T1, so query results exhibit the opposite locality of reference to sample insertion. If the most common query returned samples from all channels in a small time range then there would be no mismatch between insertion and retrieval and the problem would be trivially solved; for example a sequential logfile of samples with a sparse index of timestamps would suffice.

Locality of reference is important because it determines how to find the next sample in a query; sequential samples can be iterated without traversing an intermediate data structure. The problem is compounded when the storage medium penalises random access. This is the case for all common systems, as RAM, solid-state disks and hard disks transfer data in blocks. Hard disks have the extra problem of mechanical latency when positioning the head.

Channel Archiver at Diamond

The important figures for Diamond are presented in Table 1. The Archiver is split across multiple engines for functional isolation and to utilize multiple processor cores. Diamond also operates a redundant system with two complete Archiver servers and disks to ensure high availability, so every component in the table is duplicated.

Table 1: Archiver Parameters

Data Size	12.5 TB
Data Rate	3 GB/day
Index Size	23 GB
Archive Engines	39
EPICS Channels	148819
Server RAM	24 GB
Server CPU	2x Intel X5670
Server Cores	24 (HT)
RAID Storage	36 TB
RAID Cache	1GB (write-back)
RAID groups	5

DATA STRUCTURES

Chunked Arrays

An array contains a single type of element, and supports appends and random reads. An array is contiguous in storage so that element addresses can be calculated directly, but resizing involves allocating new storage and copying the whole array. Maintaining contiguity whilst allowing for growth is possible using the 'dynamic array' where the array is resized by a constant multiplicative factor rather than one element at a time. This gives amortized O(1) append complexity, and is commonly used for in-memory arrays such as the C++ std::Vector. Drawbacks are memory fragmentation, unpredictable delays due to copying, and the need for increasing amounts of space at the end of the array.

An alternative is the chunked array, where the array is not copied on resize and is no longer fully contiguous. Storage is allocated in chunks; now element addresses must be mapped to chunk locations using an index. This

is the storage mechanism used by the Archiver and other scientific data stores. The Archiver also chains chunks together in a linked list so that the index is only touched to find the initial chunk of a query. One common file format supporting chunked arrays is HDF5, used for beamline experimental data at Diamond [1].

The Archiver has a minimum chunk size of 64 samples. As new chunks are added to an array the chunk size is doubled up to a maximum of 8192 samples. This reduces wasted space for small arrays and at the end of chunks whilst ensuring that large arrays have reasonable runs of contiguous storage.

The Archiver also partitions array storage by date, into weekly data directories. Once written, partitions are immutable, making backups simple as old directories do not have to be scanned for updates.

R-Tree

The Archiver uses an R-Tree as the chunk index. An R-Tree is a sorted search tree optimized for efficient range intersection queries. Each tree node has M children; having large nodes reduces the depth of the tree and the number of seeks required to complete a search compared with a binary tree. At Diamond the default M value of 50 has been increased to 200 to reduce the depth of the Master Index.

The keys in the tree are timestamps and the values are chunk offsets. As the archiver does not allow overlapping chunks to be stored in an array, the index structure could be replaced with a B-Tree without loss of functionality. This is relevant as there are many robust B-Tree implementations available offering useful upgrades such as compression and file locking [2].

Hash Table

The Archiver contains many channels, so the first level of index is a chained hash table with linked lists mapping from channel names to chunk indices. The default table size of 1009 entries resulted in 150x overfilling for Diamond channels, and the linked list nodes are spread throughout the index file, making lookups expensive. An option was added to the ArchiveIndexTool to adjust the hash table size and the Master Index was rebuilt using a prime near 300000, improving channel retrieval performance.

Master Index

The Hash Table and R-Trees for an archiver partition are stored in an index file in the partition directory. The partitions are joined by merging the individual index files into the Master Index. The data type used to store file offsets was increased from 32 to 64 bits to allow the size of the Master Index to grow above 2GB. This increases usability by presenting the user with a single index for all data; previously the user was responsible for splitting queries across multiple indices. Also, the interpolation algorithms in the server only produce consistent bin boundaries when retrieval is from the same index.

HARDWARE

Diamond uses a magnetic disk system in a RAID5 configuration to store Archiver files. The Archiver services all queries from the on-disk arrays, so samples must be written soon after they are received to support timely control room diagnostics. Samples are stored in circular buffers in RAM, and written every 30s. This write operation appends samples to every chunk that has been updated in the last period, and chunks are scatted across the disks. This is illustrated in Fig. 1; numbers in the matrix are disk offsets; shading indicates write order. The write pattern is not contiguous.

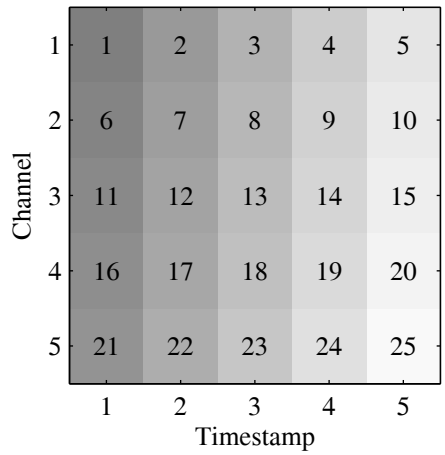

Figure 1: Archiver Write Order.

A typical magnetic disk can perform 100 I/O operations per second (IOPS) and has a sustained sequential transfer speed of 100MB/s. A disk seek costs as much as transferring 1MB of data. Each channel update costs one IOP. Therefore we can service approximately 3000 channel updates every 30s, assuming that none of the array chunks are sufficiently close together on the disk for their writes to be merged into a single IOP. This demonstrates that the key to Archiver performance is servicing write requests. RAID5 configurations typically have reduced random write performance due to the need to update parity bits, but spreading the archiver partitions across multiple RAID groups increases random write performance linearly with the number of RAID groups.

Write-Back Cache Controller

The RAID controller in the Diamond Archiver server has a battery-backed write-back cache with 1GB of RAM, enough to store 8 hours of data. Increasing the write period allows small writes to be merged, greatly increasing throughput. Figure 2 shows the write pattern after re-ordering by the cache controller.

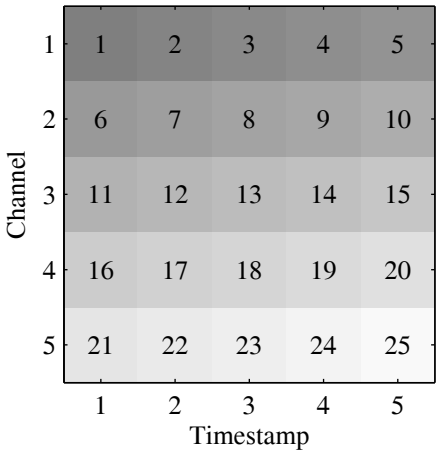

Figure 2: RAID Cache Write Order.

Table 2 shows the I/O utilization reported by the Linux tool IOSTAT when running the full Diamond archiving workload on three systems with different RAID controllers. 100% write utilization indicates that samples are discarded. Old is the previous production archiver, New is the current production archiver with upgraded cache controller, Desktop is a machine without a write-back cache controller.

Table 2: I/O Utilization

Hardware	Write%	Read%
New	3	75
Old	40	100
Desktop	100	100

RETRIEVAL

The Archiver query interface is exposed through the XMLRPC language-independent remote procedure call. This has proved pleasant to use from a variety of platforms including VB.NET, Matlab, Python and Java. However some users retrieve a large number of raw samples from the Archiver to produce multi-year reports and found the performance disappointing even after the server and disk upgrade. The XML encoding of arrays of EPICS datatypes was the limiting factor, these were packed as arrays of structures with the field names in ASCII for each sample, leading to a large space and time overhead. A new XMLRPC retrieval type was developed returning the EPICS sample array as a structure of arrays, one for seconds, nanoseconds, value, status and severity, each array packed into a byte buffer in native little-endian format and base64 encoded. Table 3 shows the performance improvement, the NFS method shows the performance of direct file access. The number of samples per request was still limited to 10000 as the RPC result is assembled in memory before sending to the client, this has since been increased to 1M samples to reduce the overhead of the RPC roundtrip.

Table 3: Retrieval Method Peformance

Method	Overhead	Time
NFS	1x	10m20s
XMLRPC	20x	112m7s
XMLRPC Base64	1.3x	26m

COMPRESSION

At Diamond backups are compressed with tar and gzip, and typically achieve a 4:1 compression ratio. Some of this is accounted for by partially empty chunks at the end of each array partition, but the low entropy of sorted EPICS time series data makes it an ideal candidate for compression. Figure 3 shows the sparsity pattern of the difference between adjacent samples for real double-precision data. High-order bytes of the timestamp corresponding to days and months, status and severity words, and padding bytes put in to enforce aligned memory access all rarely change.

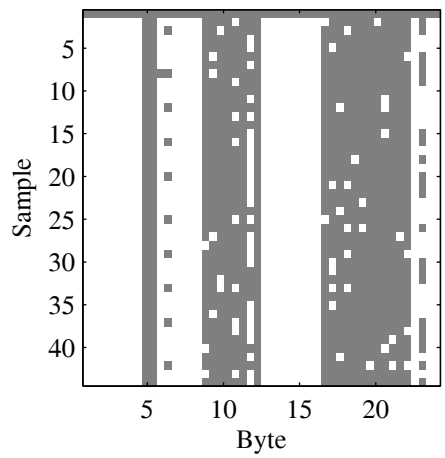

Figure 3: Differences of Adjacent Samples.

Compressed tar files are not seekable and cannot be read by the Archiver tools directly but libarchive [3] can stream decompressed data from a tar file without extracting to a temporary directory, this is used at Diamond to perform complete scans of the archive. Every sample can be read in a few days directly from compressed backups. This was used to feed the decimation tools discussed below.

Another option for direct access to compressed data is the squashfs [4] file system. This uses gzip in blocks to create a seekable compressed file system image that can be mounted by Linux. Using this to compress older data files will effectively quadruple the capacity of the Archiver storage without any software development effort. Squashfs is part of the Linux kernel from version 2.6.29.

DECIMATION

Many queries request decimated data from the archiver, and this decimation is performed on-line, traversing every raw sample on disk in the time range. As part of the upgrade program a method of pre-calculating these decimated queries was investigated. The required performance was achieved without making use of pre-decimated data, but the method is described because the data structures are more generally useful and offer an alternative to the chunked array store.

The data structures for decimated data were based on Hypertable [5], a write-optimized sorted key value storage engine developed to run on commodity hardware. Hypertable has previously been considered as a storage engine for the Archiver by INFN [6], and is itself inspired by the Google Bigtable [7] database.

Hypertable

Hypertable eliminates random writes through the use of a RAM cache. The key components of Hypertable are as follows:

- Sequential logfile for durability,
- RAM cache for data re-ordering (MEMTABLE),
- Periodic writes to immutable sorted disk tables (SSTABLE),
- Periodic external mergesort,
- Index of tables.

All operations are appended to a logfile which is periodically flushed to disk. In case of system failure, pending operations can be replayed from the logfile. Key and value pairs are maintained in a sorted data structure in RAM known as the MEMTABLE, and written to immutable sorted lists known as SSTABLEs (sorted string tables) once the RAM table is full. This provides similar functionality to the write-back RAID controller, but in software only. Keys are located in SSTABLEs by a B-Tree index.

In summary Hypertable provides a write-optimized structure to maintain partially sorted data on disk with the degree of sorting limited by available RAM. To improve sorting, SSTABLEs are periodically merge-sorted together. Typically the maximum size of the SSTABLE must be limited to prevent full-disk sorts. For EPICS time series data a suitable sort key is the (channel, timestamp) pair. This will ensure that channel samples are stored with good locality on disk for retrieval.

The decimation system uses a simple implementation of the Hypertable scheme. The sort key is (decimation rate, channel name, binned timestamp). The MEMTABLE uses the Berkeley B-Tree in-memory database. Raw Archiver samples are read from the compressed backups. If the MEMTABLE contains a binned sample containing the timestamp, the sample is added to the bin, otherwise a new bin is created. Once the MEMTABLE is full, it is saved to disk as a list of key value pairs. Once all samples have been read, the SSTABLEs are merge sorted into a single large table, and a sparse index is created containing the file offsets of each channel. The final table and index are compressed with squashfs.

Decimating all channels at 10 minute, 1 hour and 1 day intervals results in a compressed data size of 62 GB. An XMLRPC server provides the same interface as the original Archiver. Retrieval performance for long decimated queries is improved in proportion to the decimation interval.

SUMMARY

The required performance and usability improvements to the EPICS Archiver at Diamond were achieved without major changes to the software, but it was essential to consider hardware and software together to achieve this. Table 4 shows some benchmarks of the old and new systems. The DI benchmark returns decimated data for a week from a few hundred channels, the VA benchmark returns raw data for years from a few 10s of channels.

Table 4: Benchmarks

Hardware	Test	Time
New	DI	30s
Old	DI	3m30s
New	VA	8m30s
Old	VA	110m30s

For future Archiver developments the Hypertable combination of logfile and in-memory queryable cache offer a way of implementing an efficient and durable storage engine without requiring a hardware RAID controller.

LHC DIPOLE MAGNET SPLICE RESISTANCE FROM SM18 DATA MINING

H. Reymond, O.O. Andreassen, C. Charrondiere, G. Lehmann Miotto, A. Rijllart, D.A. Scannicchio,
CERN, Geneva, Switzerland

Abstract

The splice incident which happened during commissioning of the LHC on the 19th of September 2008 caused damage to several magnets and adjacent equipment. This raised not only the question of how it happened, but also about the state of all other splices. The inter magnet splices were immediately studied and new measurements recorded, but the internal magnet splices were still a concern. At the Chamonix meeting in January 2009, the CERN management decided to create a working group to analyse quench data of the magnet acceptance tests in an attempt to find indications for bad splices in the main dipoles. This resulted in a data-mining project that took about one year to complete. This presentation describes how the data was stored, extracted and analysed reusing existing LabVIEW™ based tools. We also present the encountered difficulties and the importance of combining measured data with operator notes in the logbook.

INTRODUCTION

After the melting of a busbar interconnect splice in sector 34 in September 2008 during hardware commissioning, a special campaign was initiated to find bad splices by calorimetric and quench protection system (QPS) measurements [1]. These measurements were made in sectors 12, 56, 67, 78 and 81. The sectors 23, 34 and 45 were not measured, due to the fact that they were not cold at the time of the campaign.

No bad splices were found within the detection limits of 20 nΩ, but two bad magnet splices of about 100 and 50 nΩ were found inside the dipole magnets (MBBI334 and MBBI303). When these magnets were opened 'hardly soldered' splices were indeed found between poles and apertures.

The Chamonix Workshop (January, 2009) therefore gave a recommendation to look back in the magnet test facility (SM18) data and try to find indications for bad splices looking at the old provoked quench test data.

A working group was formed with members from the Technologies, Engineering and Physics departments to make this analysis [2]. It was decided to study with priority the magnets in sectors 23, 34 and 45, for which the least precise measurements existed, as they were not cold at the time of the campaign. It was also decided to study only the main dipoles. The main quadrupoles were connected in quite a different way in SM18 than in the LHC, thus making the joint measurements very uncertain.

During the tests, after repair of the damaged magnets of Sector 34, a dedicated measurement was put in place to measure the magnet splice resistance. These measurements were compared with the quench test data and it was found that the error could easily be 20 nΩ (nominal about 0.3 nΩ), similar to the error in the calorimetric measurements made in LHC.

AVAILABLE DATA FROM THE SM18 MAGNET TESTS

Hall SM18 is the test facility used during the 4 years campaign dedicated to LHC magnets reception and validation.

The data recorded during the magnet acceptance tests primarily contained the electrical insulation of the coils and heaters and at the maximum field strength [3]. A second objective was to determine the field quality through magnetic measurements. No specific splice resistance test was performed.

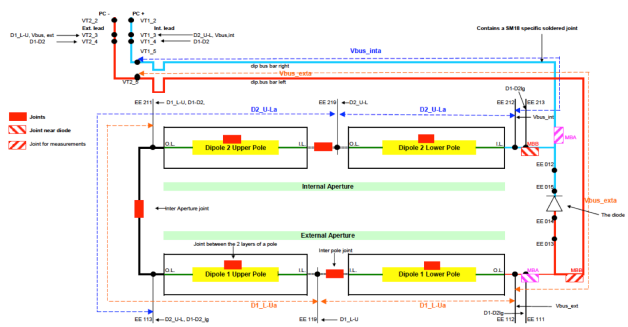

Figure 1: Electrical connections and splices of a LHC dipole.

Nevertheless the quench recorder system, used during these qualification tests, allowed acquiring and archiving hundreds of voltage signals, before and after the quench. These measurements were taken over several sections of the magnet circuit, through the existing voltage taps (see Fig. 1) inside and around the dipole. It is not possible to directly measure the voltage at a specific splice due to the positioning of the voltage taps. The data only allows for the comparison of voltage values in different segments of the magnet for constant currents: any abnormally high value in the difference of measured voltages is an indication of a relatively large resistance in the splices. The method is applicable in the assumption that the probability of having two or more large resistances in the same dipole, whose effects cancel each other perfectly, is very low.

We list here (see Fig. 2) the voltage differences used in order to infer the quality of the two inter-poles, the inter-aperture and the diode splice resistances.

$$V_{D1\_L-Ua} = V_{D1\_L-U} - V_{bus\_Ext}$$
$$V_{D2\_U-La} = V_{D2\_U-L} - V_{bus\_Int}$$
$$V_{D1-D2a} = V_{D1-D2} - V_{bus\_Ext} + V_{supra\_Ext\_lead} - V_{clamp\_Ext} + V_{bus\_int} - V_{supra\_Int\_lead} + V_{clamp\_Int}$$
$$V_{bus\_Inta} = V_{bus\_Int} - V_{supra\_Int\_lead}$$
$$V_{bus\_Exta} = V_{bus\_Ext} - V_{supra\_Ext\_lead}$$
$$V_{Diodesplice} = \begin{cases} V_{bus\_Exta} & \text{for MBA dipoles} \\ V_{bus\_Inta} & \text{for MBB dipoles} \end{cases}$$

Figure 2: Voltages used for the splice analysis.

Data Selection

The most suitable tests for our analysis were those with a long constant current at different current levels. These are present in the quench heater test at 1.5, 3, 12 and 13 kA. They have sometimes a very short constant current part, due to the fact that the operator triggered the recording manually when the current reached the desired value. The constant current recordings vary between 2 and 15 seconds at a sampling rate of 5 kHz (see Fig. 3).

The data taken at 12 and 13 kA have a recording at constant current before and after the trigger, but due to the uncertainty of the amplitude of the offset in the voltage signals, one needs a reference at lower or zero current for comparison.

Constraints of the Measurement Electronics

The electronics used for the amplification of the voltage tap signals consists of two parts connected in series: an isolation amplifier and a variable gain operational amplifier.

This last one can amplify or attenuate the signal depending on the gain setting that is adjustable with a rotary switch. The gain value for each channel has to be manually entered into a configuration database as there is no electronic read-out.

It also has a potentiometer to adjust the zero offset, which is done manually at the start of each measurement campaign.

These manual operations generate some risks, in terms of exactitude of the database content but also for the measured signals.

ANALYSIS METHODS AND TOOLS

High Frequency Data

Our first method determined the resistance of the splices, shown in Figure 3, using the voltage signals over the measured magnet current. For each magnet analysed, these values have been read from high current (around 12 kA) and low current (3 and 1.5 kA) data. Then formulas were applied to return only differential voltages of inter-pole, inter-aperture, internal bus and external bus splices. Afterwards a best-fit interpolation was done on the curves U = f (I) for the selected signals to obtain splice resistance of the related connections. We will refer to this as the fit method. It assumed that the offset is stable in time and is thus very sensitive to any offset drift. As this drift was a concern, a second method has been applied to improve the accuracy of the results.

Most of the magnets have their measurement sequence executed over several days. This leads to potential sources of offset mainly due to electronics drift over time and SM18 hall temperature variations.

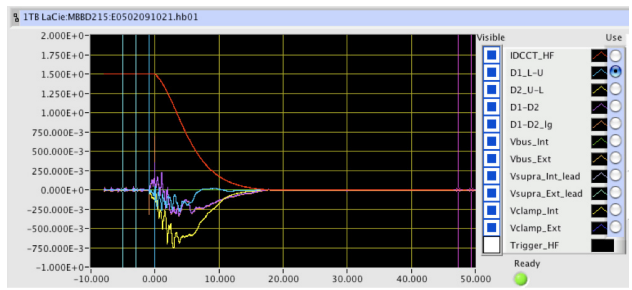

Figure 3: Magnet current and voltage signals from a 1.5 kA SM18 data file.

We assumed that offsets were constant on the voltage signals in the short time span before and after the quench, we have used the SM18 data to compensate the offsets. The resistance was then calculated in a differential way, subtracting these two voltages over the current before the quench.

The limitation of this method was that only the 1.5 kA measurements were usable, because the data taken at higher currents did not include the needed stabilized signals. Even for some quenches at 1.5 kA, signals did not always stabilize well, due to the dynamic behavior of the magnetic field and could not be used.

Another problem we found was that in about 10% of the measurements the gain for the signals Vbus_Int and Vbus_Ext was systematically too high by a factor of 400. By reading the operation logbook, it has been possible to correct these measurements. This eliminated several otherwise suspect magnets.

Low Frequency Data

After the success of the offset compensation method applied to measurements at 1.5 kA, we tried to see whether a similar method could be applied to high current data based on the low frequency signal sampling. In a short interval around the quench, the sampling frequency is 1 kHz. Outside of this interval signals are recorded when their values change by a certain minimum amount, else only once in 10 minutes, resulting in very few points. Unlike at 5 kHz sampling, offsets are compensated by the measurement electronics used for the low frequency sampling. We tried to see whether these data could be used for offset correction of the data at 12 kA. Unfortunately this was not possible, as there were too few data points in the interval following the quench.

Noise Characteristics

The voltage signals studied typically have a 1 mV noise amplitude peak-to-peak, which is much more than the DC values relevant for 10-100 nΩ resistances.

Early in the analysis we looked at frequency spectra of some signals to check if systematic features in the noise could influence the DC measurements. This turned out to be not the case. Typically there was a strong 400 Hz (and harmonics) contribution in the spectra, explained by the regulating frequency of the power converters, but no noise which could influence the DC value derived from averaging the signals measured at 5 kHz sampling frequency.

Analysis Tools

To cope with the large number of files to be processed (for 1530 measured magnets we had 23000 files) we have developed a tool for automatic data extraction and analysis.

It was designed as follows: A configuration file stored the list of the data types to use for the analysis. The tool automatically opened the files, determined the stable current plateaus and extracted the relevant voltages. Then it performed a linear fit through all the points to evaluate the resistance from the slope. Distribution plots were displayed by the application for each calculated voltage, which gave an overview of the resistances for a complete sector.

RESULTS

The Data Sample

Each dipole magnet tested in SM18 has been measured under several conditions to study its performance. Nevertheless, by only measuring those magnets that contained a long enough stable plateau in current and voltage could provide results that can be used for the resistance calculation. In addition, the linear fit method was only applied to measurements taken within a few hours of each other to avoid introducing errors due to change of conditions (drift in electronics, temperature...).

The measurement system has a 16-bit accuracy over ±10V, which gives 0.3 mV of precision. The amplifier gain was x5 on the D1 and D2 channels. The analysis used current data from 1.5 kA to 12 kA. From this we could calculate that 1 bit corresponded to 5 nΩ at 12 kA. Due to averaging over several hundred points the resolution was improved to 0.5 nΩ.

The distribution showed that the FWHM of the inter-pole resistance was ~10 nΩ. The RMS of the inter-pole resistance per magnet was 0.5 nΩ and 1 nΩ, as expected from the resolution, however this does not take into account systematic effects such as offset drift.

In the course of the analysis we found that the data set corresponding to magnets belonging to sector 78 gave particularly bad results: 33 of the 154 magnets could not be qualified at all. In depth investigation of the data showed that in most cases, even if a current plateau had been reached it was not long enough to allow all voltage signals to stabilize. As sector 78 was filled with the first magnets, we assume that the measurement procedures and tools in SM18 were not yet well tuned and that therefore the measurement conditions were not easily comparable with the other sectors.

The complete available data set was used to crosscheck the quality of the analysis tool, in particular when the individual bench behaviors were analysed. But to get results quickly, we only performed a complete study of the resistances for those magnets from sectors that had not been measured with more accurate methods, i.e. sectors 23, 34, and 45. However, to verify the reliability of our results we performed a detailed analysis of sector 67, which had more precise QPS measurements.

Analysis of the Bench Stability

The SM18 magnet test facility consists of 12 benches arranged in 6 clusters of two, sharing the same racks of DAQ electronics [4]. After analysing the data using the linear fit method, we noticed that the amount of magnets with suspect values on one of their inter-pole splice was strongly dependent on the bench it was measured on and on the date of the measurement. We therefore performed a study in order to characterize the benches (and/or their electronics).

For this we focused on two resistances, R11 and R14, which entirely belonged to the bench, as well as the clamps connecting the dipoles to the bench. We observed that:

- Data taken for the same magnet during different periods of time or on different benches could not be combined.
- The characteristics of two benches over time were unstable.

In the course of this analysis we detected several measurements indicating bench resistances substantially higher than 100 nΩ: besides being unusable for the purpose of the determination of the dipole resistances, these measurements pointed to an error in the electronics, as they could not be physically true. Indeed, in several occasions, the gain factor was wrongly entered into the configuration files associated to the data.

Comparison of Offsets

A total of 152 usable measurements at 1.5 kA were available for the magnets that showed a high resistance in the fit method. Many of the 1.5 kA measurements made on two benches gave high values for D2_U-L.

Excluding these two “bad” benches in the offset compensation method left only a few magnets with R(D2)> 25 nΩ .

A crosscheck of the best-fit and offset compensation methods has been done using all magnets measured on one good bench. These measurements showed particularly good signals. The result was that the offset method worked very well once the gain correction was applied.

Analysis Summary

Overall there were five magnets flagged for high resistance in one or several of the D1, D2, or Diode splices. One of the five magnets was known to have a bad D2 splice; the results of the other magnets were explained by non-stabilized signals. Without gain correction, four more magnets with (very) high resistance would have been flagged.

The measurements of D2 on the two "bad" benches showed signals that were not stabilized before the end of the recording. Thus we excluded these two benches for analysis of D2 with the offset compensation method.

The number of suspicious magnets resulting from the combination of both methods turned out small enough for detailed further manual analysis.

In addition, sixteen magnets could not be properly evaluated due to the poor quality or missing data.

Another faulty magnet, which was found with QPS measurements, could not be identified unambiguously with the SM18 data, as the problematic splice was the inter-aperture one.

No other magnets were identified as having a splice resistance higher than 25 nΩ on the inter-pole or diode splices.

CONCLUSION

During this data-mining campaign aimed at finding bad magnet splices, more than 23000 magnet performance measurements were scrutinized. This has been made possible by developing a specific analysis tool, based on an existing LabVIEW™ data viewer. Adding automated pattern and signal extraction and writing analytical algorithms permitted to get an overview of the splice resistance of four LHC sectors. From this, five magnets having high internal splice resistance have been flagged.

THE CERN ACCELERATOR MEASUREMENT DATABASE: ON THE ROAD TO FEDERATION

C. Roderick, R. Billen, M. Gourber-Pace, N. Hoibian, M. Peryt, CERN, Geneva, Switzerland

Abstract

The Measurement database, acting as short-term central persistence and front-end of the CERN accelerator Logging Service, receives billions of time-series data per day for 200,000+ signals. A variety of data acquisition systems on hundreds of front-end computers publish source data that eventually end up being logged in the Measurement database.

As part of a federated approach to data management, information about source devices are defined in a Configuration database, whilst the signals to be logged are defined in the Measurement database.

A mapping, which is often complex and subject to change/extension, is required in order to subscribe to the source devices, and write the published data to the corresponding named signals.

Since 2005, this mapping was done by means of dozens of XML files, which were manually maintained by multiple persons, resulting in a configuration that was error prone.

In 2010 this configuration was fully centralized in the Measurement database itself, reducing significantly the complexity and the actors in the process. Furthermore, logging processes immediately pick up modified configurations via JMS based notifications sent directly from the database.

This paper will describe the architecture and the benefits of current implementation, as well as the next steps on the road to a fully federated solution.

MEASUREMENT SERVICE OVERVIEW

The Measurement Service (MS) [1] is a vital component of the mission critical CERN accelerator Logging Service [2].

As shown in Fig. 1, the MS processes are responsible for subscribing to data published from accelerator equipment and persisting the results in either the Oracle Measurement database (MDB) or in SDDS (Self Describing Data Sets) files.

An optimized Java API has been developed, by which data for some 200 thousand signals are persisted to the MDB, from where a sub-set of the data is later transferred to the Oracle Logging database (LDB) for long-term storage. A complimentary logging to SDDS files is used typically to store data for complex data structures such as image captures or multi-megabyte beam profiles.

Java APIs are provided for extracting data from both the Logging Service databases and the SDDS file repository.

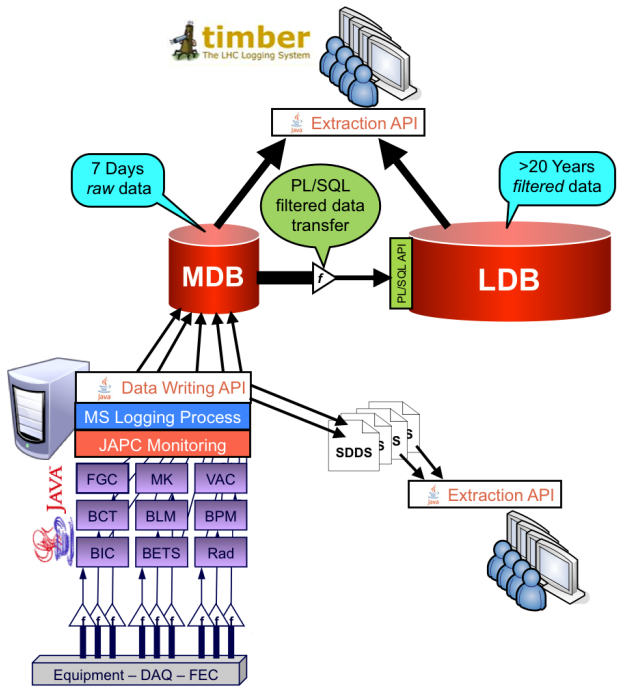

Figure 1: Measurement Service architecture and position within the Logging Service.

CONFIGURATION ESSENTIALS

In order to log data, a number of configuration steps are required:

Data Logging

It is a prerequisite to register all signals for which data needs to be logged in the MDB. The names of the signals must adhere to the well-established naming conventions, and complimentary information such as units and a meaningful description are required.

For signals whose data should be kept beyond the 7-days supported by the MDB, the filtering criteria (dead band and dead time smoothing, precision etc.) for transfer to the LDB must also be defined.

Data Acquisition

In order to acquire values to be logged, controls middleware (CMW) subscriptions via JAPC [3] need to be configured to obtain publish values. This implies declaring which device-properties to subscribe to, under which conditions (i.e. only for beams to SPS, LHC, etc.), and how the data should be time stamped (either the acquisition time, or the start time of the corresponding magnetic cycle). In addition, it is possible to specify special conversion code to be applied to published values prior to logging.

Bridging the Gap

Once signals are defined and JAPC subscriptions configured, it is necessary to bridge the gap between the two domains. This requires that individual fields of device properties are mapped to logging signals. For data published in array format, it is possible to configure the mapping of either individual elements or a subset of elements to scalar or array type logging signals respectively.

INITIAL IMPLEMENTATION

The initial implementation of the configuration of the MS was comprised of 3 components:

- Logging signals pre-registered in the MDB, and defined by means of data providers completing an Excel template with the details of the signals to be logged, which was validated by members of the logging team responsible for the MDB.
- JAPC parameter subscriptions defined in an XML file, filled by data providers, and validated by members of the logging team responsible for the MS processes.
- JAPC to logging signal mappings defined in an XML file, also filled by data providers, and validated by members of the logging team responsible for the MS processes.

This approach was quite heavy for the data providers, and susceptible to errors due to the need to manually ensure the consistency across the three separate configuration components. Flexibility was also lacking, since adding a new logging signal or modifying an existing one implied modifying 2 XML files, committing them in the code repository, and re-releasing and re-starting the relevant MS process. Although this approach was used successfully during 5 years, there was definitely scope to improve.

A FEDERATED APPROACH

The CERN accelerator control system is fully data-driven, based on several distributed Oracle databases, which collectively cover all data domains such as layout, asset management, controls configuration, and operational data. As part of a federated approach to data management, each database is considered the source for data in a particular domain, and data synchronization procedures are in place – either executed automatically or manually – to propagate necessary data to dependent databases [4].

The Controls Configuration database (CCDB) is the source for all data that describes the configuration of the control system. This includes amongst many other things the definition of multiple device-property models that describe deployed devices, and their available properties and fields, which can be subscribed to and/or modified [5]. The device-property data can be quite dynamic, mainly due to evolving requirements or to follow hardware or software developments.

The Goal

To achieve the goal of ensuring a smooth uninterrupted running of the MS, it is essential to have a consistent measurement configuration that is fully synchronized with the CCDB source data. That is to say that any changes to CCDB device-property data (such as device renames, or changes of properties and fields) should automatically be crosschecked against the MS configuration. Compatible changes should be immediately propagated to the active MS configuration, while non-compatible changes (such as removal of a property or field) should generate an alert.

On the Road

In order to reach the aforementioned goal, the first step was to provide an infrastructure inside the MDB to define the *complete* MS configuration metadata using a relational model. This metadata needed to include not only the existing definitions of the signals to be logged, but also the JAPC subscription parameters (device-property), and the mapping between the domains, as mentioned above.

Such an approach was deployed during 2010, making it possible to simplify the code and configuration of the many MS data logging processes, as well as bringing other advantages:

- A MS data logging process can now simply retrieve its full configuration by calling a single method with its process name as input.
- Requestors for data logging only need to make a single request to configure logging with a common Excel template for defining all parameters. This eliminates the possibility of having inconsistencies in the metadata describing JAPC subscriptions, logging signals, and mappings, both at the time of initial definition, and for subsequent updates to the device-property model data.
- The time required to configure logging of additional signals, or modify existing configurations is reduced significantly.
- With a single point of definition for MS process configuration, using an Oracle relational database, it is possible to envisage the simple propagation of CCDB device-property model data to the MDB using custom PL/SQL procedures.

ONLINE UPDATES

Previously, whenever requests to modify MS process configurations had been fully treated, it was necessary to restart the process concerned in order to apply the changes. This implies stopping all existing JAPC parameter subscriptions, and then restarting them based on the latest configuration. Considering that on average each MS process treats data for tens of thousands of signals, this approach was both time consuming and implied undesirable data loss. For example, to add the logging of a single new signal, it would be necessary to restart the related MS process and incur a non-negligible

downtime of logging of many of the other existing signals already being logged.

To minimize such data loss and make configuration updates more flexible, an online update mechanism was put in place (see Fig. 2):

- A virtual device-property was defined in the CCDB to indicate if a MS process configuration has been modified.
- The MS process code was adapted to subscribe to this property at start-up via JAPC.
- Once a MS process configuration is modified in the MDB, an updated value for the aforementioned virtual device-property is published directly from the MDB using Oracle Advance Queuing [6].
- When a MS process receives a notification that its configuration has been modified, it retrieves the new configuration from the MDB, compares with its current configuration, and then makes the minimum number of JAPC re-subscriptions necessary in order to get an up-to-date process configuration running.

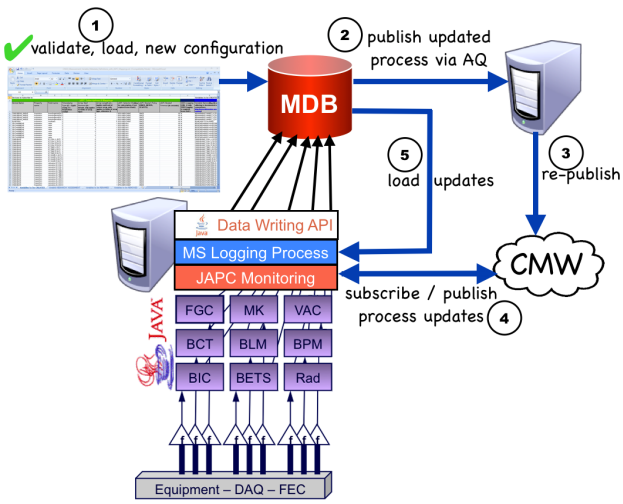

Figure 2: Online updates of MS configuration.

In summary, modifications to MS configurations can now be made online, and no longer imply data loss for other signals.

RESOURCE OPTIMIZATION

The MS writes up to 5.4 billion records per day (i.e. ~270GB) to the MDB. In order to optimize resources, some additional data driven features have been integrated into the MDB data writing API:

Log-on-Change

Depending on device-property structures and / or other requirements (e.g. continuous content for Fixed Displays), it is quite common for unchanging values to be published at relatively high frequencies. Examples include status flags, temperatures, counters etc. In most cases it is sufficient to log these values only when they change.

To implement this functionality, additional attributes were defined in the MDB metadata for each signal:

- A flag to turn on/off the on-change comparison.
- An integer value to specify a precision for on-change comparison.
- A flag to qualify if the precision refers to a number of digits left or right of the decimal point, or to a number of significant figures.
- An interval, after which to force logging of a published value even if it is not considered as changed.

These new attributes were exposed in the MDB data loading API, which then caches the last logged value for each signal which has on-change logging enabled. The new attributes are used to establish if new values can be considered to have changed sufficiently with respect to the last logged value. Newly published values are then only published on-change, or if the specified interval since the last logged value has elapsed.

Value Rounding

Numeric data is stored in the MDB using the Oracle NUMBER data type, which requires a variable number of bytes according to the scale and precision of the numeric values to be stored.

Many device-property field values are published with a much higher precision than the real physical accuracy (e.g. due to calculations prior to publishing), or what is actually required. An example would be a thermometer voltage-to-temperature conversion with 10 digits of precision.

In the same manner as for the on-change logging described above, additional metadata attributes were defined and exposed per signal – allowing the MDB data loading API to round values before writing to the MDB, thus saving storage, and improving I/O response times.

Not Just Resources

It is worth noting that while the described optimizations reduce the amounts of network activity, processing to load data, and storage required, the main benefit is actually for the users of the data, since having only significant data logged improves retrieval times and facilitates data analysis.

A CLEAR VIEW

With the configuration of MS processes and MDB signals now fully defined within the MDB, it was necessary to provide data providers, consumers, and MS experts with a means to visualize this configuration data.

To satisfy this requirement, a Web interface was developed using Oracle Application Express (APEX) to search and report on the current MS configuration (see Fig. 3).

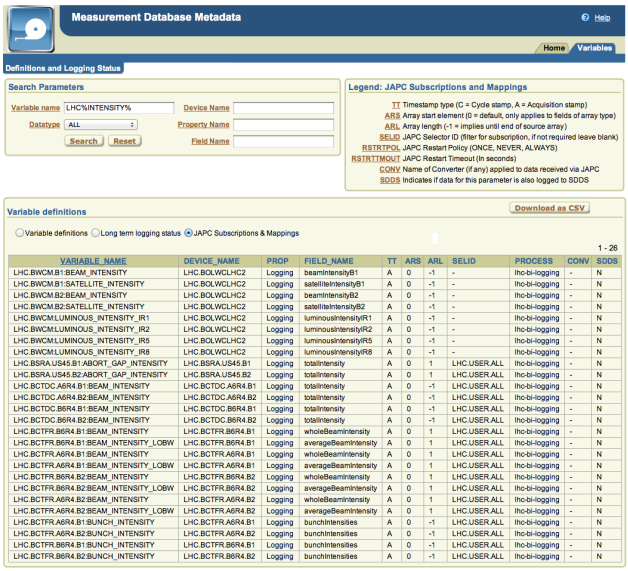

Figure 3: Measurement Service configuration report.

The report currently includes data acquisition configuration per MS process, applied data filtering criteria, and long-term storage status. In addition, the interface allows data providers to download existing configurations to a standard Excel template, from where configurations can be modified and/or extended and then submitted to service administrators for validation and integration into the system.

NEXT STEPS

In order to continue on the road to a fully federated data management solution, the links to the CCDB device-property model data need to be enforced, with automatic checks, updates, and notifications in place as outlined above.

The interfaces for browsing MS configuration data, and CCDB device-property data should be linked in both directions. This will simplify the process of browsing and configuring the MS for data consumers and providers alike. For example, it will be possible when browsing the device-property data to see which property fields are logged, and when browsing the MS configuration, to see the underlying data types of the device-property fields, or additional fields which may need to be logged.

Flexible Data Extraction

The Logging Service data extraction API currently only supports extraction of data based on signal names. However, it is foreseen to reuse the MS configuration data that maps JAPC parameters to logging signals within the data extraction API, thus allowing the extraction of logged data based on JAPC parameters. This will give users of logged data a more flexible means to retrieve data and facilitate the development of certain types of applications such as fixed displays that can optionally display a historical set of data.

SUMMARY

With respect to the initial implementation, the current infrastructure has already significantly simplified and improved the robustness of the process of configuring the Measurement Service.

The Measurement Service is well on the road to federation in the distributed database environment of accelerator controls. The foundations have been established, with all configuration data now centralized in a relational Oracle database, and the next steps to achieve the desired goals are foreseen.

DATABASE AND INTERFACE MODIFICATIONS: CHANGE MANAGEMENT WITHOUT AFFECTING THE CLIENTS

M. Peryt, R. Billen, M. Martin Marquez, Z. Zaharieva, CERN, Geneva, Switzerland

Abstract

The first Oracle®-based Controls Configuration Database (CCDB) was developed in 1986, by which the controls system of CERN's Proton Synchrotron became data-driven. Since then, this mission-critical system has evolved tremendously going through several generational changes in terms of the increasing complexity of the control system, software technologies and data models. Today, the CCDB covers the whole CERN accelerator complex and satisfies a much wider range of functional requirements. Despite its online usage, everyday operations of the machines must not be disrupted.

This paper describes our approach with respect to dealing with change while ensuring continuity. How do we manage the database schema changes? How do we take advantage of the latest web deployed application development frameworks without alienating the users? How do we minimize impact on the dependent systems connected to databases through various APIs? In this paper we will provide our answers to these questions, and to many more.

INTRODUCTION

The Controls Configuration Database (CCDB) provides the Configuration Management services for the Control System of all CERN accelerators [1]. It is a multifaceted software infrastructure composed of many interrelated components at the heart of which lies an instance of Oracle® database. CCDB relies on web deployed tools for data browsing and editing, and is accessible through Application Programming Interfaces (APIs) written in different programming languages. It is a component of a distributed database environment for the CERN accelerator complex and as such, it is linked to several other Oracle instances.

The CCDB forms the data foundation of the accelerator Control System and is used online for all controls operations. Consequently, full availability and reliability needs to be guaranteed to ensure accelerator operations and thus the CERN physics program.

No Downtime Allowed

Fortunately, the occurrences for which the CCDB was the cause of accelerator downtime have been extremely rare. However, in order to maintain its high quality, the CCDB has to evolve over time, similarly as all equipment that needs to be maintained and upgraded.

The accelerator operations follow a precise schedule per accelerator with technical stops with different frequencies and varying lengths. As for any hardware or software intervention that affects machine operations, deployments of CCDB changes need to be carefully planned in order to minimize the risk of disruptions during physics exploitation. Typically, we are granted an hour of database unavailability, every two months, to be scheduled on a single target day. Interventions requiring a longer downtime have to be scheduled during shutdown periods, i.e. outside the physics program.

Preparing the Interventions

Due to the severe constraints on deployment time and full proof quality of the intended modifications, every change undergoes prior multistage testing and comes bundled with a clear procedure for rolling back to the previous state. The sections that follow go into details of how these changes in the CCDB are dealt with. In order to better understand what type of changes are concerned, it is useful to recall the major milestones in the Controls Configuration Database.

CCDB HISTORY

The list below sketches the major modifications that were introduced in the CCDB over its 25 years of existence [2]. The important database schema modifications, interfacing technologies and functionality leaps are indicated.

- 1980 – Creating a centralized file-based data storage for some components of the Controls System
- 1986 – Introduction of Oracle RDBMS: CCDB birth
- 1987 – Data extraction scripts (embedded SQL in Pro*Fortran, re-implemented in Pro*C later on)
- 1995 – User interfaces based on Oracle Forms and PL/SQL Web Toolkit (OWA)
- 1999 – Java Directory Services
- 2003 – Introducing FESA Device-Property model
  2004 – Migration of data browsing interface to Oracle APEX technology
- 2005 – Introducing authentication and authorization mechanisms
- 2005 – Big-bang refactoring of the database schema
- 2005 – Introducing the Session Auditing and History Recording Framework
- 2006 – Redesign of the data editing interfaces using Oracle ADF technology
- 2007 – Introducing Hardware device-property model
- 2010 – Introducing Virtual device-property model
- 2011 – Introducing Configuration Change Management and Status Accounting in the CCDB [1]

The original database in 1986 was based on Oracle version 5, which was migrated through each major version up to the current Oracle 10*g*. The upgrade to

Oracle 11*g* is scheduled in January 2012 during the next winter shutdown.

The CCDB is now under the responsibility of the second generation of database engineers. Over the 25 years of the lifetime of the CCDB, programming languages and technologies change, applications and software come and go, but the data remains.

REASONS FOR CHANGE

A look at the timeline above makes it clear that the driving forces for change can be classified into the following categories:

- Changing user requirements.
- Changing software technologies.
- Internal refactoring to improve software quality and reduce maintenance burden.

Changing User Requirements

Changes in the user requirements constitute the principal reason for CCDB modifications. New functionalities are requested, existing ones change, obsolete ones are dropped, new components of the Control System are in need of data driven configuration, and users' expectations towards the IT systems evolve. Although most frequent, these modifications benefit from the highest rate of acceptance because their rationale is well understood by the users.

Changing Software Technologies

The second category of changes is forced by the evolution of the technology stack that CCDB depends upon. Since the early days of CCDB we have been using Oracle products and now that Java is also part of Oracle we are nearly 100% dependent on this vendor's products. The potential vendor lock-in is not the main concern, but as Oracle technologies evolves so needs the CCDB.

Database upgrades are necessary to ensure the long-term continuity and support, and to take advantage of new features, functionality and efficiency. These upgrades are never carefree, but have been consistently programmed towards the stable, terminal release of a major version.

The data-driven client APIs have evolved from Pro*C precompiled code to Java (although some Pro*C legacy has not yet been phased out).

For interactive user interfaces, Oracle Forms have been upgraded from version 4.5 up to 9*i* and finally replaced with J2EE-compliant Oracle Application Development Framework (ADF).

Web-deployed interfaces and reports, originally generated by the PL/SQL OWA module, left its place to Oracle HTMLDB which evolved into Oracle Application Express (APEX).

All these technological changes are imposed upon the developers as well as upon the end-users. Often this requires a change in the users' habits and requires well devised communication campaigns and careful deployment. The human factor must not be neglected here as no software product can be successful unless its users are happy.

Software Refactoring

The last – but not least – driver for change comes from our own quality assurance standards. We are aware that in order to maintain the high quality of the systems we provide, there is a need to regularly revisit existing production code and evaluate following considerations:

- Improving the performance of interfaces.
- Streamlining data propagation.
- Simplifying workflows.
- Improving data quality and integrity.
- Getting the most out of new technologies.
- Complying with our own coding and data management standards.

Modifications that result from these considerations do not necessarily give any added value or visible impact for the end user, but is purely for reasons of code maintenance and efficiency of the development team. In addition, these changes are not always transparent to the end user. For example, the introduction of referential integrity constraints across the database – which were not present in the original design – resulted in error messages seen by the users. This modification greatly enhanced the quality of data, as opposed to recording incoherent, erroneous information prior to the refactoring.

It has to be noted that all three categories of changes have an impact on the users of the services provided by the database. These users are not only human actors, but also the dependent computer systems that are linked to the CCDB. The following sections outline our time-tested strategies for managing this impact.

STABLE INTERFACES

By having well defined interfaces towards the external systems, the CCDB can afford to change underlying implementation quite freely and transparently. Data is exposed through database views. Unless a very profound refactoring takes place, the structure of views can remain identical even if underlying tables are altered. Backwards compatibility after data model changes is a primary concern. If this cannot be ensured, the interfaces have to be renegotiated with the users, and the whole deployment process becomes much more complicated. For example, hundreds of front end computers may need to be rebooted to force the correct runtime deployment. Depending on the functionality of the front end, this is something that can only be scheduled during a technical stop.

We have separate dedicated database accounts with different sets of privileges corresponding to different usages of data. This way we control in a very precise manner the data access – for reading or for editing – by a particular set of users. For distinct clients, specific views are provided, which all point to the same underlying data.

An additional layer of isolation is provided by the APIs that are exposed to the users. Nowadays, these are written in Java or PL/SQL with XML being the representation of

choice for data transfer. These APIs have proven to be very stable . One example is Java Directory Services [3] which dates back to 1999, but has been recently refactored to improve the performance and benefit from the many useful features provided by the Spring framework [4]. Even if its internals changed to a very large extent, and some new interfaces were added, the existing ones remained fully backwards compatible.

STAGED TESTING AND DEPLOYMENT

Over the years, we have worked out a staged environment that provides a complete and efficient framework for testing and deployment. We have provided dedicated instances of the CCDB in four distinct environments: DEV, TEST, NEXT, and PRO as shown in Fig. 1.

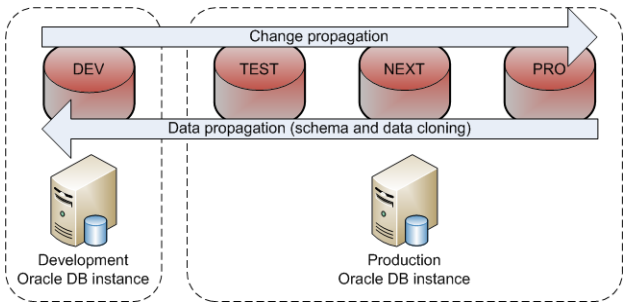

Figure 1: Overview of the four CCDB environments.

DEV is the development environment in which the database schema is installed at a development database instance. It is our "try-it-out" environment where no stability is required. DEV is used for proofs of concepts, general development and introducing new code.

TEST is the environment for functional testing. Tests are started with the database being a clean 1:1 copy of the production schema. Consequently, new code from DEV is copied across and all necessary tests are carried out in isolation from other systems that depend on CCDB. The following tests are against all existing applications that are affected by the newly introduced changes.

NEXT is a relatively recent environment (created in 2008) that has been introduced for integration testing. It is a part of the Controls Testbed since 2010 [5], a fully functional vertical slice of the Accelerator Controls System. As such it has every component from the whole control system present. The NEXT environment represents the CCDB as it will be after the following deployment in PRO.

PRO is the production environment used by the Controls System. It is guaranteed to be stable, as no changes are performed outside of scheduled interventions.

TEST, NEXT and PRO environments are hosted on the same database server, which allows us to test the performance and scalability in real life conditions. For resource demanding testing against TEST and NEXT, precautions are taken in order to avoid performance degradation of the production environment.

INCREMENTAL APPROACH

Historically some major change sets were applied to CCDB as "big-bangs" but with the LHC in full operation, this type of revolution is excluded in order to avoid any disturbance noticeable by the user community. Therefore, deployments are rolled out adiabatically and step-wise over relatively long periods of time. This method is applied to the vast refactoring of the data management services for the CERN Front-End Software Architecture (FESA) framework [6]. The objective is to fully rationalize the database schema and to eradicate inefficient XML objects inside database in favour of a relational data model. The FESA workflow is complex and consists of controls device class modelling, deployment and instantiation phases. These workflow phases are tackled one at a time, passing through all four environments. Passing to the next one is only done when the expected behaviour is ensured. This way, an effective rollback strategy is in place in case of failure and the impact on users is limited. Moreover, even when new database schema and APIs are deployed, the previous ones are maintained in parallel for a few weeks to guarantee redundancy in case of problems. The same is valid when new user applications are put in place – the old ones are supported, if possible, for a certain period (sometimes for months) in order to ensure that the users have accepted the new functionality.

The incremental approach has also been applied for the replacement of PL/SQL OWA based CCDB Data Browser with the new one built using Oracle APEX [7]. The full functionality of the existing set of pages needed to be reproduced, while adding support for new sets of data. Navigation and overall usability was to be improved, providing a new, contemporary look and feel. The major reports were developed first – i.e. roughly 80% of all content – and deployed for public use, followed by continued adding of the remaining ones. However, to gain user acceptance, a proactive communication campain and feedback channels were put in place. In parallel, the outdated data browser was kept running for one year without any development effort. Eventually access to the obsolete service was blocked, in line with the announced planning. A very similar strategy has been followed when replacing more than 150 Oracle Forms with their Oracle ADF successors.

We are convinced that incremental approach to change is a valid one. This conviction is further strengthened by looking at some examples from the "real world", especially in the domain of Web applications. One notable example of incremental functionality enhancements is Google Mail where new features are added one at a time and there is a possibility for the users to switch them off, at least for a while.

CAREFUL PLANNING

With all CERN accelerators dependent on CCDB for their everyday operations, there is no room for

improvisation when it comes to rolling out new features. Every deployment requires very careful planning.

The impact of every change to be deployed is assessed right from the start. Deployment scripts are prepared with rollback paths at every step of the process. An exact copy of the PRO environment in NEXT is created and the timed execution of the scripts is carried, indicating the time to be allocated for the final deployment in PRO. The interventions are planned in line with the accelerator schedule in order to have zero impact on the machine operations. Announcements are prepared and sent to mailing lists of the user community.

With this type of preparation, the only action on D-day is to execute the plan. In case of any mishap, a clear exit path is available and possible at every stage. In addition, every action is recorded and stored in a secure file system in a dated folder for future reference.

This scenario ensures full transparency and traceability of each software deployment session, essential for the overall quality assurance process.

DEALING WITH HUMAN FACTOR

Dealing with the human factor is probably the most delicate part of the whole software change process in the context of CCDB. The accelerator community is large and diverse from control room operators to equipment specialists and accelerator physicists. Their expectations related to the provided tools are high, but also vary for each accelerator, due to operational habits which have not yet fully converged. As designers and developers of those tools, we have to find the balance between generic implementations and specific functionality.

Twenty-five years ago, the CCDB was deployed in the scope of the CERN Proton Synchrotron complex, without covering the larger machines. Data entry was centralized and done by a team of two dedicated data management engineers, working in close collaboration with operators and equipment experts. Since 2003, with a second generation of database engineers, the CCDB scope has been extended to cover the complete accelerator complex. Focussing on the data model, interfaces and business logic, the ownership of configuration data has been transferred to the responsible people of the hardware or software, which needs to be configured through CCDB. To this end, data entry tools have been adapted, authentication and authorization mechanisms introduced and the people trained. For reasons of traceability, every single data manipulation, executed by a user, is recorded together with time stamp and session information. This mechanism also enables the possibility of reverting to a previous data situation. Currently, more than 300 unique users are active across all applications of the CCDB.

Whenever an end user tool is to be refurbished, the key users are involved very early in the development process. They are invited to test the iterative versions of the software and to provide feedback. Prior to a deployment in PRO, the changes and their possible impact are communicated to all concerned parties via the relevant announcement channels.

CONCLUSIONS

The Controls Configuration Database is an evolutive system and as such it is subject to change. However, considering that it lies at the heart of the CERN accelerator complex, there is no room for improvisation when deploying new features. The successful strategy for dealing with change that has been put in place is based on the following guidelines:

- Involve end-users right from the start, throughout the design and development process
- Provide four separate environments for development, unit and functional testing, integration testing (TestBed), production
- Analyze the impact of a change and try to apply only backward compatible changes
- Communicate timely, clearly and transparently on scheduled intervention and their impact
- Coordinate the upgrades with impacted clients

By respecting these guidelines, we have been able to perform and manage changes and have them accepted by the user community.

CERN ALARMS DATA MANAGEMENT: STATE AND IMPROVEMENTS

Z. Zaharieva, M. Buttner, CERN, Geneva, Switzerland

Abstract

The CERN Alarms System - LASER is a centralized service ensuring the capturing, storing and notification of anomalies for the whole accelerator chain, including the technical infrastructure at CERN. The underlying database holds the pre-defined configuration data for the alarm definitions, for the Operators alarms consoles as well as the time-stamped, run-time alarm events, propagated through the Alarms Systems.

The article will discuss the current state of the Alarms database and recent improvements that have been introduced. It will look into the data management challenges related to the alarms configuration data that is taken from numerous sources. Specially developed Extract-Transform-Load (ETL) processes must be applied to this data in order to transform it into an appropriate format and load it into the Alarms database.

The recorded alarms events together with some additional data, necessary for providing events statistics to users, are transferred to the long-term alarms archive.

The article will cover as well the data management challenges related to the recently developed suite of data management interfaces in respect of keeping data consistency between the alarms configuration data coming from external data sources and the data modifications introduced by the end-users.

INTRODUCTION

The Alarms Service, LASER, is a critical system, used during the Operation of CERN's accelerators.

The existing service was developed for handling the abnormal situations for all accelerators and with the Large Hadron Collider in particular [1]. Previous implementations of the system were done for the PS complex [2] and for the SPS complex [3].

The alarms data management is an important part of the Alarms service. Already since the beginning of the 1980s there was an idea to implement a data driven alarms system for the PS Complex Controls.

Since 1986 a relational database and in particular the Oracle® RDBMS was chosen as the basis for the alarms data management.

SCOPE

At present the data stored in the Alarms Database covers the needs for an alarms service for all accelerators at CERN. The database contains data for the Fault States (abnormal situations) of the accelerators' devices controlled by the Controls System, e.g. magnets, beam monitoring devices, etc. The data stored in the LASER DB is used for the Technical infrastructure alarms, e.g. alarms for the areas of electricity, cooling, etc. It covers also the safety systems, the radiation monitoring system, the computer network alarms as well as alarms data for abnormal situations in the Controls software itself.

All of the above listed domains of alarms data are called providers and there are 31 in total. This accounts for more than 3,000,000 data elements stored in the LASER DB.

AREAS OF THE ALARMS DATA MANAGEMENT

There are three distinct areas of data, which are part of the Alarms data management.

Configuration Data for the Alarm Definitions

The main pieces of data that build-up the alarm definitions are the fault family, fault member within a family and the fault code of a given family. The combination of those three pieces of data uniquely identifies an alarm at CERN and represents the fault state. Additional attributes, provided by the configuration data, are the priority of the alarm, the action to be taken, etc.

The alarm definitions configuration data is extremely important due to the principle of LASER that all fault states must be defined in the LASER DB prior to their use. The LASER service will not accept and propagated events, whose definitions are not in the Alarms database.

Configuration Data for the Users Consoles

As the name suggest the data in this area is used for configuring the displays on the Operators Alarms Consoles. It includes the operators' category structures, which help the users to group the alarm events on their screens, preferences of displayed categories on the consoles, filters for the events, etc.

Run-time Alarms Data

The run-time alarms data is the time-stamped alarm events, which are coming from more than 220 sources. An alarm event is the activation, termination or update of the fault state. The LASER server processes the events data and stores it into the LASER DB. The run-time events are distributed to approximately 50 client consoles so that the users will be notified of fault states.

OVERVIEW OF THE ALARMS DATABASE ENVIRONMENT

For the purposes of the Alarms data management several db accounts are used. The main accounts are depicted in Fig. 1 as well as the ETL processes, which are used for LASER data configuration and archiving.

Alarms Configuration Data Collection Account

The Alarms Configuration Data Collection db account is used in order to collect all alarms configuration data

from the different providers. The data could be provided in the form of different db objects, e.g. views, materialized views or tables. There are 31 starting objects, which correspond to the 31 data providers. All of those objects have a standardized structure and contain the same type of configuration data. This is done in order to solve the problem of unifying the data from so many diverse providers as well as to ease the data import process.

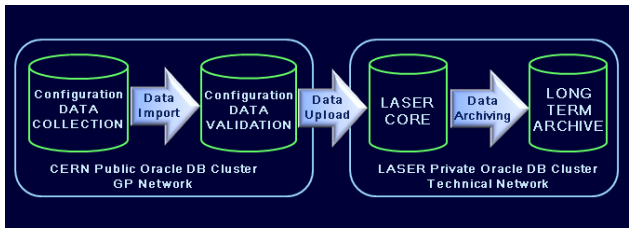

Fig. 1: Overview of the LASER data management environment – main database accounts and ETL processes.

Alarms Data Validation Account

The configuration data for the alarms definitions is not directly imported from the Data Collection into the LASER Core account. Due to the complexity of the process to validate the data and to transform it into the final destination format the loading of the alarms data passes through an intermediate stage.

LASER Core Account

The Core database account holds all the configuration alarms data, which is used directly by the LASER server. The account contains the user preferences and consoles configuration, which are extracted via a set of views and provided to the LASER consoles. The same account also stores the on-line alarm events in the form of a short term alarms archive, which contains data for the last six months. There are 200,000 time-stamped events recorded on average per day, however at peak times there could be up to 1000 events per second send to the LASER DB.

Alarms Long-term Archive Account

The long-term alarms archive has a completely denormalized schema and the structure is more like a data warehouse.

There is a PL/SQL procedure for transferring the on-line data into the long-term archive, which is executed as a db job once per day.

The long-term archive has been in operation since 2005. At the beginning of each year archiving of the previous year's data is done and between 4 to 10GB of data is added to the long-term archive. PL/SQL procedures, dedicated to this process, are used. During the long-term archiving a factor of 10 reduction of the data volume is achieved. Only the alarm record at activation time and at deactivation time for the alarm events are kept, thus all records between those two are removed.

Alarms Data Management ETL Processes

There are two main types of ETL processes, which are used for the Alarms data management.

The first type is related to the loading of the configuration data into the LASER Core account. The data needs to be validated carefully against the business rules, established for the alarms definitions and transformed into the required format. This is done in two stages due to the complexity of the data manipulations. The first process in the chain is called 'Data Import'. It takes the data from the Data Collection account and moves it to the Data Validation account. The Data Import process mainly verifies the validity of the provided data, while the second process, called 'Data Upload' has as a primary goal to transform the data into the required final format while still performing checks.

The second type of ETL processes are related to the archiving of the alarms data. There is a process that runs every day, which transfers data older than 6 months from the LASER Core to the Archiving account. Another process runs once per year in order to establish the long term archive for the previous year.

Complexity of the Database Schemas

Table 1 provides the exact figures showing the complexity of the alarms-related database schemas. The alarms database model is not a very complex one – altogether there are 207 tables and 241 constraints throughout the four main accounts. On the other hand due to the numerous validations, checks and transfers of data, part of the intensive ETL processes, there is a big PL/SQL code base.

Table 1: Alarms Database Accounts Statistics

Tables	207
Constraints	241
Lines PL/SQL code	32,000
Volume	195 GB

SERVICE QUALITY ASSURANCE

Database High Availability

One of the challenges in front of LASER DB is to provide high availability service - 24 hours a day, 365 days a year, as the Accelerators complex at CERN cannot function reliably without the Alarms system.

The high availability of the database is achieved through the use of Oracle cluster technology (RAC) which guarantees not only the hardware but also database software redundancy. The solution ensures no down time even during routine software patching of the database.

Another point in the strategy for high availability is to have a special db cluster dedicated only to LASER (private). This approach guarantees that no problem could be encountered due to other db clients on the same cluster.

Data Security

Data security is of utmost importance in the domain of alarms data management. A major improvement in this domain since 2009 was the deployment in the LASER Core account of several custom-developed diagnostics frameworks, allowing monitoring and traceability of *who* changed *what* and *when*. This is extremely important especially in the light of providing new applications to the end-users (accelerators operators) to be able to change some of the configuration data themselves.

The first framework audits every session opened in the LASER DB, while the second framework, the History one, records all data modifications and keeps them on-line, available to be accessed through a web-deployed LASER History Browser application.

Development and Testing Environments

The Alarms service is a critical one for the Operation of the Accelerators. The database part of the Alarms service is equally important and every piece of new code should be thoroughly tested.

Three environments have been provided, in order to ensure bug-free alarms data management. The ***Development*** environment is used for developing database functionality as well as developing the related Data Editing and Data Browsing applications and database APIs. The ***Test*** environment (created in 2010) is used for functional testing within the database tier as well as an integration testing environment of the vertical slice of the Alarms service – database tier and LASER server. The ***Production*** environment is the one used for the on-line Alarms data management.

ALARMS DATA MANAGEMENT CHALLENGES

Multiple Data Providers - Eliminating Scattered Sources of Alarms Configuration Data

The data management for the Controls and Operation of CERN's accelerators is implemented as a distributed database environment [9]. Previously the alarms configuration data was gathered from a significant number of databases, e.g. the Accelerators Entities and Signals Naming DB, etc. as well as some scattered db accounts.

During the last two years efforts have been put in place to eliminate dispersed sources of alarms definitions and to streamline them through the main databases, providing data to LASER DB. As a result of those efforts several db sources have been eliminated leaving only the databases shown in Fig. 2 to deliver the alarms configuration data.

An example of this strategy is the migration of the power converter alarms configuration data into the CCDB and its integration into the Hardware Controls devices framework [4]. This solution resolved the issue of synchronization between the devices data in the CCDB and the alarm definitions for the very same devices, which were previously kept in a separate db account. At present the data provided by CCDB accounts for almost 70% of the alarms definitions configuration data imported into LASER [6].

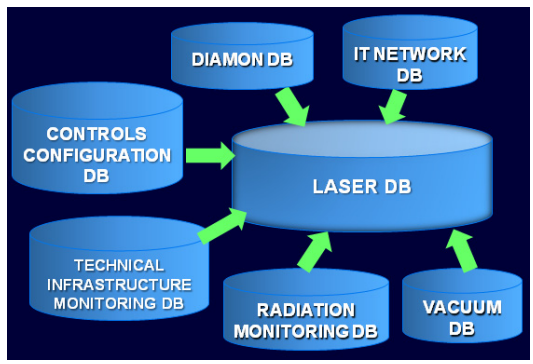

Fig. 2: Databases, providing alarms configuration data to the LASER DB.

The approach of unification of the sources of alarms configuration data guarantees not only a better maintenance of the alarms configuration data by the equipment experts, but it simplifies the process of initial import of the alarms configuration data.

Separation of Alarms Definitions Configuration Data from Users Consoles Configuration Data

An alarm system is supposed to give its users a better insight of the status of the different systems and particularly when problems arise. A badly configured alarms system (due to bad configuration data) will not achieve this goal. Typical problems, which arise in the CERN Controls Centre, are an alarm event not being seen by an operator, due to the alarm definition not being correctly configured in respect to the display category, or an alarm event appearing on the console of an operator of a given accelerator when it should not be there.

In order to solve the above mentioned issues, a clear separation needs to be achieved between the alarms definitions configuration data and the users' consoles configuration data. This means that the equipment experts should be responsible only for the alarm definitions while the operators take complete responsibility for the alarms consoles configurations data, including the assignment of alarm definitions to the operational alarms categories, which they monitor.

First steps in this direction were taken during the last year by providing some basic data editing applications through which the operators could set-up their own configurations of alarm definitions to categories assignments. One must however be extremely cautious with the data changes introduced directly into the LASER Core db as the current database model does not provide a clear split between the two alarms configuration data areas.

This problem is addressed in the new LASER Core database model, which is currently implemented in development environment and will be the basis for the renovated LASER service.

EXTENDING THE DATA MANAGEMENT FUNCTIONALITY

A lot of improvements and extensions of the alarms data management services were done during the last two years. Some of the new functionalities are related to extending the database model and some are related to providing new user applications for browsing and editing the alarms data.

Introducing Alarm Instructions

A new area of the Core LASER DB is the one of alarm instructions. This data is related to the configuration data of the alarm definitions and gives directions of what measures should be taken in case an alarm is activated.

Introducing Filtering of Alarm Events, Based on Accelerator's Beam Modes

The filtering of alarm events on the alarms consoles is an example of new functionality provided in the area of the user consoles configuration data. The alarm events that are usually displayed on the operators' consoles now could be filtered based on the beam mode of a given accelerator. This feature is extremely useful as it prevents the operators' consoles to be flooded with alarm events, which are not relevant under certain beam modes. At present the new functionality is used by the LHC Operation.

Development of a Suite of Data Management Applications

A major improvement in the Alarms Data management was the development of a suite of data management tools during the last two years. These applications give users the possibility to explore all alarms data and to maintain the configuration part of it. The choice of development technology both for the Data Browsing and for the Data Editing tools was Oracle Application Express [6].

The LASER *Data Browser* (Fig. 3) is the main reporting application. It comprise of more than 40 different reports and simple graphs with statistics, covering all areas of alarms data.

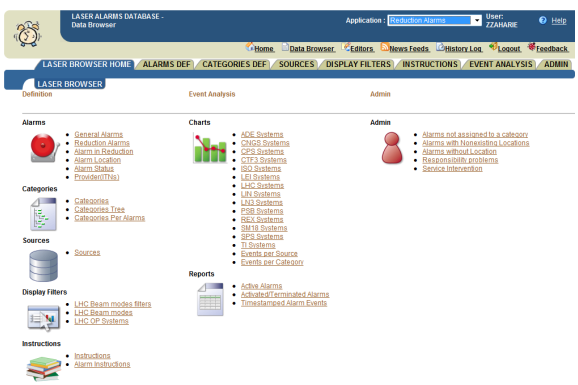

Fig. 3: LASER Data Browser.

The *Help Alarm* is a special report, which is integrated into the Data Browser. It presents all related data for a given alarm definition, which is available in the LASER DB, as well as data coming from other databases e.g. Network DB, TIMDB, DIAMONDB, CCDB, etc. The Help Alarm page is used as a reference report for any alarm by the LASER end-users.

A number of *Data Editors* were developed, targeting specific problems that the operators need to deal with. The editors are related either to giving the users the possibility to manage the Console Configurations, e.g. the *Power Converters Categories* Editor and the *TI Network Alarms Categories Editor*, or to giving the option to edit data related to the newly provided functionality in the LASER model, e.g. *Alarms Instructions Editor* and the *Beam Modes Filters Editor*. Another application, which was developed, is the *Reduction Alarms Editor*. In order to avoid an avalanche of correlated alarms on operators' consoles, special filters are declared by the users called Display or Reduction alarms. This helps to achieve a cleaner console display and to more easily spot the real cause of a problem.

CONCLUSION

The Alarms Service is a critical element, which is indispensible to the Operation of CERN's accelerators complex. The database tier plays a pivotal role and has proven to be a stable and reliable component. Continuous effort is put into its improvement through rationalization, data federation and development of new functionality at the database and interfaces level.

A new LASER Core database model is in the process of being developed catering for additional data elements for the alarms quality management and a workflow for the operators to approve the alarms configuration data.

A significant challenge in the future of the Alarms data management will be the smooth transition between the existing database model and ETL processes and the new ones to support the renovated LASER service.

Abstract

This work started in the context of NSLS2 project at Brookhaven National Laboratory. The NSLS2 control system foresees a very high number of PV variables and has strict requirements in terms of archiving/retrieving rate: our goal was to store 10K PV/sec and retrieve 4K PV/sec for a group of 4 signals. The HyperArchiver [1] is an EPICS [2] Archiver implementation engined by Hypertable, an open source database whose internal architecture is derived from Google's Big Table. We discuss the performance of HyperArchiver and present the results of some comparative tests.

EPICS ARCHIVER BRIEF HISTORY

The Channel Archiver [3] is an archiving tool-set for EPICS based control systems. It can archive any kind of record available through Channel Access [4], the EPICS network protocol. Bob Dalesio designed the original index file, data file layout, and implemented the first prototype of Channel Archiver. From then on, many people in the collaboration have been involved on this EPICS extension. The largely used Archiver version is still based on that design and last release is dated on August 29, 2006. That version is based on its own binary file format to archive the PVs. In July 2009 SNS stopped using such version and designed a new archiver. The new version can be engined with two kinds of RDB: MySQL or Oracle. All code has been written in Java and embedded into the Control System Studio (CSS)[5]. CSS can be used to browse the data and to retrieve them. The SNS archiver is based on Oracle RDB in production and MySQL for test purposes; the data base is accessible via Control System Studio (CSS) data browser. This archiver version realized at SNS embeds a Java Archiver into CSS.

TARGET

NSLS2 project at BNL expects a large amount of data that have to be acquired really fast. The goal was storing 10K PV/sec and retrieving 4K PV/sec for a group of 4 signals with a more reliable and safe archiving architecture. The SNS archiver, based on Oracle, seems not fast enough and expensive because of Oracle DB licence fee. The MySQL version has potential scalability concerns, and is designed for a single machine, then heavy processing loads may require expensive hardware and ad hoc solutions. At that time, summer 2009, two approaches were evaluated:

- Rewriting the Rtree and double-linked list embedded DB structure
- Look for a complete replacement of the embedded DB

After an initial period spent in analysing the first solution, we switched to the second one and looked for a completely new technology. The idea came from the observation that the fastest and largest DB available nowadays is Google, whose search engine is based on the proprietary BigTable filesystem. Google never published the details of Bigtable implementation, nor released a licensed version of its filesystem. However, we found an open source product based on similar concepts and technology (Hypertable [6]) and started working on it. Hypertable is a massive, parallel, high performance database, that isn't a RDB nor a SQL DB. During our first tests, Hypertable was only available as part of an open source software project (under GNU2 Licence). Nowadays Hypertable is delivered either in a free version (used for our project) and in a commercial version (by Hypertable Inc.) with payable support. We are using now the 0.9.6.0 version (the last beta release); the roadmap has fixed the first major release 1.0 in December 31st 2011, which will mark the end of the beta period and will introduce a fully functional BigTable implementation.

SYSTEM DESCRIPTION

The system used is a virtual Linux box with 16 CPUs, 10 GB Ram and 3.6 TB of ISCSI disk space on a HP server model DL380G7. A similar system running on a native OS, instead of a virtualized box, would exhibit better performances: we decided, however, to use a virtual machine to make easy cloning the “box” and sharing it with other developers, saving them the time to set-up a complete system from scratch. The virtual layer technology we used is KVM and the underlying operating system is Linux CentOS 5 (a RedHat Linux Enterprise recompiled from source).

The ISCSI disk has been tested separately to be sure it couldn't be a bottleneck for our tests and it showed a R/W

speed of 45 MB/sec; we can assume, therefore, it didn't affect our evaluation.

The bench-test core is an IOC with the following features:

- 10K Record type Analog Input
- Every record has a scan rate 1 sec

The HyperArchiver is configured to insert 10K samples/sec and to extract, from CSS, 1K samples of 4 PVs.

The HyperArchiver configuration is an hybrid system based on MySQL and Hypertable 0.9.5.0.pre6. MYSQL DB is used to store the configuration setup while Hypertable is used to store the Channel data: channelName Status, TimeStamp, Severity, Simple Mode, SimplePeriod, type, and value.

The data read from Channel Access by Channel Archive Engine v.1.2.5 through JCA are concatenated in a string and stored into Hypertable.

The Hypertable schema has only one column named "pv", the rowkey is based on a PV name with the EPICS Time Stamp as follow:

- Rowkey: 100:aiExample.1315639247116
- ColumName: pv
- Data:100:aiExample#c#LOW_ALARM#c#1315639247116#c#MINOR#c##c#jdbc:mysql://localhost:3306/archive#c#Monitor#c#10.0#c#double#c#3.0

Implementation Details

Starting from the original Archiver developed at SNS and based on Java, we made minor changes on various classes; the most important work has been done on package named org.csstudio.archive.rdb which has been designed as shown in Figure 1. The new package named org.csstudio.archive.htrdb2 (Figure 2) has deep

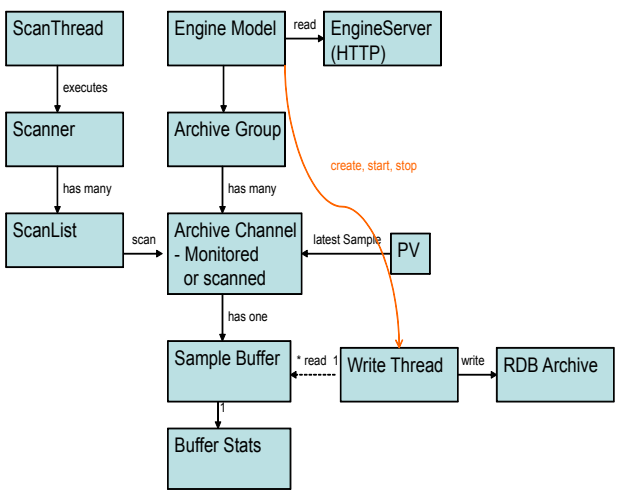

Figure 1: Generic RDB Archive Engine model.

modifications in the class named RDBArchive. Using the Trift client API we added two new classes (Figure 2) :

- HTArchive which contain connections methods;
- HtTableArchiveSerialized which contains methods to manages datas.

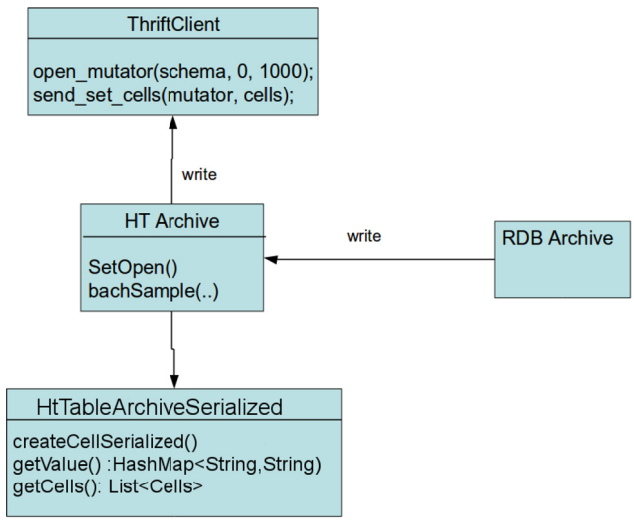

Figure 2: Classe's schema of org.csstudio.archive.htrdb2 package.

The data stored can be readout by dataBrowser2, replacing the package org.csstudio.archivereaderrdb by org.csstudio.archivereader.htrdb2. The most importat modification is on RawSampleIterator class where the Hypertable connection and retrieve task has been realized.

PERFORMANCES

Several test has been carried out at LNL. Using the BNL iocServer we started with a scan period of 0.1 sec for each PV of 10K analog input records. The archive engine seems to be unable to sustain that acquisition rate, so we decide to postpone a more detailed analysis on this and moved a step back using a scan period of 1 sec. for all PVs. With this set-up the average insertion rate is 13 MB/s and the retrieve rate of 13MB/s from CSS. Data were retrieved through the CSS GUI.

CONCLUSIONS

BNL has proposed a common test bench to evaluate the various archiver developments[7]. We used that guidelines for our tests to share and compare our benchmarks with the EPICS community. As mentioned before, the HyperArchiver is still an hybrid system in his internal architecture; it shows anyway good performances and seems a promising research line. Keeping in mind the fundamental spirit of collaboration in Epics community, future steps on this project will be done after a discussion with the laboratories interested on his development. This will help us to better focus on common targets and methods, and obtain the maximum results with the largest benefits for the community.

ACKNOWLEDGEMENTS

Sincere acknowledgements to Bob Dalesio who has made possible the beginning of this research during the stage of M. Giacchini at BNL in 2009.
Many thanks to the great BNL controls team and particularly to R. Petkus and R. Lange for their valuable help. The highly professional collaboration of K.Kasemir from SNS, his great experience and skills were essential. Last but not least, acknowledgements to ESS Bilbao, in particular to M.Campo and Prof. J.Jugo who first trusted on this project and brought it to the production stage at ESS-Bilbao's facilities at Zamundio (Spain) [8].

IMAGE ACQUISITION AND ANALYSIS FOR BEAM DIAGNOSTICS APPLICATIONS OF THE TAIWAN PHOTON SOURCE

C. Y. Liao#, J. Chen, Y.-S. Cheng, K.T. Hsu, K.H. Hu, C.H. Kuo, C.Y. Wu
NSRRC, Hsinchu 30076, Taiwan

Abstract

Design and implementation of image acquisition and analysis is in proceeding for the Taiwan Photon Source (TPS) diagnostic applications. The optical system contains screen, lens, and lighting system. A CCD camera with Gigabit Ethernet interface (GigE Vision) will be a standard image acquisition device. Image acquisition will be done on EPICS IOC via PV channel and analysis the properties by using Matlab tool to evaluate the beam profile (sigma), beam size position and tilt angle et al. The EPICS IOC integrated with Matlab as a data processing system is not only could be used in image analysis but also in many types of equipment data processing applications. Progress of the project will be summarized in this report.

INTRODUCTION

TPS (Taiwan Photo Source), a third generation 3 GeV synchrotron light facility, featuring ultra-high photon brightness with extremely low emittance which is being in construction at National Synchrotron Radiation Research Center (NSRRC) campus. It consists of a 150 MeV S-band linac, linac to booster transfer line (LTB), 0.15–3 GeV booster synchrotron, booster to storage ring transfer line (BTS), and 3 GeV storage ring.

For optimize machine operation and diagnostics applications, the two-dimensional (2D) beam profile images was used and recorded by cameras, which is widely used in synchrotron light source facility. The beam profile image has extensive information on beam parameters, including beam center, sigma, tilt angle and etc. The fluorescent screens convert the beam flux density as a function of position into a measurable signal, and charge coupled device (CCD) camera for image acquisition, were used in this application. Due to the most of machine parameters in future TPS [1] facility will be accessible as EPICS (Experimental Physics and Industrial Control System) process variables (PVs) [2]. Thus, an analysis tool use the PVs as inputs with ability to calculate and display results in complex ways is needed. In this moment, Matlab was chosen as the candidate computational tools, due to it offers a familiar environment and easy communicated with EPICS PVs. This report presents an EPICS integrated with Matlab as a data processing system which is not only could be used in image analysis but also in other equipments data processing. The hardware configuration and software structure will be summarized in this report.

#liao.cy@nsrrc.org.tw

OVERVIEW OF INFRASTRUCTURE

This infrastructure is developed by using an EPICS IOC integrated with Matlab program to build up a data processing system. For the beam diagnostic application, this system is responsible for the beam profile acquisition from YAG:Ce screens, and used to analysis to find the beam characteristic data. The infrastructure employed can be divided into hardware and software components, as shown in Fig. 1.

Hardware Components

The hardware components include a computer, Gigabit switch, and cameras. The computer system based on EPICS 3.14.10 (Linux, 2.6.18) can act as a soft IOC (Input / Output Controller) which is used to communicate to cameras and collect images data via Ethernet. The Prosilica GC650 VGA-resolution CCD camera with GigE Vision is used which consists of 659×493 (Cell size 7.4 μm) light-sensitive pixels. The cameras have external trigger input port which can be used to receive trigger signal from timing system (EVG/EVR) for periodic data acquisition.

Software Components

The software components are constructed by EDM (Extensible Display Manager, 1.12.xx) and Matlab for cameras controlling and data analysing, respectively. The camera driver EPICS support is built by the areaDetector module [3] which provides a general-purpose interface for area (2-D) detectors at lower-level based on asynDriver [4]. The EDM was used to construct a client OPI for remote control the camera parameters. In this application there are two compiled Matlab programs were used; one is analysis program, the other is display GUI. The Matlab analysis program is continuously running inside the EPICS IOC's PC, through the Channel Access (CA, LabCA) [5] it can read the raw image data from the EPICS database, analyzed it, and then store the results back to the database records. The display Matlab GUI acts as client OPI which can show the analysis results in multiple clients simultaneously. All data are transmitted over the Ethernet network. In this study, Matlab provides a familiar environment and shows easy and efficient ways to reduce the development time and effort. The compiled Matlab programs help us to develop standalone Matlab application without running it in Matlab prompt which can save budget requirement of expensive licence fee. A Matlab runtime environment which is a free download needs to be installed, in order to execute the compiled Matlab program.

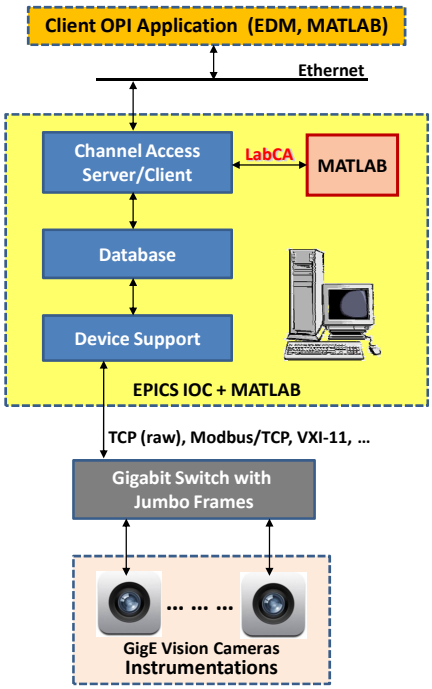

Figure 1: Overview of infrastructure.

FEATURES DEVELOPMENT

In this case, one EDM panel and two Matlab programs were created with difference functionality. The EDM panel which runs in client is used for controlling the camera parameters. The compiled Matlab programs, one is analysis program which runs as a background task in the of IOC's PC for image processing to online calculate the beam size, position and tilt angle; the other display GUI which runs in client for displaying the results and saving data. The detail program designs are shown as follows.

EDM Camera Control Panel (Client Side)

Based on the areaDetector module, using the EDM tool can easy construct a camera control panel as shown in Fig. 2. The camera parameters of exposure time and gain can be configured in this panel. The trigger mode selection include that the Free-Run is for simply monitor the image and Sync-In1 is for synchronization of linac injection (3 Hz). The *Show Image* button could pop-up a window to display the camera image. This EDM panel only offer control and simple monitoring features but do not perform any calculations.

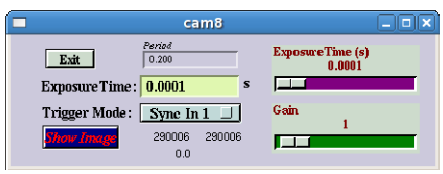

Figure 2: EDM camera control panel.

Matlab Analysis Program (EPICS IOC)

The Matlab analysis program runs in IOC's PC as a background task which can do a complex analytical work to analyze the beam parameters, including the beam center, sigma, and tilt angle. It can specify the region-of-interest (ROI) for clipping the image of each individual camera, and do an optional background subtraction and software multiple exposures. All the analyzed data will store into the EPICS IOC as PVs. The detail flow chart of the program is shown in Fig. 3. In the beginning, program will check which camera is active, then check the corresponding screen is ready or not. If not ready, the program will display some information, such as "No Camera Active" or "Screen is Not Ready". If pass the checking, the program will get raw image data (one-dimensional array) from the EPICS IOC, then go to the image process, including the reshape image array, RIO selection and projection process. Then, processing the image to find the beam center and tilt angle, and fit with a Gaussian distribution for sigma analysis. Finally, writing these results back into specific EPICS IOC PVs, then return to the START. The cycle time can be configured by timer in the program.

The least-squares curve fit, so called lsqcurvefit method was used to process the beam profile, which is one of the optimization toolbox in Matlab [6] which can solve nonlinear curve-fitting problems in the least-squares sense that minimized the sum of squared differences between the measured and predicted data, as shown by Equation (1). Lsqcurvefit is an iterative method which returns results that minimizes the residuals when the tolerances (TolX, default 1e-6) supplied are satisfied. That is, given input data *xdata*, and the observed output *ydata*, find coefficients *x* that "best-fit" the equation *F(x,xdata)*:

$$\min_x \frac{1}{2}\sum_i \left(F\left(x, xdata_i\right) - ydata_i\right)^2 \qquad (1)$$

where *xdata* and *ydata* are vectors and *F(x,xdata)* is a vector valued function. This method can be used to deal with high signal-to-noise levels image.

There are others fitting algorithms can be used, such as the polyfit method, and the moment method. The polyfit method is a non-iterative method which can be used to solve linear problem with faster and accurate analysis, but in this case the data transformed (natural log) into a linear form is necessary. However, it can't deal with the Gaussian distributions with an offset condition, due to the mixed system with non-linear and linear components. The moment method is a computationally simple method to directly calculation the image parameters. For some applications such as image tracking, this method is common to use to analyze large data sets and computationally quicker but sacrifice precision. The three methods comparison for evaluation the computing time, fitting errors and noise tolerance had been described in previous study [7].

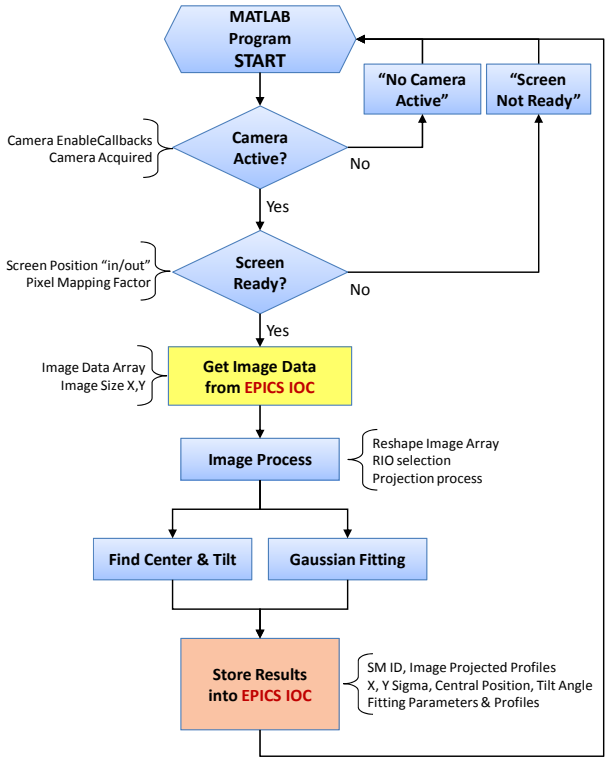

Figure 3: Flow chart of Matlab analysis program.

Matlab Display GUI (Client Side)

The layout of the Matlab display GUI is shown in Fig. 4. The GUI can run in multiple clients simultaneously and read the analysis results from EPICS IOC and display them in the window. The GUI contains six parts: menu, toolbar, control panel, fitting results, projected profile, and raw image. The menu and toolbar provide save data, colormap change, ROI specify, simulation, reset and close program, and zoom in/out functions. In the control panel it contains active the program, 3D viewing, multi-exposure, and background subtract functions. The fitting results area contains sigma and center in the units of pixel and mm, and beam tilt angle. Two directions, horizontal and vertical, of beam projected profiles of raw data and fitting curve are predrilled in two axes. The camera raw image with the colorbar is integrated into the display GUI. The function of export the raw image data and analysis results can be done. It also can create a simulated beam image for the purpose of evaluating the fitting correctness.

The detail flow chart of the program is shown in Fig. 5. In the beginning of the program, users can *Enable* or *Disable* the simulation option. If enable the simulation, the program will generate a simulated beam image then go to analysis process as previous. If disable the simulation, the program will get the analyzed data from EPICS IOC and display the results in the GUI, then return to the START. The cycle time can be configured by timer in the program.

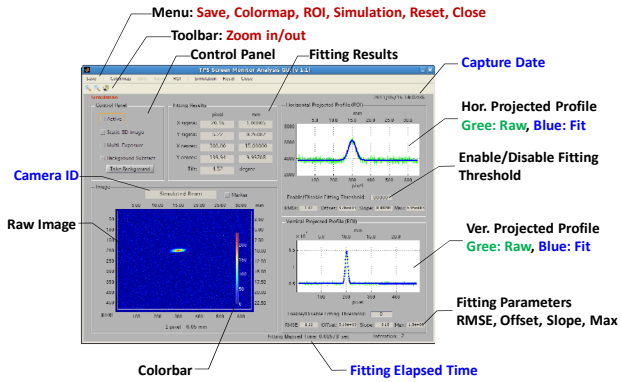

Figure 4: Layout of the Matlab display GUI.

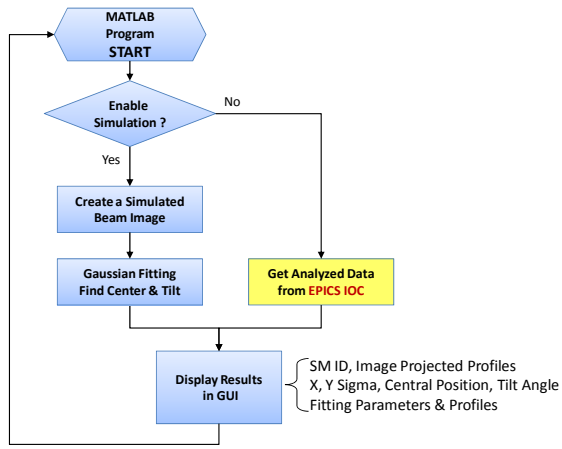

Figure 5: Flow chart of Matlab display GUI.

IMPLEMENTATION IN TPS LINAC

The beam profile of the TPS 150 MeV linac is measured by five YAG:Ce screens [8]. The screen is mounted at 45° against beam direction and driven by a pneumatic driver. The fluorescence light goes out in horizontal direction. The optics consist a refraction mirror bend the light 90° to the 75 mm lens and camera. The resolution of this configuration is ~60 μm/pixel, which is acceptable for TPS current beam size of ~0.5 mm order. The typical layout of the screen monitor is shown in Fig. 6(a). Screen monitor of the test transport line at early commissioning stage is 25 mm diameter YAG:Ce screen with 0.5 mm thickness. This screen is mounted at a manual driven mechanism. This provision solution will be used at early stage of the beam test due to tightly schedule. The typical layout of the screen monitor is shown in Fig. 6(b). The real beam profile, which on the after of gun, was analysis as shown in Fig. 7. The sigma of beam size is in sub-mm order, and tilt angle is also shown in the GUI. The unusual diffraction at position of [X=200 pixel, Y=200~300 pixel] is probably a reflection due to the edge of the YAG:Ce crystal disk. Fortunately, it can be easily ignored by the ROI function. All fitted parameters will be stored as EPICS PVs such that clients can easily access it for further usage.

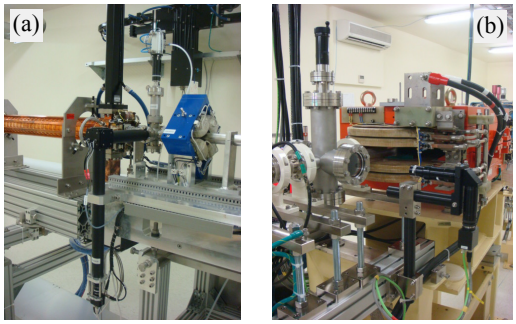

Figure 6: The configuration of screen monitor at (a) linac and (b) test transport line.

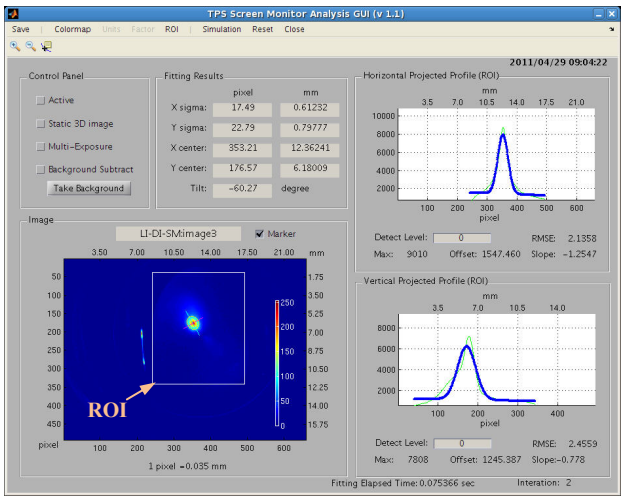

Figure 7: Screen monitor analysis GUI for real beam profile.

TIMING EVALUATION

A timing evaluation of the analysis program was made and summarised in Table 1. The specifications of computer in the experiment for preliminary test are as follows: Intel Xeon 2.26 GHz CPU, 4.0 GB DDR3-1333 RAM. There are two key processes can affect the time required for each image frame. One is read/write data from PVs via EPICS channel access, and the other is fitting projected profiles. The read/write data from PVs, including some conditions and raw image data array, take less than 30 ms. The data process, including two times of fitting process (horizontal and vertical) and tile angle recognition, takes less than 80 ms. Thus, the program requires less than 110 ms per each cycle, which means the maxima processing rate can be up to 9 Hz. This performance is the worst case due to the computer has other tasks to handle at the same time, but this result still acceptable for TPS 3 Hz facility. In future the repetition rate can expect up to 10 Hz rate or higher rate by using a dedicated computer which would be beneficial for many applications.

Table 1: Timing of the Analysis Program

Process	Time Required (ms)
Read/Write data from PVs	< 30
Data process	< 80
Total	< 110

FUTURE DEVELOPMENT

Using EPICS IOC integrated with Matlab as a data processing system is a simple way to develop an application quickly. This solution can be extended to other applications, such as beam lifetime calculation, filling pattern measurement, real-time oscilloscope waveform analysis, synchrotron radiation monitor image analysis, and other equipments data processing. Waveform analysis will be very useful to monitoring the pulse system functionality and stability likes linac microwave system, and pulse magnets system (septa and kickers).

SUMMARY

In this report, we used Matlab to assist EPICS IOC to improve its calculation ability, which will become an alternative solution for complex data analysis. Benefit of this approach can meet expertise of available manpower and more productivity. Compile version of Matlab scripts save budget requirement of expensive licence fee. There are various feature of software have been described here. This infrastructure has been implemented and regularly used on screen monitor image analysis for TPS linac diagnostics application. From timing point of view, there would be no problem running the application on TPS, due to TPS injector repetition rate is 3 Hz. Further studies of other applications of this solution are currently ongoing.

A WEB BASED REALTIME MONITOR ON EPICS DATA

L.F. Li#, C.H.Wang, IHEP, Beijing, China

Abstract

Monitoring systems such as EDM and CSS are extremely important in EPICS system. Most of them are based on client/server(C/S). This paper designs and implements a web based realtime monitoring system on EPICS data. This system is based on browser and server(B/S). Through CAJ interface, It fetches EPICS data including beam energy, beam current, lifetime and luminosity and so on. Then all data is displayed in a real time chart in browser (IE or Firefox/Mozilla). The chart is refreshed every regular interval and can be zoomed and adjusted. Also, it provides data tips showing and full screen mode.

INTRODUCTION

The BEPCII has successfully used EPICS to build up control system. It provides world-widely high energy experiments as well as synchrotron radiation experiments. Because there are many international collaborations, many scientists from outside the IHEP expects to view the status of the BEPCII running. A web based monitoring need to be developed.

In fact, there has been existing monitoring systems on EPICS data including JoiMint, WebCA and CAML.

JoiMint adopts "Java Web Start" to download Java application to local computers and runs it. In order to run Java application, Jre Plug-in or ActiveX is needed to install on client computers.

WebCA is a Web Channel Access client framework based on browser plug-in. It captures EPICS data directly to browsers and displays in text. CAML uses widgets to display EPICS data in graphics. WebCA and CAML can only run in browsers of Firefox/Mozilla.

Since Internet Explore (IE) is popular in China, many people would like to use IE. The EPICS interface to IE is planed, because Internet Explore (IE) uses ActiveX to run web applications while Firefox/Mozilla uses Plug-in. In order to display EPICS data both in IE and Firefox/Mozilla, a web based realtime monitoring system is developed to satisfy the needs of viewing the BEPCII status from all over the word. This system is based on B/S using Flex[1]. The Flex, developed by Adobe, is used to design web user interface, but it needs flash player. Normally, most of computers have been installed with flash player. So, the Flex can run both in IE and Firefox/Mozilla.

CAJ[2] is used as interface instead of JCA, for CAJ is 100% pure Java CA client library and more stable[3]. Through CAJ, Java application in web server can get EPICS data from CA gateways or IOC servers. Blazeds[4] is used as the bridge between Flex and Java while Json is data format transferred from the web server to the browser.

#lilf@ihep.ac.cn

DESIGN AND IMPLEMENTATION

The web based monitoring system is composed of applications in web server and in browser as shown in the figure 1. The parameters of the BEPCII such as beam energy, beam current, lifetime and luminosity runs on PC/Linux as a SoftIOC in control network. The web server runs on PC/Linux in campus network.

The web based monitoring system works as follows:

- The sampling thread connects CA gateways or IOC servers and keeps CA connections in the server's memory.
- Through CAJ interface, the sampling thread gets EPICS data from CA gateways or IOC servers. Then all the EPICS data is saved in the server's memory.
- When visitors view the web page of the monitoring system, the service thread in web server will return the initial EPICS data from the web server's memory to browsers.
- The browser parses EPICS data from the web server and displays it on the web page in patterns of charts and texts.
- By regular interval (10s,30s or 1minute), the browser sends a request to the web server, gets latest EPICS, and then refreshes the charts and texts.

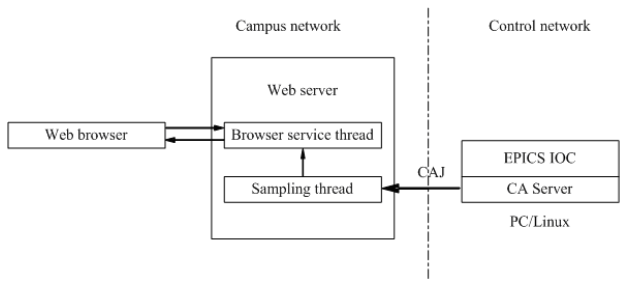

Figure 1: A web based monitoring system of the BEPCII.

Java Applications in Web Server

Tomcat is used as the web server while log4j generates running logs. The Java applications in the web server mainly contain the sampling thread and the browser service thread.

The work flow of the sampling thread in the web server is illustrated in the figure 3. The sampling thread firstly creates CA connections and keeps all of them in the server's memory. Then it gets EPICS data from IOC servers or CA gateway and saves it in the server's memory (as an "application" of the web server). All procedures above executes every regular interval (10s,30s or 1minute). But there are also some differences between the first time and the other times. In the first time, the

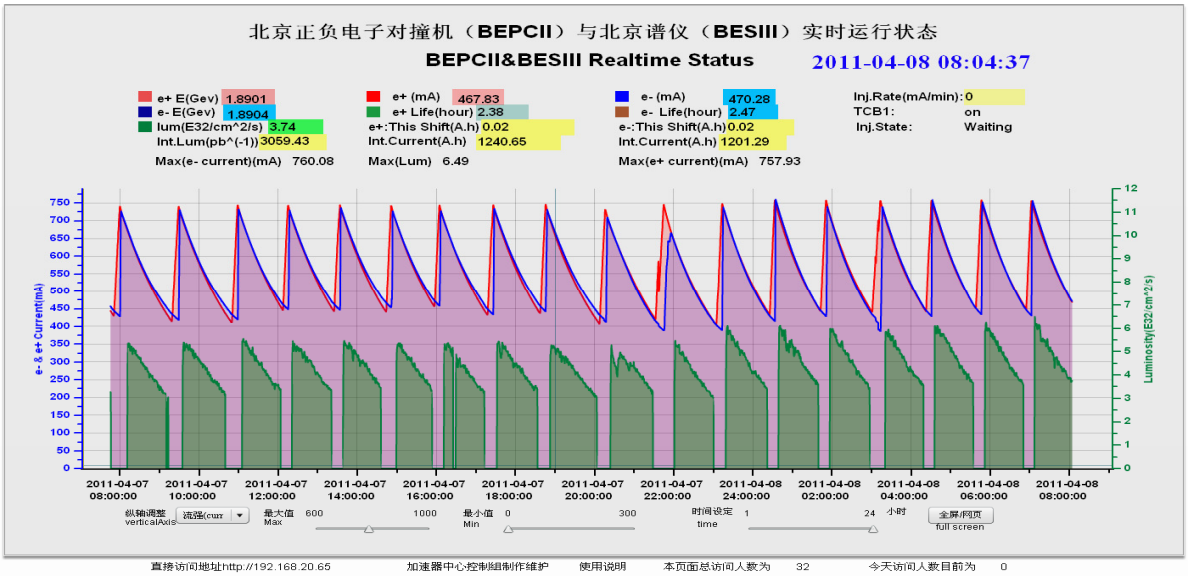

Figure 2: The web page of the status of the BEPCII running.

sampling thread creates CA connections. In the other times, it firstly gets CA connections from server's memory and checks their status. If CA is connected, the thread gets EPICS data directly. Otherwise, it recreates unconnected CA connections and keeps them in server's memory.

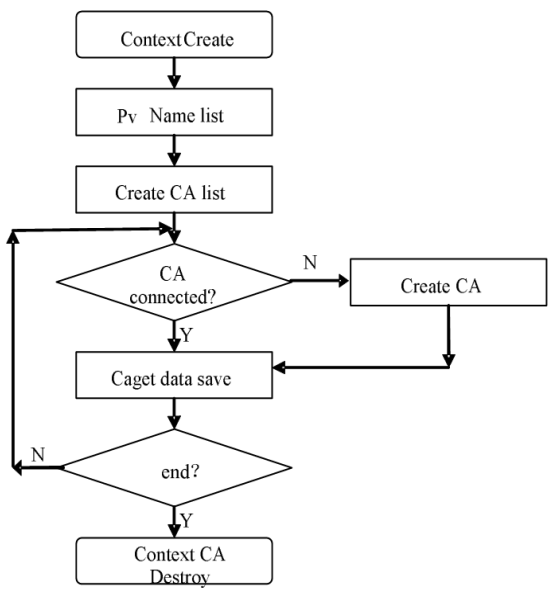

Figure 3: The flow of the sampling thread in web server.

As we know, CA connections take time and CA's UDP broadcasting times by times when recreating CA connections will cause the network traffic. To reduce the time consumed by making CA connections and the network traffic, CA connections should be kept in the server's memory so that the sampling interval will be minimized.

The browser service thread returns EPICS data in format of Json to browser from the server's memory. Then the Flex application in browser displays the data on the web page.

Flex Applications in Browser

The parameters of the BEPCII such as beam energy, beam current, machine mode and so on need to be view by the scientists all over the world. So, we use Flex to implement a web page of the status of the BEPCII running as shown in the figure 2.

This monitoring system adopts Flex and BlazeDS to design the web user interface. The BlazeDS is the bridge between Flex and Java.

When visitors view the web page, the browser sends a request to the web server and gets the initial data of 24 hours. Then, by regular interval (10s,30s or 1minute) , the browser gets the latest EPICS data from the web server and refreshes the chart and texts.

The chart in the figure 2 can be zoomed, adjusted and provides full screen and data tips showing.

Flex applications in the browser mainly include modules as following:

Data Initialization Module

This module gets data in format of Json from the web server and parses the data which is to initialize the chart.

Data Refreshing Module

By method of remote object, data refreshing module receives the latest data from the web server and refreshes the chart and texts.

Timing Module

To fresh the data of the chart and texts, a timer is used to call the data refreshing module by every regular interval (10s,30s or 1minute).

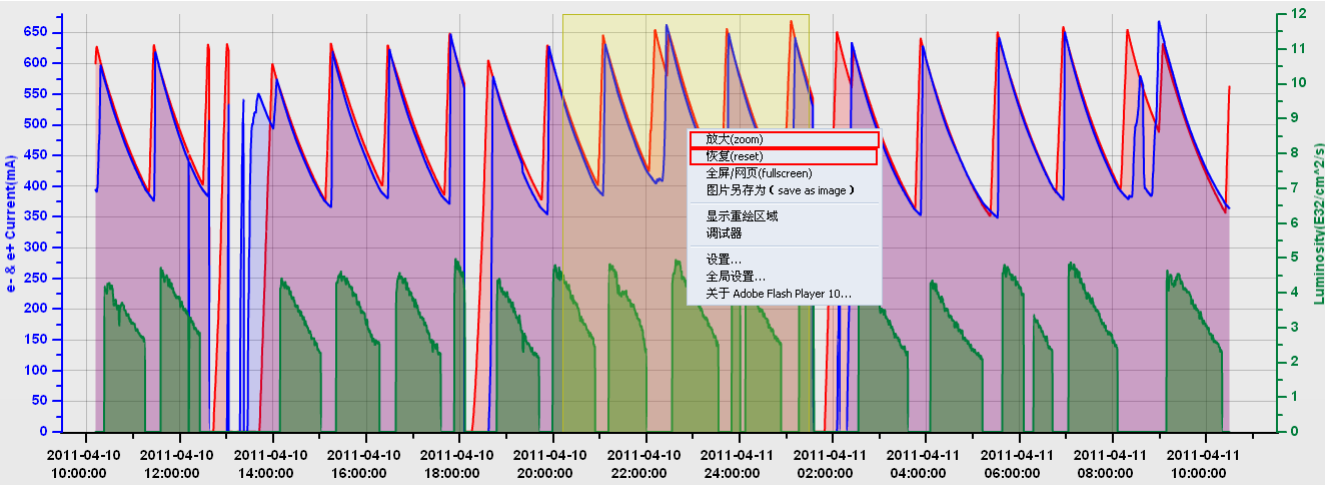

Figure 4: the selected area in the monitoring chart.

Chart Zooming Module

This module is mainly to zoom the chart to look up more detailed information. When a rectangle area in the chart is selected, the corresponding part of the chart is zoomed(see Fig. 4).

Full Screen Module

The web page of the monitoring system can be changed from the web page mode to the full screen mode like movies in media player.

Data Tips Showing Module

When the mouse is placed on the line of the chart, a tip will appears, showing the name, value and time of the EPICS data.

Chart Adjusting Module

By changing the minimum or maximum of axes, the vertical and horizontal axes can be adjusted so that the chart can move up or down, and the total time length of horizontal axes can be decreased.

PERFORMACE TESTS

A web server of tomcat has been built and running almost 2 months without breaking down.

A simple version of the system without special effects (chart zooming ,chart adjusting and full screen) has been available on the web and you can visit the address http://202.122.32.134:8080/RealTimeLineChart/.

Test Environments

- HP Compaq dc7700 (Intel(R) Core(TM)2 CPU 6420 @ 2.13GHz 2G)
- Centos4 linux (synchronizing clock through ntp)
- Tomcat6.0 as web server
- Jdk1.6
- Jprofiler for memory test and thread test
- Apache ab for load test

Performance

The test shows:

- The chart can run in many kinds of browsers(IE or Firefox/Mozilla)
- No EPICS data is lost(once data is lost, it is recorded in the server's log)
- Minimum sampling time=1s
- Concurrent visitors>100
- Web page response time <3s
- Successive working time of server >2 months
- Low load of web server

CONCLUSIONS

This system takes BEPCII running parameters including energy, beam current, lifetime and luminosity as example and fetches these EPICS data through CAJ interface. These parameters can be displayed in IE in a real time curves which can be updated automatically. The web page of the monitoring system is designed by Flex and provides some flex functions including chart-zooming, chart-adjusting, data tips-showing and full screen. On the web page, it's easy for users to adjust the time span and zoom the chart. In order to improve the sampling performance, CA connections stays in the web memory. Since this system is thin based on browser/server, it is very easy to deploy and can be used in other projects.

Abstract

ALICE is one of the experiments at the Large Hadron Collider (LHC) at CERN in Geneva, Switzerland. The ALICE detector control system is an integrated system collecting 18 different detectors' controls and general services. Is implemented using the commercial SCADA package PVSS. Information of general interest, such as beam and condition data, and data related to shared plants or systems, are made available to all the subsystems via the distribution capabilities of PVSS. Great care has been taken to build a modular and hierarchical system, limiting the interdependencies of the various subsystems. Accessing remote resources in a PVSS distributed environment is very simple and can be initiated unilaterally. In order to improve the reliability of distributed data and to avoid unforeseen and unwished dependencies, the ALICE DCS group has enforced the centralization of global data required by the subsystems. A tool has been developed to monitor the level of interdependency and to understand the optimal layout of the distributed connections, allowing for an interactive visualization of the distribution topology.

INTRODUCTION

ALICE is one of the four general purpose experiments installed around the Large Hadron Collider, at CERN in Geneva. It is composed of 18 detectors, each with its own specific technology choice.

The ALICE collaboration includes more than 1000 physicists and engineers from 105 Institutes in 30 countries. Being developed by several groups in parallel, and being based on different devices and protocols, the controls of the different detectors are heterogeneous too.

The ALICE Detector Control System (DCS), integrates the controls of all detectors in a common environment, exploiting the flexibility of the SCADA PVSS software.

INFORMATION FLOW IN THE ALICE CONTROL SYSTEM

The DCS continuously collects large amounts of data from the various detector devices. Thanks to a strong standardization effort at the beginning of the DCS project it has been possible to limit the variety of devices used and this has been very beneficial to the data collection process. For these devices the hardware diversity is managed through the use of the commercial OPC server protocol.

However, for the very important Front-End Electronics part, which has been custom designed for each detector, there is a large diversity of readout interfaces. Many different field busses and technologies are used such as CANbus, JTAG, Profibus, RS232, Ethernet and custom links. This has called for a more elaborate readout architecture based on the definition of a common high level Front-End Device (FED) which overcomes the hardware diversity.

The use of the TPC/IP based CERN DIM protocol for communication provides furthermore the means for abstracting the data flow from the hardware level. Data is mainly transported using the Ethernet but other protocols are also used.

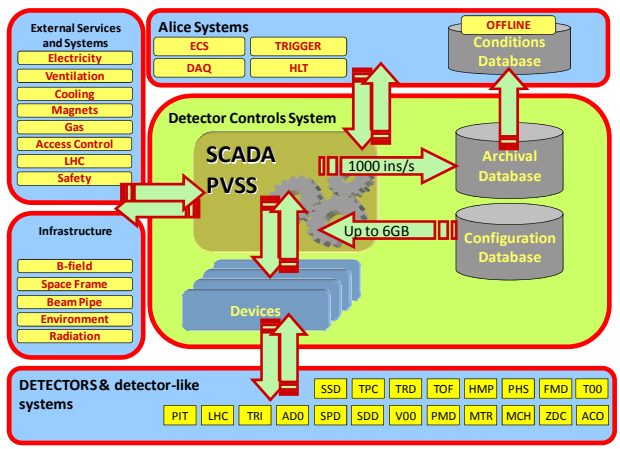

Figure 1: The main data streams managed by the central ALICE DCS.

Amongst the sources of data we count 1200 networked Front-End processors, 300 VME crates and power supplies and 4000 high voltage channels. From the detectors, the ALICE DCS receives data from 180,000 OPC items and 100,000 Front-End devices; eventually, a total of 1,000,000 parameters are supervised by the DCS at a typical rate of 1 Hz (see Fig. 1).

In order to be able to handle such a large amount of data, the ALICE DCS must process and filter the data before they are sent to the archives or transferred to the final users such as the offline analysts and the online displays. More than 100 detector computers represent the

detectors side, while a group of 60 backend servers and an Oracle Database service, which is able to process up to 150,000 inserts/s, compose the central side of the control system (see Fig. 2).

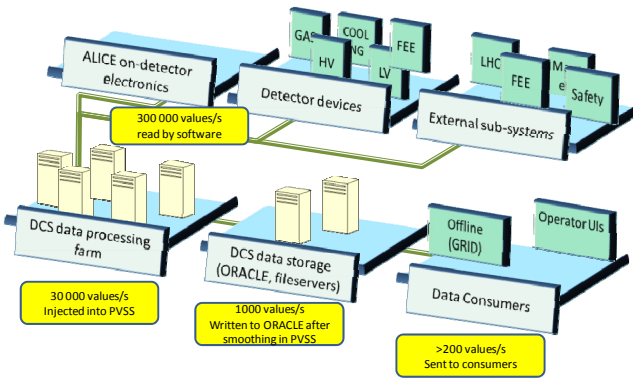

Figure 2. Data flow reduction from the detectors, to the archives and to the final customers.

The data flow is not unidirectional. Up to 6GB of configuration data is uploaded to detectors from the central ORACLE database before a physics run can be started.

Furthermore, the DCS is also the central collector of information of general interest, like the LHC beam data, data from various technical services, environmental data, radiation and magnetic field data, etc.

For example, global environment data is collected and archived and at the same time redistributed to the detectors, to be used for their calibrations or to allow for correlations with their internal variables. Much data is received from the LHC accelerator and managed centrally and distributed to several subsystems in order to define operational states and guarantee safe procedures.

In order to provide a controlled data exchange with the detectors, the ALICE DCS has exploited the distribution properties of PVSS.

The SCADA PVSS is a complex modular system where the different processes (aka managers) can run on a single machine or in a scattered way, i.e. on different machines. In a scattered system, managers run on dedicated machines, in order to distribute the load; in a distributed system, remote, single or scattered, the systems are interconnected through dedicated daemons, so called distribution managers (see Fig. 3); via this connection there is only information sharing and .no sharing of computing resources.

THE ALICE DCS TOPOLOGY

The SCADA PVSS system not only allows to collect, publish and archive the various data. Thanks to its distribution properties and its modular architecture it has been possible to design the ALICE DCS as a distributed system where each detector is a complete control system itself. The detectors have implemented their DCS on more than one machine and are therefore distributed systems themselves.

The smaller detectors have implemented their controls on a few machines which are interconnected in a hierarchical structure. The bigger detectors have implemented their controls over several machines which are interconnected in a mesh, in order to easily share the data inside the detector community. Interactive operation takes place in both cases via a remote user interface on one of the nodes.

A particular group of machines is the LHC cluster, which is responsible for collecting the data from the LHC accelerator and for the publication of ALICE information back to LHC. Some of the these parameters, such as parameters from luminometers and beam monitors, are of direct interest also to the many detectors; they are therefore collected and sent both to LHC and the ALICE detectors. Since its installation, the LHC cluster has represented an interesting testbed for the ALICE distributed topology. A big effort has been devoted to the

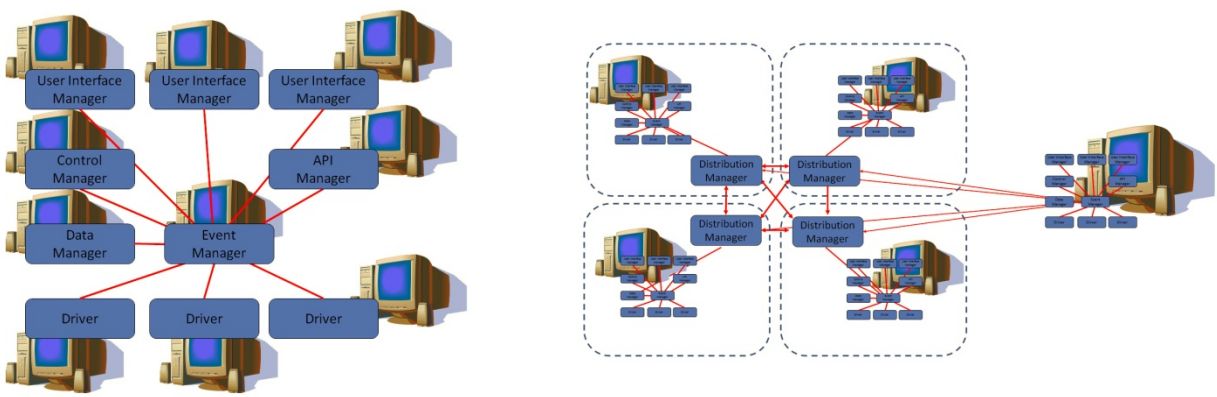

Figure 3: Schema of a scattered system (left) where the PVSS managers of a single project are running on different machines and a distributed system (right) in which the distribution managers handle the connections between remote projects

optimization of the data distribution, trying to limit interconnections, monitoring dependencies, and ensuring the availability and security of the data.

MONITORING THE DISTRIBUTED ENVIRONMENT

Within this distributed scheme, the ALICE DCS has been implemented as a hierarchical system, with the aim of limiting the interdependencies of the various subsystems. All the detectors nodes connect to the central servers (Fig. 4); in this way, ALICE DCS can provide global data, keep the systems synchronized and have a clear monitor of possible interdependencies.

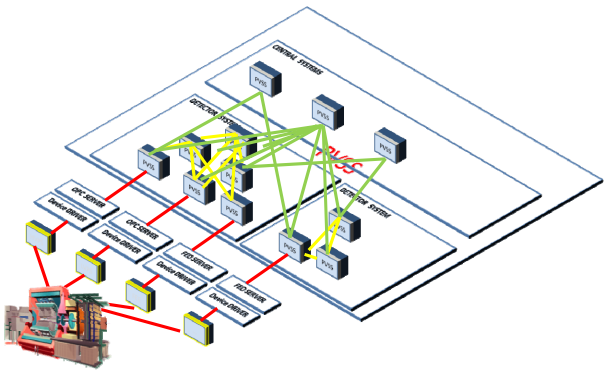

Figure 4. Central servers connect to all detectors nodes. Different detectors are not connected directly.

Connecting remote systems in a distributed environment is very simple. However, this can easily lead to unforeseen and unwished inter dependencies and unnecessary or redundant data flows. Furthermore, a distributed connection can be initiated unilaterally, even without the approval of the target system.

The central ALICE DCS group has therefore initiated a project to map, understand and monitor the data flow between central systems and detectors and between the detectors themselves. The aim is not only to prevent or block unauthorized connections, but mainly to better understand the needs of the different systems and to find the best ways to provide the data they need.

A monitoring tool has been developed which compares a list of authorized, local connections, with the actual connections observed. The authorization list can be maintained and updated from PVSS directly (Fig. 5). The tool has been built using simple PVSS control scripts.

The project provides an interactive graphical representation of the state of connections (Fig. 6). From here, it is easy to assess the degree of interdependency between the systems and to understand the optimal layout of the distributed connections. Used regularly this tool helps to optimize the flow of data between systems and to reduce the risk of faulty interactions between different systems.

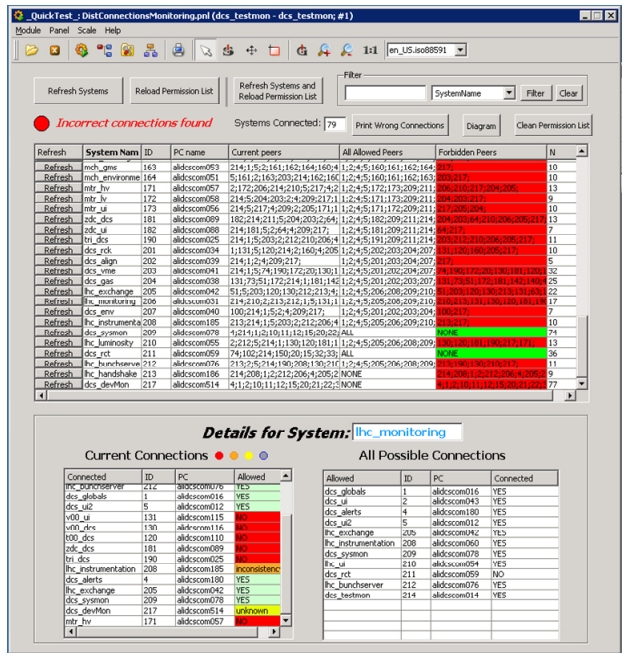

Figure 5. Expert panel to monitor the distributed systems.

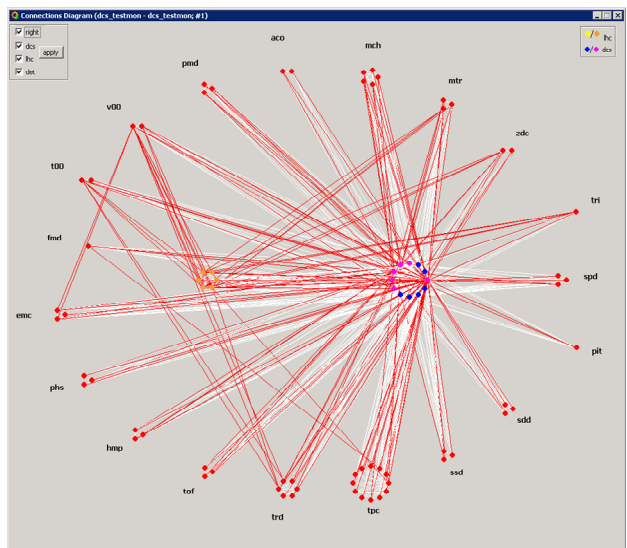

Figure 6. Graphical representation of the ALICE DCS interconnections.

CONCLUSIONS

The ALICE DCS has made a big effort to standardize, simplify and optimize the flow of data between computer systems in the ALICE experiment.

For this purpose a tool has been developed to analyze the network connections between distributed systems. This monitoring tool is raising interest inside the CERN JCOP Framework community, and will hopefully be integrated in a more general monitoring context, to give to the PVSS central developers another tool to optimize and simplify the data flows in the operational networks.

TANGO ARCHIVING SERVICE STATUS

G. Abeillé, S. Pierre-Joseph, J. Guyot, M. Ounsy (Synchrotron Soleil),
S. Rubio (ALBA), G. Strangolino, R. Passuello (ELETTRA)

Abstract

In modern scientific instruments like ALBA, ELLETRA or Synchrotron Soleil, the monitoring and tuning of thousands of parameters is essential to drive high-performing accelerators and beamlines. To keep track of these parameters and to easily manage large volumes of technical data, an archiving service is a key component of a modern control system like Tango [1].

To achieve this, a high-available archiving service is provided as a feature of the Tango control system. This archiving service stores data coming from the Tango control system into MySQL [2] or Oracle [3] databases.

Tree sub-services are provided:

- An historical service with an archiving period up to 10 seconds,
- A short term service providing a few weeks retention with a period up to 100 milliseconds,
- A snapshot service which takes “snapshots” of Tango parameters and can reapply them to the control system on user demand.

This paper presents how to obtain a high-performance and scalable service based on our feedback after several years of operation. The deployment architecture in the different Tango institutes will then be detailed. The paper concludes with a description of the next steps and incoming features which will be available in the next future.

CONCEPTS

The Tango Archiving service is a central diagnosis tool for large scientific instruments. It can be used for daily operation such as:

- Vacuum, temperature follow-up
- Insertion devices follow-up…

But also to analyse complex scientific phenomena:

- Beam orbit stability
- Post-mortem analysis…

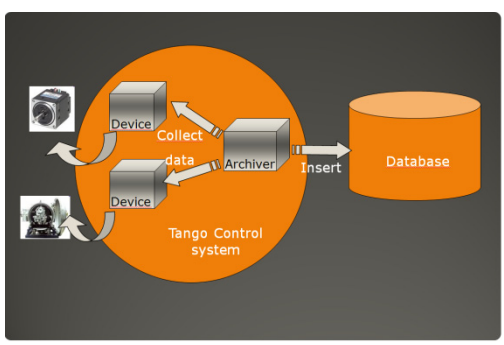

Figure 1: Tango archiving data collection.

The archiving service collects Tango control data (also called Tango attributes) to persist them in databases. The data collection is done by Tango devices called Archivers (see Fig. 1). A complete explanation of Tango concepts is detailed here [1].

All archiving components are based on a Java [4] API (Application Programming Interface), designed with JDBC [5]. Upon this API, a set of modules is rendered:

- Extractor Tango device: service to retrieve inserted data from the database.
- Watcher Tango device: monitor the archiving. Report alarms for not inserted values.
- Manager Tango device: configure, start or stop the archiving.
- GUIs in Swing: End-user interfaces to configure, start or stop the archiving; data plotting of archived values.

The archiving service proposes several data collection policies as detailed here in.

Historical/Temporary DB

The historical and temporary DB services can record data at a fixed frequency. The minimum period is 10 s for HDB and 100 ms for TDB. It is also possible to filter the data to be inserted i.e. to insert data only when it changes or when it goes over some thresholds. Due to the amount of data, TDB tables may be truncated on a regular basis (every 12 weeks at Soleil).

Furthermore, a GUI called Mambo (see Fig. 2) can configure, start or stop the archiving. It is also possible to extract data and plot it.

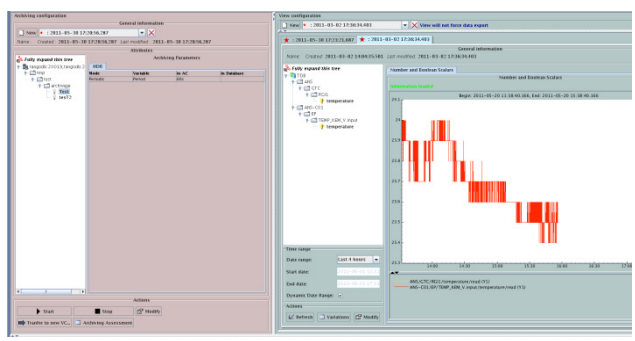

Figure 2: Mambo.

To achieve scalability, a collection of archiver devices may be deployed. Each archiver is in charge of collecting a set of Tango attributes; they may be set up in two different ways:

- Dedicated mode: each archiver collects a pre-defined list of attributes.
- Load-balancing: when a data collection is started, its archiving is allocated to the least loaded archiver.

Snapshot Database

The Snapshot service takes on-user demand "pictures" of a control system for a pre-defined set of Tango parameters (or Tango attributes). The persisted parameters may subsequently be reapplied on the Tango control system.

With the Bensikin (Fig. 3) GUI, the user can define the sets of Tango attributes. For each context, he can launch snapshots, display their contents, and reapply values to the Tango control system.

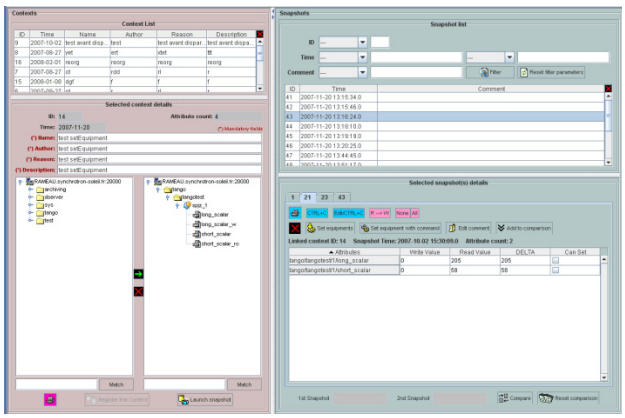

Figure 3: Bensikin.

STATUS

The archiving service is aimed to be used by any institute using Tango as a control system.

The project was initiated by Soleil in 2002. The initial design was jointly done with the ERSF [6] control team who in charge of the Tango core development. All the API, devices and GUIs were developed under the responsibility of Soleil. It was built up during the Soleil construction phase with continuous deployment on production platforms. At this time, the Soleil IT team was constantly under users' pressure to obtain a stable and high-performance system. Due to a lack of resources, most of the development was subcontracted.

Then ELETTRA joined the Tango collaboration at the end of 2003 followed by ALBA in late 2004.

Owing to different contexts and technical backgrounds, the archiving service is not used in the same configuration in all institutes. The actual deployments are described below.

ALBA

The ALBA synchrotron uses MySQL for all databases. Around 8000 HDB attributes are archived at periods between 10s and 1 minute and 2000 TDB attributes are archived at periods between 1s and 1 minute.

95% of the Archivers are deployed on the same host as the Tango archived devices in "dedicated mode".

On beamlines, it is under deployment with a centralized load-balancing mode using virtual servers.

The client applications were developed in Python using the PyTango binding.

Elettra

The TANGO archiving system is used on both Elettra and FERMI@Elettra. Each accelerator is running its own instance of the Archiving System.

Common characteristics to the two archiving infrastructures are:

- MySQL version 5.5.13 with MyISAM indexed and partitioned tables.
- Centralized infrastructure with 30 archivers running for HDB and 10 for TDB
- Management of archiving performed with an Elettra GUI based in QT, MANGO [1],
- Retrieving and data plotting done using E-Giga [1], based on PHP and MySQL.

Elettra figures are:

- 1561 attributes configured in HDB
- 7 attributes configured in TDB

Archiving system for Elettra running on a dedicated hardware based on an Intel(R) Xeon(TM) QuadCore CPU @3.20GHz with 4 GB of RAM and 1 TB of storage capacity on a RAID 6.

FERMI@Elettra figures are:

- 1798 attributes configured in HDB
- 401 attributes configured in TDB

Archiving system for FERMI@Elettra running on a Xen virtual machine using 4 cores of an Intel(R) Xeon(R) CPU E7330 @2.40GHz with 4 GB of RAM and 1 TB of storage capacity on a RAID 6 fibre channel connected external storage.

Both databases are replicated with MySQL replica system on a different machine with the same performances which is used by E-Giga to access data, so the archiving system is not loaded by such kind of requests.

Soleil

The archiving service is deployed on accelerators and beamlines. All databases are Oracle Enterprise Edition 11.1.0.7.0 with RAC (Real Application Cluster) [7] and partitioning options. There are 2 database clusters with each machine having 16 GB of RAM and 2 network interface cards (fiber channel):

- One RAC of 3 machines for the accelerators.
- One RAC of 2 machines for all beamlines.

A Disaster Recovery Plan (DRP) has been established to obtain a high-available service and no data loss:

- A degrade server can take over the RAC.
- Several backup strategies are active, e.g. RMAN (Recovery Manager) [8] does an incremental backup every day and a full back-up every two months. Data restoration is tested twice a year.
- Data are replicated in two buildings, on different media (hard disk and tape).

On top of this infrastructure, the Tango Archiver devices for data collection are configured in "load-balancing" mode and are distributed as followed:
On the accelerators, they are shared out on 4 machines (see Fig. 4 for an overview of the whole infrastructure):

- 270 HDB archivers.
- 300 TDB archivers.
- 1 SNAP archiver.

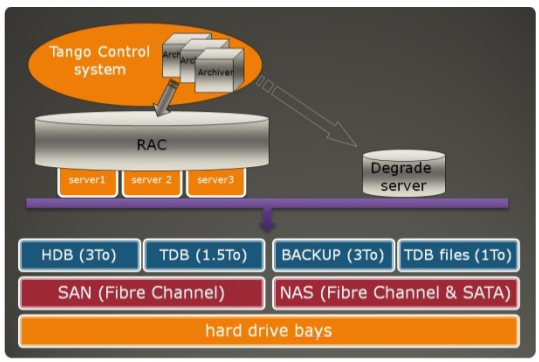

Figure 4: Soleil accelerators archiving infrastructure.

HDB and SNAP is also operational on all 25 beamlines. Some beamlines are archiving up to 350 attributes in HDB; one machine per beamline (with other services installed):

- 5 HDB archivers.
- 1 SNAP archiver.

Table 1 shows some figures for the Soleil accelerators. The numbers are growing constantly as the operators configure the archiving by themselves. Soleil machine operators are planning to collect up to 20,000 attributes in HDB and TDB.

Table 1: Soleil Accelerator Loads

	HDB	TDB	Snap
attributes	10 607	7 527	2700
Insertion/sec	480 (10TPS)	4 200	NA
size	80Go/month	20Go/day	2Go

CHALLENGES

Technical Challenges

Until recently, the main concerns at Soleil have been performance, scalability and stability issues. Various actions have resolved these issues:

- Change the whole infrastructure; install a cluster database with several storage systems.
- The Archiver devices were unstable and their performance was poor. As the code was subcontracted, it suffered from "quick and dirty" fixes, "copy-paste"… To overcome all these issues, the code had to be re-implemented.

The Archivers are now very stable at Soleil. There are no more failures after months of running. However, the code still needs to be cleaned up as has been pointed out by Soleil's quality tool, SONAR [9]. See [10] for how this tool has been used at Soleil.

The current watcher device is only able to report failures, but it is not yet able to diagnose the root cause. Indeed, there may be many reasons for a failed data insertion; for instance the archived Tango attribute may have been renamed, or its device may have been shut down. Consequently, it must be extended to identify and report the origin of a failure.

Data extraction and plotting is pretty basic today. A customisable reporting tool should be integrated in the archiving standard toolkit. The user should be able to simply configure and create reports in any format, such as pdf, csv, and so on. This tool may be also integrated into a scheduler so that machine operators can have an automatic follow-up every shift.

As all data extraction is done manually, all diagnoses are also manual. At Soleil, a project has recently been started to automate the diagnosis of orbit instability with a rule engine [11]. As soon as an orbit deviation is recorded, this tool will automatically search in archived data to identify the causes of instability, such as insertion movements, temperature drifts, power supply misbehaviour, etc.

Collaboration Challenges

A major challenge for Soleil is to fulfil all needs of the Tango community while also remaining responsive to internal user requests, under the constraint of limited human resources. The Tango collaboration has no dedicated resources, so it is at the discretion of each institute to bring some resources to the collaboration. All institutes have different technical backgrounds, it is sometimes difficult to put everything is common as some tools were designed for a specific context, but we must do our best to have the maximum in common.

Effort has recently focused on packaging in order to deliver an easy-to-install archiving system [12]. But there are still many things to improve to efficiently collaborate. The archiving service is now stable, but many evolutions may be added, so a common specification must also be written up. Moreover, this organisation must be also ready to provide support for new incoming Tango users like MAX IV [13].

To conclude, the archiving project is on the one hand a matter of technical challenges, on the other hand it is a major human challenge. It is now a mature project, but it is far from coming to an end as many improvements remain to be done. Besides, this Tango add-on reinforces the added value of the Tango framework.

FROM DATA STORAGE TOWARDS DECISION MAKING: LHC TECHNICAL DATA INTEGRATION AND ANALYSIS

A. Marsili*, E.B. Holzer, A. Nordt, M. Sapinski, CERN, Geneva, Switzerland

Abstract

The monitoring of the beam conditions, equipment conditions and measurements from the beam instrumentation devices in CERN's Large Hadron Collider (LHC) produce more than 100 Gb/day of data. Such a big quantity of data is unprecedented in accelerator monitoring and new developments are needed to access, process, combine and analyse data from different equipments.

The Beam Loss Monitoring (BLM) system has been one of the most reliable equipments in the LHC during its 2010 run, issuing beam dumps when the detected losses were above the defined abort thresholds. Furthermore, the BLM system was able to detect and study unexpected losses, requiring intensive offline analysis. This article describes the techniques developed to: access the data produced ($\simeq$ 50000 values/s); access relevant system layout information; access, combine and display different machine data.

INTRODUCTION

Beam Losses

More than 3600 *Beam Loss Monitors (BLMs)* were installed around the LHC ring at expected loss locations, in order to measure the *beam losses* in the LHC. Losses are measured every 40 μs, and these basic integration windows are continuously combined into sliding windows called *integration intervals*, ranging from 40 μs to 84 s.

All the data are used in real time: if the losses in one integration interval exceed the predefined *abort thresholds*, the beam is removed from the LHC ring. Some of these data are stored in the LHC *databases (DB)*: this article will only describe the processing of these "offline" data.

The layout of the machine where the loss was produced is just as important as the measured loss itself, and must be understood.

Beam Loss Analysis Toolbox

This article describes the techniques used to access the different databases, to combine the values of losses with the positions of the BLMs and magnets and display them. Each of these functionalities corresponds to a *module*, and they are gathered in the Beam Loss Analysis *toolbox*.

Databases

The *Layout database* holds all the information about the positions of magnets, BLMs and collimators. Its structure is the one of a standard SQL database: several tables hold all related information in different columns.

Every second, for each monitor, one value per integration interval is saved in the *Measurement database* during one week. Some values are stored permanently in the *Logging database* after applying a filter: if the difference between two subsequent values is higher than a delta set per integration interval, the value is saved; if not, one value per minute is saved. The thresholds are logged "on change", and once per day if they don't change.

Both databases have the same structure: a *variable name* `BLM_EXPERT_NAME:LOSS_RSXX` is associated to each integration interval (`"XX"` is its number). It holds two SQL columns: *timestamps* and *values* (see Fig. 1). The structure for the thresholds is the same.

Languages

The database access tool was designed to allow the access, processing and display of data in a fast, user-friendly and easy way. The language used for database access at the time of development was PL/SQL. The Layout database is still accessed with PL/SQL. The main programing and data analysis framework at CERN is ROOT [3], a C++ framework providing classes and a C++ interpretor called CINT.

The choice was made to use Python (2.4) as the developing language (and not CINT), since a true interpreter was desirable. It links easily with ROOT (5.28) objects thanks to the pyROOT project.

DATABASE ACCESS TECHNIQUES

The `database` module accesses data by PL/SQL and Java, and returns them in a format compatible with the other modules, described in Fig. 1. A direct display of the data structure is shown in Fig. 4.

PL/SQL Access

The core of the SQL access class is a ROOT object called `TSQLServer` [3]. Queries such as the time window or variable names are automatically constructed and sent as strings. The data corresponding to the required variables are returned also as strings so the user does not have to change method depending on the data type. SQL access is still used for the Layout database access.

Java Access

The current way to access the measurement databases is through an *Application Programming Interface (API)* written in Java and provided by the data management section.

* amarsili@cern.ch

$$\left\{ \begin{array}{cccc} \text{'BLM\_1'} & \text{'BLM\_2'} & \cdots & \text{'BLM\_m'} \\ \left[\begin{array}{c} \\ (\text{'}t_1\text{'}, v_1) \\ \\ (\text{'}t_2\text{'}, v_2) \\ \end{array} \right] & \left[\begin{array}{c} (\text{'}t_3\text{'}, v_3) \\ \\ (\text{'}t_4\text{'}, v_4) \\ \\ (\text{'}t_5\text{'}, v_5) \end{array} \right] & \cdots & \left[\begin{array}{c} \\ (\text{'}t_6\text{'}, v_6) \\ \\ (\text{'}t_7\text{'}, v_7) \\ \end{array} \right] \end{array} \right\}$$

Figure 1: Original structure of the object for the Logging database, reflecting the DB structure. Dictionaries are represented between curly brackets "{ }", lists between square brackets "[ ]" and tuples between parentheses "( )" The vertical spaces between 2-tuples indicate the absence of data between two times and show that all times are different.

It is able to be called from the command line, thus being more portable: the data are not returned inside one specific application. They are written to the shell standard output.

The API provides the user names and passwords for the Logging and Measurement databases, so the user does not have to. Most of the connection settings are written in a file called `configuration.properties` [4]. Rather than having the user edit this file separately (and for backward compatibility), this file is generated automatically.

The default Python `os` module provides the interaction with the unix shell from Python. The `os.popen` function executes a string as a command line, which allows easy manipulation. It returns a "file iterator", the default object for reading text files. The use of this command line is further described in [4]. The data flow is summarized in Fig. 2.

Data Structure

The object holding the data reflects the structure of the database: dynamic *lists* of immutable *2–tuples* holding the timestamp as a string and the signal as a Python float (see Fig. 1). The mapping is provided by a *dictionary* associating a key (the variable name as a string) to the corresponding value (a list).

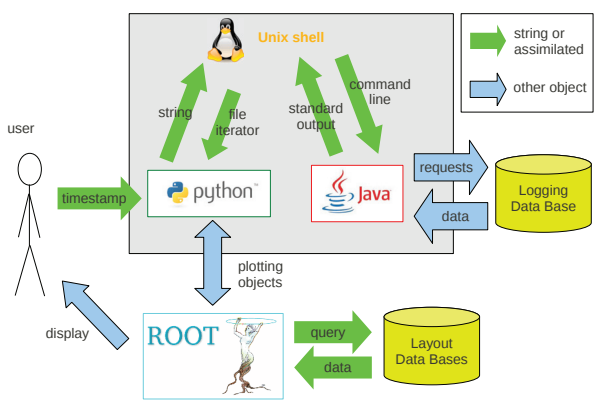

Figure 2: Data flow in the toolbox, from the user to the databases and back.

$$\left\{ \begin{array}{ccc} \text{'name\_of\_graph\_1'}, & \text{'name\_of\_graph\_2'}, & \cdots \\ \left[\begin{array}{c} (dcum_1, v_1) \\ (dcum_2, v_2) \\ \vdots \end{array} \right], & \left[\begin{array}{c} (dcum_3, v_3) \\ (dcum_4, v_4) \\ \vdots \end{array} \right], & \cdots \end{array} \right\}$$

Figure 3: Final structure of "plotdict" object after data combining. $dcum_1$ is the position of BLM_1, and v_1 the signal of BLM_1 at the plotting time. See Fig. 5 for the corresponding graph.

DATA PROCESSING

Sorting BLMs

Currently, one of the main applications of the toolbox is to display a longitudinal loss profile of a section of the LHC at a requested timestamp (see Fig. 5). The names of the BLMs are not displayed, but they contain all relevant information: type of monitor (*Ionisation Chamber (IC)* or *Secondary Emission Monitor (SEM)*), associated beam (B1 or B2), injection or extraction line. The `process` module sorts the BLMs according to these criteria. The names are then mapped with the longitudinal position of the BLM on the LHC, called *DCUM*, which was obtained from the Layout database. The resulting structure is shown in Fig. 3.

Linear Interpolation

One of the features of the Logging database is that no BLM signal is recorded every second (see Fig. 1). A specific second requested by the user may not have been recorded. The choice was made to calculate a linear interpolation between the previous and next entries to estimate the signal at this second. The algorithm in the `process` module progressively checks the requested timestamp against a list of tuples. If the same time is found, the value (2^{nd} element of the tuple) is returned. If not, a linear interpolation is calculated using the next entry in the list.

The algorithm has to do $m \times n$ operations, where m is the number of monitors and n the number of tuples before the requested second. The processing time is dominated by the data access time in the case of the Logging database, when only one second is requested in a time range composed of a few tuples. It is not the case for the measurement database (one tuple per second). If all seconds in the time range are requested, the number of operations becomes $m \times \frac{N \cdot (N+1)}{2}$ where N is the total number of tuples (seconds): the processing time is dominating the access time. In this case, a different algorithm is used with only one index for all BLMs. The number of operations is then only m.

DISPLAY

The whole `display` module relies on ROOT objects, using `TGraph` for the plots and `TCanvas` for the display on screen [3]. Each type of plot has its own class, and they all

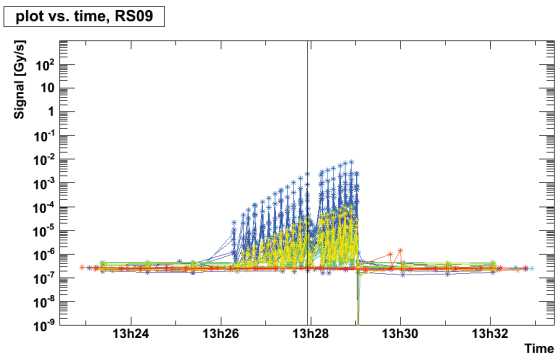

Figure 4: Plot of the data as received from DB, showing the time development of a loss (collimator scraping). Each of the requested variables are given versus time. Note that the values are not synchronised. The vertical black line corresponds to the requested second. The requested plot is shown in Fig. 5.

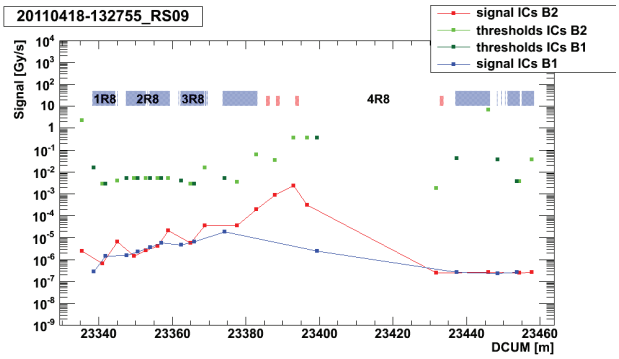

Figure 5: Final display, showing the longitudinal development of a loss (collimator scraping), and the positions of the magnets (blue boxes) and the collimators (red boxes) The vertical axis is the value of loss or threshold of one BLM, and the horizontal axis is its longitudinal position.

share methods to save the plot as seen on screen in a file with an automatically generated and meaningful name.

Time Plot

The time plots reflect the structure of the DB: each graph corresponds to one variable, with points only at recorded times (see Fig. 4). The colours are automatically selected to be as far away as possible from each other. The names are ordered so that similar variables will have similar colours.

Longitudinal Plot

For the longitudinal plot of the LHC, the positions of magnets and collimators are obtained from the Layout database. The value of the threshold is obtained directly from the Logging DB, and is mapped to the longitudinal position similarly to the BLM signals. The final result is shown in Fig. 5.

WRAPPING MODULE

All functions described previously are automatically executed when passing a timestamp and two values of longitudinal position to the loss analysis class in the wrapping module. In its basic behaviour, it:

- finds the corresponding BLMs, collimators and magnets with information from the Layout DB;
- gets the losses and thresholds for the relevant BLMs from the measurement or Logging DB;
- displays the losses versus time (see Fig. 4);
- combines all data to display the loss in the LHC at the requested time (see Fig. 5).

The wrapping module also provides additional methods to:

- save the data set;
- print all the names of the LHC elements in longitudinal order;
- search for a string in the BLM names;
- plot a vertical line at a given longitudinal position;
- plot the ratio signal/threshold for each BLM;
- order BLMs by “closeness to threshold”;
- plot the beam intensity at the time;
- plot the position of the jaws of the displayed collimators;
- plot the signals of the Beam Position Monitors;
- plot the optics in the LHC.

CONCLUSION AND FUTURE IMPROVEMENTS

In this paper, a tool allowing the access, processing and display of data in a fast, user-friendly and efficient way was presented. Data can be requested automatically with a few simple arguments such as timestamp and position, and are immediately available for display or further processing. This tool is now used as a standard database access in the CERN Beam Loss section.

The future improvements include parallel downloading and processing of data, and adaptation to the new vector format for BLM-specific databases.

Abstract

The ALICE Detector Control System (DCS) is based on a commercial SCADA product, running on a large Windows computer cluster. It communicates with about 1200 network attached devices to assure safe and stable operation of the experiment. In the presentation we focus on the design of the ALICE DCS computer systems. We describe the management of data flow, mechanisms for handling the large data amounts and information exchange with external systems. One of the key operational requirements is an intuitive, error proof and robust user interface allowing for simple operation of the experiment. At the same time the typical operator task, like trending or routine checks of the devices, must be decoupled from the automated operation in order to prevent overload of critical parts of the system. All these requirements must be implemented in an environment with strict security requirements. In the presentation we explain how these demands affected the architecture of the ALICE DCS.

ALICE DCS OVERVIEW

The mission of the Detector Control System (DCS) [1] of ALICE experiment is to provide an overall supervision of the experimental apparatus, ensuring correct and safe operation during the physics data taking and also during the standby periods.

Operating in a continuous 24/7 mode most of the year, the DCS performs hierarchical control of the 20 subdectors of ALICE, supervises common systems and infastructure services and communicates with external systems. Full remote control and monitoring is required for the devices located in the underground areas inaccessible during the beam time.

The ALICE DCS uses a variety of devices supervised by the SCADA software. The devices communicate with the supervisory layer using either ethernet networks, or industrial fieldbuses. Distributed and hierarchically designed supervisory system consists of control applications developed using a commercial system (PVSS) and CERN-developed tools.

User interfaces (UI) at different levels provide experts and operators with convenient control panels, allowing ALICE to be routinely operated by one shifter.

OVERALL DCS DESIGN

The DCS partitioning and control hierarchy follows the logical structure of the experiment. There are 20 subdetectors of different complexities and sizes, ranging from TPC and TRD (10 supervisory control nodes) down to ACO or ZDC with just one control computer.

There are several non-detector projects that provide centralized services (rack control, spaceframe monitoring, access control, global variables, DIM server) or communicate with the external systems (electricity, cooling, ventilation, magnet control, environment monitoring, radiation monitoring detector safety system, LHC services, gas control).

The field layer of the DCS consists of many different types of devices - power supplies (HV and LV supplies of several manufacturers), VME processors, custom made front-end DCS boards, TELL boards used in LHC-related projects, ELMB boards used mainly for the monitoring, PLC controllers and other commercially available or custom made equipment. While a large majority of the devices communicate via Ethernet (processors, boards featuring embedded Linux, but also a majority of the power supplies), there are also several industrial buses in use (CANbus, Profibus, Modbus, RS232, VME/VXI, JTAG).

Most widely adopted middleware communication protocols (running on top of TCP/IP) in ALICE DCS are OPC (industry standard, provides useful smoothing and data reduction) and DIM [2] (CERN-developed protocol - used in the front-end communication, state machine message passing, as well as for the communication with external systems).

The supervisory layer is based on commercial SCADA software (PVSS-II from ETM [3]) and JCOP framework [4] running under Windows (XP and Server 2003). Detector DCS experts developed the control applications for the particular subdector with the support of a small central DCS team that is also responsible for all the central DCS systems and infrastructure.

The front-end DCS boards are controlled by Linux-based applications based on a custom framework developed in ALICE. They communicate with their corresponding PVSS supervisory project by DIM.

The control hierarchy is built by the detector and subsystem developers using the finite state machine mechanism of the FSM package [5] developed at CERN. It allows to create a multilayer hierarchical tree structure distributed over several PVSS projects and control hosts. The detector top nodes are integrated into the overall ALICE control flow supervised by the central ALICE DCS node, which allows to bring the whole detector to the desired state (e.g. READY, STANDBY, OFF) by a single FSM command given at the top. At the various levels, the subsystem's FSM logic agent determines which actions should be executed for a given command and distributes the appropriate commands to the child nodes. It also calculates it's own state from the states of its sub-nodes and reports it to the parent node.

The user interfaces built on top of the control applications (based on PVSS and JCOP framework) allow experts and detector operators to bring the whole detector or its part to a desired state by one mouseclick. One top-level command creates an avalanche of commands propagated down the tree and the flow of corresponding state changes backwards. FSM inclusion/exclusion mechanism combined with the PVSS access control capabilities ensure proper ownership of a given sub-tree (either in the central tree or excluded for the experts).

The alert system based on PVSS datapoint properties and JCOP framework tools provides effective means to detect anomalous conditions so that the operators and experts can efficiently react and bring the detector or a subsystem back to the full health.

DCS COMPUTING

The design of the DCS computing cluster follows the overall DCS partitioning (detectors, central services, external interfaces).

Each detector has at least one PVSS worker node, one operator node running the user interface and most of the detectors have also a dedicated Linux front-end node. Larger detectors distribute the control tasks over several PVSS hosts according to the functionality and/or device types (HV, LV, gas, cooling, front-end) that can be further subdivided into the groups according to the detector layout (side, sector).

The detector top node runs the upper FSM control layer(s), distributes commands, collects states of the various subsystems and communicates with the top ALICE DCS node.

The operator nodes are dedicated for the experts to run their (often CPU and memory hungry) user interfaces independently so that they do not affect the main control applications running on the worker nodes.

Several common projects are running on the dedicated central PVSS nodes, such as rack control, gas control, spaceframe monitoring, global variables, alerts or PVSS access control.

The LHC interface subsystem consists of PVSS hosts supervising tasks like beam conditions and luminosity monitoring or beam injection handshake procedure with the central LHC control centre.

Apart from the described FSM control flow (commands and states) there's much larger flow of the configuration and monitoring data in the ALICE DCS hierarchy (peak rate of 150 000 changes/sec).

The configuration data (originating from the database and custom-formatted files) are sent at the various stages of the setup phase from the control layer to the devices (most of the load goes to the front-end). The monitoring data coming from the devices (via OPC, drivers and PVSS managers) are processed at several levels of the DCS hierarchy using PVSS datapoint objects and can be archived to the database by a specialized PVSS DB manager (about 1000 changes/sec archived). The total size of the data stored in the database is at the level of 20 TB/year (configuration plus archive).

The Linux-based ORACLE database system (housing the configuration database and the archive) is also part of the on-site DCS cluster, as well as several fileservers, bootservers, engineering nodes and other support systems.

Several Windows-based fileservers are used to store and backup the DCS projects, software repository and various tools. Central runtime fileserver hosts certain part of all PVSS projects (such as panels and scripts). Several Linux-based bootservers and fileservers support diskless systems (VME processors, boards based on embedded Linux).

The monitoring of the DCS hierarchy is performed at the level of PVSS (JCOP framework tools), the cluster monitoring is mostly based on Microsoft system monitoring package (SCOM) and Intel toolkit (ISM). In total we have over 200 control system computers, about 100 of them running PVSS applications, 70 serving detector front-ends and non-detector services, the rest belongs to the central services (database, fileservers, gateways etc.).

ALICE DCS NETWORK

Due to the nature of the experimental environment we decided to run the DCS on a private network decoupled from the CERN General Purpose Network (GPN).

Many networked devices used in the DCS lack important security features, others are difficult to update/upgrade. Even if the patches/updates exist they have to be first properly tested, that cannot be fully achieved in the limited lab test setups. The requirement of a continuous and stable operation also disfavors frequent changes at any level.

A CERN-wide policy for the computing and network infrastructure for controls (CNIC) [6] was proposed and implemented that allows to restrict the traffic between the security domains (ALICE, GPN, TN). Only certain vital services running in the CERN computing centre are visible from the ALICE network, as well as those provided by the LHC groups on the Technical network (TN) which is isolated from the GPN as well. The networking infrastructure (routers, switches) and tools (to

create and apply the rules) are provided by CERN IT department. It is also possible to further protect certain sensitive devices (e.g. PLCs) within a security domain, isolating them from all the DCS networked nodes but the few explicitly permitted. The data transfer to and from the DCS network is performed via a dedicated gateway, using the fileservers running inside the two security domains.

Only the central and detector DCS experts and developers are authorized to access the DCS network via an application gateway.

The network is physically divided into several starpoints provided by CERN IT that cover all experimental areas including the counting rooms and experimental cavern. In total we have over 1200 networked devices (600 DCS boards, 250 computers, 200 power supplies).

Abstract

The ATLAS experiment at CERN is one of the four Large Hadron Collider experiments. DCS Data Viewer (DDV) is a web interface application that provides access to historical data of ATLAS Detector Control System [1] (DCS) parameters written to the database (DB). It has a modular and flexible design and is structured using a client-server architecture. The server can be operated stand alone with a command-line interface to the data while the client offers a user friendly, browser independent interface. The selection of the metadata of DCS parameters is done via a column-tree view or with a powerful search engine. The final visualisation of the data is done using various plugins such as "value over time" charts, data tables, raw ASCII or structured export to ROOT. Excessive access or malicious use of the database is prevented by dedicated protection mechanisms, allowing the exposure of the tool to hundreds of inexperienced users. The metadata selection and data output features can be used separately by XML configuration files. Security constraints have been taken into account in the implementation allowing the access of DDV by collaborators worldwide.

SPECIFICATIONS AND DESCRIPTION

The DDV project aims for implementing a data viewing application for DCS data. The application primarily targets users from the whole ATLAS collaboration allowing to access and display data from database archives. The list of the specifications was the starting point of the development and it went through several revisions driven by development expertise and end-user requests:

- Platform and browser independent project,
- Reasonable application startup time (less than 10sec),
- Small response time to requests (order of second),
- All possible navigation mode options (element_name, alias, description),
- Multiple output formats (chart, table, ascii, ROOT),
- Current configuration in XML format option,
- Database protection mechanisms.

The DDV implementation is based on client-server architecture (see Figure 1). The server part is composed of two main parts, one that deals with data and another one that deals with metadata. The client-server communication is done via the http protocol. The client is composed of two main parts, the request-creation part and the output. The highly modular application offers the possibility of implementation of many interesting features which will be described in the next sections.

DDV SERVER

The DDV server is written in python. It accepts requests, it communicates with the DB, it manipulates data in case it is needed and finally returns back the results.

Metadata Organization The ATLAS DCS metadata is information that refers to an archived parameter (*element_name*) that identifies that specific item in the Oracle tables. Besides, each *element_name* can have a *description* and an *alias* which are more user friendly definitions. The metadata information is copied from the database to an SQLite [2] database cache within the DDV server. The organization of metadata in SQLite file, serves two different purposes. Firstly the SQLite tables are configured to be stored in memory offering in this way the quickest possible response time of metadata queries. Secondly, all queries concerning metadata are performed exclusively inside DDV server keeping the database resources as available as possible.

Data Retrieval In the case of data requests DDV acquires data directly from DB. The server communicates with the DB using the cxOracle [3] extension module that allows access to Oracle databases. The request engine is designed in a way that minimize the DB response time and considers possible changes in the mapping between element_name and alias or comment.

Server Stand Alone Use DDV tool can be used in *batch mode* which offers the option of accessing DB information directly by calling DDV sever (e.g. through a terminal) without the need of a browser or any other graphical environment. The server accepts HTTP requests by using a pythonic framework called cherrypy [4]. As soon as a new URL reach the server, it is decomposed and its parts are used to create a meaningful DB request information.
Requests, GET method:
[server]:[port]/metadata/[queryType]/
[selectedSchema]/[system]/[pattern]
e.g. `http:/pcaticstest07:8089/metadata/element_name/atlas_pvssmdt/ATLMDTPS2/*temp*`
Data requests, POST method:
[serverAddress]:[port]/multidata/getDataSafely
e.g. `http://pcaticstest07:8089/multidata/getDataSafely,queryInfo=atlas_pvssdcs,comment_,CICRackControlLArgY0721A2Humidity,10-10-201012:0,11-10-20100:0`

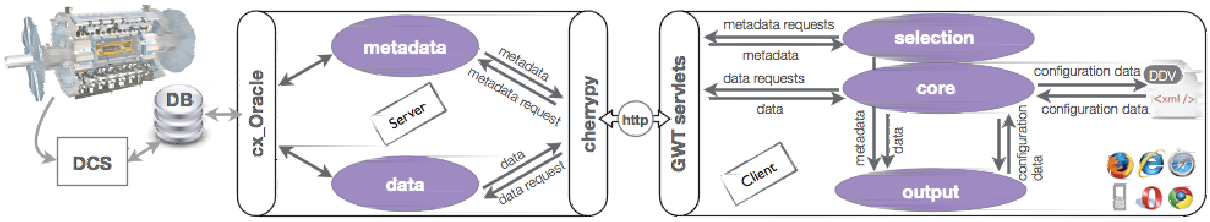

Figure 1: The DDV server-client architecture.

Relational Queries For the cases that users are interested in a subset of data that satisfy some criteria (typical example is the case of a spike) DDV provides a *Relational Queries* mechanism where an accepted range of values can be specified for the selected items. Each item can be configured separately and have its own accepted value region.

Data Base Protection Mechanism Intending to serve a high number of users , DDV aims to be more than an interface to database data. DDV validates and certifies each request with a minimum-response-time cost and finally propagates it to the DB. This protection mechanism is organised in three levels and can schematically be seen in Figure 4. Firstly DDV applies *hard cuts*. Requests with time periods of more than 2 years or including more than 200 items are considered to be potentially dangerous for the DB and are declined. A second protection mechanism performs a light test-request with a time period significantly shorter than the one requested. The number of returned rows is translated to a data rate (Hz) and by extrapolating to the full query time, a decision is made whether this request is acceptable or not. Finally, a third kind of protection mechanism is in place to cover the cases that some unforeseen reason can cause the request to hang. In case DDV does not get any answer from the DB during 20 sec, the request is cancelled before completion.

DDV CLIENT

The client part of DDV is largely based on the Google Web Tool kit (GWT) framework for web applications [5] . The development is done in Java while the result after GWT compilation is a browser independent AJAX-based web application. Keeping the development in a type-based language like Java the testability increases and the debugging of code becomes faster with the help of a Java debugger (e.g. eclipse). The client interface is organized in two main parts. The selection and configuration module (Figure 2) is developed with the use of the GWT framework . With the use of menu items, buttons, tables and other widgets the user enters the request selection criteria and a server request is constructed. The bottom part is independent of the GWT framework and hosts the output plugins.

Selection

Column based browsing DDV provides an easy navigation mode through metadata using column-tree widgets. Since the metadata information is kept in the server in cache, the server response is prompt and in each request the result is returned back to the client in a fraction of a second.

Search Engine The *column lists* is an easy navigation mode. However, the vast number of archived parameters can create difficulties to non-expert users. For such cases DDV provides a *Search Engine* for DCS metadata. The user has to provide one or more strings that will be used as a pattern, separated with the wildcard character '*' . In the DDV server side the search string is translated into a case insensitive SQL pattern which is sent as part of the database request. Apart from the user friendly search engine an *Advanced Search Engine* is in place, that supports regular expressions.

Configuration

Despite the intuitive selection interface of the tool and the optimization of the response time in every action, the selection of the wanted items and the configuration of the final output may take some time. DDV offers the possibility of saving the current configuration to a file. In this way, users can save the current configuration and in a future time upload it again and quickly visualize the wanted information. The configuration file includes general information of the request (e.g. starting/ending time and date), the selected metadata information, the selected output, configuration of the selected output and relational queries information. The configuration file is chosen to be in XML standard which is simple, easy readable and on the same time flexible enough to accommodate future diverse needs.

DDV Outputs

DDV aims to offer to users several output options which satisfy different needs. These outputs are connected with the DDV client with a thin, well defined, interface. There are two main categories of outputs, visual outputs that appear on the browser and output-files to be downloaded to the users disk.

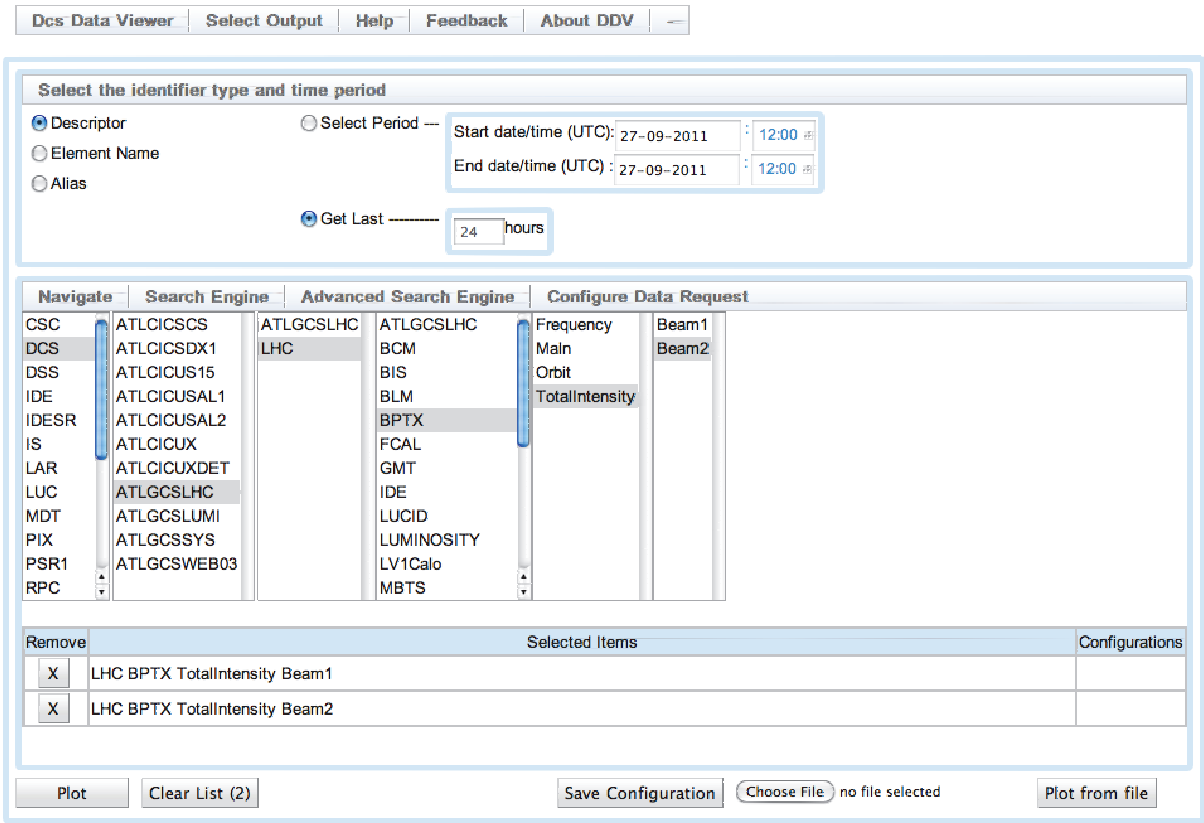

Figure 2: The main browser window interface of DDV. The top part deals with the selection of the navigation mode and the start/end date and time. The middle part offers an easy navigation among the metadata with a column-tree view. The bottom part holds the action buttons like *plot* for a graphical display of data and *save configuration* for saving the current configuration in XML format.

Chart Applet The default output of DDV is a chart (Figure 3), implemented in form of a Java Applet based on the JfreeChart [6] libraries. Depending on the format of the selected data the user can choose to display these as time series, one or two dimensional histograms. The output configuration can be defined either in the main DDV browser interface or interactively in the Applet in a flexible way.

Chart Java Script The Java Script Chart is another output for graphical representation of the data. Concerning the plot options it is more restrictive comparing with the default output but it is more light for the browser. Furthermore, since it is written in Java Script , it can be visualized in environments that do not support java applets (e.g. case of some smart phones).

Table Java Script Data table is a Java Script output that displays the database response in a table. The information held in the table is the archived parameter, the time-stamp and the value. Moreover, the output offers the options of searching and filtering.

ROOT DDV offers the possibility to download the selected data in ROOT [7] format. These files consist of one TTree for every selected data series containing times and values of the contained data points. In this way the user can process the data flexibly in ROOT macros. Besides these trees, there is also a set of predefined TGraphs for the selected data included in the output file.

ASCII Output ASCII file is a simple and highly universal output format. It keeps the information of the archived parameter, the time-stamp and the value.

External Requests

The deliberately modular design of the tool in the initial phase of the development, paid well back in the accomplishment of powerful features. With the use of *External Requests* the user can call DDV by pointing in the same time a configuration file that is pre-saved in the server. All the requested information is kept in the configuration file and in this way a single call accompanied with the configuration file location as a url parameter, is enough to pop up a new browser window with the DDV page and the chart already populated.

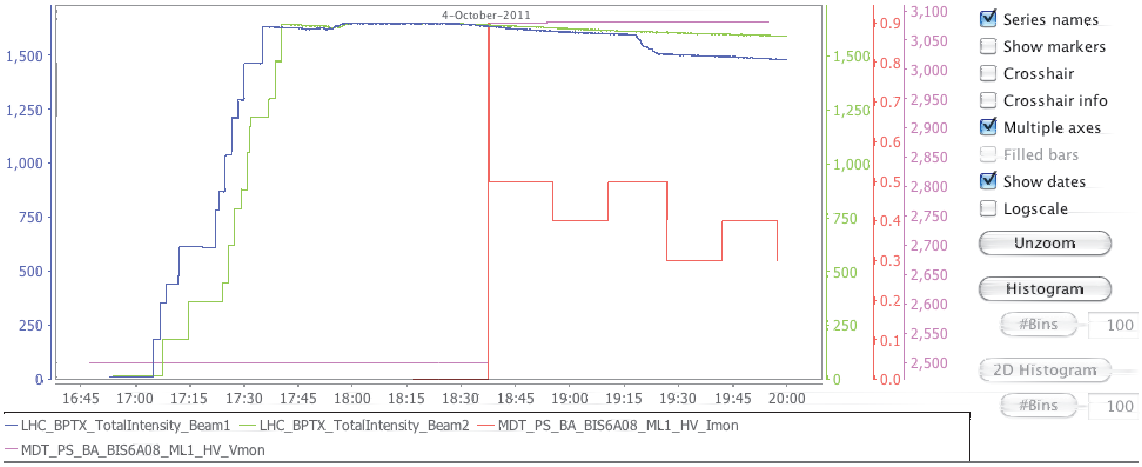

Figure 3: JfreeChart, the default output of DDV. Except of displaying graphically the data, it offers several features like multiple axes, logarithmic scale, markers display, crosshair information, projection of data to 1D and 2D histograms (where applicable).

RESULTS

DDV is officially released as ATLAS central service since the January of 2011. Security constrains have been taken into account in the implementation allowing the access of the application by collaborators worldwide. Currently the number of DDV users is about 150 and it grows constantly.

THE PSI WEB INTERFACE TO THE EPICS CHANNEL ARCHIVER

Gaudenz Jud, Andreas Luedeke, Werner Portmann. PSI, Villigen, Switzerland

Abstract

The EPICS channel archiver is a powerful tool to collect control system data of thousands of EPICS process variables with rates of many Hertz each to an archive for later retrieval.

Within the package of the channel archiver version 2 you get a Java application for graphical data retrieval and a command line tool for data extraction into different file formats. For the Paul Scherrer Institute (PSI) we wanted a possibility to retrieve the archived data from a web interface. It was desired to have flexible retrieval functions and to allow interchanging data references by e-mail. This web interface has been implemented by the PSI controls group and has now been in operation for several years. This paper will highlight the special features of the PSI web interface to the EPICS channel archiver.

INTRODUCTION

The EPICS channel archiver is used at different facilities at PSI, e.g. for the Swiss Light Source (SLS), the Swiss Free Electron Laser (SwissFEL) injector test facility, the medical cyclotron (Proscan) and others (Fig. 1). Several ten thousand process variables are archived at SLS and for the growing SwissFEL project the number is nearly twenty thousand process variables already. The arching of waveforms becomes increasingly important for the SwissFEL project. Currently more than hundred waveforms are collected at 10 Hertz.

To gain most benefit of the archived data, a simple retrieving tool is essential. It has to be taken into account that not only the machine and experiment experts, but also our maintenance staff are using the Archivers and are dependent on an easy retrieval of the archived data.

Taking everything into account, we decided that it should be possible for everybody to retrieve channel archiver data from every computer standing around. The retrieval has to be possible with a minimum of software installations. A web browser is a tool contained in the standard installation of every PC at PSI. Thus we decided to write a web-based server application which is very intuitive and can be learned to be used within minutes by persons, who are no computer experts. The use of predefined data sets was important as well as the possibility to analyze waveforms. Some export formats should allow the users to accomplish further works on the data according to their wishes.

Process variable names are often rather cryptic. Therefore it is possible to define descriptions for EPICS process variables in a dictionary, which are stored in a database. The descriptions can be used fully equivalent with the process variable names: you can either search for process variables or descriptions, and in the data plots, you can decide whether to use the original name or its description in the agenda and for the y-axis labels.

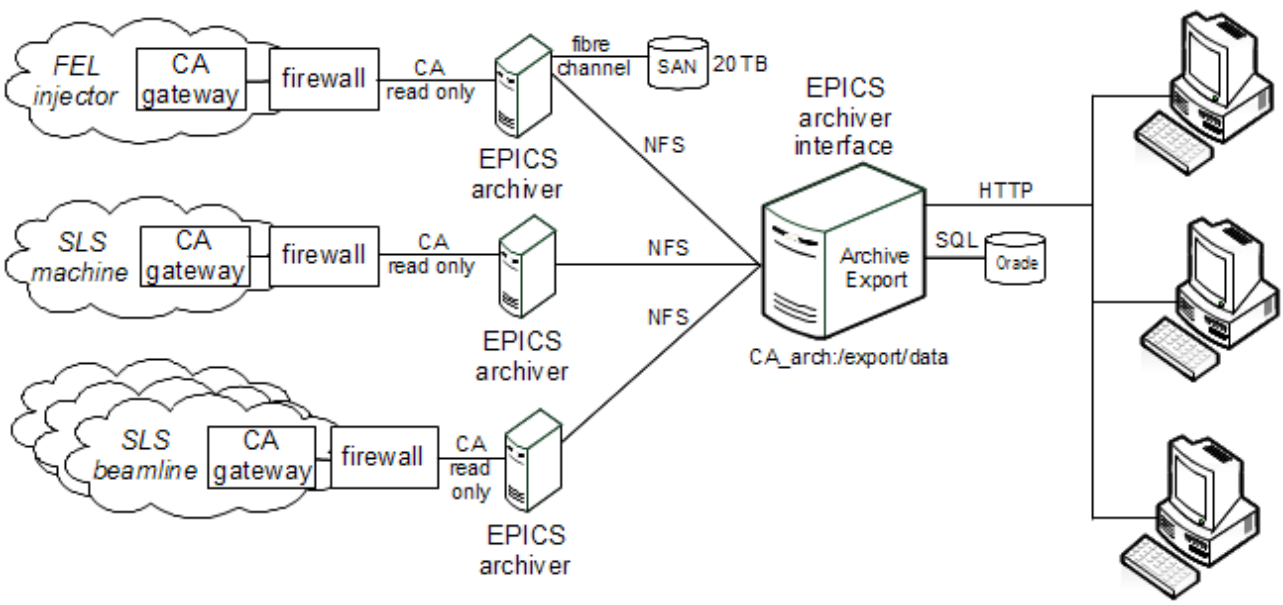

Figure 1: Overview of the EPICS channel archiver realisation at PSI.

GRAPHICAL USER INTERFACE

Scalar Data Plot

Fifty different EPICS archive processes, so-called archive engines, are running currently at PSI. When calling the main page of the archiver data interface, an overview of all these engines is given.

On this main page one can also find a navigation bar on the left. One link of it is **predefined views**, which leads to an overview of several collections of preselected channels, which can be plotted by one click. These predefined views are extremely helpful to examine collections of records routinely (Fig. 2).

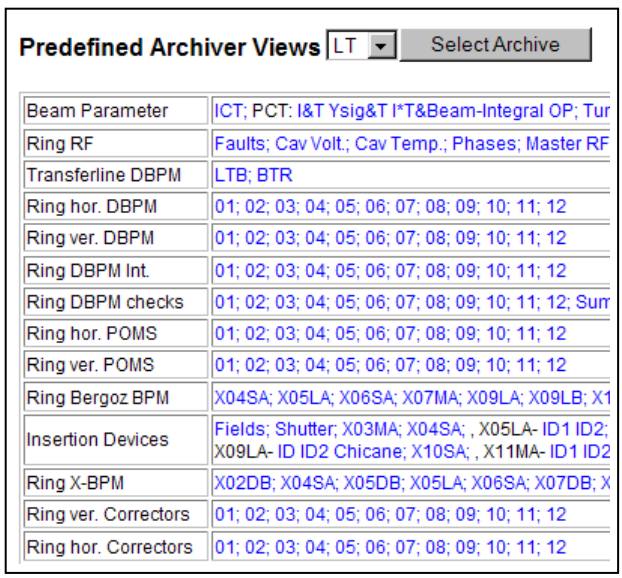

Figure 2: Partial view of predefined views.

If the user decides to select one of the archiver engines displayed at the main page, he/she is lead to a page, were the channels of interested can be entered in a text field.

Alternatively channels can be searched by means of regular expressions. The result of such a search is a list, from which the desired channels can be selected.

The next page provides handles to adjust the time range and the formatting of the axis, buttons to process the data for scalar or waveform display or data export, and several more options to format the output (Fig. 3).

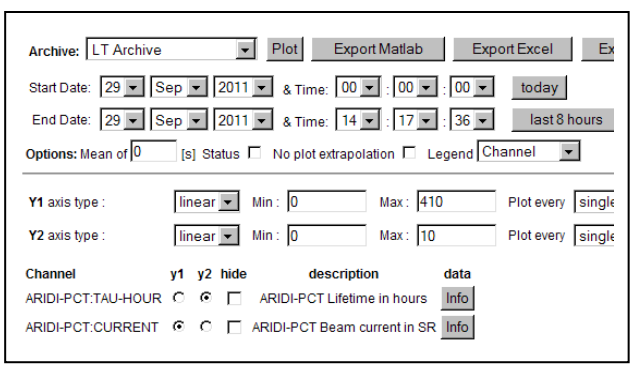

Figure 3: Partial view of the adjustment page.

A plot command with the adjustments in Fig. 2 results in the plot shown in Fig. 3.

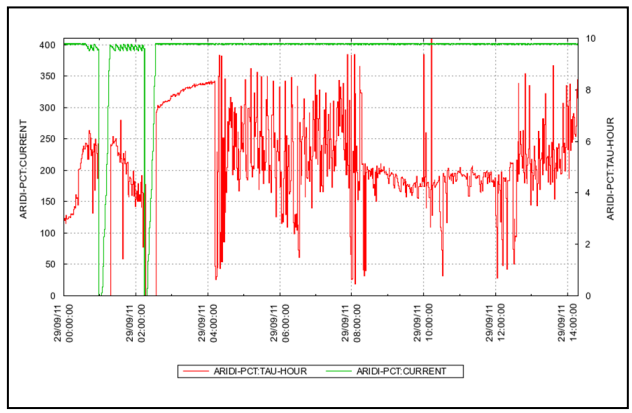

Figure 4: Ring current plot with parameters from figure 3.

Waveform Data Plot

Analogue signals from an AD converter card might be stored as waveforms to achieve a better time resolution. The low level RF group engaged in the development of an injector to be used for the SwissFEL project uses a lot of waveforms. Therefore it is inevitable to provide a tool to analyse the waveform data. A data viewer written in Java was available to perform such analysis.

The java tool was a client application but the users wished a possibility to look at their waveforms data in the same tool as they use for other data in the channel archiver. Therefore we added a waveform viewer on the web server. A lot of ideas were taken from the Java data viewer. The adjustment page of the archiver web interface allows now selecting a waveform display as an option. Then a special page devoted to control the output of the waveforms opens (Fig. 5).

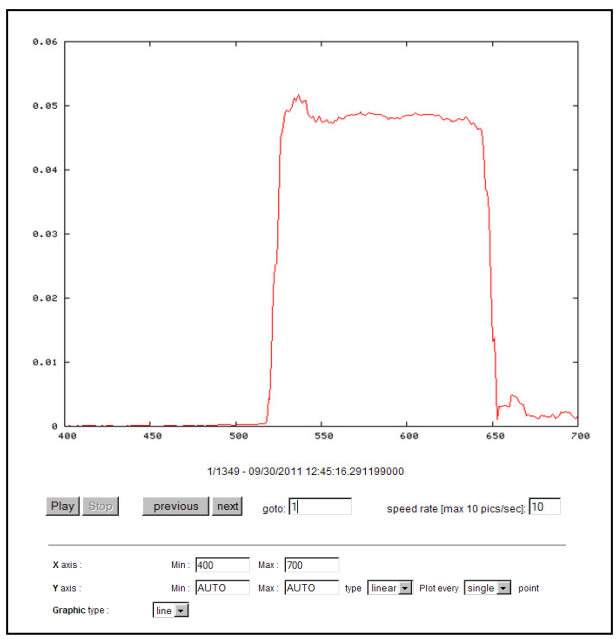

Figure 5: Waveform plot with selectable options.

All waveforms archived during the selected period are created as a sequence of plots. By pressing the play button the sequence is displayed as an oscilloscope display. The speed can be chosen between 1 and 10 waveforms per second. One can step forward and backward plot by plot or choose or choose a dedicated plot within the sequence. The plot can be filled or outlined; the x- as well as the y-axis can be selected. Otherwise an automated wide and height is chosen respectively.

Archiver Data Export

Included in the EPICS channel archiver package version 2 is the command line tool *ArchiveExport*. While useful as a debugging tool, it might be cumbersome to be used for routine data analysis. The data retrieval with our web interface is still done with *ArchiveExport*, but the graphical user interface facilitates its use. All user inputs are translated into a command line using *ArchiveExport*. The retrieved data are processed with the graphical *gnuplot* package to provide the desired plot. The data can be exported either as text, excel sheet or in matlab format.

Uniform Resource Locator (URL)

When using the archiver web interface, one might want to communicate the created plots to somebody else. To fulfil this task, the archiver web interface has an extremely useful behaviour. All features of the interface pages are contained in the URL. Therefore it suffices to copy the URL of a page of interest and send this URL to a recipient. Opening this URL shows exactly the same content as the sender was looking at.

The advantage of interchanging data references as URL compared with interchanging the data itself is many fold. The main benefit is that the recipient can refine the data: he can easily expand the time range or add other process variables in order to correlate events. At the same time the usage of URLs simplifies the access for the user, since he only needs to learn one tool to handle the data retrieval and display. And it saves of course bandwidth, not to interchange the full data of interest by e-mail.

It is possible to go even a step further and to create the URL in another application. This allows web applications to link to the archiver web interface for the display of specific data, with defined formatting for a desired time range. The Operation Event Logging System used at the SLS [1] utilizes this feature of the channel archiver web interface. It creates for each beam event links to related data. For example in case of a beam outage it creates a link to the beam current plot during the outage period, or for each orbit feedback failure it generates a link to the orbit data during the time of the failure.

TECHNICAL REALISATION

Hardware

Using the web server solution to retrieve channel archiver data imposes a powerful hardware. The server hosting the web interface to the channel archiver is a HP Bl460c G6 Proliant Blade Server with 2x quad-core E5506 @ 2.13GHz CPU, 24GB RAM and 1GB/s network. The data are stored on a hardware raid connected with a 4 GB/s fibre channel connection.

Software

The operating system of the server is Scientific Linux SL release 5.1 (Boron) [2]. We choose the development environment Eclipse Galileo [3], used with the Zend Engine v2.1.0 [4] and Xdebug v2.0.5 [5]. The web server is an Apache 2.2.3 [6], PHP used to develop and run the archiver interface has version 5.1.6 [7]. JavaScript is used to perform the control of the waveform output on the client side. The export of data into Matlab format is performed without using the Matlab program. We used the matio-1.3.4 C library [8] to program the Matlab export function. Calling this c module inside PHP enhances the conversion speed remarkably.

SUMMARY

The PSI archiver web interface for the EPICS channel archiver has proven to be a reliable, efficient and effective tool for the access and display of the archived control system data. It is easy to use; it does not depend on other client software than a normal web browser and it provides high flexibility to retrieve the data. Many useful applications derive from its ability to encode all retrieval and display parameters in a URL. This allows other web applications to link to specific data use references to the archiver web interface, instead of incorporating their own measures of data retrieval from the archiver.

ACKNOWLEDGEMENT

The PSI archiver web interface is the successor of the CGIExport tool, which was part of the previous version of the channel archiver [9]. That tool was in use at PSI, too. It was discontinued in version 2 of the channel archiver. We therefore reengineered a new tool with the same layout and functionality. Even the URL interface was kept compatible, but has been extended later for the new functionality of the PSI archiver web interface.

ASYNCHRONOUS DATA CHANGE NOTIFICATION BETWEEN DATABASE SERVER AND ACCELERATOR CONTROL SYSTEMS*

Wenge Fu, Seth Nemesure, John Morris, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

Database data change notification (DCN) is a commonly used feature. Not all database management systems (DBMS) provide an explicit DCN mechanism. Even for those DBMS's which support DCN (such as Oracle and MS SQL server), some server side and/or client side programming may be required to make the DCN system work. This makes the setup of DCN between database server and interested clients tedious and time consuming. In accelerator control systems, there are many well established software client/server architectures (such as CDEV, EPICS, and ADO) that can be used to implement data reflection servers that transfer data asynchronously to any client using the standard SET/GET API. This paper describes a method for using such a data reflection server to set up asynchronous DCN (ADCN) between a DBMS and clients. This method works well for all DBMS systems which provide database trigger functionality.

INTRODUCTION

In normal database server and client operation, the server side stores the data and makes it accessible to clients. Clients dominate the data changes by submitting requests to the server. There are many instances where a client may want notification when the data has changed on the server side by another client. There are two known ways to accomplish this task. One way is to use a database server driven data change notification (DCN) technique while an alternative approach is to have the client synchronously poll for data. The downside to client data polling is an increased (and potentially unnecessary) number of network transactions in addition to an increase in database server side work load. Additionally, depending on the data polling frequency, there may be a delay between the time that the client becomes aware of an update to data and the time the update actually took place. By contrast, database server side DCN provides the client with asynchronous (immediate) updates.

The distributed DCN message structure can be in the form of the actual changed data or can be a form of meta data (e.g. the column in the database table that has changed including whether or not the change was due to a database insert or update). In recent years, many commonly used DBMS (Database Management Systems) such as the Oracle database server[1], Microsoft SQL server[2], IBM DB2 server[3], and Sybase ASE[4] server, provide DCN support using different approaches. There are advantages and disadvantages to each DBMS system's DCN feature. Typically, in order to take advantage of a DBMS provided DCN feature the user may need to:

- Set up a data change notification handler on the server side for target data tables or target data columns, and publish data changes (or event or meta data of the data changes without actually sending the changed data) through the handler;
- Set up a data change notification receive handler on the client side and register (or subscribe) it with the listening DBMS DCN objects that will receive the data change notification (or events and meta data of the data changes) .
- Keep an open (TCP or UDP) network connection between client and database server.

Setup of DCN registration, data change publishing, and receiving DCN may differ between various DBMS to DBMS systems. At a minimum the basic steps listed above must be taken into account. Some database server side SQL programming and client side application programming may also be required to make the system work. This process can be tedious and may require additional effort to support different clients.

In typical accelerator control systems like the RHIC-AGS system running at Brookhaven National Laboratory, there exist common techniques for data communication between hardware and software. Some of these include software interfaces such as ADO[5] (Accelerator Device Object), CDEV [6] services, and EPICS[7] (Experimental Physics and Industrial Control System). These interfaces can be used to setup reflection servers to transfer asynchronous DCN messages from a database server to client without a direct connection between client and database server. This greatly simplifies the setup of the DCN process.

By taking advantage of existing accelerator control system software using the CDEV service, an example of a simple and robust method for setting up a database DCN system is presented. This method works well with any DBMS system which supports database triggers.

SETUP OF DATABASE ADCN

The ADCN system consists of three parts as shown in the Figure 1.

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

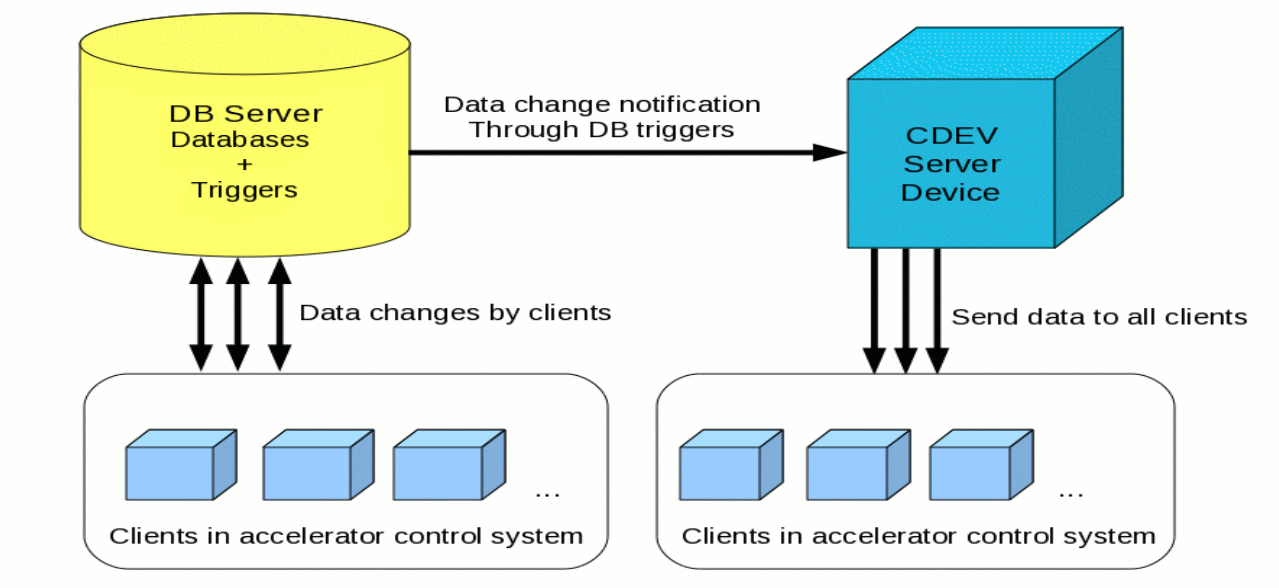

Figure 1: Diagram of ADCN system setup.

1. A database which stores the controls data. The database can exist on any DBMS system which supports the database trigger feature and able to execute system commands from the database trigger. Some DBMS examples are Oracle, MS SQL Server, Sybase ASE, and MySQL. In a target database, a specially designed trigger can be set up to fire whenever the target control data changes. The data changes can be in the form of newly inserted data, updated data, or removal of existing data. Depending on the capability of the DBMS system, the trigger can fire before or after the data changes in the database. The database trigger can also be designed to determine what kind of DCN message to send. The developer set the system up so that it sends events of data changes, meta data of the changed data, or the changed data itself. In this case the trigger will send the DCN message immediately along with the data change that occurred in the database.
2. A second requirement is for the existence of a generic server that listens for the trigger and transmits the DCN message from the database to interested clients. The generic server here can be any well established accelerator control system server such as an ADO or CDEV Server. In the example above CDEV server devices are used.
3. The third requirement is for a client to set up the communication exchange with the server. This allows the client get notified when the target data changes initiated by other clients. The data change process between client and server is independent from these clients of being notified. At the time of a DCN, the data within the database table is updated which initiates the asynchronous transaction to interested clients. In addition to being a place for control data storage, the database becomes integrated into the accelerator control system.

The key component of this system is the design of the database trigger. This is the only part that requires knowledge of SQL programming. The trigger requires the user to determine the type of data to send to clients and under what conditions. Depending on the DBMS system used, the execution of a trigger may or may not affect the database operation in the case where the trigger execution fails. It is good practice for the developer to make sure the trigger has the flexibility to support various failure modes.

In the ADCN system shown in Figure 1, the set up of the CDEV server device is straight forward due to the developers familiarity with well established CDEV (ADO) interface. The CDEV server device serves as a reflective device (the server only needs to forward data from the database server to interested clients). The server supports the same API (i.e. SET/GET methods) used by other devices in the accelerator control system. In addition to specialized applications that use the ADCN system in the Collider-Accelerator Controls System at Brookhaven National Laboratory, generic wide use applications such as GPM (Generic Parameter Monitor), pet (Parameter Edit Tool), and the logging system can also take advantage of ADCN.

ADCN SYSTEMS USED IN RHIC

In the RHIC-AGS controls system, several ADCN systems have been set up by using the methods described in this paper and have been used operationally over the past several years. The DBMS systems involved in these ADCN systems are MS SQL Server 2005 running on a Window PC and Sybase ASE 15 running on Solaris 10.

The same ADCN set up strategy can be applied to any DBMS system which supports the trigger feature. Below is a brief description of one of the ADCN system--- the RHIC access controls system for live IRIS data communication.

In the RHIC access controls system, IRIS recognition data are generated from the IRIS access control devices and stored in a MS SQL Server 2005 database on a security sub-network on a Windows PC. The MCR (main controls room) of RHIC requires asynchronous notification whenever IRIS data in the database is updated. To achieve this, a database trigger was created in the MSSQL database. The trigger initiates the transfer of the changed data to the pre-defined CDEV server running on a Linux host. The MCR application monitors and logs the data from the CDEV device and uses the live IRIS data change for security access in the CAD complex. Figure 2 shows how the system works.

In this example, the ADCN system seamlessly integrates the IRIS access control system (manufactured by LG) and MS SQL Server (2005) database with the in-house designed access control system.

SUMMARY

Asynchronous data change notification (ADCN) between database server and clients can be realized by combining the use of a database trigger mechanism, which is supported by major DBMS systems, with server processes that use client/server software architectures that are familiar in the accelerator controls community (such as EPICS, CDEV or ADO). This approach makes the ADCN system easy to set up and integrate into an accelerator controls system. Several ADCN systems have been set up and used in the RHIC-AGS controls system.

THE INTEGRATION OF THE LHC CRYOGENICS CONTROL SYSTEM DATA INTO THE CERN LAYOUT DATABASE

E. Fortescue-Beck, R. Billen, P. Gomes, CERN, Geneva, Switzerland

Abstract

The Large Hadron Collider's Cryogenic Control System makes extensive use of several databases to manage data appertaining to over 34,000 cryogenic instrumentation channels. This data is essential for populating the software of the PLCs which are responsible for maintaining the LHC at the appropriate temperature.

In order to reduce the number of data sources and the overall complexity of the system, the databases have been rationalised and the automatic tool, that extracts data for the control software, has been simplified. This paper describes the main improvements that have been made and considers the success of the project.

INTRODUCTION

The LHC Machine

The **LHC Machine** is a 27 km hadron collider, laying 100 m underground, and comprising eight sectors; each one is made of 2 long straight sections and an arc, with 23 regular cells of 107 m in a continuous cryostat.

The Controls Architecture

In each sector, the cryogenic instrumentation is controlled by two Siemens-S7® Programmable Logic Controllers (PLCs) [1, 2].

The man-machine interface for the operators is based on a SCADA (Supervisory Control And Data Acquisition) built using the commercial PVSS® software package developed by ETM, a Siemens subsidiary.

CIET (Cryogenics Instrumentation Expert Tool) is a dedicated SCADA tool used by the cryogenic instrumentation experts.

All cryogenics software (SCADAs and PLC software) conform to the CERN UNICOS (Unified Industrial Control System) framework [3] and is automatically produced by a UNICOS generator. The UNICOS generator takes as an input a specification file containing a list of instruments and parameters. The main aim of this project is to generate this file directly from the databases.

The Databases

Since 2005 the Cryogenics Group has been intensively using several databases (DBs) to manage data appertaining to 34,000 instrumentation channels.

The **Layout DB** is the principal database for centrally maintaining the topology of all CERN installations [4].

Thermbase is a dedicated DB containing the calibration data for all thermometers in the LHC. Its successor **Sensorbase**, is under development and aims to consistently manage all of the metrological data for pressure sensors, level gauges and heaters, in addition to thermometers.

The **MTF** (Manufacturing and Test Folder) **DB**, holds information about individual pieces of equipment. This includes properties, test measurements, status flags, and strict follow-up of the steps of manufacturing, assembly & test procedures.

The **Controls Layout DB** acts as an interface, combining the data from Layout, Thermbase, Sensorbase and MTF into database views which provide the complete set of information used to automatically generate the specifications for the control system.

WHY USE THE LAYOUT DATABASE FOR CRYOGENIC INSTRUMENTATION

The Layout database was initially developed in 2003 for planning the installation and commissioning of the components in the LHC. It aims to capture the system architecture and the details of the installed components in the accelerator complex. Therefore most of the Groups who are responsible for accelerator equipment describe their architecture in this database. Figure 1 shows a few examples of domains currently using Layout; however in principle any domain can be described.

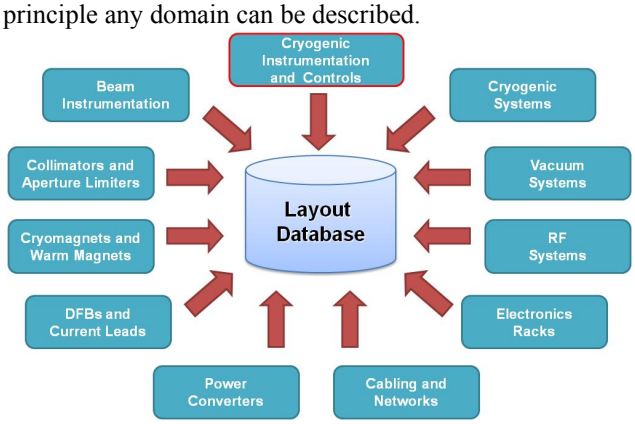

Figure 1: Domains which use the Layout Database.

Unexploitable Data

In 2005, the Cryogenic Instrumentation and Control Section needed to structure a large amount of operational data in a database so that it could be used to define the configuration of the front-end crates, for manufacturing, and also to produce the specifications for the control system.

The data describes the instrumentation attached to magnet assemblies and cryogenic distribution, as well as the electrical components of the controls infrastructure including the cables, connections, pin-outs, electronic modules, crate and racks. Up until this point it was being stored in spreadsheets, plans, drawings and technical

documents – usually on team members' local hard disks. Consequently, the data was dispersed, duplicated, incomplete and inconsistent.

This data forms the basis for nearly all of the key tasks performed by the instrumentation team, but without consolidating it in a database, it would be impossible to extract and share accurate, useful information.

Centralising and Consolidating across Domains

By deciding to integrate the majority of their data into the Layout database, the cryogenics engineers benefitted from having just one single, reliable source of information which was accessible to all team members.

Furthermore, due to the centralised nature of the Layout DB, they profit from the global integration with data from other systems, such as PLCs, field buses, magnets, cryogenics distribution, electrical circuits, etc. This integration means that maintenance across domains is easier to manage and greatly helps the machine operators to diagnose problems more rapidly.

Data Accessibility

The existing Layout web interface can be used to browse the data, easily traversing the data structure and the relationships between objects through hyperlinks. Also, since Layout is fully integrated with MTF, it is possible to directly access, via the web interface, all of the manufacturing and test data concerning the specific piece of equipment which is installed in a particular Layout position. This integration with MTF facilitates traceability, as the database can track over time all of the locations in which a component has been installed and also all repairs it has undergone. This is essential information required by international regulations on nuclear safety.

The seamless integration between UNICOS, Layout and MTF allows direct access from any instrument in SCADA to its functional information on the Layout web interface, and then to its individual properties and history in MTF.

Other useful inbuilt features of the Layout DB include versioning and the ability to track changes to the data.

EVOLVING FROM A FIRST APPROACH

Initially, only the topology of the LHC's physical instrumentation was recorded, with a limited number of object types.

Hence, conceptual objects required for the control system were not catered for in the Layout DB structure. These objects included 'instruments' which do not physically exist but are derived from others, like calculated flow or max/min values; and variables not easily related to anything physical, like spare objects or status information exchanged between PLCs.

Therefore tailor-made database structures such as tables and procedures were implemented in a supplementary Controls Layout database in order to either store or dynamically generate these new types of objects.

Rationalising the Physical and Conceptual Channels

Over time, the scope of the original Layout data model was broadened as it was acknowledged to be flexible enough to accommodate a wider range of objects and properties. Thus, it became possible to apply a coherent treatment to both physical and conceptual objects.

The major benefit of grouping data in the Layout DB and treating all types of instrumentation channels the same way was that the overall data structure became simpler and the data was easier to maintain. In addition, the views for the controls specifications became less complex, as it was no longer necessary to maintain distinct pieces of code to separately retrieve each category of instrument.

The Need for Inheritance and Relationships

The Layout DB supports inheritance. This means that derived instrumentation channels could automatically inherit properties from their parent, thus eliminating inconsistencies which could have been introduced if modifications to the parent instrument were not explicitly reapplied to the child.

As well as implementing conceptual objects in Layout, new types of conceptual relationships between instruments have also been defined; for example the link between a virtual flow meter and the instruments used in the flow calculation, such as its upstream thermometer or valve aperture, as illustrated in Figure 2.

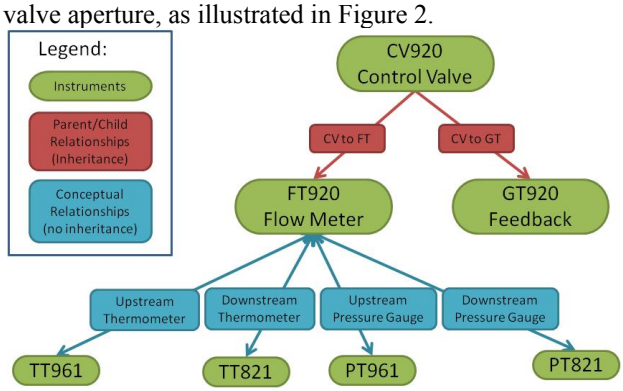

Figure 2: Inheritance and conceptual relationships.

The Introduction of Systems

Up until this point the emphasis had been focused on implementing the individual IOs in the Layout database. However there were other software objects required for the control system such as Process Control Objects (PCO), Controllers, Alarms and Interlocks, which are high-level relationships between sensors and actuators. These objects were successfully integrated into the Layout DB by defining them as "Systems", which are groups or hierarchies of Layout objects.

Figure 3 shows how high-level PCO systems are defined as a hierarchy of lower-level PCOs, which in turn are hierarchies of controller systems. At the controller level, the systems link to the IOs, as a controller is specified as a group of instrumentation channels.

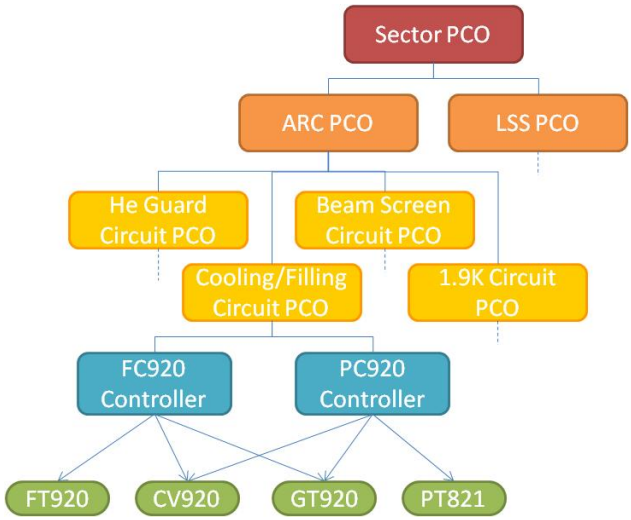

Figure 3: a hierarchy of systems.

COMPLETING THE DATA

After defining the structures of all types of instrumentation channels and control loops in the Layout DB, the data could be completed and all other data sources eliminated. Before this parametric data was integrated into the Layout DB it was thoroughly checked for consistency.

Importance of Data Quality

In the LHC, Instrument functionality is characterised by a dedicated attribute called Tag name. This implies that all instruments with the same Tag name should have similar values for Range, Scale, Deadband and Format due to having the same typical operation characteristics. For example, PT821 pressure sensors found in the magnet cold masses have a typical Range of 0 to 20bar. Whereas the PT891 pressure sensors on the DFB (deltaP line) have an operational range between -350 and +350mbar.

The SCADA display also depends on the Tag name, in harmony with the measurement range. For example, the reading from a PT821 sensor is formatted on the SCADA display as 2 integers plus 2 decimals, whereas a PT891 sensor is displayed as 3 integers. All of this information is stored in the Layout DB and propagated to the control system for use by the operators.

Maintaining Data Consistency

The original values of parameters such as Range, Scale, Deadband and Format were defined before the LHC was operational and were often estimates. Since the machine had been operational for nearly a year, many of these parameters had been manually adjusted in PVSS by experts and operators in order to improve the performance of the control system. Storing these values in the database safeguards these modifications when the control system software is regenerated.

Therefore, for each distinct Tag name present in the Layout DB, the set of current operational parameters were extracted from the SCADA. For those Tag names having conflicting parameter values, the discrepancy was resolved in conjunction with the cryogenics experts.

It was important to review these parameters because of the significant impact they have on the performance of the control system. For example, the Deadband value defines the type of filtering performed by the SCADA archiving. By default PVSS logs data at a rate of 1Hz. Filtering is required to reduce the raw data volumes by eliminating noise and keeping only relevant data long-term.

Although these corrected parameters were grouped by Tag name, they were propagated to the Layout DB as properties of individual channels. This allows future adjustments at channel level if an exception to the general rule is observed during operation.

The Description as a Key Attribute

"Description" is a very important attribute as it indicates the function of an instrument and therefore facilitates the work of the operator. In the SCADA, the description shown on the instrument panel includes the instrument functionality concatenated with field bus address, (the source of both of these pieces of data is the Layout database). This makes it easier for maintenance people to know where to find the instrument in the field bus without having to refer to other data sources.

Before the descriptions were reviewed, some were missing, incorrect or incoherent between instruments with the same tag name or similar functions. All descriptions were rechecked so that they were consistent in content and format across all types of instrument and then updated in the Layout Database.

GENERATING SPECIFICATION FILES

Business Logic in the Application

Until 2010, the control system specifications were produced by an automatic generator that extracted data from several DB views and various external files and applied a complex set of rules and calculations, to derive parameter values, relationships and secondary objects.

This Specification Generator was a very complex application which underwent a great deal of re-patching. It contained an enormous amount of code to handle each special case and exception; and thus it became difficult and time-consuming to maintain. With the rationalisation of the databases, it rapidly became unmanageable.

Transferring the Business Logic to the DB

It was critical to remove all of the knowledge embedded in the generator code and transfer it to the database. However the logic was not simply recoded. Instead, the results given by the rules were imported directly into the database as data items. This could be done because by 2010 the LHC cryogenics configuration was reasonably stable and the set of values calculated by the generator was complete. This meant that it was no longer necessary to automatically recalculate the values. Any future corrections for individual exceptions can be

manually implemented; if the original rule changes, the data can be re-imported as a batch.

The main advantage of this approach is that all of the data in the specification files is available in the database, as either persistent or aggregated values. By converting generation rules into data the amount of calculated data and information hidden in the code has been minimized. Consequently, other applications can use this data without having to re-implement the logic. Also, the code in both the generator and the database is simplified, greatly reduced and maintainable.

Simplifying the Specifications Generator

Once all of the data was coherently structured in the database, a set of views were produced which exactly replicate the structure of each page of the IO specifications. These views are stored in the Controls Layout database which acts as an interface for assembling the data from Layout, Sensorbase and MTF.

The Specifications generator has been replaced by a simple application which extracts all of the required data from each view, for a given sector and PLC. It formats the data as either a text file – in the case of the Hardware Configuration Specifications – or as an Excel file.

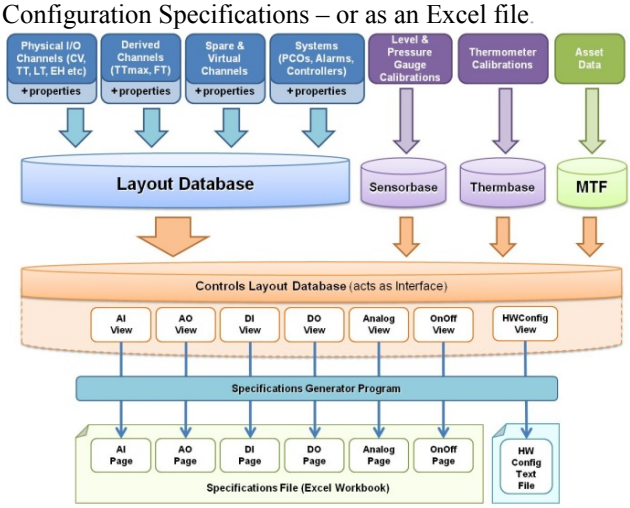

Figure 4: Generating Specifications from the Databases.

It is important to note that there is no business logic in the new generator application and it does not extract any data from external files.

FUTURE IMPROVEMENTS

Aside from on-going maintenance the cryogenics instrumentation data is currently stable.

New Client Requirements

With the upgrade of the UNICOS programming environment to version 6 in 2012, the format of the specifications files will be modified [5]. Currently, the same specification files are used to generate both the Operator's SCADA (based on UNICOS) and the Experts SCADA (CIET), but in the future two separate sets of specification files will be required. This will not imply a change in the data or the underlying database structure, but new database views corresponding to the new file formats will need to be developed. In addition, the generated files should be in xml format which implies a change to the template integrated in the new generator program.

Remodelling of the Layout Database

During 2011 the Layout database will undergo a significant restructuration. However, the specifications views should remain largely unaffected because they extract the majority of their data from an all-inclusive summary view. This complex view will have to be completely rebuilt in order to retrieve the instrumentation data from the new database structures in a way that is transparent for the specifications views.

Improved Access and Availability

A major new initiative planned for 2012 is the development of a read/write interface for the Layout Database. It will combine the browsing functionality of the current Layout web interface with writing capabilities which will allow the equipment owners to introduce modifications, making them fully responsible for their own data. Procedures for maintaining data quality will be established and integrated into the tools.

CONCLUSIONS

We have achieved our primary goal of making databases the only data source required for generating the specifications for the cryogenic control system.

Throughout this project we have strived for an excellent standard of data quality, as it is a fundamental requirement for achieving a fully data-driven system.

By decommissioning the previous Specifications Generator, the databases have become critically important. Therefore, the structure and the data must be meticulously maintained in order to ensure the reliable operation of the LHC cryogenics system.

INTEGRATING THE EPICS IOC LOG INTO THE CSS MESSAGE LOG*

K.U. Kasemir, E. Danilova, ORNL, Oak Ridge, TN 37831, U.S.A.

Abstract

The Experimental Physics and Industrial Control System (EPICS) includes the "IOCLogServer", a tool that logs error messages from front-end computers (Input/Output Controllers, IOCs) into a set of text files. Control System Studio (CSS) includes a distributed message logging system with relational database persistence and various log analysis tools. We implemented a log server that forwards IOC messages to the CSS log database, allowing several ways of monitoring and analyzing the IOC error messages.

EPICS IOC LOG

The Experimental Physics and Industrial Control System (EPICS) front-end computers, commonly referred to as Input/Output Controllers (IOCs), supports a simple TCP-based logging system. IOCs connect to the "IOCLogServer", by default on TCP port 6500, and send basic text messages. A new line character terminates each text message. The IOCLogServer annotates each message with the current time/date and the IP address of the IOC, and then writes them to a rotating set of text files [1].

This logging mechanism has proven to be very robust, but it lacks tools to analyze the log messages. Use of the IOC log at the Spallation Neutron Source (SNS) was limited to a post-mortem search for clues in case of IOC problems, based on UNIX command-line text tools like "grep" or directly reading the log files in a text editor.

CSS LOG

CSS applications utilize a Java Message Server (JMS) to issue log messages [2]. The same mechanism is also used for network traffic between components of the CSS alarm system [3]. All CSS JMS messages can be routed to a relational database (RDB) for later analysis.

Fundamentally, each JMS message can consist of arbitrary property/value pairs, but the following standard properties should be included to allow analysis of messages from different sources:

- TYPE: A value of 'log' indicates a log message.
- DATUM: Date and time of the message.
- TEXT: For log messages, this is the actual message text.
- SEVERITY: An indicator for the message severity, for example "INFO"
- HOST: The name or IP address of the computer that sent the message.
- USER: Name of the user who submitted the message.
- APPLICATION-ID: Name of the application that submitted the message.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy

Fig. 1 shows the generic CSS Message Log Viewer that can display selected properties of messages that have been logged to the RDB. This viewer also allows filtering, for example to restrict the display to messages of a certain TYPE, messages that originate from a specific HOST, or messages with TEXT that contains a certain word. This viewer allows interactive review of messages.

Since the messages are stored in a relational database, the information is accessible to a wide variety of tools. It is for example relatively easy to create reports that a re targeted to the analysis of a specific problem, as we will describe in the section called JSP Message Reports.

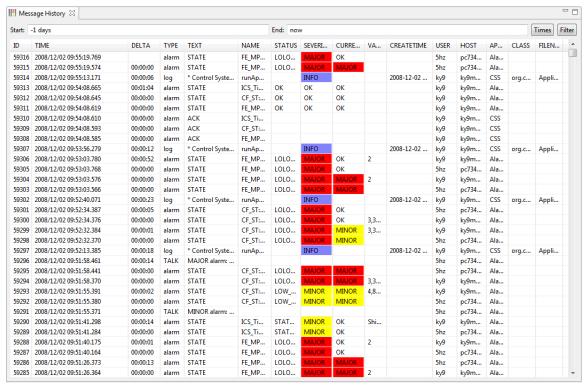

Figure 1: CSS Message History Browser.

IOC LOG SERVER REPLACEMENT

To benefit from the existing infrastructure for CSS message logging, we implemented a new IOC Log Server in Java that operates similar to the original EPICS IOCLogServer. It also listens on TCP port 6500 for text messages, but each received line of text is written to the CSS message RDB with the following properties:

- TYPE: A value 'iocLog' identifies IOC messages.
- CREATETIME: Data and time when message was received.
- TEXT: Original message text.
- HOST: IP address of the network client, i.e. the IOC.
- SEVERITY: Defaults to "INFO"
- APPLICATION-ID: "IOCLogServer"

To EPICS IOCs, the replacement of the original log server for text files with the new implementation is transparent. We simply start either the old or the new log server, and IOCs will use the current instance as soon as they attempt to log a message.

Filtering

We noticed early on that the IOC log messages were dominated by repeated messages. Certain IOCs would

often send the exact same message every few seconds. To reduce the amount of space used by such messages in the RDB, we added a simple filter:

If the same network client (i.e. IOC) sends the same message text, this is not logged as a separate message. Instead, a repeat count is updated in the REPEATED property of the original message.

The filtering is based on the last message received from each network client, only comparing a new message with the last message from that client. If a client keeps sending a message with text "A", this will be filtered by the repeat count mechanism. If a client should repeat two messages in a pattern "A", "B", "A", "B", …, this will not be filtered out. While we do observe this pattern, it has at this time not been frequent enough to warrant checking all recent messages of a client for repetitions.

In addition to filtering repeated messages, there is a pattern-based filter. Based on regular expressions for the message content, it can be configured to ignore messages that match a pattern. This can for example be used to suppress known benign status messages that we prefer to exclude from the log.

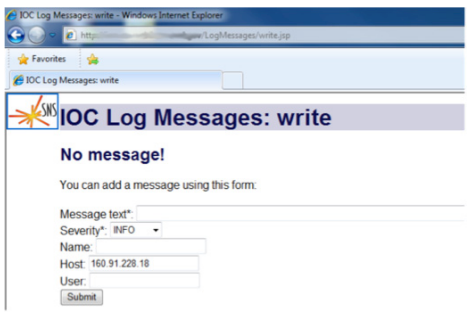

Figure 2: Web form for submitting a message.

JSP LOG WRITER

The IOC Log Server replacement is convenient for EPICS IOCs, but less accessible to control system front-end computers that are implemented by other means.

By wrapping the essential Java code for logging messages to the RDB as a Java Server page (JSP) for Tomcat [4], we created a web service that can for example be used by programs implemented in National Instruments LabVIEW to submit log messages.

The web service is accessible via a URL similar to the following for submission of a basic text message:

http://server/LogMessages/write.jsp?TEXT=…

If desired, additional URL parameters like SEVERITY or USER can be provided to set the associated message properties.

If no message parameters are included in the URL, a web form as shown in Fig. 2 is presented to allow interactive entry of the message content.

JSP MESSAGE REPORTS

With all IOC log messages available in the relational database, we are now able to create various online reports. Fig. 3 shows a Java Server Page (JSP) that summarizes recent IOC log messages.

A pie chart depicts the "Top 10" IOCs that produced the highest number of messages in the analyzed time period, which defaults to the last hour. Tables list repeated messages as well as all messages of the time period. Both tables contain the message text but also time, severity, host, number of repeats, and optional user name. By default, the tables are sorted by the time when each message was created, but users can sort the tables by any column by clicking on the table column header.

A web form allows users to configure the time range, provide pattern for the IOC name, and choose the number of messages to display.

A detailed list of messages for a particular IOC is accessible by either clicking on the associated sector on the pie chart sector (if this IOC is one of top 10 message producers), or by selecting the IOC name from drop-down lists of IOCs that are sorted by name as well as message count.

These JSP reports are available to any computer with a web browser at our site.

SUMMARY

Without any change to EPICS IOCs, we were able to transparently route IOC log messages from the original file-based system to the CSS message log that is stored in a relational database. Web reports show for example which IOC produced the most messages in the last few days.

In the past, our IOC log files were only consulted "after the fact" when an IOC had run into severe problems. Now we are able to spot an increase in message traffic, hopefully anticipating a more severe error.

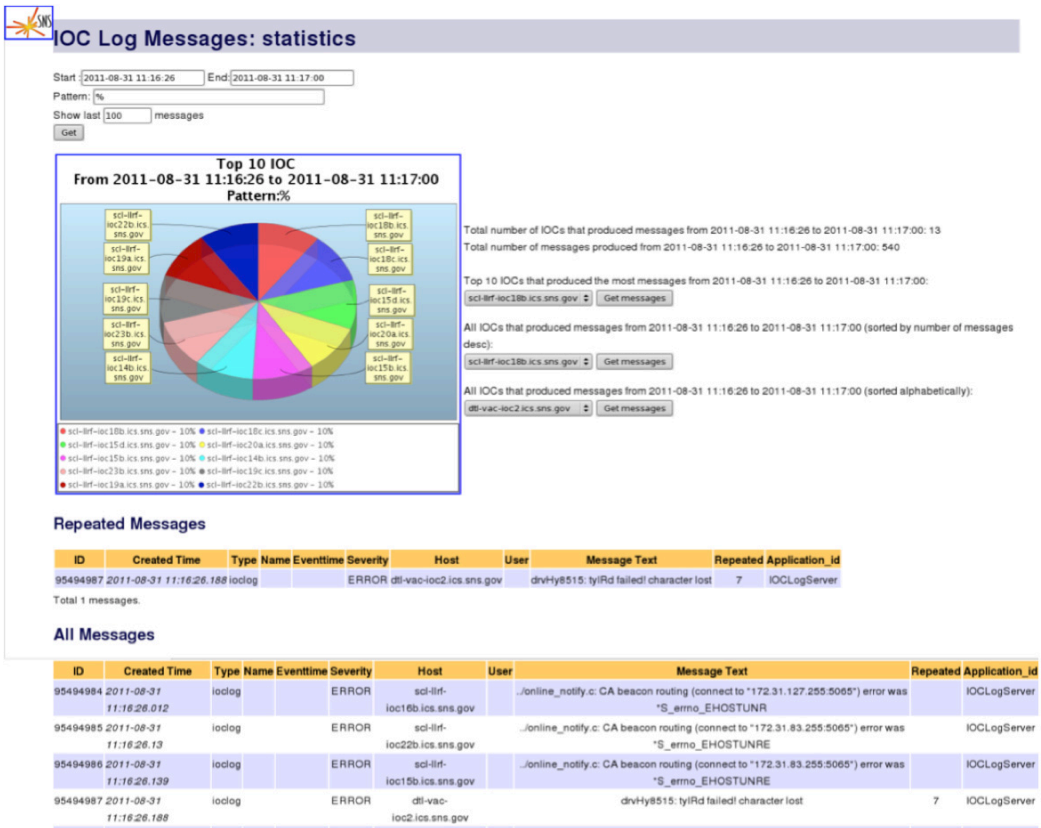

Figure 3: JSP Report of IOC Log Message statistics.

BDNLS - BESSY DEVICE NAME LOCATION SERVICE

D. Engel, P. Laux, R. Müller, HZB, Berlin, Germany

Abstract

Initially the relational database (RDB) for control system configuration at BESSY has been built around the device concept [1]. Maintenance and consistency issues as well as complexity of scripts generating the configuration data, triggered the development of a novel, generic RDB structure based on hierarchies of named nodes with attribute/value pairs [2]. Unfortunately, it turned out that usability of this generic RDB structure for a comprehensive configuration management relies on sophisticated data maintenance tools. On this background BDNLS, a new database management tool, is currently under development using the framework of the Eclipse Rich Client Platform. It uses the Model View Controller (MVC) layer of JFace to cleanly separate retrieval processes, data path, data visualization and actualization. It is based on extensible configurations defined in XML allowing to chain SQL calls and compose profiles for various cases. It solves the problem of data key forwarding to the subsequent SQL statement. BDNLS has the potential to map various levels of complexity into the XML configurations. This provides usable, tailored database access to configuration maintainers for different underlying database structures. Based on Eclipse, the integration of BDNLS into Control System Studio [3] is straight forward.

HISTORY OF CONCEPT

Views – The First Approach

Database-views are predefined SQL-queries. They are like macros with precached results. Views are ideal for frequently used large and complex queries typically used in small database-applications. A big drawback of views is, that they are not always able to update their data sources. Views are able to hide the complexity of data structures, but you have to create one view for one specific problem. If you need to create views for all aspects of a facility, then you need hundreds of them. Complexity of data structures is pseudo-simplified in a confusing amount of views.

Generalization of the Data Structure

The obvious idea to maintain full flexibility, was to separate the data sets to the maximum, like atomic elements. For that purpose, the whole data set, for example device properties or I/O specifics, has to be to modeled in data and relations. The data is not grouped by table structures or specific column names. Only links and relations connect the data. This is a clean method to retain the data and avoid redundancy. This data structure has been called Gadgets [4]. This solution has the drawback, that you manage a very complex structure of stored data. Visualizing and managing the data is problematic because it is abstract and queries on this structure are very complex. It is not a general solution for storing data.

The Experiences from a Prototype

The first graphical application was implemented using Eclipse as a Rich Client Platform (RCP) application. RCP provides many solutions of graphical interfaces and a plugin concept to assemble numerous small plugins to a full-featured application. The application was designed as well as a standalone Rich Client Application and as plugin for other Rich Client Applications like the Control System Studio (CSS) [3] Framework. The application is able to provide the location of a device and to view their properties as requested. This solution used static SQL-queries and a special view that provided all information for a complete navigation tree, broken into columns. Updates of the data is only possible with hard coded update-dialogs. Another drawback of this approach was, that data could only be updated using the dialogs provided.

The Generalized Approach

The first graphical approach revealed with following shortcomings:

- Search, read, change and insert elements in the database without knowledge of SQL by the user.
- Importing and exporting huge data sets.
- The profile contains the navigation chain to a target element, the element properties, the wizards[1] and the popup-menus available for this target.
- The profiles should be able to change during operation.
- The complexity of data structures and SQL-queries is extracted from the source code and encapsulated to a configuration file. The source code is generic.
- The application should be independent of the given data structure. You can design your own SQL-queries in the configuration file.
- With the use of Java, a platform independent application is provided.
- The application uses existing databases and no hard coded data structures. It is also not designed to follow all data relations given by data keys hence it is no competitor of IRMIS [5].

[1] A Wizard is a user interface of dialogs to help the user to manage complex inputs

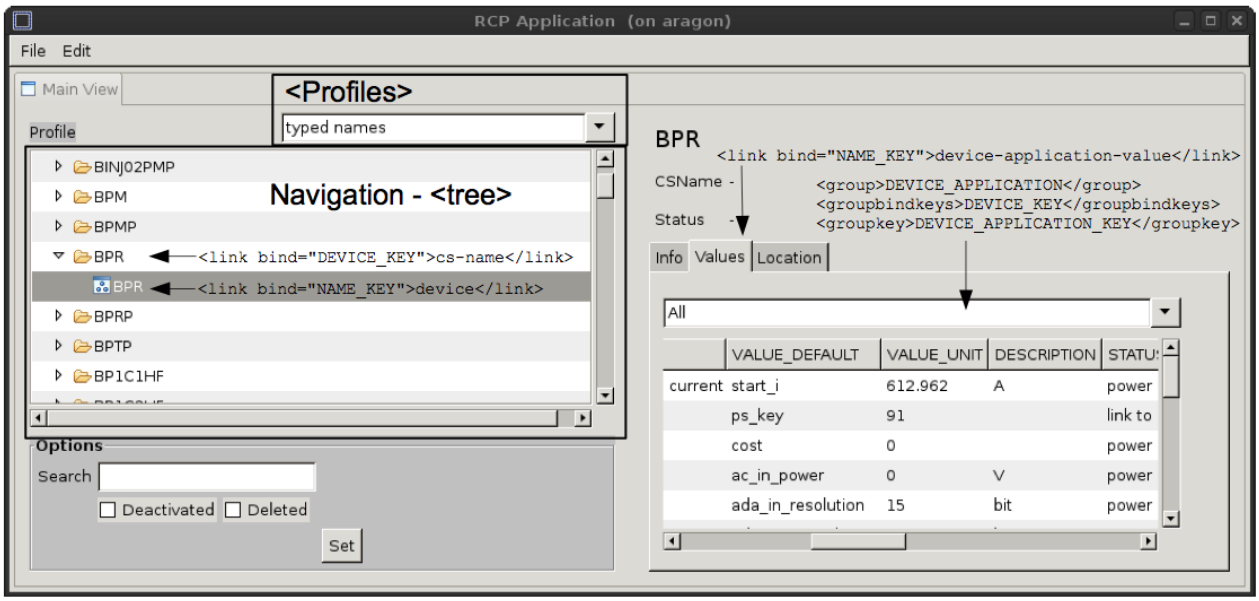

Figure 1: BDNLS prototype application; Profile selector (top), tree navigation (left), view section (right), the query section not visible.

XML CONFIGURATION CONCEPT

The whole configuration of the BDNLS-application is defined in an XML-file. The configuration file contains:

- How to access the database (URL, user name and the password).
- Definition of various profiles allowing several SQL-query sequences and different views.
- The displayed element and the data key provided by the SQL-Query.
- The definition of the navigation tree (-by profile-) and the data keys required for next tree element.
- The provided properties of a selected device, arrangement, grouping and visualization settings.
- The popup-menus and wizards provided for a device.

Profiles

A profile defines the navigation to a device and its specific properties. profile names are declared in the `<profile>`-part. The default profile used when the application starts.

```
<profiles default="1">
   <profile>located names</profile>
   <profile>typed names</profile>
   <profile>typed devices</profile>
   <profile>by facility and family</profile>
</profiles>
```

Navigation

The navigation section is divided in to different profiles. Every profile consists of the parts `<tree>` (shown as a tree elements) and `<tab>` (shown as tab elements). The tree-part is used to display and to navigate through device classes, domains, families and facilities. `<link>`-parts are called sequentially when expanding a tree element. `<link bind="xxx">` is used to narrow the results at the next hierarchy, using the keys from the last results. Clicking at the last element in the tree-part, initiates processing of the tab-part.

```
<navigation>
<profile name="located names">
   <tree>
      <link>facility</link>
      <link bind="FACILITY_KEY">cs-domain</link>
      <link bind="NAME_DOMAIN_KEY">cs-subdomain</link>
      <link bind="NAME_SUBDOMAIN_KEY">cs-name</link>
    </tree>
    <tab>
       <link bind="NAME_KEY">device-info</link>
       <link bind="NAME_KEY">device-location</link>
       <link bind="NAME_KEY">device--value</link>
    </tab>
</profile>
</navigation>
```

Query Section

The query section describes the name of the query, the corresponding statement `<statement>`, the provided key names `<key>` of the query and the column name to be shown as the element name`<label>`. The provided keys are stored and can be used to narrow the results of the next query. A statement may yield zero, one or many keys, they are separated by a comma.

```
<link name="cs-subdomain">
    <statement>NAME_SUBDOMAIN_DROPDOWN</statement>
    <key>NAME_SUBDOMAIN_KEY</key>
    <label>NAME</label>
</link>
```

View Section

Currently, the view section is only used for the properties of a device. The view part defines the name of

a tab <title>, whatether it shown as a form or a list <showtype> and which type of context menus the elements provides <showmenu>. Additionally, the output can be filtered by a group query. To group/filter the device properties, you have to define a group statement <group> and a grouping/filter key that is used to restrict the results of the device properties. To restrict the group statement itself, you can restrict the statement with another key provided by the device properties.<groupbindkeys> The tag <showmenu> links to the required popup-menus.

```
<view>
<tab name="device-value">
    <title>Values</title>
    <group>DEVICE_APPLICATION</group>
    <groupbindkeys>DEVICE_KEY</groupbindkeys>
    <groupkey>DEVICE_APPLICATION_KEY</groupkey>
    <showtype>List</showtype>
    <showmenu>device-value</showmenu>
</tab>
</view>
```

Popup and Wizard Block

Manipulation of the data, is enabled by an update or input wizard defined within the popup tag <popup>. The key expected by the wizard is defined with the tag <column>.

```
<popup name="device-value">
    <item name="create">
       <wizard>wizard-device-value</wizard>
       <column>device_key</column>
    </item>
    <item name="edit">
       <editor>editor-device-value</editor>
       <column>device_value_key</column>
    </item>
    <item name="remember">
       <history>history-device-value</history>
       <column>device_value_key</column>
    </item>
</popup>
```

IMPLEMENTATION

The Eclipse Rich Client Platform was chosen for implementation. By using and providing plugin extension points, it is possible to use other Eclipse based or third party plugins to extend the application. To connect to the database, a JDBC interface is used. The connection class can load many kinds of JDBC bridges dynamically, like PostgreSQL, MySQL, Oracle and many more. But at the moment only a Oracle OJDBC bridge is integrated in this project. The GUI of the first implementation of this project is shown in Figure 1.

CSS Integration

Adding the plugin-activator class allows to integrate this application as a plugin in CSS. Hence it is possible to exchange EPICS [6] process variables (PV) with CSS, to retrieve archived data, or to get all device information depending on a PV.

FUTURE DEVELOPMENT

- Implementation of drag & drop methods to improve the data exchange with CSS, other windows/forms and applications.
- Integration of visualization function, for example to show the location of a device.
- Integration of EPICS-PVs for fast visualization of the device state.
- Abstraction of the wizards to be fully configurable and provide plugin extension points for custom forms and visualization classes.
- Methods providing import and export formats for CSV, XML and XLS.

DESIGN AND IMPLEMENTATION OF THE CEBAF ELEMENT DATABASE *

T. Larrieu, M. Joyce, C. Slominski, JLAB, Newport News, VA 23606, U.S.A.

Abstract

With the inauguration of the CEBAF Element Database (CED) in Fall 2010, Jefferson Lab computer scientists have taken a step toward the eventual goal of a model-driven accelerator. Once fully populated, the database will be the primary repository of information used for everything from generating lattice decks to booting control computers to building controls screens.

A requirement influencing the CED design is that it provide access to not only present, but also future and past configurations of the accelerator. To accomplish this, an introspective database schema was designed that allows new elements, types, and properties to be defined on-the-fly with no changes to table structure. Used in conjunction with Oracle Workspace Manager, it allows users to query data from any time in the database history with the same tools used to query the present configuration. Users can also check-out workspaces to use as staging areas for upcoming machine configurations.

All Access to the CED is through a well-documented Application Programming Interface (API) that is translated automatically from original C++ source code into native libraries for scripting languages such as perl, php, and TCL making access to the CED easy and ubiquitous.

BACKGROUND

Previous efforts to compile a comprehensive configuration database for the Jefferson Lab CEBAF accelerator and use it to automate the setup or restoration of the electron beam have foundered on the complexity of accommodating the constantly evolving hardware installed in the accelerator and the multiplicity of elements whose properties vary with the increasing energy of each pass through the recirculating LINACS. The progress of the 12GeV upgrade project has, however focused renewed emphasis upon solving these problems by developing a central authoritative configuration database available to existing or future tools needed to operate the revamped accelerator. The resulting product has been coined the CEBAF Element Database (CED).

DATABASE DESIGN

Design

The CED has been implemented using a modified Entity-Attribute-Value with Classes and Relationships (EAV/CR) data model [1]. This design choice is appropriate because the types of information to be stored in the CED will vary from system to system. The database will necessarily evolve over time to support additional configuration attributes for existing systems as well as to model the yet-unknown parameters of the new hardware to be installed for the 12GeV upgrade.

In a traditional database schema, adding support for new accelerator hardware would involve adding additional tables and columns to the database. Such changes impose a burden by requiring software updates before the new schema can be used. In contrast, the EAV/CR data model employed by the CED is introspective – defining a new class of accelerator hardware in the CED simply involves adding rows to the already-existing metadata "catalog" tables (fig. 1). Once defined in the catalog, existing software is fully capable of interacting with the new entities after discovering their properties from the metadata tables.

Versioning

In addition to its flexibility in accommodating future data requirements, the CED schema was also designed to make use of the Oracle Workspace Manager toolkit [2]. Oracle Workspace Manager is used to version-enable the table rows in the CED, and permit simultaneous access to present, proposed, and historical versions of data.

Oracle Workspace Manager accomplishes this feat for a table by renaming it to *table name*_LT, adding a few columns to the table to store versioning metadata, creating a view on the version-enabled table using the original table name and defining INSTEAD OF triggers on the view for SQL DML operations. Clients of the CED do not need to incorporate any special logic in order to interoperate with the different versions stored in the database other than to specify which save point or workspace they wish to access.

Workspaces

A key version-enabling feature of the Oracle Workspace Manager is the ability to compartmentalize a collection of database changes into a logical construct called a workspace.

The primary workspaces is by definition the LIVE workspace and represents the current configuration of the CEBAF accelerator. Additional workspaces may be "checked out" from LIVE and used to stage upcoming configurations or to perform what-if scenarios (fig. 2). The contents of these workspaces can be merged (committed) into LIVE when appropriate.

*Notice: Authored by Jefferson Science Associates, LLC under U.S. DOE Contract No. DE-AC05-06OR23177. The U.S. Government retains a non-exclusive, paid-up, irrevocable, world-wide license to publish or reproduce this manuscript for U.S. Government purposes.

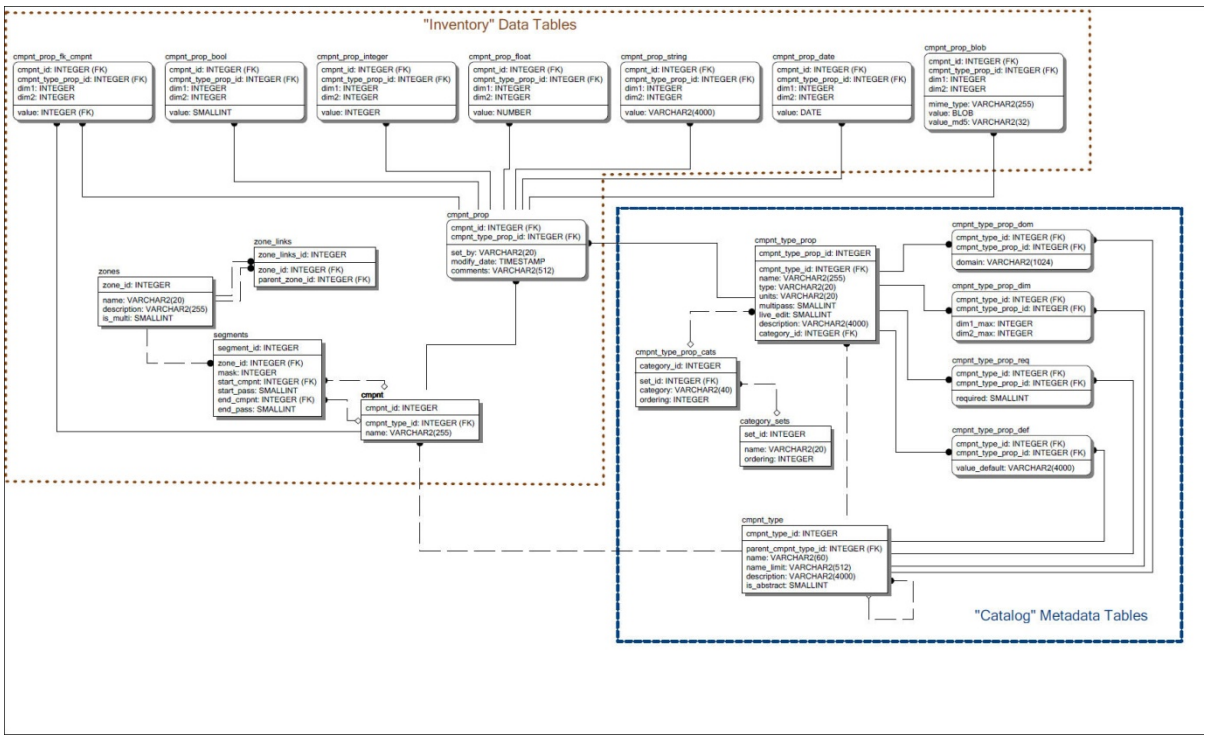

Figure 1: The core CED schema illustrating the "Catalog" tables that store the metadata defining accelerator elements. Element values stored in the "Inventory" tables as strings, floats, integers, etc. are mapped via the metadata into meaningful attributes. New types of elements may be added to the CED on-the-fly by defining their metadata – changes to the database schema are not required.

Save points

Because the Oracle Workspace Manager saves a history of all changes to a row in addition to information about its workspace membership, it is possible to query historical data simply by specifying the date and time as of which the query is being issued. To assist users, so that they don't have to specify exact dates and times, the CED provides named save points for the LIVE workspace corresponding to key configuration milestones such as the beginning or end of an experimental run or of an accelerator maintenance period (fig. 2).

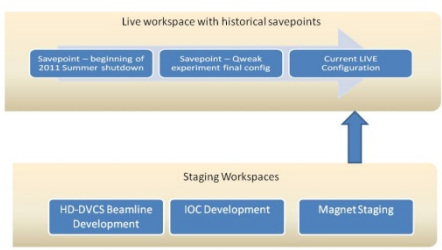

Figure 2: CED Workspaces showing historical save points and staging workspaces used to prepare upcoming changes to LIVE.

In contrast to the typical approach to preserving data history using triggers and a history table containing prior values, where accessing the history requires special one-off queries or custom reports, accessing CED historical data requires no different software and no more effort than accessing the current configuration.

Configuration Control

Workspaces are also used in the CED to effect a level of configuration control. With the exception of a very few properties explicitly identified as live-editable, the CED does not permit users to update data in the LIVE workspace. All updates to the CED must be performed in a staging workspace and audited for validity before being committed to LIVE.

INTERFACE

The generalized nature of the EAV/CR data model employed by CED requires a robust API to interpret the contents of the metadata tables and translate the abstract database storage into recognizable attributes useful to programs and users. The API is also responsible for enforcing much of the data validation and domain logic embodied in the metadata catalog.

For the CED, a shared library was written in C++ to be the sole interlocutor for applications that will access its information. Native versions of the API are available not only to C++ programs, but also to scripts written in Perl, PHP, and Tcl. The script language versions are generated

automatically from the original library via the open source SWIG (Simplified Wrapper and Interface Generator) tool [3,4]. Having the API natively available makes it easier to update the many tools used by JLAB operators that have been written in these scripting languages over the years, as well as to develop new ones. Because they stem from the same source library, all the languages have the same functionality available and benefit from the development effort that went into testing and documenting the original compiled library.

On top of the core API, two general purpose user interfaces to the CED have also been built around the C++ library and its scripting language derivatives: a RESTful web interface and a full-featured command-line tool usable from JLAB Linux workstations.

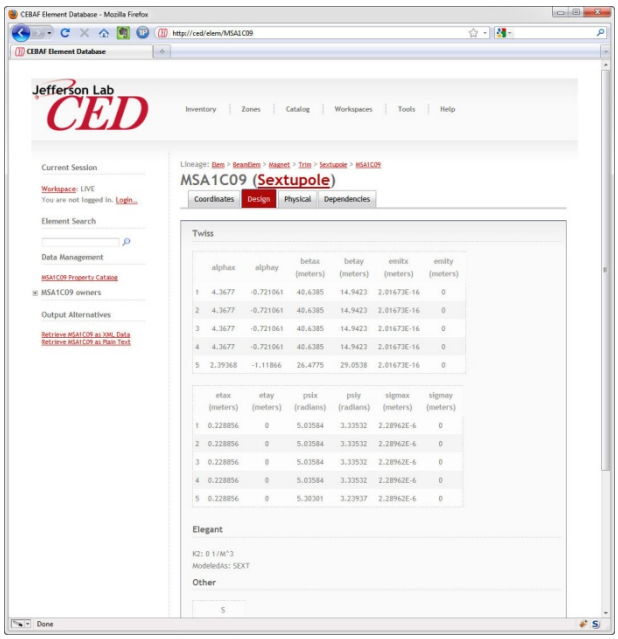

Figure 3: CED Web Interface provides access to CED data in HTML (shown), XML, or plain text format via simple to construct URL patterns.

IMPLEMENTATION

The CED was rolled out to the JLAB community in September 2010 initially populated with data for the Magnet and Input Output Controller (IOC) systems. Data for the RF and BPM systems were added soon thereafter.

In May 2011, CEBAF entered a six months duration shutdown period during which time more than the 200 large dipole magnets were removed from the accelerator to be measured and calibrated. The CED is being used to capture and disseminate key information generated during that process, such as new field maps for the magnets, locations where shims have been installed. During the same time period, software developers and operators updated many high-level applications (such as the Interactive Elegant Explorer shown in figure 4) and control system screens to utilize the CED for their configuration when operations resume.

The focus of the CED implementation will now shift to refining the tools and processes (automated where possible) that will keep the information up-to-date and accurate. In the case of the IOC information, for example, this will include building the DHCP server configuration files directly from the CED information as well as a program that crawls and inspects the IOCs periodically to verify their configuration against the database.

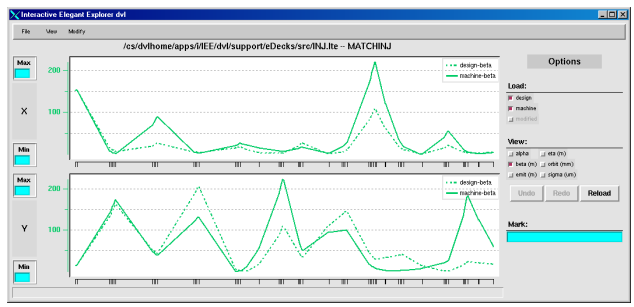

Figure 4: The Interactive Elegant Explorer now uses the CED to create a focusing lattice from a CEBAF configuration for the purpose of modeling accelerator beam transport.

DIAMOND LIGHT SOURCE BOOSTER FAST ORBIT FEEDBACK SYSTEM

S. Gayadeen, S.R. Duncan, University of Oxford, Oxfordshire, UK,
C. Christou, M.T. Heron, J. Rowland, Diamond Light Source, Oxfordshire,UK

Abstract

The Fast Orbit Feedback system that has been installed on the Diamond Light Source Storage ring has been replicated on the Booster synchrotron in order to provide a test bed for the development of the Storage Ring controller design. To realise this the Booster is operated in DC mode. The electron beam is regulated in two planes using the Fast Orbit Feedback system, which takes the beam position from 22 beam position monitors for each plane, and calculates offsets to 44 corrector power supplies at a sample rate of 10 kHz. This paper describes the design and realization of the controller for the Booster Fast Orbit Feedback, presents results from the implementation and considers future development.

INTRODUCTION

The Diamond Storage Ring Fast Orbit Feedback (FOFB) system currently meets its requirements in terms of beam stability at Diamond. However new requirements for improved beam stability, from users or as a consequence of operating with reduced electron beam height or a need to suppress new beam disturbances in the future, will require improvements to the FOFB performance. As part of the development of the Storage Ring controller optimisation, closed loop beam control has been applied on the Booster synchrotron by running the Booster as an electron storage ring at 100 MeV. The Booster has the same hardware as the Storage Ring for beam position detection and control of the corrector magnets, so the same FOFB control system can be used.

CONTROLLER DESIGN

Let $\mathbf{P}(z^{-1})$ denote the discrete-time transfer function between $\mathbf{u}[k] \in \mathbb{R}^N$, the inputs to the $N = 22$ actuators applied at time $\{t = kT\}$, where T is the sample time, and $\mathbf{y}[k] \in \mathbb{R}^M$, the signals measured at the $M = 22$ sensors at each sample time, such that

$$\mathbf{y}[k] = \mathbf{P}(z^{-1})\mathbf{u}[k] \tag{1}$$

where $\mathbf{P}(z^{-1})$ takes the form

$$\mathbf{P}(z^{-1}) = p(z^{-1})\mathbf{B} \tag{2}$$

with $\mathbf{B} \in \mathbb{R}^{M\times N}$ being the steady state (dc) response of the actuators and $p(z^{-1})$ the scalar dynamics, which are taken to be the same for each actuator. The dynamics are modeled as a first order response plus delay that is operated in "sample and hold" mode, then

$$p(z^{-1}) = z^{-d}\frac{b_0 + b_1 z^{-1}}{1 - a_1 z^{-1}} \tag{3}$$

where d is the smallest integer satisfying $dT > \tau_d$ and

$$\begin{aligned} a_1 &= e^{-aT} \\ b_0 &= 1 - e^{a(T-\tau')} \\ b_1 &= e^{a(T-\tau')} - e^{-aT} \end{aligned} \tag{4}$$

when τ_d is the delay in the system, a is the bandwidth of the actuator response (in rad.s^{-1}) and

$$\tau' = \tau_d - (d-1)T. \tag{5}$$

Table 1: Values of Parameters Used in Design

Parameter	Value
a	$2\pi\times1000$ rad.s^{-1}
τ_d	700 μs
T	100 μs

The parameters associated with this application are listed in Table so that the transfer function for the dynamic response becomes

$$p(z^{-1}) = z^{-7}\frac{0.47z^{-1}}{1 - 0.53z^{-1}}. \tag{6}$$

For $M \leq N$, the singular value decomposition of $\mathbf{B}$ takes the form

$$\mathbf{B} = \mathbf{U}\,[\Sigma\ \ 0]\,\mathbf{V}^T \tag{7}$$

where $\mathbf{U} \in \mathbb{R}^{M\times M}$ and $\mathbf{V} \in \mathbb{R}^{N\times N}$ are respectively, the left and right singular vectors and $\Sigma \in \mathbb{R}^{M\times M}$ is a diagonal matrix containing the singular values, $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_M$. By partitioning $\mathbf{V}$ as

$$\mathbf{V} = [\mathbf{V}_1\ \mathbf{V}_2] \tag{8}$$

where $\mathbf{V}_1 \in \mathbb{R}^{N\times M}$ and $\mathbf{V}_2 \in \mathbb{R}^{N\times(N-M)}$, so that $\mathbf{B} = \mathbf{U}\Sigma\mathbf{V}_1^T$, then Eq. (1) can be written as

$$\mathbf{U}^T\mathbf{y}[k] = p(z^{-1})\Sigma{\mathbf{V}_1}^T\mathbf{u}[k]. \tag{9}$$

Defining $\bar{\mathbf{y}}[k] = \mathbf{U}^T\mathbf{y}[k]$ and $\bar{\mathbf{u}}[k] = \mathbf{V}_1^T\mathbf{u}[k]$, projects the response into "modal space", so that

$$\bar{y}_n[k] = p(z^{-1})\bar{u}_n[k] \tag{10}$$

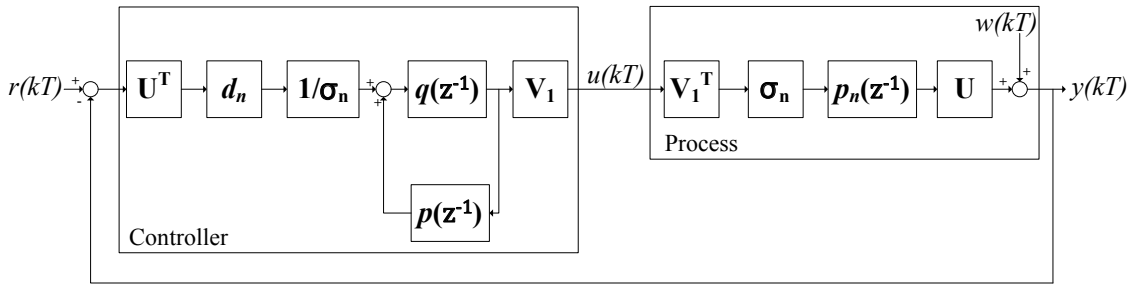

Figure 1: Structure of IMC controller.

where $\bar{y}_n[k]$ and $\bar{u}_n[k]$ are the n^{th} elements of $\bar{\mathbf{y}}[k]$ and $\bar{\mathbf{u}}[k]$. The controller structure is shown in Fig. 1 where an Internal Model Controller (IMC) [1] is applied to each mode where $q(z^{-1})$, the pseudo plant inverse dynamics is given by

$$q(z^{-1}) = \frac{(1-\lambda)}{b_o + b_1}\frac{1 - a_1 z^{-1}}{1 - \lambda z^{-1}} \tag{11}$$

and $\lambda = e^{-\zeta T}$ where ζ is the closed loop bandwidth (in rad.s^{-1}) of the controller. In [2, 3] it is proposed that the controller should take the form

$$\mathbf{C}(z^{-1}) = c(z^{-1})\mathbf{C} \tag{12}$$

where $\mathbf{C} \in \mathbb{R}^{N\times M}$ is

$$\mathbf{C} = \mathbf{V_1}\mathbf{D}\Sigma^{-1}\mathbf{U}^T \tag{13}$$

where

$$\begin{aligned}\mathbf{D} &= \text{diag}\{d_n\}\\ \Sigma &= \text{diag}\{\sigma_n\}\end{aligned} \tag{14}$$

with

$$d_n = \frac{\sigma_n^2}{\sigma_n^2 + \mu} \tag{15}$$

From Fig. 1 the controller dynamics for each mode are

$$\begin{aligned}c(z^{-1}) &= \frac{q(z^{-1})}{1 - p(z^{-1})q(z^{-1})}\\ &= \frac{(1-\lambda)}{b_0 + b_1}\frac{1 - a_1 z^{-1}}{1 - \lambda z^{-1} - z^{-d}(1-\lambda)\beta(z^{-1})}\end{aligned} \tag{16}$$

with

$$\beta(z^{-1}) = \beta_0 + \beta_1 z^{-1} = \frac{b_0 + b_1 z^{-1}}{(b_0 + b_1)}. \tag{17}$$

The same controller dynamics are applied to each spatial mode, with the dynamics being detuned by the controller gains d_n. Because $\beta_0 + \beta_1 = 1$, the controller takes the form of a Dahlin controller [4] and as a result, includes integral action.

CONTROLLER IMPLEMENTATION

Electron BPMs are used to provide information about the electron beam position at a sampling rate of 10 kHz. The Booster has 22 cells arranged as 4 sectors each of which has a computation node which receives all sensor positions but only calculates the local corrector magnet error using a block of the inverse response matrix. To achieve the required 10 kHz update rate, a custom communication controller implemented in VHDL is used to transmit the horizontal and vertical data from the 22 BPMs to each of the 4 computation nodes. Each computation node receives data from all BPMs and uses a dedicated VME processor card to calculate the vector product of the BPM values and the sub pseudo-inverse response matrix. The controller dynamics are then implemented as an eighth order IIR filter on these values. The result then corresponds to the new values for the local corrector magnets for that sector [5].

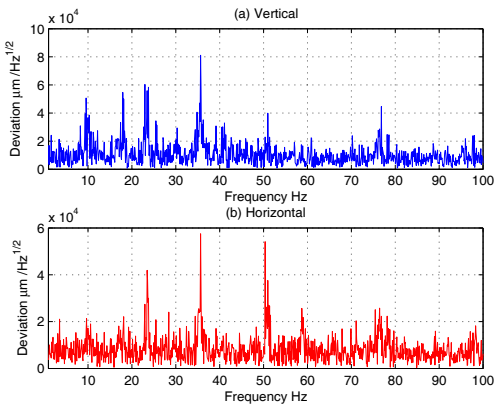

Figure 2: Magnitude of frequency response of 10s of variation observed at the 1st vertical BPM plotted against frequency in Hz.

CONTROLLER PERFORMANCE

The frequency content of the disturbance at one BPM on the Booster is shown in Fig. 2, which plots the discrete Fourier transform of the signal against frequency. It can be seen that there is a significant component in the range 10 Hz to 50 Hz with a major peak at 35 Hz. Fig 3(a) shows a colourmap of the average power (in dB) at each frequency in mode space and it can be seen that the bulk of the power is concentrated in the lower order modes (i.e. for n <10).

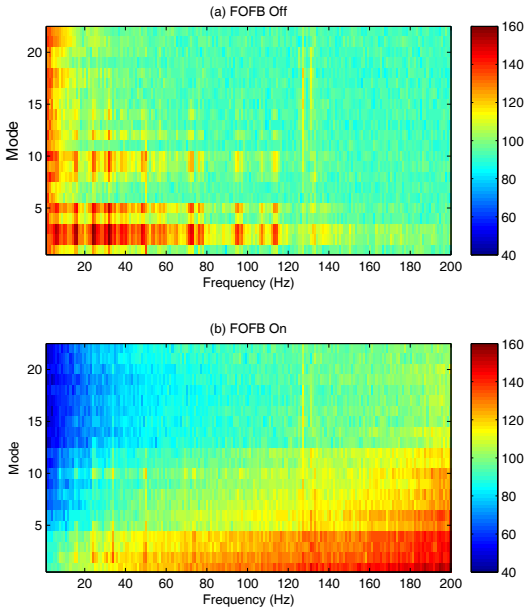

Figure 3: Colourmap of average power (in dB) in mode space against frequency (in Hz) in the vertical plane with (a) FOFB off and (b) FOFB on.

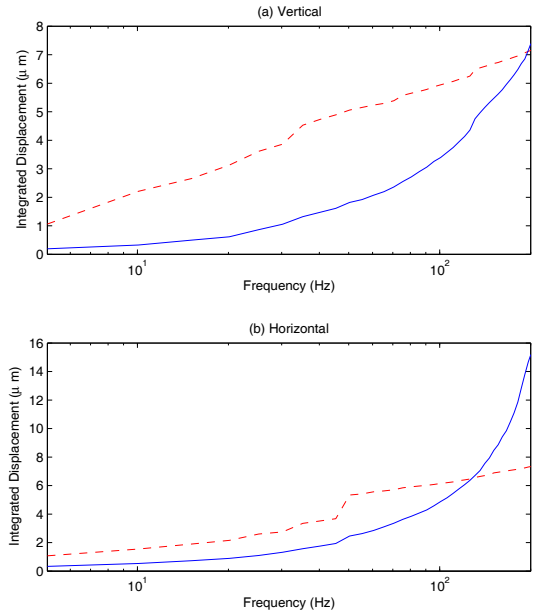

Figure 4: Integrated beam motion for controlled (solid blue line) and uncontrolled (dashed red line) beam up to 200 Hz.

There is also some variation at low frequencies (<1 Hz) in all modes.

The aim of the control system is to reduce the effect of the disturbances on the beam, particularly for the low order modes in the frequency range 10 Hz to 50 Hz, while at the same time attenuating low frequency disturbances in all modes. Figure 3(b) shows the power spectrum with FOFB on and by comparison with Fig. 3(a), it can be seen that the attenuation is focused on the low frequencies for all modes (i.e. the dark blue regions). The controlled and uncontrolled integrated beam motion for both planes, shown in Fig. 4, illustrates that the FOFB suppresses beam motion in the low frequencies where the disturbances are concentrated. However the FOFB system does not suppress disturbances as well at frequencies above to 200 Hz in both planes.

TWO DIMENSIONAL LOOP SHAPING

When a disturbance $\mathbf{w}[k]$ is included in the output $\mathbf{y}[k]$, then by defining $\overline{\mathbf{w}}[k] = \mathbf{U}_1^T \mathbf{w}[k]$, for each mode, $s_n(z^{-1})$, the transfer function from $\overline{\mathbf{w}}[k]$ to the output, $\overline{\mathbf{y}}[k]$ i.e. the sensitivity function is

$$s_n(z^{-1}) = \frac{1 - \lambda z^{-1} - z^{-d}(1-\lambda)(\beta_0 + \beta_1 z^{-1})}{1 - \lambda z^{-1} - z^{-d}(1-d_n)(1-\lambda)(\beta_0 + \beta_1 z^{-1})}$$

which can be used to analyse the behaviour of the closed loop system in Fig. 1. Figure 5 shows the Booster sensitivity both spatial and temporal dimensions $S(n, e^{-j2\pi\omega})$. The plane in Fig. 5 shows where $|S(n, e^{-j2\pi\omega})| = 0.7071$ i.e. the crossover frequency in both dimensions.

The bandwidth in the two-dimensional frequency domain can be similarly defined as traditionally done in the temporal frequency domain so that the closed loop bandwidth $\mathbf{B}_w(n,\omega)$ is defined as the contour in (n,ω) such that $|S(n, e^{j2\pi\omega})| = \frac{1}{\sqrt{2}}$ for all (n,ω) enclosed by $\mathbf{B}_w(n,\omega)$ [6]. The two-dimensional bandwidth frequency bandwidth contour is shown in Fig. 6 which also shows the effect of changing the regularisation parameter, μ and the closed-loop bandwidth, ζ. Figure 6(a) illustrates that increasing μ, focuses control effort on the lower order modes and decreasing μ, extends control to the higher order modes. It can also be seen that although μ has a significant impact on the spatial bandwidth, in this case it has no effect on the temporal component of the two-dimensional bandwidth $\mathbf{B}_w(n,\omega)$. Figure 6(b) illustrates that decreasing ζ, reduces the bandwidth to attenuate disturbances and has a negligible effect on the spatial component of the bandwidth $\mathbf{B}_w(n,\omega)$. From Fig. 6(b) it can be said that decreasing ζ has the effect of depressing the peak of the sensitivity function while reducing its temporal bandwidth.

The expected value of total power in the output is

$$E\|\mathbf{y}[k]\|_2^2 = \frac{1}{K}\sum_{k=0}^{K-1}\|\mathbf{y}[k]\|_2^2 \qquad (18)$$

In [2], it is shown that the expected total power can be written as

$$E\|\bar{\mathbf{y}}[k]\|_2^2 = \frac{1}{K^2}\sum_{p=0}^{K-1}\sum_{n=1}^{N}|S_n[p]|^2|\bar{W}_n[p]|^2 \qquad (19)$$

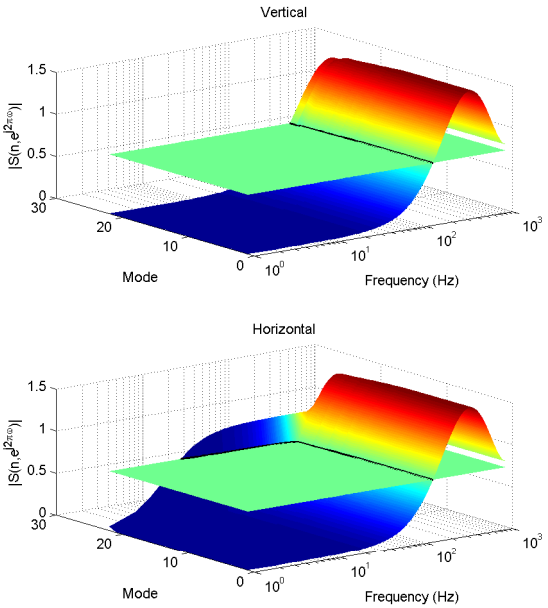

Figure 5: Magnitude of sensitivity ($|S(n, e^{i2\pi\omega})|$)for each mode against frequency (in Hz). The plane for $|S(n, e^{j2\pi\omega})| = 0.7071$ and the two-dimensional bandwidth contour (black line) are shown.

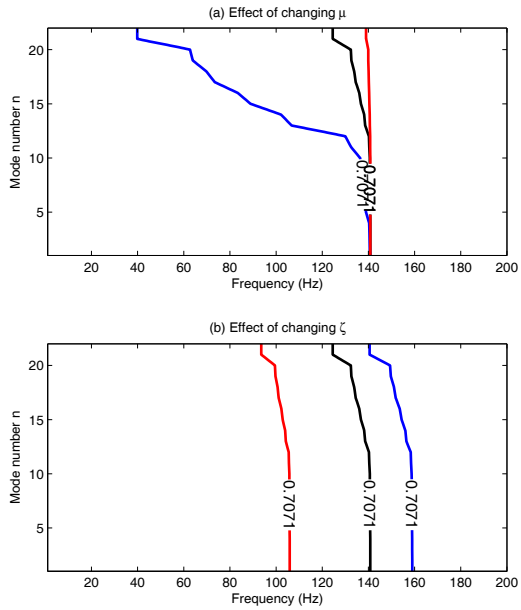

Figure 6: Two-dimensional bandwidth for (a) μ =0.1 (red), μ =1 (black) and μ =20 (blue) (b) ζ =303 Hz (red), ζ =227 Hz (black) and ζ =129 Hz (blue).

where $S_n[p]$ is the frequency response of $s_n(z^{-1})$. Eq. (19) implies that given $\bar{W}_n[p]$, the frequency spectrum of each mode of the underlying disturbance, $S_n[p]$ (and hence $s_n(z^{-1})$) can be designed on a "mode-by-mode" basis in order to achieve a specification on the expected total power observed across all sensors.

CONCLUSIONS & FUTURE WORK

FOFB control has been implemented on the Booster synchrotron at Diamond. The controller has been tuned conservatively and initial results show that the controller attenuates disturbances below 100 Hz on all modes.

The loop shaping technique developed by [6] shows that by extending traditional loop shaping techniques for dynamical systems into the two dimensional frequency domain, a framework to analyse the properties of the sensitivity function in the two-dimensional frequency domain analysis can be constructed. The sensitivity function properties in both temporal and spatial modes are used to define a two-dimensional bandwidth.

It was illustrated that tuning the temporal and spatial components of the sensitivity can be decoupled by using the dynamic closed loop bandwidth, ζ for shaping the temporal frequency response and the regularisation parameter, μ for the spatial frequency response. By considering the residual power in the output, it was demonstrated that given the frequency spectrum of each mode of the underlying disturbance, the sensitivity function can be designed on a mode-by-mode basis in order to achieve a specification on the expected average power across all sensors.

Abstract

A high resolution system designed for easy and inexpensive profile of an incident beam on a charged target, in the ion implanter installed at the Ion Beam Laboratory of the Technological Nuclear Institute (ITN) in Lisbon, Portugal, is described. This system intended to be used offline and not during the implantation, is made of a circular aluminium disc with a curved slit which extends approximately from the centre of the disc to its periphery. The disc is attached to the ion implanter target, which is capable of rotating on its axis. A cooper wire, positioned behind the slit, intersects the beam and the electric current generated, proportional to the beam intensity, is measured. As the ion implanter is capable of scanning the beam over the target, the combination of vertical beam scanning with aluminium disc rotation allows the beam profile to be measured continuously in two dimensions.

This paper describes the system developed including the computer controlled positioning of the beam over the moving curved slit, the data acquisition, the beam profile representation, and shows experimental results obtained with an Argon beam.

INTRODUTION

Traditional beam profile monitors use a matrix of detectors like Faraday Cups. The objective of this work is to develop a high resolution system for measuring the profile of an ion beam in an ion implanter. Two systems are in general use to monitor the beam profile, wire scanners and scintillation screens [1-3]. Both systems have proven their functionality and are chosen depending on the needs of the particular application. Their basic principles are well known and can be found in [4]. A third technique also used is residual gas monitors with segmented residual gas ion detecting plates, that is based on a similar principle as wire scanners regarding the reconstruction of the profile from the measured data.

Another technique is scintillation screens, which operates very fast and at very high resolution in position. They offer a convenient way to image the beam profile. Being their functionality based on (iono) luminescence [5], the most sensitive screens are made crystals like SiO_2. Using this option, the changes on the ion beam parameters influences the relative intensity of the intrinsic and activated luminescence [5]. Since the light yield also decreases with operational time, this method does not provide absolute values for the beam current. Also the lifetime of these kinds of detectors is strongly limited at higher beam powers. In such cases tantalum foils are used to illustrate the beam profile.

Absorbing the beam power a profile-dependent heat-induced glow is visible. To minimize the structure-smoothening and image-broadening heat flux inside the foil, the foils are chosen to be very thin. Nevertheless, their resolution is distinctly lower than that of crystal based scintillators. More examples for this detection system can be found in [1-2].

Wire scanners offer a quasi-non-destructive way to measure the profile in absolute current values. Their resolution and measuring speed generally behave antiproportional and depend on the number of wires used for detection and the analyzing electronics. A reliable determination of the beam profile can only be achieved if the ion distribution in the beam is Gaussian-like or at least single-peaked with only moderate asymmetry.

Problems occur if one unknowingly samples a hollow beam or a beam with more than one maximum in the current distribution. Additional details about this detection system can be found in [3, 6].

The presented system scans the beam on the target, using an off line beam profile scheme.

SYSTEM DESCRIPTION

As part of the deceleration system developed for the ion implanter, a beam profile monitor system was build to measure the shape of the beam over the target and set the optimal parameters for the deceleration lens taking into account the desired target bias.

The system developed, shown in Figure 1a, is composed by an insulated metallic disc of 25 cm diameter, which will be used as target, and a copper wire.

The target disc is mechanically attached to the implanter target, so it has the same rotating movement. On this target disc, a 3 mm wide and 10 cm long slit gap with a curved shape was made. A 3 mm wide and 10 cm long copper wire is placed behind the gap. This wire is fixed to the chamber structure and is connected to a microammeter, as shown in Figure 1b.

jgabriel@deea.isel.ipl.pt

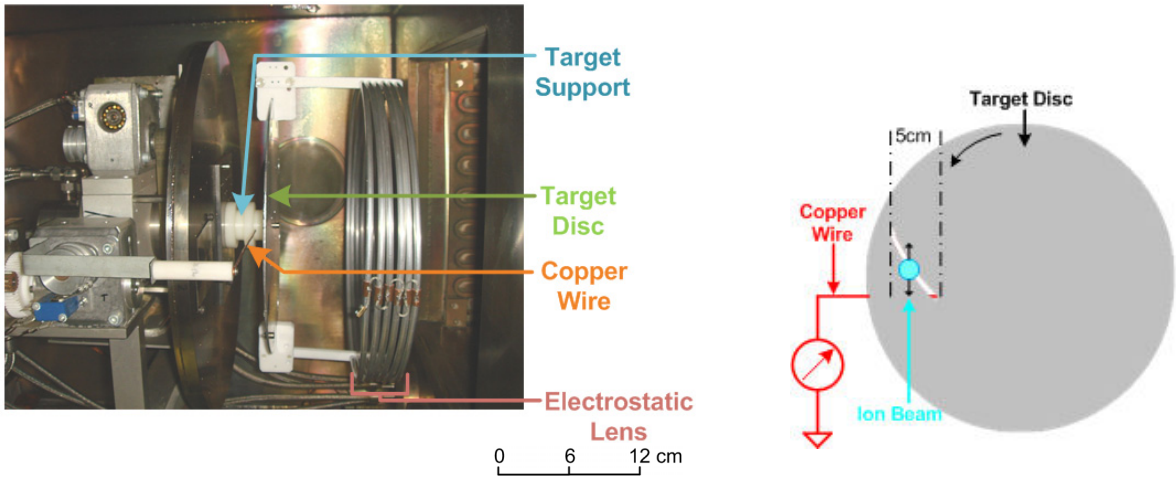

Figure 1: a) Mechanical system implemented; b) Schematic system implemented.

According to Figure 2, when the beam hits the target disc, a small part of it hits the wire and creates an electron current which is measured.

Due to the slit gap shape and the fact that the wire is fixed, when the target disc rotates, the beam strikes different parts of the wire in a way that it scans the beam in an area of 3x3 mm^2, corresponding to the slit gap x wire width, over a 5 cm distance, as shown in Figure 1b.

With the wire fixed on the horizontal, a focused beam can be scanned by rotating the target with the slit gap crossing the beam. If the beam current measured on the wire is collected one gets a beam profile section in *x*. By scanning the beam in y using the implanter beam scanning systems one gets x and y profile of the beam.

The reason to use the beam scan in y and not in x is that the drift of the beam due to the target bias changes with the distance to the edge of the target, but has no significant change if that distance is maintained.

In order to obtain an ion beam profile, two signals are required, one proportional to the beam width (x-axes) and another proportional to the beam current (y-axes).The beam current can be defined as

$$I_{Beam} = \frac{V_A}{47M\Omega} \quad (1)$$

Therefore, an optic-fiber based circuit was developed to send the beam current signal to the ground potential.

Whereas, on the resistance of 47 MΩ, the DC voltage proportional to the beam current is converted through a voltage-to-frequency (V/F), in a number of voltage pulses with a frequency proportional to its amplitude.

This signal is applied to an infrared LED connected to one side of an optic fiber. On the other side, placed at ground potential, a photo-transistor converts the light pulses to a number of voltage pulses with the original frequency. This signal is fed to a frequency-to-voltage (F/V) which is then digitized and goes to the personal computer (PC) as shown in Figure 2.

Figure 2 also shows the two high voltage (20 kV) power supplies used. One bias the lens (V_L) and the other bias the target (V_A). The resistances of 100 MΩ and 25 MΩ will allow a better stabilization of the voltage, avoiding any voltage fluctuations, while resistance of 47 MΩ is intended to measure the beam current.

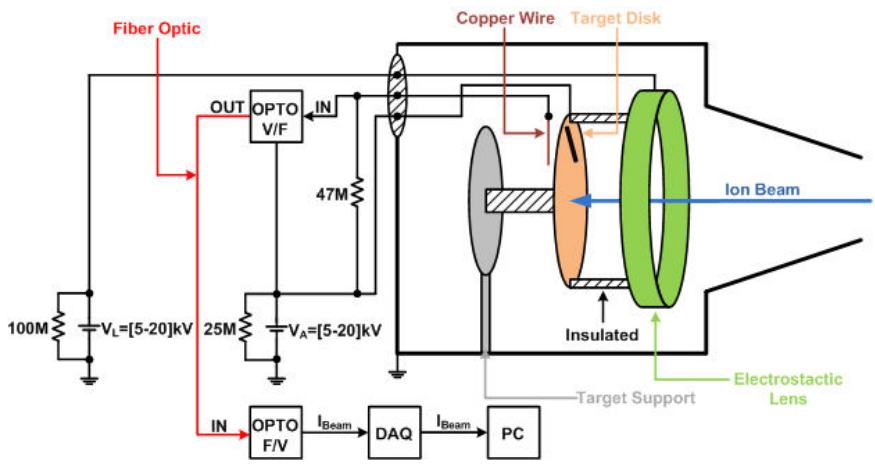

Figure 2: System developed.

A LabVIEW application was developed which controls the target position, gathers the digitized signals and determined the beam profile.

EXPERIMENTAL RESULTS

The system uses a personal computer equipped with a multifunction input/output board from National Instruments; model USB-6251. The program that was chosen for this work was National Instruments LabVIEW, a graphical programming language specially created for instrumentation and measurement, some custom made electronic interface modules and a LabVIEW application. Been integrated in a major project of the automation of the ion implanter, this is a part of the system that is considered as one of the most significant and that brings a great development and enhance to the ion implanter.

The ion beam profile measurement system developed makes integrant part of the optimization to the ion implantation, which also contemplates the deceleration of the ion beam to low energies. Checking the beam profile is important to guarantee that the implantations are successful even at low energies. In particular, as a result, it was possible to determine that the electrostatic deceleration developed for this accelerator is able to reduce the beam energy while maintaining the beam focused.

The experimental results presented in this work correspond to an ion implantation of Argon, with a beam current of 100 μA, initial energy of 15 keV.

The area of scan (x and y) is 5x7 cm^2, and the scan x corresponds to the rotational steps of the target. We made four experimental test: (1) with the target at 10 kV and the electrostatic lens with 0 kV (Figure 3a); (2) with the target with 10 kV and the electrostatic lens with 12 kV (Figure 3b), (3) with the target at 14 kV and the electrostatic lens with 0 kV (Figure 3c); (4) with the target at 14 kV and the electrostatic lens with 16 kV (Figure 3d). For the first and second test, the electrostatic lens is not charged, which means that ion beam is more scattered and less homogeneous. In the third and fourth test it is possible to see that the ion beam is more focused on the target. These two examples (Figures 3c and 3d), shows that the use of an electrostatic lens in this system gives an ion beam more focus and uniform.

In Figure 3d is possible to verify with more precision the effect of the electrostatic lens in the low energies (1 keV). In this case, the introduction of an electrostatic lens allows to obtain an ion beam more focused for low energies. When the electrostatic lens is not used, the ion beam is too disperse, which means that is not possible to proceed with the implantation for low energies (Figure 3c). Hence, the beam focus is directly related to the deceleration process, in order to obtain the desired final energy. This means that the bigger the deceleration level the more important is the beam focus.

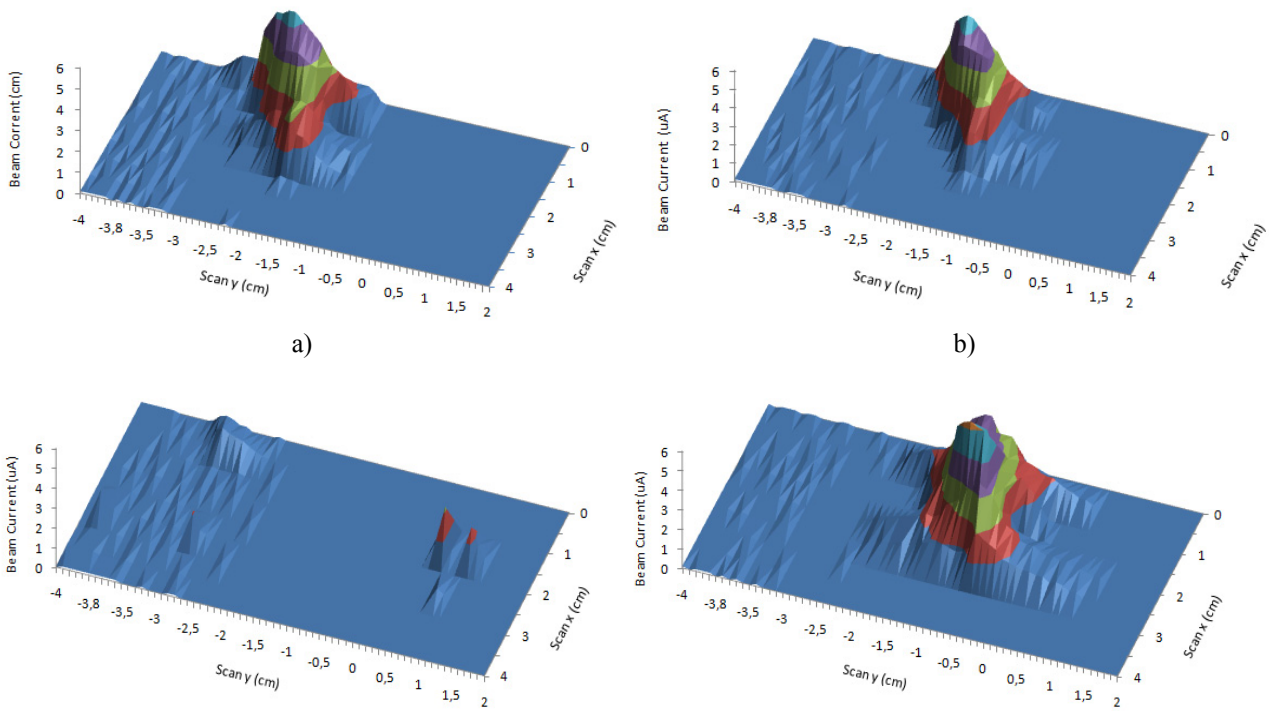

Figure 3: Beam profile for: a) E=5 keV (Target=10 kV, Lens=0 kV); b) E=5 keV (Target=10 kV, Lens=12 kV); c) E=1 keV (Target=14 kV, Lens=0 kV); d) E=1 keV (Target=14kV, Lens=16 kV).

CONCLUSION

In this paper a high resolution system designed for measuring the ion beam profile in the ion implanter installed at the Ion Beam Laboratory of the Technological Nuclear Institute (ITN) was described. The low cost and simplicity is the Figure of merit of this system.

With the system developed it is possible to measure the beam profile and to compare the differences between ion implantation based on energy and beam focus.

Detectors were used in order to be able to visualize the beam profile, in the systems there was presented. This allows obtaining tridimensional pictures of the ion beam with ion currents in the range of μA, and energies from 10 keV up to a few hundreds keV. Comparing this system with others two major differences come up, the current range and the type of implantation.

In addition is possible to obtain data for deceleration, in the future, the system will allow to test new configurations for beam focus at lower energy.

NSLS-II BEAM DIAGNOSTICS CONTROL SYSTEM*

Yong Hu#, Leo Bob Dalesio, Om Singh, Huijuan Xu, Kiman Ha, BNL, NSLS-II, NY 11973, U.S.A.

Abstract

A correct measurement of NSLS-II beam parameters (beam position, beam size, circulating current, beam emittance, etc.) depends on the effective combinations of beam monitors, control and data acquisition system and high level physics applications. This paper will present EPICS-based control system for NSLS-II diagnostics and give detailed descriptions of diagnostics controls interfaces including classifications of diagnostics, proposed electronics and EPICS IOC platforms, and interfaces to other subsystems. Device counts in diagnostics subsystems will also be briefly described.

INTRODUCTION

The NSLS-II beam diagnostics and control system is designed to monitor the electron beam of NSLS-II accelerator complex [1]. The beam quality is measured by a variety of parameters such as bunch charge, bunch structure (filling pattern), beam position/orbit, beam size/profile, energy & energy spread, circulating beam current, tunes, beam emittance, bunch length and beam losses. Figure 1 briefly shows the beam parameters to be measured from Linac to Storage Ring.

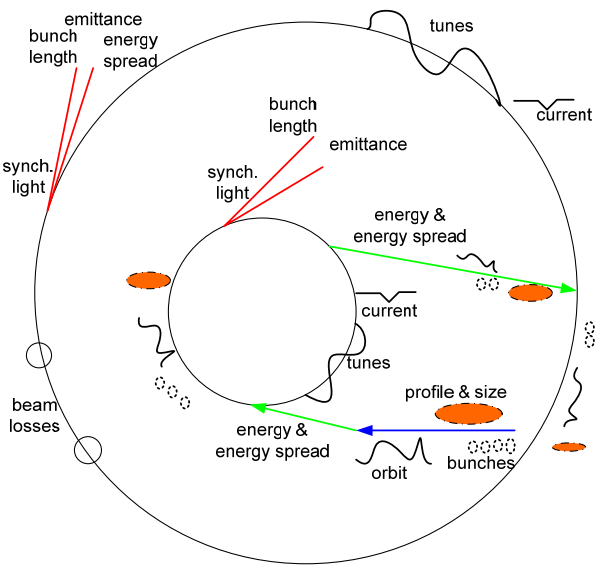

Figure 1: Beam Parameters to be measured at NSLS-II.

A correct measurement of beam parameters depends on the effective combinations of a variety of beam monitors, control and data acquisitions (DAQ) and high level physics applications. Thus, an effective collaboration between Diagnostics Group, Controls Group and Physics Group is essential. The NSLS-II Diagnostics & Instrumentation Group is in charge of the definition of beam diagnostics specifications and the design of beam monitor systems, including the layout of these monitors around the machine. The Physics Group is responsible for submitting the physics requirements for diagnostics and control, system modelling, algorithm, etc.

The scope of Controls Group on beam diagnostics system includes the following: requirement analysis and specifications for the beam diagnostics controls; Make vs. buy analysis and decision of electronics for various beam monitors; Development of EPICS [2] drivers for the diagnostic monitors and system tests on the software and hardware; Design of interfaces between diagnostics controls and other subsystems (timing, machine protection system, etc) and system integration of them.

DEVICE COUNTS IN DIAGNOSTICS

Table 1: Device Counts in NSLS-II Diagnostics

	Linac	Ltb	Booster	BtS	SR
WCM	5				
Screen/Flag	6	9	6	9	3
BPM	5	6	37	7	240
Bergoz FCT		2	1	2	
Bergoz ICT		2		2	
Energy Slit		1		1	
Faraday Cup	1	2		1	
Bergoz DCCT			1		1
Streak Camera					1
Visible Light Monitor			1		1
Pinhole system					2
Tune Monitor			1		1
Transverse Feedback System					1
Beam Loss Monitor					5
Beam Scrapers					5
Photon/x-ray BPM					2 per front-end

NSLS-II accelerators consist of one injector and one storage ring (SR). According to the functionality as well as geographical distribution, the injector is divided into 4 subsystems: Linac, Linac to Booster (LtB) transfer line (including 2 beam dumps), Booster, Booster to Storage ring (BtS) transfer line (including 1 beam dump). Table 1 gives a summary of the diagnostic monitors distributed over the whole machine. Although Linac and Booster are turnkey solutions provided by vendors, BNL will specify

* Work performed under auspices of the U.S. Department of Energy
# yhu@bnl.gov

the requirements for diagnostics and controls and vendors implement them. For better standardization and maintenance, the same type of diagnostics (e.g. CCD cameras) used in different accelerator subsystems will be provided by the same manufacture (e.g. GE1290 by Prosilica) so that they almost have the same control interfaces and requirements.

CONTROLS INTERFACES FOR DIAGNOSTICS

Diagnostics controls are actually more about data acquisition (DAQ) than device control. Diagnostics control subsystem will conform to NSLS-II control system standards. It will be EPICS-based and the preferable operating systems for IOCs are RTEMS (Real-Time Executive for Multiprocessor Systems) and Linux/Debian. For VME-based controls, the CPU board will be standardized as Motorola MVME3100.

Whenever possible, diagnostics controls pursue the utilization of commercial off-the-shelf hardware to reduce cost as well to achieve better reliability. Although NSLS-II Linac and Booter are turn-key solutions provided by vendors, it's better to standardize the diagnostics controls for the whole machine. The following section describes the classified method for controls standardization.

Classifications of Control Interfaces

From point view of controls, the beam monitors output signals/interfaces can be classified into the following several groups.

1) Analog output with high-bandwidth (>500MHz): WCM, FCT, etc. [3];
2) Analog output with low-bandwidth (<10KHz): DCCT, ICT&BCM;
3) Simultaneous 4-channle RF signals: BPM;
4) Gigabit-Ethernet camera interface: pinhole camera, flag/CCD, streak camera etc.
5) Stepper motor driven: linear stage in pinhole system, energy slit, beam scraper, etc.
6) Ethernet-based instrument: Windows XP-based network/spectrum analyzer for tune monitor and beam stability monitor;

There are other miscellaneous I/Os for diagnostics: binary input/output including TTL I/O for DCCT range settings, pneumatic actuator with limit switch in flag, limit switch in stepper-based stage, 24 V binary outputs for XIA filter inserter in pinhole system, 12-bit DAC for illuminator control in pinhole and flag system, temperature sensors for diagnostics beamline mirror, etc.

Here are some considerations and principles about the selection of electronics for the above groups of beam monitors:

1) WCM and FCT are used to measure individual bunch charge. The time interval between adjacent bunches is 2 ns so that the digitizer for WCM & FCT should have at least 500MHz bandwidth and 1GS/s sampling rate. Since NSLS-II physics requirement for filling pattern accuracy is 1% of maximal bunch charge, 8-bit resolution digitizer should be fine;
2) The output of DCCT and BCM/ICT is nearly DC voltage so that the requirement of sampling rate for digitizer is not demanding. For Booster DCCT and transfer-lines ICT, the digitizer with 16-bit resolution and 20KS/s would be suitable. For Storage Ring DCCT digitizing, the resolution requirement is determined by beam lifetime calculation considered 20mA in 60 hours with 1% accuracy. This translates to 18-bit ADC resolution;
3) For 4-button-pickup RF BPM, in-house BPM receiver will be utilized;
4) For camera controls, NSLS-II diagnostics will be standardized as Gigabit-Ethernet interface (Prosilica Gig-E CCD camera) for high bandwidth, easy cabling, good anti-EMI, etc.;
5) For stepper-motor based diagnostics, the controls will be integrated into NSLS-II motion control subsystem;
6) For Windows-based network/spectrum analyzer, it's possible to make an EPICS IOC run inside the instrument.

Controls and Data Acquisitions for Diagnostics

Each type of beam monitor requires electronics (device controller) to process its output signal. The electronics for the above groups and associated EPICS IOC platform are listed in Table 2. Figure 2 shows the controls interfaces for these various beam monitors.

Table 2: Diagnostics Electronics and IOC Platform

Beam Monitor	Diagnostics Electronics	IOC platform
WCM & FCT & FC	Acqiris DC252 (2GHz bw, 10-bit, 4~8GS/s)	cPCI/Linux
DCCT & ICT	1)GE ICS-710-A (24-bit, 200KS/s, 8-ch) 2)Allen-Bradley PLC (DAC, Digital I/O)	cPCI/Linux
BPM	In-house BPM receiver [4]	PC/Linux
Prosilica GigE Camera	PC/Linux	PC/Linux
Stepper-motor-based	Delta Tau GeoBrick LV PC	PC/Linux
Instrument controls	Windows-based network/spectrum analyzer	PC/Linux
Misc: digital I/O, DAC, temperature sensor	Allen-Bradley PLC	PC/Linux

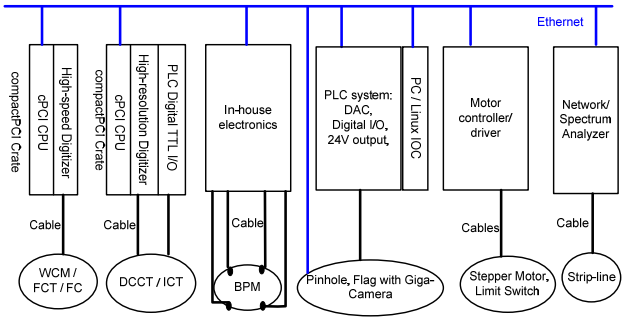

Figure 2: Diagnostics Controls Interfaces.

INTERFACES TO OTHER SUBSYSTEMS

Interfaces to Timing System

To capture the electron beam signal at the right time, the beam monitors should be sampled and synchronized to the passage of the beam. This function can be achieved by using Event Timing System to deliver delayed-trigger or clock signal to the diagnostics electronics.

The interfaces between diagnostics controls and timing system are shown in Figure 3. Some diagnostics controls, such as stepper motor, limit switch and DAC, don't need timing while other diagnostics electronics require trigger signals from Event Timing System [5] (EVR). Additionally, the reference for BPM receiver Machine Clock should be provided at the Booster/Storage Ring revolution frequency. For transverse bunch-by-bunch feedback system and streak camera system, trigger/clock signals are the only control signals.

For diagnostics timing requirements, 8ns resolution and 100ps jitter should be sufficient. Diagnostics controls require precisely time delayed trigger at injection rate (10Hz for Linac, 1Hz for Booster) to capture the beam at the right time. The delayed time for each diagnostics depends on the location of beam monitor, the cable length from monitor to its electronics and the distribution of event timing.

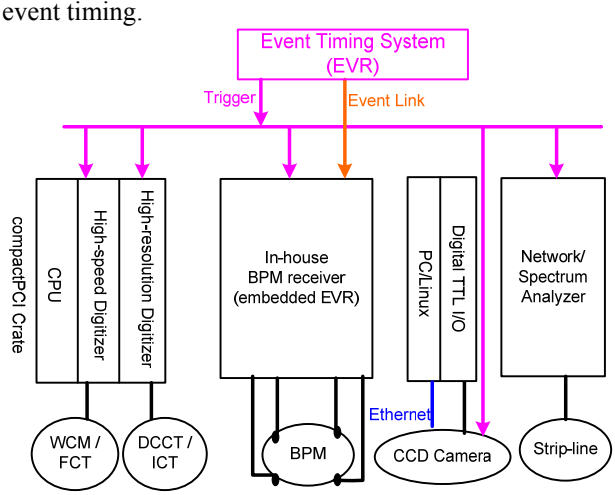

Figure 3: Diagnostics Interface to Timing System.

Interfaces to Machine Protection System

The diagnostics controls should send hardwired interlock signals, to machine protection system (MPS) if any specific parameter, such as beam positions, beam loss rate, beam current, is out of range.

The design of the interfaces between diagnostics controls and MPS are still in progress. Fig. 4 shows the draft diagram of the system.

The followings are some cases that diagnostics interlock protection should take action:

1) BPM position data are out of pre-defined position range;
2) For top off operation, the stored beam current must exceed 50mA;
3) Excessive beam loss is detected by LCM system;

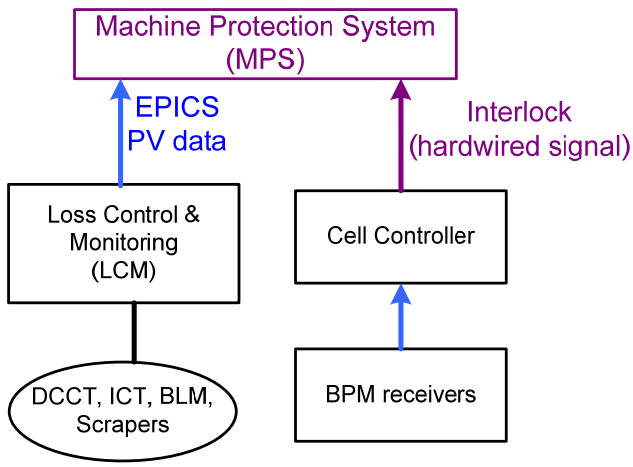

Figure 4: Interface to Machine Protection System.

CONCLUSIONS

NSLS-II beam diagnostics control system is completely EPICS-based. Utilization of commercial off-the-shelf hardware as well as in-house BPM electronics development is deployed to meet NSLS-II project requirements and schedule. All diagnostics controls hardware and software are well tested and ready for NSLS-II Injector installation and commissioning.

APPLICATION OF INTEGRAL-SEPARATED PID ALGORITHM IN ORBIT FEEDBACK *

K. Xuan#, X. Bao, C. Li, W. Li, G. Liu, J. Wang, L. Wang,
NSRL, USTC, Hefei, Anhui 230029, China.

Abstract

The algorithm in the feedback system has important influence on the performance of the beam orbit. PID（Proportion Integration Differentiation） algorithm is widely used in the beam orbit feedback system; however, the deficiency of PID algorithm is a big overshooting in strong perturbations. In order to overcome the deficiencies, the integral-separated PID algorithm is developed. When the closed orbit distortion is too large, it cancels integration action until the closed orbit distortion is lower than the separation threshold value. The implementation of integral-separated PID algorithm with MATLAB is described in this paper. The simulation results show that this algorithm can improve the control precision.

INTRODUCTION

The orbit feedback system can effectively eliminate the closed orbit distortion; a good feedback system can improve remarkably the beam orbit stability. PID algorithm is widely used in the orbit feedback system. In the standard PID feedback, the aim of introduction of the integral action is to eliminate steady-state error and improve control accuracy, but the integral action of PID algorithm will cause big overshooting in strong perturbations. In order to improve the orbit stability, an integral-separated PID algorithm is employed for the orbit feedback control. The basic idea of the integral-separated PID controller is that integral action will be cancelled when there is a big error. The integral action will work when the output value is close to the given value, which will eliminate steady-state error and improve control accuracy.

FEEDBACK THEORY

The beam orbit distortion caused by the change of storage ring state would destroy the stability of the beam orbit. There are many methods to correct the beam closed orbit distortion, but the basic idea of these methods is to eliminate the orbit distortion by using corrector magnet. In order to eliminate the beam orbit distortion, the corrector magnet intensity changes $d\Theta$ should be[1]:

$$d\Theta = R^{-1}dU \qquad (1)$$

where dU is the beam orbit distortion, R^{-1} is inverse response matrix, SVD（Singular Value Decomposition） method can be used to solve R^{-1}.

In order to correct the orbit distortion and improve orbit stability, the integral-separated PID control algorithm will be used. The control algorithm can be expressed as[2]:

$$u(n) = u(n-1) + K_p\left[e(n) + \alpha\frac{T}{T_I}\sum_{j=0}^{n}e(j) + T_D\frac{e(n)-e(n-1)}{T}\right] \qquad (2)$$

$$\alpha = \begin{cases} 1 & |e(n)| \le \varepsilon \quad \text{PID control} \\ 0 & |e(n)| > \varepsilon \quad \text{PD control} \end{cases}$$

where K_P is named as proportional coefficient, T_I ,T_D is named as integral and differential time constant separately, T is sampling interval, n is the sample number, $e(n-1)$ is the error signal for (n-1), $e(n)$ is the error signal for n, $u(n-1)$ is the output of the Integral-separated PID digital controller for (n-1), $u(n)$ is the output of the Integral-separated PID digital controller for n, ε is the artificial separation threshold.

The basic concept of the orbit feedback system is shown in the Figure 1[3][4]. The feedback controller is based on an Integral-separated PID algorithm.

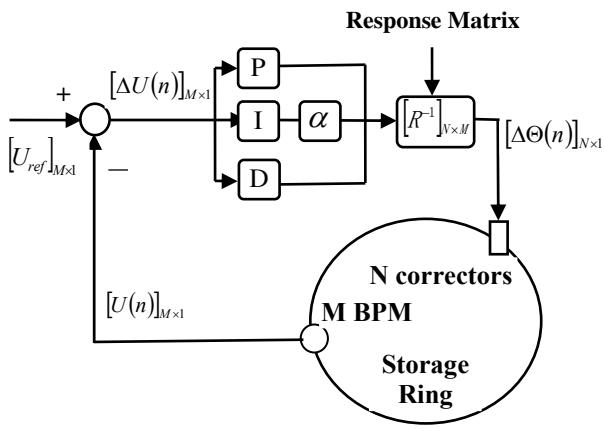

Figure 1: The schematic diagram of the integral-separated PID orbit feedback system.

Where U_{ref} is the reference orbit, $U(n)$ is the BPM value for n, $\Delta U(n)$ is the closed orbit distortion for n, $\Delta\Theta(n)$ is the corrector magnet intensity changes for n.

According to formula (1) and (2), we get the discrete integral-separated PID control formula of beam orbit correction:

* Work supported by National Natural Science Foundation of China (11005114)
#xuanke@ustc.edu.cn

$$\Theta(n) = R^{-1}U(n) = R^{-1}U(n-1) + R^{-1}K_P \times \left[\Delta U(n) + \alpha \frac{T}{T_I}\sum_{j=0}^{n}\Delta U(j) + T_D\frac{\Delta U(n) - \Delta U(n-1)}{T}\right] \quad (3)$$
$$= \Theta(n-1) + K_P\Delta\Theta(n) + \alpha K_I\sum_{j=0}^{n}\Delta\Theta(j) + K_D[\Delta\Theta(n) - \Delta\Theta(n-1)]$$

where $U(n-1)$ is the BPM value for (n-1), $\Delta U(n-1)$ is the closed orbit distortion for (n-1), $\Theta(n)$ is the corrector magnet intensity for n, $\Theta(n-1)$ is the corrector magnet intensity for (n-1), $\Delta\Theta(n-1)$ is the corrector magnet intensity changes for (n-1), K_I, K_D is named as integral and differential coefficient separately. $K_I = K_P T/T_I$, $K_D = K_P T_D/T$.

ORBIT FEEDBACK SIMULATION

The integral-separation PID feedback algorithm is studied in HLSII storage ring. The storage ring accelerator model is built by AT (Accelerator Toolbox), and the code of the integral-separation PID feedback algorithm is programmed by using MATLAB[5][6].

Concrete steps are introduced as in following:

(1) Obtain the response matrix by using AT function, and calculate the inverse response matrix R^{-1}.

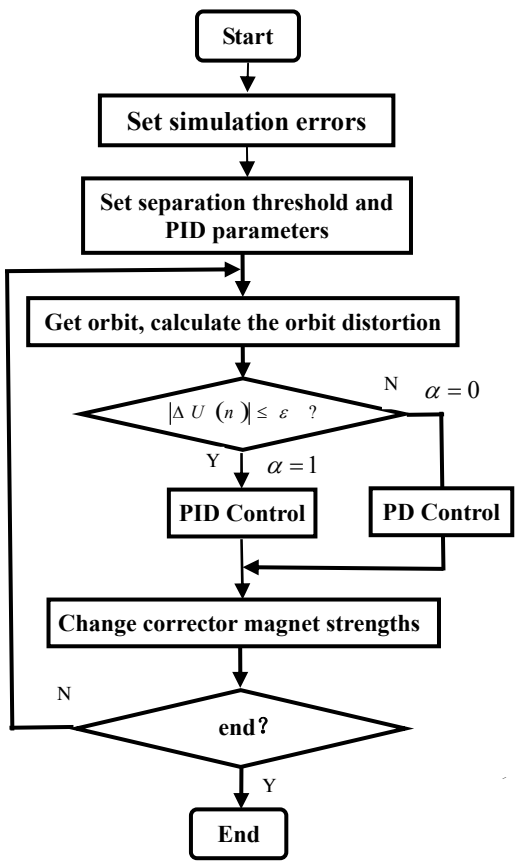

Figure 2: The flow chart of the integral-separation PID orbit feedback algorithm.

(2) Produce orbit distortion by simulating a variety of errors.

(3) Set separation threshold value and PID parameters according to the actual system.

(4) Calculate the closed orbit distortion $\Delta U(n)$, if $|\Delta U(n)| > \varepsilon$, Using PD feedback, if $|\Delta U(n)| < \varepsilon$, Using PID feedback.

Repeat 4th step until it reaches the target. Figure 2 shows the flow chart of the integral-separation PID orbit feedback algorithm.

After repeated simulation, the optimal PID control parameters and separation threshold value of the controller module can be determined:

$$K_P = 2, K_I = 0.4, K_D = 0.9, \varepsilon = 0.1mm \quad (4)$$

The effect of orbit feedback by using integral-separation PID algorithm are recorded and shown in figure 3 and figure 4.

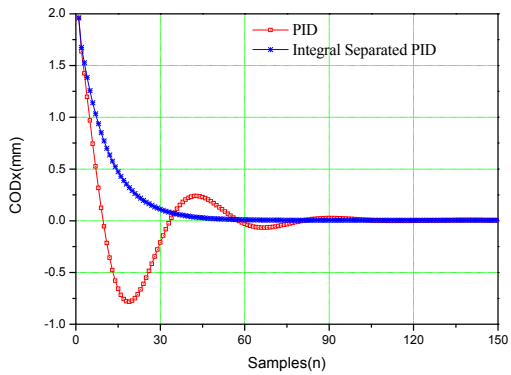

Figure 3: The horizontal orbit of PID control and integral-separation PID at the 16th BPM.

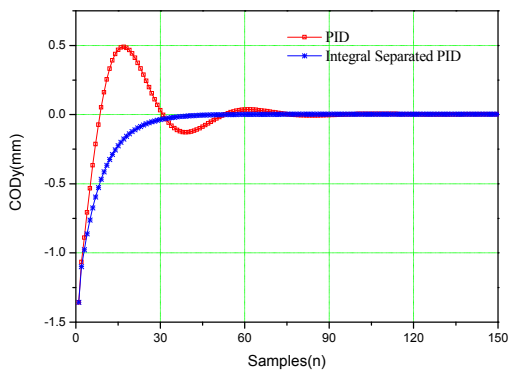

Figure 4: The vertical orbit of PID control and integral-separation PID at the 16th BPM.

Figure 3 and Figure 4 shows the beam orbit stability has been greatly improved after adding integral-separation PID feedback when the orbit distortion is large. After introducing integral action, the proportional coefficient K_P should be adjusted to ensure the stability of the feedback system.

CONCLUSION

The simulation results show the beam orbit feedback based on the integral-separation PID could be smoother and faster than normal PID control, and the control effect has been greatly improved. It is noteworthy that the separation threshold value should be determined according to the specific circumstances and requirements. If the separation threshold is too large, the integral-separation target can not be achieved; if the separation threshold is too small, it will not enter the integration area. If only the PD control, it will not to eliminate steady-state error and improve the beam orbit stability.

DESIGN OF A DIGITAL CONTROLLER FOR ALPI 80 MHZ RESONATORS

S. Barabin, Institute of Theoretical and Experimental Physics, Moscow, Russia
G. Bassato, INFN, Laboratori Nazionali di Legnaro, Legnaro (Padova), Italy

Abstract

We discuss the design of a resonator controller based mainly on digital technology. The signal frequency is 80 MHz but can be easily increased up to 350MHz; the controller can work in either "Generator Driven" (GDR) or "Self-Excited Loop" (SEL) modes. The signal processing unit is a commercial board (Bittware T2-Pci) with Xilinx Virtex II-Pro FPGA and 4 TigerSharc DSPs. The front-end board includes a set of A/D channels, which sample the RF signals coming from the cavity pickup and from the reference generator. We present results of some preliminary tests on 80 MHz quarter wave resonator installed in the ALPI Linac accelerator at INFN-LNL and discuss possible developments of this project.

INTRODUCTION

Low level RF control is nowadays implemented using digital techniques [1, 2]. The availability of high-density FPGAs commercial boards makes possible to implement in hardware computational functions that, in the past, would have required an array of high performance DSPs. The board we chose for our application contains both, but most of RF processing blocks (i.e. signal conversion and digital signal processing) are configured inside the FPGA, while DSPs and their memory are mainly used for data routing and several diagnostic calculations.

The general concepts and ideal characteristics of a digital controller are described in [2]. The main features currently realized in our RF controller can be summarized as follows:

- Capability of working in both SEL and GDR modes and switching between them;
- Capability of operating with both superconducting and room temperature cavities;
- Selection between I/Q and amplitude/phase control;
- Frequency sweep mode and frequency response plot generation;
- Provision for cavity frequency resonance control by means of mechanical tuner;
- Minimal use of analog components – no analog downconverters, vector modulators and phase shifters.

RF CONTROLLER DESCRIPTION

As shown in fig. 1 and fig. 2, the controller is based on three boards: the analog front-end for RF signal acquisition, the Bittware T2-PCI board [3] containing DSPs and FPGA, and an output board to generate the signal driving the power amplifier.

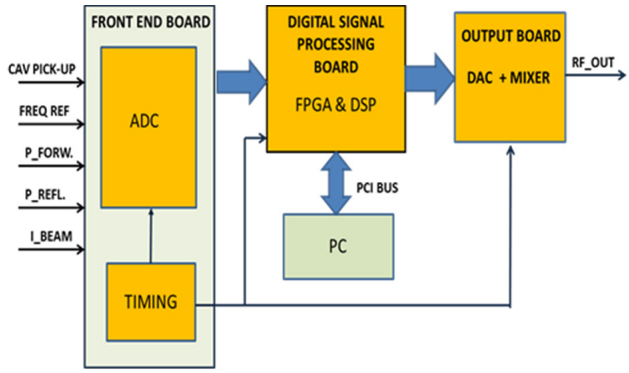

Figure 1: Resonator controller block diagram.

The analog front-end includes five A/D channels based on the AD9433 ADC. Two A/D sample RF signals coming from the cavity pickup and from the frequency reference generator. Additional ADC channels acquire information of amplifier's direct and reflected power and beam current, in order to extend the controller capability to accelerators with high current and beam loading effects. For each channel, an Epcos B39805 bandpass filter followed by a Mini-Circuits ERA-3 amplifier and an ADT1–1WT transformer provide the required filtering and impedance adaptation for the ADC input.

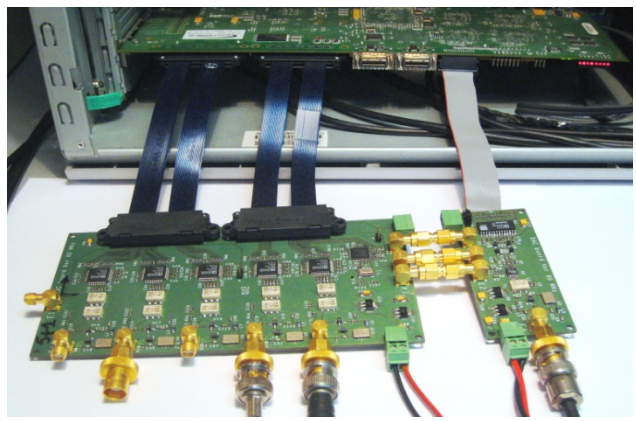

Figure 2: The controller boards.

The output signal driving the power amplifier is generated by a DAC (AD9752) at a frequency of 16MHz; after proper filtering this signal is then upconverted to 80 MHz by mixing with the 64 MHz local oscillator signal. Clock signals to 5 ADCs, DAC, mixer and FPGA are provided by the AD9516 programmable clock distributor, placed in the ADC board and featuring a channel-to-channel skew lower than 10ps. The frequency of sampling clock is 64MHz. The ADC and DAC boards are connected to the T2-PCI card through dedicated high

speed I/O channels, supporting parallel data transfer from all five 12-bit ADC and the 12-bit DAC at 64 MHz rate.

Signal Flow

Figure 3 shows the FPGA block diagram. I/Q demodulation is performed by sampling the input signals from ADCs at a frequency of 4/5 of reference signal to get a 90 deg. phase advance between two samples; the sampled I, Q components can be rotated by a rotation matrix in order to compensate the delay introduced by cables.

Digital downconversion and filtering are performed by cascaded integrator-comb (CIC) filters, to reduce signal noise. Then, signals are converted to polar form by the COordinate Rotation DIgital Computer (CORDIC) to allow phase and magnitude comparison with predefined values. The result of comparison (phase and amplitude errors) goes through a PID algorithm to generate correction signals; a further rotation on phase angle can be optionally added to compensate offsets.

Correction signals, in polar form, undergo a second CORDIC block to convert back to the complex amplitude. form. Resulting I and Q signals drive a digital quadrature modulator [4] that generates, at 16 MHz rate, patterns of 12 bit values representing samples of output signal in the time domain; these values are then sent to the output DAC.

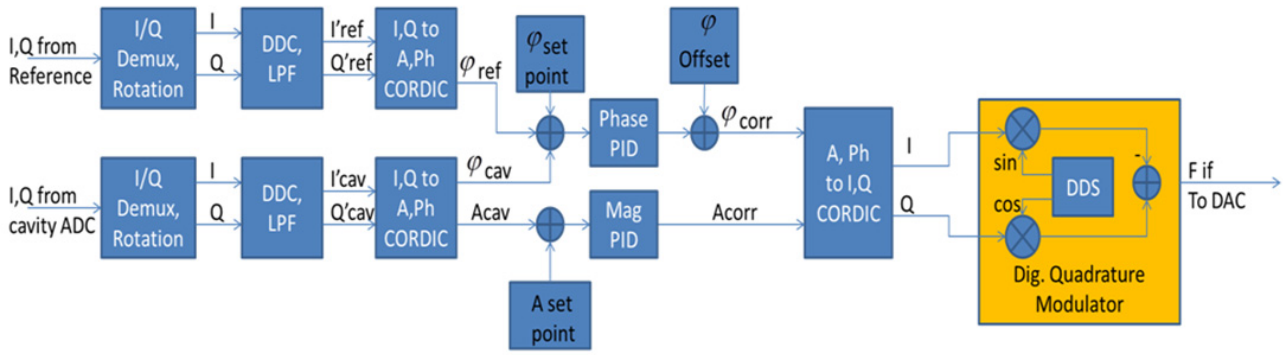

Figure 3: Signal flow inside the FPGA.

DESIGN TOOLS

The DSP code was generated by the C compiler included in Analog Devices VisualDSP++, while the FPGA project was compiled using Xilinx ISE Design Suite. Many FPGA functions are part of Xilinx System Generator module, which is a plug-in extension of Platform Studio SDK. This toolkit also supports the compilation of the PowerPC block, available in the VIRTEX-II Pro chip, we used to configure the clock generator. Matlab and Simulink (by Mathworks) were extensively used in conjunction with Xilinx System Generator module to compile and simulate several FPGA blocks.

USER INTERFACE

The program named "RF controller" implements the user interface to set and diagnose the RF field in cavity. The graphic application is written in C++ with Microsoft Visual Studio IDE. It uses Bittware's host interface library to communicate with Bittware's digital board through PCI.

User Interface Main Functions:

- Setting up desired output signal amplitude and phase;
- Switching on/off the amplitude and phase feedback;
- Select feedback type between I/Q and amplitude/phase;
- Tuning of feedback parameters like proportional and integral coefficients;
- Switching between SEL and GDR modes;
- Detection of the cavity's resonance frequency during start up (with SEL or amplitude-frequency plot);
- Tune trade-off between loop delay and noise of signal measurement, by tuning digital filters.

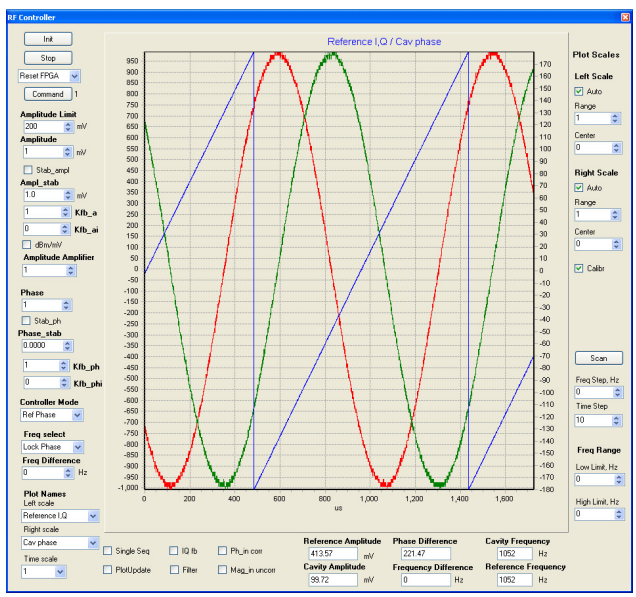

Figure 4: The "RF Controller" graphic interface.

Diagnostic Possibilities

A plot window can simultaneously present two graphs taken from different stages of signal flow. Graphs can be updated at a fixed rate, or triggered by a defined event (i.e. to view a step response). In addition, plot can show cavity's frequency response. Text windows below the plot show several parameters such as reference and cavity field amplitude, frequency and phase difference. These data are updated at approximately 8 Hz rate. Phase and frequency difference are sent by Ethernet to cavity tuner.

TEST RESULTS

Feedback Tests

Feedback capability was tested separately for amplitude and phase. Amplitude and phase PID gains have been tuned to find the optimal gain to minimize the transient response time without overshoot.

Currently, phase difference in the feedback mode can be changed with ~0.09° step, and phase difference textbox shows the same measurement value with 0.01° resolution. The signal amplitude in feedback mode can be changed with 0.1 mV (or ~0.05% from maximum value) step and measured with approximately the same resolution.

Frequency Response Tests

"RF Controller" program allows switching of the output signal frequency to the reference frequency, to the value of 5/4 of clock frequency and to any other desirable frequency (with 1 Hz step). Frequency response is achieved by automatic scan of output signal frequency.

Finding the Cavity Resonance Frequency

One possibility to find the resonance frequency on switch up is sweeping the output frequency and acquiring the cavity's response. It was shown that the reference frequency in test cavity was ~79.7 MHz, and halfwidth bandwidth was ~80 kHz.

Another possibility is using SEL mode. Before SEL mode switch-on difference between cavity and output frequency was about 300 kHz. After SEL mode activation, cavity was tuned to its resonance frequency, as visible on scope and on PC program. We also observed, after modifying cavity's resonance frequency by moving copper rings inside it, the controller was able to track frequency changes.

Feedback Tests with Cavity

It was shown that frequency locking in SEL mode is possible. Phase error in the SEL phase feedback mode was large, about 10 degrees, because of large bandwidth of the warm cavity. It is expected that the phase error for superconducting cavity can be much lower. After switching to the GDR mode (typical working mode), the phase error is reduced to 1%.

Figure 5a and 5b show the phase error under environmental disturbance conditions (mechanical vibrations) without feedback (5a) and with the cavity locked (5b) when the cavity works in generator-driven mode. The amplitude error with feedback is about 1 mV.

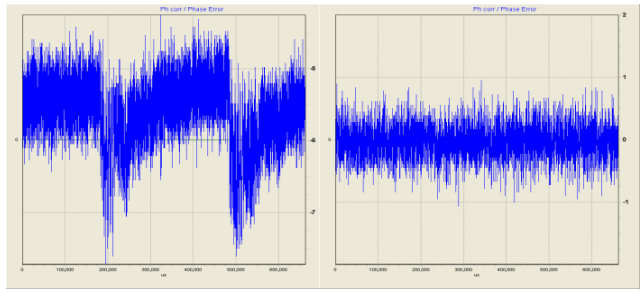

Figure 5a: cavity unlocked. Figure 5b: phase locked.

Digital Filters Addition

Amplitude and phase errors can be reduced by addition of digital filters. Using filters decreases the phase error from 1° down to ~0.25° by cost of increasing the loop delay: the loop delay, in fact, increases from ~5 to 60 µs, and the step response time grows up to 400 µs. For superconducting cavities with typical filling times up to 1 second, this loop delay is more than acceptable.

CONCLUSION

The prototype we realized demonstrates the feasibility of a digital solution fully based on FPGA. Although the preliminary results are promising, some work still need to be carried out. New features can be added by software modifications, such as:

- Feedforward beam loading;
- Power amplifier linearization;
- Any combination of amplitude, phase and I, Q control;
- Dynamic change of digital filter characteristics;
- Additional feedforward modes can be added – open loop operation at start-up, cavity conditioning/tuning, adaptive feedforward.

A significant part of hardware changes should be made by redesigning the analog section of controller, that includes: field calibration of cavity input, increase of input dynamic range by addition of variable gain amplifiers, increase of ADC resolution from 12 to 16 bit, increase of DAC resolution to 16 bit, other than its output level. Another possible change concerns with the digital board: a more modular design (i.e, changing the interface to the host computer from PCI to Ethernet) would reduce the cost, increase the flexibility and improve the performance.

FAST ORBIT CORRECTION FOR THE ESRF STORAGE RING

Jean Marc Koch, Francis Epaud, Eric Plouviez, Kees Scheidt, ESRF, Grenoble, France

Abstract

Up to now, at the ESRF, the correction of the orbit position has been performed with two independent systems: one dealing with the slow movements and one correcting the motion in a range of up to 200Hz but with a limited number of fast BPMs and steerers. The latter will be removed and one unique system will cover the frequency range from DC to 200Hz using all 224 BPMs and the 96 steerers. Indeed, thanks to the procurement of the Liberas Brilliance and the installation of new AC power supplies, it is now possible to access all the Beam positions at a frequency of 10 kHz and to drive a small current in the steerers in a 200Hz bandwidth. The first tests of the correction of the beam position have been performed and will be presented. The data processing will be presented as well with a particular emphasis on the development inside the FPGA.

INTRODUCTION

The ESRF storage ring is a high brilliance source with low emittance values (ε_x =4.10^{-9} m.rad and ε_z=4.10^{-12} m.rad) generating Xray from insertion devices installed on 5 m long straight sections. With β_x=36m and β_z=2.5m in the center of the high beta straight sections, the rms beam sizes at the BPMs located on both ends of the straight sections are σ_x= 380µm and σ_z= 14µm. The parasitic motion of the beam due to slow drifts or high frequency vibrations of the quadrupole support girders must be kept at low enough values to avoid spoiling this emittance figure. Two kinds of motions can be observed: very slow drifts and vibrations at 7Hz, 30 Hz and 60 Hz. The amplitude of these vibrations at the ends of the straight sections is 10 µm rms horizontally and 3µm rms vertically. The components of the correction scheme are shown in figure 1, all BPMs and steerers in place are used by the system.

System Layout

The design of our new system is based on the availability of the Libera Brilliance electronics and an associated "Communication Controller" developed at DLS [1] and using the Libera Rocket I/O ports. This allows the measurement and broadcast of the beam position at 224 locations with a very good resolution at a rate of 10 kHz. We are using the 96 corrector magnets embedded in the sextupole cores to steer the beam, and since the power supplies feeding these magnets are installed in four locations, this particular constraint sets the architecture and topology of this system. Therefore, the correction computation is placed close to the power supplies and spread over 8 processors, 2 per location.

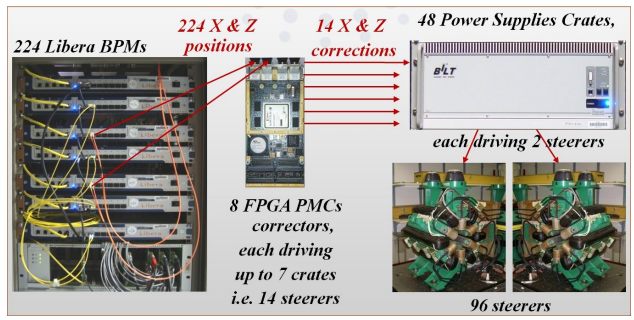

Figure 1: Fast Orbit Feedback components.

Upgrade of the Correctors Power Supplies

The present slow correctors are implemented by 3 pairs of auxiliary coils placed on the yoke of the sextupoles. Using the proper combination of currents in these 3 coil pairs we can produce any combination of vertical and horizontal kicks. The bandwidth of these correctors is affected by the eddy currents in the sextupole core and at the surface of the vacuum chamber since the vacuum chamber all over the storage ring is made of 2mm stainless steel. The inductance of these correctors is also quite large: 0.6H, however, it is possible to achieve, given the small amplitude of the high frequency currents needed for the fast correction, a small signal bandwidth of 500Hz thanks to a proper design of the power supplies. These power supplies are controlled through the Ethernet control system network and an additional trim setting can be added at a rate of 10KHz on 10% of the full dynamic range. This is done through a RS485 port used to input the data in a deterministic way and with a delay limited to 20µs. Among the features of the power supplies, a diagnostic on each of the 288 channels is available to check the proper functioning of the serial links.

Processing

For the processing, we selected a PMC module with fiber-optic transceivers and a Xilinx Virtex-5 FPGA. The code embedded in this FPGA has several functions:

1) Collect the data from the BPMs at 10 kHz with the Communication Controller

2) Obtain the parameters from the PCI

3) Process the corrections

4) Send the set-points to the power supplies

5) Send the set-points for data recording with the Communication Controller

The choice of performing the corrections inside the FPGA was driven by the fact that no real-time operating system was supported at the ESRF when we launched this development. One clear advantage of this solution is the efficiency of the FPGA: an interesting feature is the capacity to do parallel computing and also the fact that the time lost transferring the data is very limited since all the functions are performed inside the same component. One particularity of this development is the use of System Generator from Xilinx / The MathWorks to design the part dedicated to the corrections and sequencing of the system. The design can be checked with Matlab / Simulink before the VHDL code generation.

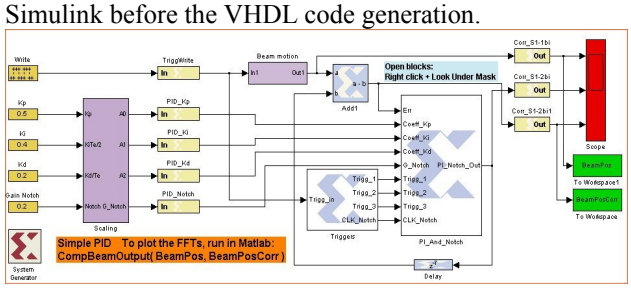

Figure 2: Corrector behaviour test with Simulink.

In order to check the behavior of the data processing at design stage, real data are introduced at the initialization of the simulation and processed with the components from Xilinx and then, output data can be transferred for analysis under Matlab. In the simulation of Fig.2, the power supplies, magnets and vacuum chambers are modeled as a simple delay of 700µs between the correction output and the reading of the beam position.

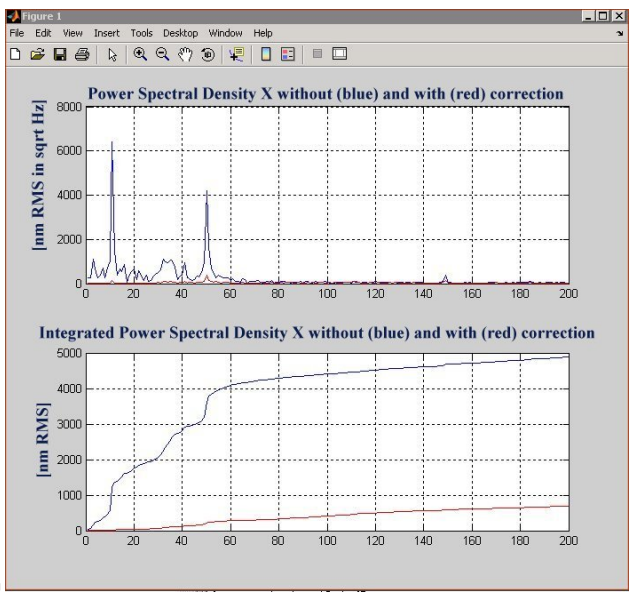

Figure 3: Theoretical results expected from the correctors.

Orbit Correction Algorithm

We derive the orbit correction from the BPM data using a correction matrix obtained from the inversion of the response matrix of the BPMs to each corrector. These response matrixes are inverted using the SVD method. We use 96 eigen vectors for the inversion of the response matrix. Before starting the 10 KHz correction loop, we will measure the average orbit and set the corrector currents in order to suppress the error measured on this average orbit; these DC values will be applied using the Ethernet input of the power supplies. We will then start the fast correction loop which will add an additional trim current to the DC current set initially. During the first tests of this fast loop, we used a PI algorithm with an additional 50 Hz notch filter aimed to improve the damping of the perturbation at the AC main supply frequency for the 10 KHz iteration of the values of the trim correction currents. Over long periods of operation, the average value of the trim currents may eventually drift up to significant values. In this case, this average current will be added to the setting of the Ethernet input of the power supply, and the average value of the fast trim currents will drop to zero. In this way, if the fast loop is stopped, setting the values of the trim currents to zero will only result in a very small orbit jump and we keep the whole dynamic range for the fast correction.

Diagnostic

In addition to the 8 feedback processor/power supply controller modules, one FPGA PMC board has been added; this board is fully dedicated to diagnostics, and is able to log up to 10s of position and correction data; this board is a duplication of the so called “sniffer” developed for the SOLEIL and DLS orbit control systems[2]. It is also used to detect errors in the data collection by counting the “BPM data not received”.

TESTS

Orbit Correction Test Set Up

All the correctors are now equipped with their new power supplies and connected to the 8 FPGA processors themselves connected to the 224 BPMs.

Tests Results

The commissioning of the whole system started in September 2011 and the results are as expected (Fig. 5) apart from the correction of the 50Hz which is missing and will be performed with an additional notch filter which has already been tested with a reduced setup [3].

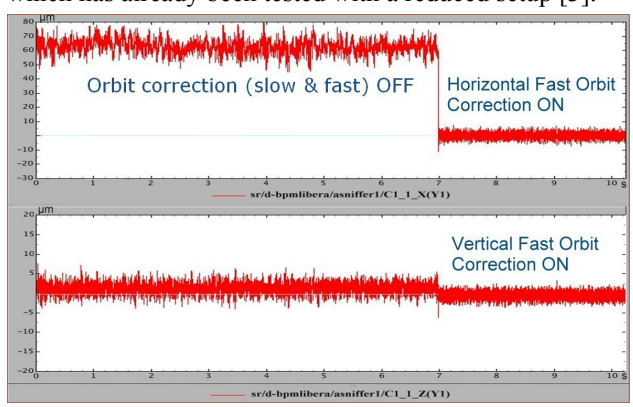

Figure 4: BPM signals with orbit correction OFF and ON.

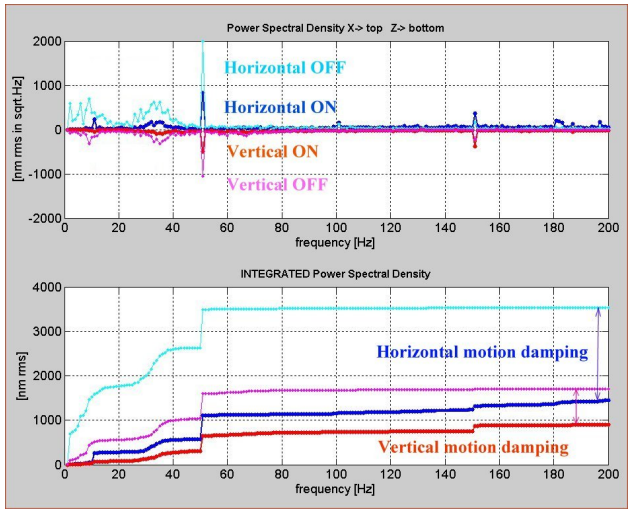

Figure 5: Beam motion averaged over 224 BPMs.

The correction bandwidth was set at 150Hz, and no weighting was applied on the damping time of the upper order eigen vectors of the SVD decomposition. We recorded the positions with the sniffer module. After the suppression of the remaining disturbance at 50 Hz, both horizontal and vertical motion will be reduced to less than 1µm RMS in a 200Hz bandwidth.

The plots of figure 5 show the reduction of the horizontal and vertical BPM signals. It is calculated from an average of the 224 positions.

We have also tested that starting from an orbit already set by a slow orbit correction, turning on or stopping the fast loop was not causing any significant orbit jumps.

Another test has been performed to assess the capability of the correction to drastically reduce the effect of the gap motion on the beam position. In fig. 6 we can see at first a record with no correction, the second part shows the result with a feed-forward control, the efficiency of which depends on the beam parameters, and lastly with the Fast Orbit Feedback "ON", the beam stays at its position within 1µm during the phase changes.

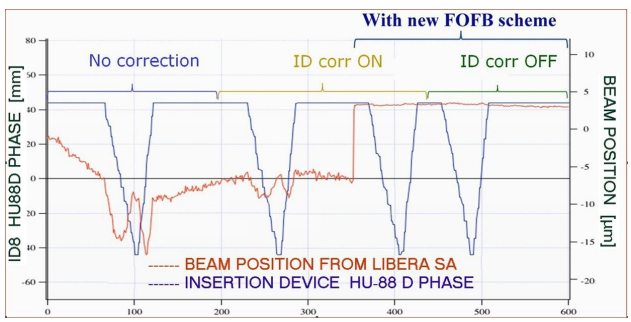

Figure 6: Correction of a beam displacement induced by an insertion device motion (Courtesy of J.Chavanne).

Other Measurements

The resolution of the 10 KHz FA data is 600nm in the range of currents that we store in operation. Such a resolution allows the measurement of SR parameters such as the measurement of the matrix of the response of the BPMs to the corrector current, or the analysis of the SR optics coupling with a very low excitation of the beam and a short acquisition time; applying excitation signals modulated by a sine signal at a well chosen frequency and a narrow bandwidth analysis of the beam response at this frequency, using the method tested at DLS [4], we checked that with a measurement time of 1s, a resolution of 6nm was achieved. We have used the sniffer to record the response of the BPMs to a 40 Hz modulated kick from a horizontal corrector over 1 second. The horizontal response amplitude is 5µm and the vertical response which is due to the coupling of the horizontal and vertical optics is very clean, though its amplitude is only 150nm.

CONCLUSION

We have tested the performance of this system and the damping of the orbit distortion that we achieved fulfils our expectation. There are some outstanding improvements to be made to the design of the correctors as well as to the control with the device servers. Then the next step will be to put this system in operation with a high level of reliability; this part requires special attention to the sequencing and diagnostic of the system. Concerning the development and commissioning, we are on schedule and we expect to put it into operation in spring 2012 at the end of the long shutdown planned for the construction work.

ACKNOWLEDGEMENTS

This project uses essential subsystems from Diamond Light Source and SOLEIL. We wish to thank G. Rehm, M. Abott and I. Uzun from DLS and N. Hubert from SOLEIL for the support that we got from them.

BEAM SYNCHRONOUS DATA ACQUISITION FOR SWISSFEL TEST INJECTOR

B. Kalantari, T. Korhonen, Paul Scherrer Institute, Villigen, Switzerland

Abstract

A 250 MeV injector facility at PSI has been constructed to study the scientific and technological challenges of the SwissFEL [1] project. Since in such pulsed machines in principle every beam can have different characteristics, due to varying machine parameters and/or conditions, it is very crucial to be able to acquire and distinguish control system data from one pulse to the next. In this paper we describe the technique we have developed to perform beam synchronous data acquisition at 100 Hz rate. This has been particularly challenging since it had to provide us with a reliable and real-time data acquisition method in a non real-time control system. We describe how this can be achieved by employing a powerful and flexible timing system with well defined interfaces to the control system.

INTRODUCTION

The 250-MeV Linear accelerator [2] at PSI has been constructed as a test bed facility to help design, development of concepts and proof of principles toward realization of the SwissFEL project. This injector test facility will be also used as the injector of the SwissFEL.

In general in operation of pulsed machines, e.g. FELs, it is very crucial to be able to study and diagnose the machine behaviour on pulse-to-pulse bases. Therefore it is required that, the data generated by the machine components is measured and collected at each pulse. Furthermore it is also required that the collected data at each pulse is clearly distinguished from those of another pulse. The reliable, pulse-to-pulse data acquisition requires a tight cooperation and well defined interface of timing system with the control and measurement systems. Considering the repetition rate of such machines, which is normally high (from several tens to few hundred Hz), the data acquisition and collection, will not be anymore a trivial task to do. Our injector currently produces beam at 10 Hz repetition rate. However, since there are several subsystems, e.g. Laser systems, which require 100 Hz operation at the same time we have to be able to cope with data acquisition at 100 Hz.

The pulse-to-pulse data acquisition across several locally separated control/measurement nodes is also known as Beam-Synchronous Data Acquisition to which we refer by BS-DAQ in the rest of the paper. In the following we first describe our BS-DAQ concept and then briefly describe the timing system features and control system interface which helped us to implement this concept.

BS-DAQ CONCEPT

The problem of BS-DAQ is in fact that of real-time data acquisition. Hence the first and the most important issue to address is, to acquire and collect data in a specified time interval. The time interval is specified by the machine repetition rate, said the other way, time interval between two consecutive machine pulses. So it is crucial that a measurement device participating in BS-DAQ demonstrates a deterministic behaviour. Hence, in our mechanism we assume that the measurement device has this important property. Closely related to this, is the issue of presentation of the measurement in the control system. In this regard we also assume that the measured data is transformed to a control system object well within the deadline determined by the repetition rate.

Local Buffering Concept

The heart of the BS-DAQ concept is the local buffering of the generated data at the Input/Output Controller (IOC) node. A similar concept has been also employed in LCLS [3]. The major reason for this approach is that in our control system the communication between IOC's is via an Ethernet-based protocol (EPICS Channel Access) which provides no guarantees in determinism of the data transmission delay (no upper bound on the delay). However since the IOC's demonstrate a real-time behaviour at the local level, we collect the acquired data locally at the beam or machine rate and then after finishing the acquisition the data collected in the buffers can be transferred via the communication network to the remote client application for offline analysis i.e. correlation studies.

Role of the Timing System

To make the local buffering work, we still need to provide a minimal but reliable, real-time communication across all locally separated IOC's which participate in a BS-DAQ run. This is because the measured data belonging to the same pulse has to be synchronously buffered at each IOC and it has to be possible to distinguish each buffered element by a *pulse ID* (pulse identification number). We use global event system of Micro Research Finland (MRF) [4] for our timing system. In the event system, an event generator in the central master timing IOC generates timing information and transmits them to all event receivers around the facility via optical links. The pulse ID or pulse marker is a unique, monotonically increasing number which is assigned to each machine pulse. It is generated in the central, master timing IOC and distributed via the timing system to all IOC's connected to the timing system (via

optical links). The pulse ID is received at each IOC via the event receiver and is transformed to a control system object where it can be used as an index of the acquired data at each pulse.

Role of the Control System

The control system at each IOC provides the means for control logic of the buffering mechanism. In our case all the logic, mechanisms and required software objects has been provided by the control system (EPICS) such that no special object type or low level driver had to be developed. The timing critical command/status data as mentioned is provided by the timing systems but finally presented as control system objects.

IMPLEMENTATION

In the implementation of the BS-DAQ mechanism, we have chosen right from the beginning to develop a generic control system software package so that the installation and usage for the control system engineers is a plug and play task which does not require any internal knowledge of the mechanism. In this regard we should emphasize that the EPICS toolkit had almost all the features that we required for implementation of the BS-DAQ.

Overview

The master timing IOC which houses the event generator is the central coordinator and synchronizer of the BS-DAQ. An EPICS program which is driven by the event systems interrupts determines, according to user specified parameters, at what pulses each IOC has to collect an EPICS channel. Then at each appropriate pulse, a command is sent synchronously to all IOC's via the timing system. When the receivers in each IOC receive the BS-DAQ commands, they find out if they have to copy value of the specified EPICS channel into the specified local buffer. The local buffers are realized by using a standard EPICS record type called "compress". Along with each data buffer there is also a pulse ID buffer to serve as the data index. A BS-DAQ run is initiated on-demand by the user for specified number of pulses. Typically the buffer length is selected such that at least 20 seconds interval can be covered. For example at 100 Hz repetition rate a buffer with 2000 element should be sufficient.

Control and Tweaking Knobs

A user (machine expert usually) who runs the BS-DAQ has some knobs to control. These are as the following:

- Number of acquisitions: this determines the total number of samples which will be collected in the local buffers at each IOC.
- Spacing: this parameter specifies the spacing between beam pulses which are sampled. For example zero spacing causes the data collection at each generated beam. A spacing of one, means samples at every second beam pulse will be collected.
- Defer cycles: this specifies how long to wait after each beam before buffering of each sample.
- Start/stop/abort/resume: these are the major control knobs to start, stop, resume or abort a BS-DAQ run.

Multi-user Operation

The BS-DAQ application is implemented such that it allows several users to simultaneously run their own independent BS-DAQ instance. Each user *leases* an acquisition *slot* and takes control over that until the acquisition is finished where the slot becomes *free* again (by the user). Currently six slots are supported and it can easily be expanded to more slots if required. In terms of logic, control and timing resources there is practically no limitation on increasing the number of acquisition slots. On the other hand number of machine experts that would use the application at the same time will not be a big number.

Dynamic Configuration

Most of the configuration parameters of the BS-DAQ can be specified at runtime. In particular the user can decide what data (EPICS channel) goes to what available buffer on an IOC. This makes the application very flexible since it is not necessary to specify measured data and the buffer which is going to be used in BS-DAQ at IOC initialization time, hence there is no need to restart the system. Furthermore, it allows better utilization of the IOC resources such as memory. It also leads to smaller and easier maintenance of the software package. Dynamic configuration, on the other hand, makes setting up an acquisition slot a rather complex task which involves several steps such as finding a free slot, slot leasing, finding free buffer, buffer assignments, etc. Currently the high level user application that retrieves and analyzes the collected data does this setup task. The high level software that our machine experts use for this purpose is Matlab.

First-Level Verifications

To provide a simple, first level cross-check in order to see if the BS-DAQ has done a successful run, we provided two verification methods. The first is to check if the data (EPICS channel) to be taken is not in the alarm state. The second is a check to see if there is any irregularities in the collected pulse ID's along with each collected data.

Support for Waveforms

The BS-DAQ is also able to collect the vector data (that has more than one element) at each sample in the same way as it does for scalar data. This was needed to collect the camera images or phase and amplitude waveforms in the LLRF systems. The BS-DAQ mechanism handles vectors data exactly in the same way as scalars. This was

achieved by introducing a parameter to BS-DAQ logic, applied to every data, as *sample size* which is 1 for scalar data and N for a vector with size N.

CONCLUSION

In this paper we have presented our approach to perform Beam-Synchronous Data Acquisition (BS-DAQ) in the SwissFEL test injector facility. The concept of local buffering was presented and our implementation was discussed in details.

Abstract

A girder control system is proposed to quickly and precisely adjust the displacement and rotating angle of all girders in the storage ring with little manpower at the Taiwan Photon Source (TPS) project at National Synchrotron Research Center (NSRRC). In this control girder system, six motorized cam movers supporting a girder are driven on three pedestals to perform six-axis adjustments of a girder [1][2]. A tiltmeter monitors the pitch and roll of each girder; several touch sensors measure the relative displacement between consecutive girders. Moreover, a laser position sensitive detector (PSD) system [3] measuring the relative displacement between straight-section girders is included in this girder control system. Operator can use subroutines developed by MATLAB [4] to control every local girder control system via intranet. This paper presents details of design and tests of the girder control system.

INTRODUCTION

TPS girder control system consists of twenty four girder control systems and a girder-position computer. A girder-position computer grabs each girder's observation values indicating six degree of freedom, three degrees of freedom come from touch sensors; two degrees of freedom are from a tiltmeter and one degree of freedom from a PSD system. The system calculates all girder best positions by minimizing global girder position errors and the algorithm [5] is developing. Each girder control system receives six motorized cam mover angles determined by a girder adjustment algorithm from the girder-position computer via intranet. A girder control system driver drives a girder with six motors to adjust quickly and precisely the displacement and rotating angle of the girder. An adjustment cycle is finish. Locking systems are applied to fix all girders after the global girder position error achieves a good required precision for the whole storage ring. One twenty-fourth of the whole ring is shown as figure 1.

Figure 1: One twenty-fourth of the whole ring consists of three girders.

A GIRDER CONTROL SYSTEM

In order to achieve one micrometer-level displacement [6] and one microradian-level revolution of the rotation of a girder, a girder control system includes touch sensors provides resolution of thirty nanometers and two micrometer of accuracy, a tiltmeter provides resolution of one microradian and a PSD system has resolution of two micrometers at thirteen meters propagating distance every four hours. A girder control system synchronously controls three girders and each girder with six motors is driven co-ordinately to keep each girder's movement at minimum rotating variations.

The whole controller systems are adopted PXI platform and Microsoft Windows 7. PXI architecture is PC-based platform for control and measurement. The advantage of PXI is easy to design control system without other extra learning. The disadvantage is that the control system is unstable without good programming techniques and schemes. A girder control system is shown in figure 2. Eighteen motor drivers are arranged in the upper cabinet, PXI controller in the middle and custom electronic circuits for motors and encoders system in the bottom of the cabinet.

Figure 2: A girder control system.

A Cam Mover Control System

In order to provide good support of magnets and align the girder precisely and quickly, each girder is constructed with six cam movers on three pedestals to realize six-axis adjustments with automation. In addition to eighteen automatic motor baker control channels, each cam mover control system possesses eighteen stepper motor control channels and twelve critical signal stops. Those stops' quantity is adjusted channels depended by practical requirements. The control system provides driving eighteen motor synchronously with three girders coordinate movements.

In order to achieve the requirements, NI PXI-7813R [7] with Xilinx Virtex-2 is chosen as a customized motion card of the cam mover control system for the girder control system. The algorithm of a motion card is programmed by VHDL in addition to NI CLIP method. Applied to NI library, the girder controller handles the rotating angle of each motor in Microsoft Window 7 environment.

To reduce the entire installation time and human errors, customized circuits are designed for wiring installation. The customized circuits includes eighteen motor control channels, eighteen automatic motor baker control channels and thirty-two critical signal stops as figure 3.

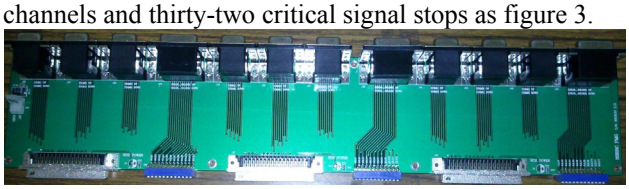

Figure 3: Eighteen motor control circuits for a cam mover system.

A Rotational Encoder and Touch Sensor Reading System

Rotational encoders and touch sensors provide absolute position with resolutions of 25-bit counts per rotation and 32-bis counts in twelve mm respectively. Sensors adopt Endat 2.2 protocol provided by Heidenhein as an interface to transit position data to sequential equipments.

In order to provide PXI encoder cards with higher channel quantity of Endat 2.2 protocol, NI PXI-7811R with Xilinx Virtex-2 is chosen as a customized encoder card. PXI-7811R does not possess differential circuits to be compatible to rotational encoders and touch sensors with Endat 2.2. The extra circuit is designed to be compatible to Endat 2.2 specs. A PXI-7811R grabs 18 rotational encoders and 18 touch sensors synchronously and the update rate achieves 10 kHz. It is similar to motion card of the cam mover system. The extra circuit board (figure 4) reduces installation time and human errors.

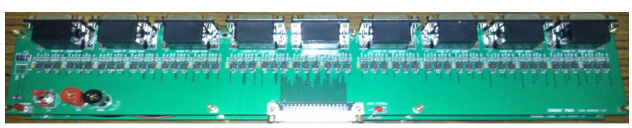

Figure 4: Eighteen differential circuits for encoders and touch sensors.

A Tiltmeter System

To measure the pitch and roll direction of a girder with one microradian resolution, Nivel 220 [8] is chosen as a tiltmeter. One twenty-fourth of the whole ring consists of three tiltmeters and those sensors connect together by RS-485 protocol. Before the installation or after any slight impact, a tiltmeter has to be calibrated.

A PSD System

The laser positioning system, a part of a girder auto-alignment scheme, will be installed on the girders located at both sides of each straight section of the storage ring. The system (figure 5) is composed of a laser and four sets of a position sensing device (PSD). The laser propagates thirteen meters along the girder and plays the role of a reference line of girders of the straight section. Based on the laser linear characteristics, the other girder can be adjusted and aligned by a cam mover according to PSD data. To achieve superior precision, the whole laser positioning system should be constructed stably. The precision of the laser positioning system can achieve two micrometer at thirteen meters propagating distance every four hours.

Each PSD provides a PCI DAQ card to detect laser position and power.

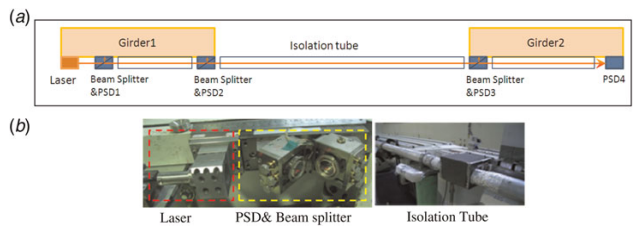

Figure 5: (a) Architecture of the laser positioning system. (b) Main portions of the laser positioning system.

A Locking System

After the global girder position error achieves to required precision for the whole storage ring, locking systems (figure 6) are applied to fix all girders. Three couples of locking systems installed on three pedestals between a girder and pedestals improve the resonance frequency. A locking system includes a wedge mechanism and electronic circuits. A couple of wedge mechanisms driven by DC motors push the wedges to reduce gaps between wedges and the girder to cause a clamping effort.

In order to control the wedge mechanism, a locking electronic circuit is designed to drive a couple of the wedge mechanisms synchronously. A DC motor is driven by PWM method and the motor rotating angle is monitored by the encoder installed at the end of the motor. The locking electronic circuit provides eighteen driven channels. Two channels can be controlled at once, and switching techniques help us to actuate eighteen DC motors. The motion card with PXI interface is programmed by VHDL with FPAG chip and also provides critical signal stops.

The locking system can provide 2000 kg of the maximum force at the condition that motor runs at 24V and 2A.

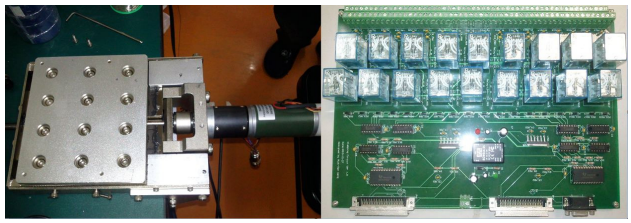

Figure 6: A wedge mechanism and electronic circuits.

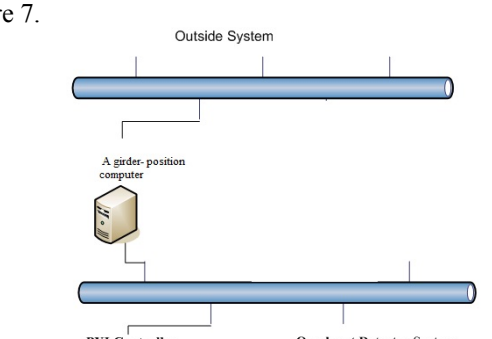
Network and System Architectures

TPS girder control system consists of 24 girder control systems and a girder-position computer. To avoid virus risks, all control systems are in the individual network except a girder-position computer connecting internet for transiting sensors massage to Archive system.

Each girder control system receives six motorized cam mover rotating angles from the girder-position computer in the individual network. To increase the facility of control hardware, the basic subroutines developed by Matlab communicates to girder control systems. Users just study the algorithm for the adjustment without understanding hardware.

The girder control system provides the control of cam movers and the reading of encoders, touch sensors and tiltmeters. To increase system stability, all functions are developed to a small program with TCP/IP. Users read the sensors' data or control actuators via the individual network. The network and system architecture is shown as figure 7.



Name	Quantity	Desciption
PXI Computer	1	Compute the argrthm of girders
RS232 Port	1	Read data from Nivel 220
Encoder Card	4	Read Endata 2.2 signals of rotary and linear encoders
Digital I/O Card	2	For limit switches
Motion Card	1	Control Stepping Motor

Name	Quantity	Desciption
Sever	2	Operation System
Quadrant Detector card	2	Read the voltage of a quadrant detector

Total quantity of local side computers is 24

Figure 7: Network and system architectures.

TEST RESULTS

After stability tests, a girder system runs normally for more six months. Many Experiments are processing by girder control systems and the statuses of the systems are stable. The graphical user interface is shown as figure 8.

The locking system is applied to lock girders and the test results are presented as table 1. The deviation of a locked girder is less than 10 micrometers in the transverse. It is not controllable in other two directions and the deviation is larger than the transverse. The vertical and longitudinal movements of the girder are due to the locking force.

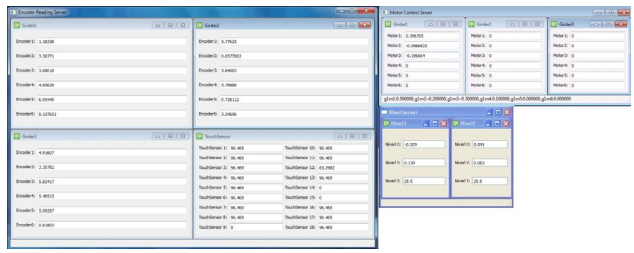


Figure 8: The graphical user interface of a girder control system.

Table 1: The Deviation of a Locked Girder

Deviation	Transverse	Vertical	Longitudinal
First	-3 μm	8μm	6μm
Second	-9μm	20μm	-17μm

CONCLUSION

A six-axis adjustments of a girder are developed automatically to adjust the displacement and rotating angle of all girders in the storage ring quickly and precisely with little manpower. The test results show that a girder control system adjusts girders quickly, precisely and stably. However, EPICS system will be adopted in Taiwan Photon Source. Therefore, our next step is to change the current system with EPICS.

BEAM SPILL STRUCTURE FEEDBACK TEST IN HIRFL-CSR*

R.S. Mao#, P. Li, L.Z. Ma, J.X. Wu, Y.J. Yuan, J.W. Xia, J.C. Yang,
T.C. Zhao, Z.Z. Zhou, IMP, Lanzhou, China

Abstract

The slow extraction beam from HIRFL-CSR is used in nuclear physics experiments and heavy ion therapy. 50Hz ripple and harmonics are observed in beam spill. To improve the spill structure, the first set of control system consisting of fast Q-magnet and feedback device based FPGA is developed and installed in 2010, and spill structure feedback test also has been started. The commissioning results with spill feedback system are presented in this paper.

INTRODUCTION

HIRFL-CSR [1] is the post-acceleration system of Heavy Ion Research Facility in Lanzhou (HIRFL), which consists of double cooling storage ring system(CSR) and a radioactive beam line (RIBLL2). The beam is accumulated, cooled and accelerated in the main ring (CSRm), and will be extracted [2] in fast extraction mode to experiment ring (CSRe) for internal-target experiments, or extracted in slow extraction (RF-knockout) mode for external-target experiments and cancer therapy.

To prevent the pileup events in particle detectors [3], and to improve the lateral dose distribution in the irradiation for heavy ion therapy [4], the ripple noises of beam spill should be suppressed. We developed a test set of the spill feedback system, which consists of two quadrupole magnets, commercial FPGA card and waveform generator.

SPILL CONTROL

In CSRm, the RF-knockout method is employed for slow extraction. Normally, the horizontal tune in CSRm is set to 3.662 by using normal quadruple pairs during slow extraction, and additional sextupole magnets are used to excite the third-order horizontal resonance. The centre frequency of RF–KO is about 1.666 times of the beam revolution frequency, and the span is 0.5%.

To improve the beam time structure, one commonly used method is RF-KO with amplitude modulation (AM) and frequency modulation (FM) [4-7], and the spill ripple can be suppressed by using fast Q magnets[8-11]. The FQ control signal should be the reverse phase of ripple noise [9], Figure 1 shows the example of FQ control signal. Figure 2 shows the block diagram of the spill feedback system in CSRm.

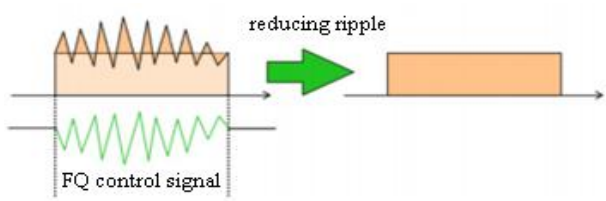

Figure 1: Spill control by FQ. [9]

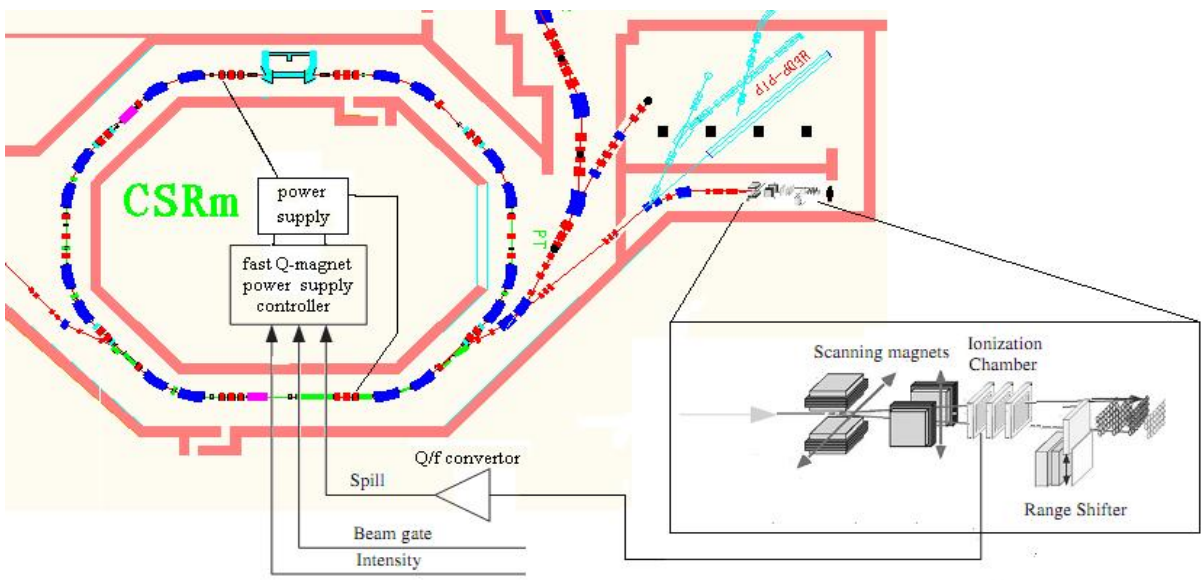

Figure 2: Block diagram of the spill feedback system.

*Work supported by NSFC…
#maorsh@impcas.ac.cn

The test set of spill control system in CSRm is based on the two methods mentioned above, system consisting of two fast Q-magnets, feedback device based FPGA and waveform generator. The beam current is measured by ionization chamber, and the output signal from Q/f convertor is TTL pulse[12], for example one pulse for 814 particles (200MeV/μ $^{12}C^{6+}$). The fast Q magnet power supply controller is (NI 7830R)[13], the parameters is shown in table 1, 1MS/s is enough for suppress the ripple lower than 500Hz. Figure 3 shows the block diagram of spill feedback processing, the maximum loop rate is 1MHz.

Table 1: Specification of NI 7830R

AO resolution	16 bits
AO update rate	1MS/s
max clock rate	40MHz
FPGA type	Vitex-2 Virtex-II 1M

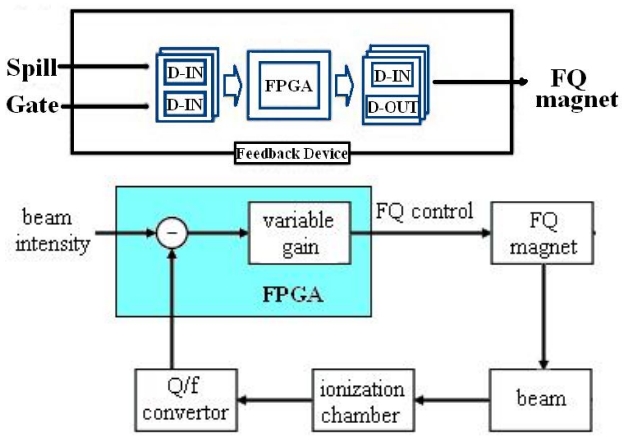

Figure 3: The spill feedback processing.

The best amplitude modulation curve [7] for RF-KO should like Fig. 4 curve(a), but the waveform generator TEK3252 [14] we have does not support real-time change of output amplitude, so we use curve(b) instead of curve(a), use software to change the output amplitude through GPIB port, refresh rate is about 35Hz.

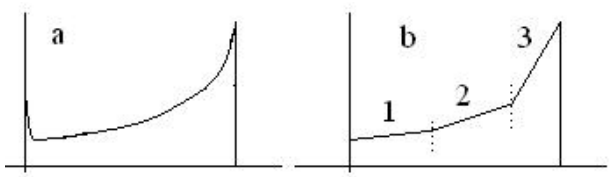

Figure 4: The AM curve for RF-KO, (a) best curve, (b) three lines.

There are two fast Q magnets symmetrically installed in CSRm, so the lattice will not change by using FQ(Fig. 5). The horizontal and vertical tune value will be change at same time because of FQ, but the change of the vertical tune value is acceptable. Table 2 shows the fast Q magnets specifications.

Figure 5: FQ and power supply.

Table 2: Fast Quadrupole Magnets Specifications

Core Material	0.5mm thick lamination steel
Bore Radius	85 mm
Magnet Length	0.30 m
Coil Turn Number	3
Field Gradient	0.2T/m@370A
Inductance	0.3mH
Resistance	4mΩ

BEAM COMMISSIONING

The commission result is shown in Figure 5. The beam in CSRm is 200MeV/μ $^{12}C^{6+}$. Normally, horizontal tune value in CSRm is set to 3.662, and RF-KO set constant RF power, Fig. 6(a) shows the beam spill. If we change the RF amplitude during extraction, beam spill and FFT result is shown in Fig.6 (b).

Because the FQ magnet power supply is still under construction, we install one BUMP magnet power supply for temporary use. This power supply is single polarity, fall time (200A-0A) is 50μs, and rise time (0A-200A) is 200μs. Before the feedback system is turn on, horizontal tune value is set to 3.660-3.661, and we find that the beam cannot be extracted without feedback system turn on under this condition. Turn on the feedback system, and carefully change the parameters set in FPGA program, finally the beam spill become flat, the best result is shown in Fig. 6(c), ripple of 50Hz and its harmonic lower than several hundreds hertz is reduced.

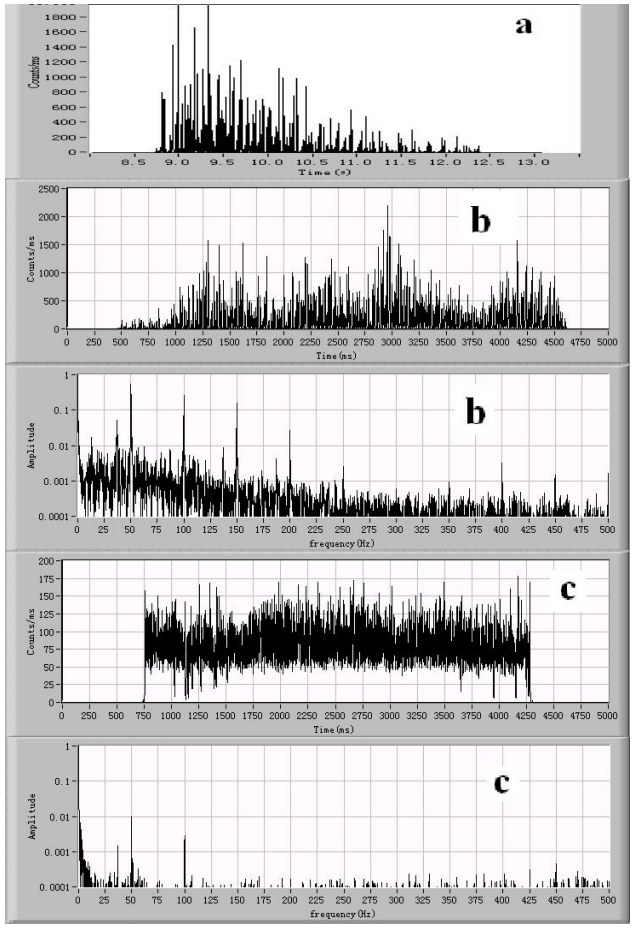

Figure 6: Beam spill structure and FFT results. (a) feedback off and RF-KO with constant RF power, (b) feedback off and RF-KO with amplitude changing, (c) feedback on and RF-KO with amplitude changing. Sample rate is 1KS/s. (200MeV/μ $^{12}C^{6+}$).

CONCLUSION AND NEXT STEPS OF DEVELOPMENT

- We finished developing the test set of spill feedback system, which consists of two fast Q-magnets, one feedback device based on FPGA, and one RF exciter based on waveform generator, and carried out the experiments in CSRm. The feedback system improved the spill structure, ripple of 50Hz and its harmonic is reduced.
- It's difficult to commission by using the single polarity power supply, so the bipolar power supply is really needed.
- The core material of fast Q magnets is 0.5mm thick lamination steel, now we begin to construct new one with 0.2mm lamination steel.

ARCHITECTURE AND CONTROL OF THE FAST ORBIT CORRECTION FOR THE ESRF STORAGE RING

F. Epaud, Jean-Marc Koch, Eric Plouviez, ESRF , Grenoble, France

Abstract

Two years ago, the electronics of all the 224 Beam Position Monitors (BPM) of the ESRF Storage Ring were replaced by the commercial Libera Brilliance units to drastically improve the speed and position resolution of the orbit measurement. Also, at the start of this year, all the 96 power supplies that drive the orbit steerers have been replaced by new units that now cover a full DC-AC range up to 200Hz [1, 2].

We are now working on the replacement of the previous Fast Orbit Correction Feedback system. This new architecture will also use the 224 Libera Brilliance units and in particular the 10 KHz optical links handled by the Diamond Communication Controller (DCC) which has now been integrated within the Libera FPGA as a standard option. The 224 Liberas are connected together with the optical links to form a redundant network where the data are broadcast and are received by all nodes within 45 µS. The 4 corrections stations are based on FPGA cards (2 per station) also connected to the FOFB network as additional nodes and using the same DCC firmware on one side and are connected to the steerers power supplies using RS485 electronics standard on the other side. Finally two extra nodes have been added to collect data for diagnostics and to give BPMs positions to the beamlines at high rate. This paper presents the network architecture and the control software to operate this new equipment.

MOTIVATION

The present Fast Orbit Correction installed in 2004 and using only 32 BPMs, 32 correctors in the horizontal plane and 16 correctors in the vertical plane, is rapidly aging and is less and less reliable. Also its' Electronics based on VME-DSP71 cards using C40-DSP and developed at the ESRF, PXI-Sundance C67-DSP cards and Windows 2000 operating systems is now obsolete. Also, we have to rely on very few spares to operate this equipment. It is working at 4.4 KHz sample frequency and corrects the beam positions in a bandwidth from 0.05Hz to 150Hz.

Also since 2 years the 224 Liberas Brilliance devices [3] connected to the 224 BPM heads and also the 48 BILT power supplies connected to the 96 steerers are in operation to perform the slow orbit correction every 30 seconds. The correction loop is performed by software using TANGO control system and several device servers reading positions data from the Liberas, calculating the corrections and writing them to the steerer power supplies over Ethernet and using standard TCP/IP protocol.

These two systems have recently being coupled [4].

Since the beginning of the slow orbit correction refurbishment we have also kept in mind the Fast Orbit Feedback upgrade and decided to use the continuous 10 KHz positions data stream delivered by the Liberas over the four 1Gbits/sec optical Links. We have also designed the BILT steerers power supplies in order to be able to apply fast correction over a RS485 serial line in addition to the slow correction coming from the Ethernet.

NETWORK ARCHITECTURE

Liberas Ring

When we bought our 224 Liberas, Instruments Technologies, the Libera manufacturer, proposed to use their standard "Gbits Ethernet protocol", but for several reasons we do prefer to use the Communication Controller protocol (DCC) developed by Diamond Light Source and already in use at Diamond and Soleil. Therefore for warranties, support and to not have to modify the Libera's embedded FPGA program, we asked to Instruments Technologies to integrate this protocol as an option of the Libera.

This add-on allowed us to connect our 224 Liberas (32 cells * 7 BPMs) all together using our standard Ethernet infrastructure. At the ESRF, the 32 cells are wired with a 12 pairs optical fibbers going to a central point behind the control room. Only one or two pairs are used for the Ethernet network and the rest is available for other purpose. Therefore we used 4 pairs to build our Liberas Fast network (4 pairs are necessary for redundancy).

The 7 Liberas of each cell are connected together with copper cables to form a primary ring then two of these Liberas are connected to the cell N-1 and cell N+1 via the optical fibber. Also two other Liberas are connected to cell N-8 and cell N+8 to make redundancy.

We had also to develop a synchronisation card which allows sending the required pulses to synchronise all the Liberas and to start the DCC, following a strict timing protocol. When the Liberas have been synchronised, the time to refresh all the X and Z positions is around 45 µs.

We have also developed tools to ease the commissioning of the Fast network, which will also be used latter during the USM (Users Service Mode) to survey this equipment. This software uses a TANGO device server which collects connections status on all the Liberas and displays them on a Java application. The Figure 1 below shows the status of the network with some faults on cell 26 which are highlighted in the window on the top to better determine the origin of the problem.

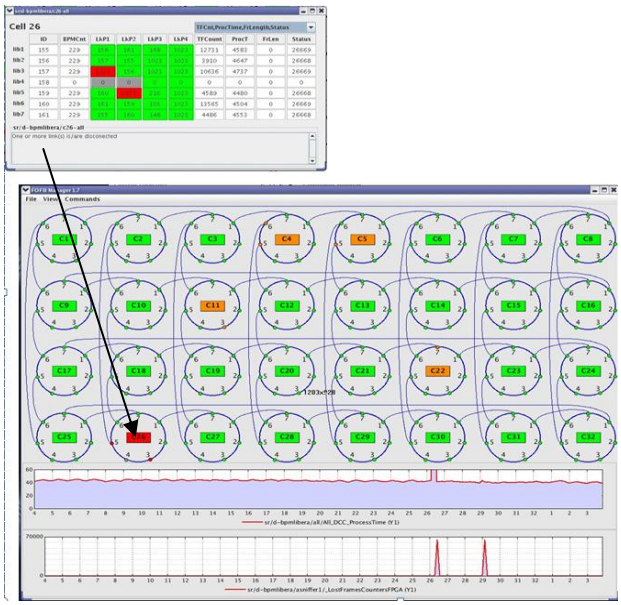

Figure 1: Java application which controls and surveys the Liberas Fast network status. Here is shown a problem with the Libera 4 of cell 26, which is not running and has lost the connection with its neighbours.

Sniffer

Even if the Liberas Fast network is running well, we need also to be able to collect the positions data. Therefore we use a PMC-FPGA-03 mezzanine module from Curtiss Wright which is connected on a PCI carrier. This module has the same optical coupler than the Liberas and allowed us to integrate the Communication Controller FPGA program to sample the data in real-time (@ 10 KHz) and sends them to a CPU with DMA cycle over PCI every 4096 frames (every 400 milli-seconds).

This card is plugged in a rackable PC running Windows XP. We finally have installed two sniffer systems: 1) To collect positions data used by a server which calculates the positions, angles, FFT and RMS in the middle of the straight sections and make them available to the beamlines, 2) To carry-on the commissioning of the whole FOFB system.

These two systems are two extra nodes of the Fast network.

Corrections Stations

At the ESRF, the steerers magnets of 8 cells are controlled by power supplies located at 4 areas around the storage ring, therefore we had to fit with this architecture already in place and had to install the corrections stations in these areas. We decided to use a card similar to the one already used by the sniffers, but more powerful and more up-to-date, the XMC-FPGA05F mezzanine module from Curtiss Wright [5]. We also used 4 Windows XP rackable PCI crates, but the FPGA simulation demonstrated that one card to handle 24 steerers was not enough and we had to use two cards per crates. This was also justified by the lack of place to connect the steerers power supplies interfaces.

Finally, each card can handle up to 14 steerers on both planes. Once again, these cards are connected to the Libera Fast network as 8 extra nodes. They collect positions data within 45 µs out of the 100 µs available, leaving 65 µs to calculate the corrections according to the correction matrix and the PID coefficients. It send also the corrections both to the steerer power supplies via RS485 and to the Fast network for debugging purpose (correction data are multiplexed at this point).

Synchronisation Mechanism

There is actually no hardware synchronisation mechanism to synchronise the start of the 8 cards of the 4 stations. They are started using TANGO group calls meaning that the jitter can be up to a few milli-seconds and more in case of network overload. This is acceptable but nevertheless we envisage to add such a mechanism.

SOFTWARE ARCHITECTURE

In fact, as far as the positions acquisition , the corrections calculation and the communication with steerer power supplies are made within the FPGA program, the control software using TANGO device servers is quite simple and is limited to provide the parameters to the FPGA cards and to survey the state of the 8 cards (See Figure 2).

FOFBCorrectionStation

This device server runs locally on each of the 4 Windows XP stations and manages two devices (one per card). One device/card can handle up to 14 steerers in both planes. Thanks to the 'fusionXP' driver, it communicates using a memory area on the PCI bus seen also from the FPGA. This area allows giving the PID, corrections and stimulus coefficients to the correction firmware. It also allows starting and stopping the correction and/or the stimulus and finally handles the errors coming from the FPGA.

FOFBCorrectionGlobal

On top of the 4 FOFBCorrectionStation device servers is the FOFBCorrectionGlobal device server allowing to manage the whole system as is there was only one correction station. This server manages two devices, one in both plane and has the knowledge of the architecture behind it. In particular it knows which steerers are managed by which stations and therefore can dispatch the corrections vectors for each steerer according to the correction Matrix provided by higher level application (matlab at the moment). Also it manages the errors of the 4 stations and can decide to stop the correction in case of problem.

FOFBSniffer

This device server handles continuously the DMA cycles coming from the FPGA via a FIFO. It collects the data and insert them into a circular buffer having a depth of 10 seconds. The clients can pick-up data on this buffer and can read BPM history. The recording can also be

frozen in order to not lose the synchronisation when several BPMs need to be read. Also the whole BPMs positions and the whole corrections values can also be read on a defined depth by one command to keep the synchronisation between data.

Applications, Commissioning

We are currently commissioning the whole system and had to develop some tools (as the LABView application below) in order to treat the huge flow of data. We also use a lot 'jive', the TANGO generic tool, to verify that the parameters coming from the higher application are dispatched on the right station and at the right place, for the right steerer. For example, this helped to discover that our steerers numbering was not the same everywhere and that the number one was the first steerer of the cell 1 for wiring aspects but was steerer 1 of the cell 4 for physics and computing aspects. One should know that at the ESRF, the first cell after the extraction to the Storage Ring is the cell number 4.

Also, Matlab is widely used by the diagnostics experts, especially this software is perfectly adapted to calculate and invert the correction matrix. Latter, an application for the Control room will be developed, may be in matlab like the previous system or in Java.

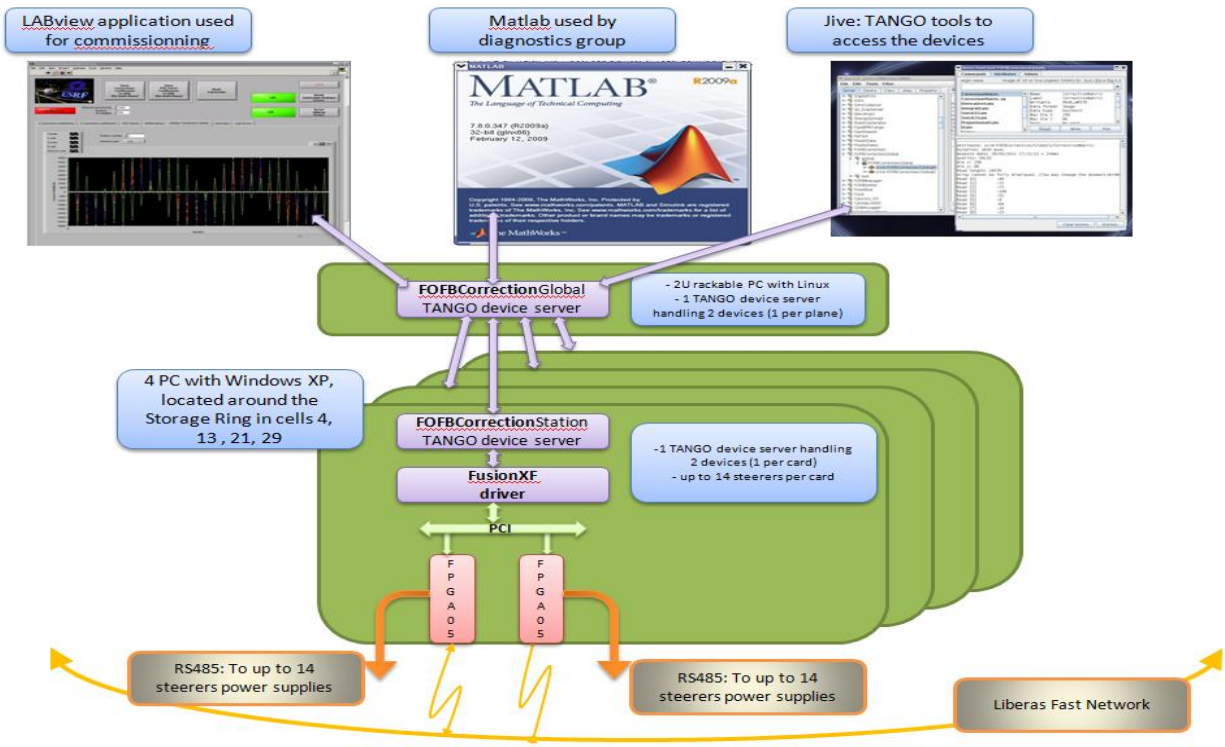

Figure 2: Software architecture of the Fast Orbit Feedback based on Liberas.

RESULTS

Very few MDT time has been allocated to the commissioning of this new equipment, therefore we are trying to make as much as possible during the USM and had to prepare carefully our MDT programs. We have also suffered from some bugs and human mistakes which provoke some beam loss or unexplained beam motion during the USM. Recently, we succeed to close the loop and to correct the beam positions in both planes [7].

DIAGNOSTICS CONTROL REQUIREMENTS AND APPLICATIONS AT NSLS-II*

Yong Hu#, Leo Bob Dalesio, Kiman Ha, Om Singh, BNL, NSLS-II, NY 11973, U.S.A

Abstract

To measure various beam parameters such as beam position, beam size, circulating current, beam emittance, etc., a variety of diagnostic monitors will be deployed at NSLS-II. The Diagnostics Group and the Controls Group are working together on control requirements for the beam monitors. The requirements are originated from and determined by accelerator physics. An attempt of analyzing and translating physics needs into control requirements is made. The basic functionalities and applications of diagnostics controls are also presented.

INTRODUCTION

State-of-the-art beam diagnostics and control systems are required for a smooth and rapid commissioning and for productive and successful operation of the NSLS-II storage ring. The NSLS-II beam diagnostics and control system is designed to monitor the electron beam of NSLS-II accelerator complex. The beam quality is measured by a variety of parameters such as bunch charge, bunch structure (filling pattern), beam position/orbit, beam size/profile, energy & energy spread, circulating beam current, tunes, beam emittance, bunch length and beam losses.

A correct measurement of beam parameters depends on the effective combinations of a variety of beam monitors, control and data acquisitions (DAQ) and high level physics applications. Figure 1 shows the relationship between these systems.

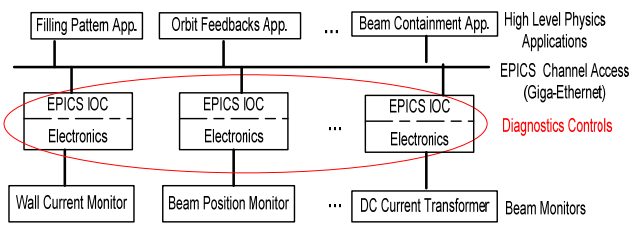

Fig. 1: NSLS-II Beam Diagnostics & Control Systems.

The following beam parameters will be monitored during regular operations:

- closed orbit (accuracy better than 10% of beam size);
- working point (tune for both planes with 10^{-4} resolution);
- circulating current (0.1% accuracy) and beam lifetime (1% accuracy);
- injection efficiency;
- filling pattern (1% of maximal bunch charge);
- emittance for both planes (10% relative accuracy);
- energy spread;
- individual bunch length (2 psec resolution);
- position of the photon beam for the insertion devices;
- coherent bunch instabilities;
- distribution of beam losses around the ring;

CONTROLS REQUIREMENTS

To measure various beam parameters, a variety of diagnostic monitors will be deployed in NSLS-II. The Diagnostics Group and the Controls Group are working together on controls requirements for these beam monitors. These Requirements are determined by accelerator physics. According to NSLS-II PDR [1], the following beam parameters will be monitored during storage ring regular operations. An attempt of analyzing and translating physics needs into controls requirements is made.

Table 1 lists the beam monitors associated with beam parameters and summaries of controls requirement.

Table 1: Diagnostics Controls Requirements

Beam Parameter	Beam Monitor	Controls Requirements
Fill Pattern	WCM, FCT, BPM button	sampling rate: 4GS/s; resolution: 8-bit; IOC rate: 10Hz
Profile/Position	Flag	Binary control for pneumatic actuator CCD: 1620*1220@15fps, IOC@10Hz
Position/Orbit	BPM	Single Pass Resolution: 30um rms 1um rms@10KHz; 0.3um rms@10Hz
Bunch Charge	Bergoz ICT & BCM	20KS/s with 16-bit; IOC@10Hz
Beam Current	Bergoz DCCT	20KS/s with 18-bit;1Hz for injection efficiency calculation;
Bunch Length	Streak Camera	Windows software by vendor
Tunes	Striplines	Ethernet-based network analyzer
Emittance & Energy Spread	Pinhole Camera	Stepper motor control with readback; CCD: 1620*1220@15fps, IOC@1Hz
Beam Stability	Spectrum Analyzer	Ethernet-based instrument control

Closed Orbit

Requirement: accuracy better than 10% of beam size. The beam position and closed orbit is measured by BPM

* Work performed under auspices of the U.S. Department of Energy
# yhu@bnl.gov

(Beam Position Monitor). The smallest beam size is expected to be 3.1 um at short ID (Insertion Device) location. So, the BPM pickup buttons and associated electronics should provide position measurement resolution (RMS noise) at 0.3um (10% of beam size) for long-term orbit drift which can be compensated by slow orbit feedback based on 10 Hz Slow Acquisition (SA) BPM data. Additionally, NSLS-II BPM system will provide 10 KHz Fast Acquisition (FA) data for fast orbit feedback (FOFB) as well as turn-by-turn (TBT) data and ADC raw data for physics studies and BPM system debugging. These applications require less position resolution, usually at tens of microns.

BPM associated with its electronics/receiver, is the key diagnostic instrument. Diagnostics Group and Controls Group are putting much effort into it. NSLS-II BPM receiver [2] provides different data flows (117MHz ADC raw data, 379 KHz TBT, 10 KHz FA and 10Hz SA) for different usages.

Working Points

Requirement: both planes with 10^{-4} resolution. There're several methods to measure tunes (the fractional par). Most of them need pickup BPM and excitation stripline. One common method is based on network or spectrum analyzer. NSLS-II revolution frequency is 378.7 KHz and the tunes are expected to be 32.35/16.28. 10^{-4} frequency resolution means ~10Hz (0.28 * 379 KHz ~100 KHz) scanning step for the analyzer. Another is to utilize (FFT) BPM turn-by-turn data to measure tunes. 10-4 resolution means that at least 5120 (1/ (2N) < =10-4, N>=5000, N = 5*1024) TBT samples are needed for FFT.

Circulating Current and Beam Lifetime

Requirement: 0.1% accuracy for circulating current and 1% accuracy for beam lifetime. This is measured by DCCT and associated electronics. Bergoz NPCT with its analog electronics can provide +/-0.1% accuracy. The NPCT has 10 KHz nominal bandwidth. Large bandwidth gives more noise in the measurement so that filtering it to 500 Hz is always a good practice. In this case, one digitizer with 1KS/s sampling rate should be sufficient. The required resolution for digitizer is determined by the requirement on accuracy of beam lifetime measurement: 2% for 20 mA with 60-hour lifetime and 1 minute measurement interval. 18-bit ADC seems adequate for all these applications.

Injection Efficiency

This is done by comparisons between the charge measured by ICTs at transport lines and that measured by DCCTs at Booster and Storage Ring.

Filling Pattern

Requirement: 20% bunch-to-bunch charge variation. Filling pattern is measured by high-bandwidth (>500MHz) diagnostics monitors such as WCM and FCT. The pulse width of the output signal from Bergoz FCT is about 1 ns. Required 20% means less than 8-bit. So, high-speed digitizer with 2GHz bandwidth, 5GS/s sampling rate and 8-bit resolution should be sufficient for fill pattern monitoring.

Emittance

Requirement: both planes with 10% relative accuracy. emittance is not directly measured by diagnostics. It's calculated from β-function value (assumed to be a constant at the dispersion free location) and beam size (measured by one pinhole CCD camera at one diagnostics beamline). 10% relative accuracy should be achievable by well-designed pinhole optics and high-resolution (1620*1220) digital camera.

Energy Spread

It's also calculated from beam size which is measured by one pinhole CCD camera at another diagnostics beamline assuming the emittance is constant and has been measured.

Individual Bunch Length

Requirement: 2 psec resolution. Bunch length is measured by streak camera which can provide 2 ps resolution.

Position of the Photon Beam

This is measured by X-ray BPM and associated electronics (current-to-voltage converter and digitizer). Additionally, the blades of XBPM are moved and positioned by stepper motors.

FUNCTIONALITIES AND APPLICATIONS

The basic functionalities of diagnostics controls can be summarized as:

- Measurement of various beam parameters (~10) via a variety of beam monitors (~16).
- Acquirement and processing of the signals from beam monitors via different electronics and EPICS IOCs.
- Provision of the processed data as EPICS PVs for high level physics applications.
- Support of Top-off operation by providing filling pattern measurement to meet the requirements of initial filling storage ring from zero to full charge at 10Hz for Linac injection and at 1(or 2)Hz for Booster injection, as well as 1-minute top-off cycle after filling up.

From the point of view of controls and applications, diagnostics and controls systems can be classified into the following groups, as shown in Figure 2:

- BPM subsystem for orbit feedbacks, lattice measuring, etc;
- Filling pattern measurements based on WCM, FCT, stripline/synchrotron light with photo-diode;
- Loss Control and Monitoring subsystem as well as injection efficiency involving ICT, DCCT, BLM and scraper;

- Camera-based diagnostics such as screen/flag, pinhole system, streak camera, and synchrotron light monitor (SLM);
- Network/Spectrum analyzer-based tune measurement and beam stability monitoring;

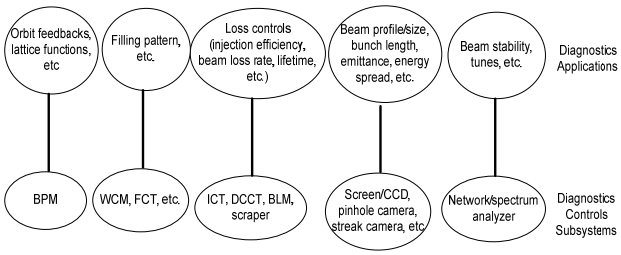

Fig. 2: Diagnostics Control Subsystems and Applications.

Orbit Feedbacks

BPM is the key diagnostics subsystem. BPM data is the source for NSLS-II storage ring fast orbit feedback (FOFB) and slow orbit feedback (SOFB). Orbit feedbacks are made of several parts including BPM pickup button, BPM electronics receiver, global BPMs data communication/exchange links, computing nodes for feedback algorithms, etc.

Diagnostics control system focuses on BPM receivers (Libera Brilliance or in-house electronics). It will provide 10 KHz fast acquisition (FA) data for FOFB over fast communication links (RocketIO-based Gigabit-Ethernet) and 10Hz slow acquisition (SA) data for SOFB over EPICS Channel Access (CA) network. Both FA and SA data from each BPM will be globally synchronized.

Besides orbit feedbacks application, BPM can be used for measuring turn-by-turn dynamics, chromaticity, dispersion, lattice functions, etc.

Filling Pattern Measurement

BPM Thanks to the high bandwidth of WCM (~3GHz), FCT (~1.7GHz), stripline (>1GHz), they can be used to observe individual bunch shape from the multi-bunch trains (80~150 bunches, 500MHz). So, WCM, FCT and stripline are chosen to measure filling pattern which is required for NSLS-II top-off operation.

The diagnostics controls will provide the data acquisition and process systems with over 1GS/s sampling rate and 8-bit resolution to observe the shape of each bunch whose duration is 2ns (500MHz) and calculate the charge of each bunch.

Loss Control & Monitoring

ICT (by Bergoz, coupled with BCM), DCCT (by Bergoz), BLM and scraper will be deployed in loss control and monitoring (LCM) which is designed for monitoring and controlling radiation losses in NSLS-II. LCM should be interlocked to top-off injection. The bunch charge losses (injection efficiency) will be monitored by ICT and DCCT. BLMs will be used to confirm beam loss locations around the ring. And scrapers can be used to intercept beam and control beam losses.

The diagnostics control system will digitize the DC voltage outputs from ICT&BCM, DCCT and then calculate the injection efficiency, beam losses rate, beam lifetime, etc.

Camera-based Diagnostics Applications

Various cameras will be used in beam diagnostics for measuring beam profile, beam size, emittance, energy spread, bunch length, etc. Screens (flags) coupled with CCD cameras placed over the whole NSLS-II accelerators are very useful to trace beam position and observe beam profile during machine commissioning. Synchrotron-light-based measurements in the Storage Ring diagnostics beamlines will be conducted on streak camera to measure bunch length and on pinhole camera to measure beam size, transverse emittances, energy spread, etc.

To standardize CCD camera controls, the digital cameras used in flags and pinhole-systems will be purchased from the same manufacture and have the same control/communication interface. Gigabit-Ethernet interface is preferable to FireWire (1394b) in terms of bandwidth, cabling, anti-EMI, etc. Prosilica Gig-E CCD camera is under evaluation. The diagnostics control system will acquire the digital image from CCD camera and then send the raw data (pixels) to MatLab-based high level application for image analyzing and processing(background subtraction, Gaussian fit, calibration, etc).

The streak camera system itself contains control & data acquisition software. It only interfaces to timing system. .

Network/Spectrum Analyzer-based Diagnostics

Tune monitor is used to measure transverse tunes by two strip-lines (signal pickup and source excitation) and one network analyzer. Beam stability monitor will observe spectrum of beam motion using one pickup strip-line and one real time spectrum analyzer.

Modern network/spectrum analyzers are usually equipped with Ethernet/GPIB interfaces and Windows XP operating system. For diagnostics controls, they can be characterized as Ethernet-based instrument control.

CONCLUSIONS

Collaboration between NSLS-II Diagnostics Group, Controls Group and Physics Group has been well established from very beginning of our project. Beam diagnostics requirements for controls are well understood.

ELECTRO OPTICAL BEAM DIAGNOSTICS SYSTEM AND ITS CONTROL AT PSI

P. Chevtsov#, F. Mueller, P. Peier, V. Schlott, D. Treyer, PSI, Villigen, Switzerland
B. Steffen, DESY, Hamburg, Germany

Abstract

Electro Optical (EO) techniques are very promising non-invasive methods for measuring extremely short (in a sub-picosecond range) electron bunches. A prototype of an EO Bunch Length Monitoring System (BLMS) for the future SwissFEL facility [1] is created at the Paul Scherrer Institute (PSI). The core of this system is an advanced fiber laser unit with pulse generating, phase locking and synchronization electronics. The system is integrated into the EPICS based PSI controls, which significantly simplifies its operations. The paper presents the main components of the BLMS and its performance.

INTRODUCTION

Free Electron Lasers (FEL) are very powerful tunable light sources for a wide spectral range with excellent coherence. One such source, the SwissFEL, will be built at the Paul Scherrer Institute in Switzerland. To achieve optimal lasing conditions for the SwissFEL, the baseline design foresees to generate electron bunches with charges between 200 and 10 pC and lengths between 10 picoseconds (ps) and a few femtoseconds (fs). Accurate and non-destructive monitoring of such short bunches during the FEL operations is not easy to implement. One possible solution of this problem can be provided by Electro Optical (EO) methods [2].

EO electron bunch length measurements are based on the interaction between the electric field E_{THz} (which is in a THz range) generated by the electron bunch and the EO laser pulse in an electro optically active crystal (such as GaP or ZnTe). The electric field can be either the direct bunch Coulomb (near) field if the measurements are performed inside the beam pipe or coherently emitted synchrotron radiation outside of the beam pipe. The field induces a birefringence in the crystal that is proportional to the applied field. This changes the polarization state of the laser pulse, which can be detected by standard optical methods.

The simplest way to determine the E_{THz} shape is to sample it with much shorter laser pulses. If the laser pulses pass a crystal with some variable time delays Δt relative to the E_{THz} field, then they overlap with different parts of the E_{THz} field and experience different polarization rotations. By measuring the degree of the polarization rotation as a function of the time delay Δt, the E_{THz} can be mapped. It is clear that this method is not single shot and requires stable measurement conditions (such as electron bunch shape and EO laser intensity) over many pulses as well as a low relative arrival time jitter between EO laser pulses and E_{THz}.

Alternatively to the E_{THz} field sampling, the E_{THz} pulse can be overlapped with a longer EO laser pulse, which will transform the entire temporal structure of the electron distribution in a bunch on a single laser pulse. The EO laser pulse is stretched in a dispersive medium or by a grating compressor leading to a chirped pulse. A temporal profile of the E_{THz} field is linearly encoded into the laser pulse and can be determined by measuring its spectrum. This single shot technique is known as EO spectral decoding. It is not sensitive to the time jitter between EO laser and E_{THz} signals but requires a treatment of frequency mixing problems.

EO BUNCH LENGTH MONITORING SETUP

A prototype of a bunch length monitoring system (BLMS) for the SwissFEL was created at the PSI. It was successfully tested in the conditions of the Swiss Light Source (SLS), the only electron machine that was available at PSI before the SwissFEL Injector Test Facility was put in operations.

There are at least two places in the SLS ring, which can directly benefit from BLMS operations. The first one is the diagnostic section at the end of the injector where typical bunch lengths are from 2 to 20 ps. The second place is the SLS FEMTO facility [3]. The facility generates coherent fs X-rays based on the beam slicing technique, which utilizes the resonant energy exchange between a long (~35 ps) electron bunch and a fs laser pulse in a wiggler or an undulator. Beam slicing also results in a small (~100 fs) gap in the longitudinal distribution of the bunch that radiates coherently in a THz range. As the bunch continues to move around the ring, the gap quickly spreads and fills with electrons. Real time monitoring of this dynamics can be used to optimize the beam slicing quality.

Because both those places are important for the SLS, it was decided to create the first BLMS as a mobile beam diagnostics station, which could easily be moved around the SLS ring.

We note that most of BLMS parameters presented in this paper are specific for the SLS but can easily be adjusted to fit the SwissFEL case.

Main BLMS Components

The core of the BLMS system is an advanced Ytterbium fiber laser unit [4] together with pulse generating, mode locking and synchronization electronics.

The laser unit was designed and built in the frames of the collaboration between the PSI and the University of

#pavel.chevtsov@psi.ch

Bern. It consists of a 50 MHz oscillator and a 1 MHz amplifier. The oscillator cavity is split in free space and fiber sections. A piezo fiber stretcher can correct the resonator length on a µm scale in order to synchronize the repetition rate to the master clock. Cavity length adjustments on a larger scale are done by free space mirrors movable by remotely controlled stepper-motors. The required EO laser operational stability is achieved with the use of laser diode controllers (ITC5xx Series, Thorlabs) and a set of heating elements connected to temperature controlling devices (CT16A, Minco). The laser diode controllers have a GPIB interface to remote computers. Temperature controllers can talk to the external world via serial (RS-232) ports.

The BLMS electronics was developed and built at the PSI. It is based on the FPGA technology and has a modular design. All active elements form two compact 19″ electronics modules: the laser synchronization (LS) unit and the universal pulse divider and generator (UPDG) unit. Both units implement RS-232 interfaces to remote computers, which allows one to relatively easily integrate them into any control system.

BLMS Controls Software and Hardware

BLMS operations at the PSI are automated with the use of controls software based on EPICS [5]. The software consists of two main parts: the laser and the LS/UDPG control modules. Both parts utilize the EPICS Stream Device support [6] package to handle RS-232 and GPIB devices.

The controls software runs on three EPICS Input Output Controllers (IOCs).

The first one is a VME based single board computer MVME-5100 running VxWorks. This IOC handles

- a PSI timing event receiver (EVR, Micro-Research) board that is used to trigger electronics equipment based on any event available from the PSI timing event distribution system;
- BLMS stepper-motors on the basis of a MAXv-8000 (Pro-Dex) VME card and standard PSI motor drivers;
- serial BLMS control devices via RS-232 ports provided by TIP-866 IPAC modules (TEWS Elektronik).

Another IOC is a LINUX microIOC (Cosylab) handling GPIB control components via an Agilent E5810A LAN GPIB multiport controller. It also runs control applications automating major BLMS operations.

Finally, the EO data acquisition and control server is implemented as a softIOC embedded on a fast digital oscilloscope running WindowsXP.

All BLMS components, except the laser unit, are placed in a mobile 19″ electronics rack. The rack is also equipped by its own EO PC. This PC primarily acts as a boot computer for the VxWorks IOC. As a result, the IOC is booted on any PSI sub-network automatically, by turning on its power, without changing its boot parameters. The EO PC also acts as a port server to access the IOC VxWorks shell and as an additional computing power for EO related EPICS development activities.

The following paragraph explains how the BLMS electronics and controls software work by way of an example of their operations for the SLS beam slicing diagnostics.

BLMS at Work

As it was shown above, EO measurements rely on a temporal overlap between a laser pulse and the electric field generated by the electron bunch in an electro optically active crystal. This requires a very good synchronization to a reference signal (RF) and a low jitter of the laser signal. On the other hand, the absolute timing is also important and needs to be taken care of. If the overlap is found once, the absolute timing should be the same after any required laser resynchronization.

In this context, a problem arises if two signals of different repetition rates have to be locked, such as, for example, the EO laser at 50 MHz and the RF at 500 MHz. As it is more precise to compare these signals at higher frequencies (the same phase mismatch at 500 MHz leads to a ten times lower temporal offset than at 50 MHz), the comparison is done at 500 MHz, which means that the 10-th harmonic of the laser repetition rate is locked to the RF. As a result, the laser can be synchronized to the reference in ten different ways in terms of the absolute timing. The following shows how this problem is solved for BLMS. It also describes how the whole synchronization system works.

The next signals are relevant for the EO diagnostics:

- RF – 500 MHz;
- EO fiber laser oscillator – 50 MHz;
- SLS revolution clock – 1 MHz;
- FEMTO slicing trigger – 2 KHz;
- SLS linac trigger – 3 Hz.

The revolution clock is synchronous to the revolution of a particular bunch in the SLS storage ring and the FEMTO slicing trigger is used for measurements of the sliced bunches.

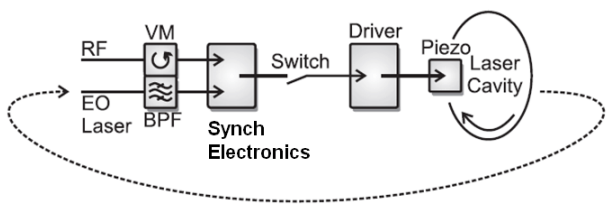

Figure 1: EO phase locked loop (PLL) scheme. The 10-th harmonic of the EO laser repetition rate generated by the bandpass filter (BPF) is locked to the RF, which can be shifted in time by the vector modulator (VM).

The 10-th harmonic of the EO laser repetition rate (see Fig. 1 above) is generated by a bandpass filter (BPF) and is compared to the RF, which can be shifted in time by a vector modulator (VM). The VM shifts the phase with a

resolution of 2^{12} steps per revolution (360°). At the RF repetition rate of 500 MHz this leads to a minimal step width of about 488 fs. Two signals are compared by the synchronization electronics, generating a correction signal. The switch between the electronics and the driver is remotely controlled in order to interrupt the PLL in case of any required interlock conditions or simply to switch the synchronization on or off. A piezoelectric device finally corrects the cavity length. The repetition rate of the laser serves as a feedback signal and is closing the loop.

In the second step, a reproducible starting point has to be found. This is done by the coincidence detector (see Fig. 2), which compares the repetition rates of the EO laser and revolution clock. As long as the signals are not synchronous the coincidence detector control software shifts the EO laser pulse in time by rotating the phase of the RF until the overlap is found. The accuracy of this method is in the order of ±5 ps, which allows one to find such an overlap very quickly.

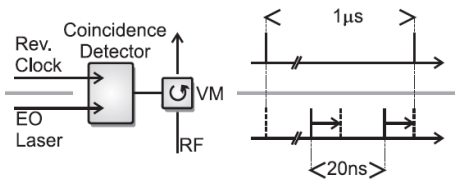

Figure 2: The second step of the EO synchronization. The coincidence detector shifts the EO laser pulse in time until coincidence to the revolution clock is achieved.

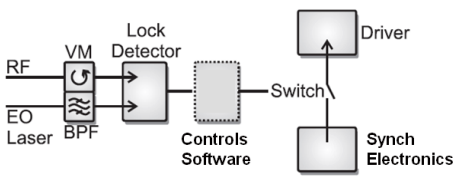

Figure 3: The lock detector control software interrupts the PLL if the offset frequency between the RF and the repetition rate of the EO laser becomes larger than 1 Hz.

In case of any malfunctions of the synchronization system, interlock signals have to be generated in order to interrupt the PLL and protect the piezoelectric fiber stretcher. It is done by the lock detector controls software (Fig. 3). As soon as the frequency difference between the RF and the 10-th harmonic of the EO laser repetition rate exceeds 1 Hz the output of the lock detector switches from logic high to low disconnecting the PLL link between the synchronization electronics and the piezo driver.

Between the oscillator and the amplifier the repetition rate is reduced to 1 MHz by an Acousto Optic Modulator (AOM). Because this pulse picker needs to be synchronous with the laser, it is triggered by the repetition rate of the EO laser. The BPF generates a sinusoidal signal at 200 MHz, which is connected to the clock of a resettable counter. The counter is reset by the 3 Hz SLS linac trigger.

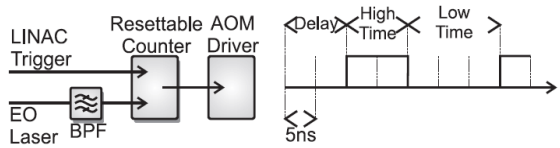

Figure 4: The trigger for the AOM is generated by a resettable counter. The delay, width and spacing can be adjusted in steps of 5 ns.

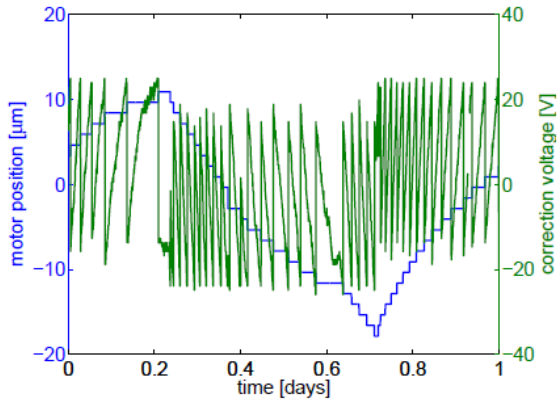

Figure 5: Typical automated corrections of the EO laser oscillator cavity length over one day. The green line is the piezo stretcher voltage, the blue line is the mirror position change.

The output is controlled in terms of a one-time delay, a high and a low time. As the device is counting with 200 MHz, these parameters can be adjusted in 5 nanosecond (ns) steps.

Besides handling the interlocks, the controls software ensures that if the piezo voltage exceeds a certain threshold then the required correction is done by one of free space mirrors. The Fig. 5 shows a typical behaviour of the piezoelectric stretcher (green line) and the mirror stepper motor (blue line), which is routinely provided by the controls software. We note that it is exactly what is expected of it.

The EO setup for the SLS beam slicing diagnostics [7] can be used for both techniques mentioned above: sampling and spectral decoding.

In case of sampling, the measurements of the signal amplitude as a function of the time delay are done by the oscilloscope software. The experiment is controlled by an EPICS high level application, which drives the VM, handles time delays, processes and stores the data.

Spectral decoding measurements are based on the use of a spectrometer. The spectrometer data are digitized and processed by embedded software, which makes these data immediately available for the control system.

CONCLUSION

The EO BLMS at the PSI has been in operations for more than one year. The system is fully integrated into the EPICS controls, which significantly simplifies all its functions. Bunch length measurement results obtained at the SLS show that the performance of the BLMS is absolutely adequate to its main task for the SwissFEL. Some additional work is required though, mostly for dealing with signal jitters in EO sampling procedures.

LOW LEVEL RF CONTROL SYSTEM FOR CYCLOTRON 10MEV*

Jiang Huang#, Tongning Hu, Dong Li, Kaifeng Liu
Huazhong University of Science and Technology, Wuhan, Hubei 430074, China

Abstract

The low level RF control system consists of a 101 MHz signal generator, three feedback loops, an interlock and a protection system. The stability of control system is one of the most important indicators in the cyclotron design, especially when the whole system has a high current. Due to the hugeness of the RF system and the complexity of control objects, the low level RF control system must combine the basic theory with the electronic circuit to optimize the whole system. The major obstacles in the research, which rarely exist in other control systems, lay in the coupling of beam and resonant cavity, requiring to be described by the transfer function between beam and cavity, the complex coupling between microwave devices and the interference signals of all loops. By introducing the three feedback loops (tuning loop, amplitude loop and phase loop) and test results from some parts of electric circuits, this paper unfolds the performance index and design of low level RF control system, which may contribute to the design of cyclotron with a high and reliable performance.

INTRODUCTION

The low level RF control system is an essential part of the RF system for CYCHU-10. The RF system should provide 12kW power to CYCHU-10 and the Frequency is 101MHz. The Specifications related to RF system are listed in Table 1.

Table 1: Main Specifications Related to RF System

Parameter	Value
Rated Power Output	12kW
Frequency Range	100.5~101.5MHz
Frequency Stability	20ppm
Output Impedance	50ohms

In the R&D of the CYCHU-10, a high power RF system has been established, which contains a klystron and its power supply and low level RF control system [1].

The low level RF control system consists of a 101MHz signal generator, three feedback loops, an interlock and a protection system. The design is basically similar to those of others electron storage rings in the world and is based on the use of conventional, stability and well-proven equipments. The scheme of low level control system is shown in Figure 1.

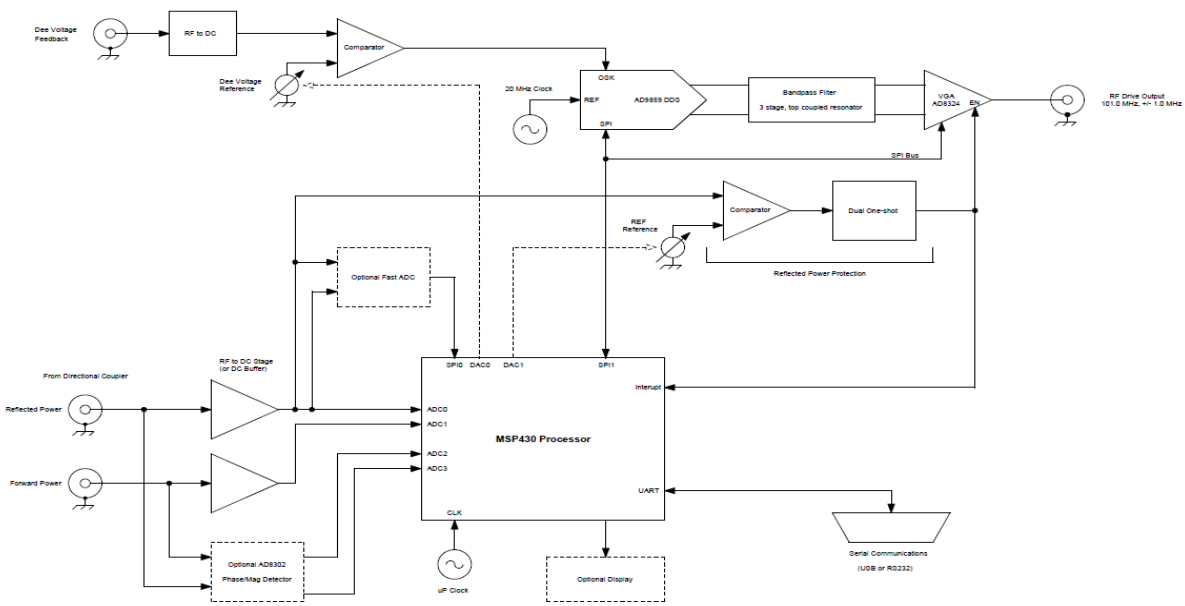

Figure 1:The scheme of low level control system.

#hjianghust@qq.com

FEEDBACK LOOPS

In the low level control system, the reference RF signal is generated by a DDS signal generator (AD9859). AD9859 is a great chip for synthesizing RF signal, which integrations a 10-bit DAC and provides 32-bit frequency tuning word. The chip also has great frequency resolution which can be 0.093Hz when system clock is 400MHz [2]. The output signal f_o is decided by system clock frequency f_s and frequency tuning word (FTW), the relationship is presented in the equation (1).

$$\begin{cases} f_o = (\mathrm{FTW})(f_s)/2^{32} \\ f_o = f_s \times (1-(\mathrm{FTW}/2^{32})) \end{cases} \quad (1)$$

In addition, the amplitude of the RF system can be achieved by adjusting the external connection resistor's value. This resistor value (R_{SET}) sets the internal DAC full-scale output current (I_{OUT}). The relationship is presented in equation (2).

$$R_{SET} = 39.19/I_{OUT} \quad (2)$$

In the above expression, the current is in A and the resistor is in Ω.

Tuning Loop

The tuning scheme is shown in the Figure 1. First, make the loop open and search the tuner position by changing the DDS's FTW. Secondly, make the loop close and compare the Reflect power and Forward power signal by phase/mag detector, then give the results to the controller. And at last, the controller set up DDS's FTW by the serial communication port, we use RS-485 in this system. The bandwidth of this loop is set up around 1 Hz. This tuning loop controls the DDS, which changes the frequency along with the cavity frequency [3].

Figure 2: The waveform of forward and reflect power.

In addition, a RF switch is set up to the end of drive amplifier, which has great effect to solve the multipactor effect. During frequency search the reflected power port can be monitored to watch the progression of reflected power level versus frequency. The waveform of forward and reflect power is shown in Figure 2. Each pulse is likely to have large spikes at turn-on and turn-off, that's because rapid change in the RF envelope spreads energy far away from the cyclotron resonance. As the frequency nears resonance and SWR becomes low enough, the controller shifts into Operate mode and applies drive continuously.

Amplitude Loop

RF signals picked up from the Dee Voltage pickup at the cyclotron, and compared with the Dee Voltage reference. Then the compared signal sent to the AD9859's OSK port, which can achieve close-cycle control of the amplitude. The protection reference value of the Dee Voltage and reflected power is setting up by the control program. Main Specifications of RF control system is shown in Table 2.

Table 2: Main Specifications of RF Control System

Parameter	Value
Power Requirement	+24VVDC, ~120mA
Forward Power Feedback Input	+10.8dBm (12 kW)
Reflected Power Feedback Input	+10.8dBm (12 kW)
Dee Voltage Feedback Input	+17dBm maximum
Forward Power Monitor Output	0-1.85VDC for 0-12kW
Reflected Power Monitor Output	0-1.85VDC for 0-12kW
Dee Voltage Monitor Output	0-2.5VDC for 0-40kV

Phase Loop

This loop is to keep phase of the fields in the cavity locked with the signal generator. RF signals picked from the direct coupler which in the front of the cavity, then sent to MSP430 processer to control DDS. The phase loop will also compensate the phase change with the RF power variance, due to the power amplifier, the circulator, the klystron, the driving electronics and so on. The components of the driving electronics are designed to have a small phase variation over a wide operating range.

The Phase Detector (PD) is the key component. The PD is a device with rather constant sensitivity against large power variations. This will prevent the effect of amplitude modulations on the operation of the loop.

SYSTEM TEST

The low level RF control system consists of a 101MHz signal generator, three feedback loops, an interlock and a protection system. It connects with the cyclotron control system by serial communication port (RS485). The RF control system is shown in Figure 3.

Monitor ports for forward power, reflected power and Dee voltage RF feedbacks are available on the front panel. These outputs, from the respective RF-to-DC converter stages, are unity-gain buffered and can drive an

oscilloscope or other >1kΩ load. No filtering is applied to the monitor outputs so response time is equal to the RF detector response. The level at the forward and reflected ports corresponding to 12 kW is approximately 1.85 VDC. The picture of control system is shown in Figure 3.

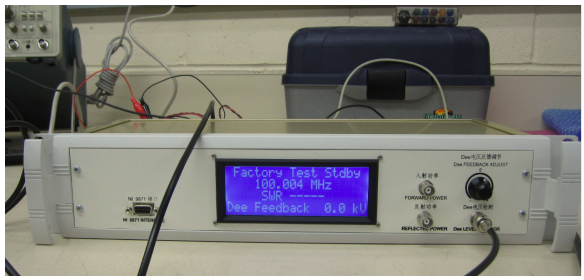

Figure 3: The picture of control system.

To prove the function of the control system, we do bench-top testing. It is possible to simulate the cyclotron load and demonstrate the controller operation using a resonant cavity. The Bird Electronics Model 211-29-05 shown Figure 4 can be adjusted to give the desired SWR, resonant frequency and feedback port attenuation for bench-top testing.

Figure 4: The picture of resonant cavity.

For bench testing an outboard amplifier is used to boost signal levels high enough for sampling by a directional coupler. The controller output drives the input of the amplifier and the controller forward and reflected inputs receive feedback from directional coupler. The picture of amplifier and directional coupler is shown in Figure 5.

Figure 5: The picture of amplifier and directional coupler.

A LabView utility program is used to set up and operate the controller. This program has a Monitor tab, shown in Figure 6, with easy-to-use command inputs and feedback of important parameters.

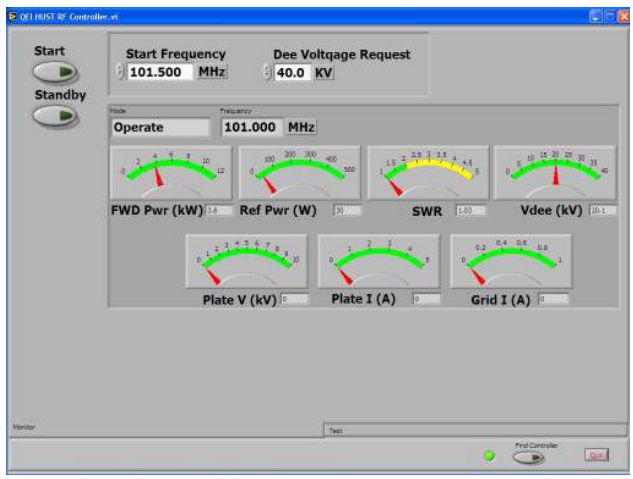

Figure 6: LabView Control Program – Monitor Tab.

The scope should show strings of four tuning pulses for each frequency step in the search. As the frequency approaches 101.00 MHz the height of the reflected pulses will become smaller and the SWR value will eventually fall below the Operate Mode threshold. At this point the controller output switches to steady-state. The process of searching resonance frequency is shown in Figure 7.

Figure 7: The process of searching resonance frequency.

CONCLUSIONS

The low level RF control system for CYCHU-10 has feedback loops which monitor Dee Voltage, Forward Power and Reflected Power. This allows the system to seek and follow the resonant frequency of the cyclotron cavity and maintain a constant Dee Voltage. The controller operating parameters are communicated via an RS485 serial interface. The system communicates using a message packet that carries commands to the system and feedback from the controller regarding its status.

The bench-top testing results of control system show that the system can achieve the designed functions. The further debugging with the whole RF system for CYCHU-10 will be carried out.

Abstract

The Korea Superconducting Tokamak Advanced Research (KSTAR)[1] plasma control system (PCS) is defined as a system consisting of electronic devices and control software, which identifies and diagnoses various plasma parameters and calculates appropriate control signals to each actuator to keep the plasma sustained in the KSTAR operation regime. The KSTAR PCS consists of a linux system with 8 processors and both analog and digital data acquisition methods are adapted for fast real-time data acquisition up to 20 kHz. The digital interface uses a reflective memory (RFM) technology to share data among various subsystems of KSTAR. RFM technology has been adopted as the real time communication method to enable PCS to interface with the actuators and to do interprocessor communications inside the cluster. To handle the fast control of the RFM data transfer, the communication using the RFM with the actuators and diagnostics system is implemented as a thread which is assigned to a separate process.

INTRODUCTION TO THE PLASMA CONTROL SYSTEM

The plasma control system is composed of real-time computers for feedback calculations, a diagnostic system for plasma information, and a communications interface with actuators. The PCS acquires plasma data from the diagnostic system and performs a feedback control loop to obtain plasma properties. Figure 1 shows the plasma control system structure. The PCS feedback algorithm calculates the difference between target and measured values, and decides how much coil current is needed in order to reduce the error from the target. Next the PCS sends coil voltages to the magnet power supply (MPS) for the desired poloidal magnetic field (PF) and receives coil current measurements from the MPS. In KSTAR this feedback operation is performed over an optical network consisting of reflective memories [2] which are high-speed replicated shared memories with up to 256 nodes featuring very low latency and wide throughput. Although the performance of the initial system [3] with a single process was acceptable, performance demand for a shaped plasma required faster control cycles up to 50 us, as well as increased interprocess communications for sophisticated magnetic controls. In 2011, the amount of I/O data exchanged in a single cycle was about 1 kB, hence the old PCI-based method was not suitable for the requirement because of 3 us time overhead for each access of the RFM space.

A method utilizing the dedicated thread for RFM is introduced for the following purpose: 1) to minimize

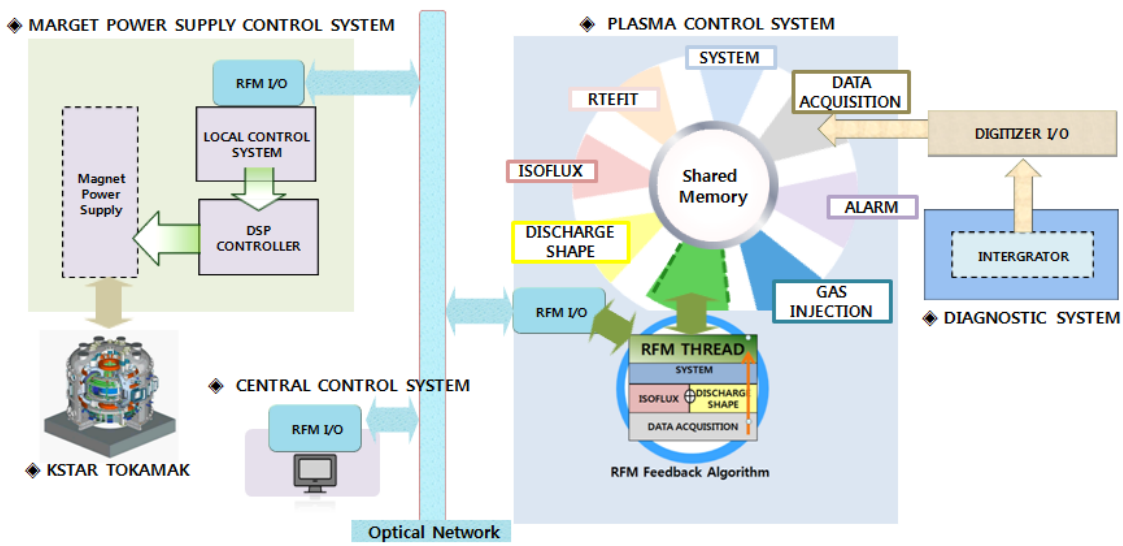

Figure 1: The structure of the plasma control system.

intrinsic time overheads for the RFM access, 2) to transfer all the RFM data within 50 us, and 3) to gather all the RFM data generated in other 3 cpu's running in the PCS via shared spaces. In this paper, we describe the principles of the RFM thread and the feedback algorithm for the PF coil control.

OPERATION OF THE RFM THREAD

The structure of the RFM thread is shown in Fig. 2. The RFM thread is spawned as a child process of one of real time processes and assigned to a separate physical processor at the start of each shot and killed at the end of the shot. The main operation of the RFM thread is to copy the RFM data to a preassigned shared memory area at every cycle to use in the feedback algorithm. In the KSTAR PCS, this shared memory is shared by all the real-time processes and is referred to as the real-time heap memory (rtheap) [4]. The rtheap is a shared memory that contains various constants and pointers to all of the other structures in the memory of the real time process. The RFM thread synchronizes itself with the real time control cycle by accessing the rtheap time counter delivered from the digitizer.

When the RFM thread starts, it calls the initialization function that creates the RFM handle, and allocates the internal memory used for communication with the RFM. If the initialization routine is successful, this routine returns the virtual address of the DMA memory address. After performing the initialization routine the RFM thread executes a continuous loop. At first the RFM thread reads values from a fixed memory area which is assigned for real-time measurement values for PF coil currents and voltages, and flags indicating the software limit defined by the central control system (CCS) or the hardware limit defined by the MPS. These measurement values are moved to an "internal buffer" memory area (see Fig. 2) and are saved in the shared memory in the same format as the acquired DMA data from the digitizers. The feedback control algorithm gets the data from the shared memory after one cycle. After reading the data, the thread waits for the current time to change by monitoring the fixed area of the rtheap. For the time synchronizations of the main and the RFM thread, a counter is used for the "new time". This counter synchronizes the internal CPU clock count of the cpu1 real-time process to the clock counter provided by the external clock of the digitizers [5]. The RFM loop waits for the counter change in order to catch this new time when the next cycle starts to determine the feedback command.

The process of determining feedback command of the next cycle is performed by the PCS feedback algorithm in the spawning process. As shown in Fig. 2, when deciding the PF coil command of the current cycle, the measured coil current of the preceding cycle is used; this coil current is the value saved in the shared memory area before the cycle. The reason for using measured value at the preceding cycle for obtaining the command of the current cycle is to reduce the feedback error occurred at the preceding cycle. The PCS feedback algorithm acquires the error value of the previous cycle by subtracting measured current in the previous cycle from the target current, and calls the PID function for adding compensation voltage at the next cycle. The answer from the PID function is sent to the RFM thread as the next PCS command. The RFM thread gathers all the commands for each MPS and writes the command to the internal buffer in order to do a DMA transfer to the fixed RFM area assigned for the MPS.

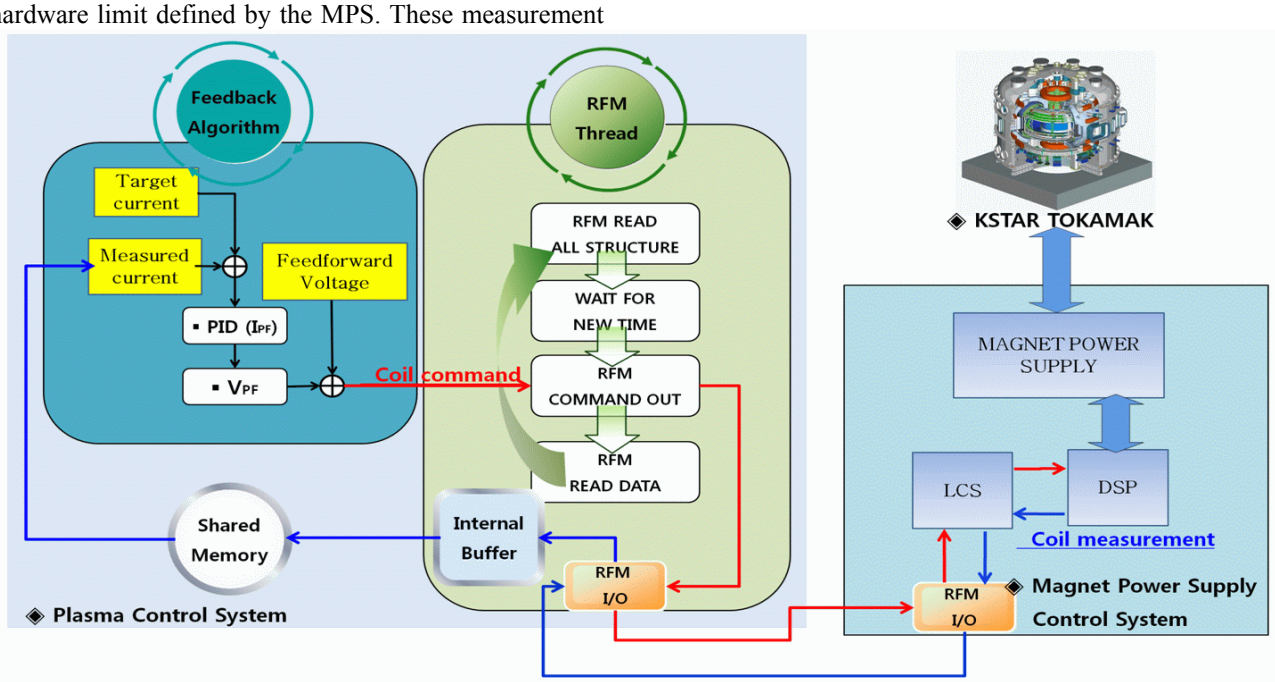

Figure 2: The RFM thread and PCS feedback algorithm.

Timeout Handling of the RFM Thread

The RFM thread has a few event handling algorithms in order to monitor its execution cycle, sync with the main thread and to prevent itself from endangering actuators under control of the PCS. The self-monitoring of the RFM loop is done by a time-out count. If the current time has not changed during the time-out period or the real-time process exits from the real time mode for any reason, the RFM thread fills zeroes in the PCS command structure which it sends to the MPS. Since the MPS (and its DSP controller) accepts PCS commands only during real-time mode, this will cause the MPS to exit out of PCS control and have the DSP controller take over control of the PF power supply. Hence the PF power supply can avoid a dangerous situation when the PCS is out of control by its own internal delay. This time-out period is set to 5 ms, which corresponds to the effective response time of a single MPS voltage command [3]. During this time-out period, the RFM thread also checks whether the main process is not updating the new time counter. If it is not, the RFM thread informs this situation to the central control system by updating a fault code so that it can spread termination signals to the other systems to abort the discharge.

Another example is a "software watchdog". This is a counter which is increased by 1 on each control cycle. Since the counter is shared as a "timestamp" in the RFM area, this counter can be monitored by any device under the same RFM network as PCS. As a kind of heartbeat, the watchdog counter is monitored by each MPS and the CCS so that it can check communication shutdown on the RFM. If the value exceeds the limit, this value sets to zero again.

When the real time mode is ON by the PCS, the CCS monitors the software watchdog counter and checks the value every 10 ms. The CCS makes a fault code to the other system, if this value is not changed by 10 ms -- which could imply that the PCS has either a communication fault or a serious internal fault such as power down or real-time process hang-up.

Some Issues about the RFM Thread

- The time counter used in the RFM operation is acquired from the digitizer. Hence the clock source of the digitizer should be accurate. If the clock source does not have good accuracy, the RFM thread will be terminated because of a timing mismatch problem.
- Although the data processing speed of the RFM thread is fast, if the MPS interface system does not operate as we expected, there is a possibility that the RFM thread receives the same data during a couple of cycles. This could cause a saturation command issue in the P loop; however, in a practical manner, the design of the algorithm considering the delays by the slower update of the measurement can avoid the saturation issue.
- When writing to the PCS command to the RFM area, the RFM thread assumes that the values in the memory structure are the most recent written by the real time process. The RFM does not keep the previous value before it is updated by the new data. Due to this property, the RFM data written by two different devices is not exactly synchronized in time. Nevertheless, the assumption is true in most cases and the data is acceptable as the most recent one if the read cycle is faster than each writing cycle by the actuators, which fits to our case.
- If the RFM thread doesn't synchronize with the real time process because of some problem such as accessing wrong memory area or time delay for writing to memory, the thread could miss cycles. Several missing cycles are reported when the RFM initialization function is called. This is due to the time overhead of the initializing hardware handle. In order to avoid timeout errors, the real time mode flag is updated as ENABLED after those missing cycles are gone, so that the PCS can get synchronized data from the MPS and the MPS can receive correct feedbacks.

The Command Structure Sent to the MPS

The entire PCS command structure is read by the local control system (LCS) of each MPS and sent to the corresponding DSP, which actually communicates with the power supply (see Fig. 2). The DSP reads each field of this command structure and decides the way of the coil control. Table 1 shows the PCS command structure sent to the MPS.

- "control method" indicates how the PF command should be interpreted (voltage or current)
- "current direction" indicates the charging direction of the PF coil. (forward or reversed)
- "timestamp" is used as a software watchdog in each control cycle (increased by one on each cycle)
- "real time mode " tells the MPS when the PCS starts the real-time feedback cycle for them.

The Data Structure of the MPS and CCS

The amount of data that is received from a single power supply is 52 bytes, but the total amount of data is about 1 kB since there are several power supplies that should be controlled by the PCS. Table 2 shows the data structure of the MPS. The RFM thread receives all of the data that is sent by each power supply at once using DMA transfer. This is possible since the memory area corresponding to each power supply is arranged sequentially.

Table 3 shows the structure used for the CCS. There is a field that indicates current time of the PCS. This field is just for reference; the CCS operates in real time mode and has the PCS fault code which is set by PCS when unusual situation is occurred. When the CCS detects the PCS fault, the CCS informs this fault code to the other systems.

Table 1: Command Structure Sent to MPS

Parameter	Description
Id	Magic id
Control method	Indicates command type of the PF coil 0: current command 1: voltage command
Current direction	Initial charging current direction 0: forward 1: reversed
Time stamp	RFM watch dog counter
rt_mode	Indicates the PCS is in real-time mode
PF command	PCS command to send to MPS
Test variable	Dummy field for test
Current trajectory	Current trajectory when voltage is selected

Table 2: Data Measurement Structure from the MPS

Parameter	Description
Id	Magic id
Voltage	total voltage form MPS
Current	total current form MPS
Time stamp	RFM watch dog counter
D-axis current	D converter output current
Y-axis current	Y converter output current
Flag	over current flag
D-axis alpha	D converter alpha degree
Y-axis alpha	Y converter alpha degree
QP voltage	Quench protector voltage
Bris voltage	Bris voltage
D-axis voltage	D converter output voltage
Y-axis voltage	Y converter output voltage

Table 3: Data Structure for the CCS

Parameter	Description
Id	Magic id
PCS current time	PCS current time
PCS fault code	Indicates what kind of fault is occurred in the PCS
Force PCS abort	Central controller uses this value to abort the PCS

CONCLUSION

We were able to transfer all RFM data within 50 us, and control the PF coil efficiently using the RFM thread. We could increase the RFM memory read/write performance by rearranging the RFM memory sequentially and using the DMA transfer. We could identify that we can manage the RFM memory efficiency by using the RFM thread.

There are some sensitive issues. We have a plan to increase the amount of data through the RFM in the future; hence, we need to increase the RFM memory performance and also upgrade the interface devices for improved communication with the PCS in the RFM network and also for better coil control.

Currently we plan to improve performance by upgrading the RFM memory card to the PCI express bus format and to improve the algorithms to safely handle other possible unintended situations.

BPM SYSTEM AND ORBIT FEEDBACK SYSTEM DESIGN FOR THE TAIWAN PHOTON SOURCE

C.H. Kuo, Jenny Chen, Y.S. Cheng, P.C. Chiu, K.H. Hu, K.T. Hsu, C.Y. Wu,
NSRRC, Hsinchu 30076, Taiwan

Abstract

Taiwan Photon Source (TPS) is a 3 GeV synchrotron light source which is being in construction at NSRRC. The BPM electronics with the latest generation FPGA and new mechanical form factor to enhance functionality of current generation products will be employed for the TPS. The prototype BPM electronics is testing. To achieve the stringent orbit stability goal of the TPS, orbit feedback system is designed to eliminate beam motions due to various perturbation sources. The design and implementation plan of the BPM system and the orbit feedback system are summarized in this report.

INTRODUCTION

The TPS [1] is a latest generation of high brightness synchrotron light source which has been under construction at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan since 2010. It consists of a 150 MeV electron Linac, a 3 GeV booster synchrotron, and a 3 GeV storage ring. The design of the storage ring has 24 cells. There are 7 BPMs and 7 horizontal/vertical correctors are winding on the sexupoles in each cell. Current generation state of the art BPM electronics is designed and delivered more than 5 years ago. To avoid obsolesce of the components, to take advantages of advanced devices and enhance functionality, it was decided to adopt new design of BPM electronics. To satisfy stringent orbit stability requirement of the TPS, low noise corrector power supply system, and orbit feedback system are also designed.

STORAGE RING BPM AND CORRECTOR LAYOUT

The design of the storage ring has 24 cells, each cell equipped with 7 BPMs and 7 horizontal/vertical correctors are winding on the sexupoles in each cell. The lattice layout is as Fig.1. The locations of BPM and correctors are to satisfy DC orbit correction under the constraint of installation space. Since vertical beam size at centre of straight section for insertion devices is around 5 μm in sigma, better than 0.5 μm beam stability are required. To meet the tight orbit stability requirement, an orbit feedback system is indispensable. Standard correctors are side winding on the sextupole magnets. These kinds of correctors could provide about 500 μrad kick while their bandwidth could be limited only several tens of Hertz due to the eddy effect of the alumina vacuum chamber. The vacuum chamber is 4 mm thick elliptical chamber with 30 mm and 60 mm in minor axis and major axis respectively. Due to eddy current effect, the possible bandwidth in horizontal and vertical plan is around several tens Hertz. This bandwidth is not sufficient to eliminate perturbation below 100~200 Hz. Therefore, extra four horizontal/vertical correctors per cell will be installed on the bellows site as shown in Fig. 1 to obtain higher correction bandwidth. These correctors have fast response but smaller kick strength around 30 μrad. Thus the orbit feedback system plans to use two kinds of correctors simultaneously. The DC component of the fast correctors will transfer from fast to slow correctors smoothly and avoid saturation of the fast correctors as well as provide capability to suppress orbit drift.

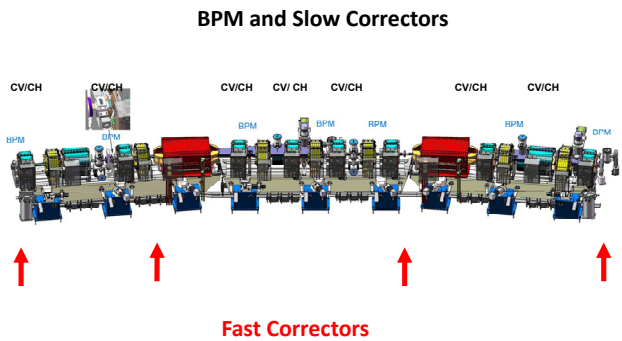

Figure 1: The slow (winding on sextupoles) and fast correctors layout in one cell of TPS storage ring.

BPM SYSTEM

BPM Electronics

The TPS BPM electronics was contracted to the Instrumentation Technologies in May 2011 for the Libera Brilliance+ as BPM electronics which is the latest member of the Libera family. The family covers the requirements of wide variety of the circular light source machines [1]. The BPM electronics delivers unprecedented possibilities for either building powerful single station solutions or architecting complex feedback systems. New electronics allows even more extensive machine physics studies to be conducted due to large data buffers and the new true turn-by-turn position calculation. There are 168 BPM units at the storage ring except some special BPM at straight sections. All 168 BPM electronic modules will installed at 48 BPM platforms. The first field tests of the new product had been performed on real beam at Taiwan Light Source (TLS) [2, 3] to test validation for the usage for the TPS. Figure 2 shows the tested installation.

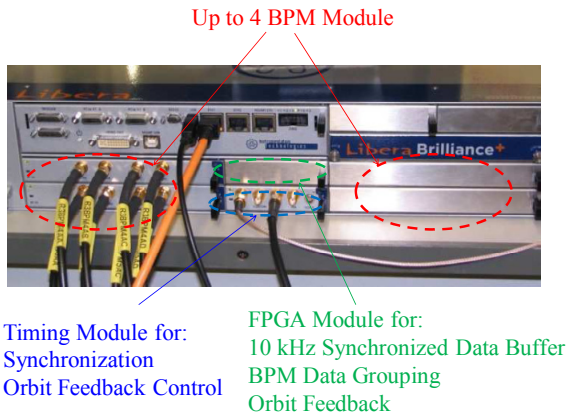

Figure 2: Libera Brilliance+ installation in the TLS.

Intensive test for performance and functionality were performed for the prototype to ensure that the new electronics satisfy the requirement of TPS. The test combined by using simulated signals from signal generator as well as real beam of the existed 1.5 GeV synchrotron light source. The long-term stability has been tested for bench measurement where input power level was set to several power level between -20 dBm to 0 dBm. Position stability is around 100 nm in rms for both planes for one day record. The temperature dependence has also been tested and almost could be ignored while ambient temperature was controlled within ± 0.1˚C. The resolution of FA data at 10 kHz meet specification where σ x and σ y is less than 150 nm. Besides, turn-by-turn data has been achieved 10 μm resolution for short bunch train.

The real beam tests at the TLS have also been performed. SA and FA reading had been acquired and analyzed for the stored beam. Current dependency affects position variation could be within 3 um from 30 mA to 360 mA. The instrument also possesses a useful feature which provides two approaches to process from ADC data to turn-by-turn data. One is classic DDC approach; another is time domain processing (TDP). This functionality is useful for peculiar filling pattern.

The preliminary testing ensures that the Libera Briliance+ BPM can meet the requirement of TPS storage ring. To simply the complexity, the same platform will adopt for the booster synchrotron also. There are 60 BPM units at the booster synchrotron. All 60 BPM electronic modules will be installed at 24 BPM platforms around the 24 CIAs.

BPM Data Access and Grouping

There are several data format flows are provided by the BPM platforms with EPICS interface, include of 10 Hz rate data for DC closed orbit correction, turn-by-turn data with software/hardware trigger and on demand access for accelerator physics study, streaming 10 kHz fast data for orbit feedback application. The fast data is also very useful for beam diagnostic.

The BPM platform is composed of a COM Express CPU module running Linux to control up to 4 BPM modules. Embedded EPICS server on this module could deliver 10 Hz rate access of BPM information, includes matrix elements of the orbit feedback system as well as handle the basic configuration.

A GDX FPGA module will be installed at the BPM platform to support 10 kHz synchronized data buffer for 4 BPM modules, and group with the other BPM platforms for the whole storage ring together. The fast orbit feedback control and fast corrector interface protocol are also processed in this module. There are four SFP ports on the front plane. There are several LVDS links in the BPM modules that can collect all ring BPM data with 10 kHz rate. The data is through the bi-directional multi-gigabit links to the adjacent nodes. Each FPGA module will serve as one node of the BPM grouping around the ring. We refer to this functionality as BPM grouping. The communication of the grouping is done by two SFP ports. The bitrate of the grouping can be up to 6.25 Gbit/sec. One of the remained SFP port will be used as fast corrector control interface with AURORA protocol. The last SFP port will provide functionality for grouping data output either use AURORA protocol or UDP/IP protocol, to support the slow corrector control or the diagnostic related application. The Ethernet packet supports jumbo frame to satisfy all BPM data grouping. Due to BPM data grouping and orbit feedback control use the same FPGA module, orbit feedback is also part of BPM platform.

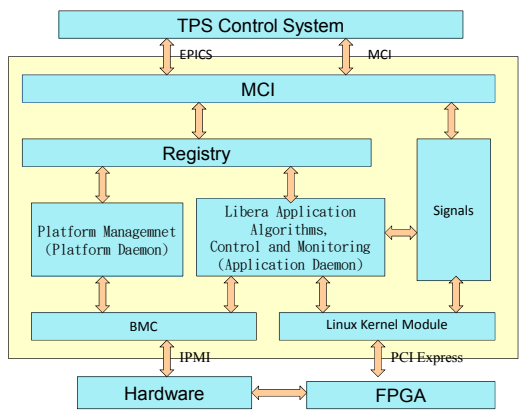

Figure 3: BPM platform software structure.

BPM Platform Software Structure

BPM platform software is organized in a few layers, see fig 3. In the bottom layer there are BMC library and Linux kernel module which communicate with FPGA and hardware through IPMI (Intelligent Platform Management Interface) and PCI Express respectively. On the top of that there is signal processing library and the application daemon for control and monitor algorithms processing. Beside application there is also platform management (Platform Daemon), which is responsible for monitoring health status of the hardware. The application and

platform daemon communicate with outer world through the MCI (measurement and control interface) which uses registry and signal library underneath for accessing application properties, signals, changing the application behavior, etc. On the top of MCI various adaptors to different control systems can be implemented [4].

ORBIT FEEDBACK SCHEME

The TPS aluminium vacuum chamber of storage ring is 4 mm thickness that prevents fast orbit correction by standard correctors in both planes which are back winding on 168 sextupole magnets. In order to satisfy fast orbit feedback request, 96 sets of fast corrector at bellows site are added. So, the TPS orbit feedback system is a global orbit feedback system combined fast and slow corrector in one system.

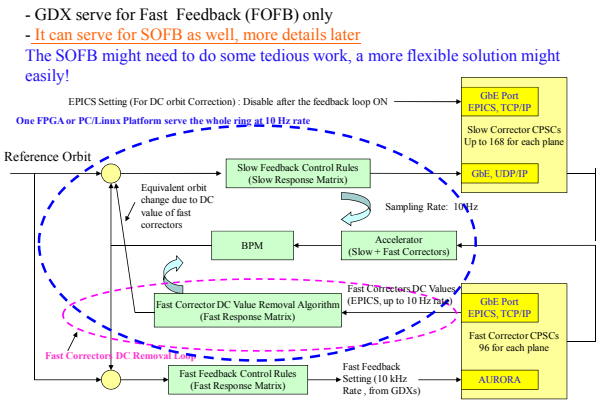

Figure 4: Control infrastructure in one cell of TPS storage ring power supplies.

Orbit Feedback Infrastructure

The infrastructure configuration of orbit feedback with fast and slow corrector is shown in Fig. 4. There are 24 cells in the TPS storage ring. Each cell will be equipped with two BPM platforms which can accommodate 7 BPM electronics at Phase I. Each BPM platforms has a slot which can allocate an FPGA module used for communication with the other module in other cells as a clockwise and counter-clockwise multi-gigabit redundancy link to group BPM data for the whole ring. Two FPGA modules of each cell will handle fast orbit feedback control algorithm and control 4 fast correctors in horizontal and vertical plane respectively. Correctors are controlled by a custom designed Corrector Power Supply Controller (CPSC) of each cell [5]. The CPSC module will be installed at slot of power supply crate to control up to 8 modules in the same chassis. At each cell, there are three CPSC modules installed at three power supply crates include of horizontal slow correctors (7 PS modules), vertical slow correctors (7 PS modules), and combined horizontal (4) and vertical (4) fast corrector. Fig. 4 shows

Besides fast correctors computation executed in FPGA modules, the slow corrector control will be handled by general purpose CPU. It would acquire the BPM grouping data through the rest SFP port of FPGA module configured as Gigabit Ethernet. The slow corrector will be controlled with 100 Hz update rate and be delivered at phase I to keep from fast corrector saturation. The slow corrector setting rate is expedited that is possible in the future. The possible candidate platform would be aTCA.

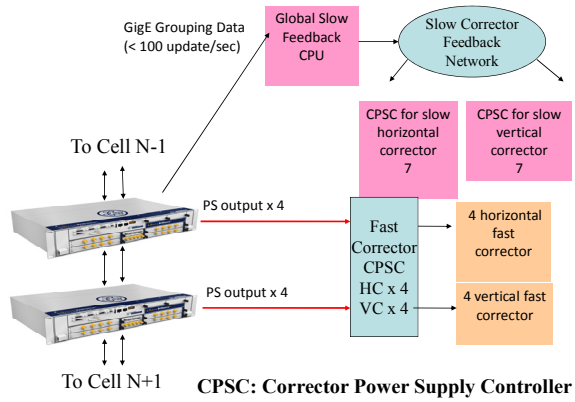

Figure 5: Configuration of global orbit feedback for corrector power supply.

Corrector Power Supply and its Control Interface

Fig. 5 shows the small power supplies applied for both slow and fast correctors and skew quadrupoles. There will be 8 power supply modules in one crate and the most left slot will be plugged in one CPSC. Besides general control, monitor and configuration, the fast correctors will be also applied for the fast orbit feedback. The CPSC with EPICS IOC is therefore dedicatedly designed and the embedded FPGA will handle fast update application. Built-in waveform and synchronization mechanism are also supported.

The power supply for both fast and slow corrector magnets in the range of ±10 Amp will be controlled by analogue interface directly. The CPSC is dedicated to be designed for both EPICS control system and fast orbit feedback application which is based on AURORA of Xilinx to support high speed communication and control. Fig. 6 shows the corrector power supply crate which includes 8 power supply modules and one CPSC at the most left slot. The CPSC with EPICS IOC is dedicatedly designed and the embedded FPGA will handle fast update application. Synchronization mechanism and built-in waveform are also supported. The setting reference of the corrector power supply is generated by 20 bits DAC and readback is from 24 bits ADC. This controller is also a embedded EPICS IOC for slow control. Fast setting ports are to receive fast data from orbit feedback module (GDX).

Control Rules Scheme

The response matrix R_s and R_f, which relates the orbit shifts to the slow and fast correctors respectively could be decomposed by singular value decomposition (SVD) as Eq. 1 and Eq. 2.

$$R_s^{+} = V_s \Sigma_s^{+} U_s^{T} \quad (1)$$

$$R_f^{+} = V_f \Sigma_f^{+} U_f^{T} \quad (2)$$

where R_s is 168×168 matrix; R_f is 168×96 matrix. These two loops of correction are operated at different platform but shared the same BPM data streaming. As well as the other light sources, to avoid saturation of fast correctors and counteraction of fast and slow loop, the different controllers would be applied for two loops respectively to separate the working frequency domain.

Figure 6: Corrector power supply crate. There are 8 power supply regulation modules in one crate and the most left slot will be plugged in one CPSC.

Fast Orbit Feedback Loop

The fast orbit feedback loop will be performed in the GDX FPGA modules in the distributed manner; each FPGA module control four fast correctors. The matrix elements download and feedback parameters will be done by the EPICS IOC located at the platform of the GDX FPGA module. All feedback loop of platform will be synchronous by grouping and external signal, such as feedback on/off.

Slow Orbit Feedback Loop

The slow orbit feedback loop processing will use PC running Linux. The individual BPM and fast corrector setting value in each cell will be combined in the local net, and transfer to a waveform type of EPICS interface to satisfy software real-time access request for slow orbit feedback control. The CPSC is also EPICS IOC that will receive slow setting value from typical EPICS interface or UDP packet port. Each CPSC module would extract their setting data by specific address within the packet.

Communication between Fast and Slow Orbit Feedback Loop

The plan FOFB system will working down to DC. A slow system will have to read the DC part of the current in the fast corrector from the CPSC module and transfer it on the slow correctors by multiply inverse of the slow transfer matrix. The two systems would not be independent; a reliable communication needs to be implemented between them. The main advantage of this solution is to reduce beam movements in the whole frequency range. This scheme were high successful in ALS and Synchrotron Soleil [6, 7].

SUMMARY

The design of the BPM system and corrector power supply system were performed for the TPS storage ring. The BPM electronics contract to the vendor in June 2011. All BPM electronics will be delivered in late 2012. Orbit feedback FPGA module is in call for tender process. Corrector power supplies will be delivered in later 2012 also. System integration is scheduled in 2013. Full scale test of the system will be possible in late 2013. Test with beam will be possible in 2014. Preliminary test for the system will be possible in 2013. All necessary hardware and software are in preparation.

Abstract

The primary (M1), secondary (M2) and tertiary (M3) mirrors of the Thirty Meter Telescope (TMT), taken together, have over 10,000 degrees of freedom. The vast majority of these are associated with the 492 individual primary mirror segments. The individual segments are converted into the equivalent of a monolithic thirty meter primary mirror via the Alignment and Phasing System (APS) and the Primary Mirror Control System (M1CS).

In this paper we first provide an introduction to the TMT. We then describe the overall optical alignment and control strategy for the TMT and follow up with additional descriptions of the M1CS and the APS. We conclude with a short description of the TMT error budget process and provide an example of error allocation and predicted performance for wind induced segment jitter.

INTRODUCTION

The Thirty Meter Telescope (TMT) is a collaborative project between the California Institute of Technology, the University of California, the Association of Canadian Universities for Research in Astronomy, the National Astronomical Observatory of Japan, the Department of Science and Technology of India, and the National Astronomical Observatory of China.

The TMT design is a f/15, wide-field, altitude over azimuth, Ritchey-Chretien telescope with a 30 m primary mirror composed of 492 hexagonal segments. The telescope when pointing at zenith is ~ 51 m high and weighs approximately 1800 metric tons.

The tertiary mirror is articulated and in combination with the large Nasmyth platforms enables the mounting of eight or more different AO/instrument combinations. The telescope will support observations from 0.31 to 28 μm. The TMT will include integrated advanced adaptive optics capabilities, including a laser guide star system, supporting diffraction-limited observations at wavelengths beyond 1 μm over most of the sky. The wide, 20 arc-minute diameter, field-of-view will enable the use of wide-field, multi-object spectrographs. The "early light instruments" that are delivered as part of the construction effort include IRIS (Infrared Imaging Spectrometer), WFOS (Wide Field Optcal Spectrometer) and IRMS (InfraRed Multi-slit Spectrometer).

TMT will be sited at Mauna Kea, Hawaii. Construction of the telescope is scheduled to begin in 2014 with first light with all 492 segments in 2021.

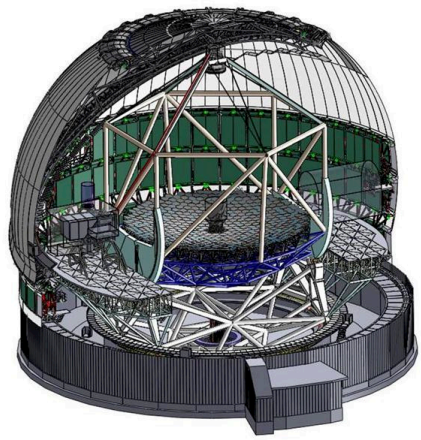

Figure 1: The Thirty Meter Telescope.

CONTROL SYSTEM OVERVIEW

The TMT image quality control architecture can be decomposed into two major systems; Active and Adaptive Optics. Active Optics (aO) is accomplished by the three mirror telescope and is responsible for the image quality of the optical beam delivered to the seeing limited science instruments or the Adaptive Optics system. The Adaptive Optics (AO) system is responsible for delivering diffraction limited image quality to the infrared instruments by attenuating the blurring effects of the atmosphere, reducing image jitter induced by the telescope drives and wind shake, and reducing residual image quality errors in the beam delivered by the aO system. The remainder of this paper is focused on the aO system.

The aO system maintains TMT image quality with a total of 11,815 degrees of freedom distributed across four principle local control loops; the Mount Control System [1], the M1CS, the M2 Control System (M2CS), and the M3 Control System (M3CS). Each of the principle control loops, with the exception of the M3CS, takes advantage of real time corrections based on on-sky measurements provided by an outer control loop. The on-sky corrections can come from one of three sources; the APS,

an Acquisition, Guider and Wave-Front Sensor (AGWFS) system located in each of the seeing limited instruments [2], or offloads from the AO system. The APS is used only when aligning the telescope optics and calibrating the sensors associated with the principle local control loops whereas the other two sources of correction are used during science observations.

An accounting of the degrees of freedom along with a listing of the key characteristics of each principle local control loop is tabulated in Table 1. Table 1 also includes a description of the relationship between each of the principle local control systems and the APS and AGWFS outer control loops used during alignment and science observations respectively.

Table 1: Characteristics of M1, M2, M3, and Outer Control Loops

Principle Local Control Loops							Alignment and Calibration Loop		Operational Outer Loop	
Name		Degrees of Freedom	Actuators	Sensors	Update Rate (Hz)	Loop BW (Hz)	Sensor	Refresh Rate	Sensor	Update Rate (Hz)
Mount	Azimuth & Elevation	2	Direct Drive	Tape encoders	≥ 40	~ 1	APS camera	Monthly	AGWFS (Guider)	1
M1	Global Tip, Tilt, Piston	3	Segment actuators	Actuator sensors	≥ 10	~ 1	Surveying/FEM	> 1 year	No outer control loop	
	Segment Tip, Tilt, Piston	1476	Segment actuators	Edge sensors	≥ 10	~ 1	APS	2 to 4 weeks	AGWFS (WFS)	0.003
	Warping Harness	10,332	Warping harness	Strain gauges	Set & Forget	na	APS	2 to 4 weeks	No outer control loop	
M2	De-center	2	Hexapod	Local encoders	≥ 10	< 1	APS	2 to 4 weeks	AGWFS (WFS)	0.003
	Tip/Tilt	2	Hexapod	Local encoder	≥ 10	< 1	Surveying	> 1 year	No outer control loop	
	Piston	1	Hexapod	Local encoder	≥ 10	< 1	APS	2 to 4 weeks	AGWFS (WFS)	0.003
M3	Tilt	1	DC drive	Local encoder	≥ 10	< 1	APS (Pupil Tracker)	> 1 year	No outer control loop	
	Rotation	1	DC drive	Local encoder	≥ 10	< 1	APS (Pupil Tracker)	> 1year	No outer control loop	

For simplicity we can describe the TMT aO image quality control strategy using five objectives. Each objective is accomplished using one or more of the four principle local control loops defined previously in combination with the APS or the AGWFS. The five objectives are M1 global shape, M1 Segment Shape, Alignment, Acquisition and Pointing, and Guiding. In practice these objectives are coupled but for the purposes of this paper we assume they are independent. Although Acquisition and Pointing is not, strictly speaking associated with image quality, it is included here for completeness. Each objective is briefly described below.

M1 Global Shape

The APS is used on-sky to determine the 2772 M1 edge sensor readings that result in the formation of the equivalent of a 30 m monolithic mirror. The APS achieves this by accurately measuring, and then positioning each of the 492 segments in piston, tip, and tilt. Once the APS determines that the global shape of the M1 is correct the corresponding edge sensor readings are recorded for later use by the M1CS.

In operation the M1CS will use the edge sensor readings recorded by the APS to maintain the overall shape of the M1 despite structural deformations caused by temperature and gravity, and disturbances from wind and vibrations. In addition the M1CS will receive low temporal and spatial frequency real time corrections from the AGWFS. These corrections reduce residual errors in the desired edge sensor readings as well as attenuate temporal and thermal drifts in the M1, M2, and M3 shapes.

M1 Segment Shape

The individual segments will have shape errors associated with polishing, coating stresses, and the support system. In addition, there will be segment shape errors associated with segment positions in the telescope deviating from their ideal positions.

The shape of each segment can be adjusted via a 21-actuator warping harnesses that is built into the support assembly for each segment. The APS measures and partially corrects, via the M1CS, the shape of each of the 492 segments using the 21 warping harness actuators. These corrections are typically made after a segment exchange and held constant until the next exchange. Ten segments are exchanged every two weeks for re-coating.

Alignment

The optical axis of the telescope is defined by the global position of the M1. The global position (piston, tip, tilt) of the segmented M1 is allowed to systematically follow the deformations of the M1 support structure due to gravity as the telescope rotates about the elevation axis in a manner that minimizes the maximum stroke of the 1472 segment actuators. To achieve this result the desired global position of the M1 as a function of elevation angle is determined via analysis of the telescope structure Finite

Element Model (FEM). Real time measurement of the global M1 position in operation is achieved by determining the best fit plane through M1 as determined by the actuator sensors

In operation the M2 is constantly re-positioned in translation to maintain alignment with the M1 and in piston to keep the optical system in focus. The proper position of the M2, as a function of telescope elevation angle, is determined on-sky by the APS. In operation the M2CS will use the translations recorded by the APS to maintain proper alignment with the M1. In addition the M2CS will receive real time corrections from the AGWFS's on-sky measurements. These corrections reduce residual errors in the M2 position determined by the APS and correct thermal and temporal drifts in the M1 and M2 positions and M1-M2 de-space.

Acquisition and Pointing

Acquisition and Pointing is the process of positioning the telescope, without on-sky feedback, so that the desired object is at the correct location on the science detector. As described above, the M1 defines the optical axis and wanders systematically with elevation angle. In addition the M3 needs to be properly positioned, as a function of telescope elevation angle, to direct the optical beam to the correct instrument

Meeting the required one arc-second RMS pointing error requirement over the full sky requires an accurate model of the non-ideal telescope structure behaviour. On a monthly basis pointing models are built using data collected with the APS acquisition camera. The pointing model is used to correct systematic structural deformations, axis misalignments, mount encoding errors, M1 motion relative to the azimuth and elevation axes, and systematic errors in the positioning of M3.

Guiding

After acquiring an object the telescope mount and the M3 must move in a coordinated fashion to remove the effects of earth's rotation and maintain the object in the correct location on the science detector. This is accomplished using the pointing models described above complemented with real time optical feedback via the AGWFS. The AGWFS is mounted in the field of view of the instrument and measures the position of a bright object relative to the nearby science object. The corrections from the AGWFS are used to maintain the science image at the correct position by correcting residual low temporal frequency pointing model errors and thermal and temporal drifts. The corrections are applied to the Mount Control System.

The M3 does not receive real-time optical feedback. Since there is degeneracy between the articulated M3 drive and the mount elevation drive, image position errors are corrected on the mount while the M3 is driven to maintain pupil alignement. This requires that the M3 rotation and tilt axes to be well calibrated.

M1CS

The M1CS is responsible for maintaining the overall shape of the segmented M1 mirror over all conditions. Properly supported, the mirror segments can be treated as rigid bodies; hence, their positions can be described by six parameters. The three in-plane motions are controlled passively via the Segment Support Assembly [3]. The three out-of-plane motions (piston, tip, tilt) are actively controlled by the M1CS via three actuators per segment and two sensors per inter-segment edge. In total the M1CS contains 1476 actuators and 2772 sensors. The M1CS also provides local control of the warping harnesses used to adjust segment shape.

The M1CS can be considered a stabilization system that works to maintain the shape of M1 based on previously determined set-points. The set-points vary as a function of zenith angle and temperature.

The starting point for the design of the TMT M1CS is the M1 control system used on the successful 10 m Keck telescopes [4]. The TMT actuators and sensors are technically challenging as a result of their aggressive cost target, and performance and reliability requirements.

The two sensors located on each inter-segment edge measure a linear combination of height difference and the dihedral angle between adjacent segments as well as providing a separate measurement of the gap between adjacent segments. The difference between the sensor measurements and the desired sensor readings determined by APS are processed by the control algorithm at a 20Hz rate to determine the actuator commands necessary to maintain the correct shape of the primary mirror. The TMT and Keck edge sensors are capacitive but the TMT design diverges significantly from the Keck design in detail. The TMT design is simpler, cost effective, and eases the effort associated with segment exchanges [5]. These benefits come with a price though; the TMT sensor is more sensitive to in-plane motions of the segments and hence requires a innovative calibration scheme.

The actuator design is based on a parallel combination of a 10 Hz control loop bandwidth closed on a voice coil using an accurate commercially available optical sensor for fine positioning and an offload loop that works to minimize the power dissipation in the voice coil. The offload loop provides the quasi-static force required to support the weight of the mirror at all zenith angles with near zero power dissipation. The voice coil control laws create equivalent stiffness and damping properties that achieve high positioning accuracy even in the presence of external disturbances such as wind [6].

In addition to the technology challenges above the TMT control design is significantly more challenging than what was required at Keck. TMT requires a 1 Hz global bandwidth for wind rejection compared to the 0.1Hz bandwidth at Keck. The required 1 Hz bandwidth coupled with the additional compliance resulting from TMT's much larger structure results in a significant Control Structure Interaction challenge which is dealt with by clever control design and adding damping to the actuators. In addition, uncertainty in the control matrix

requires significant care in determining the appropriate margins on the control design [7, 8].

ALIGNMENT AND PHASING

The APS uses a Shack-Hartmann wave-front sensor to measure and correct the shapes of the individual segments and the overall image quality of the telescope and a phasing camera to phase the individual segments of the M1. APS achieves the required image quality by using on-sky measurements and adjusting segment piston, tip, and tilt, segment surface figure via warping harness adjustments, and the rigid body degrees of freedom of M2 and M3. APS will be used after segment exchanges.

The design of the APS is based on the Phasing Camera System (PCS) used at the Keck telescopes. The alignment process and algorithms that were developed for Keck are directly applicable to TMT [9].

There are some critical differences and challenges when scaling up PCS to the APS. In both the PCS and APS, segment piston, tip, and tilt corrections are accomplished in parallel. On the other hand measurement and correction of segment shapes is a serial process at Keck whereas it will be a parallel process at TMT. In addition, at Keck the adjustment of the warping harnesses is accomplished manually in the mirror cell the day after the PCS measurements were taken. At TMT the corrections are automated allowing for efficient iteration and convergence; and therefore will be performed in the early evening of the same day as the segment exchange.

PERFORMANCE, REQUIREMENTS AND PREDICTION

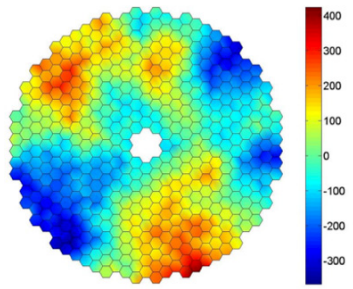
TMT is using a formalized system engineering approach to the development and flow-down of performance requirements. In addition TMT has developed and is utilizing a new metric for characterizing the seeing-limited performance of large telescopes, the normalized point source sensitivity (PSSN) [10]. In PSSN space unity means no performance degradation relative to a perfect telescope operating under identical atmospheric conditions. The overall PSSN requirement for TMT is 0.85 which is equivalent to saying that the telescope performance cannot degrade relative to the perfect telescope operating in a similar atmosphere by more than 15%.

A comprehensive description of TMT performance requirements and prediction is beyond the scope of this paper. Instead, we provide an example where we discuss the flow down of the top level requirement on segment dynamic displacement residuals to the allocation on wind driven segment motion and illustrate the corresponding predicted performance.

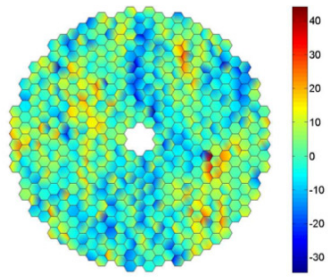
A tabulation of the errors sources and PSSN allocations is shown in Table 2. The allocation for wind driven segment motion is 0.994. Figure 2 illustrates the amount of segment jitter induced under mean wind conditions with the M1CS on and off. The results indicate that the performance meets the allocated PSSN error.

Table 2: PSSN Error Allocation for Segment Dynamic Displacement Residuals

Segment dynamic displacement residuals	**0.989**
Edge Sensor noise	0.996
Actuator noise	0.999
Segment wind buffeting	*0.994*
Segment micro-seismic vibration	0.999
Segment equipment vibration	0.999



M1CS Off, 127 nm RMS, PSSN = 0.956



M1CS On, 7.5 nm RMS, PSSN = 0.994

Figure 2: Comparison of wind driven segment motion with M1CS off and on.

Abstract

In order to preserve beam stability with nominal bunch intensity in the LHC, longitudinal emittance blow-up is performed during the energy ramp by injecting phase noise in the main accelerating cavities. The noise spectrum spans a small frequency band around the synchrotron frequency. It is generated continuously in software and streamed digitally into the Digital Signal Processor (DSP) of the Beam Control system where it is added to the pick-up signal of the beam phase loop, resulting in a phase modulation of the accelerating RF. In order to achieve reproducible results, a feedback system, using as input the measured bunch lengths averaged over each ring, controls the strength of the excitation, allowing the operator to simply set a target bunch length. The spectrum of the noise is adjusted to excite the core of the bunch only, extending to the desired bunch length. As it must follow the evolution of the synchrotron frequency through the ramp, it is automatically calculated by the LHC settings management software from the momentum ramp and RF voltage. The system is routinely used in LHC operation since June 2010. We present here the details of the implementation in software, FPGA firmware and DSP code, as well as some results with beam.

INTRODUCTION

Effective control of the bunch length in the LHC is essential to avoid loss of Landau damping leading to longitudinal instability during the energy ramp [1]. A longitudinal emittance blow-up system has been developed, inspired by the system that has been used in the SPS for several years [2]. The beam is excited with RF phase noise acting on the fundamental RF system (400.8 MHz). The frequency spectrum of the noise is tailored to the synchrotron frequency spread of the particles in the bunch so as to selectively excite a chosen portion of the particles centered around the core of the bunch [3]. The frequency of a single-particle synchrotron oscillation depends on the peak amplitude of its trajectory ϕ_{pk}

$$\Omega_s(\phi_{pk}) \approx \Omega_{s0}\left[1-\left(\frac{\phi_{pk}}{4}\right)^2\right] \qquad (1)$$

with Ω_{s0} the synchrotron frequency of the zero-amplitude oscillation. For $\phi_{pk} = \frac{\pi}{2}$ the synchrotron frequency is $\sim \frac{6}{7}\Omega_{s0}$. A rectangular frequency spectrum extending from $\frac{6}{7}\Omega_{s0}$ to Ω_{s0} will excite particles in a 1.25 ns window of the 400 MHz bucket. We extend the spectrum to $1.1\Omega_{s0}$ to guarantee that we do not miss the core. The noise is injected into the RF via the beam phase loop, whose main purpose is to keep the accelerating RF in phase with the beam [4]. The noise signal is added digitally into the phase loop error signal, "shaking" the phase of the accelerating cavity voltage with respect to the beam to produce the desired excitation.

* michael.jaussi@cern.ch

REQUIREMENTS

The system needs to generate band-limited noise that must follow the synchrotron frequency and with an amplitude that eventually achieves the desired bunch length. It must be able to run for a long period of time, since the ramping process in LHC lasts for 11 minutes (it was 40 minutes in 2010). The system must allow great flexibility in the noise generated as it was not well known at the commissioning of the blow-up process what would be the most effective settings for the beam, and how to achieve the targeted bunch length.

IMPLEMENTATION

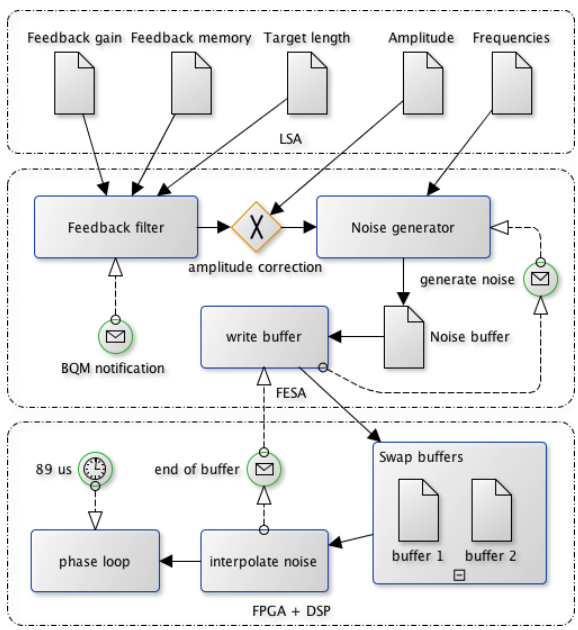

Figure 1: Block diagram showing the 3 layers.

The system is subdivided into 3 layers (see Fig. 1). From the bottom up, we have the hardware layer, implemented

in a VME board, containing a Field Programmable Gate Array (FPGA) and an Analog Devices TigerSHARC DSP, responsible for the digital processing of the beam control loops. In the CPU of the VME crate we have the device driver and the front-end software, written in C++ under CERN's Front-End Software Architecture (FESA) [5] framework. Finally we have the control system application software based on LSA [6], and written in Java, which handles settings management for the whole accelerator.

FPGA AND DSP

The FPGA and DSP are in the phase loop module of the LHC beam control. The FPGA implements a double-buffering scheme to allow continuous operation for the DSP. It provides 2 buffers of 4096 float values which are alternately filled via the VME bus by the front-end software. The FPGA presents the data one point at a time to the DSP which injects it into the phase error correction. Once a buffer is empty, the FPGA swaps the buffers and sends an interrupt to the CPU asking for the empty buffer to be filled.

The start of the noise generation is triggered from the software by writing a bit in the appropriate register. The processing rate of the phase loop is once per machine turn, so the DSP has to calculate a new value about once every 89 μs. With a synchrotron frequency varying between 60 Hz and 28 Hz during the acceleration ramp, the spectrum of the excitation data does never extend beyond 70 Hz. The DSP code specifies the rate at which the buffer should be read and intermediate samples are interpolated to achieve the 89 μs period. In the buffer, the noise samples are at the 2 kHz rate (one value every 500 μs.) so with a buffer size of 4096, we need to fill a new buffer every 2 seconds. The FPGA has a few registers for buffer handling. This allows us to set the interpolation rate, specify the buffer size (up to 4096), enable the interrupt and flag a buffer as ready. A flag is also raised when a buffer is empty and a new buffer is required.

FESA CLASS

To control the FPGA and DSP, the FESA class accepts settings from the control system and then generates the noise. The settings are :

- 2 functions for programming the upper and lower frequency during the ramp.
- 1 function for programming the maximum amplitude allowed.
- 2 functions programming for the feedback system.
- 1 scalar or function for programming the target bunch length.
- A way to start the system, either manually or through a trigger.

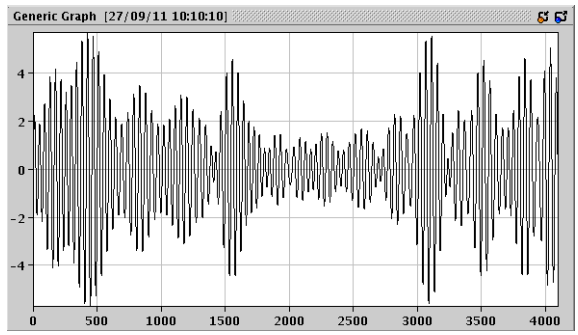

Figure 2: Noise buffer calculated by the FESA class.

As the noise generated cannot fit entirely in memory, it is generated in partial records (example Fig. 2), and we keep track of the position in time within the functions by counting the number of noise samples generated. This gives us a time precision equal to 500 μs with the current settings, which is more than good enough as the frequencies variy slowly (see Fig. 4). In order to react quickly to the interrupt sent by the FPGA when a buffer is empty, one buffer of noise is always generated in advance. When the interrupt is sent, it triggers a FESA real-time task which writes the noise data into the buffer and then acknowledges it. This task then fires a user-event which triggers another real-time task with a lower priority in charge of generating the next noise buffer. If any of the settings was updated, either by the feedback or by human intervention (such as changing a function), then the new values are taken into account at this point of time. If for some reason, the noise cannot be generated before the next interrupt, an alarm is raised and the system set the noise output to zero.

Noise Generation Algorithm

To allow the generation of precisely band-limited noise, a dedicated noise generation algorithm was developed [7]. It uses sine and cosine generators which are initialized to a random phase, scaled with a random amplitude and that generate noise in a normalized frequency range, with the generators frequencies equally spaced between 0 and 1. The noise is then translated numerically to the correct frequency range, defined by two parameters, named f_{up} and f_{low} in [7], which reflect the upper and lower bound of the range. To allow different spectral shapes, there is a weighting of all generators amplitudes, allowing for the generation of any spectrum, with a resolution depending on the number of generators. Another parameter specifies the RMS amplitude of the noise. To modulate the amplitude, each value is simply multiplied by the desired scaling.

Feedback

The feedback system is divided into two blocks. The first one is the measurement and the second one is the correction of the excitation by continuously adjusting the amplitude of the phase noise. It must be noted that, because of the next

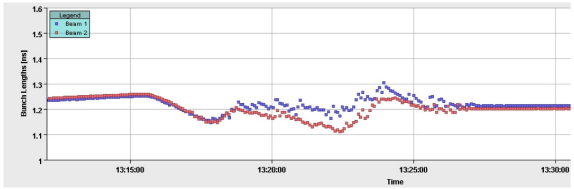

Figure 3: Four-sigma bunch length evolution during a ramp with the blow-up system set for a 1.2 ns target. Start of ramp at ∼13:16, end at ∼13:27

buffer already generated in memory, the change induced by the feedback is only taken into account for the next buffer, which might be used only after 2 to 4 seconds. This could be reduced by using smaller buffer size, but then a new noise buffer must be provided more often, inducing a bit more overhead on the CPU as more interrupts need to be handled.

Bunch length measurement: In order to see the result of the noise injected, we need to measure the length of each bunch (or at least have a mean length over all bunches). To do so, we use an existing diagnostic system called the Beam Quality Measurement (BQM) [8], which uses high-speed digitizers to acquire the signal from a wideband longitudinal beam pickup over a complete turn of the machine and then calculates from the signal a length for each bunch (see Fig. 3). The calculation extracts the Full Width at Half Maximum (FWHM) for each bunch, and estimates the 4σ equivalent length assuming a Gaussian profile. As this system is also implemented using a FESA class, it allows other systems to subscribe to the measurement, thus allowing our system to be notified each time a new measurement is available. The measurement rate of this system is about 5 seconds at the time of writing, which is rather slow, and is in fact one of the major limitations on performance of the blow-up. A upgrade is underway to improve the data rate of this system.

Filter: The feedback system is a simple low pass filter, with two variable parameters, defined as functions of time to allow fine tuning of the system. One parameter is the gain, which is increased during the ramp to compensate for the reduced sensitivity to RF noise with energy. The second one is the time constant of the filter, intended to smooth the bunch length measurements.

CONTROL SYSTEM

The control system provides a way to store, generate and send the settings to the FESA class. Most of the settings are defined as functions which vary along the ramp. Some settings are declared as being dependent on other settings. This is the case for the frequencies as they are calculated as a band around the synchrotron frequency (Fig. 4). This frequency is in turn dependent on the momentum and the RF voltage. The target bunch length (Fig. 5) is typically set

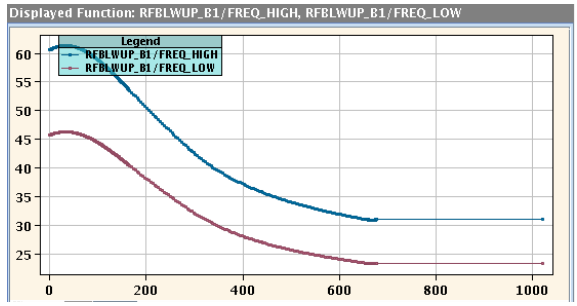

Figure 4: Upper and lower frequency bound functions in LSA. Horizontal axis: time in ramp (sec), vertical axis: frequency (Hz).

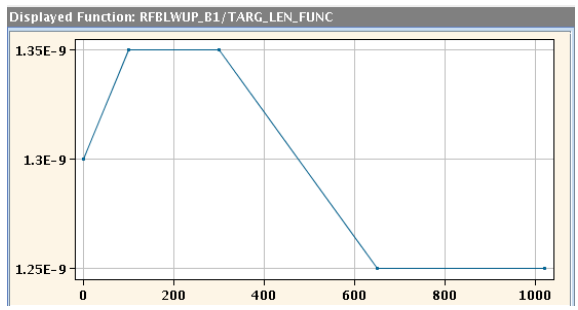

Figure 5: Target bunch length function in LSA.

to a higher value at the beginning of the ramp to mitigate the shrinking which occurs due to the increase of the RF voltage. The feedback gain (Fig. 6) is increased during the ramp as the beam becomes less responsive to the excitation as the energy increases. The control system is in charge of updating the frequency values if any of the dependent parameters changes. It is also responsible for arming the system before the ramp, allowing it to start on reception of an event from the accelerator timing system. The arming process is needed as the event used as a trigger is far from unique and could happen also when the machine stays at injection energy. Instead of having a dedicated timing, the sequencer software that prepares the entire ramp process takes care of arming the trigger. The control system also monitors any alarm that could be raised by the FESA class.

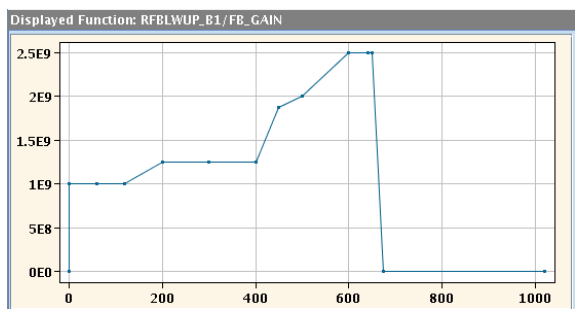

Figure 6: Gain function in LS.

RESULTS AND CONCLUSIONS

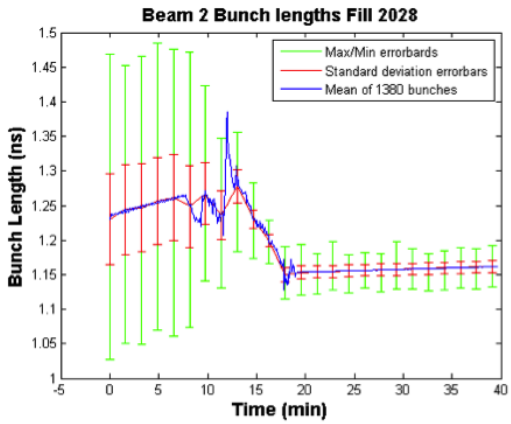

Figure 7: Statistics on bunch length (mean, min, max and standard deviation error bars) measured by the BQM during the ramp.

The first results without feedback, for a few bunches, were encouraging. It demonstrated that the system was working, but also that a feedback system was required to ensure reproducibility of the results. Once the feedback system was in place, the results were seen to be highly reproducible, and the system has been in use operationally since June 2010. A good feature of the blow-up is that it reduces the spread of bunch lengths. As can be seen in Fig. 7, the spread of bunch length at injection is large, with a standard deviation of about 60 ps, which after the ramp is reduced to around 15 ps. We often observe periods of very fast change in the measured bunch length, and this limits the final accuracy of bunch length control. We believe that these transients come from a change in bunch profile that has a significant impact on the FWHM measurement without much increase in longitudinal emittance. This has an impact on the stability of the feedback and sometimes results in missing the target bunch length at the end of the ramp. To mitigate this type of problem, the BQM system is being updated to provide measurements at a higher rate, which will allow higher feedback gain settings without becoming unstable.

OPERATIONAL STATUS OF THE TRANSVERSE MULTIBUNCH FEEDBACK SYSTEM AT DIAMOND

I. Uzun, M. Abbott, M.T. Heron, A.F.D. Morgan, G. Rehm
Diamond Light Source, Oxfordshire, UK

Abstract

A transverse multibunch feedback (TMBF) system is in operation at Diamond Light Source to damp coupled-bunch instabilities up to 250 MHz in both the vertical and horizontal planes. It comprises an in-house designed and built analogue front end combined with a Libera Bunch-by-Bunch feedback processor and output stripline kickers. FPGA-based feedback electronics is used to implement several diagnostic features in addition to the basic feedback functionality. This paper reports on the current operational status of the TMBF system along with its characteristics. Also discussed are operational diagnostic functionalities including continuous measurement of the betatron tune and chromaticity.

INTRODUCTION

The 3 GeV Diamond storage ring is currently serving photon beam for users with a current of 250 mA in a multibunch fill of 900 bunches. In addition, a hybrid mode where 3/4 of the ring filled with a multibunch and a high intensity single bunch sitting on the opposite side is run for certain experiments. Multibunch instabilities have been clearly observed and studied at Diamond from the early days of commissioning [1]. Indeed the operation with the nominal zero chromaticity lattice is prevented at multibunch currents as low as 10 mA in a uniform fill with 936 bunches. Therefore, it was necessary to create a transverse multibunch feedback system to combat the instabilities towards achieving our final target current of 300mA in multibunch mode.

OVERVIEW OF THE TMBF DESIGN

The Diamond TMBF System is a wideband feedback correcting the positions of individual bunches, spaced 2ns apart. Figure 1 shows the system level structure of the TMBF system. It is composed of a detector in terms of pickup buttons, hybrids (Figure 2) and an in-house developed RF front end (Figure 3) inspired by an existing ESRF design, a commercial digital FPGA based feedback electronics called Libera Bunch-By-Bunch from Instrumentation Technologies [2], stripline kickers and 100W power amplifiers.

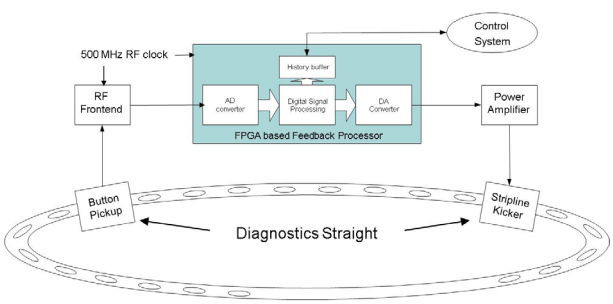

Figure 1: Block diagram of the Diamond TMBF system.

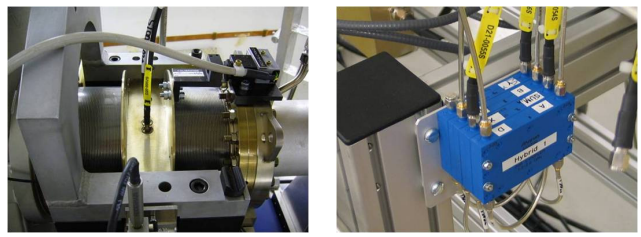

Figure 2: 4-button pickups and hybrids installations in the ring.

Wideband position signals are picked up by a set of four button pickups, and then passed through a set of hybrid combiners to generate the X and Y position signals. These wideband signals are passed to an RF front end, where the signal is mixed and filtered to 0-250 MHz baseband signal and then amplified to the correct level for the electronics.

The position signal is directly sampled at the RF frequency with 4 ADCs (f_{rf} = 500MHz and $f_{adc} = f_{rf}/4$). On the basis of the betatron motion measured for each bunch, FPGA-based electronics performs FIR (Finite Impulse Response) filtering to feedback the signal

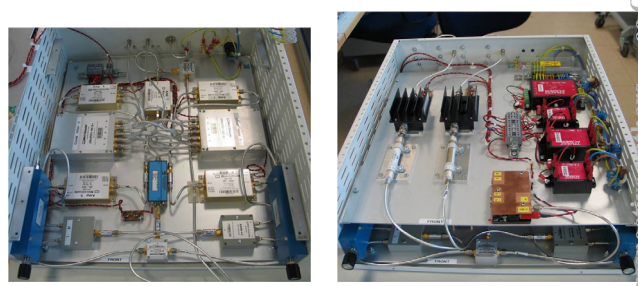

Figure 3: In-house developed RF front end occupies a 3U 19" rack and built over two layers. The bottom layer (left) houses the input comb filters and the mixer, while the the timing module, output filters, splitters and power supplies are located on the upper layer (right).

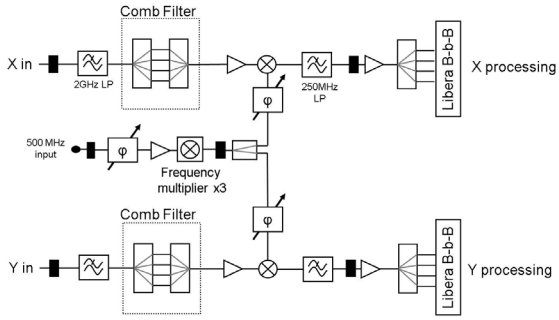

Figure 4: RF front end schematics. A phase shifter was added on the 500MHz RF clock input path to compensate electron beam phase shifts relative to the RF clock.

necessary for oscillation damping of a given bunch turn by turn. This information is passed to a power amplifier which, through some low pass filters, drives two sets of kicker striplines differentially (one in X and one in Y) to apply the corrections to the beam.

The details of the TMBF system and its FPGA-based digital feedback processing capability have previously been discussed [3, 4]. Since our last status report [5], the main modification on the system was the addition of a phase shifter operating at 500MHz to the local oscillator chain in the front end electronics as shown in Figure 4. This was required as the RF phase of the synchrotron drifts slowly relative to the 500MHz timing signal. This has the effect of moving the sampling point on the bunch. If the phase shift is too large, the sample point moves off the bunch completely and the tune signal disappears. As the drift is very slow (on the order of days or weeks), this new phase shifter is not in a control loop; rather the operators can adjust the bunch intensity as necessary.

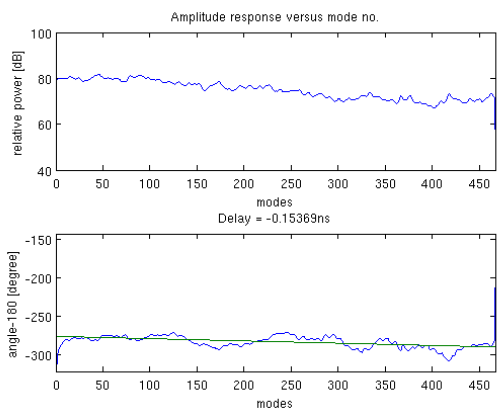

Figure 5: Variation of loop gain (top) and open loop phase response (bottom) as a function of mode number for the horizontal plane. The straight-line fit on the phase response reports 153ps of loop delay.

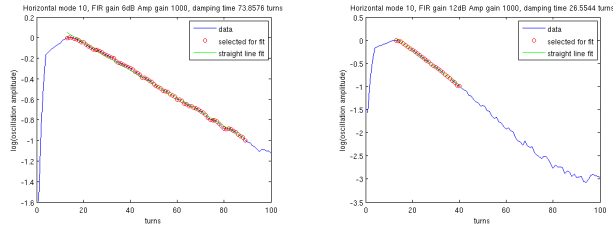

Figure 6: Damping time measurement for mode 10 in the horizontal plane. The fitting reports 73 and 25 turns damping time at FIR gains 0dB and 12dB, respectively.

PERFORMANCE

The stability of the feedback loop for all 936 modes is studied by exciting the beam at each mode frequency in turn using the internal Numerically Controlled Oscillator (NCO) and measuring the amplitude and phase response of the open loop at the output of the feedback FIR filter as shown in Figure 5. A straight-line fit on the phase response gives the overall loop delay, which guarantees a successful loop closure in terms of feeding back on to the right bunch in the train. The loop delay is tuned in 2ns steps in the FPGA, whilstt further tuning within the 2ns is achieved by modifying cable lengths in the loop.

To characterise the TMBF system, the feedback loop can be opened and closed momentarily in order to measure the growth and damping rate of individual modes. This measurement is carried out under the control of FPGA frequency sweep logic and internal timers. The routine to measure the damping time has been further automated to include post processing, including a straight-line fit on the decay. This produces a single number (the damping time) as an output. Figure 6 shows a typical damping time measurement.

Figures 7 shows a damping time scan for all modes in the horizontal plane at 250mA beam current with 2/3 fill and chromaticity set to 2. The damping time increases with rising mode number, as the gain of the feedback loop decreases with rising frequency. This is the conglomerate effect of the RF front end, the ADC, the drive amplifiers and the striplines. However, at low modes, where resistive wall effects drive instabilities more strongly, we achieve damping times of 73 in Horizontal and 82 turns in Vertical plane with FIR gain set to 0dB.

The feedback loop has been successfully closed to stabilise the beam up to 300mA with full fill, which is more challenging than the usual 2/3 fill. Figure 8 shows the transverse beam sizes as captured on a pinhole camera when the beam is stabilised by the feedback and when the beam is unstable without being lost.

In order to facilitate the measurement of the system characteristics and performance, a set of high-level graphical user interfaces has been developed using Matlab (Figure 9). It is our aim is to carry out these measurements routinely in order to understand the machine behaviour.

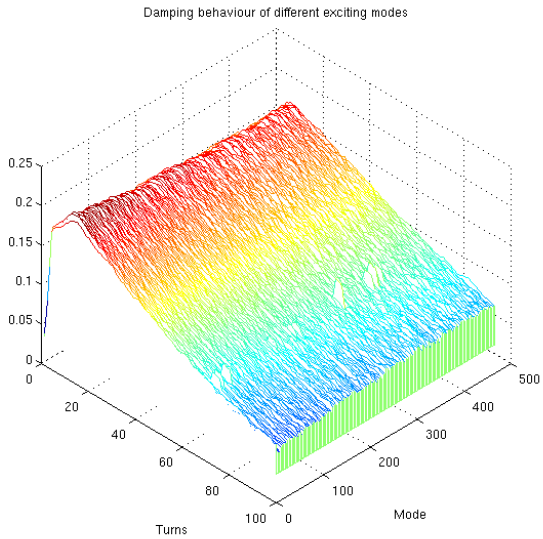

Figure 7: Damping time measurement for all instability modes in the horizontal plane.

FPGA DIAGNOSTICS APPLICATIONS

The ability of the FPGA design to act on a selected single bunch in terms of applying feedback or excitation, or simply doing nothing, has enabled us to develop techniques for online tune and chromaticity measurements with no visible disturbance to user beam [6].

Measurement of continuous betatron tune with no visible disturbance to the user beam is achieved by exciting only a single bunch at a frequency near the nominal tune. The bunch motion is then detected by mixing the measured bunch position with a sine and cosine output of the excitation frequency and accumulating the result for a certain period over 100 turns. The excitation sweep is repeated for 4096 different frequencies with small increments and completed in less than a second. The result is delivered by the FPGA as waveforms of I and Q value per frequency point through the control system interface as shown in Figure 10.

The frequency-sweeping-based excitation for the tune measurement also produces information about the synchrotron oscillation sidebands to the tune. From the relative magnitudes of the tune sidebands, the chromaticity (tune shift with energy shift) can be derived. This application is currently in the commissioning phase, and is used at machine start-up when the chromaticity is assumed to be constant. It will subsequently be employed during user operation and allow us to replace an invasive measurement with a passive one giving a measurement of the chromaticity from the tune spectrum available every second. In doing so it will both reduce the impact on machine operations and improve our understanding of the behaviour during run time. Work-in-progress test results recorded on our stripline tool are shown in Figure 11.

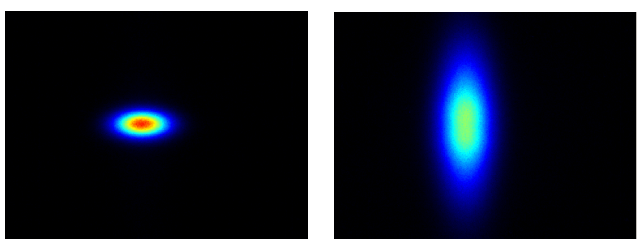

Figure 8: Pinhole screen captures of the electron beam with TMBF on (left) and TMBF off (right) at 250mA, 2/3 fill and chromaticity set to 0.

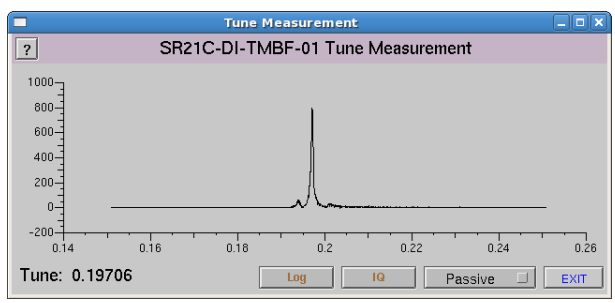

Figure 10: Online tune measurement (horizontal plane). The raw IQ data from FPGA can also available as Epics waveforms.

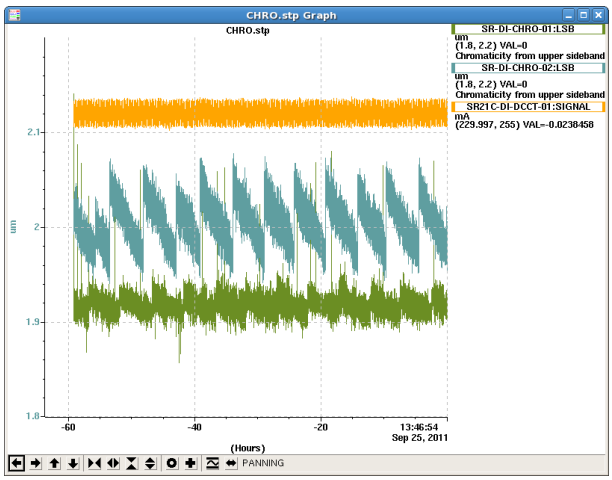

Figure 11: 60hrs of online acquired chromaticity data from the tune sidebands of a single bunch during top-up operation. Presently there is no bunch charge adjustment which explains the zig zag pattern.

CONTROL SYSTEM INTERFACE

The operation of the TMBF system is fully integrated into the Diamond EPICS control system. The user interface is divided into two modes of operation. The "Simple Mode" provides the higher level control interface in order to operate the TMBF system and reports basic status information such as feedback status, bunch amplitudes and the tune value (Figure 12 left). The "Expert Mode" provides a comprehensive control interface enabling access to all lower level control parameters on the FPGA (Figure 12 right). The expert mode is used mainly for commissioning and system debugging purposes.

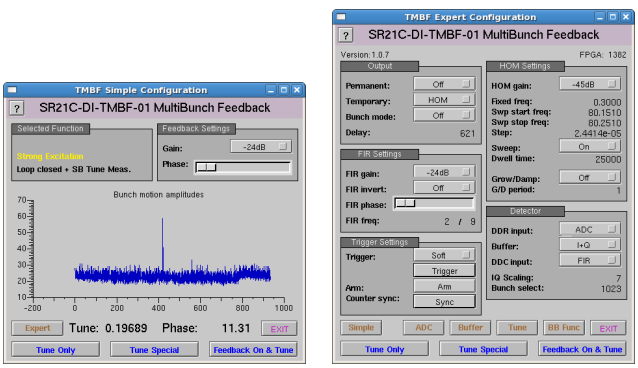

Figure 12: EPICS user interfaces. The selected function panel on the Simple Mode screen (left) shows that the feedback loop is closed and the single bunch tune measurement is activated as well. The spike on the bunch motion amplitude window confirms the excitation of a single bunch used for online tune measurement. The Expert Mode screen (right) provides access to all control registers.

CONCLUSIONS

The current status of the TMBF system at Diamond has been reported along with its performance. The feedback system has proven its ability to correct horizontal and vertical instabilities at 250mA with chromaticity set to 0. The feedback system is fully integrated into the EPICS control system for machine operation and supported by a useful set of Matlab applications for system analysis purposes.

USING TANGO FOR CONTROLLING A MICROFLUIDIC SYSTEM WITH AUTOMATIC IMAGE ANALYSIS AND DROPLET DETECTION

O. Taché, F. Malloggi
IRAMIS, LIONS, UMR SIS2M 3299 CEA-CNRS, CEA-Saclay, Gif-sur-Yvette Cedex, France

Abstract

The microfluidics is the science and technology of systems that process or manipulate small amounts of fluids, using channels with dimensions of tens to hundreds of micrometers. Since a decade microfluidics has become a powerful tool for fundamental and applied researches. Microfluidics influence subject areas from chemical synthesis and biological analysis to optics and information technology. At CEA / LIONS, we integrate microfluidics technology in several research projects. The present work deals with the development of tools for the detection and the analysis of complex calibrated micro-drops.

Although this technique uses small volume of chemicals, it requires the use of numbers of accurate electronic equipments such as motorized syringes, valve, pressure sensors and video cameras with fast frame rate coupled to microscopes.

We use a TANGO control system [1] for all these heterogeneous equipments in microfluidics experiments and video acquisition. We have developed a set of device servers which allow image acquisition and droplets detection (size, number, velocity) almost in real time.

Using TANGO, we are able to provide feedback to actuators, in order to adjust the size and the rate of the droplet formation.

MICROFLUIDIC PRINCIPLES

This technology is based on the manipulation of continuous liquid flow through microfabricated channels. In the lab we use rapid prototyping of polymer (polydimethylsiloxane-pdms) casting [2] and we designed original microfluidic chips for droplet formation.

The basic principle is the following. Two immiscible fluids (oil and water for instance) meet at a cross junction (see Figure 1a-b). Due to the viscous shear the liquid/liquid interface is deformed until a drop is created. In this particular case the local shear is well controlled leading to a very reproducible process [3]. The straightforward consequence is the formation of a monodisperse emulsion as it can be seen on the Figure 1c where a droplet crystal is shown.

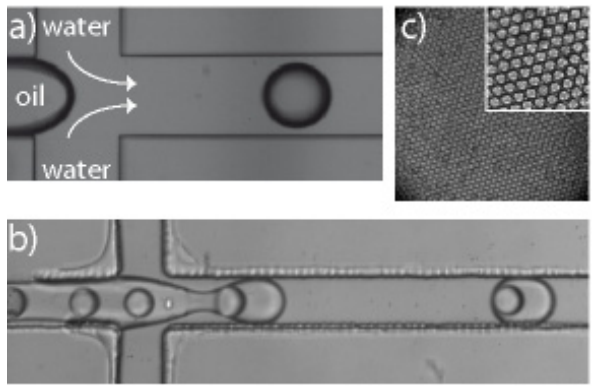

Figure 1: a- Droplet formation at a cross junction. b- Complex droplet formation at a cross junction (double emulsion). c- Crystal of droplets.

MICROFLUIDIC SYSTEM DESCRIPTION

The microfluidic system used here (see Figure 2) is composed by Nemesys [4] motorized syringes, an inverted microscope (Olympus IMT-2) with a x10 magnification objective and a fast video camera Phantom from Vision Research [5]. Syringes system and video camera are controlled by the computer. This combination gives a pixel size on images of 1.92µm.

For producing oil drops we use two syringes filled with water+surfactant and one filled with oil. Products are injected in a dedicated microfluidic chip designed in the laboratory. Flow rate can vary typically from 0.1µl/min to 50µl/min.

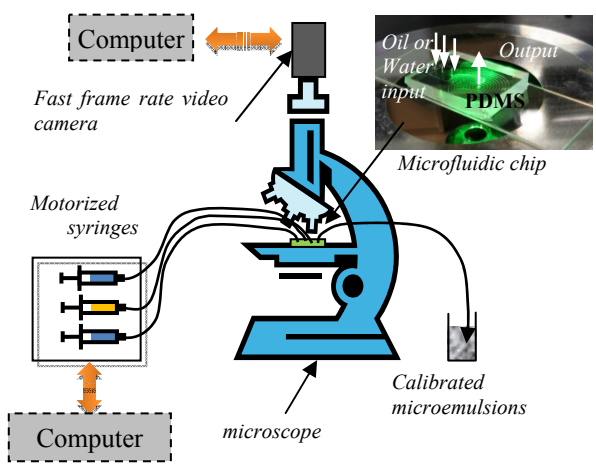

Figure 2: Sketch of the experimental microfluidic system.

CONTROL-COMMAND SYSTEM DESCRIPTION

We use TANGO as the control-command system. TANGO is an object oriented distributed control system based on CORBA and is being actively developed as a collaborative effort between the Alba, Desy, Elettra, ESRF, FRM II, MAX-lab and Soleil institutes.

This system can interface each component of the experience, whether hardware (sensors, motors...) or software, and distribute them over a network. TANGO operates like a software bus, allowing all system components (called device servers) to communicate (see Figure 3).

TANGO provides generic tools for configuration, testing, deployment, supervision. This facilitates the developments and changes to the experiments.

LIONS have developed a package of tools in Python language; enable us to write Python scripts in order to control TANGO device servers in command line.

TANGO Device Servers

The Phantom video camera is interfaced with a C++ device server based on PhCon (control libraries for the Phantom high speed cameras given by Vision Research). For testing, we also use TANGO devices that can publish previously recorded images or video on image attributes.

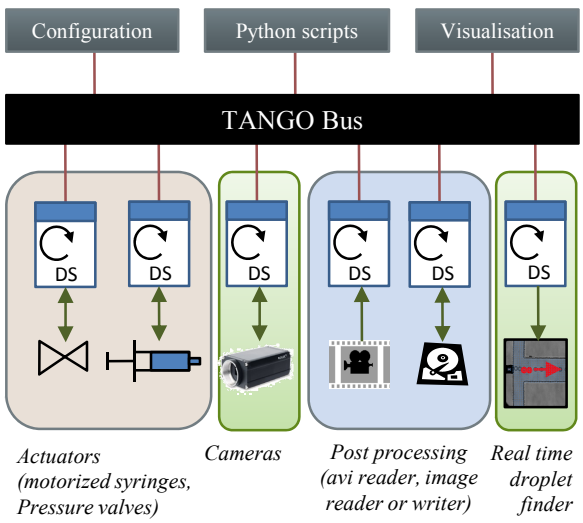

Figure 3: Scheme of the different TANGO layers. Device Servers (DS) are programmed in C++ or Python languages and have the TANGO interface (blue).

Droplet Detection

The "droplets finder" application developed in the present work can connect to all these devices and process the image to find drops. The software is developed in C++, for providing fast results, and is based on the OpenCV [6] (Open Source Computer Vision) libraries, which give programming functions for real time computer vision.

From these libraries, we are using the `cvHoughCircle` function which implements a Hough [7] algorithm and can find circles on a grayscale image. Some parameters have to be specified: maximal radii of circles, minimal distance between circles, and two method (Hough) specific parameters. The function returns a list of circles with their centres coordinates and radii. A post processing (for brightness and contrast) is made on the image for improving the results.

The user can tunes parameters through TANGO. The finding process can be paused in order to test some parameters on the same image. The program yields the averaged radii of found circles and the distance between drops (centres coordinates are sorted vertically or horizontally).

We used Jdraw application (which is a rapid interface designer tool provided with TANGO) for testing the system (see Figure 6), and display the video camera image and the processed image. Circles are drawn over detected droplets.

TIMING CONSIDERATIONS

Image Acquisition

The exposure time on the Phantom camera is typically in between 0.01ms and 0.1ms, and one drop is typically formed in 1ms. This video camera acquires 2000 images/s in full resolution (512x512) and more when decreasing the picture size. For the present application, it is sufficient to have few measurements per second.

We consider that a TANGO device server must respond in less than 300 ms (value widely accepted in the TANGO community and beyond that, a multi-threading system must be programmed). As the acquisition time was very short, we decided to acquire a new image on the camera each time it is asked by a remote TANGO client (when reading the image attribute).

Droplet Detection

The droplet detection device server is compiled with Microsoft Visual C++ 2008 express version, in "debug" mode, and "release" mode, with the corresponding TANGO and OpenCV libraries. Execution times of the droplet detection (see Table 1) are given by the software, and have been obtained on a simple laptop computer with the following configuration: Intel Core 2 Duo P8600 @2.40 GHz and 4 Go ram.

Table 1 : Processing Time for Droplet Detection

Number of detected circles	Detection time	*Complete processing time*
6 (debug mode)	170ms	240ms
6 (release mode)	80ms	120ms
17 (debug mode)	430ms	500ms
17 (released mode)	200ms	240ms

The complete process consists of image access from remote device (on the same computer), a pre-processing of image, search of circles, sort of circles, and a publication of the results over the TANGO device server. This process is separated in his own thread on the device server in order to let the server answer to remote clients.

We can notice that detection time is increasing when there are more circles to find on the image. As we can expect, the software is quicker in "releases" mode of C++ compilation, and processing time is reduce by twice.

Image access to remote servers and all the pre-processing procedure takes only around 70ms in the debug mode, and 40ms in the released mode, which is really acceptable for 512x512 pixels by image. There is no difference of timing when the device server is started as a Windows service by the TANGO starter application.

RESULTS

Drops are produced in the microfluidic chip. We have check that number of drops, sizes and distances given by the software are corresponding to real values by a remote analysis of the images with ImageJ [8], an open source image processing program. The device server can also detect a high number of drops with different radii (from 10µm to 30µm).

By varying rate of water or oil in injected by motorized syringes, we can measure in real time the variation of size (Figure 4), the number of drops (Figure 5) or the distance between drops. During measurements, the parameters for detection are not changed. Values have been obtains by averaging 10 images for each rate.

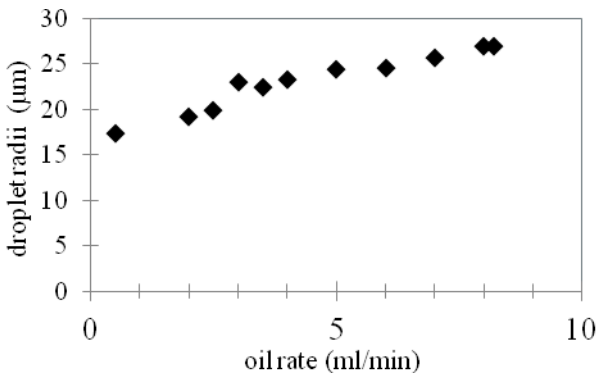

Figure 4: Measured droplet radii obtained by detection when oil rate is varying. The water rate is constant (5µl/min and 80µl/min).

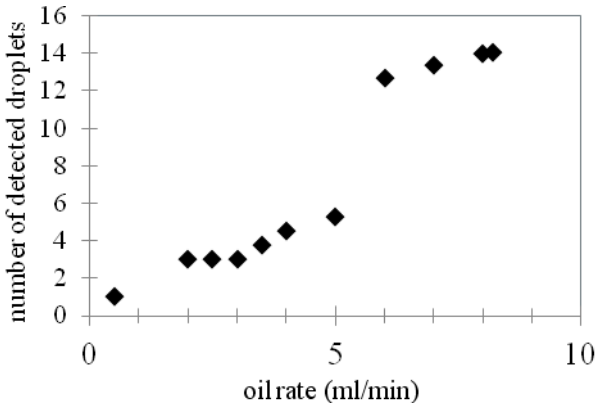

Figure 5: Number of detected droplets when the oil rate is varying. The water rate is constant (5µl/min and 80µl/min). The gap observed is due to real evolution of droplets, and not of detection errors.

Discussion and Future Work

The droplet detection system is working and allows the records of droplets evolution. However for the moment only 80% of droplets are detected. Moreover, the size measured is not always correct. This is the reason why we decided to average the result over 10 images. One possibility to avoid such errors will be to upgrade the software, i.e. by adding a system of averaging on the past images.

Detection process could also be improved: for the moment we try to find circles but; it could be interesting to detect "joined lines", and make a selection by fitting circles or ellipses. OpenCV offer some functions to do that. We could also try to detect "blobs", regions in the image that are either brighter or darker than the surrounding.

CONCLUSION

We have developed an automatic image analysis software with droplet detection for microfluidic systems. Microfluidic is a technic where electronic equipments are important. We demonstrate here that TANGO control command system, normally designed for synchrotron, is usable for more simple laboratory applications.

Our droplet detection is fully functional. Averaged radii and number of droplets are displayed almost in real time. This application can help researchers to control the micro fabrication parameters.

We thank Clélia Timsit, for the experiments preparation.

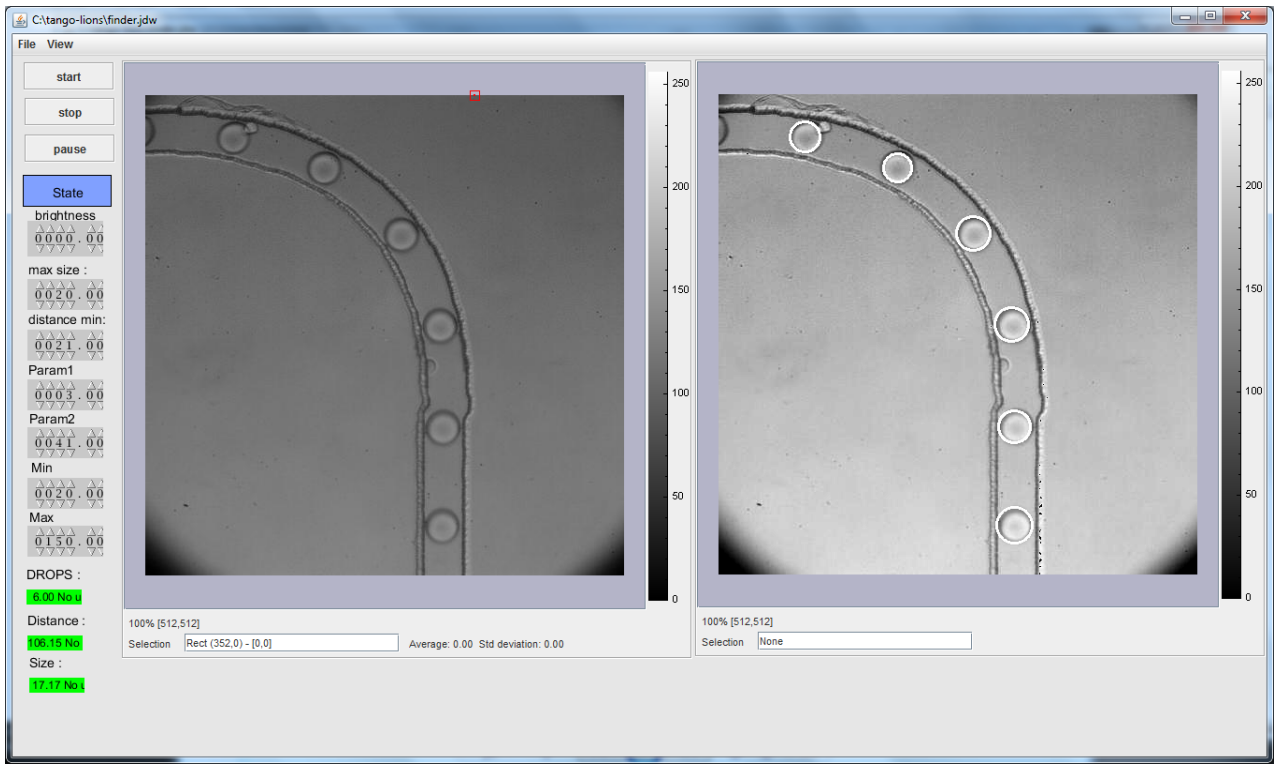

Figure 6: Interface of the application. On the left, the user can start the detection process and tune parameters in real time. Left image is the video camera display. Right image is the processed image, with detected circles drawn on it. Number, size (radii) of drops, and averaged distance between drops are indicated.

THE CODAC SOFTWARE DISTRIBUTION FOR THE ITER PLANT SYSTEMS

F. Di Maio, L. Abadie, C. Kim, K. Mahajan, P. Makijarvi, D. Stepanov, N. Utzel, A. Wallander
ITER Organization, Route de Vinon sur Verdon, 13115 Saint Paul Lez Durance, France.

Abstract

Most of the systems that constitutes the ITER plant will be built and supplied by the seven ITER domestic agencies. These plant systems will require their own Instrumentation and Control (I&C) that will be procured by the various suppliers.

For improving the homogeneity of these plant system I&C, the CODAC group, that is in charge of the ITER control system, is promoting standardized solutions at project level and makes available, as a support for these standards, the software for the development and tests of the plant system I&C.

The CODAC Core System is built by the ITER Organization and distributed to all ITER partners. It includes the ITER standard operating system, RHEL, and the ITER standard control framework, EPICS, as well as some ITER specific tools, mostly for configuration management, and ITER specific software modules, such as drivers for standard I/O boards.

A process for the distribution and support is in place since the first release, in February 2010, and has been continuously improved to support the development and distribution of the following versions[1].

THE CODAC CORE SYSTEM DISTRIBUTION

Plant System I&C Components

The architecture of the Instrumentation and Control (I&C) for the ITER plant systems is illustrated in Figure 1.

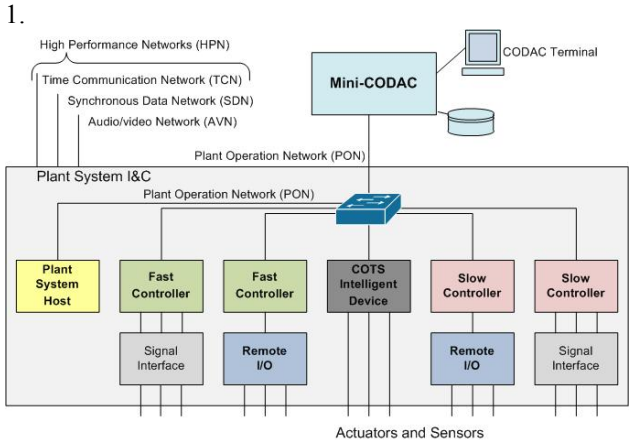

Figure 1: I&C Architecture before integration.

The components are:

- Siemens PLC for "slow" conventional control (up to 10 ms loops) and for "slow" interlock controls (up to 100 ms loops).
- Fast controllers, which currently are PICMG compliant industrial computers controlling a PXI/PXIe/cPCI remote I/O chassis over a PCIe link. The operating system is Red Hat Enterprise Linux (RHEL) that can be enhanced with real-time extensions for applications requiring high predictability.
- A system named Plant System Host (PSH) to implement the standard services, such as operating state management or health monitoring. The PSH is similar to a fast controller except that it includes no specific I/O. The PSH is also a gateway to communicate with the Siemens PLCs.

Fast interlock controllers as well as high range xTCA I/O for fast controllers are under development and will be within scope of future distributions.

Mini-CODAC

The CODAC acronym means "Control Data Access and Communications" and also designates the central control infrastructure at ITER. During the development phase of a Plant System, the central CODAC services are replaced by a Mini-CODAC system (see Fig. 1). It is both a system development and a runtime platform while providing a subset of CODAC central services, such as alarm handling and archiving facilities.

The operator software on Mini-CODAC is built with Control System Studio (CSS).

The Software Distribution Variants

The CODAC Core System distribution includes the software required for the Mini-CODAC, the fast controllers, the PSH and for additional operator consoles. The distribution covers both the development of the plant system I&C and its operation, during tests. Two set of packages are made available: "development" and "production". The packages that will be installed on a particular system are determined according to the role that the user assigns to the system when installing the CODAC Core System distribution.

For each platform, the distribution bundles, as a common base, the operating system and the EPICS framework.

PLC Support

The development for PLC is based on the Siemens Step-7 software and is not within scope of the CODAC Core System distribution. The CODAC Core System includes however the standard templates for Siemens Step-7 software that shall be used for developing the PLC software and the communication software for the

integration of the PLCs into the ITER controls are included.

The development software for Mini-CODAC and PSH includes the tools to declare variables on PLCs and to generate the communication software to exchange data between EPICS variables and the PLC ones. The generated variable declarations shall be included in the PLC application software by the developer.

Fast Controllers Support

The ITER Organization issues some hardware catalogues for the supported I&C components covering the recommended hardware modules for the PLC and the fast controllers.

A set of PXI/PXIe boards is defined in the fast controller catalogue, which is regularly extended. The software for supporting these selected boards will be added in the distribution in an incremental manner

The current distribution includes the software for the following boards:

- NI PXI-6259: a multi-function data acquisition board (16 analog input, 4 analog output, 32 digital I/O).
- NI PXI-6682: a synchronization and timing board (IEEE-1588)

The software for the following boards is under development and will be included in the 2012 versions:

- NI PXIe-6368: a higher performance multi-function data acquisition board (16 simultaneous analog inputs at 2 MS/s)
- NI PXI-6528: a digital I/O board (24 input, 24 output, optically isolated)
- NI FlexRIO boards (FPGA) with adapter boards. In particular PXI-7951R with 6581 (digital) and 5781 (analog) adapters. The software shall be compliant with other FlexRIO hardware and also with cRIO I/O boards connected over PCIe interconnect link.

For each board, the software support includes the Linux device driver and the EPICS device support.

The configuration tools (SDD, see below) are also extended to allow generating the configuration files for these boards from the controller's configuration.

CODAC Core System Versions

The CODAC Core system distribution is produced with a major release every year, very few (1-2) intermediate minor in between and maintenance releases for distributing bug fixes or minor extensions whenever required[2].

The CODAC Core System versions are defined as: *major_id.minor_id.maintenance_id*. Examples: 3.0.0 is the base release for the version 3 and 2.1.1 is the 1st maintenance release for the 2.1 version.

The installation of a maintenance release will update an installed version so, by default, the application software does not require being re-built. A minor release shall be backward compatible with another minor release within the same major version so, in principle, the application software requires being re-built but not being modified. Major release may include a new version of the operating system or of EPICS and, up to now, require a full installation.

Preliminary versions are also produced before any official release with alpha/beta identifiers replacing the maintenance release number (ex: 3.0b1 for the 1st beta version of 3.0).

Self-Description Data (SDD) Tools

The promoted approach for ITER controls is to have the configuration data for the plant system I&C structured with a common schema defined at project level [3].

This is implemented in the CODAC Core System with a set of configuration management tools that maintain the plant system I&C definition in relational databases

This definition includes:

- The functions
- The variables (EPICS PVs, PLC variables)
- The signals
- The controllers with their I/O boards
- The links between variables, signals and I/O boards
- The configuration for alarms
- The configuration for archiving

When the CODAC core system distribution is installed on a Mini-CODAC system, a local database is configured in order to store/retrieve the plant system I&C definitions. In IO, a central repository is also maintained. The local databases are initialized with data copied from the central database and can be synchronized with the central ones in order to update local copies with the central one or to commit new definitions (see [4] for details).

An editor (SDD editor) allows the creation/edition of the plant system I&C into the local database. A web application (SDD browser) is also provided to allow accessing the plant system I&C definitions from web browsers.

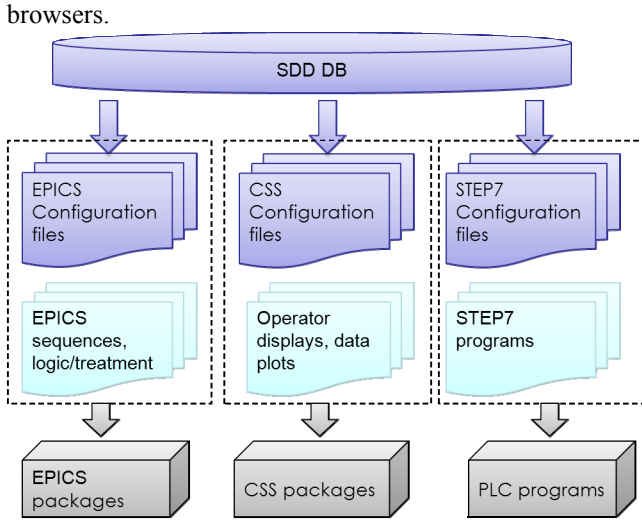

Figure 2: SDD generated configuration files.

As illustrated in Figure 2, the SDD toolkit includes translators for generating all specific files:

- the build files (makefile, scripts…),
- the EPICS configuration files (record databases, IOC scripts…),

– the Control System Studio (CSS) configuration files for alarms and archiving,
– the variables declaration for the PLCs.

The EPICS database files, which define the set of EPICS records implementing the application, are usually edited with text editor or graphical "database configuration tool" such as VDCT. In the ITER environment, these files are generated by the SDD tools but, it will also be possible, in the 2012 version, to use EPICS tools to edit these files and have any resulting change or addition retrofitted into the SDD database.

The SDD tools also include validation functions, which allow verifying the completeness of the definition during the development and the compliance with ITER standards, such as the naming convention, before delivery.

BUILD OF THE CODAC CORE SYSTEM DISTRIBUTION

Different software distributions are built for the different "system roles": Mini-CODAC/development, Mni-CODAC/Operation, PSH/Operation, etc.

These distributions are built from:

1. The operating system.
   RHEL 6.1 will be provided with the CODAC Core System vs3 in 2012 (today: 5.5). RHEL-MRG-R (6.1 with real-time extensions) can also be provided with the fast controller distributions.
2. EPICS components.
   It includes the EPICS base and EPICS modules, such as the SNL sequencer, CAJ/JCA (Java client library) and VDCT.
3. Control System Studio (CSS) and CSS applications: BOY, BEAST, BEAUTY and SNL editor, in the Mini-CODAC distributions.
4. ITER specific development tools.
   Self-description data (SDD) tools and maven-based build process are included in the "development" distributions.
5. Software support for the standard I/O modules in the fast controller distributions.

Changes made by ITER in the EPICS components, such as extensions for 64 bits or support for the PostgreSQL database are, as far as possible, retrofitted in the shared EPICS sources but the ITER distributions are only built from the ITER source repository (SVN).

ITER Build Tools

The steps for building software components from the source code in repository to the packages in installation servers are supported by commands implemented with the Apache maven (mvn) tools.

The system packages as well as the application ones are built with standardized mvn commands:

- mvn checkout - extract a software unit from the source repository (using versions' branch or tag)
- mvn compile – build all object files
- mvn test – run the tests of the unit
- mvn package – build the RPMs for deploying the unit to target hosts.

These commands are executed by the developers during development and, when a unit is included in the distribution, by the build servers for producing the different software releases. Build servers are configured with the Jenkins continuous integration tool.

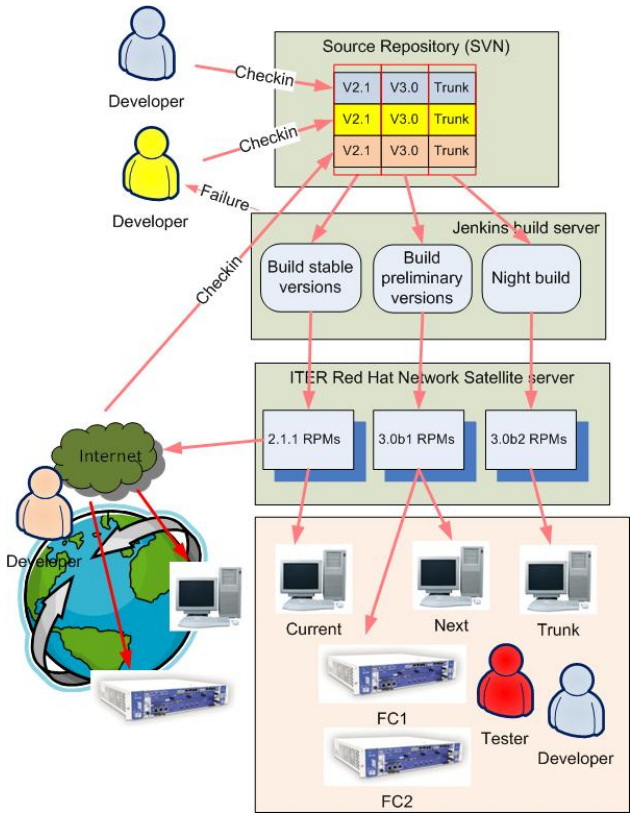

Figure 3: Build and distribution process.

The next actions executed by the build servers are the following:

- Sign the RPMS and copy them to network shared directories.
- Copy the official releases RPM, tagged with a version id, to the distribution servers at release time.
- Copy the RPMs that are generated for continuous integration, tagged with a branch id and a SVN id, to distribution servers every night.

Test computers are thereafter updated with new releases, automatically for the nightly built ones.

Whenever a compilation or a test executed by a build server fails, the package owner is informed by mail. Build logs can be consulted with the Jenkins tools.

Verification of the Java code with static code analysis tools, such as CheckStyle, will be added in order to also provide the developers with reports on the quality weaknesses detected in their code.

Installation of the ITER Distribution

The ITER distribution servers are configured with the Red Hat Network Satellite management system. The

operating system distribution, the ITER packages distribution and the subscription management are centralized on these servers.

Users are grouped into organizations that can be remotely administrated by authorized users for allocating RHEL subscriptions and configuring the local systems.

For any installation, the user shall have access to the distribution servers. However, once configured, the local systems do not require permanent access to the ITER servers, except for delivering software in the ITER repositories or for accessing support information.

Installing a local system is an automated procedure using the IO supplied installation disk images. They provide a selection of the CODAC Core System, bundled with the RHEL operating system and a suitable role for the target system.

CONCLUSION

The integrated process for building and distributing the CODAC software allows automating the compilation, testing and packaging of software components from different sources. It also allows maintaining a unique distribution system for the systems in Cadarache and the ones used by the suppliers and partners that are very widely distributed.

It requires constant resources for the maintenance but the automated processes reduce a lot the time and cost for the integration and tests of the software releases. This is very valuable to cope with the increase of the test and maintenance releases that will be required during the development phase of the plant system I&C.

BEAM SHARING BETWEEN THE THERAPY AND A SECONDARY USER

K. Gajewski, The Svedberg Laboratory, Uppsala University, Uppsala, Sweden

Abstract

The 180 MeV proton beam from the cyclotron at The Svedberg Laboratory is primarily used for patient treatment. Because of the fact that the proton beam is needed only during a small fraction of time scheduled for the treatment, there is a possibility to divert the beam to another location to be used by a secondary user. The therapy personnel (primary user) control the beam switching process after an initial set-up which is done by the cyclotron operator. They have an interface that allows controlling the accelerator and the beam line in all aspects needed for performing the treatment. The cyclotron operator is involved only if any problem occurs. The secondary user has its own interface that allows a limited access to the accelerators control system. Using this interface it is possible to start and stop the beam when it is not used for the therapy, grant access to the experimental hall and monitor the beam properties. The tools and procedures for the beam sharing between the primary and the secondary user are presented in the paper.

INTRODUCTION

The synchrocyclotron [1] at The Svedberg Laboratory (TSL), originally built in the early fifties and almost totally reconstructed in the years 1977-86, can accelerate protons and different ions, ranging from helium to xenon. Until 2005 TSL had been so called national facility and was financed from the state budget. The research groups, both from Sweden and abroad, could send the proposals for an experiment to be done at TSL. The beam time has been granted to the projects selected by the lab's Program Advisory Committee. After closing down CELSIUS storage ring at TSL in 2005, the laboratory has been reorganized and changed the orientation from being the laboratory hosting the basic research experiments to an accelerator facility dedicated mainly to patients' irradiations with protons. TSL is financed now by the Uppsala County Council (the patient treatment) and by selling the beam time to the other clients. The contract signed between TSL and the University Hospital in Uppsala specifies that thirty five weeks a year are reserved for the patients' treatment. Because the proton beam is needed in the treatment room only for a small fraction of time scheduled for the therapy irradiation, there is a possibility to use the beam in other experimental areas of the laboratory at "the same" time.

BEAM SHARING PREREQUISITES

The beam is shared between the irradiation therapy (primary user) and users in other experimental locations (secondary users). The switching between two different beam lines is done with help of a bending magnet but a number of other parameters are also changed in order to satisfy the beam requirements of both therapy and the secondary user. The beam that is used for the therapy irradiation is a 180 MeV proton beam and although the beam characteristics can be different for the therapy and the secondary user, we can't change neither particle nor it's energy when the beam is shared.

During the "therapy" weeks the beam is available for patients' irradiation according to the following schedule:

- Monday 1 pm. - 8 p.m.
- Tuesday-Friday 8 a.m. – 6 p.m.

The number of patients is usually between 6 and 9 per day and each patient receives two or three fractions (irradiations from different angles). The beam time needed for each fraction is usually less than one minute and repositioning of the patient between the fractions takes about 5 minutes. The quality assurance tests performed every morning before the first treatment require the beam for about an hour. Thus the real beam time (adding usual delays and a beam switching time) using by the therapy is about 3 hours (counting 5 min. for one fraction) a day.

THE PRIMARY USER

The primary user is the one that controls where the beam is led. He can take away the beam from the secondary user at any moment. There is a delay (which is set by agreement between the therapy and a secondary user) between the request to take away the beam from the secondary user and actually doing it. After that delay the beam is switched to the primary user. When taking the beam from the secondary user the therapy operator specifies the expected time (based on number of fractions) the beam will be not available for the secondary user. When sending the beam back to the secondary user, the therapy operator specifies also the approximate time the beam will be available for him before the next switching. The control of the dose delivered to the patient is the responsibility of the therapy operator and is independent of the accelerator control system.

THE SECONDARY USER

The secondary user gets the beam when the primary user decides to release it. The exact moment when it happens is unknown to the secondary user but there is information when the beam is supposed to be switched. The same is true for taking away the beam from the secondary user, with the exception that there is a delay between the beam request from the therapy and actual switching the beam. This delay is set during the beam switching set-up and depends on the secondary user's requirements.

The secondary user has a very limited access to the control system. He can perform the following actions:

- Forbid and allow access to his experimental hall (clear / release clearing). The hall must be in "cleared" state to put the beam into it.
- Monitor the parameters important for the experiment
- Stop and start the beam if it is available for him or enable/disable the beam when it is used by the therapy. When the beam is directed to the secondary user and it is enabled, it will be turned on, otherwise it will be turned off and the secondary user can start the beam at any time as long the beam is available for him.

BEAM SHARING SETUP

Before the therapy operator can use the switching procedure the cyclotron operator must set it up. The following steps must be taken:

- Decide what parameters should be changed during the switching process in order to fulfill the requirements for the beam properties (such as intensity, focus, position on target) both for the therapy and the secondary user
- Set the required delay between the beam switching request and actual beam switching when taking the beam from the secondary user
- Set the beam current limits for both therapy and the secondary user
- Set-up the required beam properties to both therapy and the secondary user
- Test the switching procedure
- Set-up the alarm conditions for the secondary user
- Set-up the parameter reservation
- Start/enable the billing for the secondary user's beam time

When the procedures listed above are completed, the beam switching can be performed by the therapy operator without any help from the cyclotron operator. In fact, the cyclotron operator is usually not longer present in the control room but is doing other job in the laboratory and is available "on call" in case of unexpected problems.

SERVICES

There are a number of programs that are used to make it possible to share the beam between the therapy and the secondary user without the need for the cyclotron operator. All these programs use the services that are essential for such a beam sharing scheme working satisfactory in real life. The most important services are shortly described below.

Logging

All programs used by the therapy operator and the secondary user log all their actions using syslog facility. The programs can (and usually are) executed on different computers but syslog daemons are configured so that all the log messages are saved on one syslog server. The entries in the log file are tagged with the time stamp (all computers are synchronized with the network time server), computer name, user name, log entry priority and the program name. The log file is saved on a week basis and archived on Sunday night (done by a cron job). The log file is an invaluable help when it comes to understand the problem that could have occurred, to spot the unexpected actions of the therapy operator or the secondary user or just to follow the use of the beam. The log file is also used for calculation of the beam time that the secondary user is charged for (billing).

Alarms

As in any system things might go not as planned. The quick observation of the problem and passing information about it to the cyclotron operator is essential. It is also important that some actions will be performed automatically (like stopping the beam and the billing). The alarms from the programs involved in the beam sharing are distributed by two independent systems:

- Local text paging infrastructure (radio transmitter using a license free 439 MHz frequency band, alphanumeric pagers)
- SMS (via email gateway) to the mobile phones. The message is usually delivered within 1 minute (not guaranteed).

The message sent to the pager or the phone contains the time stamp of the event, originating program's name and a short description of the failure.

Parameter Reservation

TSL's control system has a global mechanism for limiting the rights to access control system's parameters based on the user's account uid and gid (uid – user id, gid – group id). The write access rights for every parameter in the control system can be set to the following states based on uid and gid:

- Free – write access for everybody
- Reserved – write access only for the specific uid/gid
- Locked – no write access

After the beam switching is set-up, the cyclotron operator locks the parameters that should not be changed by any user and reserves those that must be changed in the beam switching process for use by the therapy operator. The switching program changes access rights to some parameters during the switching process to allow beam control by the secondary user when the beam is used by them, and to prevent them to control the beam when the beam is used for the therapy.

Billing

The secondary user is charged for the beam time he has to his disposal. It's not possible to exactly predict how much time beam time will be used by the therapy and manually keeping track of it is out of question. Therefore there is a virtual parameter BILLING that can be in the following states:

- **Enabled** - the beam is used by the therapy but as soon as it will be switched to the secondary user and the beam's parameters will be accepted, the state will changed to "Started".

- **Started** - the beam is available to the secondary user, the state will change to "Enabled" when the beam is taken back to the therapy or to "Stopped" in case of some failure.
- **Stopped** - the beam is not available to the secondary user, either because of some failure or deliberate action taken by the cyclotron operator.

The secondary user can see the actual state of the billing in his user interface. The cyclotron operator can at any time generate a billing report.

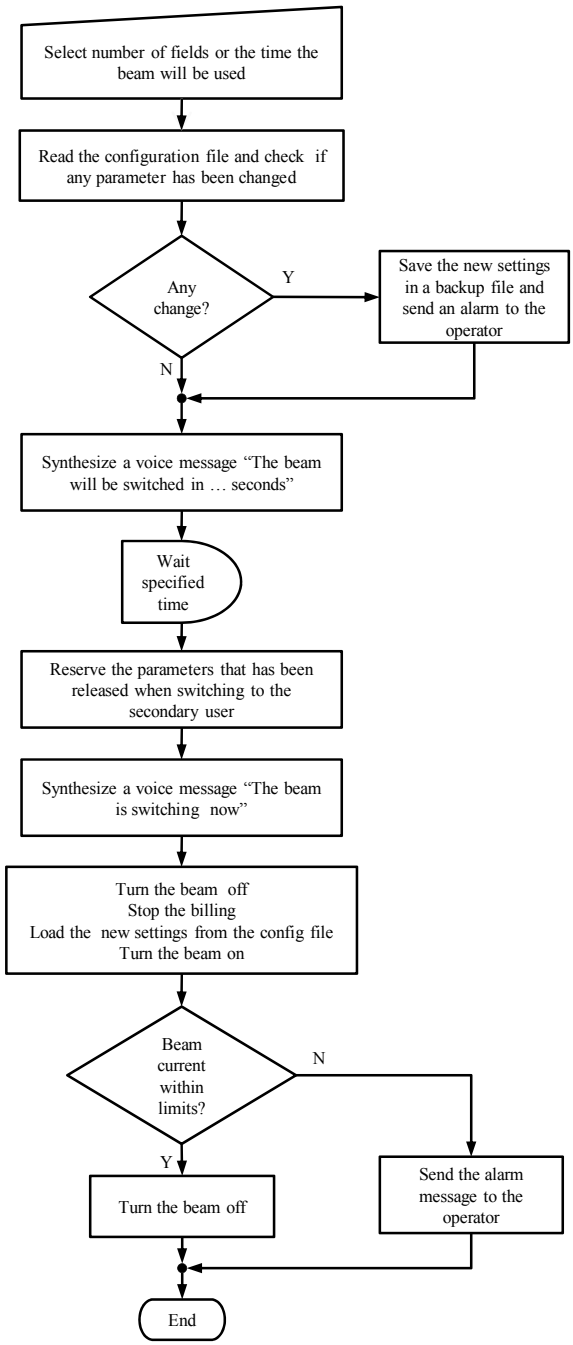

Figure 1: Beam switching from the secondary user to the therapy.

Synthesized Voice Messages

It turned out to be very useful to create the voice notifications during the switching process and distribute them over the network to different locations in the laboratory. Festival speech synthesis system has been used for implementation of this feature.

BEAM SWITCHING

As said before the beam switching process is controlled entirely by the therapy operator. The program to control the beam switching is written in tcl/tk and it has slightly different user interface depending on if it is used by the cyclotron or therapy operator (features needed for the beam switching set-up are not visible in the therapy interface).

The main window has only two buttons and one status field indicating into which location (therapy room or experimental hall) the beam is directed. The buttons are for selecting the area the beam should be switched into.

When one of the buttons is pressed the pop-up dialog and status windows are shown during the switching process.

Figures 1 and 3 show the algorithm implemented for switching the beam from the secondary user to the therapy and vice versa.

USER INTERFACES

The user interfaces are built using TSL's control system standard tools and components. The therapy operator uses a workstation connected directly to the control system network and controls the accelerator via a "synoptic" program.

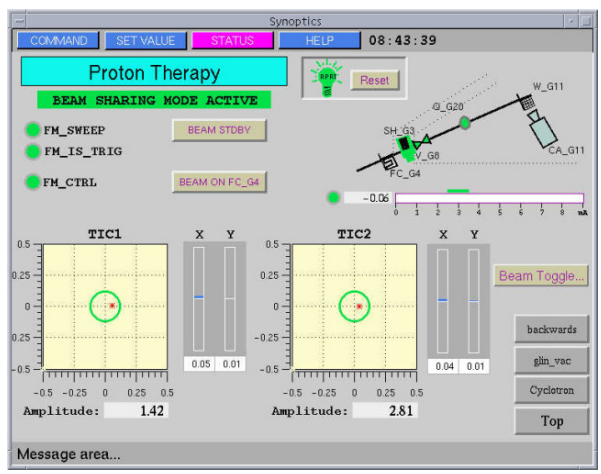

Figure 2: Synoptic screen for the therapy user.

The secondary user works on a workstation connected to the laboratory "public" network and connects to the control system via a firewall using secure shell protocol. The account that he logs into the control system allows only limited access to the control system. The examples of the "synoptic" screens used by the therapy user and the secondary user are shown in figures 2 and 4 respectively.

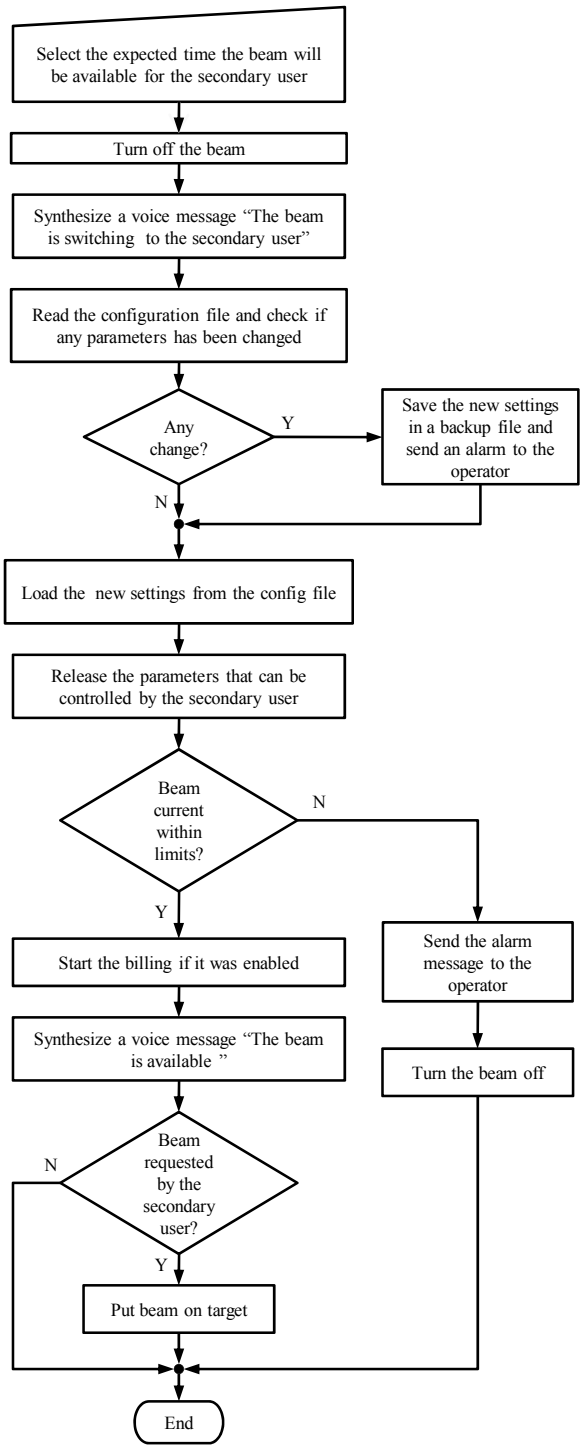

Figure 3: Beam switching from the therapy to the secondary user.

Here follows a short list of the tasks that therapy operator and secondary user can perform using their interfaces to the control system.

Therapy User

- Perform the beam switching process
- Monitor the beam position during the irradiation
- Turn on and off the beam
- Check the beam current before starting the irradiation
- Monitor the parameters in the end of the therapy beam line

Secondary User

- Control the access rights to the experimental hall (radiation protection).
- Request the beam when it is used by the therapy.
- Turn on/off the beam when it is not used by therapy.
- Monitor the parameters relevant for the specific experiment (beam current, signals from particle detectors, position of the target, billing status)

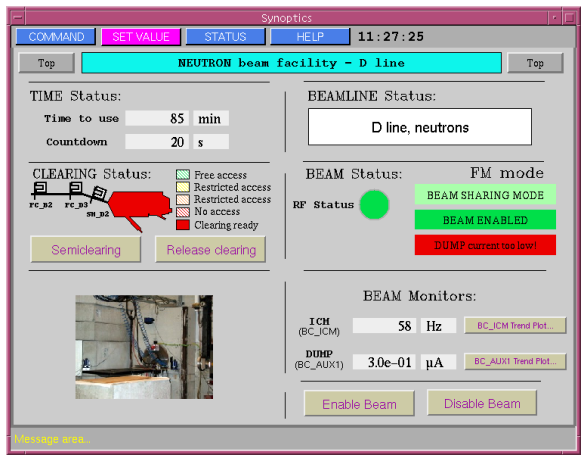

Figure 4: Synoptic screen for the secondary user.

CONCLUSIONS

The beam sharing described in this paper has routinely been used at TSL for the last few years. During this time many adjustments has been done to improve the quality of the system and to make the switch process easy to use for the therapy operator. Several synoptic screens for different beam lines and test stations have been created for the secondary users. A possibility to control the beam current by the secondary user is planned to be implemented in the near future.

Abstract

Fast and accurate beam-dynamics simulation programs within accelerator control systems can advantageously assist the operators and provide a more detailed insight into the actual machine status. The V-Code simulation tool implemented at TEMF is a fast tracking code based on the moment approach. In this contribution an overview of the numerical model is presented together with implemented features for its dedicated integration into the control system of the superconducting linear accelerator S-DALINAC.

INTRODUCTION

The Superconducting Darmstadt Linear Accelerator S-DALINAC [1], installed at the institute for nuclear physics (IKP) at the Technische Universität Darmstadt is designed to allow nuclear- and astrophysical experiments with electron beams in an energy range from 1 MeV up to 130 MeV with beam currents up to 60 μA. The electrons are emitted from a 250 keV thermionic gun or alternatively from a recently installed source for 100 keV spin-polarized electrons.

The beam is bunched in the chopper and prebuncher section in order to prepare the particles for the acceleration within the radio frequency cavities. The provided bunches are first accelerated up to 10 MeV within the injector linac and subsequently deflected by 180 degrees into the main linac. This main linac section is composed of 8 superconducting 20-cell cavities and is designed to provide an energy gain up to 40 MeV. The main linac can be passed up to three times using the beamlines of the first and second recirculation, leading to a maximum bunch energy of 130 MeV.

The layout for beam recirculation shown in Fig. 1 together with the few beam diagnostic instruments render it quite complicated to find optimum settings for the individual beamline elements. Fast online beam-dynamics simulations can assist the operators because they provide a more detailed insight into the actual machine status.

The moment approach allows to implement a beam-dynamics simulation tool that is on the one hand much faster than classical beam-dynamics simulation codes which track numerous macro particles and on the other hand more accurate than matrix-based beam-dynamics codes.

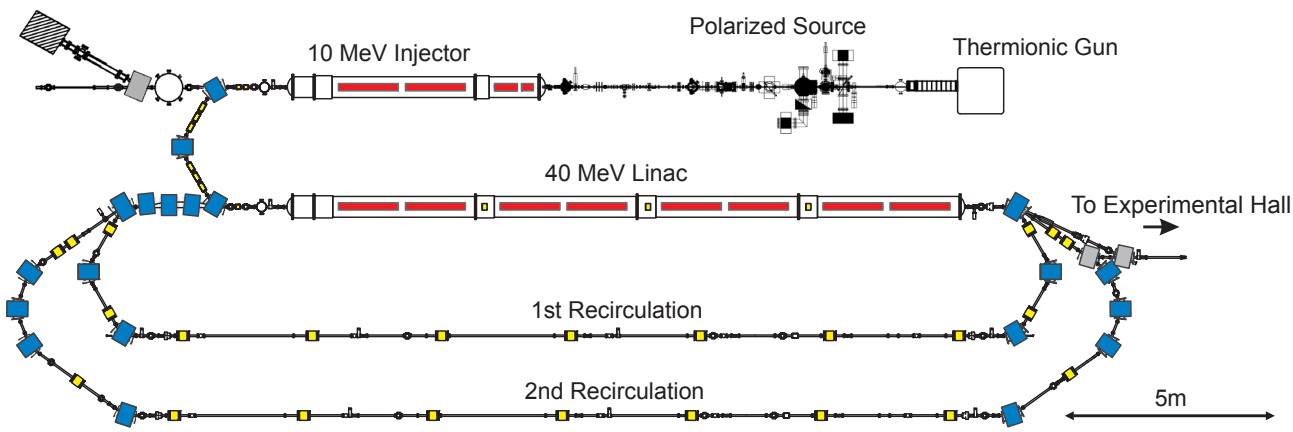

Figure 1: Schematic layout of the Superconducting Darmstadt Linear Accelerator S-DALINAC.

THE MOMENT APPROACH

The moment approach to beam-dynamics consists in representing the particle distribution function f in the 6-dimensional phase space Ω spanned by the Cartesian coordinates x, y, z and the momentums p_x, p_y, p_z by a discrete set of characteristic moments [2].

Moment Definition

The moments are obtained by a weighted integration over the whole phase space

$$<\mu> = \int_{\Omega} \mu \; f(\vec{r}, \vec{p}, \tau) \; \mathrm{d}\Omega. \qquad (1)$$

A numerically advantageous choice is given by the first order raw moments $\mu \in \{x, y, z, p_x, p_y, p_z\}$ and centralized moments

$$\mu \in \{(x - <x>)^{l_1} \cdot \; \ldots \; \cdot (p_z - <p_z>)^{l_6}, \; \ldots\} \; ,$$

for the higher orders $n = l_1 + ... + l_6 \in \mathbb{N}$, $n \geq 2$.

Following this idea one automatically obtains the center of mass position and a translatory invariant description of the shape of the particle distribution [3].

Moment Evolution

A fundamental time evolution equation can be stated for each moment $<\mu>$ by means of the Vlasov equation:

$$\frac{\partial <\mu>}{\partial \tau} = <\frac{\partial \mu}{\partial <\vec{r}>}><\frac{\vec{p}}{\gamma}> + <\frac{\partial \mu}{\partial <\vec{p}>}><\frac{\vec{F}}{m_0 c^2}> + <\frac{\partial \mu}{\partial \vec{r}} \frac{\vec{p}}{\gamma}> + <\frac{\partial \mu}{\partial \vec{p}} \frac{\vec{F}}{m_0 c^2}> \qquad (2)$$

This set of ordinary differential equations can efficiently be evaluated with standard time integration methods [4] if proper initial conditions are given and all essential forces are known.

Force Calculation

The Lorentz force $\vec{F} = q \cdot (\vec{E} + \vec{v} \times \vec{B})$ specified in the fundamental time evolution equation (2) can be evaluated as a sum of forces resulting from superposed external fields and internal space charge effects. A numerically useful way to provide all external field components in the vicinity of the particle distribution is given by a paraxial approximation using a series expansion of the external fields. For the calculation of internal space charge forces a model assuming a certain particle distribution can be applied to reconstruct the distribution within the bunch from the moment description. An alternative approach consists of representing the particle distribution through multiple interacting sets of moments in a multi-ensemble environment [5].

IMPLEMENTATION

The beam-dynamics simulation tool V-Code has been implemented at the Computational Electromagnetics Laboratory (TEMF) at the Technische Universität Darmstadt on the basis of the moment approach.

Beamline Representation

For applying the moment approach even to a long accelerator beamline it is useful, especially in terms of an efficient memory management, to represent the beamline as a consecutive chain of several independent beamline elements along a straight axis. Drift spaces between beam forming elements are represented by beamline elements which are free of external electromagnetic fields. Within bending magnets a reference path has to be defined. This path fixes the length of the magnet along the projected axis within V-Code. The actual bunch position within the bending magnets is then determined via a normal projection onto the reference path [6].

Recirculations

Several beamline elements are repassed multiple times by the beam during the two recirculations. Beamline elements that are passed n times are placed n times along the beamline representation within the V-Code. Proper reference paths have to be defined for all instances of a bending magnet that is passed by the beam at different energies during the recirculations.

The length of the S-DALINAC beamline can be adjusted mechanically in order to match the path length of the recirculated beam with the phase of the fields inside the cavities. This is realized by means of extendable bends within the first and the second recirculation. In V-Code this path length variation is implemented through drift spaces with a variable length placed in front of and behind the movable beamline elements.

Overlapping Fields

The proximity of some beamline elements leads to overlapping fringe fields between consecutive elements. The V-Code database of disjunctive beamline elements has to be extended accordingly.

The fundamental time evolution equation (2) can be separated into drift terms and transport terms. The drift terms represent the fundamental internal feedback and depend on the momentum whereas the transport terms consider the interaction with the external forces. If linear materials can be assumed, the specified force can be evaluated as a sum of forces resulting from various superposed fields and it is also allowed to apply one transport term for each overlapping field component [7]. This approach was implemented in a new enveloping macro element which enables the user to combine all beamline elements with overlapping fields.

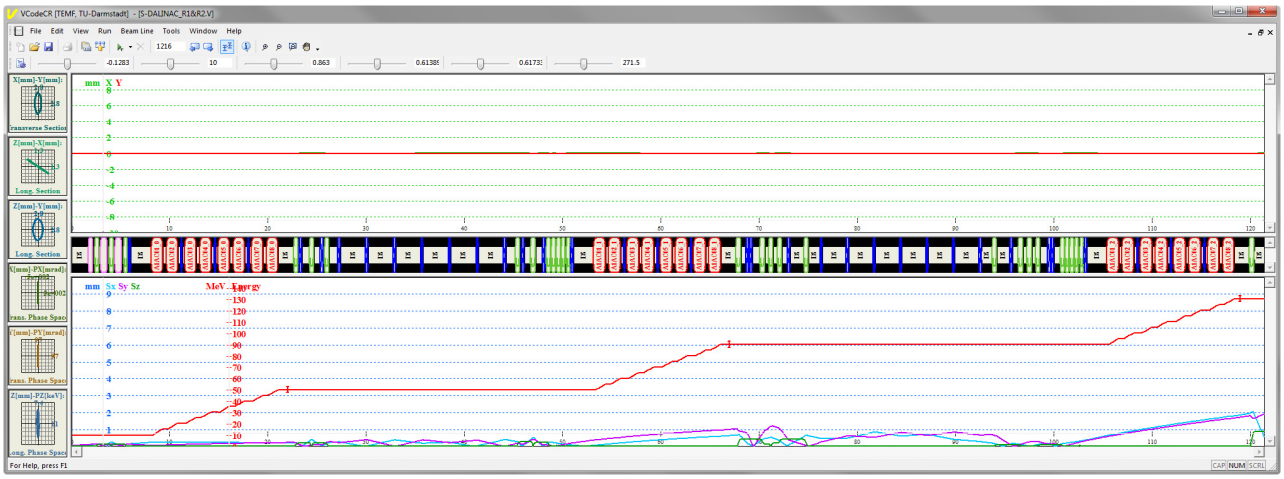

Figure 2: Screenshot of the V-Code graphical user interface showing simulation results for the S-DALINAC recirculating machine. The simulation was initiated right after the injector and the corresponding 10 MeV bunch was subsequently accelerated three times within the main linac. Reference markers for 50, 90 and 130 MeV beam energy are displayed.

User Interface

A comfortable and clearly arranged graphical user interface is essential in order to provide the operators of the accelerator a utile simulation tool. Figure 2 shows a screenshot of the V-Code user interface. Several beam parameters like the position of the center of mass in x and y direction, the dimensions of the beam σ_x, σ_y and σ_z in Cartesian coordinates and the energy are displayed along the longitudinal axis z in the panes above and below the representation of the beamline. On the left side six phase space projections on different planes can be observed at any position in time.

The user interface also provides access to each parameter of the various beamline elements by double clicking on a specific element in the beamline representation. Another way to tune the settings of the beamline elements is implemented via arbitrary assignable sliders in the menu bar.

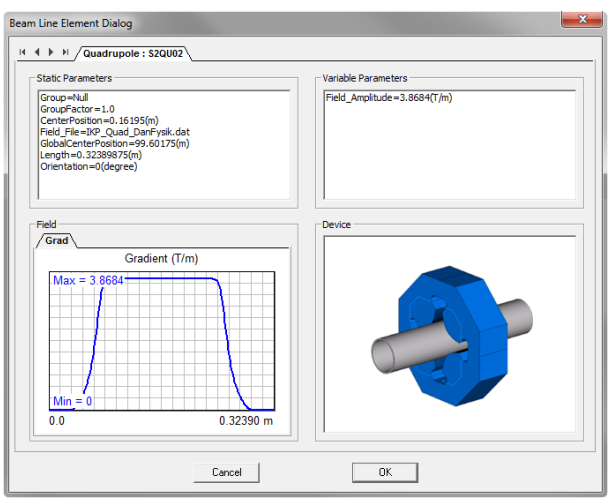

Figure 3: Dialog providing access to all static and variable parameters of a quadrupole. In addition the distribution of the quadrupole strength and a schematic representation of the magnet are displayed.

Online Simulation

Supplementary to the possibility to manipulate the parameter setup of the beamline elements within the V-Code through the user interface an online simulation mode has been implemented. Within this operating mode the parameter settings are read from an external source. This external source may be either an other software tool or for example the control desk of the accelerator machine.

Markers

During each simulation run the actual bunch parameters at the interfaces between the consecutive beamline elements can be stored. These specific sets of moments can be used as initial start ensembles for upcoming simulations of subsets of the beamline. This feature helps to further speed up the iterative process of finding an optimal machine setup.

Reference Markers

In order to additionally assist the operator, reference markers can be displayed on top of the simulation data. This can be used for instance to superimpose expected data or measurement data received from a diagnostic device installed within the beamline.

Automatic Beam Adjustment

Finding an optimal parameter setup for the S-DALINAC beamline is a laborious task as the number of variable parameters is very large. The V-Code opens up the possibility to analyze a multitude of parameter sets in a reasonable time. This procedure can be automated by implementing objectives and evaluation rules. Further, a connection between the V-Code and the accelerator diagnostic software allows to take into account measured parameters in the automated optimization process. A promising prototype for an automatic beam adjustment algorithm applying the V-Code has been published in [8].

APPLICATION

The V-Code has to be accurately initialized with the geometrical setup of the beamline, the field distribution within the various beamline elements and an initial set of moments for its dedicated application within the S-DALINAC control system.

Initialization

The S-DALINAC beamline shown in Fig. 1 consists of over 100 beam guiding elements and for each of them the electromagnetic fields have to be provided. The field distribution along the reference paths of the dipoles, the quadrupole strength along the axis within the quadrupoles and the accelerating electric field within the cavities were extracted from field calculations with the appropriate solvers included in the CST STUDIO SUITE [9].

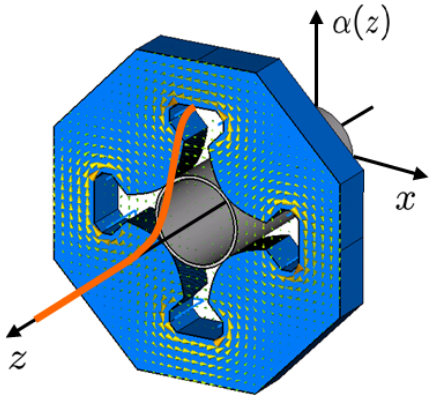

Figure 4: Computational model of a quadrupole magnet together with the extracted quadrupole strength $\alpha(z)$.

The position of the beamline elements within the V-Code beamline is defined by the length of the field data sets of the consecutive beam guiding elements and drift space elements which represent intervals without external electromagnetic fields.

Within the S-DALINAC beamline no diagnostic device exists that is able to measure at one position all the bunch parameters required to initialize the V-Code properly. Nevertheless, the measured bunch data can be used to ensure the bunch parameters achieved from start-to-end simulations.

Simulation Results

The V-Code was initialized with values provided by experienced operators of the S-DALINAC in order to examine its applicability to simulate the recirculating setup. The simulation was started right after the injector section with a 10 MeV bunch with the dimensions $\sigma_x = 0.060$ mm, $\sigma_y = 0.060$ mm, $\sigma_z = 0.014$ mm and a transversal bunch divergence of 0.1 mrad. Results of this simulation are displayed in the screenshot in Fig. 2. More details concerning the simulation of the S-DALINAC recirculations are published in [10].

SUMMARY

The moment approach together with a paraxial field approximation allows the implementation of a fast and accurate beam-dynamics simulation tool. Changing the order of moments or the number of applied ensembles permits to adapt the simulation to the required accuracy while keeping the simulation times in an acceptable level. With the help of the reference-path concept this code can be used to simulate even recirculating machines like the S-DALINAC. With its customized graphical user interface the V-Code is designed to assist the operators in finding an optimal setup for the accelerator beamline.

Abstract

Alba maintains a central repository, so called "Cabling and Controls database" (CCDB), which keeps the inventory of equipment, cables, connections and their configuration and technical specifications. The valuable information kept in this MySQL database enables some tools to automatically create and configure Tango devices and other software components of the control systems of Accelerators, beamlines and laboratories. This paper describes the process involved in this automatic setup.

INTRODUCTION

ALBA is the first Synchrotron Light Source built in Spain[1]. Its 3 GeV Storage Ring has been commissioned during 2011, receiving in 2012 the first users for the 7 beam-lines. Most of ALBA control system [2] have been developed on top of Tango Control System [3][4].

An amount of 5531 devices are controlled up-to-now in ALBA accelerators (linac, booster and storage ring) using 150 control Linux PCs. Those devices are accessed from the control system using several hardware interfaces (ethernet, fiber optics, serial lines, GPIB, PLC inputs, …) that had to be configured in the Tango database.

To populate the tango database, information related to hardware configuration and connections has been imported from ALBA's Cabling and Controls Database (CCDB) [5]. The cabling database keeps information of all hardware connections and the network configuration of all ethernet equipments. We used this information already in CCDB to automatize the creation and configuration of several control subsystems, like vacuum, front-ends, motor controllers and EPS [6]; speeding-up the process and minimizing the errors.

THE CABLING AND CONTROLS DATABASE

The Cabling and Controls database was developed in-house by ALBA management and information software section (MIS) to be used as the main knowledge support for design, control, tendering, progress follow up and a search tool providing multiple views of the system.

This MySQL database has been used since 2007 to keep a knowledge base of all the equipments and devices used at ALBA accelerators and beam-lines. The Cabling database keeps all the information about equipment types, cable configurations, connections between devices distribution of hardware in racks, routing of cables between equipment and network configuration. It also provides fast access to all available documentation for each type of equipment. It actually contains in 346 racks with 6326 equipments of different 638 equipment types. These equipments are connected using 17623 cables of 292 different cable types with a total length of 167,43 Km.

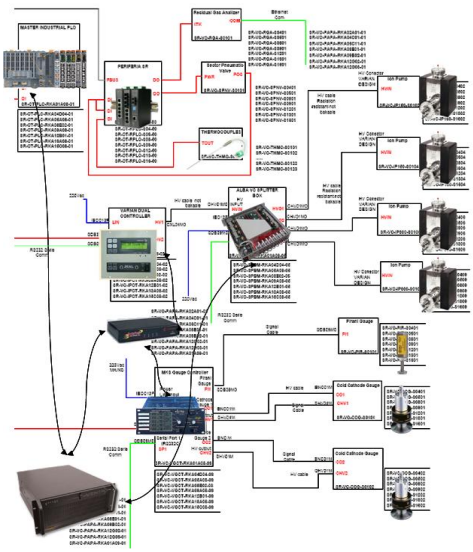

Figure 1: Diagrams of every subsystem have been produced prior to its introduction in our cabling database.

Introducing Cables in the Cabling Database

Filling this database required and intensive effort by a group of engineers (one dedicated to each subsystem). They introduced most of the information in the cabling database during 2008, although installation continues and the database is updated almost daily. All the documentation used to populate the database has been kept attached to each equipment and rack; so it is possible to download original diagrams (Fig. 1) and equipment manuals from the CCDB web client (Fig. 2).

The maintenance of the database is managed by a group of electronic engineers. Modification or insertion of new cables in the database is done using spreadsheet files, that contain source and destination equipment-terminal pairs and cable types. Every file is cross-checked prior to insertion to avoid errors and collision with previous data.

The Cabling Database API

The common method for visualization and modification of information in the cabling database is the CCDB web client. This tool browses all the information in the database and provides many methods for viewing and exporting the data to text files. The first integration with

*On leave

the control system was based on reading these exported files, but soon a better interaction was needed to guarantee a system up-to-date.

Now the CCDB database becomes available to the control system using the CCDB python API. This python module provides methods to search for equipments and get lists of connections, names and network information. Some translation features have been added to the API to store links between every Control and Hardware object, this links will allow every single script to update or cross-check the properties of a Control object from the CCDB.

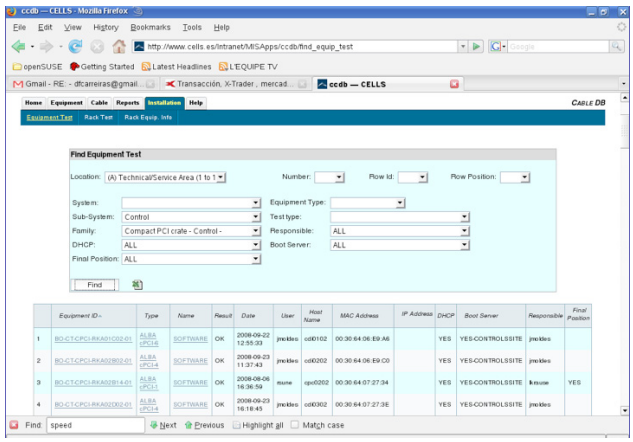

Figure 2: The cabling database web client.

GENERATING A CONTROL SYSTEM

Creating Vacuum Controls Devices

The accelerators vacuum control, with 1496 devices, is the largest control system in our Tango database. Creation of vacuum devices have been done automatically for all subsystems, using the cabling database python API to extract all needed information and all connections between equipments.

For each vacuum device (gauge, pump or valve) that belongs to our accelerators we obtain:

- Port and controller reading the device.
- Serial line and Controls computer connected to the controller
- PLC managing the pressure interlock
- Valves controlled by this interlock.

A Tango database entry is generated for each device and every configuration value. We initially used the same text format as Jive (the default Tango configuration tool), but finally we moved to comma-separated values files. A column based format allowed us more flexibility to add some Tango information like device host and run-level. These methods for massive insertion and modification of Tango database have been added to functional-Tango [7] python module, available from Tango repositories.

The architecture of hardware and software objects may differ, not having a one-to-one conversion between CCDB and Tango. The translation features of the API allow to link a different Tango device with each connector of a patch panel (e.g. serial lines) or link a single complex devices with all the software controllers of its parts (e.g. a single mirror translates into a group of gauges, pumps, motors and thermocouples). This translation allows to rebuild the whole control architecture from the cabling.

Distributing Tango Devices in Control Hosts

The Tango devices (control software processes) declared in our database are distributed in 150 PCs in our racks area. Although the control of most equipments is distributed by location (e.g. front-end devices are controlled from dedicated front-end racks) some subsystems have no dedicated racks and use spare ports of other devices, optimizing the number of devices and length of cabling connections.

Furthermore, every Tango process is assigned to a particular host from the CCDB, following the connection between the gauge in the tunnel to a controller in the rack and then the serial line from the controller to the patch panel of that particular industrial PC where the serial line controller will be configured.

Configuring Devices

There are many parameters that are configured in the Tango control database using the information updated from the CCDB. The most common is the number of ports to be used in those devices that have multiple configurations (serial lines, ADC´s, ion pump splitters), the device configuration will get this value from the CCDB to configure which channels will be used and which will be ignored when connecting to the hardware. Also dynamic attributes will be created for used channels only.

Another example are the sizes of ion pump, this value will be used by the control system when converting the current readings to an estimated pressure value. In some cases the sizes of ion pumps change. For example, when vacuum sections are replaced by insertion devices. These changes must be updated in the Tango database and the information is queried from CCDB.

Information relative to networking (IP, masks, host-names, routing) helped to control or update existing hardware that is interfaced with the control system using TCP/IP. This allows to check and restore the status of these devices (splitters, Icepaps, DAQs,) after a powercut.

Keeping the Databases up to date.

During the last year several modifications have been done in our accelerators. Diagnostic elements have been moved and several vacuum chambers have been replaced by new insertion devices. These changes required to modify racks and cables and introduce the new equipment and connections in the graphical applications.

In case that any change of the routing is done, the technicians will update the information in the CCDB and the control system can detect the change and advice to update it. New CSV files, containing device names and all its property values, are extracted from either CCDB or

Tango databases and are compared to detect missing information, errors or not applied changes.

INTERACTION WITH GRAPHICAL INTERFACES

The information available in the cabling database is used to extend the displays of the control system and allocate equipments in generic browsers. The cabling API enables applications to sort and search by location of controllers or by location of the gauges connected to them (racks and equipments in tunnel don't follow the same name). It allows to group equipments affected by same logics and also make them findable in the racks area when searching for problems.

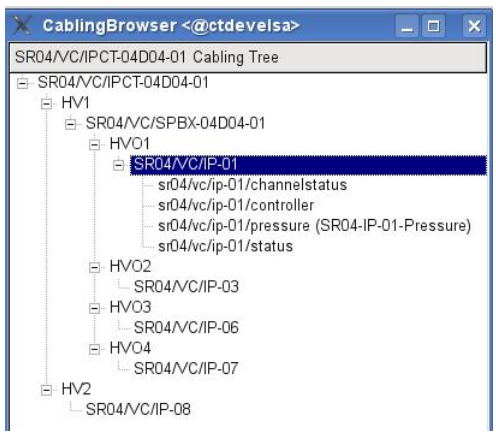

Figure 3: Tango devices can be shown in trees using the physical connections between equipments.

This extra information is added to the GUI's in two ways:

- In the Tango Database, adding cabling names as aliases of devices or labels of attributes (Fig. 4).
- In cabling-enabled widgets, browsing widgets (Fig. 3 and Fig. 5) that translate Tango names into CCDB to group the devices or attributes using their location or connections.

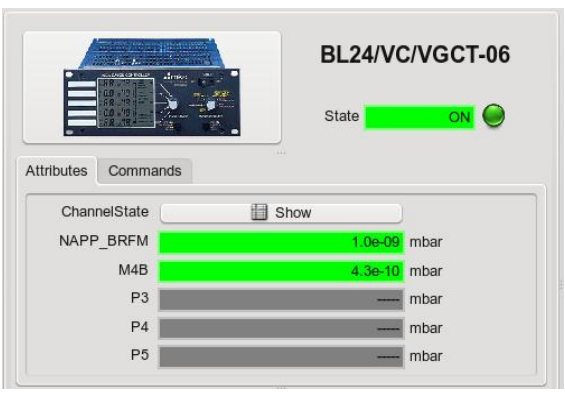

Figure 4: Names of vacuum gauge ports are labelled with the tag of the device connected to them.

When ports of a same controller are used to read different equipments (e.g. an in-vacuum mono-chromator and a mirror separated by valves) the grid widget (Fig. 5) scans the controllers in the vacuum rack and then it obtains the experimental instrument connected to each port. This information is used to reorganize values in panels and assign labels to pressure values.

Figure 5: Labels from cabling are used to group in grids the experimental equipment pressures.

CONCLUSIONS

Automated creation and configuration of big Control systems is a recurrent topic due to its applications in big facilities, reducing the amount of work and human errors when configuring thousands of devices. Acquiring and maintaining a cabling database is hard to do in a running facility, but it is a unique opportunity for new machines as this kind of database is a valuable tool at all levels.

An important application of automated configuration is the fine-tuning of the whole control system, modifying configuration parameters in many devices at the same time (new time-outs in all serial lines, different polling period in different groups of devices, update all host names at once). We used it during commissioning to optimize our control system performance, having also a fast way to do configuration roll-back.

We have now an automated way to load new values to all properties: reducing the time needed to deploy generic systems in beam-lines or adding subsystems once the machine was already operating (insertion devices). A lot of work has been saved and a lot of extra information became available to users.

AN OPERATIONAL EVENT ANNOUNCER FOR THE LHC CONTROL CENTRE USING SPEECH SYNTHESIS

S. Page, R. Alemany Fernandez, CERN, Geneva, Switzerland

Abstract

The LHC Island of the CERN Control Centre is a busy working environment with many status displays and running software applications. An audible event announcer was developed in order to provide a simple and efficient method to notify the operations team of events occurring within the many subsystems of the accelerator. The LHC Announcer uses speech synthesis to report messages based upon data received from multiple sources. General accelerator information such as injections, beam energies and beam dumps are derived from data received from the LHC Timing System. Additionally, a software interface is provided that allows other surveillance processes to send messages to the Announcer using the standard control system middleware. Events are divided into categories which the user can enable or disable depending upon their interest. Use of the LHC Announcer is not limited to the Control Centre and is intended to be available to a wide audience, both inside and outside CERN. To accommodate this, it was designed to require no special software beyond a standard web browser. This paper describes the design of the LHC Announcer and how it is integrated into the LHC operational environment.

SYSTEM ARCHITECTURE

Announcements are generated on a dedicated server computer running Scientific Linux. The server generates announcement text based upon received data and translates the announcement into an audible message which can then be delivered to clients by a web server. In order to prevent disruption of the operational version of the Announcer, there are separate web servers for the CERN Control Centre and users not on the operational computer network. Figure 1 illustrates the processes involved to create an announcement and deliver it to a user's web browser.

ANNOUNCEMENT SOURCES

There are two sources of announcements at present: the LHC Timing System and software surveillance processes within the control system.

Announcements from the LHC Timing System

The LHC Timing System [1] is a good central source of information about both the current state of the LHC and new events that occur within the machine. As such, it was the first source of events used for the LHC Announcer. A timing receiver (CTRI) is installed in the LHC Announcer server, allowing the reception of timing

Table 1: Announcements from the LHC Timing System

Category	Events
Beam	○ Energy in 0.5 TeV increments ○ Fill numbers ○ Next injection ring, bucket and no. bunches ○ Injection ○ Beam dumps
Collimation	○ Collimators starting and stopping
Experiments	○ Beta* in 1m increments during squeeze
Feedback	○ Start dynamic changes
Instrumentation	○ Wire scans
Mode	○ Accelerator mode changes ○ Beam mode changes ○ Operational mode changes
Post-mortem	○ Global post-mortems
Power	○ Power converters start and abort ramps ○ 60A PC Permit changes ○ Sector Access changes
RF	○ Start and stop dampers

Figure 2: Example event files with meta data encoded within their names.

events. Each timing event may have a corresponding 16 bit payload, indicating a value associated with the event. Many events within the timing system are not suitable for direct mapping into announcements, so received events are processed by call-back code written in Perl. This allows announcements to be triggered on the arrival of a particular combination of timing events or when a timing event's payload changes by a given amount or passes a configured threshold. For example, the beam energy is received from the timing network at 10Hz. The event processing code will generate an announcement whenever the energy passes through a 0.5TeV boundary or if the energy stabilises at a particular value for more than 10 seconds. A deadband prevents repeated announcements.

Table 1 shows events that are currently announced using data received from the LHC Timing System and the categories to which they belong.

Announcements from Control System Surveillance Processes

After the LHC Announcer had been running for some time using only the LHC Timing System as a source, it became clear that it would be useful to allow other control system processes to make announcements. This was achieved by implementing a device server for the Announcer using the standard controls framework for the LHC (known as FESA) [2]. The LHC Announcer appears as a standard device within the control system, with a single property that triggers an announcement when set. This allows applications to communicate with the Announcer using the standard Controls Middleware (CMW) [3]. In order to limit who may trigger announcements, access to the controls device is protected by the Role-Based Access Control system (RBAC) [4].

Since messages announced by systems surveying the state of the LHC may potentially be sensitive, the FESA interface allows a flag to be set for each announcement to determine whether it should be sent to the publicly visible web server.

Details of the LHC Big Sister software that uses this mechanism to make announcements are given later in the paper.

SPEECH SYNTHESIS

Announcements from the Timing System or FESA server are added to a message queue in text form. A server process reads each message from the queue in turn and passes it to the Festival Speech Synthesis System [5] in order to generate the announcement audio. The audio is stored in an Ogg Vorbis file with the associated meta data (timestamp, category and message text) encoded within the name of the file as shown in Figure 2. Since a burst of events may occur at a faster rate than clients are able to play the audio, the 10 most recent events are stored at any time.

Several synthesised voices were tested when the LHC Announcer was originally developed, with the objective to find one which was both realistic and clear in its enunciation of the event messages. Finally a voice known as 'Nick' developed by the University of Edinburgh was chosen. The use of the synthesised voice required a non-commercial use agreement to be signed.

WEB INTERFACE

In order to make the LHC Announcer easily available to as wide an audience as possible, it was decided to use a web interface. As a result, only a standard web browser is required to run the LHC Announcer [6], rather than a dedicated application.

Features

The LHC Announcer web interface (shown in Figure 3) plays audio announcing any events that occur from the moment that the web page is opened. A rolling history of the last 20 received events is displayed at the bottom of the page, along with the time at which they occurred.

Categories of event (e.g. Beam, Collimation and RF) can be enabled or disabled, allowing the user to select the types of events that they wish to hear. A further option allows events from disabled categories to be included within the event history, in which case they will be shown greyed-out to distinguish them from events that were audibly announced.

A drop-down menu allows the user to add a Vistar fixed display to the web page, allowing the status of the LHC and the other elements of the accelerator chain upon which it depends to be shown visually in parallel to audio event announcements.

Implementation

The web interface uses Javascript to retrieve events and to update the event history and Vistar image (if displayed). When the web page is opened, the current

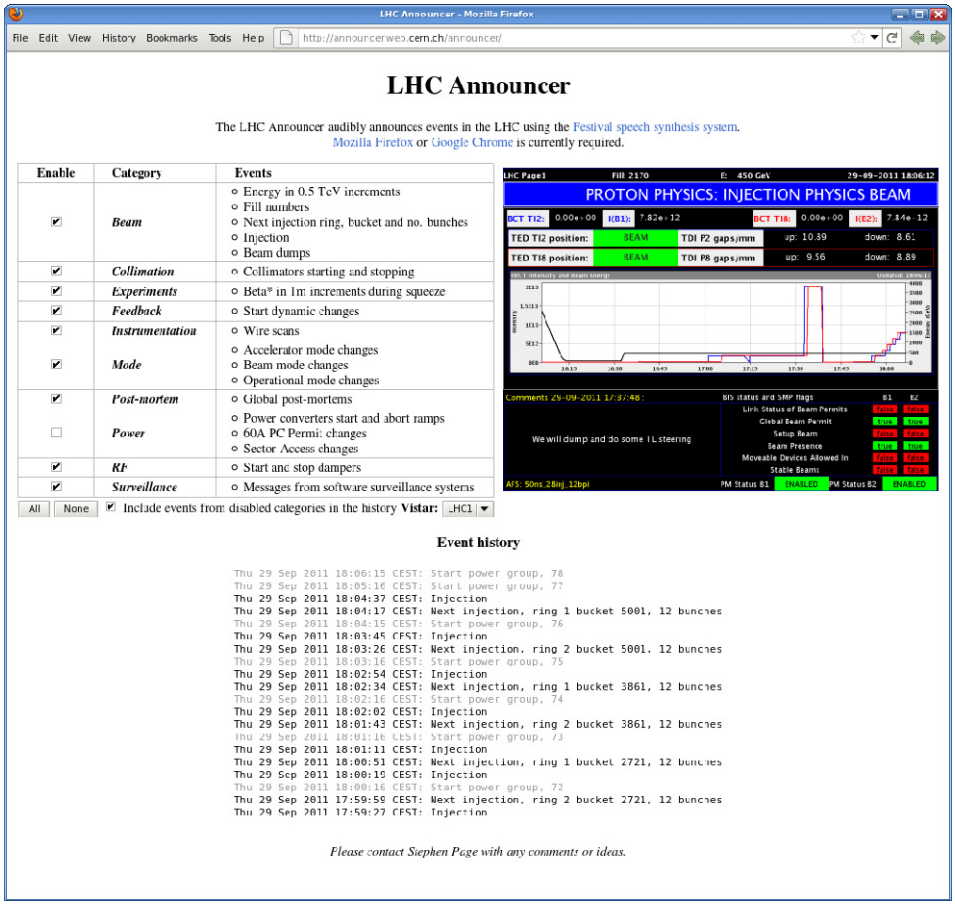

Figure 3: The LHC Announcer web interface.

UTC time is read from the client computer's local clock. That time is then passed in a call to a Perl CGI script which returns meta data for the next of the 10 known events that occurred after that time. The request for new event data is repeated periodically. When a new event is received by the browser, the timestamp of that event is passed with new requests, ensuring that all events are announced, even if a series of events occur faster than the corresponding audio can be played. On reception of meta data for a new event, the web page's Javascript determines whether to retrieve the Ogg Vorbis audio file from the web server and to update the event history based upon the options selected by the user.

This implementation works well when the number of active clients is reasonably low. For systems with a large number of clients, the periodic execution of the Perl CGI script used to retrieve data about new events could become a bottleneck. In this case, it may be more efficient to investigate technologies allowing new announcements to be 'pushed' from the web server, such as WebSockets (though browser support for these is rather immature) or so-called 'long polling'.

Web Browser Compatibility

The LHC Announcer uses relatively recent technologies that require explicit support by the web browser. The web page is written in standard HTML5, which is supported by the majority of modern browsers. However, the HTML5 Specification [7] does not dictate which audio codecs browsers must support for the *<audio>* tag, which the LHC Announcer uses for announcements. Unfortunately, there is no single compressed audio format that is currently supported by all of the most common web browsers, with most of them supporting either MP3 (which has commercial licensing and patent issues) or Ogg Vorbis (an open alternative). Ogg Vorbis is used for the LHC Announcer as it is supported by Mozilla Firefox, which is the most common multi-platform web browser in use at CERN and is also the only web browser available on all of the CERN Control Centre consoles. Google Chrome has also been found to work. Note that if it were important to support all HTML5-compliant browsers, then it would be possible to generate audio in multiple formats, though of course this would involve additional processing overhead.

SURVEILLANCE PROCESSES – THE LHC BIG SISTER

During 2011 a new monitoring infrastructure called Big Sister was put in place for the LHC based upon the architecture of the Software Interlock System [8].

Through a rather complex logic which correlates information from different accelerator systems, the LHC Big Sister can anticipate failures, providing operators with enough warning time and preventing the beams from being dumped, allowing more efficient operation of the LHC.

The logic trees are very flexible and quickly configurable. They can be associated with a measurement of a condition, a device state or property, beam mode, beam quality. The measured parameter is compared to a reference value, with the outcome that the measurement either matches the desired value (condition is true) or not (condition is false). Each of these basic building blocks is associated to one piece of accelerator equipment and they can be combined to produce a more elaborated logical condition. The top-level condition can be either true or false depending on the condition of the elementary building blocks via logic ANDs, ORs or NOTs.

As many alarms and warnings in the LHC Control Room provide visual information, there is always the risk that the operator overlooks some of those alarms or warnings because of a saturation of visual information. Since the LHC Big Sister tries to catch situations that will, in a short while, result in a beam dump, giving the warning messages visually was discarded as an option because failing to react to a warning may result in the loss of the LHC beams. Therefore, the LHC Announcer was chosen as the communication mechanism from Big Sister to the operations team. In this way, the operator does not need to actively seek the information, rather the information comes to him in the form of an audible message. Many beam dumps have been avoided thanks to the combined action of Big Sister and LHC Announcer.

When a condition monitored by Big Sister is false, the associated message is exported to the LHC Announcer which then reports the message and warns the operators about faulty equipment or a forgotten action. The shift crew reacts to the warning, fixing the problem and avoiding a potential dump of the beams. For example, one of the logic trees monitors the status of the Radio Frequency Cavities of LHC. If two or more cavities enter into a faulty state the beams will be dumped. The Big Sister continuously monitors the status of the cavities and as soon one of them enters a faulty state it is announced via the LHC Announcer. Consequently, the operator switches it back on and operation proceeds. Of course, there is also a visual alarm if a cavity becomes faulty, but it has been overlooked on several occasions Since the message has been reported by the Announcer, this type of fault has always been corrected without loss of the beams

LHC ANNOUNCER USAGE

The LHC Announcer has proved useful to a number of different types of user. Its main purpose is to inform operators within the CERN Control Centre of events occurring in the LHC, which may require their attention. Additionally, some equipment experts use the Announcer in order to be informed of events that may relate to tests that they are performing.

The public version of the LHC Announcer web interface has also been popular with people around the world who are interested in the operation of the LHC. As such, it also makes a useful contribution to the publication of CERN's activities and the fostering of public interest.

Abstract

MedAustron is a centre for ion-therapy and research in currently under construction in Austria. It features a synchrotron particle accelerator for proton and carbon-ion beams. This paper presents the architecture and concepts for implementing a procedure framework called ProShell. Procedures to automate high level control and analysis tasks for commissioning and during operation modelled with Petri-Nets and user code is implemented with C#. It must be possible to execute procedures and monitor their execution progress remotely. Procedures include starting up devices and subsystems in a controlled manner, configuring, operating O(1000) devices and tuning their operational settings using iterative optimization algorithms. Device interfaces must be extensible to accommodate yet unanticipated functionalities. The framework implements a template for procedure specific graphical interfaces to access device specific information such as monitoring data. Procedures interact with physical devices through adapter software components that implement one of the following interfaces: (1) state-less or (2) state-driven device interface. Components can extend these device interfaces following an object-oriented single inheritance scheme to provide augmented, device-specific interfaces. As only two basic device interfaces need to be defined at an early project stage, devices can be integrated gradually as commissioning progresses. We present the architecture and design of ProShell and explain the programming model by giving the simple example of the ion source spectrum analysis procedure.

INTRODUCTION

MedAustron [1] [2] is an ion therapy and research centre presently under construction in Wiener Neustadt, Austria. The facility features a synchrotron-based accelerator (Figure 1) with up to 5 ion sources for protons, carbon ions and possibly other light ions. It will provide ion beams with energies up to 800MeV to 5 beam lines, one of which is a rotating proton gantry.

The Procedure Shell Execution Framework (ProShell) is a C# application to automate high level control and analysis tasks for commissioning and during operation. Each task called a procedure implements a standardized procedure interface and is deployed as .NET assembly (shared objects). Key features of the ProShell are:

- Allocating resources on behalf of a procedure.
- Uniform access to system, software and physical devices independent of communication protocols for monitoring and control purposes.
- Reception and visualization of device measurements
- Management of generic procedure lifecycle and custom procedure workflow.
- Parallel execution of multiple procedures
- Automatic procedure execution without user intervention
- Manual procedure execution to step through the procedure specific workflow.
- Provide access to control system services hiding implementation specific interfaces and communication protocols.

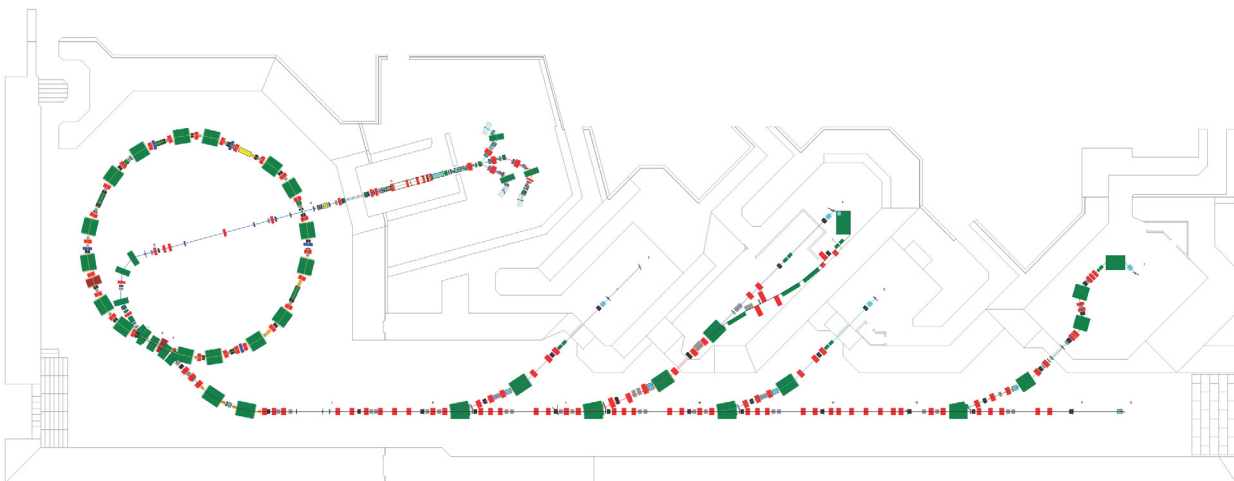

Figure 1: MedAustron accelerator layout.

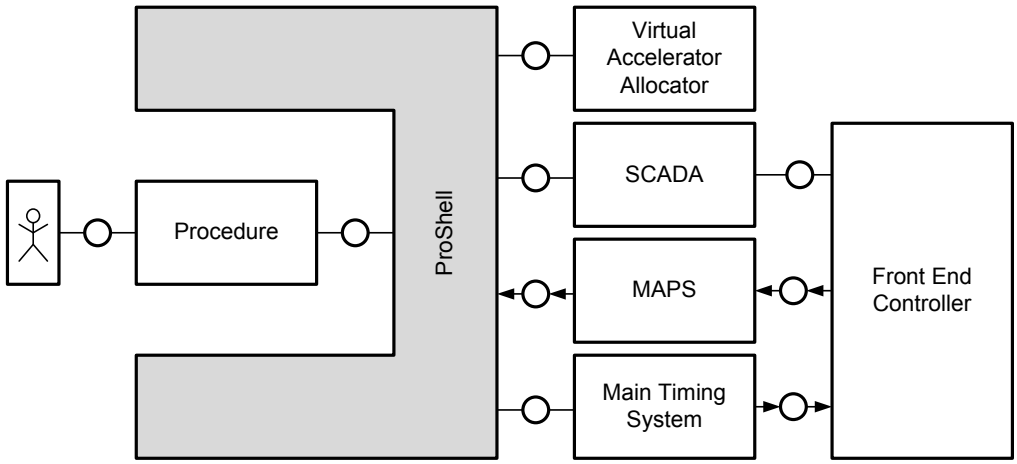

Figure 2: General ProShell architecture and main communication partners.

ARCHITECTURE

Overview

ProShell is a framework to dynamically load and execute procedures implemented as C# classes. As outlined in Figure 2 it provides access to system, software and physical devices for monitoring and control purposes. These services are accessible from ProShell through service-specific *Driver* objects that are used internally and are not directly accessible from the loaded procedures:

- *Virtual Accelerator Allocator* (VAA) is the scheduler of the system that allocates resources for exclusive usage on behalf of a user application.
- *WinCC OA* is a Supervisory Control and Data Acquisition (SCADA) tool from Siemens [5]. It acts as the main communication backbone between user interfaces and procedures on tier 1 and frontend controllers and devices on tier 3 [7].
- *MAPS services* are a set of data servers implementing a publisher subscriber protocol. It forwards measurements and main timing information from front-end controllers to user applications in non-real-time.
- *Main Timing System* (MTS) generates events for beam generation that are delivered to the frontend controllers with a precision of 100ns [4].

In MedAustron the last three services provide a communication channel to the *frontend controllers* running on National instruments PXI crates. Each frontend controller can host multiple *frontend devices* that implement device specific tasks in LabView to control the connected physical device. They also provide a unified interface to WinCC OA through a shared variable OPC server and may emit fast monitoring data through MAPS.

Procedure

A *Procedure* encapsulates specific repetitive control and processing tasks for operation and commissioning written in C#. It is compiled into a .NET assembly (shared library) and implements a common interface to be managed by the ProcedureContext independent of its task.

Procedures may call any available C# functions and libraries. However, procedures should mainly use the API provided by the ProcedureContext to interact with system devices and services.

Procedure Context

ProShell encapsules execution of procedure instances in separate *ProcedureContexts*. Each ProcedureContext acts as a container that provides coordinated access to devices and control system services and manages the procedure lifecycle. Thus it provides the capability to execute procedures in parallel. In case of resource conflicts the VAA will delay the allocation of one procedure and subsequently ProShell will delay the execution of this procedure. As depicted in Figure 3 each ProcedureContext manages the following objects separately:

- *Procedure* implements a specific control or processing task and provides a standardized interface to be controlled by the ProcedureContext.
- *ProcedureLifecycle* handles the general lifecycle of the procedure that is common to all procedures.
- *PetriNetEngine* is a workflow engine that executes the procedure specific workflow defined in a Petri Net Modelling Language (PNML) file [3].
- *DeviceCache* allocates resources on behalf of the procedure using the VAA driver and keeps a cache of C# adapter objects for communicating with the resources.

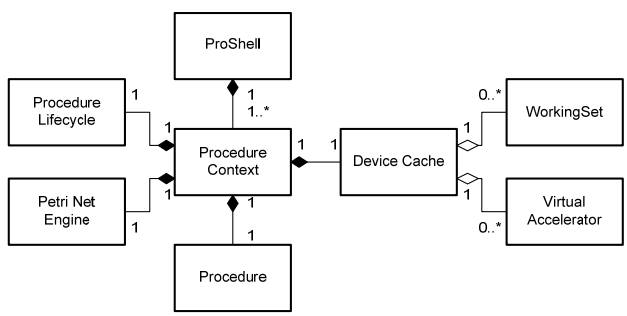

Figure 3: Class diagram for object owned by the ProcedureContext.

Resources

All device instances and types are represented in WinCC OA as data points (DP) and data point types (DPT). In addition each DPT contains a set of data point elements (DPE) that are name-value pairs with a defined value type. Each device implements one of the following interfaces:

- *BasicDevice* is a state-less front-end device interface that only provides a minimal set of DPEs for monitoring.
- *StateDrivenDevice (SDD)* is a state-driven front-end device interface that extends the BasicDevice with additional DPEs to provide an interface for commanding and login to guarantee exclusive access to a device.

WinCC OA also provides two special resource types to control a set of devices concurrently through a single virtual device:

- *Working Set* (WS) is a virtual device that implements the SDD interface and controls a set of SDDs.
- *Virtual Accelerator* (VAcc) controls a set of Working Sets and subsequently a set of devices. It also implements the SDD interface. In addition a VAcc also contains a dynamically assigned Main Timing Generator that allows a procedure to emit timing information for beam generation with an accuracy of 100ns.

Resource Adapters

ProShell encapsulates communication over a number of different communication technologies, shielding procedures from the underlying addressing and communication specifics by providing devices as object that follow the adapter pattern [6].

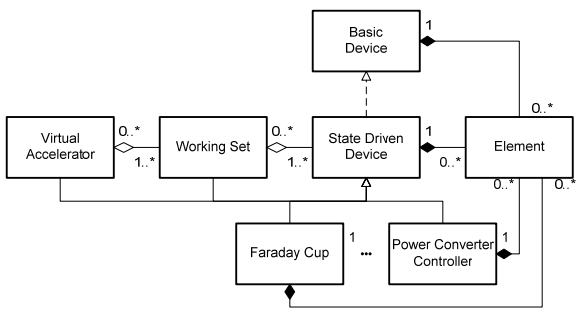

Figure 4: Class diagram of resources adapters for devices, Working Sets and Virtual Accelerators.

Adapter objects provide an object-oriented API that implement BasicDevice or StateDrivenDevice interfaces as shown in Figure 4. Each device exposes a number of elements and functions:

- *Elements* wrap a single name-value pair (i.e. DPE) independent of communication protocol using a specific Driver internally. Classes implementing the element interface provide data type conversion for complex data types and client-side validity checks not supported by WinCC OA.
- *Functions* provide access to multiple Elements that require a specific workflow when reading or writing. In this case the Elements will be available only as protected fields within the device adapter.

General Procedure Lifecycle

The *ProcedureLifecycle* manages the lifecycle part, which is the same for all procedures following the state machine depicted in Figure 5.

When a procedure is opened a new ProcedureContext is created, the procedure specific PNML file is loaded and the state is moved to *Hold*. At this time no resources are allocated.

Subsequently the user can issue the *Initialize* transition to request the allocation of the specified resources from the VAA. The procedure lifecycle state moves to *Ready* when all resources have been allocated.

Thereafter the user may emit an *Enable* transition that parameterizes the procedure specific Petri net and moves the state machine into *Op* state. While in *Op* state the procedure specific Petri net can be executed in steps or run until termination.

The *Disable* transition stops the execution of the PetriNet and the *Finalize* transition releases all allocated resources. If an error is detected, the state moves to *Failed* and a subsequent *Clear* transition stops the petri net and releases all resources.

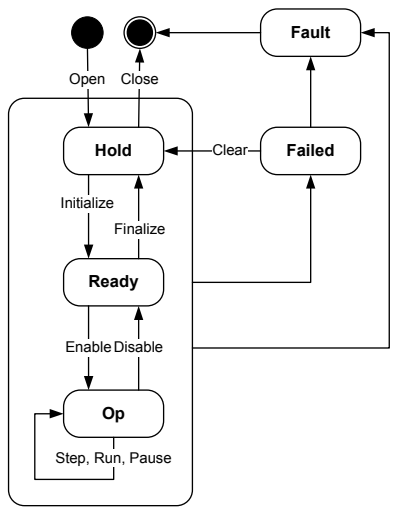

Figure 5: Procedure Context Lifecycle.

Petri Net

The Petri net for each procedure is specified in a Petri net modelling language (PNML) file [3]. The implemented petri net engine extends the standard petri net defined in PNML with the following functionalities:

- Support *coloured tokens* to pass data between transitions.
- Attaching *callback functions* to transitions to execute procedure specific code.
- Extension for asynchronous execution by putting tokens into places programmatically during runtime. This is symbolized in the PNML with asynchronous arcs (dashed lines).

BEAM SPECTRUM ANALYSIS

The ion source beam spectrum analysis procedure detects the particles types generated by a specific ion source. Therefore a current is applied to the bending magnet and the generated field deflects the generated particles depending on the particle mass. The energy of the particles that hit the following faraday cup is measured. Due to the correlation of current to particle type, the generated particles can be detected with peak detection algorithm on the energy over current plot.

```
public override void OnEnable()
{
 _faradayCup.Move(true, 20);
 PetriNet net = Context.PetriNet;
 net.BindParameter("n", (uint)Currents.Cur.Count);
 IPlace place = net.GetPlace("conf");
 foreach (Tuple<double> current in Currents.Cur)
 {
   CurrentToken token = new CurrentToken()
   { Current = current.Item1 };
   place.AddInitialToken(token);
 }
 Context.PetriNet.Trigger();
}
```

Figure 6: *Enable* transition for beam spectrum analysis.

This procedure will allocate an ion source working set containing the power converter for the bending magnet and the following faraday cup during the *Initialize* transition. The subsequent *Enable* transition as depicted in Figure 6 moves the faraday cup into the beam line and configured the *conf* place with n current tokens.

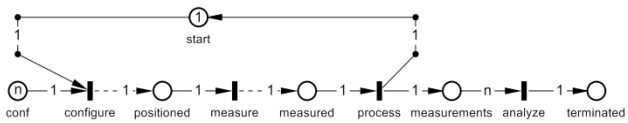

Figure 7: Ion source beam spectrum measurement with synchronous arcs (solid lines) and asynchronous arcs (dashed lines).

After the procedure was brought into *Op* state, the Petri net depicted in Figure 7 becomes active. The Petri net engine will remove a token from *conf* and *start* places and fire the *configure* transition (Figure 8) that applies the current specified in the token from the *conf* place. When the set-point was reached a token will be put into the *positioned* place and subsequently the *measure* transition is fired. During this transition the faraday cup is instructed to perform a measurement that will be put asynchronously as a token into the *measured* place.

```
private void Configure(PetriNet petrinet,
  ITransition transition,
  Dictionary<IArc, Queue<IToken>> input,
  Dictionary<IArc, Queue<IToken>> output)
{
 List<CurrentToken> tokens =
  petrinet.GetTokens<CurrentToken>(input);
 if (tokens.Count == 1)
 {
  var cycleToken = (CurrentToken) token;
  _pcc.CurrentAqn.Subscribe(
   petrinet.GetPlace("positioned"), token[0].Current);
  _pcc.CurrentCcv.Value = token[0].Current;
  petrinet.GenerateTokens(output);
 }
}
```

Figure 8: Petri net callback function for *conf* transition.

After a measurement has been performed for each current token in the *conf* place, n tokens with measurement results will be available in the *measurement* place and the *analyze* transition will be fired. This transition will plot the measurements and performs a peak detection to detect the generated particles.

SUMMARY

This article presented the architecture and selected architecture significant components of the MedAustron Procedure Shell Execution Framework. The application follows a container-based approach where each procedure is executed in its own sandbox. Accelerator devices are controlled and monitored through resource adapter objects that provide an object oriented API to hide communication specific details.

Integration with the main systems (WinCC OA, MTS, VAA and MAPS) has been concluded. First tests have been carried out in the MedAustron test column with the presented procedure and generic procedures that execute beam cycles using physical devices where available and emulating not-available devices through WinCC OA scripts. These tests have shown that generic tasks such as allocation, data conversion and validity checks can be encapsulated in ProShell to provide a simplified interface for procedures and that the Petri net provides valuable feedback for the currently running procedure.

Next steps for ProShell include extending element classes for additional protocols, and specifying and implementing adapter objects and procedures required for commissioning and during operations.

LASSIE: THE LARGE ANALOGUE SIGNAL AND SCALING INFORMATION ENVIRONMENT FOR FAIR

T. Hoffmann, H. Bräuning, R. Haseitl
GSI Helmholtzzentrum für Schwerionenforschung GmbH, Darmstadt, Germany

Abstract

At FAIR, the Facility for Antiproton and Ion Research, several new accelerators and storage rings such as the SIS 100, HESR, CR, the inter-connecting HEBT beam lines, S-FRS and experiments will be built. All of these installations are equipped with beam diagnostic devices and other components, which deliver time-resolved analogue signals to show status, quality and performance of the accelerators. These signals can originate from particle detectors such as ionization chambers and plastic scintillators, but also from adapted output signals of transformers, collimators, magnet functions, rf cavities and others. To visualize and precisely correlate the time axis of all input signals a dedicated FESA based data acquisition and analysis system named LASSIE, the Large Analogue Signal and Scaling Information Environment, is currently being developed. The main operation mode of LASSIE is currently pulse counting with latching VME scaler boards. Later enhancements for ADC, QDC, or TDC digitization in the future are foreseen. The concept, features and challenges of this large distributed DAQ system will be presented.

INTRODUCTION

At all particle accelerators analogue signals are derived from detectors, rf cavities, function generators, transformers and other sources. A common way to observe these signals in order to understand, trim and operate the accelerator is the readout and signal presentation by oscilloscopes. With an increasing amount of signals at large facilities like GSI or FAIR, this solution gets expensive. Furthermore, it can not be easily integrated into a common accelerator control system, which must provide safe remote operation including data recording, storage and time-correlated presentation.

There are already solutions for analogue signal acquisition and presentation such as OASIS [1] at CERN and ABLASS [2] at GSI. With respect to the high costs of switching matrices and powerful front-end digitizers, the concept of OASIS was rejected as a solution for FAIR. However, long term experience with the low cost ABLASS system has already been obtained at GSI and the reduced performance in resolution compared with oscilloscopes was accepted for most of the signals. The principle of ABLASS is based on the conversion of analogue signals into frequencies, which are then counted in a modular VME system. To provide time-correlated signals acquired over the complete FAIR complex for the future digital control room, the concept of ABLASS will not only be ported to the new control system environment. In contrast to ABLASS the new DAQ system, which is called LASSIE ('Large Analogue Signal and Scaling Information Environment') is designed from the start as a distributed system. As such, LASSIE will be used at all FAIR [3] accelerators, which are part of the modularized FAIR start version: SIS100, HESR, CR, S-FRS, HEBT and pLinac.

GENERAL CONCEPT

LASSIE will be the data acquisition environment for a wide range of beam diagnostic systems. Most diagnostic systems consist of particle detectors like ionization chambers, scintillators, secondary electron monitors or beam loss monitors. Other signals handled by LASSIE include the output of current transformers or direct current measurement from cups and collimators.

However, the concept is not restricted to signals from beam diagnostic detectors. Other arbitrary signals like magnet ramps or accelerator rf-signals can be added for correlation purposes.

The acquisition, analysis and presentation of time correlated signals will provide essential information for beam setup, optimization, control and experiments. This is essential for beam transmission measurement, spill structure analysis and beam loss monitoring.

The system itself will not change or set accelerator hardware i.e. react on beam like feedback systems would do.

For normal operating tasks, it is sufficient to sample the signals with a frequency in the order of 1 kHz. For dedicated beam experiments higher sampling rates (currently up to 1 MHz) will be supported.

LASSIE is based on the Front-End Software Architecture (FESA) [4]. Originally developed at CERN, FESA is now advanced in a collaborative effort between CERN and GSI, allowing for GSI specific modifications. The use of the FESA framework results in a clear separation between the data acquisition part and the graphical user interface part. LASSIE includes both these parts: the data acquisition using FESA and Java based analysis and display tools. In addition, the FESA part will strictly implement the currently emerging guidelines for FESA development at GSI. This will allow the seamless integration of the LASSIE system into the new FAIR control system.

DATA ACQUISITION

LASSIE currently implements one FESA class: the LArge Scaler Array (LASA). This FESA class reads and stores the data of one or more latching scalers as a function of time over one accelerator cycle. With respect

to the high amount of expected channels and the availability of high-performance acquisition modules the VME standard was chosen. All analogue signals not directly suitable for counting are converted into frequencies using I/f or U/f converters. These frequency pulses are counted in VME scaler modules like the Struck SIS3820, a 32 bit and 32-channel multi-scaler. For the time being, a GSI-built timing module decodes the accelerator timing and provides a list of machine events with their corresponding time within the accelerator cycle. This correlates the machine events with the time dependent scaler data.

Modern accelerators have the ability to deliver different beams quasi in parallel. At GSI this is currently done using the concept of virtual accelerators of which there can be up to 16. FESA allows for multiplexed data storage, i.e. data is stored for each virtual accelerator separately. By design, memory allocation within the FESA framework is quite static, although the upcoming FESA 3.0 version allows for a slightly more dynamic memory handling. Nevertheless, as the LASA class is designed to handle 200 or more scaler channels and to store the data over full accelerator cycles of varying length of up to 15 s with selectable sampling frequencies, a more flexible memory handling is required. In addition, the required possibility of selecting sampling frequencies up to 1MHz mandates the ability to disable almost all of the scaler channels but the few ones of interest. This is caused not only by the memory required but also by the bandwidth of the VME backplane, which restricts the data rate. Therefore, the LASA class implements a custom memory management allocating a fixed amount (typ. 50%) of the system memory and is using two memory banks. While new acquired data is stored in one bank, the data of the previous cycle can be read by clients from the other bank. The downside of this implementation is that the LASA class is not truly multiplexed. Data for every accelerator is sent to the clients and it is the client's decision whether to ignore or display it.

Often, beam physics experiments require the storage of data on disk for later offline analysis. This data storage in ASCII or binary form is handled by the FESA class either to a network file-system or to an attached local solid-state disk. The storage procedure is realized in a thread, a so-called concurrency layer, separated from the data acquisition and the full spill data is copied to a memory buffer before writing. This ensures that data acquisition is not hampered by blocking write operations.

In the FAIR control system it is expected that data acquisition classes like the LASA class will also be responsible for setting DAQ related components like amplifiers etc. The LASA class is designed for this task. However, for the time being the class can only obtain these settings from the current GSI control system.

General guidelines for designing the interface of FESA classes at GSI/FAIR are currently being prepared. According to these guidelines FESA classes should return (and accept) physically meaningful values to clients. Using device settings from the current GSI control system, the LASA class can convert the scaler data into the physical input data like currents or voltages. For many diagnostic systems these currents or voltages are proportional to the beam current, i.e. the number of particles per second passing the detector. The proportionality factor however is usually dependent on the energy loss in the detector, which in turn requires information like beam energy, charge state and isotope mass to be calculated. Although these calculations are currently implemented in the LASA class for test purposes, it is still discussed whether this is the appropriate place for such calculations. It requires, that the FESA class is informed of the beam parameters either by the FAIR control system or by the central machine timing system. Both are not available yet.

The LASA class always reads all active scaler channels and stores them in memory. Clients are usually interested only in a few channels. To facilitate easy access to single channels without the need to send all data to the clients, the LASA class uses the ability that a single FESA process running on a front-end computer can present several devices to the clients. Thus, the LASA class running on a front-end computer presents each scaler channel as a single device to the clients. Clients accessing this device can obtain the integrated data over the full accelerator cycle or between two selected events and, if desired, the time dependent spill data also between two selected events. This allows easy use of the LASA class from generic GUIs and other applications of the future control system.

EXPERT TOOLS

In addition to the LASA class, the LASSIE system consists of several expert GUI tools, which are written in Java and are based heavily on CERN libraries for communication with the FESA classes and graphical display.

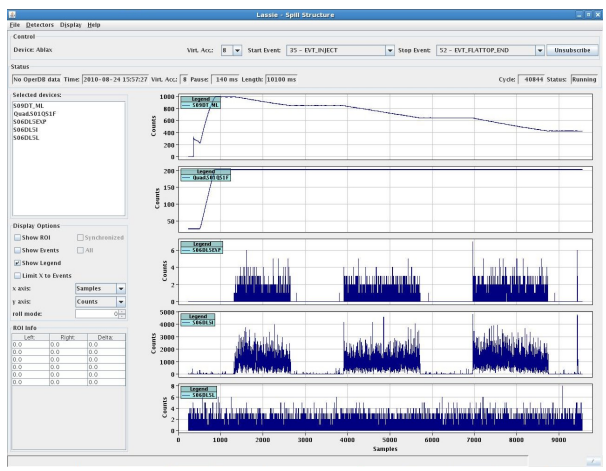

Figure 1: The Lassie spill structure tool for analysis of synchrotron signals (from top to bottom: current transformer, quadrupole ramp and beam loss monitors).

This tool-set contains a general control and monitor tool for the LASA classes running on different front-end

computers, a spill structure analysis tool [Fig. 1], a counter display tool [Fig. 2], a dose level tool [Fig. 3] and others. Using the object oriented approach of Java, the major part of the core functionality, like obtaining data from the FESA classes via suitable providers, storing and analyzing the obtained data and many GUI widgets, could be put into packages common to all tools. This makes the GUI part of the LASSIE system more like a framework and gives it a great flexibility with respect to developing new and dedicated tools. Furthermore, most of the tools are not restricted to use the LASA class. Any FESA class implementing the same interface for the devices it handles could be used. This would for example include the readout of an ADC, which in principle also represents time dependent data.

With the exception of the general control and monitor tool, the expert tools do not address a LASA class (or scaler array) but the devices presented by the running LASA classes. As such, the expert tools inherently can deal with a distributed system, which consists of FESA classes running on different front-end computers in different locations of the accelerator complex.

Of course, the possibility of missing or delayed data from one or more front-end computers must be taken into account. Currently the virtual accelerator number and the UTC timestamp of the GSI machine timing transmitted once per cycle are used to assure the correlation of the data received and to detect any errors. With a first test setup using two LASA systems approximately 300m apart, no significant error rate could be observed for typical SIS cycles of a few seconds.

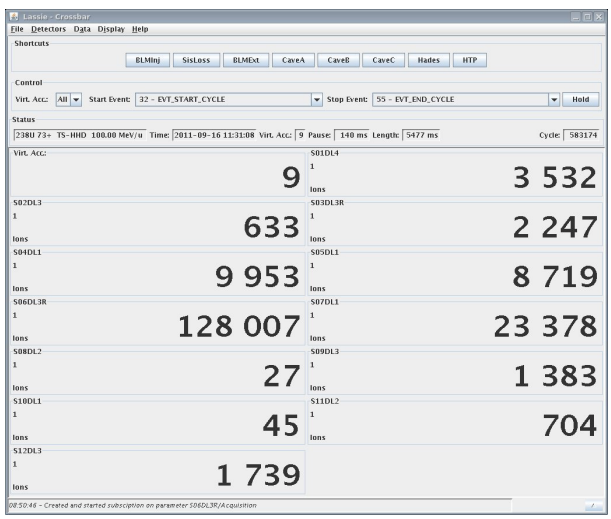

Figure 2: The counter display tool shows the total counter sum of a detector or device after each cycle.

In the FAIR control system the machine timing will be handled via the White Rabbit timing system. This new timing system is based on Synchronous Ethernet, the Precision Time Protocol (PTP), new developed hardware and a field-bus like topology [5]. It provides deterministic data with sub-ns accuracy. Thus, every VME system will be equipped with a White Rabbit timing receiver card.

As every event will be tagged with a time stamp, precise data correlation between the distant crates is assured. In the future this precise tagging may also allow data correlation throughout different timing domains of the accelerator complex.

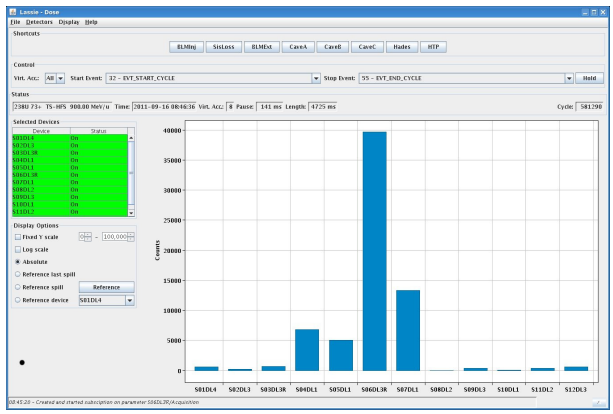

Figure 3: The dose level tool shows the total counter sum of a detector or device after each cycle and is mainly used for beam loss detection.

CONCLUSIONS

LASSIE presents the first implementation of a major beam diagnostic system using the FESA framework and Java based expert GUIs at GSI. It is extensively tested with diagnostic devices from the current SIS18 accelerator of GSI and the current machine timing system. Although many details of the FAIR infrastructure like the new White Rabbit timing system are not available right now, adaptation of the current LASSIE system is expected to be straight forward.

The possibility to extend LASSIE with other FESA classes acquiring time-dependent data e.g. DAC driven magnet power supplies, transforms it into a powerful tool. It will provide oscilloscope-like features fully integrated into the control system, making most of the expensive cables and hardware scopes in the control room obsolete.

FIRST EXPERIENCE WITH THE MATLAB MIDDLE LAYER AT ANKA

S. Marsching*, aquenos GmbH, Baden-Baden, Germany
E. Huttel, M. Klein, A.-S. Müller, N.J. Smale, KIT, Karlsruhe, Germany

Abstract

The MATLAB Middle Layer has been adapted for use at ANKA. It was finally commissioned in March 2011. It is used for accelerator physics studies and regular tasks like beam-based alignment and response matrix analysis using LOCO. Furthermore, we intend to study the MATLAB Middle Layer as default orbit correction tool for user operation. We report on the experience made during the commissioning process and present the latest results obtained while using the MATLAB Middle Layer for machine studies.

INTRODUCTION

Synchrotron light sources are an excellent tool for a wide range of studies in biology, chemistry, physics and medicine, as they provide very bright light from hard x-rays to the far infrared.

Most of these light sources are based on electron storage rings, in which electrons circle around at relativistic speed, thus emitting synchrotron light.

For ensuring a maximum performance at the generation of synchrotron light, it is crucial to have tight control over the various operational parameters of the underlying particle accelerator and adapt to changing demands or environmental conditions, like the air temperature.

The MATLAB Middle Layer (MML) [1] is a collection of scripts for the MATLAB programming environment, designed to control and measure parameters of an accelerator. This software creates an abstraction layer enabling the user to write scripts independent of the accelerator's control system. For most uses, even the magnet lattice of the accelerator itself is abstracted. Thus, scripts written for one accelerator can be used for a different accelerator, even if this accelerator has a mostly different design.

Recently, we have adapted the MATLAB Middle Layer for use at ANKA. ANKA is the synchrotron radiation facility of the Karlsruhe Institute of Technology, located in Southern Germany.

In order to use the MML at ANKA, we had to make an interface to the ANKA control system. First we implemented our own control system interface in the MML. Later we migrated to the built-in LabCA support and used a gateway to make data from our control system available via the Channel Access (CA) protocol.

We use some of the existing tools that are part of the MML, like code for orbit response matrix and dispersion measurements as well as the orbit correction code. However, we extended the code for beam-based alignment to provider better fit results and thus improved data for the beam position monitor (BPM) offsets. Finally, we wrote some code to wrap the mostly used functions of the MML in a nice graphical user interface (GUI).

CHOOSING THE MATLAB MIDDLE LAYER

ANKA has had a software that links the control system to a physical model of the accelerator for quite a long time [2]. However, this software was completely implemented in Java, and thus did not provide the simple scripting mechanisms of the MATLAB Middle Layer. Therefore it was only used for some specific applications (e.g. the orbit correction code still in daily use), but was not used by the accelerator physicists to write their own code.

Learning from this experience, a software for linking the ANKA control system to the MATLAB-based Accelerator Toolbox was developed [3]. Using this software, physicists could finally write simple MATLAB scripts for controlling the accelerator. However, the software suffered from the lack of existing application code. As it was specifically written for ANKA, code from other accelerators could not be used without changes. Thus this software's benefits for daily operation were limited.

Therefore, we decided to adapt the existing MATLAB Middle Layer code for ANKA, reusing parts of the control system link written to connect MATLAB to the ANKA control system. This way, we could link the advantages of having an interface for simple MATLAB scripting with the advantages of already having a number of useful applications.

ADAPTING FOR ANKA

In order to adapt the MATLAB Middle Layer for use at ANKA, we had to create the data-structures specific to the accelerator's lattice and we had to implement a link to our control system.

Creating the Data-Structures

For adapting the MML for a new accelerator some data-structures have to be generated. While their structure is the same for all accelerators and can just be copied, their content (e.g. magnet calibration curves and names of control system properties) has to be customized. The total effort for finishing this task did not exceed a few days.

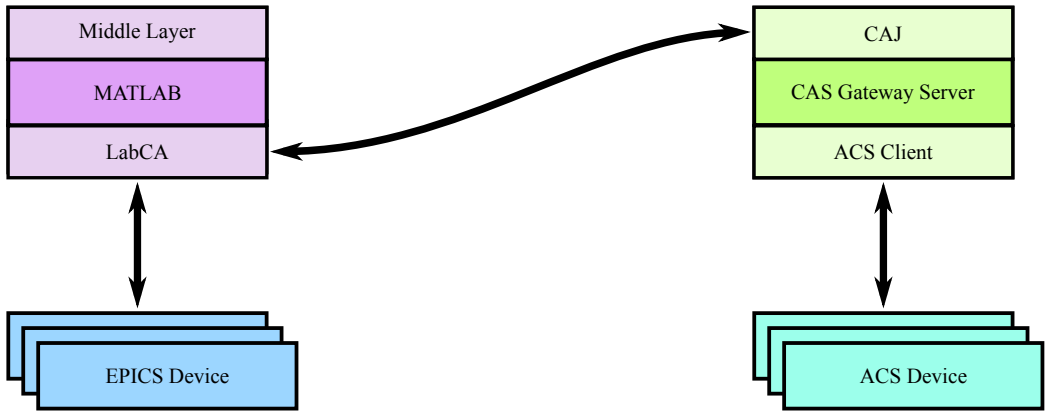

Figure 1: Structure of the control system access for the MATLAB Middle Layer at ANKA. MATLAB communicates directly with EPICS devices using the LabCA library. ACS devices are accessed through the CAS Gateway Server specifically developed for ANKA.

Link to the Control System

At ANKA, most of the devices relevant for the MML (mainly power supplies and beam position monitors) are controlled via the ALMA Common Software (ACS) [4] control system. The MML had no built-in support for this control system, thus we had to develop our own control system link.

As integrating an ACS client directly into MATLAB was not feasible [3], we wrote a server based on the Hyper-Text Transfer Protocol (HTTP) [5]. Each property of the control system would be mapped to a unique resource identifier (URI) identifying this property. A property could then be read by sending a HTTP GET request to the server and written to by sending a HTTP POST request. The actual data would be encoded in the request's or response's body using the JSON protocol [6], a simple, text-based platform-independent protocol for structured data. This solution proved to work well and minimized the implementation effort in MATLAB.

Later, a new beam position monitor (BPM) system based on the Libera Brilliance device manufactured by Instrumentation Technologies was acquired by ANKA. However, this system was not integrated into the ACS-based control system, but uses existing EPICS software developed at DIAMOND [7].

Adding EPICS support was not trivial, because the control system link support of the MML basically depends on two specially named functions (getpvonline and setpvonline). As there is no way for specifying different versions of these functions for different control system properties, we could not use EPICS- and ACS-based devices from the MML in parallel.

We identified two feasible alternatives for integrating both systems in parallel: We could either extend our HTTP server to connect to EPICS-based devices or we could use one of the existing Channel Access (CA) implementations included in the MML and talk to the new BPM devices directly. In the latter case, we would need to use the CA protocol for communication with the legacy control system as well.

We chose the second option for mainly three reasons: First, we would not have another layer of software for the communication with the new BPMs, thus increasing the reliability and performance. Second, using the CA protocol instead of HTTP promised a slightly better performance, because this was a binary protocol specifically designed for control system communication. Finally, we anticipated that in the future more hardware at ANKA might use EPICS instead of ACS and therefore the first argument might become more and more important.

Therefore, we changed our gateway software to provide a Channel Access server instead of an HTTP server, resulting in the setup depicted in Fig. 1. We could reuse major parts of the code communicating with ACS and used the Channel Access for Java (CAJ) [9] library for implementing the server side.

IMPROVEMENTS FOR BEAM-BASED ALIGNMENT

The MATLAB Middle Layer brings a set of functions for running a beam-based alignment (BBA). This is a method to determine the offset of BPMs by changing the magnetic field of a close-by quadrupole for different orbits. These different orbits are set by changing a single corrector magnet. When the orbit does not change when the quadrupole field is changed, the beam is in the center of the quadrupole and thus regarded to be in the center of the close-by BPM.

The quadplot function included in the MML determines the BPM offset by fitting a linear or quadratic function to the orbit change at each BPM for the different position at the aligned BPM. Figure 2 shows the fit for real data measured for BPM S2.01 (horizontal) at ANKA.

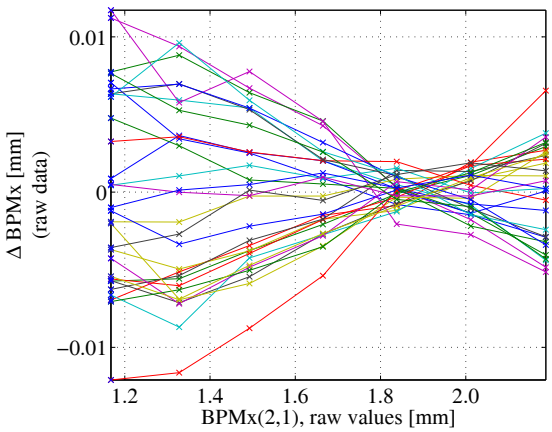

Figure 2: BBA data evaluated with the quadplot function. Apparently the BPM center is at about 1.9 mm. However, due to the noisy data, quadplot miscalculates the BPM center to be at 0.83 mm.

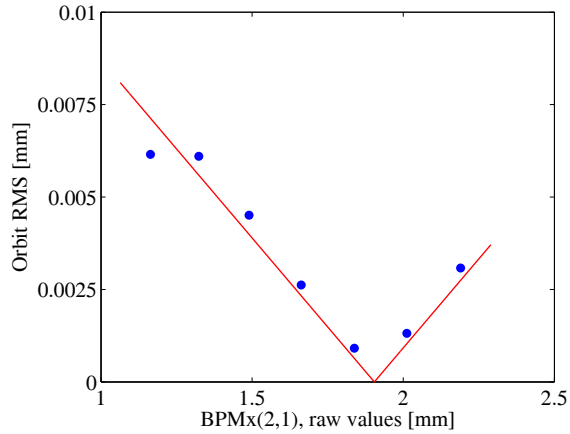

Figure 3: BBA data evaluated with the quadplot2 function. The measured data is shown in blue, the fit is shown in red. Using the same data as in Fig. 2, this function calculates the BPM center to be at 1.90 mm, which is in the expected range.

However, this fitting method is sensitive to single defective values and does not work nicely if the measuring range is far off-center. Therefore we wrote a function called quadplot2, implementing a different algorithm:

This function does not regard single BPMs but calculates the root-mean-square (RMS) of each orbit difference. This RMS value is plotted over the beam position measured at the BPM to be aligned. Subsequently we fit a function of the form

$$f(x) = |x - a| \cdot b, \tag{1}$$

where x is the beam position at the BPM to be aligned, $f(x)$ is the RMS of the orbit difference for the respective orbit, a is the BPM offset and b is a free fit parameter.

The result of the fit for the same data as in Fig. 2 is depicted in Fig. 3. For the example data, this algorithms improves the result, because it is less sensitive to the asymmetry of the measured data and less sensitive to noise.

Still, single data-points used for the fit can be invalid, e.g. because the change for the corrector magnet sent to the control system has not been applied correctly. Therefore, we added an interactive mode, where the user can see the measured data and the fit and select or deselect individual data-points to be included in the fit. In this way, the user can remove obviously faulty data-points and gets an idea of how good the fit results are. The improvements achieved by using this interactive mode for a partly defective measurement are shown in Fig. 4.

USER-FRIENDLY GUI

In order to make the frequently used functions of the MML available to those users who do not want to learn how to use the command-line interface, we created a simple GUI which serves as a starter for these functions. Figure 5 shows the start panel, which then opens sub-panels for

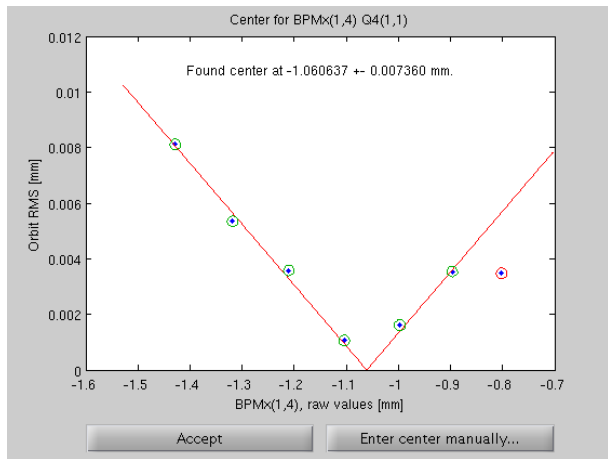

Figure 4: Interactive fitting GUI. The last data-point has been deselected, because it is obviously flawed.

the different functions like dispersion and orbit-response-matrix measurements, beam-based alignment and orbit correction.

This panel is even useful to those users who know the command-line interface, but just want to quickly run a measurement without having to look up the exact syntax of the corresponding function.

THE MATLAB MIDDLE LAYER IN ACTION

As important measurement tools like orbit-response-matrix and dispersion measurements are provided in a standardized way by the MML, it very easy to use LOCO [10], a tool for analyzing the linear optics of an accelerator using orbit-response-matrix measurements. In fact LOCO is already included in the MML distribution and only a few

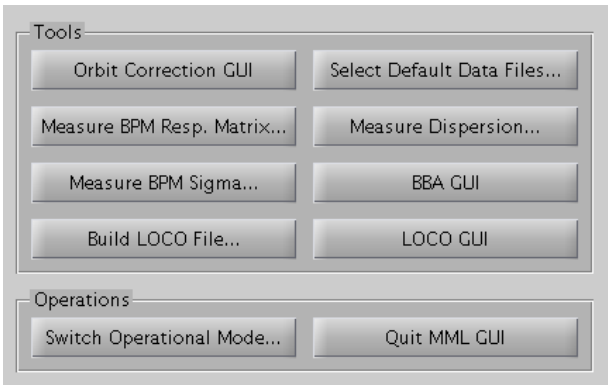

Figure 5: Starter GUI panel for the MML at ANKA.

accelerator-dependent parameters have to be adjusted.

One of our first analyses using LOCO and the MML revealed, that the kick strengths used for measuring the response matrix strongly dependend on the corrector magnet.. The kick strengths fitted by LOCO are shown in Fig. 6.

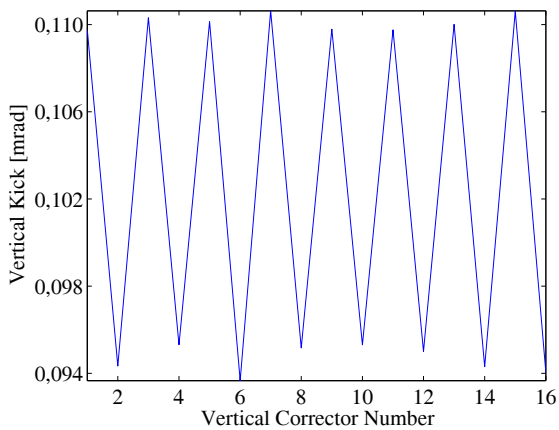

Figure 6: Vertical corrector kicks fitted using LOCO.

First, because of the alternating structure, we suspected numerical noise causing a defective fit. However, closer investigations revealed, that this was caused by an error in the calibration curves converting from magnet current to kick strength and vice versa.

For geometrical reasons, there are two types of vertical corrector magnets at ANKA. Both are expected to have a slightly different kick strength of 1.485 mrad A^{-1} GeV^{-1} and 1.650 mrad A^{-1} GeV^{-1} respectively.

However, as we now discovered using LOCO, in reality both types seem to have the same kick strength of about 1.5 mrad A^{-1} GeV^{-1}.

CONCLUSION

We commissioned the MATLAB Middle Layer for use at ANKA. The commissioning process was quite simple and would have been even simpler if we had used one of the control systems directly supported by the MML.

We now frequently use the MML for machine physics studies and are investigating the option to use an MML-based orbit correction code for regular operation, too. Physicists at ANKA writing their own code for machine physics measurements have already started using the MML to get information about the state of the accelerator.

The alternative BBA code we have written shows significant advantages over the code distributed with the MML in handling imperfect measurement data. The MML simplifies the task of performing a beam-based alignment dramatically compared to our old solution which required the user to copy the measured data into Microsoft Excel for further evaluation.

By creating a GUI for the most commonly used functions, we could even convince those users to use the MML, who are not familiar with the Middle Layer's MATLAB command-line interface.

In summary, adapting the MATLAB Middle Layer for use at ANKA has already brought significant benefits within the first few months of use and we are looking forward to exploit the features of the MML to an even larger extent.

DEVELOPMENT OF A SURVEILLANCE SYSTEM WITH MOTION DETECTION AND SELF-LOCATION CAPABILITY

M. Tanigaki*, T. Sano, Y. Hirai, M. Miyabe, S. Fukutani, H. Kawabe, Y. Kobayashi, Y. Kuriyama, N. Sato, K. Takamiya, and Y. Morimoto
Research Reactor Institute, Kyoto University, Kumatori, Osaka 590-0494, Japan

Abstract

A surveillance system with the motion detection and the location measurement capability has been in development for the additional surveillance of the facilities in our institute. Each remote box, which consists of a surveillance camera, a GPS unit and a Wi-Fi unit, sends the motion picture along with its location data over the network. The server analyzes such information to detect the unwanted access and sends the status or alerts to the clients. The system is about to be installed for the actual surveillance.

INTRODUCTION

Surveillance cameras and sensors are widely used for the security control in various types of institutes and facilities. Our institute also has surveillance cameras and sensors, which have the primary responsibility for detecting unwanted accesses to our institute. One of the problems in the present surveillance cameras is the lack of the motion detection capability, therefore security agents are required to watch the display throughout the day to find such unwanted accesses. Another problem is the fixed positioning of units because the devices used for the surveillance system are based on hardwiring connections for analog signal of video transmissions. This restriction prevents us from adding temporary cameras for increased securities or for subsidiary purposes. Even worse, the old-fashioned hardwiring system requires locating the position of surveillance cameras by hand. To eliminate such problems, we are constructing a surveillance camera system with motion detection and self-locating features based on a server-client scheme. A monitoring unit consisting of a network camera, Wi-Fi and GPS modules, acquires its location by use of GPS or the radio wave from surrounding Wi-Fi access points (AP), then sends its location to a remote server along with the motion picture over the network. The server analyzes such information to detect any unwanted accesses and serves the status or alerts on a web-based interactive map for the easy access to such information. We report the current status of the development and expected applications of such self-locating system beyond this surveillance system.

* tanigaki@rri.kyoto-u.ac.jp

SYSTEM OUTLINE

The present system is based on a conventional serve-client scheme. A typical configuration of the present surveillance system is shown in Fig. 1. The surveillance is performed by a remote box, which consists of a network camera, a GPS module, a single board computer, and a Wi-Fi access point. All the devices inside the remote box are basically operated by either 5 V DC or 12 V DC, expecting the battery-driven operation. The network connection between the remote box and the server is managed by the local area network in our institute and Wi-Fi connection.

A conventional network camera is in a waterproof housing and placed outside the remote box. This camera can be connected by Power-over-Ethernet technology (PoE) to realize the data transmission and power supply by a single wire. A USB-type GPS module is also implemented in this waterproof housing to ensure the detection of the exact place of the network camera. The USB connection required for this GPS module is prepared by a pair of USB - RJ-45 conversion adapters, which can extend a USB connection up to 50 meters, almost the same distance as that a PoE connection. Therefore, the camera can be placed up to several tens meters away from the remote box, which gives a greater flexibility for the installation.

A linux-based single board PC is embedded in the remote box. The GPS module placed in the camera housing is finally connected to this single board PC for the analysis of GPS location. The NMEA sentences of GPRMC and GPGGA are interpreted to obtain the coordinates of the camera and the time and date of GPS measurement. Obtained location data is sent to the server and used as the position of the camera. This single board PC is also expected to be used as the interface to the devices, such as the control of the floodlight and making sounds for the alert etc.

As for the self-locating feature, the cases that the GPS signals from satellites are not available(e.g. inside or behind the building) should be assumed. To deal with such cases, a self locating technique by using the Wi-Fi signals of surrounding AP is also developed as the alternative way to determine the location. In this technique, the locations of APs are previously determined as the reference points. The number of reference APs varies depending on the places, but at least three reference APs are expected with in the radius of 50 meters. In theory, the intensity of radio wave should follow the inverse squares law, but such simple cor-

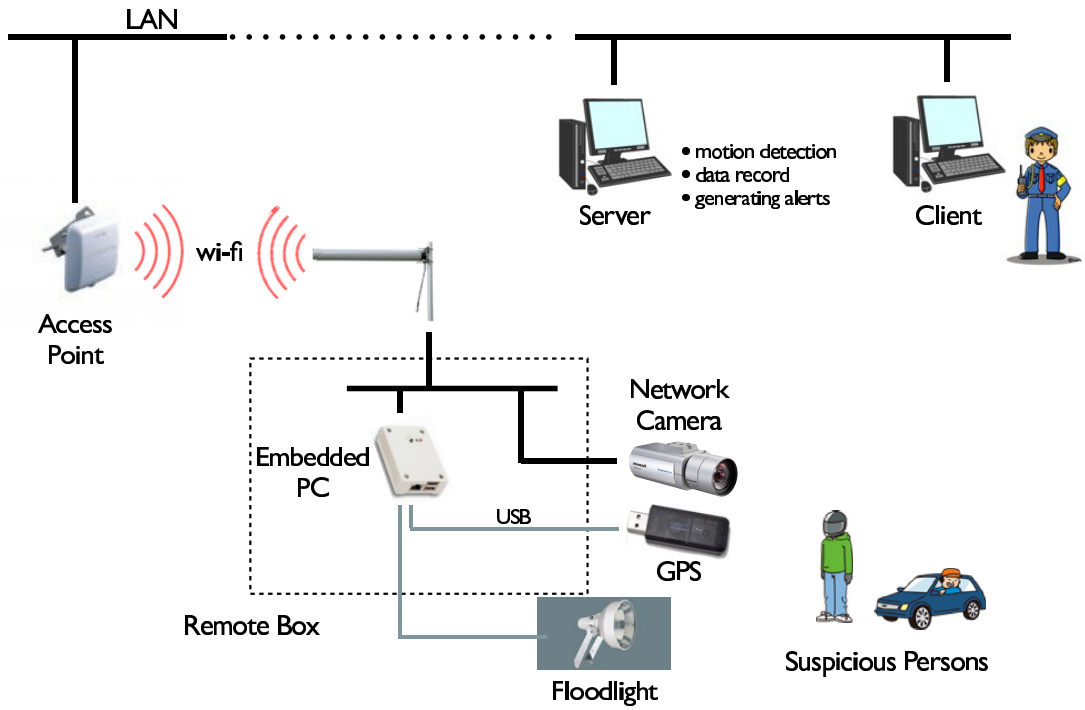

Figure 1: Configuration of the surveillance system.

relation is largely disturbed in real cases by the multipath propagation or reflections caused by the surrounding obstacles. Therefore, the correlation between the signal intensity vs distance are measured and empirically approximated to simple functions (Fig. 2). In the remote box side, the Wi-Fi signals detected are identified by their BSS-IDs, and respective distances among reference APs are determined from their respective signal intensities. The location is obtained as the weighted mean of the coordinates of detected reference APs with distance as weights. In the trials for the cases inside the building, approximate positions of the remote box can be determined in the accuracy of 10 meters.

The visual data obtained by the network camera is continuously sent to the server as streaming data. The server is responsible to detect any unwanted accesses and manages the alerts and responses to such accesses. The motion detection is based on motion[1] and kmotion[2] is used as the default front-end for this system as well as archiving the obtained activities. Additionally, each alert is shown on GIS softwares such as Google Earth in client PCs as an icon at the position corresponding to the latitude and longitude data obtained by the GPS module implemented inside the camera housing. Other responses to an unwanted access can be arranged with the combination of a single board PC in the remote box, such as turning on a floodlight at the camera as a warning to suspicious persons.

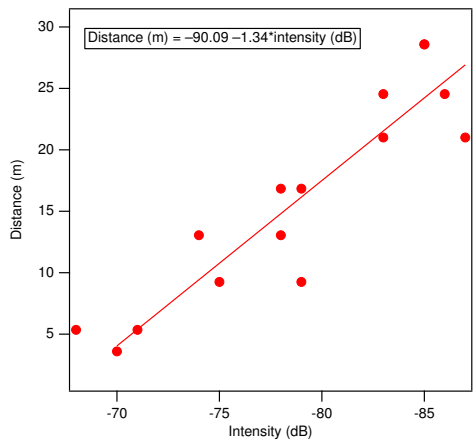

Figure 2: A typical correlation between the distance and wave intensity measured for a reference AP. The correlation is well approximated by a simple linear function. This kind of correlations are measured for every reference AP.

CURRENT STATUS

The developments of each component are almost finished and now the installation of the remote box is now

on the way for the surveillance towards unlawful dumping in the premise border of our institute. In such applications, the surveillance system is often in danger of the destructive behaviors by the suspicious persons who are about to dump the refuses. To avoid such destructive behaviors, the remote box will be placed at a safe place inside the premise of our institute, and only the camera unit will be placed about 30 meters away from the remote box with the help of implemented PoE and USB extension features. Since the camera is set outdoors, the self-locating feature by GPS is used in the present case. Now the adjustment of parameters for the motion detection is on the way because the malfunction caused by the rain drops is not negligible.

KURAMA - A SPIN-OFF OF THIS SYSTEM

The magnitude-9 earthquake in the east Japan and the following massive tsunami resulted in the severe damage at Fukushima daiichi nuclear power plant, i.e., the worst nuclear disaster Japan has never experienced before. One of the contribution of our institute to the recovery from the disaster is to develop KURAMA (Kyoto University RAdiation MApping system) for the carborne γ-ray survey in Fukushima and surrounding regions. KURAMA is installed in an automobile and records the readout of γ-ray survey meter along with the location data obtained by GPS while driving around the region. The readouts are simultaneously transmitted to the observation base in a remote place over the mobile phone network and displayed on Google Earth in realtime (Fig. 3). KURAMA is used as the standard system for the carborne γ-ray survey by Fukushima prefectural government and the Ministry of Education, Culture, Sports, Science and Technology in Japan. Results are available to the public from their websites[3] [4].

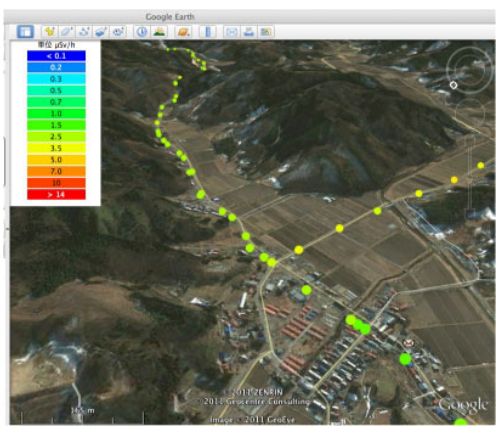

Figure 3: A typical radiation data obtained by KURAMA. The readout of radiation are displayed on Google Earth along with the geographical features.

In the development of KURAMA, some of the techniques which stem of the present surveillance system are introduced. For example, the GPS handling technique used in KURAMA is based on the one in the present surveillance system. Also some techniques developed for KURAMA are imported to the present surveillance system. In KURAMA, the radiation intensity and location of each measurement point are displayed as icons with the respective color on Google Earth. This feature is realized by the dynamic generation of a KML file with the combination of Apache and PHP, which will be used as one of the schemes for the alert in the surveillance system.

THE ELECTRONIC LOGBOOK FOR LNL ACCELERATORS

S. Canella, O. Carletto, INFN – Laboratori Nazionali di Legnaro, Legnaro (Padova), Italy.

Abstract

In spring 2009 all run-time data concerning the particle accelerators at LNL (Laboratori Nazionali di Legnaro) were still registered mainly on paper. The electrostatic accelerator TANDEM-XTU and its Negative Source data were logged on a large format paper logbook. For the ALPI booster and the PIAVE injector with its Positive ECR Source a number of independent paper notebooks were used, together with plain data files containing raw instant snapshots of the RF super-conductive accelerators. At that time a decision was taken to build a new tool for a general electronic registration of accelerators run-time data. The result of this effort, the LNL electronic logbook, is here presented.

INTRODUCTION

The LNL Electronic Logbook is a new many-layers software tool; it was put into operation at the end of 2010 after 12 months of work including several plan-do-check-fix cycles.

Here this tool is described in its main components and features. The most significant steps of the long commissioning phase are also described.

CONFIGURATION

An electronic logbook is made of data sets and software programs. It is used to register states, events, texts, images, notes and files according to the shift structures in the working time of the systems to which it applies, here the LNL accelerators and their experimental set-ups. The same tool is used both to register data (to write new data sets) and to retrieve them (to read old data sets) .

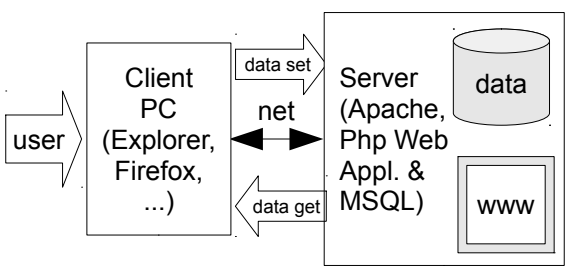

Figure 1: LNL Logbook structure.

The LNL Electronic Logbook has a client-server structure (Fig. 1). A web server application supplies a web interfaces to data. It may be accessed by standard browser (Explorer, Firefox) on any platform (MS Windows, Linux). For a medium and long time range endurance, data are stored in RDBMS (Relational Data Base Management System) structures, At LNL the RDBMS is MySQL in an Apache http server environment. Php procedures dynamically build (on request) the web forms to write or read data from tables in the data base.

Because LNL accelerators are subjected to periodic reconfigurations and rejuvenations, a high degree of flexibility is necessary in the data structures and related web-forms. This was achieved adding to the electronic logbook some intrinsic editing capabilities on the data set configuration and form pages. So the system itself is highly configurable.

General Layout

The main components of the LNL Electronic Logbook are installed on a Linux PC (Fedora) and are:

- An instance of MySQL RDBMS for data table structures and registered data [1].
- The Apache [2] web-server and the related PHP language interpreter, to access data, tables in write and read mode, for configuration and registration.
- AJAX (Asyncronous Javascript And XML) [3] to support dynamic, interactive data throughput from and to the user on the web browser.

Figure 2: LNL Logbook – The main Accelerators Menu.

Data Structure

In LNL Electronic Logbook the data system has a hierarchic, tree structure.

At the top of all there are different electronic logbooks, one for each accelerator (Fig. 2): the electrostatic TANDEM-XTU (with its negative ion source), the ALPI booster and the PIAVE injector (with its positive ECR ion source). In each specific logbook, the root of data tree relies on the calendar experimental shifts list.

The calendar of experiments contains the list of experimental shifts, on a start-end dates basis, plus some attributes for each shift, where these last two terms mean also periods reserved for tests, accelerators maintenance, set-up or shut-down. In the table of shifts, which is updated every 3-6 months, the configured fields are: a code (unique), a spoke-person, start date, end date, experimental set-up, beam-line, beam type (ion specie), ion mass (ion isotope), required energy, energy range (if different energies are required), beam current, accelerator configuration, notes (Fig 3).

All accelerators registrations are therefore associated to the specific accelerator and to its shift defined by the registration date.

On the time side, data registrations are of two kinds: day registrations and hour registrations. The first are written, generally, in the first hours of the day by the operators' team working between midnight and 7 A.M. This set of data may be deleted, updated or changed all the day long and is frozen at midnight. The second set of data (hour registrations) are automatically linked to the current day registration, and to the due shift, too. Hour registration data may be deleted, updated or changed only by the operators who wrote them and only up to the following hour registration, which, automatically, freezes the preceding one.

A special user (administrator) has the privileges necessary to delete or correct any data set at any time.

Besides conventional data sets, specific for each logbook, i.e. integers, decimals, time and string values, attached files, in LNL Electronic Logbook two other tables are foreseen to help shift accelerator logging: Annotations and Announcements. Annotations are free text registrations linked to the current day. They must be one a day for each operator, may be inserted, changed or deleted all the day long but only by its author. Its purpose is to better explain, in textual form, special events, to make comments to current data, or textual amendment to frozen data.

Annotations are always tight to current day data and current accelerator configuration. They may also be characterized by an alert flag that makes them always visible for a given (user settable) amount of time.

This mechanism may be particularly useful for important and/or urgent exchange of messages among operators.

Announcements are similar, but are general purpose and not specifically tight to a given accelerator (logbook) or day registration: they are more free and intended for general messages exchange on accelerators status and necessities. There is no limit in writing these entries.

System Access and Use Modes

The LNL Electronic Logbook is installed on a Linux PC in the LNL data network and there is a limited set of users that may access and use it: the TANDEM-PIAVE-ALPI operators' team, the source team, the experiments coordinator, the administrator.

There are three levels of privileges:

1. administrator
2. calendar coordinator
3. operator

The administrator may do everything, i.e. read, write, create and delete any data, text and defined structure. He is responsible of logbook configuration (defining fields and related attributes included in each logbook) and of DB data maintenance for serious data mistakes that may not be fixed simply by annotations.

Table 1: DB Objects Sizes.

Type of object	n. of items
Accelerators (logbooks)	3
Configuration Tables	7
Data Tables	14
Total n. of Tables	21
Total n. Records in 12 months	~1500

The calendar coordinator has the responsibility of filling the experimental shifts calendar, so determining the associations between accelerators registrations and physic experiments. He only may write, modify or delete current (in terms of date) and future experimental shifts (but not the old ones, which are automatically frozen for him also, after midnight).

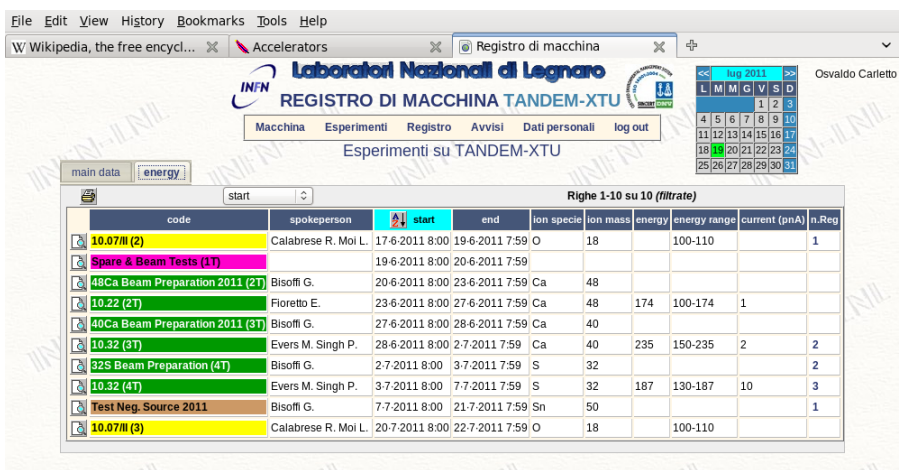

Figure 3: The list of experimental shifts for the TANDEM accelerator.

Figure 4: The external tank of the LNL 15 MV Tandem electrostatic accelerator with photos of an old paper logbook and of the new system.

The operators may read everything, i.e. the calendar tables and registered data of all days and hours in all logbooks, but they may write, delete and change only current day registration and only last hour data (and only if they are the authors of that registration).

Any defined logbook user, no matter which privileges he has, may access in read/write mode to his personal data (name and password).

FINAL NOTES

At the end of 2010 three debugged logbooks have been configured: TANDEM-XTU, ALPI and PIAVE.

TANDEM-XTU (Fig. 4 shows the external tank of the accelerator, its operators' team an photos of its old and new logbooks) is a one-to-one mapping of the old paper logbook into MySQL tables and records.

Differently from the previous, ALPI and PIAVE logbooks both include only a set of essential data and a number of attached files to describe the minimal run-time configuration description of the two accelerators.

The commissioning of the system took place in two steps. A first amount of debugging, especially on table and user privileges and data read/write permissions was performed in June 2010, with the help of two summer students. A second and finer set of check-and-fix cycles took place in autumn 2010 when the system was delivered to LNL operators. At this time a large amount of data configuration or re-configuration, in addition to the final debugging, through proper and intensive use, was performed, together with some deep re-design of the experiments calendar structure.

At the end of 2010 the system was largely debugged and stable.

ACKNOWLEDGEMENTS

The first acknowledgement is for ing. R. Tecchio, who patiently implemented and fixed the DB configurable structure and php-ajax procedures of LNL Electronic Logbook. Then the work of A. Gnec and A. Turcato was of great help for the first debugging phase. Dott. P. Posocco gave us useful suggestions in the fist planning step of the work, while C. Ur is the final proposer of the actual structure and format of the experiments calendar table.

At last all the LNL accelerators operators have to be thanked for their collaboration in the final debugging phase of the system.

OPERATIONAL STATUS DISPLAY AND AUTOMATION TOOLS FOR FERMI@Elettra*

Claudio Scafuri, Sincrotrone Trieste, Trieste, Italy

Abstract

Detecting and locating faults and malfunctions of an accelerator is a difficult and time consuming task. The situation is even more difficult during the commissioning phase of a new accelerator, when the plants are not yet well known. Faults involving single devices are easy to detect, however a fault free machine does not imply that it is ready to run: the definition of malfunction depends on what is the expected behavior of the plant. In the case of FERMI@Elettra, in which the electron beam goes to different branches of the machine depending on the programmed activity, the configuration of the plant determines the rules for detecting malfunctions. In order to help the detection of faults and malfunctions and to display the status of the plant, a tool , known as the "Matrix", has been developed. It is composed by a graphical front-end which displays a synthetic view of the plant status grouped by subsystem and location along the accelerator, and by a back-end calculation engine. The graphical front-end gives also the possibility, once a problem is detected, to focus on its details. The calculation engine is composed by a set of objects known as Sequencers. The calculation rules have been determined by analyzing the various subsystems and global working of the accelerator with plant and operations experts. The Sequencer is designed so that it can also issue commands to the plant. This will be used in the next releases of the Matrix for actively switching from one accelerator configuration to another.

INTRODUCTION

FERMI@Elettra is the new 4th generation synchrotron light source currently under commissioning in Trieste, Italy[1]. It is based on a 1.5 GeV electron linac and seeded free electron laser photon generation. The FERMI@Elettra controls system [2] is based on Tango and is presently made up of about 2800 different Tango devices. The control room operator can access the plant by means of about 1600 different instances of control panels and tens of Matlab applications. These numbers show that the plant is large and complex and can be quite difficult to manage also for experienced users. Another source of complexity comes from the fact the the electron beam can be brought through different paths according to the task that must be performed: several spectrometers for measuring the energy and other characteristics of the beam at different acceleration stages, two bunch compressors, and finally two different undulator chains.

In order to help detecting faults and misconfigurations of the plant, we designed and implemented a tool - known as the "Matrix" - to give a comprehensive and simple view of the state of accelerator to the control room operators. The Matrix analyzes many accelerator components - interfaced by means of Tango devices - and checks if they are ready to transport the beam to a certain destination. The analysis is done mostly utilizing the *State* of the tango devices and the desired *Scenario*.

States

Every Tango device exports a standard *State* variable. The *State* variable can assume a set of pre-defined values: ON, OFF, FAULT,STANDBY, etc.... By reading this variable we can know wether a device is working or not or if has any problem. Further diagnostics of possible problems is done by means of specific, device dependent informations. The value of the *State* variable is calculated from the operating conditions of the equipment that the Tango device is controlling. All the Tango devices in FERMI@Elettra use the *State* variable consistently.

Scenario

The *Scenario* is a coherent collection of rules used to check that the accelerator is ready to transport the beam to a desired destination, such as one of the various electron spectrometers, or one of the two undulator chains. Each rule is in charge of a well defined section and subsystem of the accelerator. Many of the rules are re-used in different scenarios, reflecting the fact the the electron beam must go through the same sections of the accelerator. The *Scenario* is selected and activated by the control room operator.

GRAPHICAL INTERFACE

The graphical interface (see Fig. 1) is horizontally divided in two areas. The upper area display the accelerator Matrix, the lower area shows a diagram of the accelerator and in formations about the selected scenario. The Matrix displays the state of the accelerator by means of a number of "coloured lamps". The lamps are organized in tabular format. Columns are associated to accelerator sections and ordered according to the beam path. Rows are associated to different sub-systems of the accelerator equipment: magnets or power supplies, diagnostics, vacuum, RF, laser. A lamp of a cell thus shows the status of a family of devices of a certain section of the accelerator. The colour of the lamp indicates if these devices are working as expected (green) or not (red). The lamp can be also grayed out when the

*This work was supported in part by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3

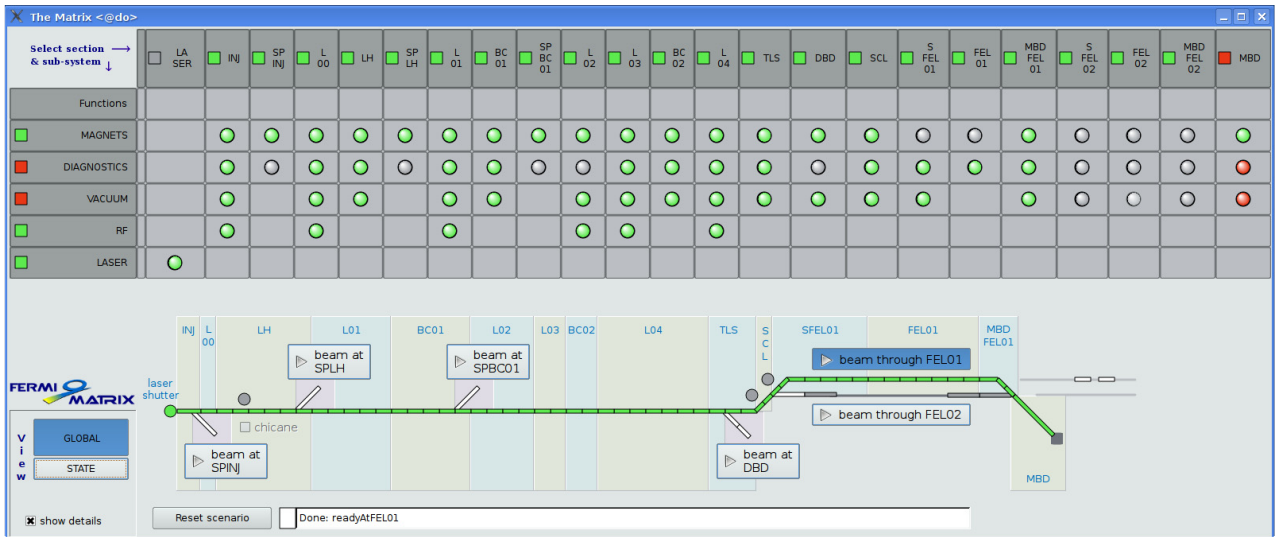

Figure 1: The Matrix panel.

cell is not taken into account in the active *Scenario*. Row and columns headings are also coloured. Their colour summarizes the state of the accelerator section or sub-system according to the active *Scenario*.

Diagnosis of Problems

In case of a problem, signaled by a red lamp, the operator can click on it and check which are the devices that do not behave as expected (see Fig. 2).

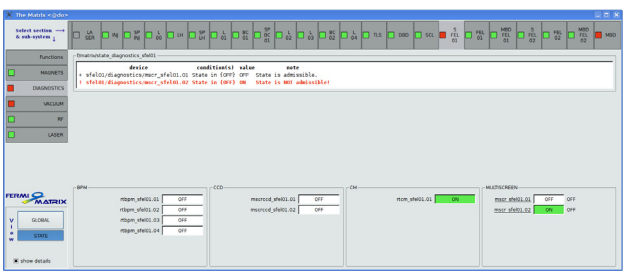

Figure 2: Diagnosis of a problem.

The view is switched to a table that emphasizes the rules which are not met. The state of all the devices involved in the calculations is also displayed in the lower part of the table. By clicking on the state label is then possible to start the control panel dedicated to the specific device. With just two mouse clicks most of the problems or misconfigurations are detected and explained.

Accelerator Diagram

The lower part of the graphic interface displays a schematic diagram of the accelerator and a number of buttons for selecting and activating the different *Scenarios*; the button corresponding to the active *Scenario* is highlighted. The schematic of the accelerator is divided in segments. Each segment is linked to a charge sensitive instrument (BPM, Charge Monitor), so that when the beam is transported through the instrument the corresponding segment is coloured in green.

SEQUENCER

The Sequencer is the building block of the calculation engine used by the Matrix. It is developed in Python starting from the *SequencerBlock* class which derives from standard Python threading.Thread class. The *SequencerBlock* class overrides the run() method (this is required by the Threading class; the run method is called indirectly by the the start() method of the Threading class), implementing the activity diagram shown in UML format in Fig. 3. The run() sequence codifies and formalizes the standard steps that must be done in order to verify equipment conditions or actively modify them; it is foressen in fact that Sequencers will be used also to automate the operations of FERMI@Elettra such as start-up, shutdown, changing of beam path, etc. . .

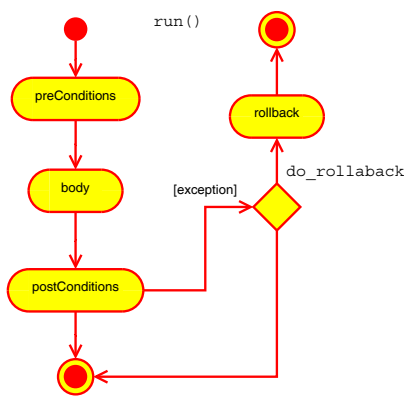

Figure 3: Calculation Engine: main sequence diagram.

The design of the Sequencer comes from many years of practice and experiences of accelerator operations automation [3], which have been thoroughly reviewed and upgraded to object-oriented programming concepts and techniques. The Sequencer has been designed from the start to be easily integrated with the Tango control system.

preConditions, body, postConditions

The Sequencer action is logically divided in three steps, which are called by the run() method. First, check if there are conditions to start the action; this is done in *preConditions* method. Then execute the effective action in the *body* method: calculate the State (that is colour) of a lamp of the Matrix, or issues commands to equipment to change the operating conditions of the plant. Finally check the outcome of the previous steps; this is done in the *postConditions* method.

Errors and Recovery

The three steps:*preConditions*, *body*, *postConditions*, notify errors by rising exceptions which are caught and handled by the *run* method. The Sequencer also provides a *rollback* method which can be used to try to restore the initial conditions in case the *postConditions* are not checked. The call to *rollback* must be explicitly enabled by the programmer of the Sequencer.

Implementation of Real Sequencer Objects in Python

The Sequencer provides a base class and a pattern; the effective knowledge (or intelligence) of the plant that must be checked by a real instance of the Sequencer must be coded by the programmer and is provided by machine and operations experts. The programmer must always derive new Sequencer object from *SequencerBlock* class. The new Sequencer implements directly the three main methods and can add other methods which can be useful for the specific situation. At the same time the programmer can use already existing Sequencer objects by aggregation. Sequencers are written in Python. With Python the programmer can very easily load end execute some Python module at runtime. In this way the programmer can modify the behavior of a Sequencer object at runtime. This feature has been extensively used in the Matrix for changing the behaviour of the program when a new *Scenario* is selected.

MATRIX SEQUENCERS

Several Sequencers have been developed for the Matrix. They perform two main tasks: first, calculate the state of Matrix cells, rows or columns headers: they are derived from *StatesBlock*; second, manage the setting of *Scenarios*: these objects are derived from *ScenarioBlock* (See Fig.4).

StatesBlock

The *StatesBlock* class is a sequencer that analyzes the Tango *State* variable of a group of devices and calculates a resulting *State*. A *StatesBlock* object is configured with a list of Tango devices and their respective admissible states. The *StatesBlock* body method periodically samples the configured devices and analyzes if the group is in an admissible state. The *StatesBlock* contains also some auxiliary methods to report in detail the result of the analysis. The report is used by the Matrix when the detailed view is selected. All the Matrix cell states are calculated by dedicated specializations of *StatesBlock* (e.g. diagnostics_dbd in Fig.4) *StatesBlock* is also the base class for *HeaderStatesBlock* objects which are used to calculate the State (that is the colour of the lamp) for a column or row of the Matrix. *HeaderStatesBlock* use simple syntactical rules to automatically create the list of Tango devices and admissible States.

Deployment

The Matrix needs one *StatesBlock* object for each of its active cells. All these objects are managed by a dedicated Tango device server written in Python, which exports a simple and clean interface for interacting with a *SequencerBlock* object. This deployment scheme makes all the stuff needed by the Matrix generally available as standard control system components. The most important technical reason for this deployment scheme is that it ensures that there is exactly one instance of each of the configured

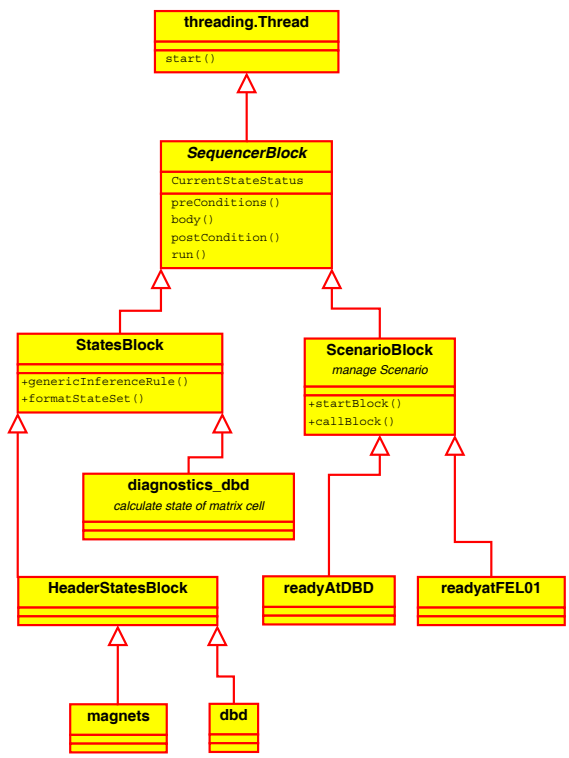

Figure 4: Calculation Engine: class diagram.

SequencerBlock running in the control system of the plant: in this way, when the *SequencerBlock* objects is be used to modify the plant configuration they will do it in an ordered and consistent manner.

ScenarioBlock

Objects of the *ScenarioBlock* class manage the activation of *Scenarios*. A *ScenarioBlock* is programmed with the list of Tango devices and the corresponding *StateBlocks* objects that must be activated for the given *Scenario*. The configured Tango devices are loaded with the chosen *StatesBlock* and started when the *ScenarioBlock* is activated. The *ScenarioBlock* class is derived from *StatesBlock* so that we can reuse the Tango State analysis and reporting features.

CONCLUSION AND OUTLOOK

The Matrix has been used during the commissioning shifts and has shown to be an effective tool for monitoring the general status of the plant. The effectiveness of the Matrix depends strictly on the quality and completeness of the Scenarios: a good collaboration and mutual understanding between machine experts and programmers is of paramount importance in order to correctly and completely analyze and define the various rules. We expect to improve and extend the Scenarios and the diagnostics capabilities of the Matrix with the knowledge gained during the commissioning of FERMI@Elettra.

The next important development of the Matrix will be the automation of operations. As the new accelerator will start operations for FEL light users, standard procedures will be defined for setting up the plant and guaranteeing optimal and repeatable operating conditions. These procedure will be analyzed and implemented by means of *SequencerBlock* objects and supervised by the Matrix. The ultimate goal is to make FERMI@Elettra operable by a team of two control room operators.

THANKS

The initial design and development of the system described in this paper was done by Fabio Asnicar.

Abstract

Muon Reconstruction is a key ingredient in any of the experiments at the Large Hadron Collider LHC. The muon spectrometer of ATLAS comprises Monitored Drift Tube Chambers (MDTs) and Cathode Strip Chambers (CSCs) for precision tracking as well as Resistive Plate (RPC) and Thin Gap (TGC) Chambers as muon trigger and for second coordinate measurement. Together with a strong magnetic field provided by a super-conducting toroid magnet and an optical alignment system a determination of muon momentum with high precision up to the highest particle energies accessible by the LHC collisions is provided.

The Detector Control System (DCS) of each muon subdetector technology must efficiently and safely manage several thousand of LV and HV channels, front-end electronics initialization as well as monitoring of beam, background, magnetic field and environmental conditions. This contribution describes the chosen hardware architecture, which as much as possible tries to use common technologies, as well as the implemented controls hierarchy. Emphasis is given to reviwing the experience from the first year of LHC and detector operations, and to lessons learned for future large scale detector control systems.

INTRODUCTION

The Muon Spectrometer forms the outermost layer of the ATLAS [1] detector, as shown in Fig. 1, covering a rapidity range up to $\eta = 2.7$. It comprises four different detector technologies who have been chosen for optimal performance, as either trigger or precision tracking muon chambers, and according to particle rates. Track reconstruction is based in the full muon spectrometer except the innermost region of the endcap ($2.0 < \eta < 2.7$) on in total 380000 **M**onitored **D**rift **T**ubes (MDTs) of 3 cm diameter and up to 6m in length, which are assembled into in total 1150 MDT chambers. Chambers are equipped with an alignment system to in situ monitor and record chamber deformation and relative displacements between chambers, which is required to achieve the design track reconstruction resolution of 50 μm per muon station. In the region of highest background rate, 32 **C**athode **S**trip **C**hambers (CSCs) take the role of tracking detectors. CSCs are multi-wire proportional chambers whose wires are oriented in radial direction and with a segmented cathode. Track reconstruction is done by a fit to the charge distribution, resulting in a track resolution per plane of $< 60\mu$m.

Resisitive **P**late **C**hambers (RPCs) are used as trigger chambers in the muon barrel; ATLAS RPCs are built as a doublet of gas gaps, each formed by 2 bakelite plates separated by a 2mm spacer. Perpendicular readout strips on both sides of the gas gaps allow 2-dimensional track coordinate determination and by requiring a particle track to fall into a predefined geometrical road efficient and fast triggering on muons with a defined momentum. In the endcap region, **T**hin **G**ap **C**hambers (TGCs) are used as trigger chambers; TGCs are multi-wire proportional chambers with a wire-to-wire distance smaller to the wire-to-cathode distance and operated in quasi-saturated mode. In total there are 3588 TGC units, forming 3+2+2 layers in each side's big wheel and 2 layers in the small wheel. Some operating parameters of the 4 detectors are summarized in Table1.

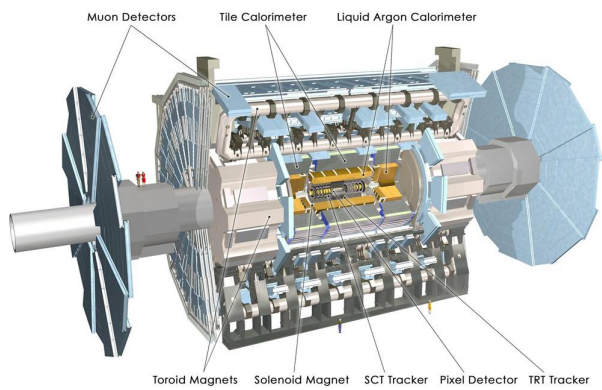

Figure 1: Schematic view of the ATLAS Detector. Elements shown in light blue belong to the Muon Spectrometer which forms the outer most layer of the detector and is split into a cylindrical Barrel part and a set of disk like wheels known as Endcaps.

* On behalf of the ATLAS Muon Collaboration

MUON DCS

The primary tasks of the Muon DCS are

- Controlling the detector power system
- Monitoring environmental conditions and accordingly adjusting operating parameters to maximize efficiency
- Monitoring parameters like voltages, temperatures and RPC trigger rates of the on-chamber electronics
- Monitoring the detector gas system and reacting to changed or abnormal situations by eg adjusting the detector HV
- Configuring the MDT and TGC frontend electronics
- Reacting on information from the DAQ, reinitializing chambers when needed (MDT)
- Controlling/reading out the optical alignment system
- Archiving all relevant information on the detector status as needed for physics data analysis and to trace problems

Power System

For CSC LV, power supplies from Wiener's [2] Maraton series are used; for all other muon LV and HV the commercial EASY[1] system from CAEN [3] was chosen. CAEN's EASY solution is based on a master-slave architecture with a controlling mainframe which houses a set of branch controllers, which each act as master for a chain of up to 6 EASY crates which in turn house the actual LV and HV boards. Crates and boards are compatible with operation in magnetic field and under radiation conditions as those present in the ATLAS experimental cavern during beam operation, while the mainframe and branch controllers are located in a non-hostile area accessible also during beam operation. Table2 summarizes equipment type and the number of devices in use. The RPC system differs from the other muon subdetectors in so far as it contains CAEN ADC and DAC boards in addition to LV and HV types. ADC boards are used for all RPC environmental monitoring and for measuring HV currents on individual gap level; DAC channels are used to control the threshold for the RPC frontend electronics, a function being taken by a different hardware for MDT and TGCs as explained in the next section. The choice of components in the RPC DCS was driven by the strategy to have a single hardware technology, the CAEN EASY solution, to interface to DCS [4].

ELMB Based Monitoring And Control

Besides the power system, Muon DCS relies heavily on so called **E**mbedded **L**ocal **M**onitoring **Boards** (ELMBs), which have been custom developped for use in ATLAS and other LHC experiments. Each ELMB, which is magnetic and radiation tolerant, contains a 64 channel 16-bit ADC, 18 general digital IO lines, 8 digital inputs and 8 digital outputs, plus a CAN interface to communicate with. For a detailed description of the ELMB please refer to [5] and [6]. Muon DCS uses around 1300 ELMBs, in a version known as MDM or **M**DT **D**CS **M**odule with a custom firmware and motherboard in the MDT system and around 1500 ELMBs in the TGC system.

MDT MDMs are used to monitor environmental conditions, reading out approximately 14000 temperature probes installed on the MDT chambers, 1650 3D hall probes for determination of the magnetic field map in the ATLAS toroid magnet region and more than 50000 voltage and temperature values from the MDT frontend electronics cards. The MDM in addition handles the initialization of the frontend electronics by downloading configuration parameters to the boards via JTAG. More details can be found in [7].

In the TGC system, ELMBs supply more than 8000 thresholds for the frontend electronics ASD chips, readout and monitor around 3700 chamber displacement sensors and 1600 temperature probes as well as configure and monitor over 23000 on chamber ASICs. A dedicated firmware

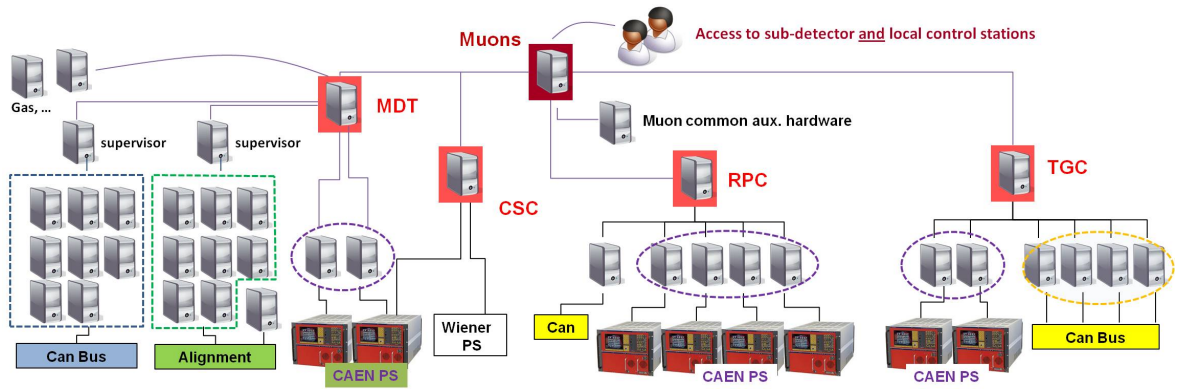

Figure 2: Muon DCS computer hierarchy. MDT MDM and barrel alignment systems have an additional supervisor layer between device layer and subdetector control station. In this the muon DCS system differs from any other ATLAS subdetector control system.

together with custom TGC DCS-PS boards allows detailed monitoring of the chambers' charge spectrum and thus low level information on the detector performance itself. For further details, refer to [8].

MDT Optical Alignment System

The third set of hardware handled by the Muon DCS system is the optical alignment system [9],[10]. Optical alignment is based on monitoring and ananalyzing patterns imaged onto CCD cameras along so called optical lines. Within MDT chambers, alignment lines monitoring deformations consist of a patterned mask, a light source, a lense and the CCD camera. The assembly is known under the name RASNIK [11]. The system is implemented following a hierarchical structure with 3 layers, achieving a high level of multiplexing; acquisition of images is done using 8 PCs and commercial framegrabber video cards. In the endcap the RASNIK technology is complemented by so called BCAM modules, readout in this case is via dedicated multiplexers implemented as VME modules. The results of the image analysis in both cases are stored in a database and used in muon track reconstruction to correct for changes in muon chamber positions.

DCS Software and Architecture

The Muon DCS controls layer has been implemented using the commercial SCADA system PVSS [12] as integrated part of the overall ATLAS DCS system. Components of the common JCOP framework [13] have been used where possible. A total of 40 PCs, running both Windows (XP and 2003) and Linux (SL5) as operating system is used for running the DCS software layer, following a hierarchical architecture (Fig. 2) with a separation between a low-level device layer handling communication with the various hardware and a higher layer of supervisors and so called sub-detector control stations, one per muon technology, dedicated to user interactions and combining information from the different parts of the system. In 2010 an additional layer and node 'MUON' was added which combines information from the various muon sub-detectors and allows unified/common operation; this was driven by ATLAS shift operations moving towards combining shift tasks.
CAEN and Wiener hardware is interfaces to PVSS via the OPC servers provided by the manufacturer; ELMBs are controlled via CanBus from Kvaser PCI cards; for interfacing the Can communication to PVSS the ATLAS developed CanOpen OPC server is used in case of MDTs and a custom PVSS driver in case of TGCs.

OPERATIONAL EXPERIENCE

Power System

The CAEN power system hardware overall is performing as expected, with a board failure rate, usually on individual channel level, well below the 10% level allowed for in maintenance and spares planning. An initial high failure fraction for the TGC A3535 type HV boards was traced to an underdimensioned electronics component which makes the boards very sensitive to any excessive heat e.g. in case of a failure of the rack cooling. Additional checks and actions have thus been added to DCS to detect such situations and react by turning off concerned equipment.
One type of problem still seen from time to time and without yet an optimal way found to handle is boards for which the output voltage V_{out} exceeds the set voltage V_{set}, in some cases by several 100V for HV channels and occassionally exceeding even the hardware voltage limit. 2 cases of broken wires in the CSC system are believed to have been caused by such overvoltage. A second issue are occassional losses of communication with individidual EASY boards, mostly after a power cut, which in the beginning required an access to the ATLAS experimental cavern for a manual reset. To adress this problem, at the beginning of 2011 the so called 'Muon CAEN Reset Network' has been implemented which allows a DCS controlled remote reset of boards. An extension to the reset of branch controllers is planned for the shutdown at the end of this year.

One unexpected finding was that the CAEN OPC Server Event Mode, which became available with CAEN's OPC server version 3, turned out as unsuitable for the use for both MDT and TGC systems[2], due to the large number of HV channels which undergo ramping all at the same time. During the ramp phase the large amount of data updates overloads the OPC server leading to crashes and data loss. Reverting back to the previous polling mode and tuning extensively the OPC group configuration an acceptable and stable situation was found; For the future and possible hardware upgrades, improving the sustainable refresh intervals for HV and LV readings via the OPC chain and PVSS seems however highly desirable. In addition, rare but recurring cases of a full hangup of the communication with the power system have been and are observed. To deal with this a set of watchdog and alert mechanisms has been implemented which proved to allow spotting such problems immediately.

ELMB based Functionality

Experience with the ELMB based part of Muon DCS is very good with an excellent reliablity of the used hardware components. In the full muon system only 2 out of more than 2500 ELMBs failed up to now; both were of MDT MDM type. In the first case the communication with the node via CAN was no longer working; in the second only the ADC part was affected.
The MDT frontend electronics initialization done via JTAG from DCS works very well. With a scheme were string download to the chamber electronics is carried out in parallel on all 96 CanBusses in the MDT system the full detector can be reinitialized in approximately 2.5 minutes. Further improvements are under discussing by storing configurations in the MDM's memory and handling sending the predefined configuration to the MDT chamber electronics by an updated MDM firmware. This would eliminate the current need for sequential string download to chambers on the same CanBus.

Operator Interactions and User Interface Layer

Substantial efforts have been spent during the last year in unifying user interfaces as exposed to non-expert shifters, among other things by developing a set of libraries for a uniform geomtrical representation of the the 4 muon subdetectors and status information on their various components. As an example, the top layer Muon Shifter UI panel is shown in Fig. 3.

CONCLUSIONS

The first full year of LHC operations has proven the chosen design for the Muon DCS a good one, both with respect to hardware and software architecture. No major problems or showstoppers have been found. Feedback gained from shifter operations has lead to several additions and additional efforts of unification, a work which is still ongoing.

[2] no such problems are present in the RPC system

MULTI CHANNEL APPLICATIONS FOR CONTROL SYSTEM STUDIO (CSS)

K. Shroff#, G. Carcassi, BNL, Upton, Long Island, New York, USA
R. Lange, HZB, Berlin, Germany

Abstract

With the development of the ChannelFinder[1][2] directory service and the PVManager[3] client library, a new set of applications have been developed for Control System Studio(CSS)[4]. These applications have simplified user interaction by requiring the user to provide them with only the criteria of the channels they are interested in, instead of the complete set of channels. They have improved performance with the use of PVManager to manage the collection of control system data.

INTRODUCTION

The High level applications tend to prefer an hierarchical view of the control system name space where they can group channel by location, physical function, etc. These applications also require connections to large set of channel access connections to retrieve the value, alarm state etc.

Using the ChannelFinder we are able to provide High level applications with a hierarchical view of the control system with a simple mechanism to create muti-channel connections using PVManager.

ChannelFinder Service

ChannelFinder tries to overcome the flat name space limitation of the EPICS Channel Access protocol by implementing a generic directory service, which applications can query for a list of channels that match certain conditions, such as physical functionality or location. It also provides mechanisms to create channel name aliases, allowing for different perspectives of the same set of channel names.

ChannelFinder directory server is implemented as a REST style web service, with a relation database (RDB) backend. A client sends an HTTP request to the service to query, create, update and delete directory entries. The data (list of channels and their attributes) is sent/returned in XML (or JSON) notation.

PVManager

PVManager is client library aimed to simplify gathering and composition of control system data. When writing a client application for a control system, common elements always have to be implemented such as rate decoupling, queuing, caching, aggregation, notification on the the correct thread. PVManager allows you to assemble your pipeline starting from commonly used elements , instead of re-implementing every time.

*Work supported by U.S. Department of Energy
#shroffk@bnl.gov

PVManager provides support for composite datatypes like MultiChannelArray, MultiChannelMaps, etc. and provides mechanisms to define expressions to govern the manner in which the control system data is collected and presented to the application.

ChannelFinderClient (CFC)

An eclipse plugin which provides various clients to the various CSS applications to query the channelfinder service. The plugin also provides a set of utility methods to simplify the querying of the service and perform some common operations on the result of these queries.

ARCHITECTURE

The figure 1. shows the architecture of the new CSS applications which use the ChannelFinder service along with PVManager and CFC library plugins. The applications use the CFC plugin, to query the service for a group of channels based on set of criteria which might include positional, physical or operations properties and/or tags associated with the channels, the resulting channels are then used by PVManager to create channel access (CA) connections to retrieve their values.

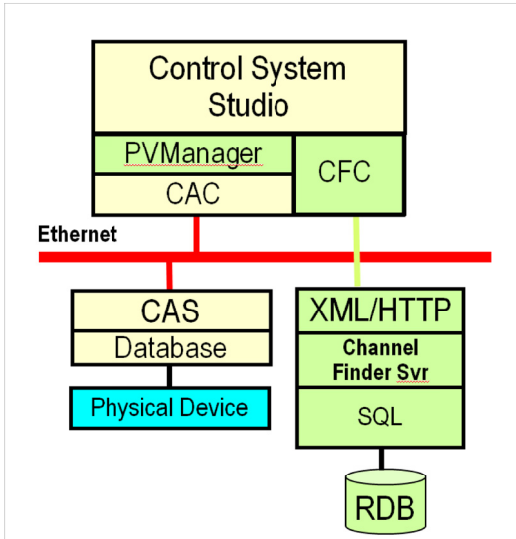

Figure 1: Architecture.

CSS APPLICATIONS

ChannelViewer

The ChannelViewer is a simple graphical application which can be used to query the channel finder. The input

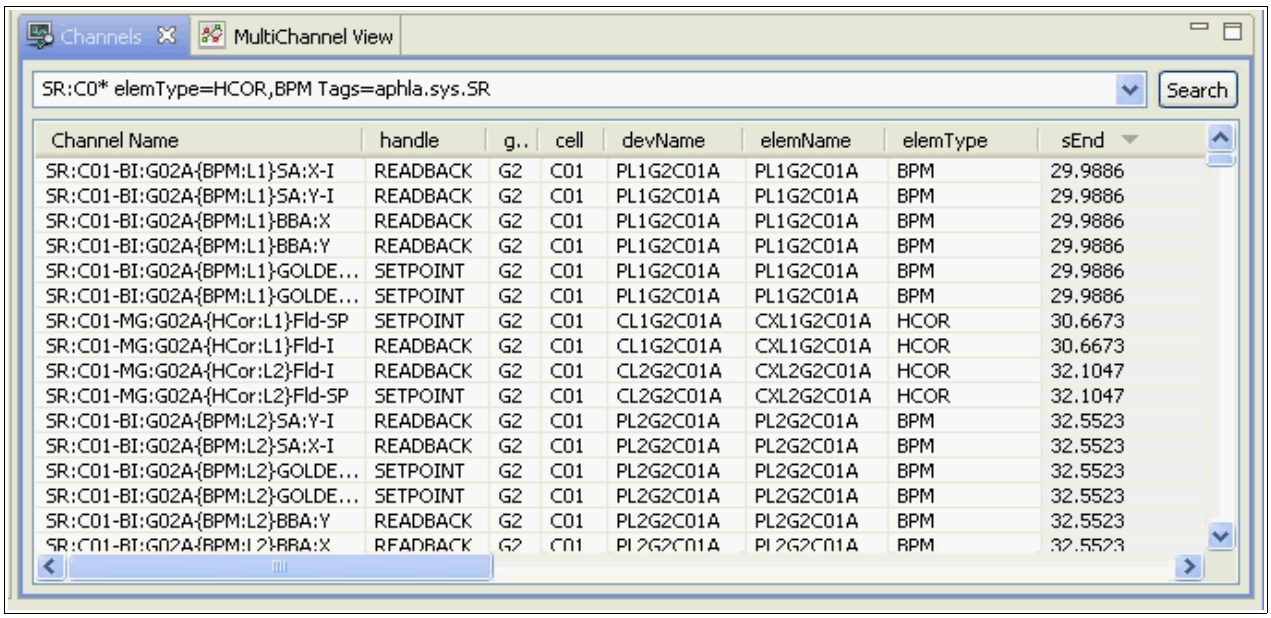

Figure 2: The Channel Viewer can be used to query the ChannelFinder service for a set of channels. The figure shows the result of a query for all the channels in the Storage ring associated with Beam Position Monitor (BPM) or Horizontal Correctors (HCOR) with the tag aphla.sys.SR.

consists of a query can be based one or any combination of the criteria: Channel name, Property values, Tags.

The resulting Channels can be sorted, grouped and tagged. They can be exported to any other CSS application as a set of process variables, thus the end user need not remember details of each process variable but can rather work with logical group determined by the query conditions.

MultiChannel Viewer

The MultiChannel Viewer application shown in Figure 3 is designed to plot the values of a group of channels which are ordered based on a user specified criteria i.e. s-position

The MultiChannel viewer accepts a query (similar to the one used in ChannelViewer) which represents a logical group of channels on the ChannelFinder server.

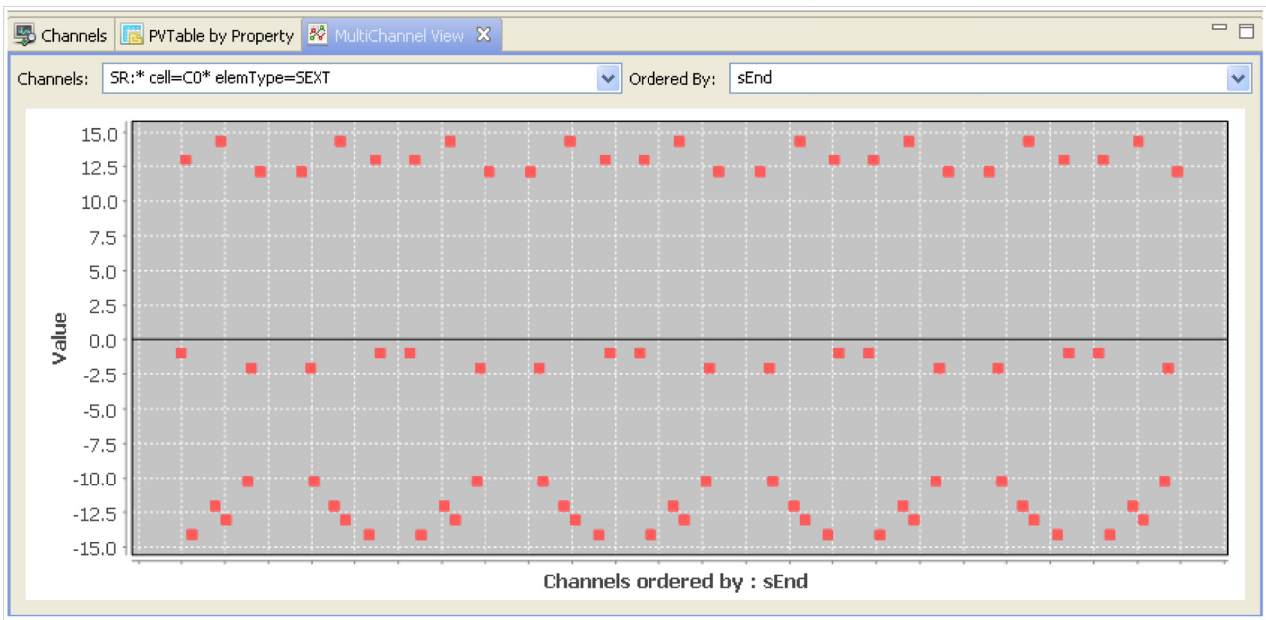

Figure 3: Shows an example use case of the MultiChannel Viewer, the application queries ChannelFinder for all the process variables associated with sextapoles(elemType=SEXT) in the storage ring (SR:*) and plots each channel ordered by the sEnd value.

QM2G4C01B	1.2220868085732814	1.2223

Figure 4: Example of a full-width figure showing the distribution of problems commonly encountered during paper processing. This figure is labeled with a multi-line caption which has to be justified, rather than centered.

The result of this query, a group of channels, is then plotted with their order along the x-axis being determined by the "Order By" property selected in the drop box.

PVTable by Property

Figure 4 shows the PVTable by Property application. It allows user to organize the output of many channels in a table, based on the value of two properties, thus each cell of the table represents the current value of a single channel, the position of each channel is determined by the value of selected row and column properties. The list of channels and the properties used to create the rows and columns are obtained by querying the ChannelFinder.

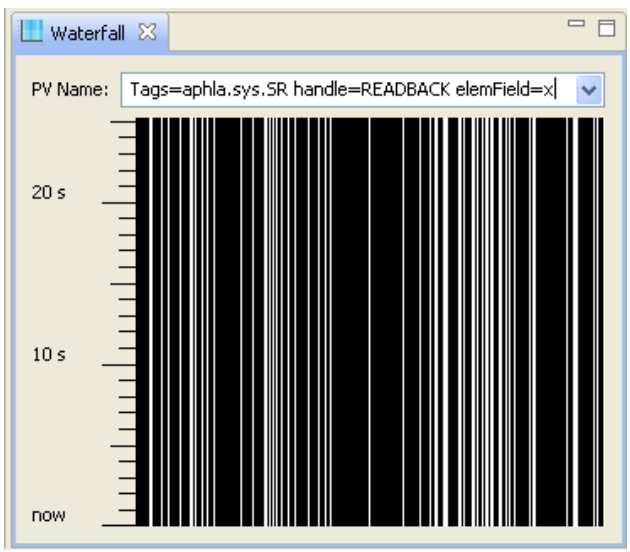

Figure 5: Waterfall plot generated from PVManager using the the result of the query for all channels with Tag=aphla.sys.SR and are readback values for element field x.

WaterFallPlot

The Waterfall plot shown in Figure 5. creates a time plot for all the values of a channel query or of a waveform.

CONCLUSION

- Use of the ChannelFinder service and client eliminates the need for configuring and remembering each individual channel.
- PVManager simplifies and improves performance of applications by handling various problems associated with use of large number of channel.

THE SPIRAL2 RADIOFREQUENCY COMMAND CONTROL

D. Touchard, C. Berthe, P. Gillette, M. Lechartier, E. Lécorché, G. Normand GANIL, Caen, France
Y. Lussignol, D. Uriot CEA/DSM/IRFU, Saclay, France.

Abstract

Mainly for carrying out nuclear physics experiences, the SPIRAL2 facility based at Caen in France will aim to provide new radioactive rare ion or high intensity stable ion beams. The driver accelerator uses several radiofrequency systems: RFQ, rebunchers and superconducting cavities, driven by independent amplifiers and controlled by digital electronics: the low level radiofrequency subsystem which is integrated into a regulated loop driven by the control system. A test of a whole system is foreseen to define and check the computer control interface and applications. This paper describes the interfaces to the different RF equipment into the EPICS based computer control system. CSS supervision and foreseen high level tuning XAL/JAVA based applications are also considered.

SPIRAL2 AND RF CAVITIES

The SPIRAL2 project is originally designed to produce new intense rare ion beams (RIB). The main production scheme is based on fast neutron induced fission of uranium target using a carbon converter. The driver accelerator facility composed by sources, followed by a Radio Frequency Quadrupole (RFQ), 3 bunchers, and a superconducting linear accelerator (LINAC) will be able to accelerate also proton, deuteron or heavy ion beams. The LINAC will be composed of 26 quarter wave superconducting resonators closed into 19 cryo modules. All cavities will be driven by independently power amplifiers at 88.0525 MHz [1].

COMMAND CONTROL MAIN CHOICES

Two kinds of users are identified today. On one hand beam drivers and operators working in the control room are in charge of delivering beams. On the other hand, engineers have to make sub systems and equipment working even if the general control command system is not available.

Figure 1 gives an overall view of process control architecture. As usual command control systems, two main layers can be identified. The supervision layer provides high level tuning applications, supervision screens and specific human interface tools. The process control layer provides access to different actuator and feedback information generated by sensors.

For the command control room, and control process associated, EPICS was early chosen to ease development and integration of software components developed by all laboratories involved in the SPIRAL2 collaboration. Industrial PC Linux or VME Vxworks crates will host EPICS input output controllers (IOCs) [2][3].

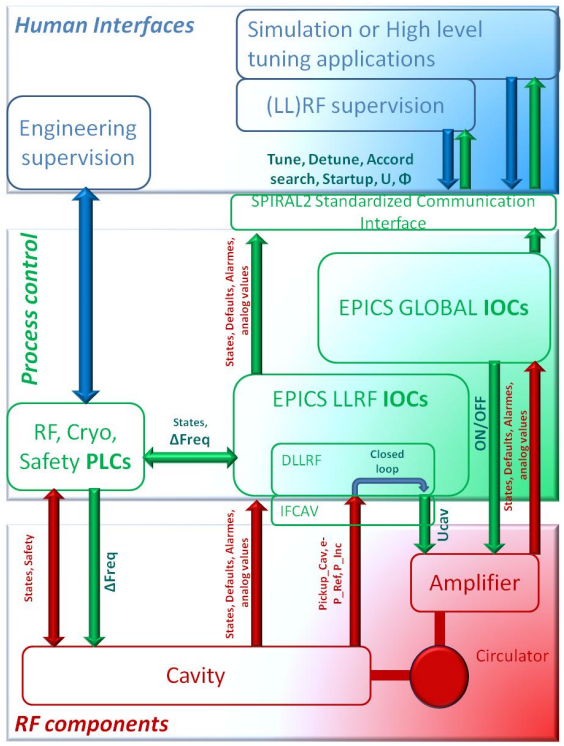

Figure 1: Main RF CC functional architecture.

Siemens S7 programmable logic controllers (PLCs) will be dedicated to slow control material protection, safety and local engineering applications. On one hand, supervision screens are produced with EDM or CSS/BOY, on the other hand more sophisticated high level tuning applications derive from the Java XAL framework [4][5].

To control Radio Frequency (RF) equipment, a dedicated command control (CC) sub system is identified. The main piece of this sub system is a low level radio frequency (LLRF) control process which will regulate the accelerating field of each cavity with a fast automatic closed loop [6].

POWER AMPLIFIERS

Amplifiers foreseen to drive RF cavities will be able to deliver up to 20 kW for solid state amplifier and up to 60kW for tube amplifiers. Both are provided by industrial companies and a special care has been taken on prototyping and testing. To ease engineering support, supervising PLCs applications are delivered with. A special care is going to be taken for putting the tests with EPICS components that will be used for the final command control [7].

Figure 2 shows the CSS/BOY supervision screen developed for bench tests of tube amplifiers.

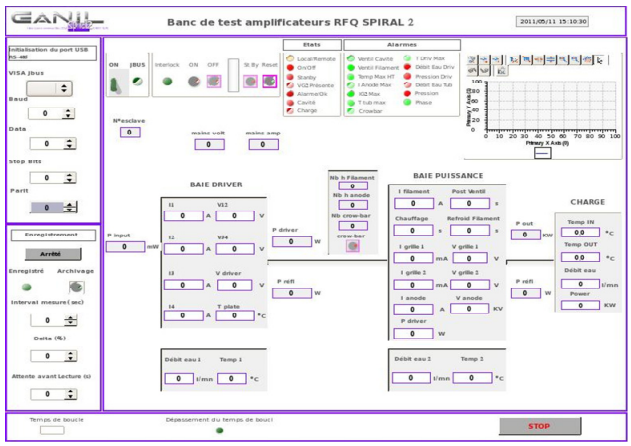

Figure 2: Tube amplifier supervision screen.

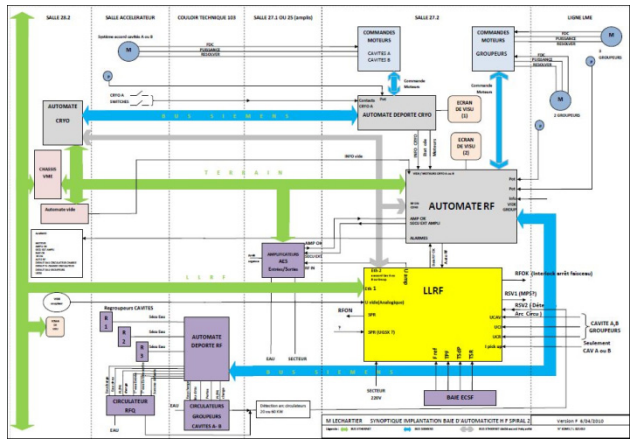

Figure 3: Implantation diagram.

LLRF CC

The LLRF will mainly provide the control analogue signal to each cavity's amplifier. Among others, it will also control the frequency, the start-up in an automated way, and will monitor the electric arc phenomenon. In order to fulfil these functionalities, the first digital subsystem (DLLRF) will acquire and process data from the second subsystem (IFCAV) which will host RF components to interface cavities. In addition to control the amplitude and phase, the DLLRF will be in charge of communicating with global command control applications throw a standardized interface. To ease the integration in the whole command control architecture, technical choices for this sub system respect the main EPICS and VME command control choices.

PROCESS CONTROL

VME Process Control

To ease high level application access to the process control layer, a SPIRAL2 standardized communication interface has been designed [8]. Dedicated RF applications will tune a cavity with the U voltage value and the Φ phase value. The EPICS channel access (CA) protocol and this standardized interface enable applications to discover equipment remote values, and lists of state, defaults, and alarms.

Global EPICS IOCs aim to interface specific RF equipment command to supervision layer. They could also be an interface to LLRF EPICS IOCs that include all specific cavity functionalities.

Implantation Diagram

Figure 3 shows implantation diagram designed for RF command-control. This implantation could evolve before final integration of each command control component, engineering needs, like cable path or command control crate, are nearly well identified today.

PLC Process Control

In addition to general functions described above, PLCs take a particular place for RF command control. Amplifiers will be interfaced via dedicated PLCs solution. In the same way, a well tuned and regulated cavity which drifts in frequency should be adjusted by mechanical or thermal constraint. As shown on figure 1, for the special case of mechanical according cavity delta frequency, dedicated brushless motors driven by PLC are under prototyping.

HUMAN INTERFACES

Introduction

To drive a machine like the SPIRAL2 facility, a set of high level and supervision applications as shown on figure 4 are going to be developed [9]. After configuring equipment, conditioning dedicated sub systems like RF equipment, and setting theoretical beam values, RF equipment can be tuned and optimized for different kind of beams. CSS/BOY applications will assume to put each equipment and servitudes into work when more complicated JAVA XAL applications will tune the machine.

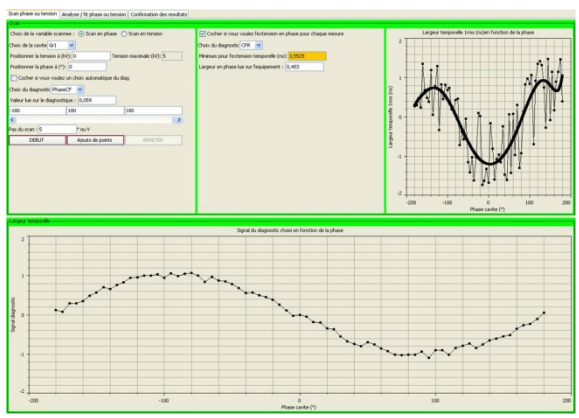

Figure 4: Cavity tuning application (preliminary).

High Level Applications

Two steps are foreseen to tune rebunchers and LINAC cavities.

At first, consigns will be set on cavities and associated quadrupole magnets, one after the other, with an application named "Cavity tuning" shown on figure 4. Theoretical values come from simulation application software named GenLinWin [10] developed by "D.URIOT et al." at CEA. Scans around theoretical amplitude and phase values associated with a time of flight measure value will be used.

Secondly the "Optimization" application shown on figure 5 will adapt the beam to the channel created, using the three rebunchers and four quadrupole magnets.

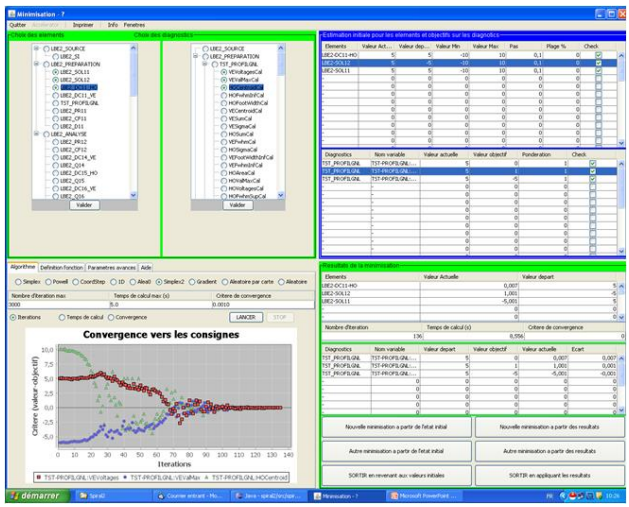

Figure 5: Optimization application.

REBUNCHER CC TESTS

Rebunchers (figure 6) used on the medium energy line have been prototyped at GANIL. Power tests started in 2010 have been performed till July 2011 [11]. They have confirmed the Q factor, the shunt impedance and maximum substained voltages as well as cooling and coarse tuning capabilities.

Figure 6: Rebuncher prototype.

The next step planned on the beginning of 2012 will qualify this cavity with the whole LLRF and CC systems. LLRF sub system has already been used on partial test-bench platforms to qualify the two families (A and B) of the LINAC cavities. Furthermore, setting and validating the whole command control during these tests will be an essential step before the final integration phase. To achieve this task, special RF CSS/BOY supervision screens to control the rebuncher will also be developed.

FIRST RESULTS AND NEXT STEPS

RF command control architecture is today well seen and designed. The tests already made on the amplifier bench have confirmed the interface between IOCs and PLCs. First LLRF tests on cavities A and B have shown that first command control prototype components reach projected performances. Simulations on the first RF tuning applications confirm the choice of XAL/JAVA. Brushless motors prototype is nearly well known now and next rebuncher tests should confirm the whole command control system. After that, the strategy to integrate the definitive command control should be confirmed.

ACKNOWLEDGMENTS

Authors would like to acknowledge warmly M. Di Giacomo J.F. Leyge for their work and availability. They take this opportunity to thank P. Baret, F. Bucaille, B. Ducoudret, G. Duteil J.C. Deroy, C.H. Patard and J.F. Roze who have made the study and the completion of these first results possible.

TOOLCHAIN FOR ONLINE MODELING OF THE LHC

G.J. Müller, X. Buffat, K. Fuchsberger, M. Giovannozzi,
S. Redaelli, F. Schmidt, CERN, Geneva, Switzerland

Abstract

The control of high intensity beams in a high energy, superconducting machine with complex optics like the CERN Large Hadron Collider (LHC) is challenging not only from the design aspect but also for operation towards physics production. To support the LHC beam commissioning, efforts were devoted in the design and implementation of a software infrastructure aimed at using the computing power of the beam dynamics code MAD-X in the framework of the JAVA-based LHC control and measurement environment. Alongside interfaces to measurement data as well as to settings of the control system, the best knowledge of machine aperture and optic models is provided. In this paper, we will present the status of the toolchain and illustrate how it has been used during commissioning and operation of the LHC. Possible future implementations will be discussed.

MOTIVATION

Since the startup in 2009 the LHC has been smoothly commissioned and reached an outstanding performance. The 2011 target integrated luminosity of 1.0 fb^{-1} was already reached in June and currently increased to a total of 4.0 fb^{-1}. This was to a great extent achieved by the two-step reduction (initial 1.5m and 1.0m as of 09'2011) of β*, the extremal optical β-function in the interaction point (IP). New settings had to be generated for the LHC for each of these β* reductions. A flexible, extendable and maintainable framework was required, which allows the transfer of simulation data to the control system and verification of the generated settings which are based on this input.

The complexity of the LHC itself, combined with the required possibility to handle of a variety of complicated operational configurations, especially in the IP's, raised a demand for online modeling. There is an interest in simulations representing the current status of the machine to determine e.g. the beam position at all machine elements or the beam size according to the configuration resident in the machine. Furthermore the simulation of changes before they are driven to the machine is essential to estimate their impact concerning restrictions imposed by the aperture of the machine and machine protection.

In this paper we present the toolchain which was developed to cope with the above mentioned challenges. Applications are provided to address individual problems and a core software structure was established to provide a simulation environment used by the *Aperture Meter* [1]. The work is based on an initial implementation of a framework for the commissioning of the transfer lines [2] which was extended for the LHC commissioning [3] in 2010.

ENVIRONMENT

The main purpose of the online modeling is to establish the connection between the accelerator simulation and the real machine. The relevant systems the toolchain has to interface with, are presented in the following.

Accelerator Physics Simulation MAD-X is the de facto standard accelerator lattice design and simulation software at CERN. A large amount of machine lattice models and optics for MAD-X are available and maintained by the accelerator physics community. Alongside other features the software can calculate the optical functions and the aperture information for a given machine configuration. MAD-X input is defined via its own scripting language. The optics of an accelerator is described by a specific set of optics functions (twiss) calculated by MAD-X. The optics include the design orbit and the β-function. To calculate an optics in MAD-X, a strength value has to be defined for each lattice magnet. JMad the JAVA API to MAD-X [4] was chosen as the interface to the computing power of MAD-X. JMad provides object-oriented access to MAD-X and allows to define and maintain machine and optics definitions in `JMadModelDefinition`'s hiding the complexity of the script based interaction.

Control Infrastructure Access to the control system and online measurement data of the LHC is provided by the LHC Software Architecture (LSA) [5]. Two essential entry points are exposed to clients: The JAVA API for Parameter Control (JAPC) to retrieve measurement data and the LSA Client API for access to all LSA functions related to optics and settings. The main concepts *Parameter* (settable or measurable entity), *Context* (collection of parameter values over a period of time), *Setting* (representation of a parameter value) and *Trim* (manipulation of a number of settings) are explained in detail in [5]. Besides the online measurement data from JAPC, the CERN Accelerator Logging Service (CALS) [6] provides a JAVA API to retrieve measurement data from the logging database.

Optics (strengths and twiss outputs) have to be uploaded to the LSA database as input for the settings generation. A context (in the case of the LHC: *Beamprocess*) is defined by the sequence of optics that should be established in the machine when the context settings are driven to the hardware. In the example of the LHC squeeze all required optics are defined from the injection optics to the current 1m β* optics at the end of the squeeze beam process. The LSA settings generation is used to generate all required settings for the LHC devices. In the case of the power converter settings all parameter settings in the hierarchy are generated

from the optics strength input: PC strengths (K) down to the PC reference currents (IREF) which are driven to the hardware.

Adjustments of physics parameters like tune, chromaticity, coupling as well as orbit steering with bumps for beam crossing and separation in the IPs is done via knobs. A knob is a LSA parameter which has a unique hierarchy of dependent K parameters called knob definition. Each assigned parameter K_i is connected to the knob by an optics dependent multiplication factor f_i. Therefore a trim on the knobs setting value A is propagated to the dependent parameters like $\Delta K_i = \Delta A \cdot f_i(\text{active Optics})$.

REQUIREMENTS

The following requirements have to be fulfilled by an online modeling toolchain:

1. handling of the different machine optics configuration and data transfer to LSA
   (a) definition of optics models and tools to follow their evolution
   (b) automatic creation of optics and knobs
   (c) transfer of optics/knob data to the control system
   (d) verification of generated settings in LSA
2. provide the information of the mechanical aperture for the whole machine, including the information available from cold bore measurements and the movable device positions (e.g. collimator's and roman pots)
3. create a simulated machine, based on the current state and settings driven to the hardware
4. combine measurement data with the simulation data (e.g. orbit interpolation)
5. simulate the effect of parameter variation (virtual knobs)
6. support the extraction of all control system settings and measurements required to build a simulated model for any given time in the past

ARCHITECTURE

Package Structure Suitable for the variety of systems the online model (OM) toolchain needs to interact with, the functionality is distributed over eight 'library/service' projects and three main application projects as shown in Fig. 1.

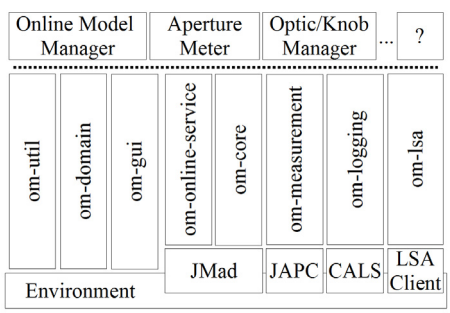

Figure 1: Online Modeling Toolchain Project Overview.

This modular design, allows to maintain and improve each part separately. The *om-util* project contains utilities for file interaction, date/time formatting, etc. The *om-domain* project contains data objects which are shared toolchain wide. Common GUI elements are gathered in *om-gui* project. The *om-online-service* project provides the online simulation from LSA settings and is explained in more detail later on. Calculations and the aperture model are implemented in the *om-core* project. The *om-measurement*, *om-logging* and *om-lsa* projects contain interfaces to interact with their respective systems, providing access to measurement or setting data. Online model applications are independent as far as possible from external packages and depend on the toolchains own packages according to the functionality required. By following this approach improvements, adjustments and bug fixes need to be performed only in one place and all application profit.

Build Project Maintaining eleven projects and ensuring that they are released in the right sequence to correctly resolve the dependencies, can be a cumbersome and time consuming task. Therefore a project was introduced into the OM framework which allows with a one click operation to release all OM packages in the correct sequence. It also provides some tools to check the currently released versions and when they have been released.

Continuous Integration and Testing To ensure that the functionality provided by the online model toolchain resumes performing in the expected manner, unperturbed by updates of software the framework depends on (JMad, LSA, ...), automatic code testing and building has been introduced. Therefore suited project/packages have been equipped with JUNIT [7] test cases covering the critical functionalities and automatic build plans have been created on the continuous integration server BAMBOO [8] provided by the CERN BE/CO group. This set-up allows to create dependency relations between the build plans of the required projects and the build plans of the OM projects. Code changes committed to the code repository trigger the building and testing of all projects related to the changed project.

FUNCTIONALITY

Optics and Knob Management

Optics Models To cope with the increasing number of optics required for simulation and operation (a total of 133 optics), it was decided to define them in `JMadModelDefinitions`. This interface is defined by JMad and is used to create a `JMadModel` which is the facade to one dedicated MAD-X process. A `JMadModelDefinition` defines the required MAD-X files to initialize the desired machine and a collection of `OpticDefinitions` which can be loaded to the `JMadModel`. An `OpticDefinition` is a named entity that

defines the required set of MAD-X input files and the sequence in which they have to be loaded in MAD-X to specify a certain machine optics. Mechanisms are provided in JMad to save the `JMadModelDefinitions` to XML files and synchronize the required input files with the optics repository, maintained by the accelerators and beam physics group. Dedicated projects have been created containing the `JMadModelDefinitions` and all required input files. These projects are in the controls software repository under version control.

When new optics are required, the corresponding `OpticDefinitions` are created and added to the proper `JMadModelDefinition`. The XML file is generated, the required input files are loaded from the optics repository into the project folder and the changes committed to the software repository. In the following build step all files are packaged into a jar file. Client application simply have a dependency to the jar which contains the required `JMadModelDefinitions`.

This set-up allows client applications to use MAD-X computation completely independently of MAD-X syntax and required input files. New optics can be used without code changes in the clients. The model definition jars represent a common source of optics definitions to ensure that simulations are performed using the same input. The versioning of the model projects allows to perform simulation on historic input data. The interaction with JMad is described more in detail in [4] and goes beyond the content of this paper.

Optic/Knob Manager Application The generation and transfer of simulation data to the control system LSA is performed using the Optic/Knob Manager. As shown in Fig. 2 it uses JMad as calculation engine and the LHC JMad model package as source for optics definitions. The available optics models are: the nominal optics model for physics production at 1m β*, the Achromatic Telescopic Squeeze (ATS) Scheme [9] optics model and the 90m β* Un-Squeeze [10] optics model for e.g. the **TOT**al cross section, **E**lastic scattering and diffraction dissociation **M**easurement (TOTEM) experiment.

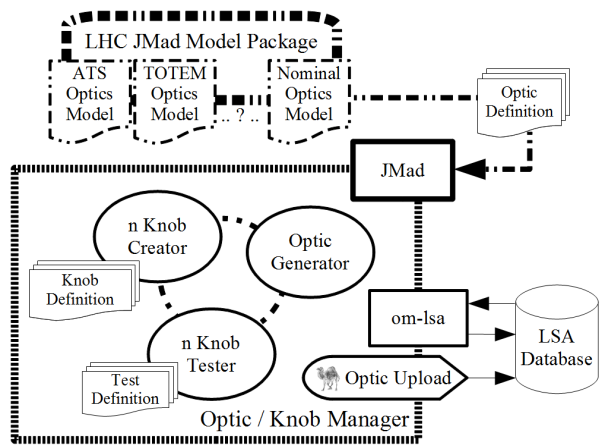

Figure 2: Optic and Knob Manager.

A simple GUI is provided in which the user can select the optics model and a set of optics to generate and upload. The `OpticGenerator` is responsible for loading the requested optics to JMad, executing possible checks for tune and chromaticity and writing the optic functions to a twiss file. A set of PERL scripts is then executed in a JAVA process to upload the generated optic data to LSA.

The same GUI also allows the selection of knobs to create for a selection of optics. The available knobs are defined by `KnobDefinitions` which have an assigned `KnobCreator` which is used to create the knob from the `JMadModel` passed. A `KnobManager` is responsible to loop over all requested optics, load the optic to a `JMadModel` and for each requested knob initialize the assigned `KnobCreator` with the model and trigger the creation process. `KnobDefinitions` are available for knobs defined by flags in the MAD-X input files (separation and crossing knobs), knobs created by MAD-X matching routines for global machine parameters like tune and chromaticity as well as for 4-corrector knobs used for local adjustment (luminosity leveling knobs). This design allows the extension of the set of available knobs by creating solely a new `KnobDefinition` and the required `KnobCreator` without touching the creation routine. `KnobTesters` are defined to ensure that newly created knobs follow definitions already present in LSA, are created correctly or produce the desired setting change when trimmed in simulation.

The import of knobs defined as a set of name value pairs is supported to define arbitrary knobs in LSA. Names can be one of the following: LSA parameter names, LSA device names or MAD-X strength names. The `om-lsa` package is finally used to transfer knob data to the control system as well as retrieve available knob definitions from the LSA database. The possibility to copy existing knob definitions to other optics is provided as well.

Setting Verification

To ensure that the settings generated in LSA are complete and correct and to apply possible corrections, the following tools have been developed in the OM toolchain based on the extraction functionality provided in the `om-lsa` project.

Beamprocess Scanner This tool can scan over the full power converter setting functions defined in a beamprocess. A snap shot of the settings is extracted at given times in the setting functions of a beam process. The settings are translated to MAD-X strength values and loaded in JMad to calculate the optic functions. The key optics parameters (tune, chromaticity, beta-beat...) can then be evaluated as function over the beam process duration. The tool has been essential for the setting optimization for the LHC squeeze [11]. It can be used to verify that the settings are valid in general (e.g. they produce reasonable tune and chromaticity evolutions) and to precalculate feed-forward correction for tune and chromaticity [12].

Online Model Manager Next to other functions, it is possible to visualize the sequence of optics in a beamprocess together with the nominal evolution of the optics key parameter values (tune, chromaticity and β*). The display acts as selection interface for the time in the beamprocess where the power converter settings should be extracted, either to display or to write them to a file in MAD-X input format. When loaded to display, the generated settings can be checked with respect to the nominal settings expected from the optics input saved in LSA. The settings saved to file can be loaded in a MAD-X script to calculate and display the optic functions. A plotting environment is provided that allows the display of multiple e.g. orbits on top of each other. The evolution of knob bump shapes can be visualized by a sequence of knob trims performed with the LSA Trim application, followed by an extraction and a MAD-X run based on the extracted settings.

Online Aperture Model

The *static* aperture model is implemented in the `om-core` package. It provides the dimension of the clearance in the vacuum layout in transverse coordinates. The data is based on the theoretical aperture with the cold bore measurement results. The model was extended with the current positions of the movable devices (collimator's and roman pots), read online from the hardware. This functionality is provided by the `om-measurement` package. The measured data from the movable devices are translated into aperture information by using the movable device information (angle, type, beam it acts on,...) that are available from the `om-lsa` package. The aperture model is an essential ingredient for the aperture meter [1].

JMad Online Service

The `JMadOnlineService` is implemented in the `om-online-service` package as the online extension to JMad. The current configuration of the machine is simulated based on the active optic and the optic dependent definitions and current settings of a set of knobs that represent the relevant orbit configuration (separation, crossing, luminosity leveling knob settings and a set of aperture scan knobs). The active optic is the one that was the basis for the generation of the settings that are currently resident in the machine hardware. A `ModelManager` allows to access, manipulate and retrieve data from the underlying `JMadModels`. Two manipulators are provided to transfer settings from LSA to the underlying `JMadModels`: One can update the models to the current state resident in the machine. The second on loads the settings that have been resident at a given point in time. This service is the basis for the aperture meter [1].

Measurement Data Treatment

Regarding measurement data the online modeling toolchain provides two more features: The interpolation of the measured orbit to all machine elements and the determination of the current state of the machine based on online data from the collimator hardware and from data distributed over the timing system. The orbit interpolation is implemented in the JMad core package and uses transfer matrices to calculate the orbit positions between two adjacent monitors. The measured orbit data are either received by a JAPC subscription to the orbit feedback service unit, or by extraction from the logging database. The identification of the online machine state is performed by merging the status and current time in the setting function retrieved from a given collimator front-end with the information about the beam mode distributed over the LHC timing system.

CONCLUSION AND OUTLOOK

The basic architecture and features of the online modeling toolchain have been presented. It was successfully used for the preparation of all LHC optics configuration for physics production as well as machine development studies and provides a good basis for future developments. The usability was shown in applications presented in this paper and as basis for the aperture meter [1]. Further developments will include the full integration of new features provided by LSA and the toolchain itself and changes towards a strict distribution of the functionality into the packages of the toolchain architecture.

CONTROLLING AND MONITORING THE DATA FLOW OF THE LHCb READ-OUT AND DAQ NETWORK

Rainer Schwemmer, C. Gaspar, N. Neufeld, D. Svantesson, CERN, Geneva, Switzerland

Abstract

The LHCb read-out uses a set of 320 FPGA based boards as interface between the on-detector hardware and the GBE DAQ network. The boards are the logical Level 1 (L1) read-out electronics and aggregate the experiment's raw data into event fragments that are sent to the DAQ network. To control the many parameters of the read-out boards, an embedded PC is included on each board, connecting to the boards ICs and FPGAs. The data from the L1 boards is sent through an aggregation network into the High Level Trigger farm. The farm comprises approximately 1500 PCs which at first assemble the fragments from the L1 boards and then do a partial reconstruction and selection of the events. In total there are approximately 3500 network connections. Data is pushed through the network and there is no mechanism for resending packets. Loss of data on a small scale is acceptable but care has to be taken to avoid data loss if possible. To monitor and debug losses, different probes are inserted throughout the entire read-out chain to count fragments, packets and their rates at different positions. To keep uniformity throughout the experiment, all control software was developed using the common SCADA software, PVSS, with the JCOP framework as base. The presentation will focus on the low level controls interface developed for the L1 boards and the networking probes, as well as the integration of the high level user interfaces into PVSS.

LHCB READ-OUT CHAIN

The LHCb DAQ system is built around an Ethernet based network, which transports the experiment's data from the detector to a Linux based filter farm. This farm consists of 1500 computers and processes the data of every accepted event and then decides whether the event is interesting or if it should be discarded. Accepted events are then sent on via IP over Ethernet to a group of computers which replicates the stream of accepted data to the disk writing processes and to a dedicated monitoring farm.

Data is accepted at a maximum rate of 1.1 MHz which translates to a data rate of approximately 50 GByte/s on the input of the network. On the border between network and detector is a set of 350 FPGA based converter boards – Trigger Electronics and Level 1 board (TELL1) [1] – which receive the data via optical links from the detector. The data is first checked for consistency and then compressed into a sub-detector specific format. After that, the event data is combined with meta information and a unique event ID. In the last step, data is coalesced into IP packets and sent to an on-board, 4 port Gigabit Ethernet (GbE) card. The TELL1s then send the data to the filter farm through two main data switches and a set of 50 fan-out switches. The total packet rate in the network is about 35 MHz.

Inside a filter farm node, the event fragments are assembled into complete events and then handed off to trigger applications which do a partial reconstruction and filter process. From the filter farm onward, the data rate drops to a more manageable rate of 200 MB/s and is again aggregated on two dedicated machines before being replicated to the online monitoring farm and the storage layer. The local storage system is only a temporary buffer for the data though. Data is written in sets of 3 GB files. Once a file is full, its consistency is verified, check sums are calculated and the file is sent off to permanent tape storage at CERN.

Throughout this chain, there are many points, at which data can be sporadically lost or which can halt the data taking process completely.

TYPICAL LOSS POINTS AND BOTTLENECKS

Read-out Boards

When a read-out board fails to produce data, there will not be enough fragments to rebuild the event in the farm and the event will be discarded. If a TELL1 stops sending any data at all, the whole read-out chain is stopped. If it cannot cope with the data rate for some reason, and slows down, the whole DAQ process is affected. In order to quickly diagnose problems inside the read-out board, the data flow is already monitored on its way through the board.

There are five FPGAs on each board, where four are responsible for checking and compressing the sub-detector data and one is assembling the data from the four preprocessors. Additional meta information from the Timing and Fast Control (TFC) system is then added to each event, before it is sent to a buffer for network transmission.

Typical problems here can be a front-end not sending data or the data transmission over the board between chips. The compression and gathering algorithms, if they are overwhelmed by too much data due to noisy channels in the detector or unexpectedly high occupancy events can also slow down the process or fail completely.

Network

At the design time of the read-out system it was deemed too unpractical to have a reliable transport protocol between the TELL1 boards and the filter farm. The huge number of farm nodes and TELL1 boards would necessi-

tate a substantial amount of memory for state information and data buffering on the read-out boards, which at that time was just not an option. The chosen protocol is a pure push protocol, where data is being sent as IP packets whenever bandwidth is available on the read-out boards. In a way the protocol behaves like UDP. In case the switches decide to drop packets, there is no retransmission.

The situation is further complicated by the fact, that all the fragments for a particular event have to be sent to a single farm node. The fragments leave the TELL1 boards all at the same time and for a short time there is a strong overcommitment of the output port to the farm node where the data is supposed to go to. The average rate to a single farm node is still far below the 1 Gigabit/s limit, but for a switch this is a typical situation to throw away packets, if it runs out of buffer space.

Farm Nodes

Inside the farm computers, the data is received by the network card, assembled into events and then passed on to the trigger applications[4]. If the machine is too busy, data can be lost already on it's way from the network card to the kernel, before it enters any application. Other problems can be trigger processes getting stuck and not processing events any more, or a machine in general having hardware problems which influences performance.

Storage Layer

As the data rate is reduced to about 200 MB/s after the trigger farm and there is only inter-computer communication, the read-out chain uses the TCP/IP protocol from the farm onward. TCP is a reliable protocol, so data loss in the network is not as much of a problem any more as in the steps before. However, switches can fail and processes can die unexpectedly, so this part of the system is monitored as well.

The actual process of writing at a sustained rate of 200 MB/s for several hours per day also requires special hardware, especially if it has to be protected from single mode failures. For data storage, we use a fiber channel based Storage Area Network (SAN) consisting of several head nodes and a fully redundant hard-disk array. The entire SAN is set up in an active-active configuration and again each connection point in the fiber network is monitored to make sure that all components continue working and share the load.

READ-OUT CHAIN PROBES

In the end one wants to be able to diagnose, as quickly as possible, why the system's performance is degraded and which link in the read-out chain is responsible. In order to find the culprit, we have – over time – inserted many probes to gather statistics throughout the entire DAQ process. At the same time, care had to be taken to not overload the components with probes, because they are usually all highly utilized by the DAQ process.

Read-out Boards

On the TELL1 boards, the number of event fragments that come in on every optical link is already counted, to find misbehaving front-ends. After the pre-processing stage, event numbers are counted as they leave the pre-processing FPGAs and when they enter the aggregation FPGA. A final count is done when they are assembled into IP packets and how many packets are sent to the GbE card.

The TELL1 comes with an embedded 486 CPU that sits on each board and which is capable of talking to all the FPGAs and other micro-chips on the board via PCI and I^2C buses. A program on the PC periodically gathers all the counters and publishes them through a unified messaging layer, called DIM[2], to the Experiment Control System (ECS) [3].

Network

Since we are using only off-the-shelf network equipment we can use the standard counters that come with the switches and routers. What makes the situation a bit more complicated is the fact that a switch does not know anything about event fragments but only about network packets. It also has persistent counters, that are not reset on every run change. Additionally, on the core routers, which have to cope with the full 50 GB/s, 35 MHz packet rate, we cannot permanently run the full statistics gathering, because it overloads their CPUs and slows down normal network operations.

Nevertheless, this is the only semi-blind spot in the system, and by monitoring the data leaving the TELL1s as network packets and the data entering the farm nodes also as packets, we can trace back problems to the switches and then check in more detail where the problem is by switching on specific counting features in the switches.

General data, like port counters are directly gathered via scripts from the ECS. For more in depth debugging sessions, the system administrators have to directly log in to the switches and check the statistics manually or use dedicated console scripts.

Farm Nodes

We also had trouble with data being lost on the way from the network card to the application. We are using the counting features of the Linux Firewall to count packets as they are arriving. The packets are filtered by source IP addresses, which can then be mapped to the sending TELL1s.

Further up in the chain we count again the number of assembled event fragments and from which source they came. Finally, the total processed and accepted/rejected events are counted as well.

Again, like on the read-out boards, a special program was developed to gather the statistical counters of the fire-

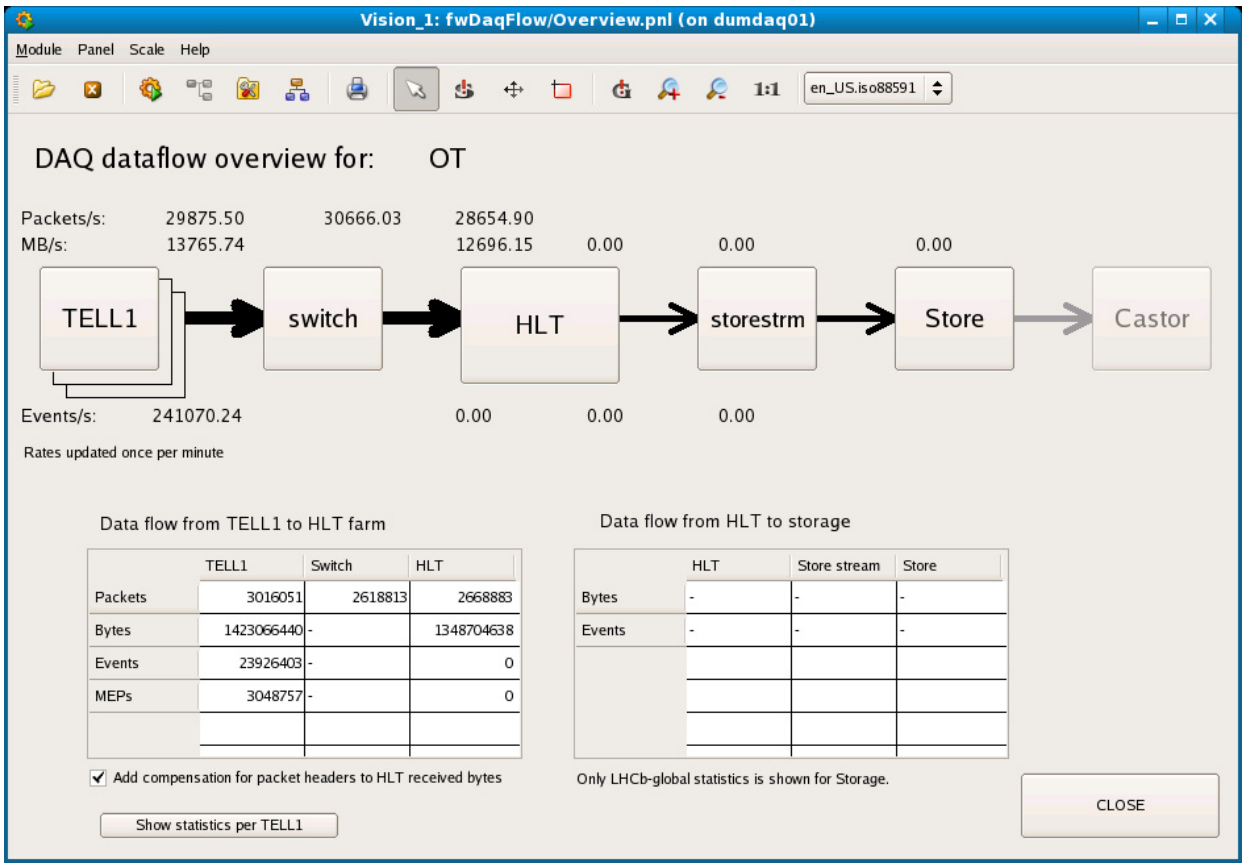

Figure 1: Top overview panel of the DAQ flow monitor. The User can click on the buttons of the different routing points to get a more a more detailed view of the subsystem.

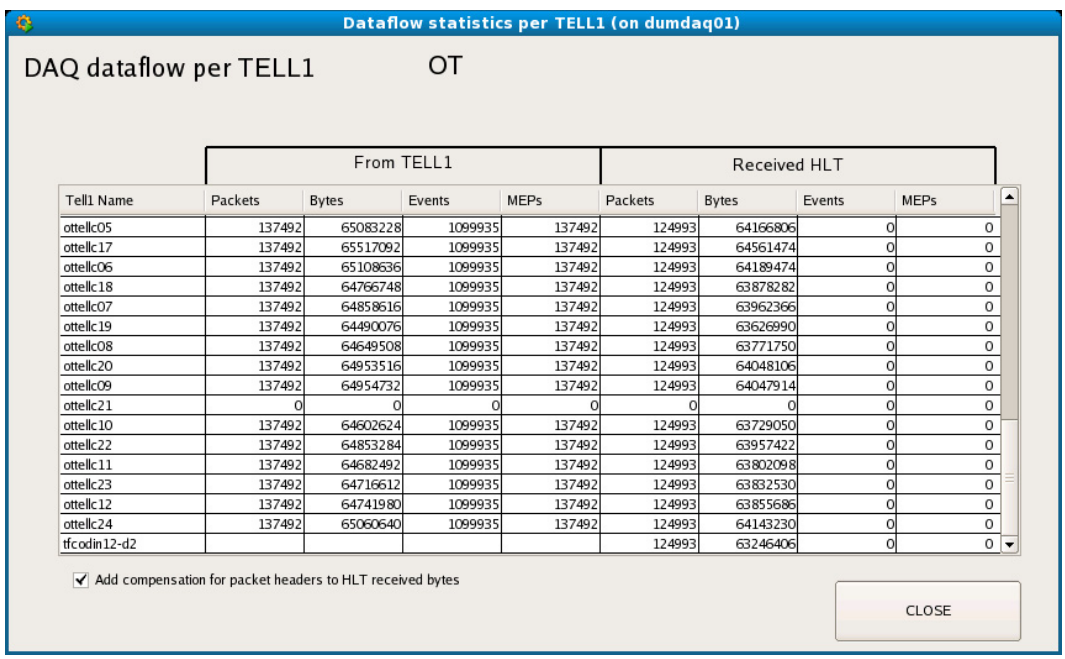

Figure 2: Detailed counters of the intersection between TELL1s and the trigger farm. ottellc21 is not producing any data and subsequently no events are produced.

wall and the trigger processes and publish them to the ECS. In this case more effort had to be put into the program, since it has to process several times the number of fragments times the number of TELL1s times the number of farm nodes.

We developed a tiered process hierarchy, where programs on individual farm nodes send their statistical information to higher level nodes where the data is added together and then sent to a central processing program, which again adds the sub-results and publishes them. The gathering programs also tap into the control system to detect when runs start and stop, and to detect which parts of the detector are actually part of the read-out. This is necessary, because the detector can be split into its individual sub-detectors which can run in standalone mode.

Storage Layer

Finally the accepted data has to be written to disk. Again there are a number of critical processes, which can fail and contribute to the loss of data. Since this part of the read-out is based on TCP, data loss is not caused by network packet drops or disappearing events, but through loss of performance. If the data cannot be written to the disks fast enough, or there are general hardware problems on the way to the disks, the system will slow down, decreasing the amount of physics data that is gathered over time.

Data arrives from the farm on two dedicated machines, which aggregates the events from the 1500 sources into file streams. There are usually several files being written in parallel for better load balancing. The files are then written by a simplified distributed file system [5]. All written events are again counted by the writing daemons and published to the ECS.

While we are still counting events up to the point where the data is written into actual files, we switch to purely rate based monitoring on the actual SAN back-end. There are fairly good standard tools like Munin[6] and problems in this area are outside the scope of what the operators of the experiment are usually dealing with. Subsequently we are using these tools directly instead of relaying the information to the ECS. Information is gathered from the storage head nodes directly, on the Fiber Channel switches and from the disk storage system itself. We developed dedicated plug-ins for munin, to monitor individual raid sets in the SAN and the throughput through each individual fiber channel path that leads to them. The results are then displayed on a dedicated web page. A permanent screen in the control room displays a sub-set of the most important rates to the operators.

USER INTERFACE

All the information gathered from the different counters and probes throughout the network has to be compiled into an easily understandable interface, which allows the user to quickly pinpoint problems. To hide the fact that there are hundreds of thousands of counters, we developed a dedicated master process, which gathers all the counters, sorts them into categories of either event counters, network packet counters or byte counters and calculates the rates of these for all the major routing points in the system.

A UI panel then shows a schematic representation of these points and the rates at which data is passing through them. In case of problems, the operator can quickly diagnose the point at which the disruption is happening. For more in-depth analysis, all the routing points have dedicated UI expert panels, which show the full multitude of counters. The top overview panel is shown in Fig. 1. In the case shown here, there is a problem with the assembly of the event fragments. Packets are arriving at the farm, but no events are produced by the event building processes. Looking at the detailed view of the TELL1 - HLT connection in Fig. 2, one can see a single TELL1 not producing any data.

CONCLUSION

We have developed a multi-tiered hierarchy of programs, which are capable of reading the various statistics counters that are present throughout the LHCb DAQ chain and moreover, are capable of coping with the enormous amount of information. The data is brought into a unified format which makes it easier to spot points of data loss in the system.

All the counters are analyzed by a dedicated process and then presented to the user in a simple panel, which hides most of the complexity of the system, but gives access to more detailed information if necessary. This system has helped us to quickly find problematic network links, failing read-out boards and front-ends and has improved the response time from the time a problem occurs to being fixed.

INTEGRATING CONTROLS FRAMEWORKS: CONTROL SYSTEMS FOR NA62 LAV DETECTOR TEST BEAMS

O. Holme, CERN, Geneva, Switzerland and ETH Zurich, Switzerland
J. Arroyo Garcia, P. Golonka, M. Gonzalez-Berges, H. Milcent, CERN, Geneva, Switzerland

Abstract

The detector control system for the NA62 experiment at CERN, to be ready for physics data-taking in 2014, is going to be built based on control technologies recommended by the CERN Engineering group. A rich portfolio of the technologies is planned to be showcased and deployed in the final application, and synergy between them is needed. In particular two approaches to building controls application need to play in harmony: the use of the high-level application framework called UNICOS, and a bottom-up approach of development based on the components of the JCOP Framework. The aim of combining the features provided by the two frameworks is to avoid duplication of functionality and minimize the maintenance and development effort for future controls applications. In the paper the result of the integration efforts obtained so far are presented; namely the control applications developed for beam-testing of NA62 detector prototypes. Even though the delivered applications are simple, significant conceptual and development work was required to bring about the smooth inter-play between the two frameworks, while assuring the possibility of unleashing their full power. A discussion of current open issues is presented, including the viability of the approach for larger-scale applications of high complexity, such as the complete detector control system for the NA62 detector.

INTRODUCTION

NA62 is a fixed-target experiment [1] being constructed at CERN that aims at studying ultra-rare decays of K particles (kaons) and thus follow the research performed by the NA48 detector. The detector is scheduled to start Physics Data-taking in 2014, yet many of its components will already take part in preliminary operations in autumn 2012 to measure their performance.

The NA62 apparatus is composed of 10 subdetectors positioned inside and at either end of a 115 meter long vacuum tank. It is expected to observe around 100 ultra-rare K particle decays in two years of operation with proton beams delivered by the SPS accelerator at CERN.

The detector hardware of the NA62 experiment is a mixture of legacy NA48 equipment, such as its unique high-resolution Liquid Krypton calorimeter and brand new equipment that exploit the newest technologies, such as the ultra-fast Gigatracker [2] and the Large-Angle Photon Veto (LAV) subdetector.

In terms of controls, the detector is bigger and more complex than other contemporary fixed-target experiments at CERN, yet smaller than the scale of the LHC experiments. In the order of 5,000 high voltage channels and 10,000 analog and digital values and parameters need to be commanded and monitored.

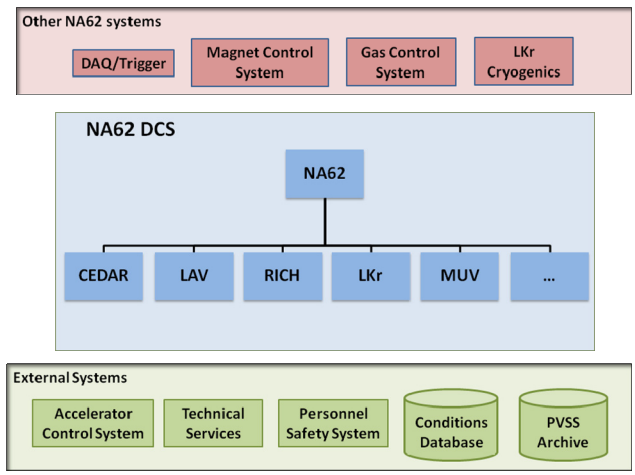

Figure 1: The NA62 DCS subdetectors and other essential systems from the CERN and NA62 infrastructure. [3]

To develop the Detector Control System (DCS) for NA62 (Fig. 1), a collaboration between NA62 and the CERN Industrial Controls & Electronics group (EN/ICE) was established in 2009. The aim is to develop and deliver the full-scale control systems for the final physics run, as well as other control systems that might be necessary for NA62 to test and commission their equipment. In this paper an example of the control systems used for beam-testing of the prototypes of the LAV subdetector is presented. These beam tests have been conducted in two-week periods of October 2009 and February and August 2010, and made use of the controls tools that are described in later sections. In April 2011 an application that monitors the environment of the storage area for the LAV equipment was developed using the same technology. This control system is still in operation.

CONTROL SYSTEM FRAMEWORKS

The supervisory control software called WinCC Open Architecture (WinCC OA is the new name for the product previously known as PVSS) [4] was selected as the basis of the NA62 DCS, in line with the selection made by the JCOP (Joint COntrols Project) collaboration for the LHC experiments. The EN/ICE group at CERN develops and supports two controls frameworks based on WinCC OA. These are the UNICOS (UNified Industrial COntrol System) and JCOP frameworks. These frameworks have been successfully deployed in large scale control systems

in the LHC accelerator and experiments, enabling considerable practical experience to be gained, permitting continual improvements and extensions of the features of both frameworks.

In addition to the WinCC OA frameworks, a suite of CERN communication systems are available for the exchange of information between systems and between the supervisory level and front-end. These systems include CMW (Controls MiddleWare) [5], DIM (Distributed Information Management) [6] and DIP (Data Interchange Protocol) [7].

UNICOS Framework

UNICOS [8] is a CERN framework developed to produce control applications for three-layer control systems (Fig. 2). UNICOS provides developers with the means to rapidly configure and generate full control or monitoring applications and provides operators with ways to interact with all the items of the process from the most simple (e.g. I/O channels) to high level compound devices with little effort.

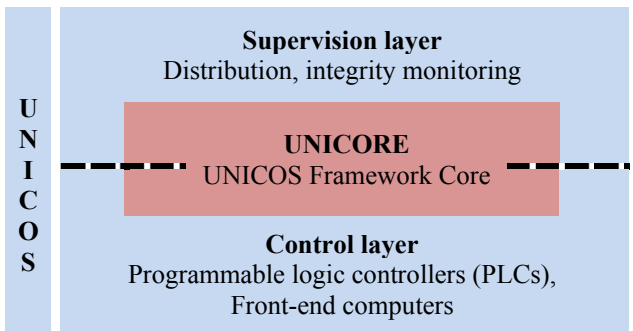

Figure 2: The three-layer control system architecture of the UNICOS Framework.

UNICOS offers tools to diagnose problems in the process being controlled and the control system itself as well as tools to access and operate the devices without specific development. The framework proposes a reusable environment composed of a set of components for the UNICOS-WinCC OA and UNICOS-Front End parts. At the supervision level in both Linux and Windows operating system, functionality such as application distribution across many SCADA data servers, monitoring the integrity of the application (e.g. status of the front-end) and configurable device trending are available. In addition it offers operators and application developers a configurable and homogenous user interface that is entirely customizable and which does not imply prior knowledge of the WinCC OA scripting language and the use of basic WinCC OA device access interfaces.

JCOP Framework

The JCOP Framework [9] focuses on providing a set of guidelines and software tools that can be used by control system developers to facilitate the building of controls applications. The framework provides a simple and standardised high-level programming interface to common functions that are required at configuration and runtime in a controls application. In addition, developers are able to directly access the underlying WinCC OA features, enabling developers to go beyond the scope of the JCOP framework in order to take advantage of all the functionality offered by WinCC OA itself.

The software tools provided allow simple creation, configuration and hierarchical organisation of instances of device classes. The device centric nature of the JCOP framework defines the architecture of the final application. The JCOP framework provides a substantial library of functionality targeted to applications based on this architecture. A pre-defined set of hardware devices is provided as standard, covering devices that are commonly used in the LHC experiments at CERN.

Functionality of the JCOP framework includes:

- Saving and restoring hardware configurations and settings, with data being stored in a database.
- Organising devices into multiple hierarchical tree views, based on off-detector and on-detector layouts.
- Control of all devices via a hierarchy with integrated Finite State Machine logic.

Comparison of Frameworks

Historically, features of both the JCOP and UNICOS frameworks were developed by coordinated effort between the relevant development teams, meaning that at a low level, several fundamental principles of the framework internals are similar. However, due to their very different aims, there are considerable differences in some conceptual models and design assumptions upon which the frameworks are based. For instance, both frameworks are based around a method of modelling classes of devices. Yet the modelling concept of each framework is different, so any integration of the two must first address the issue of how to enable interoperability of tools previously designed to work with only one of these specific model types.

UNICOS offers a methodology to create a ready-to-use controls application by following a series of configuration and generation steps. It provides a framework that encompasses the hardware interfaces up to the final operator's view of the system. This high-level, comprehensive approach allows a developer to create a complete system without needing to understand many of the internal workings of the framework or WinCC OA.

The JCOP philosophy offers a set of tools and a defined architecture which the developers of control systems can use as a basis for building the complete application. The advantage of this is that an application developer has a greater degree of flexibility in the design of the final application, particularly at the level of the operator user interfaces. However, the JCOP approach requires a good understanding of the functionality of the framework itself and more knowledge of the WinCC OA scripting language as the developer must build their application from a library of pre-defined components.

The concept of combining both frameworks in the DCS of NA62 was inspired by the different and

complementary features of the two frameworks. By combining the functionality associated with many pre-existing JCOP device classes, with the simple and holistic application generation approach of UNICOS, the maximum benefit could be derived from these frameworks. NA62 is the first target of such a unification effort, acting as a driver for the innovative work that is required for this task. It is important that the functionality should be merged seamlessly for the final application builders and operators. There is a considerable amount of design, prototyping and testing effort needed to achieve the goal of a smooth harmonisation of these frameworks.

INTEGRATION APPROACH

As mentioned previously, the device modelling concepts of UNICOS and JCOP are different and the unification of frameworks at this level is the key to interoperability of tools from each framework. Previously, the high-level UNICOS application tools could only work with UNICOS-specific devices and front-end devices. The JCOP devices cannot make use of these tools by default.

One solution to this would have been the creation of duplicate models and instances of devices for both frameworks. This approach would have increase complexity and maintenance effort and, as such, is clearly not desirable. In order to avoid such duplication, a novel proxy interface was designed (Fig. 3). This proxy enabled JCOP device instances to be visible within the UNICOS domain with little effort for the application builder.

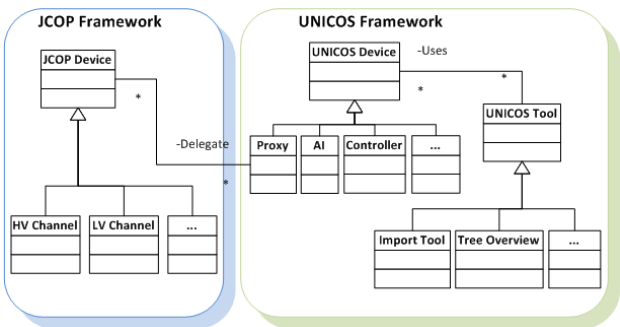

Figure 3: The proxy concept for enabling interoperability between UNICOS and JCOP domains.

In order to use this proxy mechanism, it is necessary to create a device or front-end in the UNICOS domain that contains no data. This object will act as the proxy to the JCOP device. Whenever a UNICOS utility is used with a UNICOS device, the proxy checks if the JCOP object is available and, if so, provides a transparent access to the data in the JCOP domain.

The proxy interface allows flexibility in the way devices are mapped between the JCOP and UNICOS frameworks. For instance, a UNICOS powering device could act as a proxy for a single JCOP powering channel, or a group of devices such as a multi-channel power supply.

FIRST PRODUCTION SYSTEM

As part of the collaboration between EN/ICE and the NA62 experiment, two prototypes were developed with the dual purpose of testing the framework integration concepts and providing the necessary control applications for the LAV subdetector.

The LAV subdetector is composed of 12 independent stations situated at points between 120 and 240 meters along the experiment. Each station is composed of 160 to 256 lead glass crystals with photomultipliers attached. These are assembled into rings, with 4 or 5 rings in each station (Fig. 4).

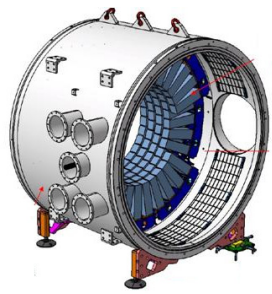

Figure 4: A representation of a LAV station. [1]

In the first LAV station alone, there are 30 PT1000 sensors to measure temperature as the LAV is sensitive to rises in temperature in the order of tenths of a degree. It is expected that 2496 high voltage channels will be needed, distributed between the 12 LAV stations.

LAV Prototype

The DCS for the LAV prototype (Fig. 5) was needed for operations of the LAV in test beams. It controlled and monitored two ELMBs (Embedded Local Monitor Boards) [10]; one to readout temperature sensors and the other to supervise vacuum pressure. The high voltage is provided by a single channel ISEG power supply and distributed via a Hamamatsu distributor, providing 160 negative high voltage channels. Both ISEG and ELMB devices were already supported by the JCOP framework.

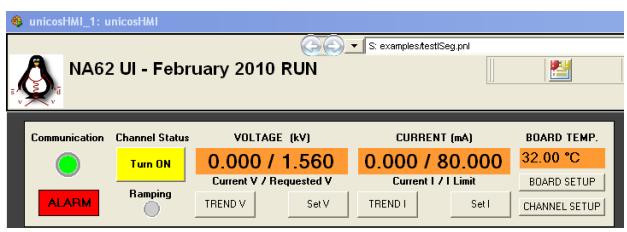

Figure 5: Extract from the LAV prototype DCS user interface.

The monitoring and control of the ELMBs and ISEG power supply was performed with WinCC OA and the combined framework approach mentioned in earlier sections. The high voltage distributor was controlled directly from a front-end program using a CAMAC controller and a CAMAC analog-digital converter.

In addition to the device level controls, a series of application level features were configured in the LAV

prototype DCS. These included an alarm screen, SMS notification of problems and checks on the DCS integrity.

LAV Environment Monitor

An additional application was required to provide long-term temperature monitoring of the area in which LAV stations are stored prior to installation. This application uses one ELMB with 32 PT100 sensors. The DCS application built upon the previous UNICOS-JCOP integration work for the LAV prototype DCS. Further work on this integration provided additional cohesion enabling the use of features such as the UNICOS trending tool. Other application features include access control and Oracle archiving to CERN central servers.

This application has been running in production for 6 months so far and was able to successfully detect of failure of the climate control system in the storage area.

CURRENT STATE AND FUTURE PLANS

In September 2011 the DCS for NA62 reached its first milestone: the completion of the "LKr (Liquid Krypton Calorimeter) Vertical Slice" application. This application provides integrated hierarchical control for custom high and low voltage systems of the LKr.

In this application, the synergy between the UNICOS and JCOP frameworks was raised to a higher level. The hardware that has typically been used in UNICOS, namely PLCs, has been brought under the supervision of the finite state machine based hierarchical control tool of the JCOP Framework and combined with analog value readout provided by JCOP ELMB devices. In addition, the hierarchical control tree has been embedded in the standard UNICOS user interface to act as the main navigation mechanism [11], providing the standardized look and feel compatible with other EN/ICE applications. The details of these integration efforts will be presented in a future paper.

The roadmap for future development of the NA62 DCS assumes that further synergy between the frameworks is achieved, so that a coherent and standardized engineering process could be established for future applications of a similar type. Based on the current experience and achievements of the "LKr Vertical Slice" milestone, a gradual evolution of the control application will proceed by including subsequent sub-detectors. An integration run in spring 2012 is planned to demonstrate the complete application in one quarter of its complete scale.

The work performed so far has demonstrated a significant interoperability between the frameworks. However, in order to reach the goal of closer integration, some topics will require further work:

- Further integration of the two device models.
- Widening of system integrity checks across the UNICOS and JCOP domains.
- Unified application generation including JCOP device instantiation.

CONCLUSIONS

The NA62 LAV and LKr applications have validated the approach to gain the benefits of both the UNICOS and JCOP frameworks. The device proxy concept enables the high level UNICOS tools to access JCOP data required at operations time. This provides a seamless interface to the control application operator.

Additional synergy can be obtained by integrating the frameworks together more closely. There are tools that are still limited to functioning in one of the two framework domains. As these issues are tackled, the full benefits of this combined framework approach will become available.

The further work required on the NA62 DCS will provide a suitable test bed and showcase for future integration work. There are still significant conceptual and design efforts ahead, but experience to date shows that the results of such work should be reusable in many future applications, providing a sustained improvement in efficiency of application building and maintenance.

DATABASE DRIVEN CONTROL SYSTEM CONFIGURATION FOR THE PSI PROTON ACCELERATOR FACILITIES

H. Lutz, D. Anicic, Paul Scherrer Institute, 5232 Villigen PSI, Switzerland

Abstract

At PSI there are two facilities with proton cyclotron accelerators. The machine control system for PROSCAN which is used for medical patient therapy, is running with EPICS. The High Intensity Proton Accelerator (HIPA) is mostly running with the in-house developed control system ACS. The control of dedicated parts of HIPA runs already under EPICS. Both these facilities are configured through an Oracle database application suite. This paper presents the concepts and tools which are used to configure the control system directly from the database-stored configurations. Such an approach has advantages which contribute for better control system reliability, overview and consistency.

INTRODUCTION

Control system configuration for HIPA and PROSCAN facility is kept in its own databases HIPADB and PRODB (see Fig. 1). The database information can be split into the following categories :

- Device Reference contains all information about the machine layout in terms of Device names, sections, positions, and their topology.
- IOC (Input Ouput Controller) configuration for EPICS. The IOC configuration for the ACS control system has been already described in detail in [1].
- Interlock configuration data which are used for the Run Permit system in both facilities HIPA and PROSCAN.
- Beamline Reference data are used to produce input files for the automatic beam control and for the simulation tool Transport as well.
- Archiver configuration for the in-house developed data archiver software.

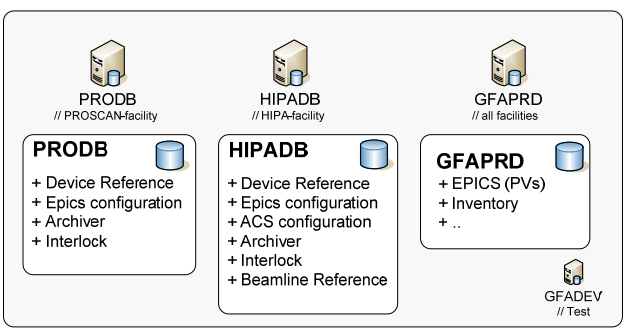

Figure 1: Oracle databases for HIPA/PROSCAN control system configuration.

A third Database GFAPRD displayed on Fig. 1 contains data used for all facilities in common. As an example these kind of information includes

- Hardware Inventory and Computer configuration.
- EPICS PV (Process Variable) names for all facilities.

DATABASE ENTRY

Figure 2 shows the building blocks for the database driven configuration. Oracle Webforms delivered from an Oracle Application Server are used in order to enter the data by the enduser.

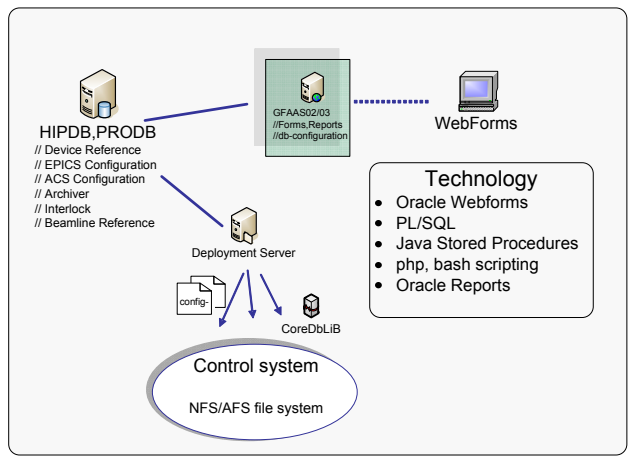

Figure 2: HIPA/PROSCAN Configuration Infrastructure.

PL/SQL libraries are used to provide procedures and functions for database extraction and Java Stored Procedures and php scripts are used to deploy the configuration files on to the NFS (Network File System) shared file system. The deployment itself, is done on a dedicated deployment server and is triggered directly from the Webforms.

The described method has been used in production for many years (since 2002). Several redesigns and adaption has been made in order to fulfil new requirements. One example is the EPICS configuration system which is used for the PROSCAN control system. There are different categories of information which are stored in several database schemas. Each category has its own Webform editor.

Device Reference Editor

Device Reference holds everything about definition and organization of all the elements in the PSI proton accelerator complex as seen by the operator. This may be a bending magnet, quadrupole, profile monitor, a pump etc. Each element has a unique name (up to 8 characters)

according to our Device Naming convention and is arranged into machine parts. Each element is connected to a parent according to the physical arrangement along the beamline. Device listings ("Holy Lists") may be produced from this information. The Device Reference tables are directly connected to the EPICS configuration and Beamline Reference tables.

EPICS Configuration, IOC Setup

The definition of the IOC configuration consists of defining a name, attributes like the EPICS version and a set of startup script lines. According to the placement (slot, channel) of hardware modules the corresponding DriverConfig strings must be filled in. For each module one or more configuration strings can be defined in the form DriverConfig (p1,p2,..). Each record in the DriverConfig table has a unique key which is used in the Template record definition. The configuration of Soft IOCs without connection to a piece of hardware is supported as well.

EPICS Configuration, Templates

With a Template editor we can setup and maintain a pool of EPICS templates with its records and field values and their logic (forward links etc). New templates can be uploaded from the NFS file system. Minor changes in the template structure (add a new record, field) can be handled by the editor itself. For each template the macro variables with default values can be extracted.

EPICS Configuration, Macro Substition

The substitution of the macro variables is the final stage of configuration. For a given Device eg. a magnet, the Device name is mapped to the corresponding IOC configuration slot together with the corresponding Template. From the Template Designer's point of view we have implemented two constraints. It's not allowed to have more then one references to the IOC configuration slot. Each Template must have at least one macro called $DEVICE. This macro is automatically replaced by the Device name which is optional connected to the Device Reference table. All other macro values can be manually defined in the substitution editor.

DEPLOYMENT & TEST

The deployment of IOC specific configuration files which can be triggered by the "install button" from the Webform is shown in Fig. 3. For the selected IOCs the following tasks are done on the deployment server :

- From the set of IOC configuration tables the common startup script together with a driver config script is generated.
- A unique substitution file for each IOC is generated which contains all the macro values with a reference to the corresponding template.
- At the end all files are deployed to the NFS file system structure and the IOC can be rebooted through the corresponding BootServer.

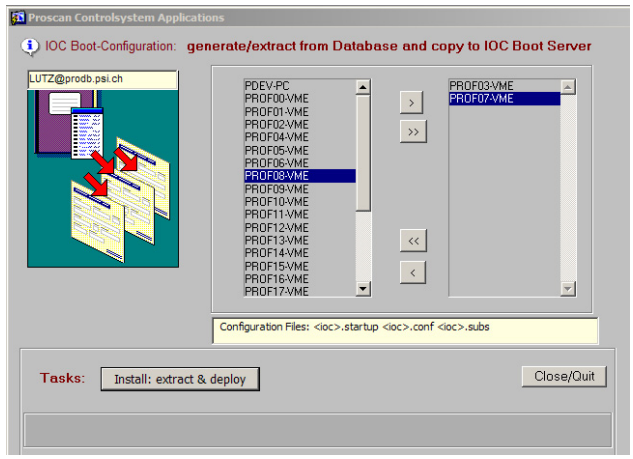

Figure 3: Deployment of IOC configuration files.

The database relevant tasks which are done on the IOC boot server are explained in Fig. 4. During the IOC boot process all the created record names together with some useful attributes like RecordType, IOC name, timestamp etc) are loaded into the EPICS PV database. New records are inserted, and records which do not exist anymore will be marked as deleted.

The information in the EPICS PV database is used by several database tools. Findrecords is a comandline tool which allows to query the PV database with several filter option. "duprecords" lists all duplicated records inside a facllity. "capv-view" is a Java application which lets filter all the PVs by IOC and Device name. After setting the filter all PVs values are displayed. The corresponding Web-Tool has been developed using Microsoft .NET technology. In the web-based Inventory tool the PV names together with the current values can be displayed as well. Database Reports are used to display or check the Device Reference-PV database relationship.

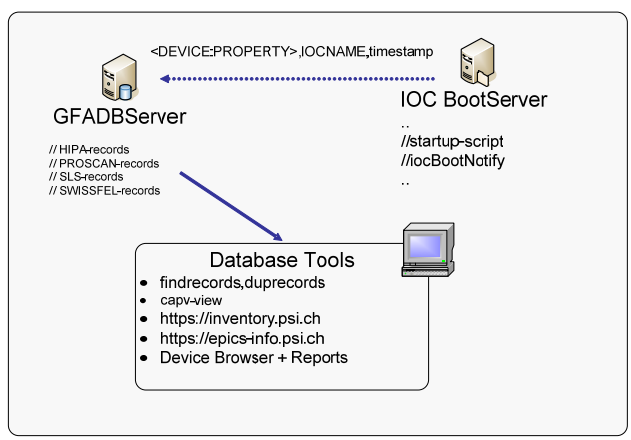

Figure 4: Loading EPICS record names during IOC boot process.

The following table shows some statistics about the number of EPICS IOCs, Devices and PVs in the PROSCAN control system. PROSCAN operates with 27 VME IOCs which are configured with 70 templates. Only 3 Soft IOCs are used. In summary PROSCAN is controlled with 1700 Devices and 50000 records. The values for the HIPA EPICS control system (eg. 50 IOCs + 100 templates) mentioned in table [1] are estimated values as most of the systems are running with the ACS control system.

Table 1: Statistics PVs IOCs Templates

DB (Facility)	PVs (record:device)	IOCs (vme+soft)	Templates
PRODB	50000:1700	27+3	70
HIPADB	100000:2700	50+5	100
HIPA values are estimated, 90% is still under ACS Control			

APPLICATION CONFIGURATION

Interlock Data

Interlock holds data tables for description of the Run Permit system. Interlock modules are organized into areas, groups and sections. Each module is mapped to an IOC slot and has configurable input/output function tables. The Interlock tables feed data input for the Interlock monitor application.

Beamline Reference Data

In order to specify input information for the calculation of beam envelopes using the Transport code [2] the Beamline Reference Editor is used to fill the data sets which are connected to the Device Reference tables. Each entry consists of a predefined Transport type code, driftspace and an optional value string. together with a 4 char Transport Label. Depending on the type code the required driftspace is automatically filled in. This configuration is mainly used in the HIPA facility. The input files can be generated and deployed to the file system on request. These files are used in the control room during Beam Setup and Tuning. A second customer is the automatic beam control application.

Archiver Configuration Data

For the HIPA/PROSCAN facility an in-house developed archiver software for data archiving is used. The configuration file with all the PV-Names together with the corresponding logging period (5 sec, 1 min, per hour, per shift) is configured by a dedicated Configuration Editor. The Editor is connected to the EPICS PV database and supports functions like adding/removing PVs and restart the archiver server which is running on a dedicated machine.

DATABASE TOOLS

Device Browser

With the Oracle Reports tool an EPICS Device browser based on html pages has been developed. On a start page the user can enter some query conditions and gets afterwards information about Devices, EPICS templates, macro substitions and IOC configurations.

Database Reports

Several Paper Layout reports have been built using Oracle Reports Builder. After building a report the corresponding executable (rdf-file) is delivered to the Application Server, see Fig 2. The Intranet Webuser can retrieve the new report with information in different output formats (html/pdf/xls). This includes Device Reference lists, dedicated information about Interlock database, Magnet parameter settings, database statistics etc. These Reports are permanently modified and built on request.

CONCLUSION

The database driven configuration has been successfully implemented in both facilities PROSCAN and HIPA for operation with two different control systems. There are many advantages for using this method :

- A lot of information about the configuration of the control system is kept in a single database instance.
- It helps a lot when upgrading tasks have to be done.
- The whole system is maintained by only a few persons (in our case 3-5).
- Applications are configured centrally. Additional applications can be easily integrated.
- Documentation of the system can be easily derived from database reporting.

Besides these positive aspects one negative aspect has to be mentioned. It is not easily editable as with text files on a file system. Therefore it is not well suited in a Test & Development scenario.

PRELIMINARY DESIGN AND INTEGRATION OF EPICS OPERATION INTERFACE FOR THE TAIWAN PHOTON SOURCE

Y. S. Cheng, Jenny Chen, P. C. Chiu, C. H. Kuo, C. Y. Liao, K. T. Hsu, C. Y. Wu
NSRRC, Hsinchu 30076, Taiwan

Abstract

The TPS (Taiwan Photon Source) is the latest generation 3 GeV synchrotron light source which has been in construction since 2010. The EPICS framework is adopted as control system infrastructure for the TPS. The EPICS IOCs (Input Output Controller) and various database records have been gradually implemented to control and monitor available subsystems of the TPS at this moment. The subsystem includes timing, power supply, motion controller, miscellaneous Ethernet-compliant devices etc. Through EPICS PVs (Process Variables) channel access, remote access I/O data via Ethernet interface can be observed by the useable graphical toolkits, such as the EDM (Extensible Display Manager) and MATLAB. The operation interface mainly includes the function of setting, reading, save, restore and etc. Integration of operation interfaces will depend upon properties of each subsystem. In addition, the centralized management method is utilized to serve every client from file servers in order to maintain consistent versions of related EPICS files. The efforts will be summarized at this report.

INTRODUCTION

The TPS [1] is a latest generation of high brightness synchrotron light source which has been under construction at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan since 2010. It consists of a 150 MeV electron Linac, a 3 GeV booster synchrotron, and a 3 GeV storage ring.

The EPICS (Experimental Physics and Industrial Control System) is a set of open source software tools, libraries and applications developed collaboratively and used to create distributed soft real-time control systems for scientific instruments such as the particle accelerators, telescopes and other large scientific experiments [2]. In the field of accelerators, many facilities have good practical experiences for EPICS and adopt it as the accelerator control systems. Many resources and supports are available as well as numerous applications for accelerator have been developed.

As a result, the EPICS framework was also selected as control system infrastructure for the TPS project. The EPICS platform has been gradually built and tested to control and monitor the subsystems of TPS. The various database records can be created for accessing the I/O data and setting parameters at the IOC (Input Output Controller) layer. Adopting the EPICS channel access mechanism with specific toolkits, the data can be accessed between the IOCs and the clients.

During the implementation process of the EPICS support for various subsystems, the operation interfaces of each subsystem are also developed according to the different operation methods. To simulate the operation process, the various operation interfaces are needed to integrate. The centralized management of the EPICS related files is also adopted, and the mechanism of save and restore will be continuously developed. The efforts will be summarized as following.

SOFTWARE ENVIRONMENT

The client consoles are adopted the Linux operation system. All of the EPICS base, modules and extensions are installed at the Linux system. The software versions are shown as Table 1 where most of applications are developed base upon this software environment.

Table 1: Software Environment of the Control Consoles

	Version
OS	RHEL 5.4 (32-bit) (kernel 2.6.18)
EPICS	base-3.14.10
Modules	asyn-4.11a StreamDevice-2.4
Extension	edm-1.12.xx labCA-3.1

FILES MANAGEMENT

All EPICS related files at control consoles are mounted from the file server by using the NFS service [3] to simplify software version control. Various directories are created and saved into various versions of related files for various hosts and purposes. Various directories provide a mount point for hosts mounted according to various purposes. The directories include EPICS base, modules, extensions, saved data, temporary data and etc.

Several file servers are established to share the loading of NFS file service. The hosts mount specific file server according to its location and purpose. By loading testing, the NFS file service is divided into three parts. Two servers provide the NFS service for hosts of all cells; the other server is for engineer development.

To keep the same version at each NFS file server, the "rsync" function is used with the "crontab" schedule service [4]. One main NFS file server is established for development purpose; the other NFS file servers are adopted "rsync" function to synchronize all data from the main NFS file server with using the private Ethernet

communication. The system architecture is shown as the Fig. 1. The dedicated spare NFS file server is also established for redundant purpose, and the related data is synchronized from the main file for backup purpose.

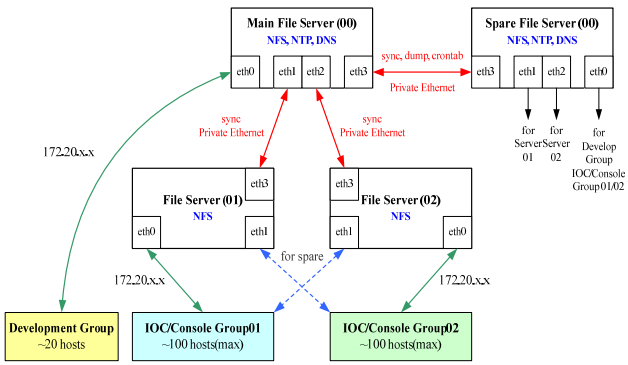

Figure 1: The system architecture of file servers for EPICS related files mounted with backup mechanism.

SAVE AND RESTORE

To readily restore a set of the machine parameters for subsystems during operation as well as to optimize and record working points for different machine condition, the mechanism of save and restore is developed. The save and restore function is initially built by using the MATLAB with labCA [5]. The various files of grouped PVs (Process Variables) list are created for saving the respective parameter values of each subsystem. The file with PVs and saved parameters is also selectable for resume the settings. The preliminary interface of save and restore mechanism is shown as the Fig. 2. Both of consumed computer resource and process time are acceptable after preliminary testing.

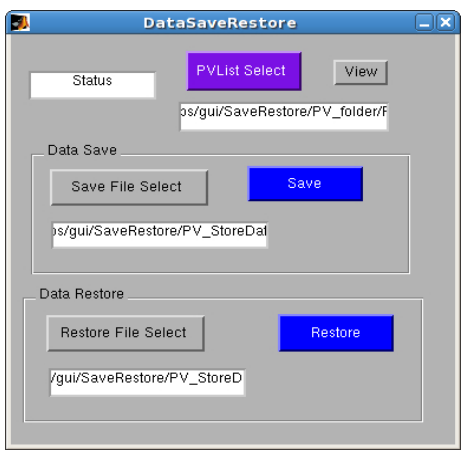

Figure 2: The operation interface of save and restore.

PRELIMINARY CONTROL PAGE

At the development phase, the GUI of TPS control system adopts the EDM (Extensible Display Manager) toolkit to develop main graphical operation interface. The EDM pages of various subsystems are created and saved into the NFS file sever for client console operation.

The EDM is an interactive GUI builder and execution engine, the EPICS documentation uses the term display manager, and maintained by the ORNL EPICS community [6]. All "objects" of EDM are loaded from shared libraries. The EDM administrator can add and remove objects from the list of available objects without recompiling EDM itself. The objects are versioned, carefully coded objects can be upgraded without impacting existing displays.

The preliminary main control page is built by the EDM toolkit shown as the Fig. 3. All control pages can be launched from this GUI. All control components are located at the foreground of the TPS accelerator illustration. For example, the LTB (Linac to Booster) dedicated control page is linked from the main control page for operation shown as the Fig. 4. The related control parameters or components are also located at the same page for tuning easily, such as the control page for the TPS timing as shown in the Fig. 5. These pages will be continuously refined and developed for the future commissioning.

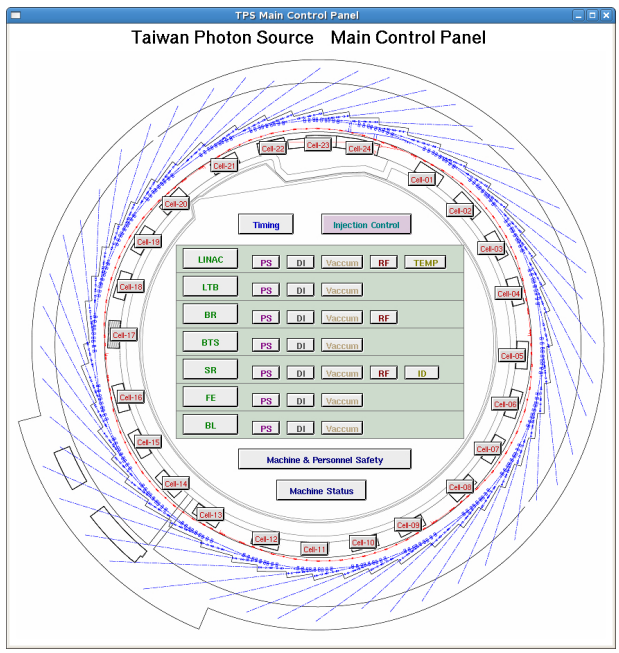

Figure 3: The preliminary TPS main control page.

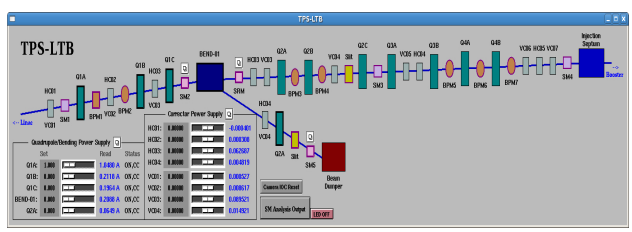

Figure 4: The LTB control page for operation test.

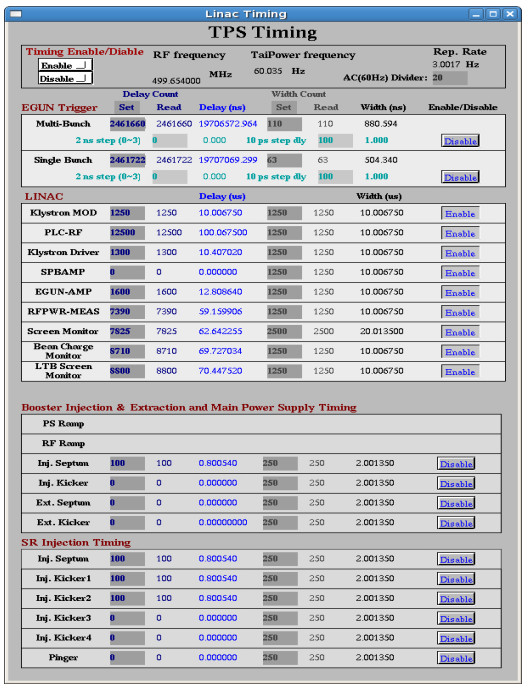

Figure 5: The overview control page for the TPS timing.

POWER SUPPLY OPERATION INTERFACE

The EDM toolkit is also adopted to develop the operation interface of power supplies. The client console can operate the specific EDM page to access the data via PVs channel access. The preliminary GUI page of storage ring dipole, quadrupole and sextupole power supplies controls as shown in Fig. 6. The Fig. 7 shows the GUI page of storage ring vertical corrector, horizontal corrector and skew quadrupole power supplies controls. The macro name method was regularly used to switch each display page. The main control page was shown critical information for observing status easily, and the main operation process functions are also executed from the panel.

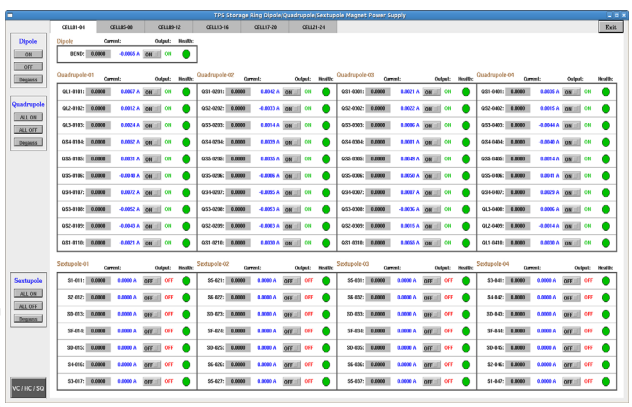

Figure 6: The control GUI of storage ring dipole, quadrupole and sextupole power supplies.

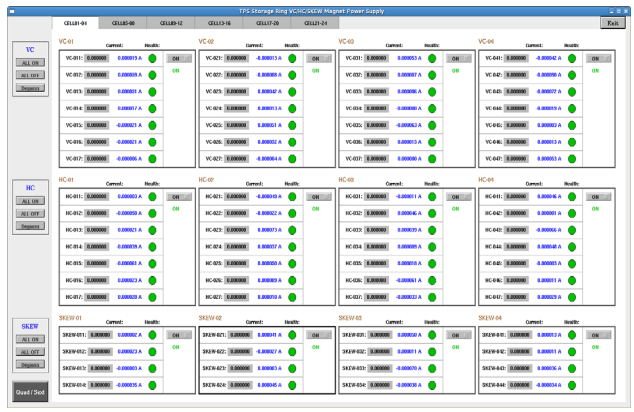

Figure 7: The control GUI of storage ring vertical corrector, horizontal corrector and skew quadrupole power supplies.

The MATLAB toolkit with labCA is adopted to develop the high level application programs for commissioning and diverse operational procedures. The applications include the specific overall power on/off control, degauss process, checking power supply status, operation performance analysis, operation statistics and etc. The various operation processes will be developed and tested according to the various operation modes. The detail control page of power supplies has the trend plot for observing. The Fig. 8 shows the current variation during the degauss process executed. The degauss application is also developed with the specific function of batch process to reduce the peak of power consumption for saving energy.

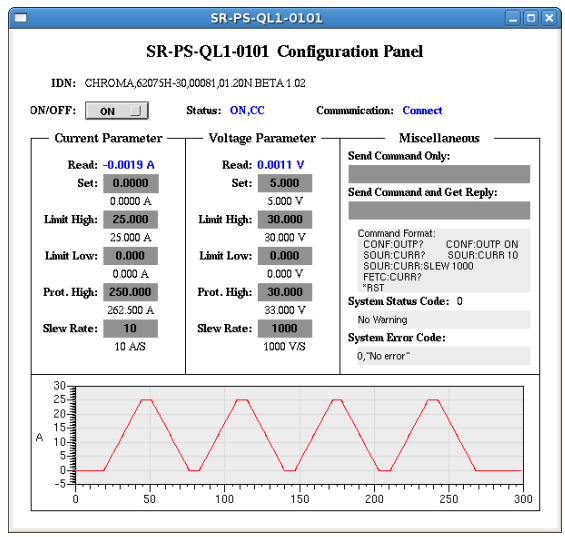

Figure 8: The current trend is shown at configure page of a quadrupole power supply during the degauss process test.

ARCHIVE

To record the variation of specific subsystem for long time observation, the archive can be use to save data. The EPICS channel archiver [7] is under research and evaluation. The archive view is the java based toolkit, and

can be easy to use at the different operating system platforms. The server loading and saved files size of archive system will be estimated in the future.

SUMMARY

The TPS control system adopts the EPICS framework as the control infrastructure. The EPICS supports of various subsystems are built gradually. The operation interfaces of various subsystems are also developed in the meantime. The various GUIs are designed according to the different operation methods. The management of the EPICS related files system is also established for maintaining files versions easily. The mechanism of save and restore are needed to apply parameters for operation process. Various operation interfaces will be integrated and improved continuously during the TPS control system construction.

NEW SPring-8 CONTROL ROOM: TOWARDS UNIFIED OPERATION WITH SACLA AND SPring-8 II ERA

A. Yamashita*, R. Fujihara, N. Hosoda, Y. Ishizawa, H. Kimura, T. Masuda, C. Saji,
T. Sugimoto, S. Suzuki, M. Takao, R. Tanaka, JASRI/SPring-8, Hyogo, Japan.
T. Fukui, Y. Otake, RIKEN/SPring-8, Hyogo, Japan

Abstract

We have renovated the SPring-8 control room. This is its first major renovation since its inauguration in 1997. In 2011, the construction of the SACLA (SPring-8 Angstrom Compact LAser) was completed. Plans are to control it from the new control room for it to work in close cooperation with the SPring-8 storage ring. It was expected that the upcoming SPring-8 II project would require more workstations than the current control room could accommodate. We have therefore extended the control room area for these anticipated requirements. In this renovation, we employed new technologies that did not exist 14 years ago, such as a large LCD and silent, liquid-cooling workstations for a comfortable operation environment. We have incorporated many ideas which were obtained during the 14 years experience of the operation. Operations in the new control room were started in April 2011 after a short period of construction.

INTRODUCTION

The SACLA (SPring-8 Angstrom Compact free electron LAser) [1], which has been constructed in the SPring-8 campus, successfully generated 0.12 nm wavelength X-ray laser in June 2011, three months after the start of its commissioning run. The SACLA has an unique feature that allows experimentalists to use synchrotron radiation from SPring-8 and an X-ray laser from the SACLA simultaneously and perform an experiment such as a pump-and-probe experiment. And also, the SACLA is designed to act a high performance injector for SPring-8. Therefore, it is planned that SPring-8 and the SACLA will be controlled from the same SPring-8 control room for a closely coupled and unified operation. They are controlled from separate control rooms during the commissioning period. We are also planning major upgrade for SPring-8 which is named SPring-8 II [2] to be implemented over the next decade. We expect SPring-8 II will require more workstations to control. The previous control room did not satisfy this requirement. For this purpose, we decided to renovate the SPring-8 control room. Fig. 1 shows a view of the new control room.

When the old control room was constructed in 1997, there were no liquid crystal displays (LCD), water-cooled, silent workstations, or large LCD panels for display wall, which are popular for use in modern control rooms. We renovated the control room to take advantage of the those modern technologies that did not exist in 1997.

* aki@spring8.or.jp

DESIGN GUIDELINES

Before the design, we set the design guidelines as follows.

- SPring-8 and SACLA should be controllable from the same control room.
- The control room should be scalable for implementing SPring-8 II.
- The control room should be such as that there is no partition between the two accelerators.
- The control room should have function in cooperation with the safety and facility systems.
- The control room should have consoles and the numbers of machine control CPUs (e.g. VME) should be as low as possible for quiet environment.

We designed the new control room according to the design guidelines.

FLOOR LAYOUT

Fig. 2 shows the floor layout of the new control room. We divided the control room area and the back area using the display wall. Approximately half of the old control room was the back area and was filled with racks for servers and workstations. Extenders were used to connect workstations in the back area with keyboards, mouses and displays in the control area. This arrangement helped reduce the noise generated by workstation and keep the control area quiet for maintaining a good working environment. We had to place each workstation at the back of the control desk in the new control room because the extender and the long and thick cables resulted in a maintenance problem. The use of a silent type of workstation solved the noise-related problem. We reduced the size of the back area and moved the servers to the newly constructed dedicated server room.

Twenty-four control workstations could be distributed among five desk *islands*. One island in front of the display wall had four main terminals for an overall SPring-8 accelerator control and one safety interlock panel with the emergency stop button, access keys, and a display panel for displaying interlock status. Terminals from the other islands were needed to monitor and control individual accelerator components. The fish-shaped desk islands design enabled the operators at the main terminals to view information related to all the terminals at a glance and have face-to-face communication with to all the other operators. In addition, the fish-shaped design is scalable as required by the design guidelines and it can be extended by adding extra desks.

The number of consoles was selected based on current usage for SPring-8 and the SACLA plus the expected re-

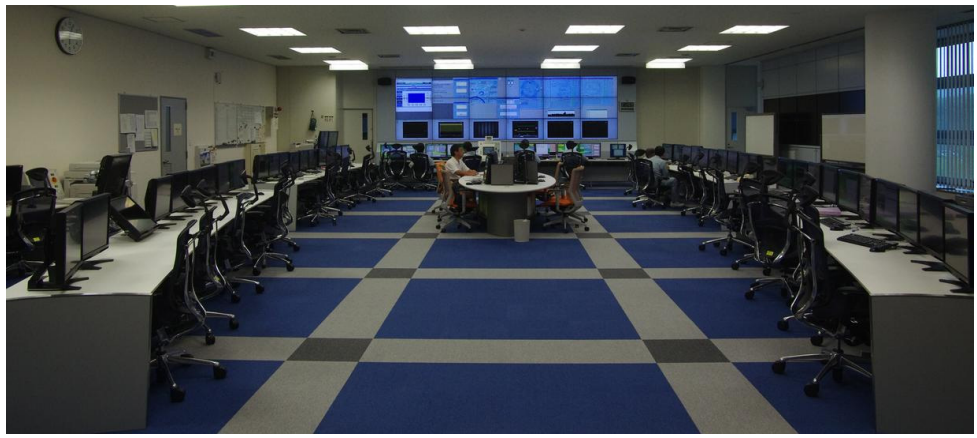

Figure 1: View of the new SPring-8 control room.

quirement in the future. Currently, SPring-8 accelerators and beam lines are controlled by less than 17 workstations in the control room. There are more than 7 spare spaces for workstations.

In the center oval table accommodated six PCs. They were used for office work. We accommodated six thin client terminals on the side desk island. These terminals were used for monitoring the data acquisition status and the alarm. They were also used for program development.

Control Desk

Each control desk measured 1150 mm (Width)×855 mm (depth) for one operator. The depth was reduced for LCD screen because the old desk had a depth to fit a large CRT display. The width was sufficient to place for setting two 24" diagonal LCD displays side by side. The desks were built such that they were jointed with each other. The desk had space for a workstation at the back. The back panel could be removed without using any tools for workstation maintenance (Fig. 3). The workstation was water cooled and of the silent type for reduced noise. There were sufficient space at the back for a typical middle tower type case. In addition to the two LCDs, the desk was designed to fit four panels. Two holes on the side supported the poles for LCD stand. Fig. 4 shows the four panel setup.

Meeting Space

There was no dedicated meeting space in the old control room. We created meeting space with 12 chairs. Sometimes access to the accelerator was required during meetings. For this reason, the meeting space and the control section were not separated by a partition. The table had AC power sockets for note PCs belonging to individual participants.

Center Table

The oval table in the center had six PCs, which were used for office work such as for writing reports, reading documentations, and a simple analysis. We added a shelf under the oval table to place recent logbooks and manuals. The shelf helped to minimize the number of papers scattered on the desks.

Figure 3: Back view of the control desk. A workstation is built in. Two lines of AC power are supplied. One is stabilized by UPS for the workstation and the other is not stabilized.

Monitoring Space

The alarm and data acquisition systems were monitored from the side island. The thin client terminal displayed the processes performed at servers. Thin client terminals occupy very little spaces but their graphic display performance is poor. Tasks that do not require very good display performance are performed with the help of thin client terminals.

Back Area

Currently, the back area has very few components unlike the old control room, which was filled with server and

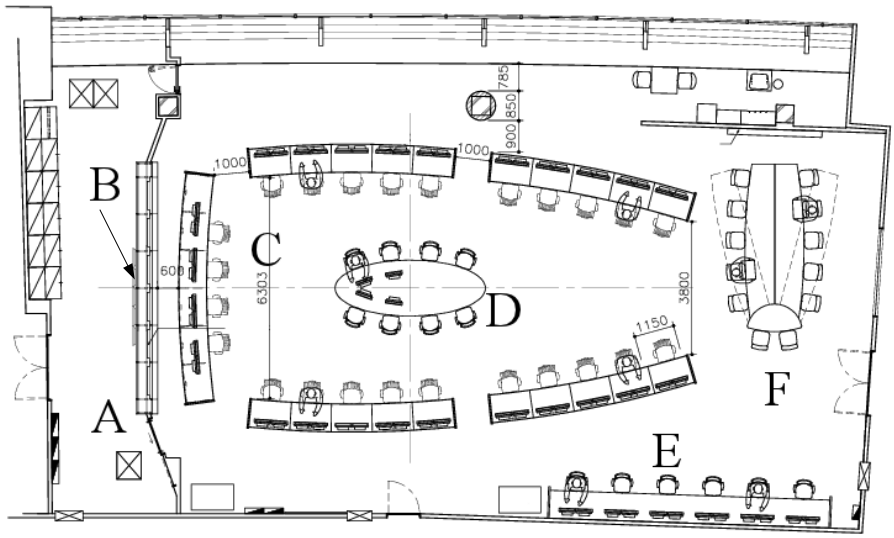

Figure 2: Floor plan of the new SPring-8 control room. A: Back area. B: Display wall, C: Control desks, D: Oval desk, E: Monitoring desks and F: Meeting space.

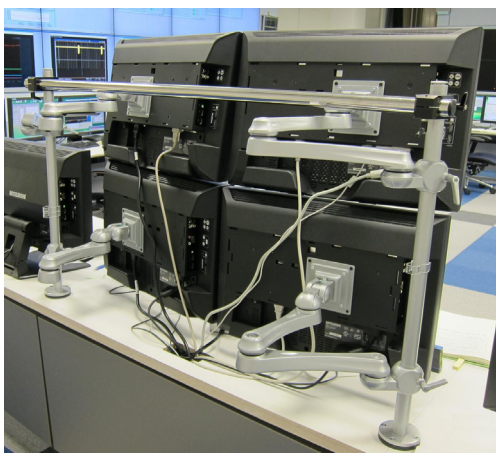

Figure 4: A desk has two poles to support 4 LCD panels.

workstation racks. The current back area is almost empty space aside from the three racks for networking and interlocks and sliding shelves for document archives. The operator sometimes resets the interlock signal on the rack, but this is relatively rare. Placing interlock equipment in the back area is convenient for the operator and satisfies the design guideline, which require the number of machines to be as low as possible.

Cabling

The control room was constructed on a 50 cm height raised floor to enable easy cabling. We removed almost all the cables that has been accumulated in the old control table like stratum, set cable ladder under the raised floor and routed cables.

TECHNOLOGIES

Built-in Workstations

In the old control room, workstations were placed in the back area and connected to the keyboard, video monitors and the mouse via an extender and thick cables to reduce the noise in the control section. Workstations were placed at the back in the control desk to allow easy maintenance. The use of the water-cooled, silent but high-performance workstation eliminated the noise-related problem owing to its noise level of less than 30 dB. The reliability of the water-cooled workstation is quite acceptable, given that none of the twenty workstation have experienced any water leakage problem even after half a year operation. The specifications of the workstations are shown in Table 1 Those workstations are suitable for SPring-8 control tasks.

Table 1: Workstation Specifications

Item	Value
CPU	Intel®Xeon®X3450 2.66 GHz Quad core
Memory	4 GB
Disks	250 GB × 2 Raid1

Networks

SPring-8 networks are classified as office LAN, DMZ LAN, control LAN and SACLA control LAN. Firewalls between them control the data flow. In the control room, we limited the use of the wired control LAN, wired SACLA LAN and the wireless office LAN. None of workstations are connected to more than one LAN simultaneously. PCs used for office work are connected to the office LAN using wireless connection even when they are desktop PC. Dividing the network into wired and wireless simplifies network cabling and reduces the chance of incorrect wiring. We concealed network ports inside the desk to avoid the problems due to an unexpected PC connection.

New Display Wall

In the previous ICALEPCS 2009, we presented a display wall hiring a 6x2 configuration[3]. We have designed another 6x3 configuration display wall to display more information that will be required in SPring-8 and the SACLA combination operation. The old display wall has been shifted to the side of the room. The new display wall employs an ultra-narrow bezel (7 mm between the screen and the next screen) 46" diagonal LCD[1] . The previous display wall was driven by a cluster consisting of seven PCs. On the other hand, the 18 panels of the new display wall are driven by just one PC equipped with three graphics cards. Each graphics card has 6 mini-DisplayPort sockets[2] , Currently MS-Windows is installed on the driver PC, because its display driver software has better stability and usability than that of the Linux OS. As shown in Fig. 1, the display wall displays accelerator status, alarm status, video images and more to share information between operators.

Analog TV Signal Viewer

Previously we monitored the screens of oscilloscopes, spectrum analyzers, and beam monitors which installed close to the accelerators after converting their information to analog NTSC video signals. In the renovation, thee control room was designed to use only digital data and analog signals were removed from the control room. Camera servers[3] that converts NTSC signals to motion JPEG are attached to the source of the video signals and video images are transmitted using the HTTP protocol. Although standard web browsers can display such images, we developed a dedicated viewer using web APIs provided by vendors [4] and used widget libraries [5] for easy operation and to save the display area and the ability of motion JPEG files to record data.

[1] NEC LCD-X462UN
[2] ATI Firepro™ V9800
[3] AXIS 24x series

CONSTRUCTION

The construction for the renovation was carried out during the spring shutdown period of 2011 so as to not affect the SPring-8 operation. We reduced the duration of construction by completing as many tasks as possible before the construction.

Cable ladders were installed under the raised floor during the summer shutdown period of 2010. In addition, equipment for interlocks was moved during the same period. We also examine cables which were unrecorded their end points before the construction.

Approximately 40 days were required for removing old furniture and cables, replacing the old display walls, painting walls, refurbishing the floor, constructing new display walls, installing new furniture, changing the lighting and etc. The construction was complete on schedule, and we have been operating SPring-8 from the new control room since April 2011.

SUMMARY

The new SPring-8 control room has been constructed within a short period. We conformed to the design guidelines as follows. The fish-shaped desk islands met the scalability requirement for the SACLA and SPring-8 II, The interlock panel placed at the center of the consoles and the interlock signal at the back area enabled close coordination between the safety systems and the accelerators operations, and the division between the control area and the back area helped to create an environment specific to the control area.

ACKNOWLEDGMENT

The authors would like to thank Mr. T. Hamano for his effort in constructing the display wall.

THE LHC SEQUENCER

Reyes Alemany-Fernandez, Vito Baggiolini, Roman Gorbonosov, Denis Khasbulatov, Mike Lamont, Pascal Le Roux, Chris Roderick, CERN, Geneva, Switzerland

Abstract

The Large Hadron Collider (LHC) at CERN is a highly complex system made of many different sub-systems whose operation implies the execution of many tasks with stringent constraints on the order and duration of the execution. To be able to operate such a system in the most efficient and reliable way, the operators in the CERN control room use a high level control system: the LHC Sequencer. The LHC Sequencer system is composed of several components, including an Oracle database where operational sequences are configured, a core server that orchestrates the execution of the sequences, and two graphical user interfaces: one for sequence edition, and another for sequence execution. This paper describes the architecture of the LHC Sequencer system, and how the sequences are prepared and used for LHC operation.

THE LHC SEQUENCER ARCHITECTURE

The LHC Sequencer Architecture is made of two core components: the Sequencer Executor and the Database. Two Graphical User Interfaces (GUI), one to interface the executor and another one to interface the database, provide the operators in the CERN Control Centre (CCC) with the required control on running sequences and on the creation or modification of sequences, respectively.

The Sequencer Executor part has been extensively presented in [1]. Here a small summary of the main components will be recalled, but emphasis will be given to the database part and the operational sequences used in the daily life operation.

Sequencer Server and Sequencer Client

The architecture and technology used by the Sequencer follows the CERN accelerator controls software standards: a 3-tier architecture implemented in Java using the Spring Framework [2]. This architecture is shown in Figure 1. The sequencer middle-tier server (running Linux) contains the core functionality, mainly, sequence execution, temporary sequence storage and interface via Java libraries to the controls of the different LHC sub-systems, i.e. the LHC Software Architecture (LSA) [3] and the accelerator controls Common Middleware (CMW) [4].

The client tier consists of an execution GUI, shown in Figure 1, from which the execution of the sequences is controlled by the LHC operators in the Linux or Windows consoles at the CCC. Many GUIs may connect to the same middle-tier server.

Database Persistent Storage of Sequences

All sequences are persistently stored in the Oracle database. The database schema consists of a series of tables that map the sequences representation in the following way:

- Sequence table: stores the sequence name, the display name as will appear in the GUIs, brief description, date of creation, name of the person that created the sequence and the sequence category. Each sequence is uniquely identified by a primary key (PK); the name is constraint to be unique since the sequencer server retrieves sequences by name, not by PK.

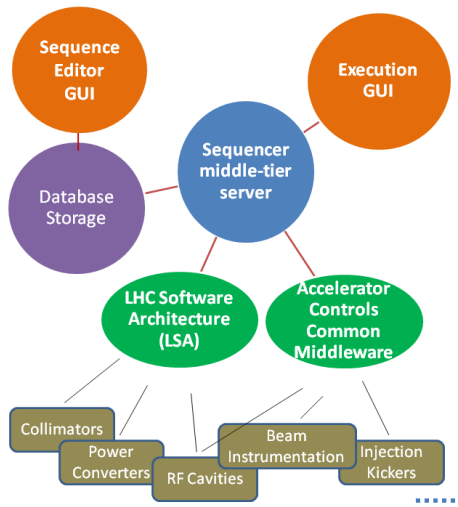

Figure 1: LHC Sequencer Architecture.

- Subsequence table: stores the same information as the sequence table. Each subsequence is uniquely identified by a primary key, and, for the same reason as above, the name is unique.
- Seq-subsequence table: each sequence is made of one or several subsequences. This table contains the list of subsequences that belongs to each sequence. A subsequence can be used by different sequences
- Sequence_components table: each subsequence is made of a number of components which can be of two types: atomic tasks or subsequences. Each atomic task component can be described by a number of parameters which corresponds to columns in the same table. Those parameters are: the name of the hardware group to be addressed by the task (for example a name referring to all the power converters in LHC); tasks can act on a group of hardware or on a single device, therefore another parameter is the device name; the name of the LHC cycle during which the task will have to act, e.g. LHC.USER.INJECTION, LHC.USER. RAMP. If the component is a task, there are a set of separate tables that describe those tasks, uniquely identified by a

primary key which is referred to within the Sequence_components table. Each task component can be further configured to have certain behaviour in case the task fails the execution. The behaviour can be the execution of another task, or another subsequence, or a complete sequence, or simply, stop or continue. Four columns in the components table are reserved to define the on_error behaviour. Once the on_error behaviour is executed by the server, the main sequence can continue execution or stop. This is configured in the same components table via another column. Finally, components are assigned an execution order, an integer number that the server uses to establish the execution order of all the tasks inside the (sub)sequence. If two or more components of type task have the same order, they are executed in parallel at the server level, and only when all the parallel tasks are finished (either successfully or with errors) the server returns the control to the GUI for that particular (sub)sequence. The tasks or subsequences have a default action that can be run, skip or break. All components configured to run are executed (following the established order) when the (sub)sequence is executed; if a component is configured to be skipped, then it will not be executed; if a component is configured as a break component, the execution of the (sub)sequence will be stopped at this component.

- Category table: each (sub)sequence is categorized according to the following criteria:
    - Physics: final version of a (sub)sequence, which has been debugged and it is ready to be used in routine operation.
    - Development: (sub)sequences under construction and debugging, not to be used during routine operation until they are validated and become operational, i.e. of physics category.
    - Machine development: (sub)sequences dedicated to machine development periods.
    - Equipment specific: (sub)sequences to test specific accelerator equipment for commissioning.
- Task type table: within this table, general task configuration parameters can be specified, i.e. parameters that precise if the task will be executed using LSA methods or it is a CMW type task.
- Task instance and task instance parameters tables: once a task type is defined, instances of it can be further created. Each instance can be parameterized to act on a particular property of the task type. For example, a task type frequently used in LHC sets the beam mode. The task type is called SET BEAM MODE and it is a LSA task. Several instances of it exist in the database, each sets the mode to a given value, e.g. SET BEAM MODE TO INJECTION PROBE BEAM, SET BEAM MODE TO RAMP, etc. Within the task instance parameters table the different modes are specified which are columns of the table called, parameter_name and parameter value. Parameter_name in this example is called mode, and the parameter_value is the mode name: INJECTION PROBE BEAM, RAMP, etc.

One of the most important advantages of using the database as persistent storage platform is that the sequences can be edited, modified and new sequences, subsequences and task instances can be created without the need of releasing any software component. The database provides with a very dynamic user interface.

Sequence Editor and Sequence Executor

Every of these tables and columns is filled using the Sequences Editor, a Java program that access directly the database via SQL statements. The editor is protected with Role Based Access [5] in order to restrict the edition of sequences to authorized people only. A picture of the Sequence Editor is shown in Figure 2. On the left hand side panel the user can select the sequence to be modified. There is a filtering panel in order to show only the sequences of a given category. From this panel access to task type and task instances tables are possible, as well as the possibility to create a new sequence. On the right hand side panel different Java tables map the tables in the database and different buttons allow adding the required information. The Java tables are editable.

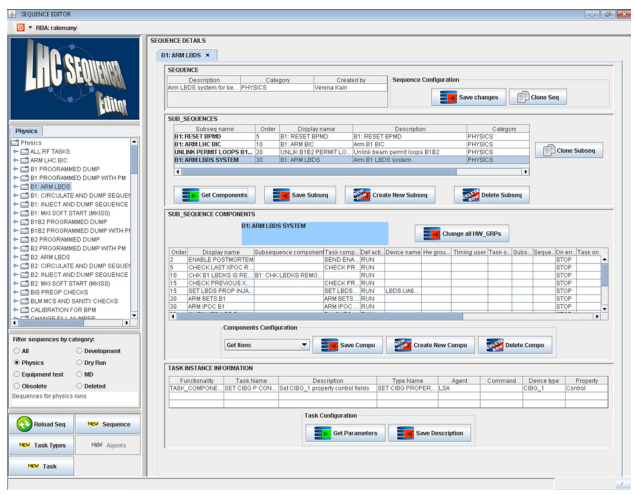

Figure 2: LHC Sequence Editor GUI.

Several of all those columns presented before are freign keys to columns within the LSA database tables. For example, the hardware group column of the table sequence_components, is filled with the content of the hardware_group column of a particular LSA table containing this information. In this way the user cannot enter any name which could not be recognized by the system, but the Editor shows, in the form of a combobox, only the allowed hardware_groups.

Once a (sub)sequence is created or modified by the user, the sequencer server retrieves it from the database and it is converted into a Java source file. The right compilation of the source code is a way of ensuring, to a great extent, the coherence of the sequence.

The Sequencer Executor is a graphical user interface (GUI) developed using the Standard Widget Toolkit[6]. Figure 3 shows a picture of the Executor.

The operator can search for a given sequence, or using the Quick Launch Panel (Figure 4) can search for the most used sequences which are organized by functionality, e.g. Specific Equipment sequences, Experiment sequences, etc. Once a (sub)sequence is selected, the GUI shows the corresponding tree structure of the sequence where the component names displayed are the ones defined by the user as displayed names in the database tables. Clicking on a particular task, the parameters of the tasks, as read from the database, are shown in the tab called "Details". The GUI allows for drag and drop of subsequences.

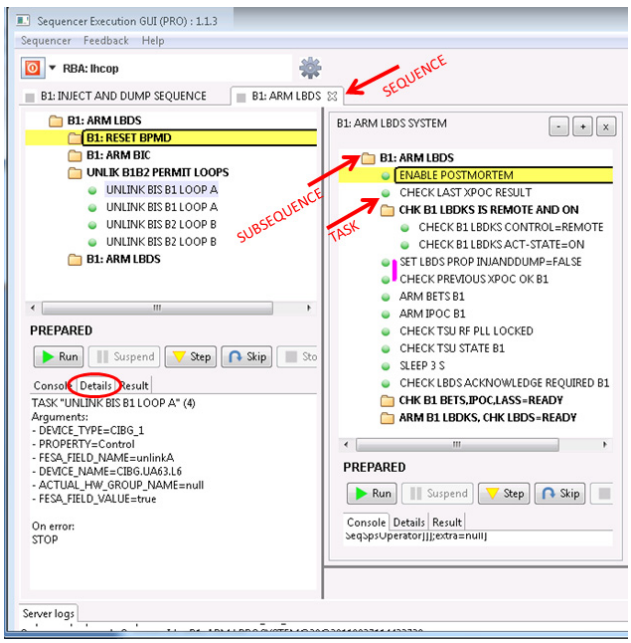

Figure 3: LHC Sequence Executor GUI.

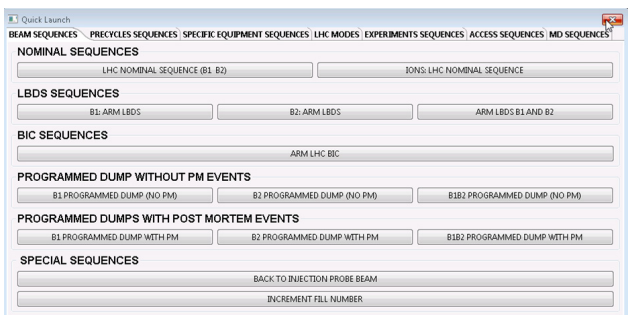

Figure 4: Quick Launch Panel.

In Figure 4 the subsequence B1: ARM LBDS has been dragged and dropped on the right and can be executed as an independent sequence. The vertical magenta bar in the picture indicates that the two tasks called SET LBDS PROP INJANDDUMP=FALSE and CHECK PREVIOUS XPOC OK B1 will be executed in parallel since they have the same execution order in the database. The default action configured in the database (run, skip or break) can be modified online within the executor GUI, but it is not propagated to the database. Modifications of the database configuration can only be done with the Editor. The subsequences can be (un)collapsed to show more or less details of the tree.

USE OF SEQUENCES FOR LHC OPERATION

The LHC operation in routine mode, like luminosity production, certain machine development periods, machine optimization studies, relies fully in the execution of sequences; nothing is done "manually". In the following we explain two cases rather representative of the LHC operation: Inject and dump sequence and LHC nominal sequence.

Inject and Dump Sequence

The distinctiveness of this sequence is that uses a particular functionality of the executor server, the possibility of coming back to a given task after completion of the execution and re-starting again the execution in an automatic way. This functionality is achieved via two tasks, one labels the position within the sequence from where the execution will have to be repeated, the other task instructs the executor to go to the label task. This functionality is very important in this sequence because it allows the arming of the beam dump system and the beam interlock system, injection into LHC and dump in a continuous way when performing injection steering or injection studies.

LHC Nominal Sequence

The LHC nominal sequence contains more than 1000 tasks and is organized in a set of subsequences that maps the LHC cycle: preparation for injection, injection, ramp, squeeze, collisions, and after more than 10 hours of stable beams, programmed dump and ramp down, as depicted in Figure 5. The LHC nominal sequence addresses all the LHC equipment at different steps in the cycle. It is not run in one go as the case above, but every subsequence is run separately, or step by step, since in between subsequences, beam measurements and corrections have to be performed which are not included in the sequence.

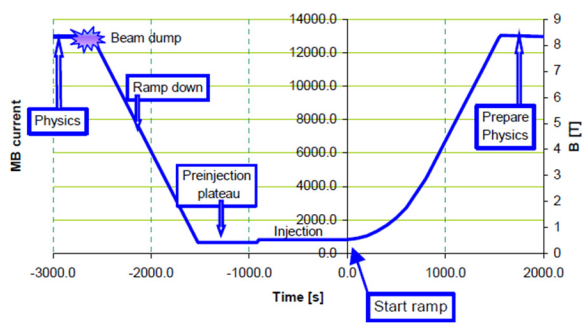

Figure 5: LHC nominal cycle (for 7 TeV flat top). All the different steps in the cycle are driven by the LHC Sequencer.

AUTOMATED VOLTAGE CONTROL IN LHCb

L. Granado Cardoso, C. Gaspar, R. Jacobsson, CERN, Geneva, Switzerland

Abstract

LHCb is one of the 4 LHC experiments. In order to ensure the safety of the detector and to maximize efficiency, LHCb needs to coordinate its own operations, in particular the voltage configuration of the different sub-detectors, according to the accelerator status.

A control software has been developed for this purpose, based on the Finite State Machine toolkit and the SCADA system used for control throughout LHCb (and the other LHC experiments). This software permits to efficiently drive both the Low Voltage (LV) and High Voltage (HV) systems of the 10 different sub-detectors that constitute LHCb, setting each sub-system to the required voltage (easily configurable at run-time) based on the accelerator state.

The control software is also responsible for monitoring the state of the Sub-detector voltages and adding it to the event data in the form of status-bits. Safe and yet flexible operation of the LHCb detector has been obtained and automatic actions, triggered by the state changes of the accelerator, have been implemented.

This paper will detail the implementation of the voltage control software, its flexible run-time configuration and its usage in the LHCb experiment.

INTRODUCTION

As an LHC experiment [1], LHCb relies on the LHC machine to provide the conditions for the production of events. In order to acquire the data from the events that happen in the experiment, LHCb has an infrastructure composed of several subsystems, namely several sub-detectors to record different parameters of the events. This infrastructure is sensitive to the type of configuration of the LHC accelerator and can be damaged if it's not configured properly according to the LHC status. As the experiment is built underground and is composed of many custom built detector components, it is not easily accessible nor can the parts be easily replaced in case of damage.

Furthermore, the efficiency of the detector must be optimized in order not to lose important beam time and record the most number of events with the best possible quality. In order to have the best efficiency, the LHCb detector must be configured as soon as possible into a state that matches the requirements for each particular LHC status.

As the LHCb detector is composed of several sub-detectors, for a given LHC status each of them must be configured in a particular state, which often differs between them. The configuration of all of them into the required settings one by one would prove inefficient as well as prone to errors.

A control software was developed that can, for each of the LHC states, drive each of the sub-detectors equipment into the appropriate voltage level and can easily be configured according to the sub-detector needs.

As this control software knows the current status of the voltages it is also able to calculate it in the form of status bits, which is then added to the event data and provides more information regarding the quality of the recorded events.

VOLTAGE CONTROL

The voltage control of the LHC experiments is based on the PVSS SCADA system [2], which interfaces the drivers of the equipment to the Finite State Machine toolkit [3].

The LHCb sub-detector voltage control is modelled into a FSM tree which has as the bottom nodes the modelled hardware devices (HV/LV) which are then grouped as sub-detector HV and LV systems, grouped then into logical units which contain all the sub-detectors HV/LV Voltage systems; these are all under the top node ECS (Experiment Control System) [4].

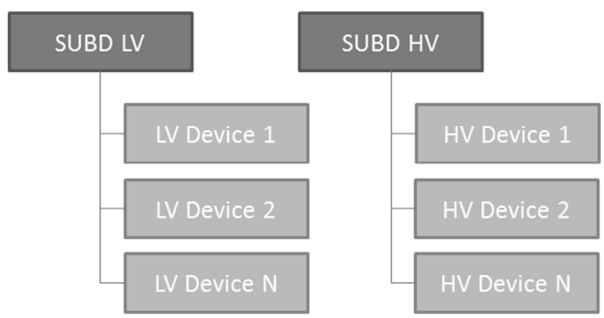

Figure 1: Typical sub-detectors voltage control FSM trees.

The commands flow down the tree, i.e. an action sent to the sub-detector top node flows down to the devices which perform it, while states flow up the tree, i.e. a state change at the device level is propagated up to the top nodes.

For the automated voltage control actions are sent to the top level nodes which group the HV and LV systems of each sub-detector.

Voltage FSM Control Units

The voltages in the LHCb experiment are controlled via the FSM control hierarchy and in order to set a particular voltage system into the desired state, commands are sent to the respective system top control node.

The nodes that group all the voltages for each of the systems (HV/LV) and each sub-detector are FSM Control Units and they can be in the following discrete states:

For the Low Voltage:

- NOT_READY – when not all of the low voltage devices are ON
- READY – when all the low voltage devices are ON
- OFF – when all the low voltage devices are OFF
- ERROR – when any of the low voltage devices is in ERROR
- EMERGENCY_OFF – when any of the low voltage devices has switched OFF due to an emergency action or trigger

For the High Voltage, as the time it takes to reach the appropriate voltage level is not negligible, the states can be of 2 types: stable states and transition states.

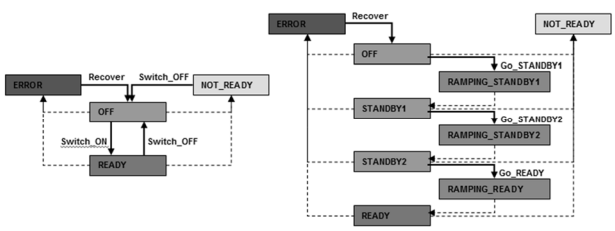
For the stable states, the voltage systems can be in the following states:

- NOT_READY – when not all of the high voltage devices are in a stable state
- OFF – when all the high voltage devices are OFF
- STANDBY1 – when all the high voltage devices are STANDBY1
- STANDBY2 – when all the high voltage devices are STANDBY2
- READY – when all the high voltage devices are READY
- ERROR – when any of the high voltage devices is in ERROR
- EMERGENCY_OFF – when any of the high voltage devices has switched OFF due to an emergency action or trigger

The transition states are called RAMPING_<Stable_State> and are set whenever the voltages are moving to that particular stable state.

The actions available to these Control Units are of the type GOTO_<Stable_State> and can take a parameter RUN_TYPE which allows for the selection of the proper recipe for the configuration settings of the devices.

These FSM objects serve as templates for the sub-detectors to model their voltage systems and allow for a transparent integration of its systems into the global LHCb Control System.



(a) DCS Domain (b) HV Domain

Figure 2: Simplified Voltage Control FSM Domains.

LHC State

The LHC machine publishes the status of the accelerator to all the experiments at CERN via DIP (Data Interchange Protocol).

LHCb subscribes to the LHC data and computes the state of the LHC accelerator, using this data; a FSM Device Unit models this data into 12 discrete states, 10 for different LHC configurations and 2 for error reporting ("ERROR", "UNKNOWN). This Device Unit can then be included in the FSM control hierarchy and be used as a trigger for automated actions as well as information for other FSM Units in the hierarchy.

Some of the computed LHC states are:

- PHYSICS – stable beams are declared and LHC is running with its nominal parameters
- PHYS_ADJUST –
- INJECTION – the beams are being injected into the LHC accelerator, the detectors voltages need to be in a safe state.
- MD – Machine Development; the LHC is adjusting operation parameters in order to optimize operation (e.g. cleaning, injecting probes). The detectors voltages need to be in the safest state possible
- DUMP – the beams have been dumped from the LHC accelerator

The actions available on the automated voltage control system can then be configured according to each of these individual computed LHC states instead of particular voltage states.

For the most dangerous states of the LHC, in respect to possible damages to the front end systems, LHC has implemented a handshake system to insure that the operation in these states is acknowledged by the experiments and they have set their systems to safe parameters of operation.

AUTOMATED VOLTAGE CONTROL

The automated voltage control system developed takes advantage of the FSM control hierarchy and is based on the FSM toolkit.

By using the voltage control FSM objects templates implemented by the sub-detectors, which are integrated into a global control FSM, and knowing the possible LHC states, it is possible to develop a control software which can configure the voltage systems in coordination with the specific needs for each LHC state.

For each sub-detector voltage system, you can define, for each of the available LHC states, in which voltage setting the respective voltage system should be set. The voltage settings can be any of the available states for that voltage system as well as a state called "_ANY_". In this case the sub-detector voltage system is allowed to be in any of its available voltage settings (safe for ERROR) and the state of this system in respect to the LHC state will always be OK. This is to allow for independent control from the part of the sub-detectors, when the LHC is in a state that allows for periods of development (e.g.

"NO_BEAM") without interfering with the global state of the experiment voltage systems control.

The configuration of the voltage states required for each sub-detector and each LHC state is easily done via a configuration table, which is also useful as an overview of the settings.

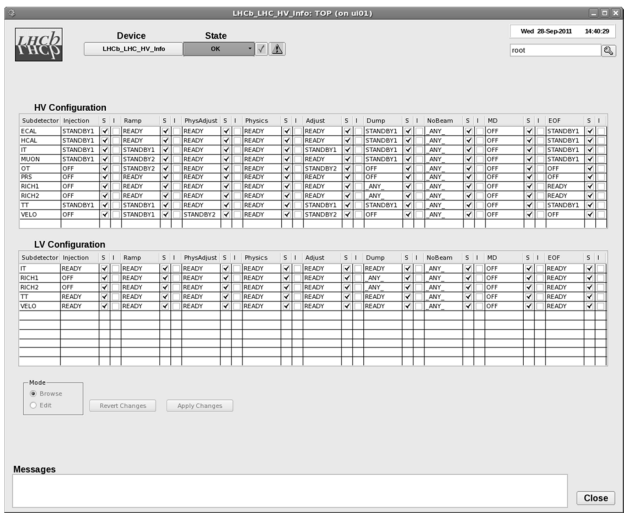


Figure 3: Configuration table (LHC state – LHCb voltage settings).

The Automated Voltage Control software is based on a set of FSM objects which will now drive the voltage systems, acting as a proxy between requests for configuration for a particular LHC state and the required HV configuration and a new FSM tree built upon these units and with references to the particular voltage systems to control.

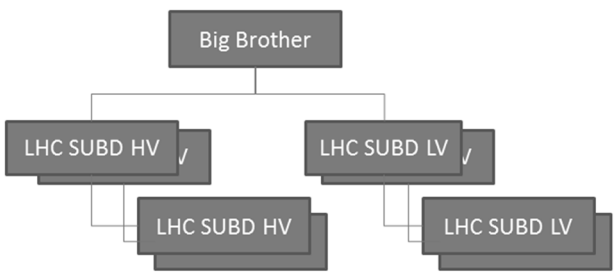

Figure 4: LHCb – LHC voltage control FSM Tree.

This new FSM tree will be the main control system for the LHCb sub-detectors voltage systems. It should have a top node with the CUs (Control Units) for the Voltage Systems to control as children. Typically each of these CUs is a sub-detector voltage system and references, as its children, the sub-detectors FSM voltage objects. These references serve as configuration for the new FSM object which will now drive the voltages.

The new discrete states of all these FSM objects are now a reflection of the state of the sub-detectors voltage systems in respect to the possible LHC states defined for the LHC state device unit. The actions are now, as well, commands to configure the voltage systems according to the configuration needed for each particular LHC state. This means that that the actions are no longer e.g. "GOTO_STANDBY" but e.g. "GOTO_INJECTION", and the voltages of each sub-detector will be configured according to the setting which corresponds to the "INJECTION" LHC state. Also the transitional states represent the movement of the voltage devices into the final requested LHC state configuration settings (e.g. "RAMPING_INJECTION").

Device Units

There are 2 Device Unit types needed to properly run the voltage systems.

One retrieves the parameter RUN_TYPE from a PVSS datapoint, in order for it to be correctly defined when the action for the voltage systems to go to a particular LHC state is requested.

The other Device Unit is the object that now drives the voltage systems. This Device Unit holds the proper configuration of all the required voltage settings for each LHC state per sub-detector and voltage system (e.g. "LHC_MUON_HV", "LHC_OT_LV").

There are also some other possibilities for configuration settings for each of the actions to be sent in respect to each particular LHC state request:

- Send action – The action can be set not to be sent until a user manually does this. The user does not need to know the correct voltage state needed but it does need to intervene in order for the voltage systems getting configured to the proper state.
- Ignore State – The action can be configured to automatically exclude the voltage system.

This Device Unit, on startup, connects to the states of the voltage system references of the particular sub-detector it controls and its state is computed from the accordance of the state of the voltage systems with respect to the last requested LHC state configuration. Its states are defined as follows:

- UNKNOWN
- ERROR
- RAMPING_<LHC_STATE>
- WAIT_MAN_CONFIG – Manual Configuration for this sub-detector for this LHC state is required
- OK – State of the Voltage systems IS in accordance with the needed state for this LHC state
- NOT_OK – State of the Voltage systems IS NOT in accordance with the needed state for this LHC state

High Voltage Status Bits

This Device Unit also computes a set of status bits for each High Voltage system, which is then saved with the events data in order to provide more information of the quality of the events.

For each sub-detector a majority limit threshold for the number of not working HV channels is defined and the status bits computed are based on the information of the individual channel states of each sub-detector and whether the number of incorrectly configured channels is greater than the majority threshold defined.

The status bits are as follows:

- 00 – All HV channels are correctly configured and running;
- 01 – There are some HV channels in an incorrect state in regards to the LHC state, but their number is below the majority threshold set.
- 10 – The number of channels in an incorrect state in regards to the correct state is above the defined majority threshold

The computation of the status bits is done by a thread which is launched for each controlled voltage system. This thread monitors periodically the state of each sub-detector High Voltage channel states and sets the status bits.

LHCb OPERATION

The Automated Voltage Control System implemented in LHCb is connected to a handshake system with the LHC. The LHC state based voltage operation allows this integration to be simplified as, whenever the LHC state changes and requests a handshake to move to a particular state, a simple action is the only required input from the part of the operator. A PVSS panel displays the readiness of all the sub-detectors Voltage Systems for the current LHC state. In this panel it is also visible the percentage of the each sub-detector which is in the correct voltage state (in terms of number of channels).

Further automation has also been implemented, and several actions can now be auto-piloted, providing a greater level of efficiency.

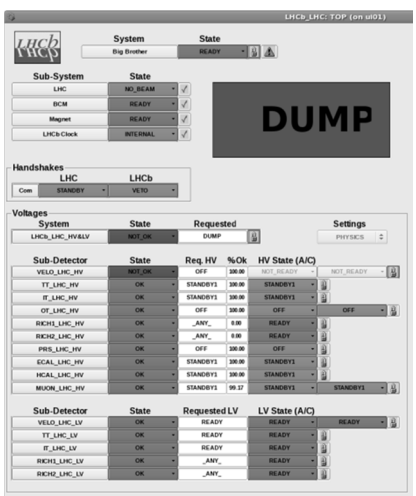

Figure 5: LHCb – LHC voltage control PVSS Panel.

CONCLUSION

The control software developed to drive the voltage systems in LHCb in accordance to the required settings for each of the LHC states proved to be a very efficient way of running the voltage systems of the experiment. The Automated Voltage Control is able to remove complexity from the system and improve the operation of the Experiment Control System as there is no need to track the different voltage settings for each of the sub-detectors at the different LHC states.

The safety of the detector is also assured as incorrect and unsafe voltage configurations can now easily be viewed in the main panel of the LHCb voltage control system and adjusted according to the current LHC state requirements.

The development approach based on the already implemented control system via the FSM toolkit also proved to be very reliable and configurable as well as scalable. Other voltage systems that use the LHCb FSM voltage control objects can easily be added.

This system also provides a base for further automation as LHC state changes can automatically trigger the correct voltage settings in a way very easily integrated in the current control system.

SPIRAL2 CONTROL COMMAND: FIRST HIGH-LEVEL JAVA APPLICATIONS BASED ON THE OPEN-XAL LIBRARY

P. Gillette, E. Lemaître, G.Normand, L. Philippe, GANIL, Caen, France

Abstract

The Radioactive Ions Beam SPIRAL2 facility will be based on a supra-conducting driver providing deuterons or heavy ions beams at different energies and intensities. Using then the fragmentation and ISOLD method, exotic nuclei beams will be sent either to new physics facilities or to the existing GANIL experimental areas. To tune this large range of beams, high-level applications will be mainly developed in Java language. The choice of the OPEN-XAL application framework, developed at the Spallation Neutron Source (SNS), has proven to be very efficient and greatly helps us to design our first software pieces to tune the accelerator. The first part of this paper presents some new applications: "Minimisation" which aims at optimizing a section of the accelerator; a general purpose software named "Hook" for interacting with equipment of any kind; and an application called "Profils" to visualize and control the Spiral2 beam wire harps. As tuning operation has to deal with configuration and archiving issues, databases are an effective way to manage data. Therefore, two databases are being developed to address these problems for the SPIRAL2 command control: one is in charge of device configuration upstream the Epics databases while another one is in charge of accelerator configuration (lattice, optics and set of values). The last part of this paper aims at describing these databases and how java applications will interact with them.

THE SPIRAL2 FACILITY

Overview

The SPIRAL2 facility (Fig. 1) is based on a high power, superconducting linac driver, which will deliver a high intensity, 40 MeV deuteron beams as well as a variety of heavy-ion beams with mass-to-charge ratio of 3 and energy upon to 14.5 MeV/nucleon. A possibility of construction of a second injector for heavy-ions with a mass-to-charge ration of 6 is incorporated in the design. The main RIB production scheme of SPIRAL2 is based on the fast-neutron induced fission of uranium target. Using a carbon converter, a 5 mA deuteron beam and a high-density (up to 11g/cm^3) 2.3 kg uranium carbide target, the fission is expected to reach a rate up to 5*10^{13}/s. A direct irradiation of the UC_2 target with beams of protons or 3,4He could also be used. The extracted 1+radioactives ions will be injected in the 1+/n+ charge breeder (ECR ion source) and post-accelerated by the existing CIME cyclotron.

The SPIRAL2 project is divided in two phases (Fig 1): the first one (LINAC buildings and associated experimental AEL) and the second phase (RIB production building and DESIR facility).

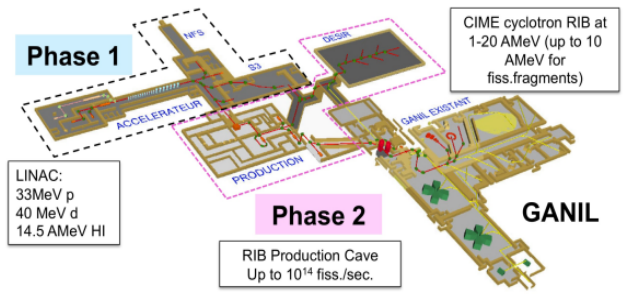

Figure 1: Accelerator layout.

SOFTWARE ARCHITECTURE

Control System Main Choices

The choice of EPICS [1] as a common framework was early decided to ease pieces of software development and integration efficiency. Mainly remote terminal units are VME VxWorks crates with MVME 5500 CPUs and Red Hat Enterprise Linux PCs hosting EPICS Input Output Controllers (IOCs). On the other side, Siemens S7 programmable logic controllers (PLC) are mainly dedicated to slow material protection systems needed for radio frequency, cryogenic, vacuum, or interlock systems.

Software Development

To ease software sharing, a unique EPICS SPIRAL2 working environment, an equipment naming convention, and operational rules for interfaces have been specified. To survey a large facility as SPIRAL2, supervision screens developed with EPICS Extensible Display Manager (EDM) are needed[2]. An archive engine using the one provided by Control System Studio (CSS) integrated development environment has been set up this year. For the tuning of the accelerator, more sophisticated high level applications are involved. XAL [3],[4],[5] Java based library and framework originally developed at the Spallation Neutron Source (Oak Ridge National Laboratory), and dedicated to accelerator tuning, have been adopted. The accelerator hierarchy and model design, fulfilling the Spiral2 specific needs, have proved to be very effective.

Among the numerous tools included in XAL, the high level API for wrapping EPICS Channel Access protocol are widely used to read, write and monitor values on devices.

Some news applications have been written or adapted from the ones already provided by the SNS.

THE MINIMIZATION APPLICATION

This software acts on a set of equipments to achieve the minimization of objectives on a set of diagnostics.

Some algorithms (Simplex, Powell, Coordinated steps, One dimension, Aleatory, Aleatory by map, Gradient) have been implemented, improved (when needed) and tested in order to face the situations that could occur during the tuning of the beam. It is based on standard XAL Framework and library tools, using node selector and PV selector, Scorer and AlgorithmSolver classes [6].

The application is divided in four parts: the user chose which active and passive elements he wants (up left), enters the start and the end desired with some options (up right), and then chooses and sets up the algorithm (bottom left). The results are drawn in real time in the same frame. The numerical results appear in the bottom right.

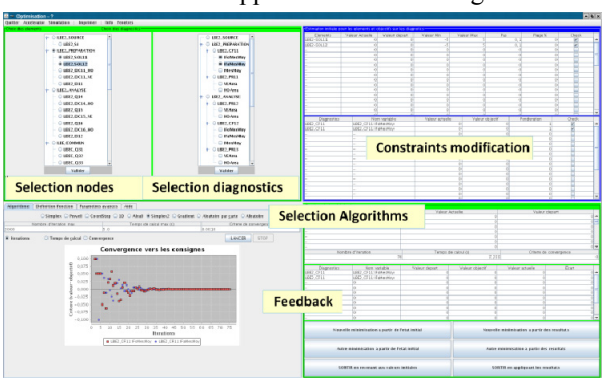

Figure 2: The minimisation software.

THE HOOK APPLICATION

A general purpose software named "Hook" has been developed for directly interacting with equipment of any kind (for the moment power and high voltage supplies, harp wire monitors, motorisations, current diagnostics, slits). For each kind of equipment, a generic component is used to assign elements on a graphic grid and provide complete access to the equipment. It was designed to reflect the same look and feel as the one (written in Ada) used in the legacy control system of GANIL.

Using the tools of the XAL library, the user selects elements in a hierarchical presentation of the accelerator. Once the elements are selected, each one can be assign to a sizable cell of a grid which the user can interact with. The grid component is in charge of the realisation and destruction of the items views.

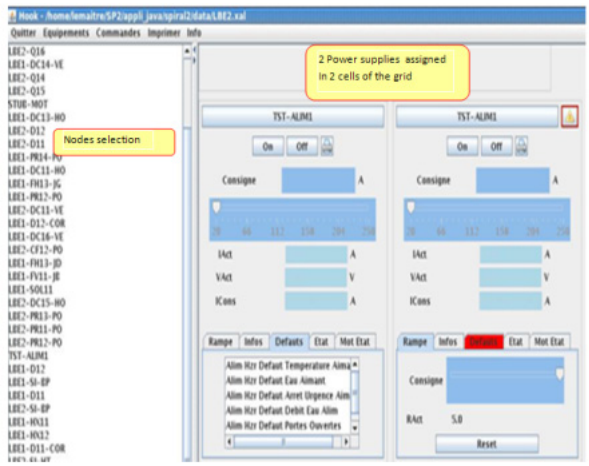

Figure 3: The hook software.

THE PROFILS APPLICATION

To visualize and control the SPIRAL2 beam wire harps the application Profils has been developed. It offers a complete control over the electronic devices and specific calculations on the data read from IOC Profils. It allows the user to select several sections of a profile to calculate areas, half widths, centers etc. The results of calculation are available to Epics clients via virtual process variables generated by a Java server.

As for the hook application, a set of harps can be assigned on a grid. General purposes commands are then available for all the harps assigned (scaling, printing, saving, insertion into the beam line, integration time or high voltage setting, mean and offset set-up etc)

Individual commands are also available in the window of each element: electronic device set-up, graphical comparison between live, theoretical, saved or snapshot data, selection of the wires to take in account for drawing and calculation, fit method for reconstruction of broken wires etc.

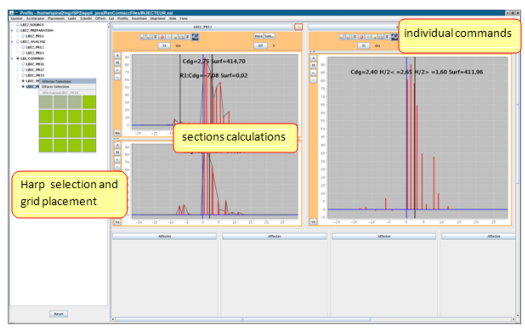

Figure 4: The Profils software.

DATABASES AND DATA MANAGEMENT

The command control group of GANIL is accustomed to databases usage on order to manage data and configuration linked to the system. The first Ingres database has been introduced in 1990.

For Spiral2 project, four topics rely on databases:

- Devices configuration
- Accelerator configuration
- Alarms handling
- Archiving

Device Configuration

To describe and exploit the 2500 equipments which are envisaged for the control of the SPIRAL2 facility, a relational database and associate management tools are developed at GANIL.

This database will be used offline and describes "simple" equipments such as slits, motors or power supplies. It enables generation of IOC configuration file (connections, substitutions and sequencers definition) as shown in Figure 5.

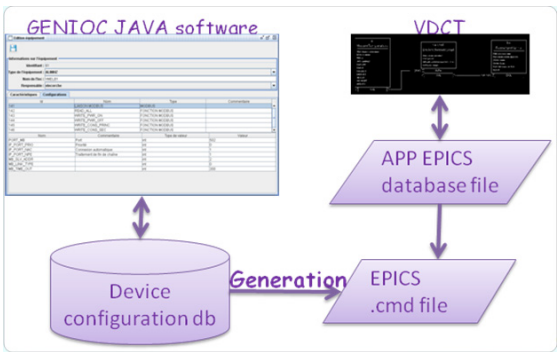

Figure 5: Device configuration process.

The main concept of this database is to describe a device type dynamically into the database's tables and instantiate this type to create a new device.

A first mock-up has been developed and tested with slits and power supplies devices.

Accelerator Configuration

To manage Accelerator configuration, a relational database and associate management tools are developed at GANIL

This database will be in charge of accelerator configuration. It describes accelerator hierarchy, optics and enables generation of XAL file defining the accelerator .xdxf.

The hierarchy is made up of 4 levels shown in Figure 7:

- Level: setting unit for operation. A level is made up of Paths.
- Path: path followed by the beam. A path belongs to a unique Level. A path is made up of sequences.
- Sequence: Grouping by tuning function. A sequence belongs to one or many paths. A sequence is made up of parts.
- Part: It's a unit introduced to facilitate computing management. A part belongs to one or many sequences. A part is made up of nodes (devices that affect or survey the beam).

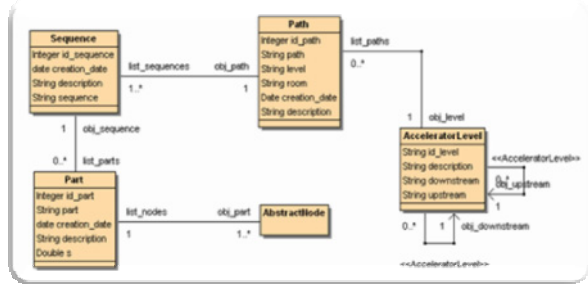

Figure 6: Accelerator hierarchy.

This database can be read and update off-line by a new dedicated software which enables generation of XAL file defining the accelerator optics files.

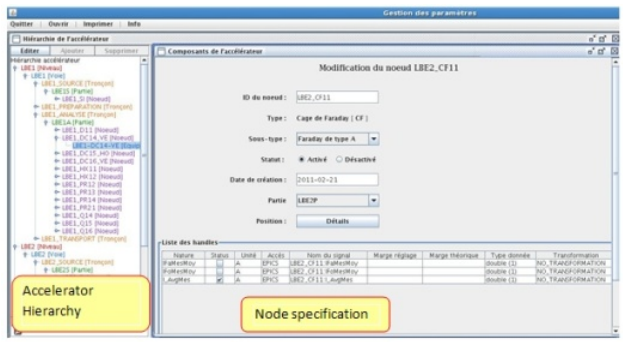

Figure 7: Accelerator configuration database tool.

This database will be used off-line to assign values for a new beam and to schedule operation. The set of values of a new beam is either theoretical or extrapolated from beams realized previously. Theoretical values for a beam to be produced are exported from Tracewin software developed by D.URIOT (CEA) [7].

This database will be used online to apply or save sets of values.

An application dedicated to the setting of the accelerator allows the user to choose the injector to use, the beam to accelerate and the set of values to apply. Once these settings have been applied, numerous operations (setting, reading, comparing values, computing data for new energies or magnetic rigidities) are available. 50-60 percent of functions are implemented

Alarms Handling

For reasons of compatibility and consistency between GANIL alarm handling process and that of SPIRAL2, we decide not to use EPICS standard Alarm Handler.

The alarms handling process, illustrated in Figure, rely on an Ingres database. This database assumes two main functions:

- Configuration of the process : how to build alarms messages and which alarms should be caught
- Storage of alarms issued.

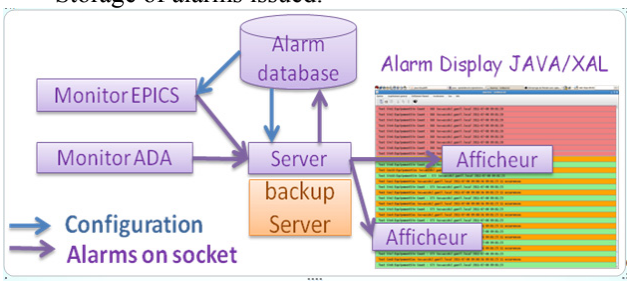

Figure 9: Alarm handling process.

The alarms process is made up of four software:

- Monitor EPICS: JAVA based development. It relies on channel access monitor. It is in charge of catching and formatting alarm message.
- Monitor ADA: ADA Based development. It assumes the same function as Monitor EPICS for GANIL alarms.
- Server: JAVA Based development. It receives alarms from monitor and dispatches them to displays. A failover server takes over if the main server failed.
- Display: JAVAL/XAL based development. It displays alarms in the form of button list.

This process has been tested and supports a throughput of 330 alarms per second.

Archiving

The archiving system is planned to be implemented witch archive engines upstream a MySQL database, jointly the CSS Client operator interface.

The software architecture used for tests, illustrated in figure 6, shows that the load is balanced between two servers: one for insertions and one for reads.

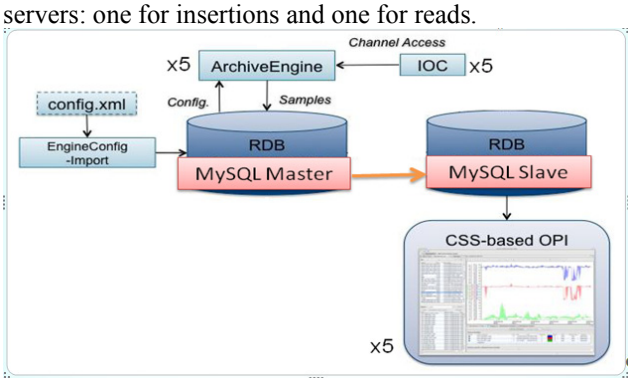

Figure 10: Test architecture for archiving.

The writing tests, presented in Table 1, were performed in September 2011.

The first results showed that we needed to update the MySQL JDBC driver and settle the **rewriteBatchedStatement** property to true to enable bulk insert and a huge performance gain.

Table 1 : Archiving Test

Number of IOC	Number of PV/IOC	Number of Archive Engine	Number of PV/ Archive Engine	f	PV/s
5	80	5	80	10Hz	4000

The reading (CSS client) tests using MySQL partitioning started recently.

CONCLUSION & NEXT STEPS

The use of the XAL library has been very efficient. While some of the SNS applications have been reused without modification: scanning applications, virtual accelerator, launcher, etc., others have had to be adapted to fit our needs: optimisation, magnet cycling, radio-frequency cavities tuning. Specific applications were designed from scratch using the XAL library and framework: admittance limitation, alignment, profiles monitoring and equipment control. New developments are foreseen: ion source spectrometry, beam power monitoring, longitudinal emittance measurement, etc.

Most of the applications require data from the database for their configuration especially through xdxf file. Furthermore, databases are at the heart of central service like alarms or archiver.

ACKNOWLEDGEMENTS

Other contributors are: from the Ganil control group, D. Touchard (Epics environment and tools), C. Haquin (real time), P. Lermine (databases); from IRFU, D. Uriot (Tracewin), JF. Denis and F. Gougnaud (Tests at Saclay).

The basic hardware and software infrastructure and the network architecture are managed and provided by the Ganil Computing Infrastructure group.

A special thanks to the OPEN XAL team for the software and support provided.

THE NEW CONTROL SYSTEM FOR THE VACUUM OF ISOLDE

S. Blanchard, F. Bellorini, F.B. Bernard, E. Blanco, P. Gomes, H. Vestergard, D. Willeman

CERN, Geneva, Switzerland

Abstract

The On-Line Isotope Mass Separator (ISOLDE) is a facility dedicated to the production of radioactive ion beams for nuclear and atomic physics. From ISOLDE vacuum sectors to the pressurized exhaust gas storage tanks there are up to five stages of pumping for a total of more than one hundred pumps including turbo-molecular, cryogenic, dry, membrane and oil pumps. The ISOLDE vacuum control system is critical; the volatile radioactive elements present in the exhaust gases and the high and ultra high vacuum pressure specifications require a complex control and interlock system. This paper describes the reengineering of the control system developed using the CERN UNICOS-CPC framework. An additional challenge has been the usage of the UNICOS-CPC in a vacuum domain for the first time. The process automation provides multiple operating modes (rough pumping, bake-out, high vacuum pumping, regeneration for cryo-pumped sectors, venting, etc). The control system is composed of local controllers driven by PLC (logic, interlocks) and a SCADA application (operation, alarms monitoring and diagnostics).

INTRODUCTION

The ISOLDE Facility

The On-Line Isotope Mass Separator ISOLDE [1] is an experimental facility located at the Proton-Synchrotron Booster (PSB), CERN, dedicated to the production of a large variety of radioactive ion beams for many different experiments in the fields of nuclear and atomic physics, solid-state physics, materials science and life sciences.

Description of the Vacuum System

In terms of vacuum, the ISOLDE facility is an array of beam lines used to distribute radioactive ion beams to a number of experiments. The beam lines are separated into sectors which are often generically represented by the equipment used in that part of the machine. For example, the front-ends refer to the two separate target stations where both heating and high voltage are an issue for the vacuum system and the separators refer to the sectors where the separating magnets are located.

The new vacuum control system replaces a fifteen year old control system based on old obsolete PLC (Programmable Logic Controller) without dedicated supervisory software. The old control system became difficult to maintain and was no longer adapted to present day upgrades of the facility.

The new control system has been installed in two steps:

- In 2010, installation of the vacuum control system for ISOLDE front-ends, separators and experiments
- In 2011, installation of the vacuum control system for the post-accelerator REX-ISOLDE [2] (Radioactive beam EXperiment at ISOLDE)

ISOLDE machine requires high vacuum(1) and ultra high vacuum(2) provided by turbo-molecular and cryogenic pumps respectively. An additional bake-out system allows achieving ultra high vacuum. All the exhaust gas from the pumping systems (with volatile radioactive elements) are collected and stored into pressurized tanks. This specification is unique at CERN.

In order to optimize the gas collection and reduce maintenance, the number of primary pumps is reduced to a minimum. There is a first set of nine primary pumps for the exhaust of fifty-four turbo-molecular pumps and four cryogenic pumps; and a second set of nine primary pumps for the rough pumping of thirty-one beam-line vacuum sectors. A complex process has been developed to control this pump configuration (Fig.1).

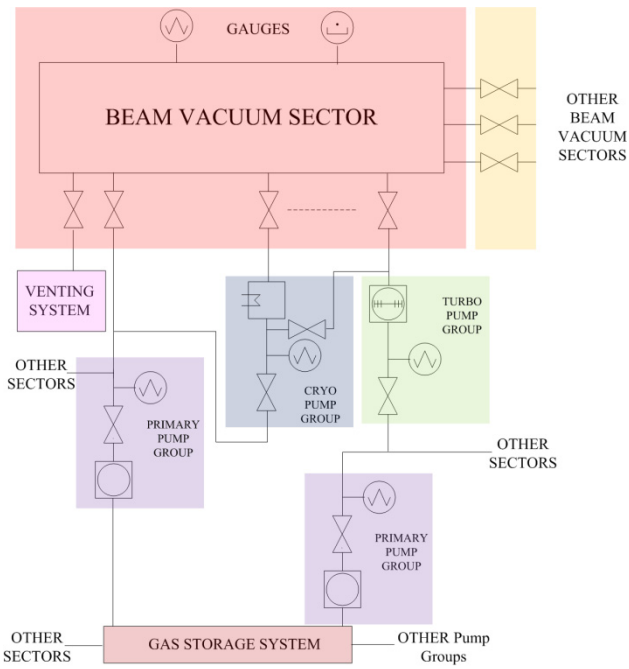

Figure 1: Typical pumps configuration.

(1) Pressures below 1.10^{-6}mbar
(2) Pressures below 1.10^{-10}mbar

CONTROL PROCESSES

The vacuum system is split in one hundred and twenty-seven processes of ten types (beam sector, turbo-molecular pump, cryogenic pump, primary pump, venting, storage, etc).

The pump process interlocks the client process (the client can be another pump or a beam-line sector). A pump process has several statuses: stop, starting, nominal (nominal pressure reached), recover (pressure increases after the pump has reached its nominal pressure), leak detection, etc. The pumping valve of the client remains closed if the pump process is not in "nominal" or "recover" status and the opening is disabled if the pump process is in "recover" status.

Some processes are multi-client (Fig.2); to avoid that two clients are pumped at the same time (retro-diffusion and contamination problems), a « token » system has been developed with low and high client priorities.

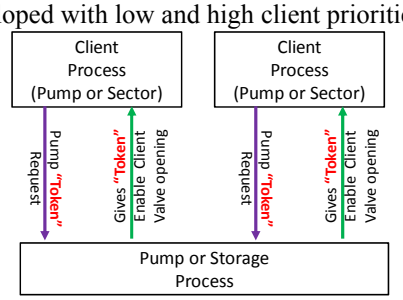

Figure 2: Pump and clients relation.

Processes are linked together with multiple interactions (Fig.3).

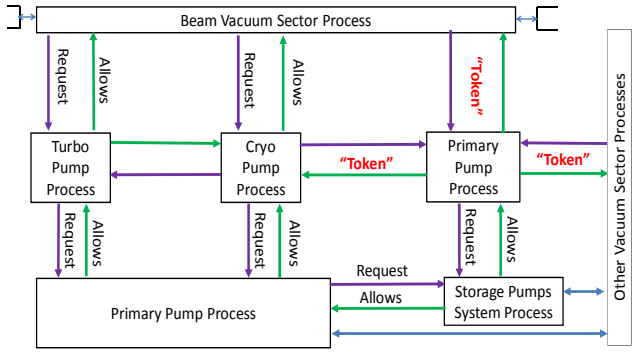

Figure 3: Processes interactions.

HARDWARE

Hardware Architecture

The hardware architecture (Fig.4) is based on Programmable Logic Controller (PLC). The vacuum control hardware is a five layer architecture: SCADA[(1)] Application, PLC, remote input/output, device controllers and field devices.

The remote input/output station and controllers are installed close to the field devices to reduce cabling.

Unfortunately, approximately a third of the vacuum equipments are located in radioactive and restricted areas. For these devices, specific radiation hard gauges, captors, local crates and cables have been installed.

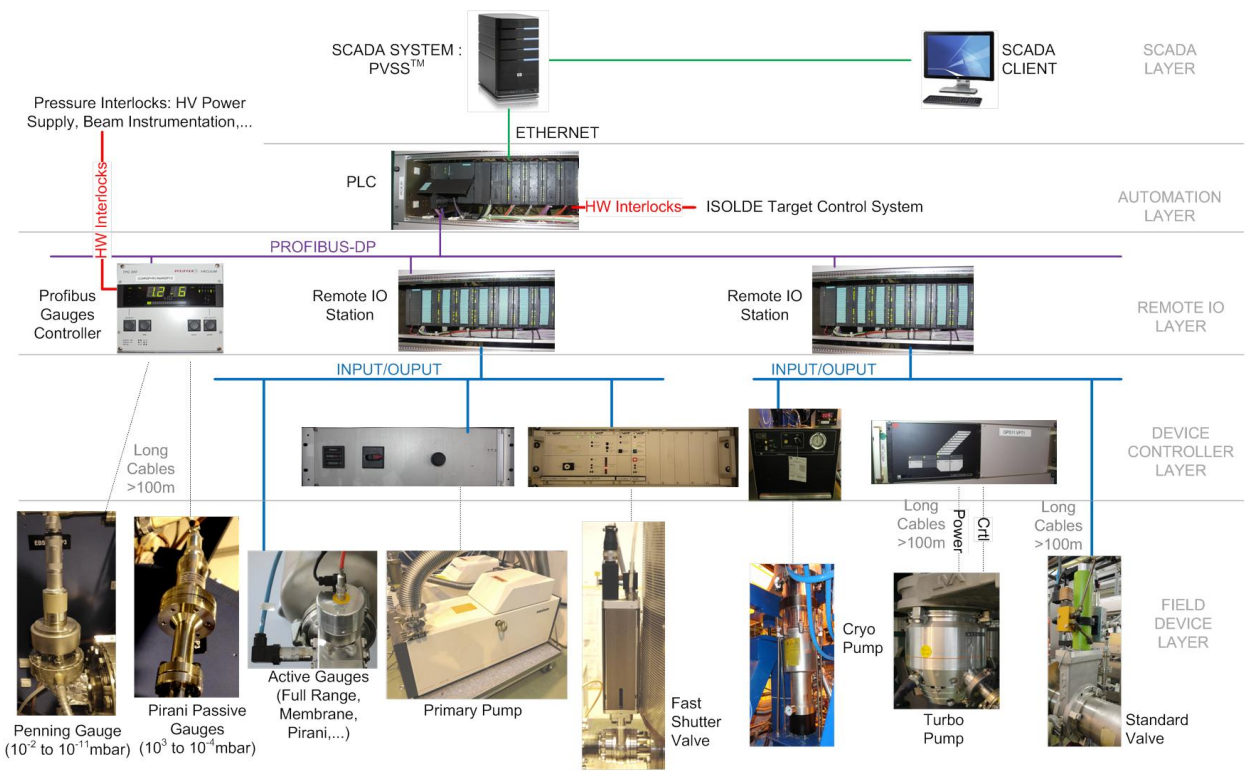

Figure 4: Hardware Architecture.

(1) Supervisory Control and Data Acquisition

Long distance cables (longer than one hundred meters) were installed and some specific cabling development for turbo-molecular pumps was required. The standard cable was replaced by two cables, one for the power of the pump motor and a second cable for the pump captors and signals.

ISOLDE and REX-ISOLDE vacuum controls are independent systems with two PLCs and two SCADA applications. The two SCADA applications and software are installed on the same Linux server.

The architecture is quite similar for the two systems and resumed by the Fig. 4.

Hardware Interlocks

The hardware interlocks are potential free relay contacts. The PLC provides hardware interlocks to other equipments like transformers, water cooling, target heaters, etc. The interlocks are the results of logic combinations of pressure levels and process status.

The gauge controllers provide fast pressure hardware interlocks to high-voltage power supplies. A PLC function has been developed for the asynchronous communication with the gauge controllers via the Fieldbus Profibus-DP™. This function allows to set, monitor and diagnose a large number of hardware interlocks.

SOFTWARE

UNICOS-CPC Framework

UNICOS (UNified Industrial COntrol System) [3] is a CERN framework to produce control applications. The UNICOS-CPC package proposes a method to design and develop complete industrial process control applications. It is based on the modelling of the process in a hierarchy of devices (e.g. I/Os, field and abstract control devices). These devices establish the base on which process engineers and programmers define the functional analysis of the process. The package is deployed both in the supervision layer (WinCC OA) and in the PLCs (Schneider and Siemens). UNICOS-CPC also provides tools to automate the instantiation of the devices in the supervision and process control layers and to generate either partially or completely the specific control logic code. The framework is flexible enough to be able to add customized devices to cover new client requirements.

Phases Sequencer

The ISOLDE vacuum control system largely uses Grafcet(1) to drive devices and activate alarms and interlocks.

The Grafcets are directly monitoring a SCADA panel (Fig.5). The operator can follow the process and see the active steps and transitions.

(1) Sequences of actions with conditions and time dependencies to achieve discrete event

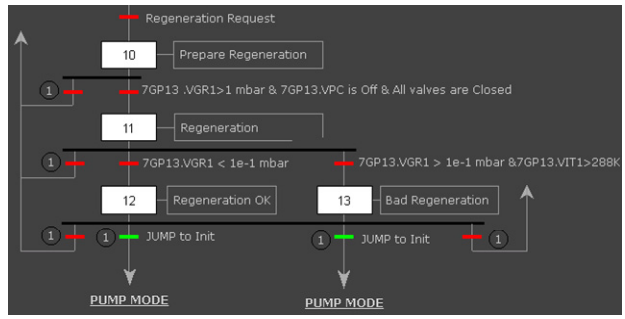

Figure 5: Part of a cryogenic pump process Grafcet (SCADA Panel).

Thirteen different Grafcets provide a fully automatic system with a large choice of operating modes: pump, leak detection, vent, bake-out, regeneration, etc. Transitions between modes can be automatic or manually requested.

Software Production

The process objects use phase sequencers to control the vacuum equipments. Physical values such as valve positions or gauge pressures are acquired through input objects and commands are set via output objects.

Phases sequencers (Grafcets) and PLC function templates are produced using the logic specifications. The "vacuum" library is composed of PLC functions developed for specific vacuum devices (analogue gauges with on/off commands, complex gauge controller devices, etc). This library was created especially for the vacuum system of ISOLDE (Fig.6).

The PLC source code is obtained using:

- Baseline code generated by UNICOS-CPC framework.
- Function templates, Grafcets and "vacuum" library.

The SCADA application is obtained using:

- Baseline application produced by the UNICOS-CPC framework.
- SCADA application objects automatically generated from the objects database and specifications.
- Fully configurable panel templates developed using the ISOLDE vacuum layout.

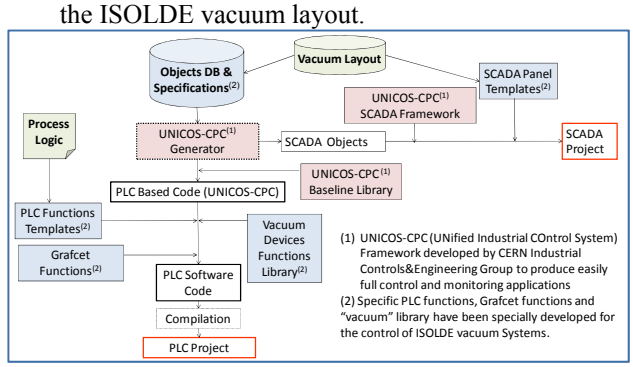

Figure 6: Software production diagram.

Software Interlocks

The project integrates phases sequencer time-out and alarm conditions to interlock devices and processes. The sector valves need to be interlocked in case of pressure increase. The PLC provides software interlocks for the sector valves, a low pressure threshold is set to disable the opening of a valve and a high pressure threshold is set for a fully interlocked valve (valve closure and inhibit opening). The SCADA panel (Fig.7) displays the detail and the source of the interlock providing a rapid and easy diagnostic.

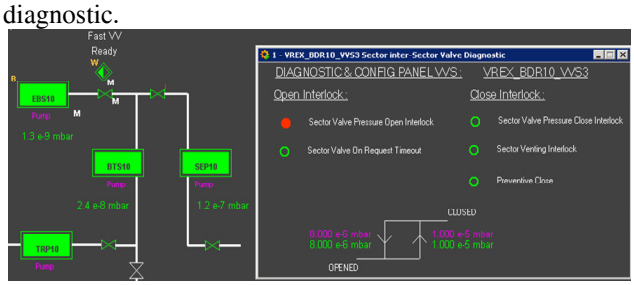

Figure 7: Sector valve interlock details panel.

SPECIAL CASES

Ultra High Vacuum: Bake-Out Control

The REX-EBIS sector is an ultra high vacuum sector and needs to be fully baked-out (Fig.8). The bake-out reduces the chamber's gas desorption and activates the in-house guetter pumps. The vacuum components are fragile and require an advanced regulation and control system. The bake-out control system is compact and mobile with PID (Proportional/Integral/Derivative) regulation, complex temperature cycles, interlocks, error management, remote control, alert and diagnostic tools. The bake-out control rack is composed of a PLC and electronic power components. This bake-out controller was developed previously by the Control Section of the VSC[(1)] Group for all the CERN accelerators[4].

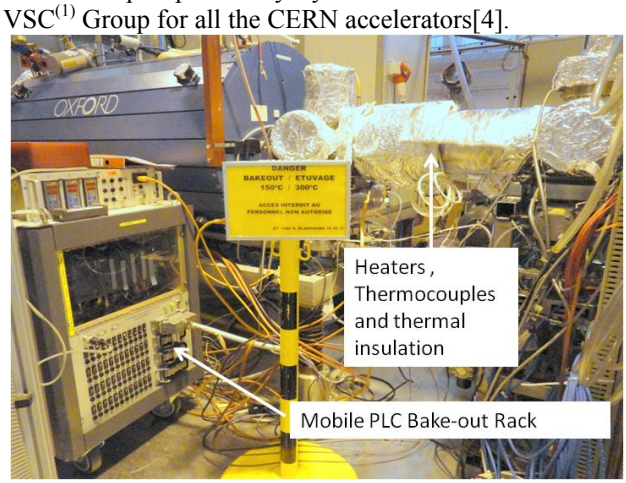

Figure 8: Bake-Out system of REX-EBIS sector.

(1) Vacuum, Surfaces and Coating Group (CERN)

Control of the Exhaust Gas Collecting and Storage System

The exhaust gas collection (Fig.9) and storage process is one of the most important processes as its failure would result in the complete shutdown of the ISOLDE vacuum system. The system is redundant and is not running permanently. Between the pump groups and the storage system, an array of decantation pipes and filters can independently accumulate gas up to a pressure of 700 mbar. The control has been designed to avoid stops or at least to prevent them. For example if the pressures in the storage tanks increase abnormally, the responsible client process is preventively stopped yet the storage system is still available for other processes.

Figure 9: Exhaust gas collecting station.

CONCLUSION

The vacuum control system of ISOLDE including REX-ISOLDE is the result of a successful CERN internal collaboration between the Control Section of the Vacuum, Surfaces and Coating Group and the Industrial Controls&Engineering Group. This system provides all the features to fully operate and monitor the vacuum system of ISOLDE. The diagnostic tools and the ability to access them remotely have considerably reduced the vacuum intervention time.

LHC SURVEY LASER TRACKER CONTROLS RENOVATION

C. Charrondière, M. Nybo, CERN, Geneva, Switzerland

Abstract

The LHC survey laser tracker control system is based on an industrial software package (Axyz) from Leica Geosystems™ that has an interface to Visual Basic™, which we used to automate the geometric measurements for the LHC magnets. With the new version of the Leica software, this Visual Basic™ interface is no longer available and we had to redesign the interface software to adapt to a PC-DMIS server that replaced the Axyz software. As this package is no longer supported, we have taken the decision to recode the automation application in LabVIEW. This presentation describes the existing equipment, interface and application showing the reasons for our decisions to move to PC-DMIS and LabVIEW. A comparison between the new and legacy system is made

INTRODUCTION

The Large Hadron Collider (LHC) is CERN's biggest accelerator. Thousands of magnets of different varieties and sizes are used to drive the beams around the accelerator. These include 1232 dipole magnets of 15 m length, which are used to bend the beams, and 392 quadrupole magnets, each 5 to 7 m long, to focus the beams. Prior to collision, another type of magnet is used to 'squeeze' the particles closer together to increase the probability of collisions. As the required tolerances on the geometry [1] of the LHC cold masses and on the positioning of some of its components are very tight, the final steps of the assembly are assisted by 3D optical measurements. From 2001, a Visual Basic™ program written at CERN (ie: Magnet Geometric Measurement – MGM) with direct access to the command library of the Leica Geosystems™ software, called Axyz, executes every sub-routine of the measurement process [2]. To be able to use the geometric measurement program for the LHC lifetime, the upgrade of the software components was decided.

Measuring Sequence

To identify the geometry of the cold mass cold bore tubes, a motor pulls through the tubes a mechanical mole carrying a reflector whose position is measured by the laser tracker (Figure 1). Since the measurement of both tubes requires the displacement of the measuring system with respect to the cold mass, an external reference system is needed to link the different stations. This system consists of a number of fixed points, distributed around the cold mass and equipped with reflectors. The cold bore tube axes are measured followed by an on-line analysis that links the cold mass shape to the virtual theoretical shape. Once the cold mass shape is known with respect to the theoretical reference system, the cold mass components can be aligned with respect to their theoretical position. The main components to be positioned w.r.t the reference co-ordinate systems are the corrector magnets, the end covers, the cold feet pads and the extremity of the cold bore tubes. The MGM program guides the operators with instantaneous graphical representation of the measured objects and gives indications about the acceptance and the necessity of further adjustments. During the full assembly of the magnets, the relevant information about the cold mass shape and the components position are kept and used to fill in the final report.

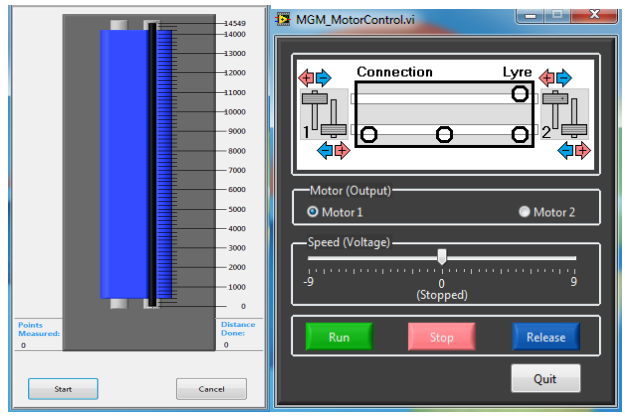

Figure 1: New motor control interface pulling the mole in the magnet cold bore tubes.

Legacy Software and Hardware

The system was running on WindowsXP, using Visual Basic™ 6.0 and Axyz software to control a LTD500 Laser Tracker. The communication between MGM and Axyz was based on OLE commands. The measurements were performed through the Laser Tracker Module (LTM) after having defined many operational parameters. The results were stored in the Core Data Module (CDM), which was accessible by the MGM for mathematical treatment of the raw data.

The list below explains the reason for an upgrade of the system:

- WindowsXP will become obsolete in the coming years.
- Visual Basic™ 6.0, is already obsolete.
- Axyz is obsolete from 2007 and not supported by Leica Geosystems™ from 2011.
- LTD500 are in good working conditions. However they are obsolete devices, thus they may need to be renewed in the coming years with more recent machines.

Software and Hardware from 2011

Following these observations, it was clear that the system had to be adapted. However the end users must not be affected and we have to keep similar GUI and work procedures (Figure 2).

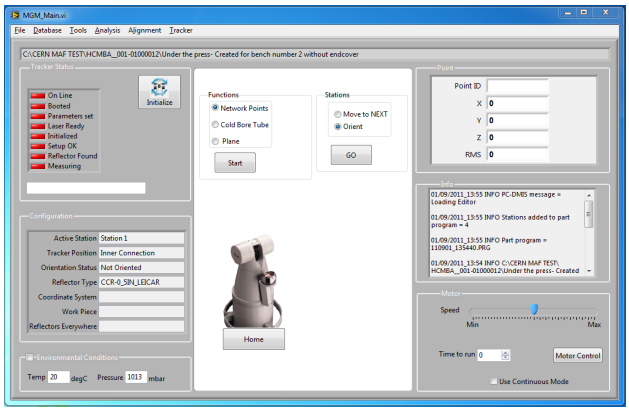

Figure 2: New MGM main panel that keeps the consistency with the previous version [3].

The most expensive tool used is the LTD500. This hardware is obsolete from the manufacturer point of view, but fulfils CERNs requirements to build and repair magnets for the LHC. However, when the need will come to buy a new laser tracker, the MGM will have to be adapted with a minimum effort. The application proposed by Leica Geosystems™ is called PC-DMIS, developed by Wilcox™, both companies being owned by Hexagon™. This application supports custom automation and can be used manually by the operator if special procedures or measurements are needed. PC-DMIS cannot be connected to the laser tracker directly, and a server (ie: emScon server) has to be added in the chain of equipment (Figure 3). The emScon server translates the request from PC-DMIS to commands understandable by the laser tracker.

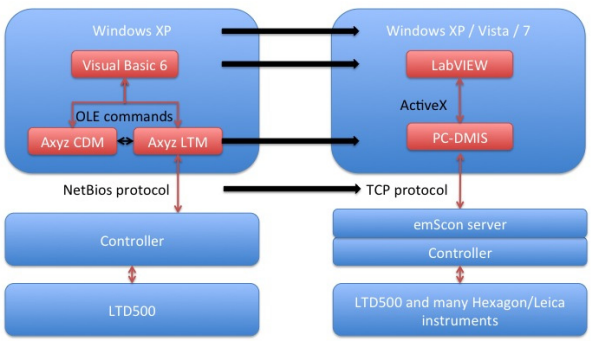

Figure 3: Software and hardware evolution.

The main difference between Axyz and PC-DMIS is that the former is point oriented while the latter is feature oriented. In Axyz the user measures a set of points and can decide later on if they describe a circle, a line …etc… In PC-DMIS the user select a feature and then measure all the points describing it. PC-DMIS is also highly graphical while Axyz is more a textual interface.

The choice was made to develop MGM using LabVIEW™, as it was the most suited to fulfil the requirements of flexibility, adaptability, quality, integration into industrial control software and light maintenance (Table 1).

Table 1: New Structure Pros and Cons

Parts	Status
Windows XP / 7	Can be upgraded to CERN standard
LabVIEW2010	Easy move from one version to another
PC-DMIS	Fully supported by Hexagon™
emScon server	Supported at least until 2017
Controller	Obsolete – can be changed
LTD500	Obsolete – can be changed

Using emScon Direct Commands

Communicating with the emScon server means sending and receiving byte-array datablocks over an asynchronous network connection. Leica Geosystems™ offers an emScon Tracker Programming Interface (TPI) for sending commands directly to the laser tracker from an external application without passing through PC-DMIS. The versatility of the emScon TPI based on standard TCP/IP allows its usage on different operating systems (Windows, Linux, UNIX, Mac…). All measuring functions are available in the emScon library. However, as PC-DMIS will use the emScon server, it is not wise to access emScon with a third party application at the same time, as this will cause conflicts at the server level. Using the emScon TPI would be way lighter for the online sequence, but features such as data storage and mathematical analysis would have to be developed in addition, while they already exist in the PC-DMIS package. For this reason emScon will be used for smaller projects not requiring heavy treatment of data. In any case, this protocol has not been chosen for MGM application.

Using PC-DMIS Commands

PC-DMIS automation gives the ability to automate repetitive tasks within a custom built application running scripts called “part programs”. Thus PC-DMIS automation is language independent and provides a list of methods, properties and events for each PC-DMIS automation object. Methods are functions that usually perform actions. Properties allow reading or writing characteristics of an object. Events are routines that get called when certain conditions are met. Performing an action like measuring a point usually involves inserting a command to the script and executing it.

One of the main advantages of using PC-DMIS is that the script describes the measurement sequence being run and stores the data in the same script. This means that an expert can open the scripts, check the raw data as well as the settings used for any measurement and re-run an offline analysis. This has proven to be highly efficient when it comes to debugging the MGM. The scripts are not only used by the expert at CERN, but also by the developers to require help from the hotline (ie: Hexagon™).

Issue Encountered

The original MGM application was developed following specifications for all the modules used to align the magnet components. From 2001 on, tuning of the application has been done on the fly and not always well documented. For this reason, details and specifications for the new version has to be sought for in the VB code. Doing the first automation of a laser tracker in 2001 using Axyz was already a challenge and the developer team had to contact Leica Geosystems™ hotline regularly for information about the hardware and the software. Now, the hardware is under the responsibility of Leica Geosystems™ and the software is under the responsibility of Wilcox™. This dual interface makes it challenging to find the right answer to a technical question involving both parts, even if Hexagon™ is managing both teams.

PC-DMIS scripting has mainly been made to automate tasks, still showing its main user interface to the operator. However, the task automation had to be transparent for the end users. A large amount of work was needed to find workarounds and to be able to play the measuring sequence in the required way.

PC-DMIS is a high level application capable of interfacing lots of different hardware and contains specialised modules for many companies. This gives thousands of objects that can be selected. Magnet manufacturing is a very narrow fields and MGM is making use of a small part of this application. For this reason, it is sometimes challenging to point out the right methods, properties or events to be used

Some functions have been added into PC-DMIS automation following requests from companies or from CERN. For instance, the function called “bundle”, used to link measurement from several laser tracker positions, was only accessible in manual operation in PC-DMIS2009 while it was a built-in feature with Axyz. From PC-DMIS2010 this feature is also accessible from the automation mode on our request.

Speeding Up Development and Maintenance

Designing the MGM with Visual Basic™ in 2001 was a real challenge. Not for the code writing itself, but the user interface and all the graphical goodies were all homemade. The mathematical treatment and graph display was taking so long to be developed in Visual Basic™ that it was already decided to develop separate modules in LabVIEW™ for these purposes. Now that LabVIEW™ has been chosen for the main application, access to the ActiveX component are just as easy as with Visual Basic™. However, the calculations, displays and data storage were already built-in functions that only needed to be arranged together.

To ease the development, a LabVIEW™ to PC-DMIS library of drivers has been created including the main functions required for the MGM. Then for each alignment module, the developer will not have to go through the entire PC-DMIS library again. If a desired function is not available, it can easily be added to perfect this LabVIEW™ to PC-DMIS palette. Each of these components is documented using the built-in online help from LabVIEW™. A homemade tool extracts this help file to create an html file, ready to be published on the web.

At the level of the application, the MGM functions are documented with a text document explaining in broad terms the action performed, and a flowchart describing in detail the action executed (Figure 4).

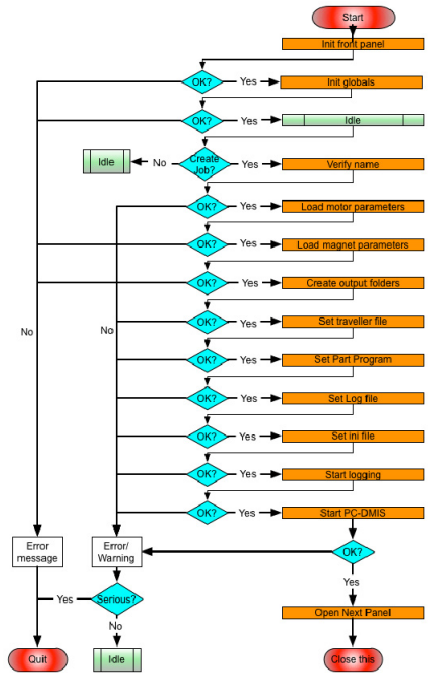

Figure 4: Flowchart for the MGM startup sequence.

A set of configuration files has also been put in place to take care of the hardware and the tolerances for the different types of magnets, as well as a database of points.

CONCLUSION

The existing MGM Visual Basic™ application has given successful results during the magnet construction for the LHC. Now the new system looks promising and the development time has been shortened a lot using LabVIEW™ and a homemade dedicated palette to PC-DMIS. The next step could be to develop a second palette for LabVIEW™ to emScon to avoid using the heavy environment of PC-DMIS for small automations.

THE EVOLUTION OF THE CONTROL SYSTEM FOR THE ELECTROMAGNETIC CALORIMETER OF THE COMPACT MUON SOLENOID EXPERIMENT AT THE LARGE HADRON COLLIDER*

O. Holme, D. Di Calafiori, G. Dissertori, W. Lustermann, ETH Zurich, Switzerland
S. Zelepoukine, ETH Zurich, Switzerland and University of Wisconsin-Madison, U.S.A.

Abstract

This paper discusses the evolution of the Detector Control System (DCS) designed and implemented for the Electromagnetic Calorimeter (ECAL) of the Compact Muon Solenoid (CMS) experiment at the Large Hadron Collider (LHC) as well as the operational experience acquired during the LHC physics data taking periods of 2010 and 2011. The current implementation in terms of functionality and planned hardware upgrades are presented. Furthermore, a project for reducing the long-term software maintenance, including a year-long detailed analysis of the existing applications, is put forward and the current outcomes which have informed the design decisions for the next CMS ECAL DCS software generation are described. The main goals for the new version are to minimize external dependencies enabling smooth migration to new hardware and software platforms and to maintain the existing functionality whilst substantially reducing support and maintenance effort through homogenization, simplification and standardization of the control system software.

INTRODUCTION

The CMS ECAL DCS monitors the environmental conditions and provides control and supervision over the powering systems of the ECAL detector which forms part of the CMS experiment at CERN. The ECAL detector consists of three partitions: Barrel, Endcaps and Preshower. In total, the system comprises 972 temperature sensors, 180 humidity probes and it provides control of over 1400 bias voltage and 1000 low voltage channels. The details of the control system architecture and the operating status have been reported previously [1,2].

The CMS ECAL DCS software is built upon the supervisory control software called WinCC Open Architecture (WinCC OA) [3], formerly Prozess Visualisierungs und Steuerungs System (PVSS), from ETM professional control. The CERN developed JCOP (Joint COntrols Project) Framework [4] provides extensions to WinCC OA for the high energy physics domain and was used to facilitate the development process. The system was built over a period of more than seven years. During that time, there have been contributions from nine software developers and four hardware developers.

The CMS ECAL DCS models each piece of hardware as a separate device object. Using the JCOP Framework, the devices are organised in hierarchies, which provide views of the system in terms of off-detector hardware layout or on-detector location. One particular hierarchy includes a Finite State Machine (FSM) implemented with SMI++ [5] which provides a way to summarise the state of the whole detector and to disseminate high level actions such as power switching. The FSM is also used to sequence actions and to perform automatic protection actions when conditions of the detector deviate from the normal range.

The JCOP Framework provides several other useful features, including a Configuration Database (ConfigDB) which is used to store details of the device configuration and of groups of hardware settings, known as recipes. These features were used in parts of the control system and the application of this tool is being extended throughout the system.

The CMS ECAL DCS runs on 14 computers with all WinCC OA applications being linked together in a distributed system. The CMS ECAL DCS is integrated into the CMS DCS [6], which aggregates all sub-detector control systems.

EXPERIENCE FROM LHC DATA TAKING

Throughout the 2010 LHC data taking period and so far during 2011, the CMS ECAL DCS has shown high levels of availability and has proven to be capable of taking protective actions based on anticipated safety hazards. A 24/7 expert on-call service has ensured that requests for actions on the detector and fixing of problems are carried out promptly. All of these factors have contributed to a high level of readiness for data taking.

Statistics from October 2010 to August 2011 from CMS DCS indicate that the ECAL had a readiness of 97.8% during periods when LHC was delivering stable colliding beams. These data represent a combination of all services such as the DCS, the bias voltage, the low voltage and cooling. The predominant factors contributing to the 2.2% of non-ready time include failures of power supplies and problems with external infrastructure such as delivery of chilled water. The DCS itself was responsible for almost no downtime.

Outside LHC data taking periods, the CMS ECAL DCS continues to monitor the conditions of the detector and enables parts of the detector to be powered on and off as required. This means that the control system software must be available all of the time. Experience shows that the DCS applications have high availability and that most down time is due to planned software upgrades as well as planned and unplanned cuts of power to the DCS computers. In 2010, there was a period of degradation in a temperature monitoring system that forms part of the

*Work supported by the Swiss National Science Foundation

DCS. This was due to a single fault in the power distribution that meant that all temperature probes from one of the monitoring systems could not be read out. Work to overcome this issue is ongoing and will be discussed in the next section.

Records have been kept of the activity of the on-call service for a period of more than 12 months. The on-call activities are two-fold; detector operation during development phases and fast trouble shooting in LHC data taking periods. The data show that the frequency of trouble shooting requests has considerably dropped in the past year. This demonstrates that the software improvements, based on the feedback from the operators, combined with an increase in overall operating experience have lead to a smoother operation of the ECAL detector.

HARDWARE UPGRADES

Changes to the hardware were performed during 2011 in order to further improve the control system robustness as well as to lower its recovery time in case of faults.

The first change was a modernisation of the Controller Area Network (CAN) bus [7] interfaces. PCI-based CAN cards installed in the DCS computers have been replaced by external USB-CAN interfaces from SYS TEC Electronic GmbH [8]. These allow readout of CAN based devices via USB ports and this will save time if a faulty CAN-equipped computer needs to be replaced because there will be no need to transfer the PCI card between machines. Instead, the only step required is to connect the USB-CAN interface box and install the necessary drivers. A software library [9] from the CERN Industrial Controls & Electronics (ICE) group enabled a transparent migration between PCI-CAN and USB-CAN interfaces.

From the experience in 2010 with the fault in the temperature monitoring system, it was decided that the power distribution for this system should be improved. This involved sourcing new power supplies and constructing new power distribution blocks that allow individual switching of power to each CAN-based readout device. The system was divided into two independent parts, limiting the impact of a single fault and allowing independent power interlocks.

Further upgrades are under development. One of them aims to provide relative humidity measurements below 60% using the installed humidity probes, which is presently not possible. This system will use custom readout electronics communicating with WinCC OA via Modbus [10]. The system is being developed and manufactured at the University of Belgrade, Serbia. The Modbus data channel will be converted to Modbus TCP with a Modbus RTU-TCP adapter such that the data can be read via the standard CMS Ethernet network.

Finally, an upgrade of the Preshower bias voltage distribution system is foreseen. In the Preshower, each power supply bias voltage channel is distributed to multiple detector elements. The extension presently developed will provide greater granularity for the monitoring of currents drawn by the Preshower detector elements. While not solely a DCS issue, this additional monitoring system will require both software and hardware changes by the CMS ECAL DCS team.

SOFTWARE ANALYSIS PROJECT

Due to a reduction in the number of people working on the CMS ECAL DCS project after CMS commissioning it was essential to focus on the long term maintainability of the system.

The system functionality can be divided into monitoring applications and combined monitoring and control applications. These applications were originally assigned to individuals who then developed the software to achieve the control and monitoring goals of that application. This approach enabled the system to be delivered on time and with sufficient functionality to operate the detector.

In the current phase of the project the approach is different, with a central team of three developers being responsible for the whole DCS. This has required a large shift of information from the original developers to this new core team. During the process of centralising the detailed information about the software, certain aspects were identified that could be improved upon or standardised between applications.

As the software met all the operational requirements, the team was able to concentrate efforts on investigating ways to streamline and standardise the software. This led to the creation of the CMS ECAL DCS Software Analysis Project which took place throughout 2010. The goals of the project were to evaluate the existing software and identify ways in which the support and maintenance load over the next years of LHC operation could be reduced. This involved discovering potential simplifications, identifying areas of weakness and revisiting the original design assumptions that were embedded in the code during the original development. As the control system must run for several years, it is unavoidable that its operating environment will change. For example, operating system versions and WinCC OA versions will continue to evolve. Plans are already in place to upgrade the computers with considerably different hardware. So the analysis project considered the preparedness of the software to handle transitions such as these.

The analysis project delivered a detailed investigation of each application. This consisted of both static code analysis and dynamic analysis of the running application. The following aspects were evaluated:

- Security.
- Use of JCOP Framework and CMS DCS tools.
- Efficiency of architecture and implementation.
- Dependencies on software versions.
- Interfaces to external systems.
- FSM logic and hierarchy.
- User interface functionality and look and feel.

As an additional benefit, the analysis project produced detailed written documentation of the internal workings of the system. Previously, the documentation was focussed more on operating the software rather than how to

maintain it. As the original developers began to leave the project, detailed maintenance documentation became a high priority.

The final stage of the system analysis was the summarising and integration of the individual application analyses. This stage provided particularly good findings regarding features that could be factored out and made into generic components. Also, the compatibility amongst applications was studied to evaluate the feasibility of running multiple applications on the same machine. This would enable the number of computers to be reduced and allow more efficient use of the new generation of powerful computers.

SOFTWARE ANALYSIS OUTCOMES

Results

The process of analysing the software was successfully completed by October 2010.

The metric of lines of code (LOC) is useful to indicate the effort required to understand and maintain a code base in the long term. The total LOC of the CMS ECAL DCS is 200,000. The code required for installation and core monitoring and control functionality accounts for 40,000 LOC. The remaining 160,000 LOC are dedicated to user interface code and graphical widget configuration.

The FSM was analysed and found to have around 4,000 low-level objects to model hardware devices. There were an additional 1,000 high-level objects that summarise the device data into a hierarchical structure. A total of 61 object classes are used to instantiate all 5,000 FSM objects. It was found that a reduction in the number of classes could be achieved by combining similar classes.

The analysis detected several bugs, highlighted some deficiencies in functionality and discovered security issues that had not been identified from the experience of using the software in the CMS environment. One particular area of concern was the installation process, which ideally should be fully automatic, but in many cases was seen to fail certain steps or require additional manual configuration after installation.

In terms of consistency between components, it was noticeable that each application was developed by a different developer. Where common interfaces were required between applications, these interfaces had been defined and adhered to. Internally, architectural concepts, naming conventions, coding styles and the amount of use of the JCOP Framework varied between applications.

Planning

With the qualitative and quantitative results of the software analysis, it was possible to take informed decisions about how to reduce the maintenance effort of the system. Due to the proven stability of the existing software, it was essential that any plan for developments should not compromise the current reliability. On the other hand, there were several changes that could clearly provide benefits by reducing the complexity and heterogeneity of the software.

Two possible strategies were considered for the renewal of the CMS ECAL DCS applications. The first was to take a radical approach and re-write complete or significant parts of the existing applications. The alternative strategy was to focus on specific elements of the applications and to substitute relatively small functional blocks with newly improved elements. The former approach offered the possibility to start from scratch and re-develop a system with the advantage of the considerable knowledge acquired in the development of the existing software version. The latter piece-by-piece method provided a more cautious way to target specific problematic areas while preserving the remaining structure and code of the application.

A decision was taken to follow the piece-by-piece approach to resolve a series of issues throughout 2011. This strategy minimized the risks of altering the source code while still providing a way to significantly improve the software. With this approach, goals such as the global standardisation of function names and data object names are immediately out of scope as these would require a complete overhaul of the software. However, the benefits of a broad code cleanup did not outweigh the risks, so it was decided to keep the majority of the existing code, including its known imperfections.

The piece-by-piece approach made it possible to deploy the improvements into the production environment with minimal delay. The LHC has regular technical stops throughout the year, roughly every two months, providing opportunities to update systems without compromising LHC data taking. A laboratory setup was available for testing and validation of the software. This setup has recently been upgraded to include a computer of the new type foreseen to be introduced in CMS DCS, enabling realistic performance tests to be undertaken.

The analysis project highlighted areas in the user interface where improvements or standardisations could be made. However, operators are used to the existing screens, so only a small set of important changes were put in the software development plan.

MAJOR DEVELOPMENTS

Essential Modifications

The first priority in terms of development was to fix the security issues. These were resolved by following the CERN security team guidance [11].

The second priority of development was to ensure that the applications of CMS ECAL DCS could be installed with a completely unattended process. This is important to reduce downtime that occurs when a computer fails and the application has to be installed on a new computer. As a short term measure, work was done to improve the existing installation procedures for each application. These changes were tested in December 2010 during a long shutdown of CMS where a complete re-installation of the CMS ECAL DCS software was performed. The results showed that the installations could be completed

with almost no user interaction, although some work remained to achieve a completely unattended installation.

Configuration Database

In early 2011, emphasis was placed on moving hardware and software configuration data and hardware setting recipes into the ConfigDB. Some applications used the ConfigDB previously, but none made use of the full range of possibilities available.

One desirable feature was the facility to apply and verify hardware settings each time before switching on the low voltage and bias voltage channels. This approach ensures that all settings are correct before switching on the voltages and was previously available in the low voltage application only. In order to deploy this functionality across the whole CMS ECAL DCS, a new generic component was written that was capable of interacting with the FSM and the ConfigDB to apply recipes on demand and then verify that these have been correctly applied. In addition, the software checks to see if there is any spontaneous change of hardware settings that deviate from the stored recipe values. This component was based on development already undertaken by the CMS Tracker DCS team [12], which in turn was inspired by a tool provided by JCOP. A new generic component was designed and implemented for the CMS ECAL DCS with a view to it being used elsewhere in the CMS DCS. This component was first deployed in the CMS DCS in April 2011 and the component was integrated into all the CMS ECAL DCS applications that control low voltage and bias voltage power supplies.

Installation Mechanism

The installation procedures of the individual CMS ECAL DCS applications were all developed individually and although they all performed similar steps, the approaches were very different. From the analysis of the installation procedures, it was noted that there was a considerable mixing of code and data. As a result, each application was tuned to perform the required installation but the code to execute these steps was not generic. Based on the work performed to concentrate the configuration data in the ConfigDB, there was an opportunity to standardise and streamline the installation process.

A new data driven installation method was developed, where a single generic installation mechanism can install any application. To achieve this, a custom data object was defined that contains the data required to drive the installation process. A common piece of code interprets this data at installation time to perform all the necessary steps to setup the system. The first unattended application installation using this method was in July 2011.

SOFTWARE STATUS

The changes in the CMS ECAL DCS software so far have yielded a reduction of around 20% in the number of lines of code, when excluding the user interface. This equates to around 8,000 lines of code and has been achieved with no loss of functionality. In fact additional functionality has been added including a new application displaying the status of equipment racks.

Further developments are planned to factor out common functionality and reduce the overall software complexity. An associated reduction in LOC is anticipated. Particularly in light of the upcoming hardware changes to some CMS ECAL DCS monitoring applications, the option to make a more radical redevelopment of certain applications will be reassessed.

Changes to some applications are required to ensure that multiple applications can run together on a single computer. Performance tests are also required to test that such combinations are feasible.

CONCLUSIONS

Experience from 2010 and 2011 shows that the CMS ECAL DCS meets the required standards and has matured into an extremely reliable system. Changes have been made to the software and hardware to ensure reliability of operation and reduction of the maintenance load. The changes were implemented in a piece-by-piece way to minimize the risk associated with modifying a working system. This strategy also enabled deployment during regular technical stops of the LHC. The control system now has greater functionality even though the code base of the project has been significantly reduced. As a result of changes to both the hardware and software, the system is more robust for LHC data taking periods and better prepared for future hardware and software changes.

FIRST EXPERIENCE WITH VMWARE SERVERS AT HLS

G. Liu*, X. Bao, C. Li, J. Wang, K. Xuan, NSRL, USTC, Hefei, Anhui 230029, China.

Abstract

Hefei Light Source(HLS) is a dedicated second generation VUV light source, which was designed and constructed two decades ago. In order to improve the performance of HLS, especially getting higher brilliance and increasing the number of straight sections, an upgrade project is undergoing, accordingly the new control system is under construction. VMware vSphere 4 Enterprise Plus is used to construct the server system for HLS control system. Four DELL PowerEdge R710 rack servers and one DELL Equallogic PS6000E iSCSI SAN comprises the hardware platform. Some kinds of servers, such as file server, web server, database server, NIS servers etc. together with the softIOC applications are all integrated to this virtualization platform. The prototype of softIOC is setup and its performance is also given in this paper. High availability and flexibility are achieved with low cost.

INTRODUCTION

Hefei Light Source (HLS) is a dedicated second generation VUV light source, which was designed and constructed two decades ago. In order to improve the performance of HLS, especially getting higher brilliance and increasing the number of straight sections, an upgrade project is started from the end of 2009. This provided an opportunity to reconstruct the server system. The old server system includes several SUN workstations and some rack-mount servers providing file services, net services, database services and development environments, and these computers were all purchased 5 years ago. These years virtualization technology is applied widely, for example, it is applied successfully at CLS[1]. After evaluating the performance and cost, VMware vSphere 4 Enterprise Plus is chosen to build the new server system. Besides file services, net services, database services and development environments, softIOC applications will be also integrated to this new virtualization servers.

HARDWARE AND SOFTWARE SYSTEM

After making the decision to use virtualization technology to construct the server system, VMware vSphere 4 Enterprise Plus is chosen because it is a mature product and used most widely. The products of Dell are chosen to build the hardware platform, which consists of 4 Dell PowerEdge R710 rack servers, 1 Dell PowerEdge R210 rack server and 1 DELL Equallogic PS6000E iSCSI SAN. The figure 1 is the photo of the server system.

The technical specification of Dell PowerEdge R710 is below:

- 2 Quad-core Intel Xeon 2.53GHz processors
- 48GB DDR3 memory
- 64GB SSD
- 8 1Gigabit Ethernet ports

Figure 1: Photo of HLS server system.

The Dell Equallogic PS6000E iSCSI SAN is configured with 16*1TB SATA disk, 8*1Gigabit Ethernet ports, dual power supplies and dual controllers. It runs RAID 6 and has a hot spare drive. The usable disk space is about 11.34TB, as shown in figure 2.

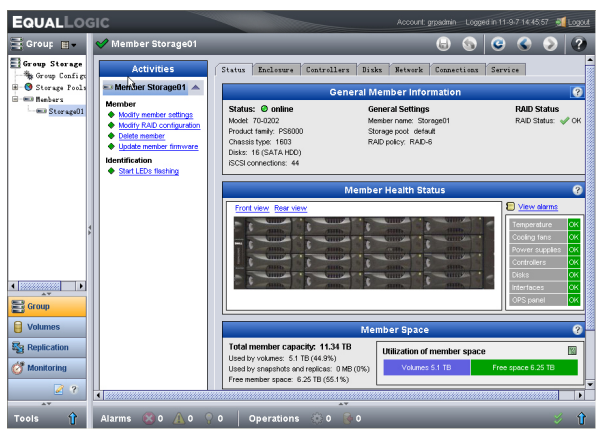

Figure 2: Management interface of Dell EQ iSCSI SAN.

The network topology is very important to the communication performance of server system. 2 switch are adopted, one for storage, the other for product, as shown in figure 3.

*gfliu@ustc.edu.cn

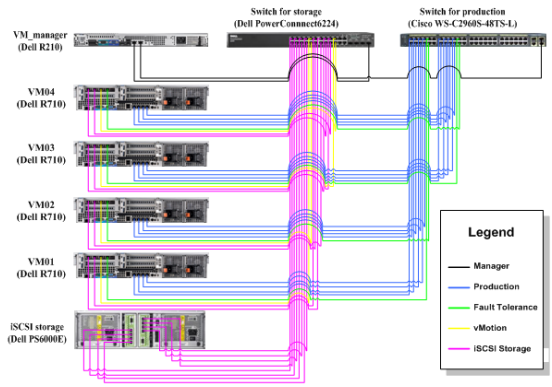

Figure 3: Network topology of HLS server system.

The virtual machine list is shown in figure 4. The virtual machine "Develop_Server" is used as the development environment, which runs CentOS5.5, "Database_Server" runs Orace10gR2, "File_Server" provides files service and svn repository, "PS_ioc" is the server for softIOC, other virtual machines are for pre-configured templates and operating system tests.

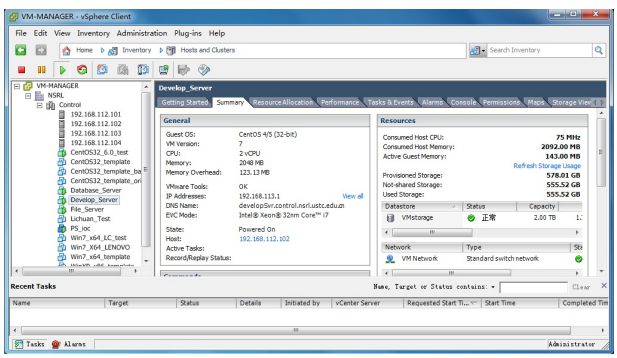

Figure 4: VMware vSphere client.

The following 4 features are related to the availability[2]:

- VMware vMotion. It enables the live migration of running virtual machines from one physical server to another with zero down time, continuous service availability, and complete transaction integrity.
- VMware Storage vMotion. It enables the migration of virtual machine files from one datastore to another without service interruption.
- VMware High Availability(HA). It provides high availability for virtual machines. If a server fails, affected virtual machines are restarted on other production servers that have spare capacity.
- VMware Fault Tolerance. When Fault Tolerance is enabled for a virtual machine, a secondary copy of the original (or primary) virtual machine is created. All actions completed on the primary virtual machine are also applied to the secondary virtual machine. If the primary virtual machine becomes unavailable, the secondary machine becomes active, providing continuous availability.

When VMware vMotion, VMware Storage vMotion and VMware Fault Tolerance are tested on the virtual machine "Develop_Server", the users of "Develop_Server" are unaware during the virtual machine migration. It looks that the service is continuous. However, VMware High Availability(HA) is related to virtual machine restarting, the service interruption is not ignorable.

THE AVAILABILITY TEST OF SOFTIOC

In order to investigate the availability of softIOC, a test system is setup, as shown in figure 5. A softIOC runs on a virtual machine, it communicates with 2 Agilent 34970A over MOXA serial device server NPort6650. A DAC board is installed on each Agilent 34970A. A SNL program running on the softIOC controls the output of each DAC board, the waveform is triangle with100ms step and is monitored by the oscilloscope Tektronix DPO4054.

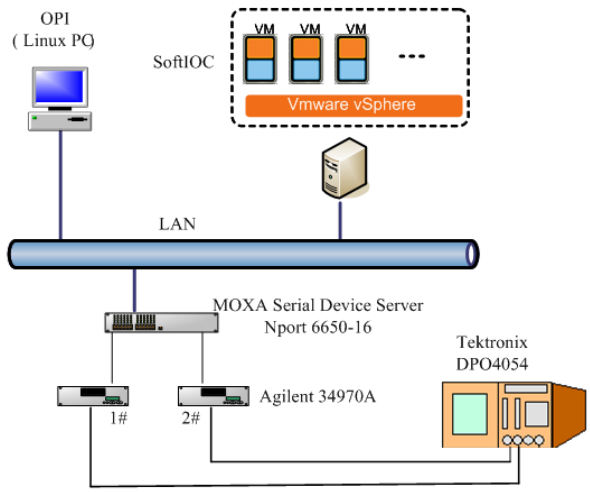

Figure 5: Hardware structure of SoftIOC test system.

The test results for VMware vMotion and VMware Fault Tolerance are shown in figure 6 and figure 7.

The figure 6 is the monitored output waveform during VMware vMotion, the interruption time is about 1600 ms. The figure 7 is the monitored output waveform during VMware Fault Tolerance, the interruption time is about 2600 ms. Although the down time is not zero, it is acceptable in our case.

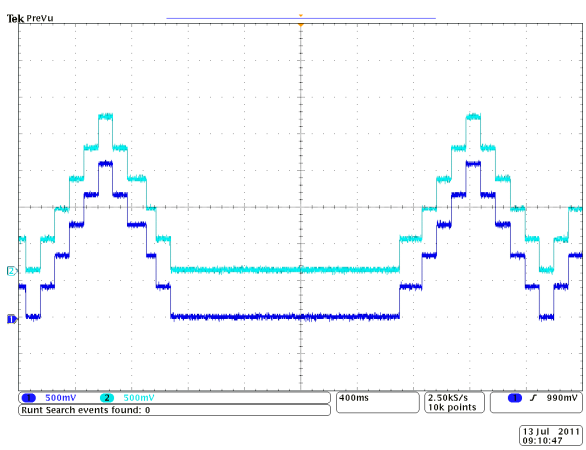

Figure 6: Output waveform during VMware vMotion.

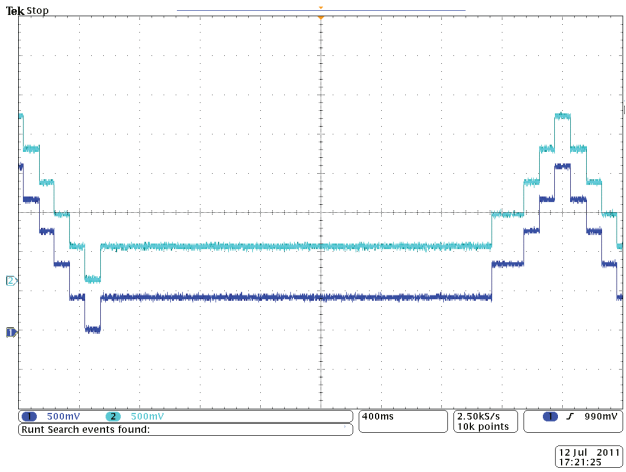

Figure 7: Output waveform during VMware Fault Tolerance.

CONCLUSION

Our first experience with VMware servers shows that the virtual infrastructure can provide a reliable, flexible, extensible and manageable environment. The down time of services during virtual machine migration is not zero, but it is acceptable at HLS. Although VMware vSphere is not cheap, cost per virtual machine will be lower when increasing the number of virtual machines.

THE UPGRADED CORRECTOR CONTROL SUBSYSTEM FOR THE NUCLOTRON MAIN MAGNETIC FIELD

V.A. Andreev, V.A. Isadov, A.E. Kirichenko, S.V. Romanov, G.V. Trubnikov, V.I. Volkov,
JINR, Dubna, Moscow Region, Russia

Abstract

This report discusses a control subsystem of 40 main magnetic field correctors which is a part of the superconducting synchrotron Nuclotron Control System (NCS). The subsystem is used in static and dynamic (in dependence of the magnetic field value) modes. Development of the subsystem is performed within the bounds of the Nuclotron-NICA project.

Principles of digital (PROFIBUS-FLNR RS-485 protocol) and analog control of the correctors' power supplies, current monitoring, remote control of the subsystem via IP network, are also presented. The first results of the subsystem commissioning are given.

INTRODUCTION

The superconducting synchrotron Nuclotron [1] is one of the JINR basic facilities. It is intended to produce beams of charged ions (nuclei), protons and polarized deuterons with energies up to 6 GeV per nucleon.

The existing magnetic structure of the Nuclotron consists of 8 superperiods. Each superperiod includes 3 Regular FODO-periods and 1 period with a long drift space between the lenses. A regular FODO-period consists of one focusing and one defocusing quadrupole lenses each 0.45 m long, four dipole magnets each 1.5 m long and two free spaces for multipole correctors and diagnostics equipment placement. A long drift space is occupied by injection and extraction magnets, the internal target and etc.

The particle orbit is deformed in the real magnetic structure because of various kinds of perturbations which affect negatively on the accelerator complex operation. The orbit correction system (OCS) brings compensative perturbations of the same kind in the magnetic structure of the accelerator. The purpose of the OCS is to correct the equilibrium orbit and provide its stable position during acceleration process.The system consists of 40 correcting multipole superconducting magnets (21 horizontal and 19 vertical).

The control subsystem of the OCS is integrated to the Nuclotron Control System [2]. It gives the accelerator operators the opportunity of wide and flexible control of the correction system from the OCS console as well as from any authorized workstation of the Nuclotron LAN [3].

THE CONTROL SUBSYSTEM STRUCTURE

The common structure of the corrector control subsystem is illustrated in Fig. 1.

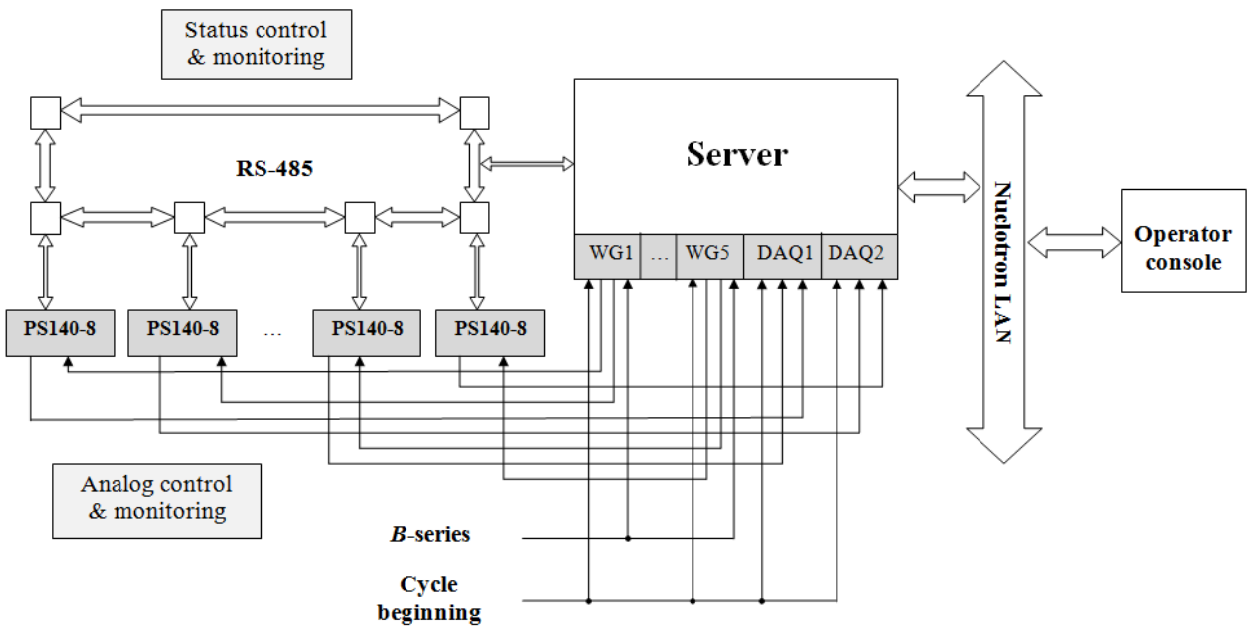

Figure 1: The control subsystem structure scheme. WG means waveform generator, DAQ – data acquisition board.

Power Supplies

The correcting multipoles are supplied by PS140-8 – the sources of current which were specially designed to supply electromagnetic elements of accelerators by «EVPÚ a.s.» (Slovakia). These sources replaced the out-of-date previous ones which had the insufficient output current range and stability. The PS140-8 power supply is a transistor converter serving as a source of DC current for R-L load with high stability of time and thermal conditions. The output current is regulated within the range of 0 to 140 A by a corresponding input signal between 0 and 10 V. The power supplies can work in a static mode as well as in a dynamic one with the current change rate from 0 to 100 A/s.

As it is mentioned above the PS140-8 output current can be controlled remotely by the external voltage reference signal. Such commands as load switching on and off, checking of the power supply status, changing of the load current direction and so on, can be carried out remotely via communication channel RS-485 (protocol – PROFIBUS-FLNR).

The Subsystem Server

The main part of the control subsystem is a rack-mounted industrial PC. It performs all interactions with power supplies such as generation of reference signals, monitoring of the power supply output current and status controlling. The server also provides the remote control of the subsystem via IP-Network (see The Control Subsystem Software section below).

Waveform Generators

To produce a reference signal of the output current we have used five National Instruments NI6733 PCI boards installed in the server backplane. These boards provide eight 16-bit resolution analog output channels with the update rate up to 1 MS/s. As it is mentioned above there are two modes of the correction system operation: static and dynamic. In the static mode the output power supply current is permanent during acceleration. If it is necessary to change the output current value the NI6733 module generates the corresponding gradual transition of the voltage. In the dynamic mode the power supply current depends on the instant value of the main magnetic field. So the image of this relation function is written to the waveform generator memory. The Nuclotron B-timer is used as an external clock source for the NI6733. Every B-timer pulse corresponds to magnetic field changing by 10^{-4} T (repetition rate is up to 10kHz).Also the module is triggered by a digital signal of “acceleration cycle beginning” in this case.

Data Acquisition Modules

For monitoring of the power supply output current two National Instruments NI628433 PCI boards are used. These modules are also installed in the subsystem server backplane. The NI6284 DAQ board provides 32/16 single-ended/differential analog input channel with an 18-bit resolution. In the dynamic mode these modules are triggered by the “acceleration cycle beginning” pulse as well as waveform generators. In the static mode DAQ boards work continuously writing the acquired waveforms to the server memory every 4 seconds.

RS-485 Communications

For status operations the subsystem server interacts with PS140-8 via RS-485 interface forming a ring topology. This communication runs on 115200 baud speed. The MOXA CP-132 PCI board provides a RS-485 interface on the server side. Power supplies are grouped on ten boxes placed along the accelerator ring. Links between the boxes are made with multi-mode fiber optics. The conversion between the fiber and serial interfaces is provided by the MOXA TCF-142-M module.

Network and Remote Station

The Nuclotron Control Room is placed 400m away from the accelerator hall where the power supplies and subsystem server are located. So it is necessary to have a remote control of the subsystem. The remote control is carried out via 1 GbE Nuclotron LAN (which is a subnet of the LHEP/JINR network). The operator can access the subsystem server from any authorized workstation connected to the LAN and running the special developed client software.

THE CONTROL SUBSYSTEM SOFTWARE

The software complex of the OCS control subsystem consists of two parts: application running on the subsystem server and client application running on operator workstations.

Server Software

The application running on the server computer performs the following main tasks: power supply status control, power supply output current setting and monitoring, data presentation and remote control providing.

To monitor the state of the PS140-8, the server starts separate thread for scanning all the power supplies in a specified address range along the RS-485 network. The thread requests the detailed status from every detected power supply and displays it on the corresponding panels of the server GUI (see Fig. 2).

One can see that the operator can give a command to power supplies to turn the load on and off, change the output current polarity and reset the error signal. It is also possible to set the output current value (in the dynamic mode it means that the current corresponds to the main magnetic field at the beam injection level). It should be noted that the waveform generators produce a reference signal for the power supply only if its load is on.

The acquired waveforms of the power supply output current may be displayed in the assembled diagram on the server application form (see Fig. 3).

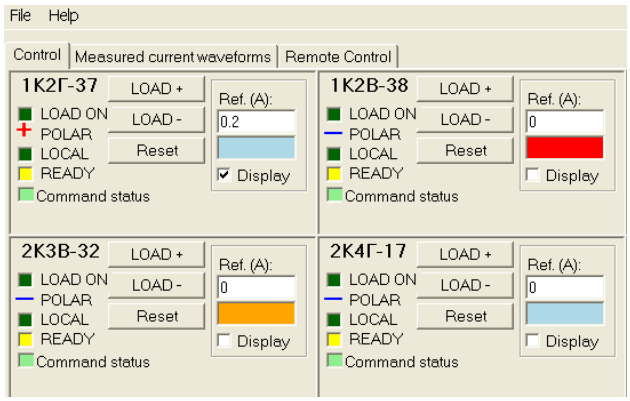

Figure 2: The PS140-8 control panels.

For the remote control realization the server starts another separate thread. It listens, checks and serves the incoming connection from the operator workstation. Any information acquired from power supply is sent to the remote client immediately.

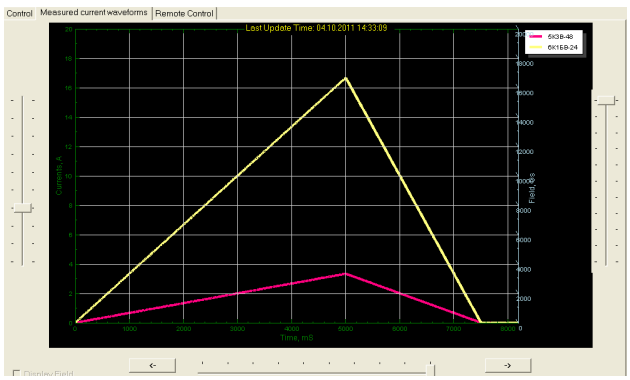

Figure 3: The assembled diagram of the acquired current waveforms.

Remote Client software

The main conception of the subsystem remote control is that the authorized user can operate corrector power supplies from the remote station just the same way as from the subsystem server console. The remote client application interface is practically identical with the server one. The server supports only one remote connection simultaneously to maintain the operation consistency. Communication between the server and remote client applications is carried out by the socket technology. The Client and Server were both developed for the .NET Framework.

FIRST RESULTS OF THE SUBSYSTEM EXPLOITATION

The new corrector control subsystem was put into operation in November, 2010. During the two latest Nuclotron runs it worked in the static mode. The subsystem has proved to be an effective instrument of the accelerator tuning. As a result of the modernized OCS exploitation the intensity of the deuteron beam (accelerated to the energy corresponding to the main magnetic field - 0.2 T) reached $5 \cdot 10^{10}$ particles [4]. It is planned to use the OCS in dynamic mode during the next Nuclotron run (November-December, 2011).

At the moment the development of the project NICA (Nuclotron based Ion Collider fAcility) [5] is carried out at JINR. The experience of the corrector control subsystem construction can be used in another part of the NICA complex – a superconducting Booster [6].

SARAF BEAM LINES CONTROL SYSTEMS DESIGN

E. Reinfeld, I. Eliyahu, I. Gertz, A. Grin, A. Kreisler, A. Perry, L. Weissman,
Soreq NRC, Yavne, Israel

Abstract

A new beam line was constructed and operated for the first phase of the SARAF LINAC in order to deliver beams to various experiments. In this report concept of the beam line and different subsystems are presented. The details on the hardware and control software are given.

INTRODUCTION

The first phase of the linear accelerator of Soreq Applied Research Accelerator Facility (SARAF) has been commissioned [1]. At the moment CW proton beams at energy up to 3.5 MeV and at intensity up to 1 mA are routinely operated, while deuterons beams at energy up to 4.8 MeV and beam intensity up to 1 mA are operated only at low duty cycle. A new beam line was built in addition to the existing beam dump line, in order test new targets while protecting the superconducting LINAC from dirt coming from the target. The beams are delivered to several experiments which have broad range of requirements. The new beam line infrastructures consist of several interconnected parts: magnetic beam optics elements, beam diagnostics elements, vacuum control and machine safety system (MSS) [2].

CONTROL OF BEAM OPTICS ELEMENTS

The purpose of the magnets control is the providing the magnet currents necessary for beam transport. The control system also provides the "magnets ready" interlock for the accelerator MSS. The following magnetic elements were used for control of beam optics: 1) Two 45° dipole magnets for transporting the beam to the new beam line. 2) Five quadruples lenses (two doubles and one single) for containing the beam and preparing the required beam spot for various targets. 3) two x-y steer magnets. All the magnets except the first doublet are water cooled. The thermo switchers with 60° limits are placed on the magnet coils. Some of the magnets (dipoles, a quadruple and steers) were DANFYSIK. The two doublets were recuperated from other institutions.

The magnet control hardware located in a mountable rack located in the RF Hall (approximately 30 meters from the magnets). It is containing NI compact reconfigurable Input/Output (cRIO) platform control system and the appropriate power supplies for each magnet.

The rack includes the following elements:

1. NI AI-9201: Analog input for reading the current of the different power supplies.
2. NI AI-9264: Analog voltage Output for setting the current of the different magnets.
3. NI AI-9425: Digital Input, for indication of the operation status of the power supplies and input signals for the accelerator MSS.
4. NI AI-9476 : 32-Channel, 24 V, Sourcing Digital Output, for operation of the powers supplies.
5. GenesysTM power supplies for dipole and quadruple magnets.
6. Delta Elektronika power supplies ES030-5 with changeable polarity, for the steerer magnets.

The control system provides "magnets ready" signal for the accelerator MSS. This signal requires the conditions when all the power supplies are enables, the chain of thermo switchers is intact and the current values on the dipole magnets in the predetermined range. The power supplies could be enabled only when there is sufficient magnet cooling water flow. The beam transport condition (beam line rather than beam dump) is chosen by signal received from the accelerator control system. In the case when the beam dump line is chosen the current on the first dipole is forced to be zero in order to get "magnets ready" signal.

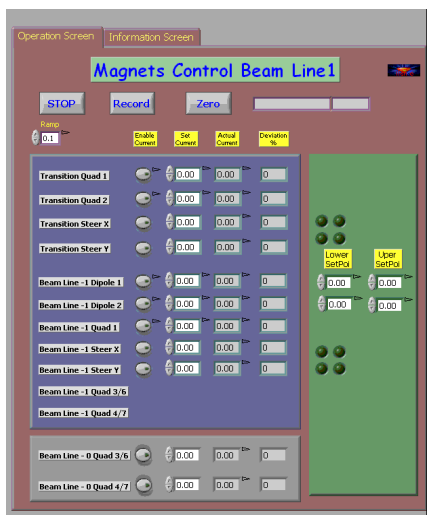

Figure 1: Beam lines magnets control system HMI.

The main screen of the magnets control application is shown in Figure 1. The application allows the user to see whether the beam line or the beam dump is chosen for beam transport. The user enables the magnet supplies and set the desirable currents. The system presents the output current and the deviation from the required current for

every magnet. The magnets are ramped to the set values with a ramping speed which also controlled by the user. For the two dipole magnets the upper and lower current threshold can be set thus enable preventing damage to the accelerator. The Information screen presents the status of thermo switchers, cooling water flow, beam line selection switch [3].

BEAM DIAGNOSTICS CONTROL

The purpose of the beam diagnostics system is beam tune and preparation beam on a target within requirements of specific experiment. The control of the beam diagnostics facilitates operation of the diagnostics elements. it also protects beam diagnostics from damage from intense beam. The beam line diagnostics consists of three of X_Y wire-profilers stations and adjustable beam collimators ("4-jaw").

Each X-Y scanner station consists of two "forks" installed in a 6-way cross. An electrically insulated 150 micron thick tungsten wire is stretched between the ends of the fork. Both ends of the wire are connected to electrical feedthroughs, so the resistance of the wire can be tested externally. The forks are moved vertically and horizontally perpendicular to the beam axis using linear motion mechanisms (Huntington) and stepping motors (NI, NEMA 23 T21NRLC). On each motion axis there are two limit switches, aimed to restrict the fork movement and thus to avoid damage to the system. The motion of the vertical and horizontal scanners is not performed on the same plane, thus, eliminating the risk of mechanical collision. After introduction into the beam, electrical charge collected on the wire is converted into voltage signal using a 1kΩ resistor. The dependence of the wire signal on its position yields information on the beam profile. These wire scanners can work only in pulsed beam (diagnostic mode) at a relatively low duty cycle. To synchronize the signal from the wires the master accelerator trigger was used as a trigger for digitizer. The wire scanners can't be used for CW beam operation (normal mode).

The control system hardware is installed in another 19' rack mountable in the RF Hall. The system is composed of several subsystems:

1. PXI chassis – with real time integrated control 8108, 2.53 GHz dual core.
2. Motion controller PXI 7350.which provides a fully-programmable motion control for the six independent axes of motion.
3. UMI 7774 for connection of the stepper servo drives (feedback and digital I/O) to the motion controllers.
4. P70360 stepper driver reading the signals from the UMI and provides the desired current to the stepper motors.
5. Digitizer PXI 5105 60MHz with eight simultaneously sampled channels.
6. The PXI 6229 digital I/O card that is used for general purpose.
7. The Motion controller (National Electrostatic Corp) provides control of the Slit Motor Drives

The control software project includes two parts: the RT controller software (PXI) and the Host computer (PC). The host computer Vi's handle the graphical user interface (GUI) and data record, while the RT controller loaded to the PXI includes the main operation Vi's and the Shred Variable Library (SV). This configuration of the VI's makes it possible to run the main program on the PXI without the need to operate the host computer, making it much more reliable and robust.

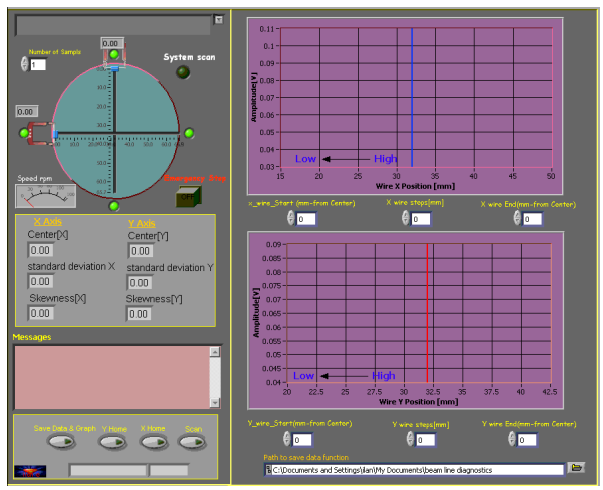

Figure 2: Diagnostics control system HMI.

Wire scanners control application is shown in Figure 2- The right part of the screen presents the scan results as an X-Y graph and the scan parameters. The profile characteristics: centroid, standard deviation and skewness, are presented in the left middle screen. The upper left corner presents the current wires positions, their velocity and operation status (scan mode). Additionally there is a message field for error notifications and scan status. At the bottom left corner the user sets the operation mode. The application allows the user:

1. Scan process: the system starts the scan process based on the defined parameters (range, steps).
2. Returns the wire to the home "out of beam" position.
3. Save data file and plot picture
4. Emergency stop of the profiler movement.

In order to prevent damage to the system there are several software protection features:

In the scan process the system will not start if both limits (Home and Forward) are inactive. b) Scan process will be stopped if the home limit in the perpendicular second axis is inactive. c) If the requested scan distance is greater than the distance between the limits, then the program will correct it automatically with a corresponding message. The "diagnostics out" signal based on the status of the profiler limits is sent to the accelerator MSS. The accelerator cannot operate in full power mode if the profilers are inserted in the beam pipe.

The High Power Beam Slits "4Jaw Collimator"

The National Electrostatic Corp 4Jaw Collimator is located at the end of the beam line. Its purpose is to scrap the beam tails and eliminate possibility of irradiation of the target vicinity. The system consists of four cylindrical elements which intercept and define a partial beam which passes between them. The elements are constructed of tantalum, and are directly cooled, by de-mineralized water. Each cylindrical element has a power dissipation >1000 Watts with highest working temperature up to 200°C. Position of each element can be varied in the range of 17 mm which defined by two limit switchers. The current from on each element can be read only for the case of CW beam. The data slit controller (from National Electrostatic Corp) handles the movement of the four slits.

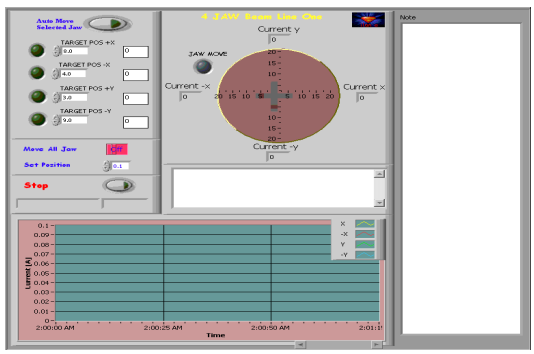

Figure 3: 4Jaws collimator control system HMI.

The main screen (Figure 3) enables the user to control the four slits. The right side of the screen presents the current location of each slit and the current evolving on it (mA). The left side enables the user to select which slit to move (by pressing the green button), and to which location (0-16mm). Moreover the user can choose to move all the slits simultaneously to the same location by using the command button “Move All”. The centre of the screen presents the messages centre. The evolving current (mA) is shown in a graph format at the lower part of the screen.

BEAM LINES VACUUM CONTROL SYSTEM OVERVIEW

SARAF vacuum control system was designed by ACCEL and commissioned at SARAF. The system was delivered to SARAF team to control the accelerator's seven vacuum sections. The control system was able to display the vacuum reading, operate gauges (open and close commands) and start the pumps.

When the first beam lines were constructed, they required additional control mechanisms and a new design concept was tailored to control the new vacuum sections. In addition, the older accelerator vacuum control system and the new beam lines control systems were unified into one control system which standardizes the display and operation, and creates common principles on which the control system operates (Figure 4) [4].

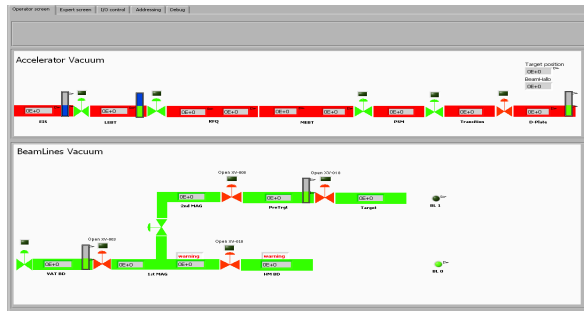

Figure 4: Vacuum control system HMI.

Principles of Design

The older accelerator control system is a simple system on which the raw information is displayed on screen with minimal processing (only scaling is performed on the vacuum readings to fit them to the various sensor types). Operation commands and statuses are also directly connected to the HMI and so no processing is done. Much unnecessary data was displayed on screen, as well as some dysfunctional controls which created an unfriendly system to use.

To correct these issues, a new display method was chosen, which minimizes the operators need to read and process the vacuum readings. The system was reorganized to display current status of the system according to a simple colour code, where green status is good (and open in case of gauge display), red status is bad (or closed), yellow status is hardware error and gray status is initial state. In normal mode, where all vacuum readings are correct and no set points were triggered, the display is all green.

The beam lines control system includes a control software element for every physical hardware element. This allows the system to be parametric, as each new addition of hardware such as gauges, pumps and sections requires a similar addition of compatible control element and with relative ease (Figure 5).

The control elements are all similar, and are configured by a central configuration method which is located at the HMI expert screen. The complex system which was implemented in the older accelerator vacuum system was reduced to a collection of control elements running in parallel and is reflective of the vacuum hardware elements installed in the facility.

Any information or feature which is not necessary and/or required during normal operation of the system was removed from the main operator HMI control panel and placed in the HMI expert screen. All configuration methods and features were placed in configuration tabs available to expert operators only.

Additional Features

As the system now shows a full view of the vacuum system, it allows the addition of new control displays such as beam blockers which are now displayed in the HMI operator screen. Additional layers of information can be added or removed from the HMI according to the operators requirements.

The control system processes the information retrieved by the control channels and indicates hardware errors in addition to good or bad operation status. Processing the current state of the vacuum system in real time also allows the implementation of machine safety procedures, so that the system can prevent the operator from making basic mistakes such as open gauges when they should not be opened.

The application includes an alarm scheme which warns the user from various situations such as gauge override command localized hardware issues.

Implementation

The system is implemented using Labview and National Instruments data acquisition (DAQ) devices. The parallel characteristics of the system require methods to prevent race conditions especially at the data out points. The parallel functions are managed by a top layer, which handles the I/O channels of the DAQ device. As there is only one DAQ device handling the I/O it has to be controlled via one connection from the control system. The management layer of the application communicate with the control elements, and convey the current snap shot of the output signals to the DAQ device. In addition, the input signals are read by the same layer and distributed to the control elements running at the system.

To prevent access to the shared resource which is the output signals snap shot, the control elements use semaphores to lock access to the output table and update its relevant signals. When done updating, the control element releases the semaphore allowing for another element to update the table and so forth.

To allow fast addition of control elements, the system is configurable. Each element is controlled by its function which is instanced when the application is started and runs continuously. As each control element acts the same, the point of configuration is when it is instanced. This configuration is done via configuration tables, so that the user has full flexibility to configure the system without changing the source code apart from instancing a new control element.

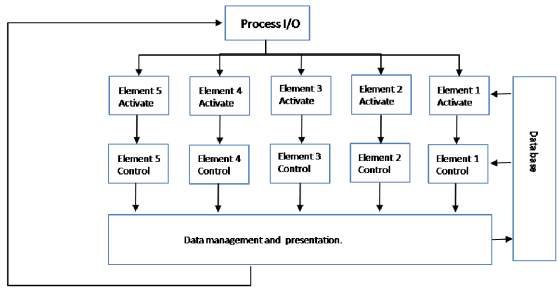

Figure 5: Vacuum control system block diagram.

SUMMARY

The SARAF beam lines control systems consists of various hardware design by the SARAF engineering team, and are currently in various stages of operation and delivery.

IMP, LAN Zhou 730000, P.R. China

Abstract

System is mainly composed of hardware, the data for a given waveform scanning power supply controller, dose-controlled counting cards, and event generator system. Software consists of the following components: generating tumor shape and the corresponding waveform data system, waveform controller (ARM and DSP) program, counting cards FPGA procedures, event and data synchronization for transmission COM program.

INTRODUCTION

HIRFL cooling storage ring (HIRFL-CSR) is a national big science project. It consists of injector (SFC), beam transport line, the main loop (CSRm), experimental ring (CSRe) and connecting to the main ring and the ring of secondary radioactive beam experimental line (RIBLL2) and other components, the total length of about 500m [1]. Figure 1 show an Overall Layout of HIRFL-CSR. It is the heavy ion beam acceleration, accumulation, cooling, storage, and then proceeds to internal / external target experiments and high-resolution particle detection of large-scale experimental apparatus. It's built and put into operation for the physical and related research, experiments provide a good platform. Since 1995, Institute of Modern Physics, Lanzhou heavy ion accelerator using cooling storage ring (HIRFL-CSR) to provide heavy ion beams to carry out the biological effects of heavy ion beam irradiation and its mechanism, has laid a heavy ion beam cancer treatment technology base[4]. In 2009, we built on the HIRFL-CSR depth treatment of the terminal used for deep tumors. The control system is to realize the point of scanning mode in deep tumors.spot-scanning system of deep tumors is to solve the scan uniformity and conformal requirements automatically carried out.

SYSTEM STRUCTURE

The system mainly consists of hardware and software. Hardware to complete the scan waveforms output, measured data channel count and the establishment of the function. Software for data processing, transmission and analysis capabilities. System components as shown in Figure 2.

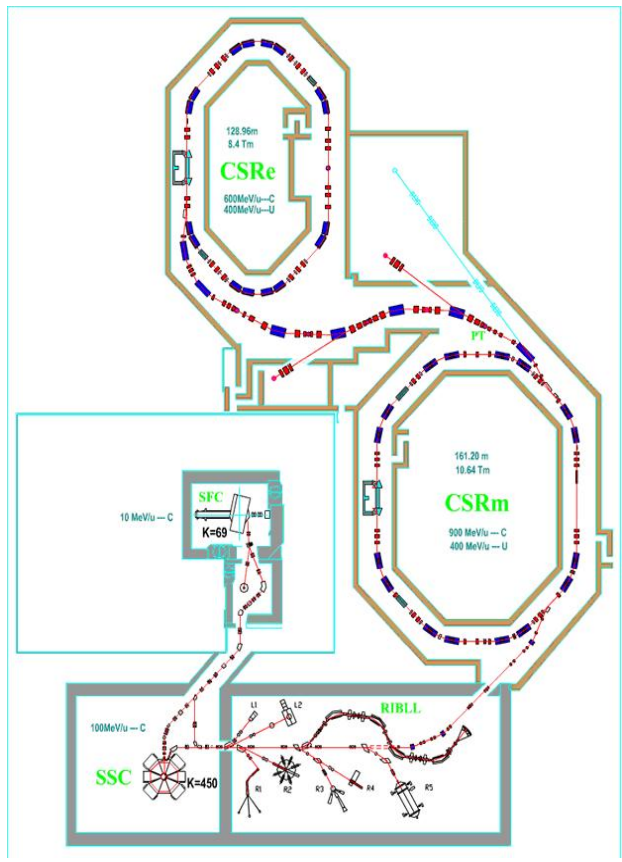

Figure 1: Overall Layout of HIRFL-CSR.

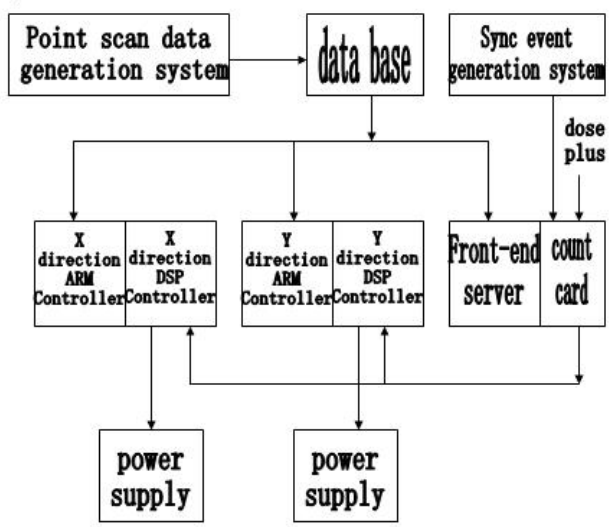

Figure 2: System components.

HARDWARE COMPOSITION

The hardware is composed of the data waveform controller hardware, counters and event generator system. The data waveform controller designed by our own is by the ARM controller and DSP controller composition. ARM controller is responsible for contact with the database. It requires the output of the waveform data from the database, then put it into a format defined by DSP controller memory. DSP controller is responsible for the corresponding input data processing, and the corresponding required output waveform. Counting cards is by our own design of the FPGA controller. It is the main achievement of the input dose pulse count and pulse required to issue hop and protection signals. Event generator system is also designed by our own FPGA controller. It is mainly to achieve our own definition of the output pulses formed by a series of examples, for the synchronous control system equipment.

SOFTWARE COMPONENT

There are three main parts. The first part is the bottom of the control equipment procedures, including ARM controller, DSP controllers, counters, and event generator system program. The second part is to generate waveform data corresponding to the tumor shape and the program. The program is the main interface operating procedures in deep spot-scan. The interface shown in Figure 3[2]. The third part is the transfer case and the COM data synchronization process [3]. It implements the DSP controller output waveform database and data synchronization, Provide the conditions for the active transformation of energy. The fourth part is the output signal monitoring procedures. It implements the DSP controller, real-time monitoring of the output waveform. The monitoring interface is shown in Figure 4 [2].

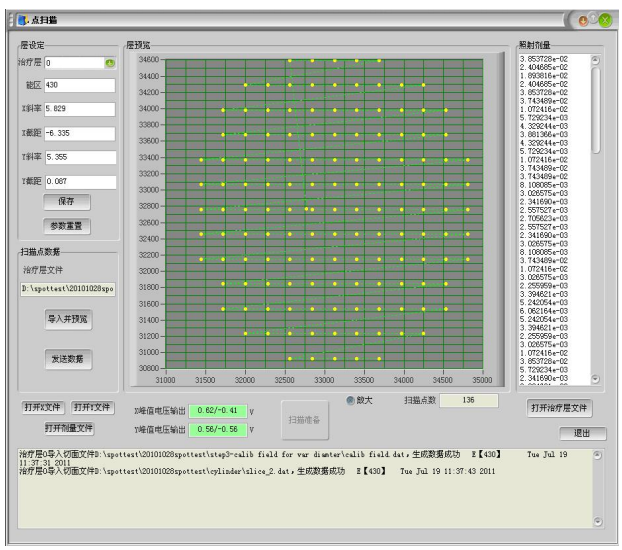

Figure 3: Interface operating in deep spot-scan.

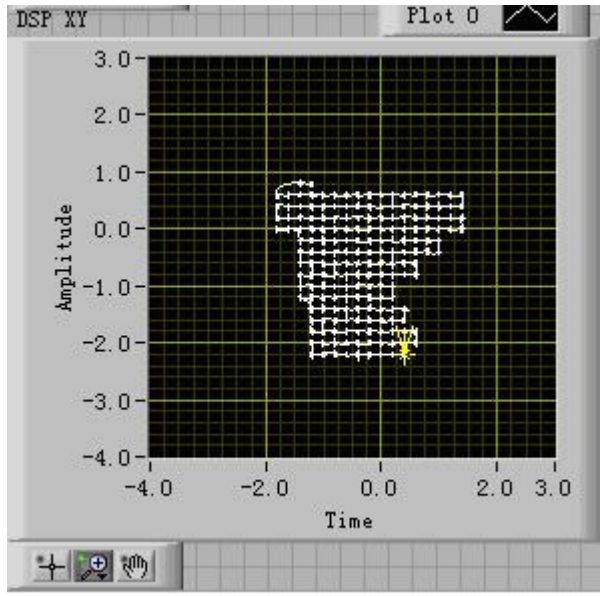

Figure 4: Output signal monitoring interface of DSP controller.

WORK PROCESS

The shape and the points according to the tumor dose requirements，Prepared using our own point of scan data generating system generates the appropriate power supply output data and counting card data。And the data pass the database, when the database receives the data, it will simultaneously transmit data to the corresponding ARM and the front-end servers。The ARM will then pass the data in DSP, waiting for the trigger pulse to the output after the。At the same time front-end server will count card data transmitted through the PXI bus, counting cards. When the count received by sync event generator card issuing an example of the start of scan, the count of cards received by the dose given detector pulse began to count, When the count to the count stored when the card count to send a pulse to the DSP, DSP receives a pulse from the current output value will be a smooth transition to the next treatment point of X, Y output value, Counting cards at a time to continue to receive from the dose given detector pulse counting, counting to then send a pulse to the DSP, this loop until the scan is complete, a layer of points. Repeat the above steps for different layers can be. Through the above process can be achieved on the different shapes of the spot scanning treatment of cancer.

CONCLUSION

In January and May 2010, we conducted a spot scanning system, the overall test, the test results meet the design requirements, and on-site test is shown in Figure 5 and Figure 6. In July 2011, point scanning control system through the acceptance of experts.

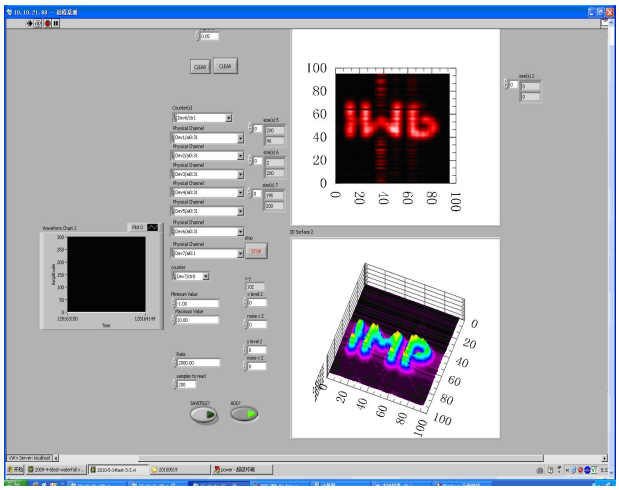

Figure 5: On-site test is shown 1.

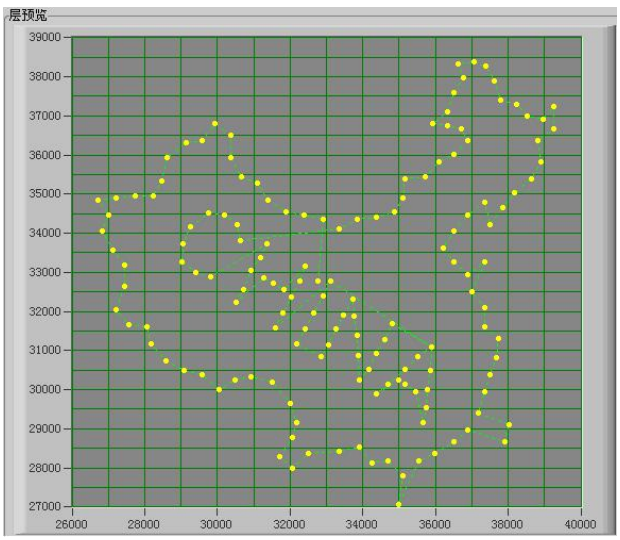

Figure 6: On-site test is shown 2.

Abstract

Several experiments are being prepared or conducted at the first phase of the SARAF linac. Two of these experiments are: the Liquid Lithium target and the Foil target. The present report describes the new hardware and software control systems which are currently being built for these experiments.

INTRODUCTION

A temporary beam line has been built for the 4 MeV 1 mA CW proton beam at phase I of the Soreq Applied Research Accelerator Facility (SARAF) [1,2]. Two of the experiments planned for this new beam line are the Liquid Lithium Target (LiLiT) [3,4,5] and the Foils target [6]. New hardware and software control systems were built and being tested for these experiments. The LiLiT target will be used to create an intense keV neutron source, produced via a $^{7}Li(p,n)^{7}Be$ reaction. This target was successfully tested off-line and will be installed at the accelerator beam line in the near future. The foils target is planned for irradiation experiments, examining issues of radiation damage in thin metallic foils. The control systems of both experiments include various diagnostic elements, vacuum control, temperature reading etc. These systems were designed to be modular, so that in the future new targets can be efficiently replaced.

THE LiLiT TARGET

The LiLiT target is a windowless forced liquid-lithium jet in vacuum [3,5]. Lithium is heated to ~ 200°C (above the melting temperature of 181°C). The liquid-lithium loop is designed to generate a high velocity lithium jet (10 m/s or larger). The lithium nozzle and the concave supporting wall are located inside the target vacuum chamber. An electromagnetic (EM) induction pump (figure. 1, E) drives the lithium flow from the containment tank (figure. 1, D) to the lithium nozzle. After passage through the target vacuum chamber, the lithium is collected back into the containment tank (figure 1, D). A heat exchanger, based on a separate loop of oil, circulating around the lithium tank, was designed to remove heat from impinging proton beam (up to 10 kW).

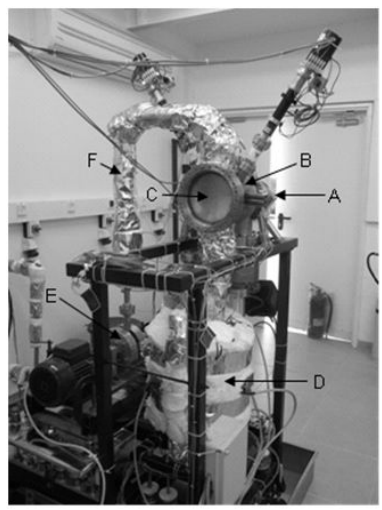

Figure 1: The LiLiT target: A-proton beam entry (will be connected to SARAF proton beam line), B-Target chamber (with lithium nozzle inside), C- neutron port, D-Lithium containment tank, E-Electromagnetic (EM) pump, F-lithium jet loop line.

A stand-alone fire resistant laboratory was built to test the liquid-lithium loop, its heat removal capabilities using an attached electron gun as a heater and to establish the safety regulations. The LiLiT control system provides full and safe control of the lithium and its cooling oil loops. The control system is based on a National Instruments compact field point (cFP) 2020 controller. The controller governs the following I/O interface modules:

1. NI-AI-111 analog current input for reading the temperatures values at various positions of the Li tank. The temperature readings are converted to current by a ConLab USD-2 universal transmitter.
2. Two NI-AI-110 modules, of analog voltage and current inputs for reading the vacuum, Li speed, temperature etc.

3. AI/O 610 analog input/output module for operation of the Li and oil flow control, linear control etc.
4. DO 401 digital outputs for Li heaters, fans, Li and oil motor etc.
5. DI 304 for monitoring of Li temperature status and alert signals.
6. TC 125 for direct temperature reading.

Additionally, the control system includes drivers for the Li and oil motors, vacuum controllers, linear motors for the diagnostic wire scan and for the beam blocker, temperature controllers, etc.

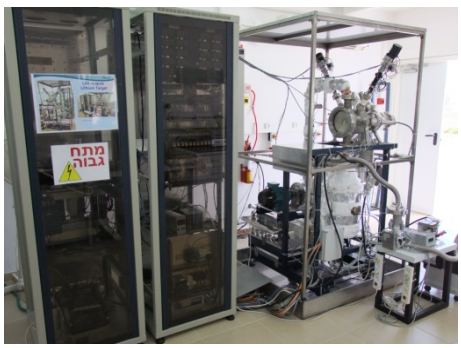

Figure 2: LiLiT target and control racks in the off-line lab

The code for the cFP controller is divided in two subsystems. The real time controller program with the critical code controls the most important parameters: the different set points (lithium speed, vacuum safety level, etc.) and the parameters of lithium heating process. The host computer program handles all the other control functions.

The Humane Machine Interface (HMI) was built to reflect as closely as possible the system structure, presenting its functionality and parameters in the most intuitively clear way (figure. 3).

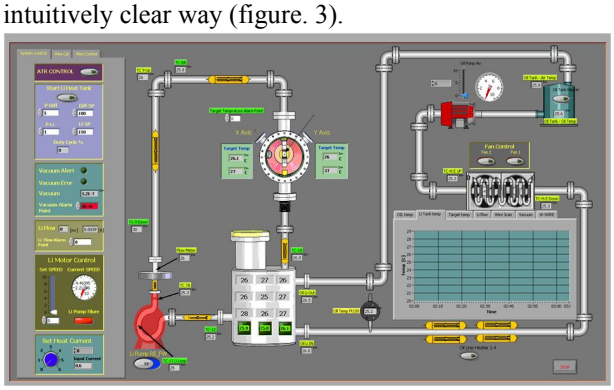

Figure 3: LiLiT control HMI

The left side of the screen enables operation of the various systems, such as the local temperature controllers, the Li tank and other heaters, the EM pump motor and wire control. Given the safety concerns associated with liquid lithium, the initial heating process of the solid Li must be performed carefully using a proportional temperature feedback algorithm. The Li loop is presented in the centre of the HMI. The diagnostics of the loop include the temperature mapping of the various locations in the loop (in the Li tank, target and pipes) and control of the EM pump. The oil loop is presented on the right side of the screen. This loop handles the operation of the oil motor, cooling fan and the oil heaters in the pipes. On the same side, the different parameters are also shown in the running plot.

Before installing the LiLiT experiment at the SARAF proton beam line, we intend to substitute the controller of the system with a new one, a cRIO which has field-programmable gate array (FPGA). This is necessary because the current controller has a relatively low performance and memory and it lacks an FPGA.

FOIL TARGET

The foil target is used to examine the effects of proton irradiation of thin foil targets. A 25 microns thick Havar foil of 20 mm diameter is irradiated by an intense proton beam. Another side of the foil is cooled by liquid metal NaK alloy, which is in contact with a water cooled stainless steel plate.

The Foil target control hardware is located in a mountable rack in the RF Hall (approximately 30 meters from the target). It contains an NI compact reconfigurable Input/Output (cRIO) 9073 control system. The cRIO includes three components: a real-time controller, a reconfigurable FPGA, and industrial I/O modules. We used the following I/O modules:

7. NI AI-9205: Analog input for reading the different devices inputs.
8. NI AI-9264: Analog voltage output for operation of the water flow and the x-y scanner.
9. NI AI-9421: Digital input used to indicate the status of the flow switch.
10. NI AI-9421: Digital output for the operation of the accelerator Machine System Safety.

The Foil control systems HMI (figure 4) is divided to two parts, the first of which operates and controls the water cooling systems (figure 4). This part presents the differential pressure gauge, temperature of the water in different locations along the pipe line, ultrasonic water flow meter, pressure gauge, water valve control and water flow switch. The second part in the HMI presents the target parameters (figure 5) such as target currents, temperatures in several locations (measurement by 4 thermocouples) and target temperature as measured by a

pyrometer sensor. The control systems enable the user to direct the pyrometer to a specific point on the target or to perform a two dimensional scan. The scan system consists of two drivers (MicroMaxTM Series 671) and of two accurate mirror positioning systems.

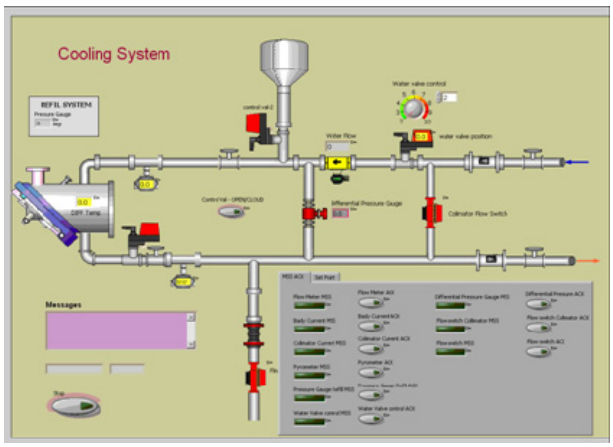

Figure 4: Foil target control system – water cooling systems.

The control system provides a "target ready" signal for the accelerator Machine Safety System (MSS). We therefore used the FPGA, which provides high reliability, high speed and determinism. The "target ready" signal is set by the chain of the following signals: water flow value, pyrometer temperature reading and flow switch status. The "target ready" signal ensures that the target cooling system is operating and that the target temperature is in the permitted level.

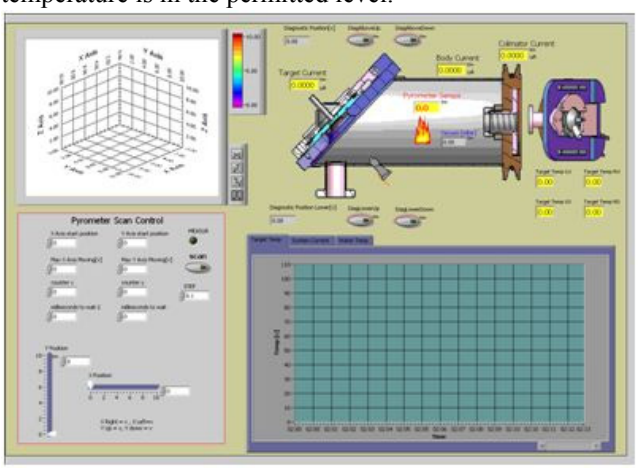

Figure 5: Foil target control system – target parameters.

SUMMARY

The present report gives a brief description of the control systems of the two experiments at the SARAF accelerator temporary proton beam line. Both systems are fully operational, enabling an excellent control of the targets. At the moment, the Foil target experiment is routinely running at SARAF. The LiLIT experiment is routinely in operation, irradiated by an electron gun and will be moved to the proton beam line in early 2012.

Abstract

The IFMIF-EVEDA (International Fusion Materials Irradiation Facility - Engineering Validation and Engineering Design Activity) linear accelerator will be a 9 MeV, 125mA CW (Continuous Wave) deuteron accelerator prototype to validate the technical options of the accelerator design for IFMIF. The primary mission of such facility is to test and verify materials performance when subjected to extensive neutron irradiation of the type encountered in a fusion reactor to prepare for the design, construction, licensing and safe operation of a fusion DEMO (Fusion Demonstration Reactor). The RF (Radio Frequency) power system of IFMIF-EVEDA consists of 18 RF chains working at 175MHz with three amplification stages each. The LLRF (Low-Level Radio Frequency) controls the amplitude and phase of the signal to be synchronized with the beam and it also controls the resonance frequency of the cavities. The system is based on a commercial cPCI (Compact Peripheral Component Interconnect) FPGA (Field Programmable Gate Array) board provided by Lyrtech and controlled by a Windows Host PC. For this purpose, it is mandatory to communicate the cPCI FPGA Board with an EPICS Channel Access [1], building an IOC (Input Output Controller). A new software architecture to design a device support, using AsynPortDriver class and CSS as a GUI (Graphical User Interface), is presented.

INTRODUCTION

The RF System is defined as the equipment necessary to convert the high-voltage AC (alternating current) primary power to suitably conditioned RF power for input to the IFMIF-EVEDA accelerator cavities [2]. The quality of the RF delivered to the accelerator cavities is controlled to within ± 1 degree in phase and to within $\pm 1\%$ in amplitude, using a low-level RF-drive modulated control system. Each RF Module Local Control System (RF Module-LCS) is a device that will monitor and control all physical parameters within the RF Chains located in the same RF Module. Each RF module comprises 2 RF Chains, so the 18 RF Chains will be monitor and controlled by 9 RF Module-LCS connected via Ethernet to the Central Control System (CCS) [3], this Local Control System scheme is shown in Fig. 1. Furthermore, The primary role of the Low Level Radio Frequency system (LLRF) is to control the amplitude and the phase of each cavity (fast regulation) and to control the tuning of each cavity to keep its resonant frequency close to the accelerator operating frequency. For doing so, the LLRF will generate the RF signals (RF drives) for the amplifiers feeding the cavities, depending on their voltage and forward power. The IFMIF-EVEDA LLRF system has to work under CW mode operation and it has also to support pulse mode operation (during the commissioning and tuning of the prototype accelerator) [3].

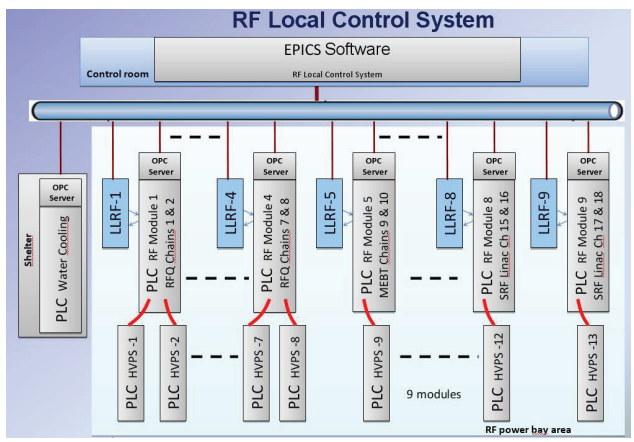

Figure 1: LLRF local control system scheme.

For controlling and operating this LLRF System, IFMIF-EVEDA decided to chose EPICS some years ago. EPICS is a set of Open Source software tools, libraries and applications developed collaboratively and used worldwide to create distributed soft real-time control systems for scientific instruments such as a particle accelerators, telescopes and other large scientific experiments. Nowadays, EPICS is widely used in big accelerators like Diamond Light Source and huge experiments like ITER. EPICS provides a number of tools for creating and operating a control system. This minimizes the need for custom coding and helps ensure uniform operator interfaces [4]. These features make EPICS the most appropriate architecture for IFMIF-EVEDA, hence, the main purpose of this paper is to present the LLRF control system based on EPICS.

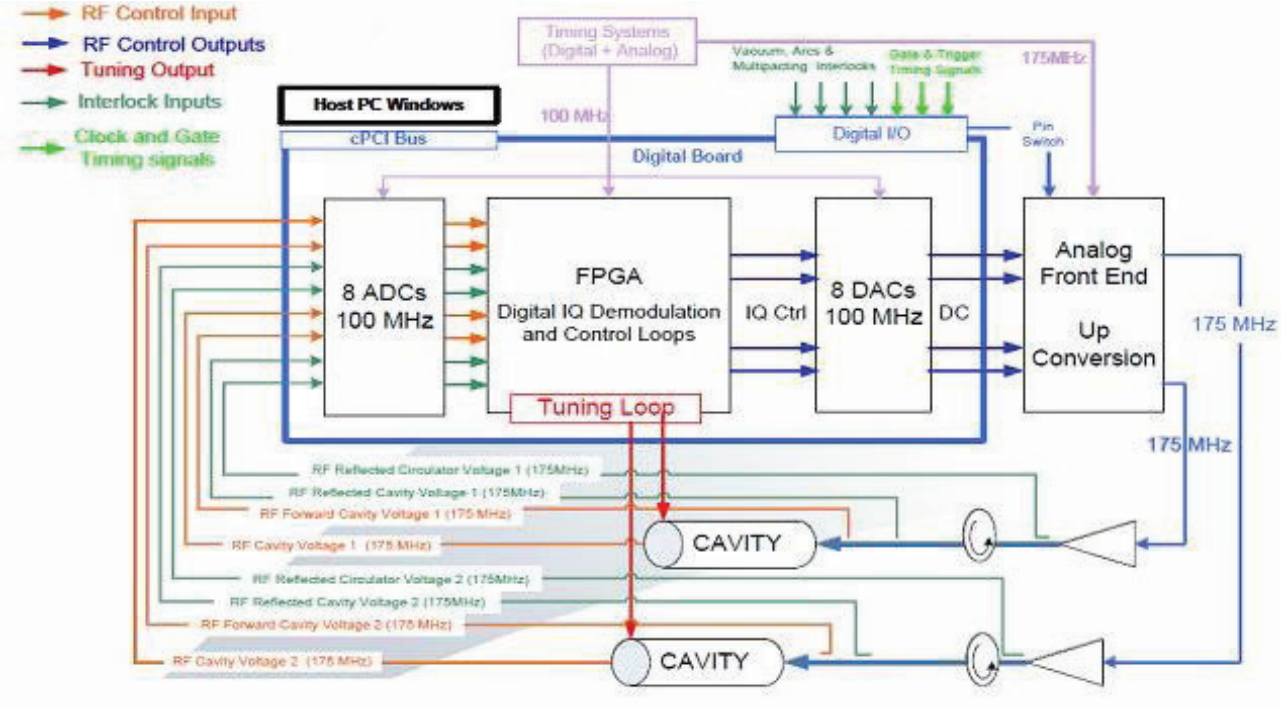

Figure 2: LLRF System general overview.

SYSTEM ARCHITECTURE

Hardware Architecture

The LLRF System is composed by three main subsystems: a digital board with fast FPGA, the analog front end and a local timing system.

- Digital Board: The digital board contains one Virtex-4 FPGA, 8 ADCs and 8 DACs with 14 bits resolution and capable to work up to 105MHz. It is a commercial board with cPCI format provided by Lyrtech and it will be controlled by a Windows CPU. This board will acquire different kind of signals: RF control inputs (cavity voltage and forward cavity power), RF interlock inputs (cavity reflected power and circulator reflected power), digital interlocks (arcs, vacuum and multi-pacting) and timing signals (gate and pulse signals). It will also provide the control outputs of the LLRF: Direct Current (DC) control outputs for signals. It will also provide the control outputs of the LLRF: DC controls amplitude, phase, tuning and interlocks outputs of the cavities. The LLRF general system overview is shown in Fig. 2.
- The front end: It is in charge if up-converting the DC control outputs from the digital board into RF. For doing so, the LLRF employs a quadrature IQ modulator.
- The local timing system: It consists of a PLL board with a 100MHz VCXO (CDC-7005-EVM from Texas Instruments). This board provide 100MHz TTL signal to clock the digital board. This signal will be phase locked with an external 10MHz signal provided by the general timing system.

Sotfware Architecture

The presented architecture is developed over EPICS Base 3.14.11, using Visual Studio 2008 C++ Express Edition, Asyn4-13-1, Application Programming Interface (API) for Lyrtech boards and Control System Studio (CSS).

This solution consists of the following EPICS components:

- IOC (Input/Output Controller): The IOC is any platform that can support EPICS run-time components, including the database, and its access routines, device drivers, record types for various input and output and scanning and monitoring functionality [5].
- Database: The EPICS database [6] is a basic element in an IOC. The database is composed by numerous instances of records. A Record is a collection of Processes Variables (PVs) which is implemented on an IOC where a Process Variable (PV) is a piece of data which can be accessed by its unique name. Often the PV name consists of a record name and the name of a record field, connected by a dot [7]. In the LLRF control system, the records have an associated hardware, Lyrtech boards.
- Device Support: We could define it as an interface between records and hardware. A device support routine has knowledge of the record definition. It also knows

how to talk to the hardware directly or how to call a driver which interfaces to the hardware. Thus, device support routines are the interface between hardware specific fields in a database record and device drivers or the hardware itself [8].

- AsynDriver: It is a general purpose facility for interfacing device specific code to low level communication drivers. A primary target for asynDriver is EPICS IOC device support but it is independent of EPICS [9].
- LAN: Local Area Network. This is the computer based network which allows the communication between IOCs and Operator Interfaces (OPIs). EPICS provides a software component, Channel Access, which provides network transparent communication between a Channel Access client and an arbitrary number of Channel Access servers [5].
- OPI: Control System Studio (CSS) is a combined effort of several parties, including DESY (Hamburg, Germany) and SNS (Oak Ridge, TN). It provides a collection of control system tools in a common environment, based on Eclipse [10].

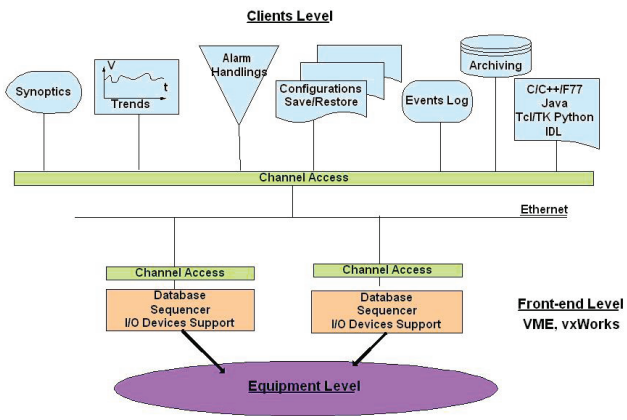

Figure 3: EPICS five layers structure.

This architecture is module based and it follows the EPICS five layer model, this architecture is shown in Fig. 3. In client level we have used CSS as software that allows PVs to be accessed and modified from the network, using the second layer, the Channel Access, that is the communication protocol used by EPICS to transfer information through the network. The next layer is the record support one, where the IOC is settled; here, we have the software which implements PVs for the use with Channel Access. The fourth Layer, device driver layer, it is the heart of the architecture and permits the communication between records in the DataBase and the device. The fifth level corresponds with the instrumentation level, FPGA boards. The proposed architecture is shown in Fig. 4. Due to the Common Software Platform of IFMIF-EVEDA, where all the computers must include the same version of Linux, Vxworks core and EPICS, but cPCI FPGA Board is controlled by a Windows Host PC, carrying out independence of the hardware from the operating system was one of the main challenges of the presented architecture.

USER INTERFACE

The graph user interface, Figure 4, has been designed using CSS. Initially, the proposed GUI package for IFMIF-EVEDA was Extensible Display Manager (EDM). Despite the initial effort that is necessary to implement a clean and robust design, we consider that we made the right decision. We have tried to design a friendly and operative GUI. The operator and the machine engineer can easily tune the system, control the parameters and program Lyrtech boards through the set of designed pages but, following the EPICS philosophy, the whole logic involved have not been developed in the client level, CSS, but on the IOC, then everyone can reach it.

SUMMARY AND FUTURE PLAN

We have developed a Device Support for IFMIF-LLRF Control System. This new software architecture is running properly in a Windows CPU connected in the same chassis of the Lyrtech cPCI board and solves the operating system dependency. This new architecture allows both client and server run in different machines. This solution will be used to control the LLRF of two plants in the final accelerator prototype which will be built in Rokkasho, Japan, on the 2013. Thanks to CSS and EPICS Channel Access, process variables can be seen in any computer of the IFMIF-EVEDA Central Control System. The EPICS based characteristics of the system makes it useful because of its modularity and it can be easily upgradeable and modifiable, the choice of EPICS as a control toolset was very important to achieve this success.

The further work line moves on the testing of the system within the overall prototype accelerator. Else, adding more elements to the GUI and creating an auxiliary database in order to store the historical values of the diagnostics signals is necessary. When these signals are out of certain margins, some warning messages should appear next to the relevant diagnostic signal, these warning messages will be defined later on.

LANSCE CONTROL SYSTEM FRONT-END AND INFRASTRUCTURE HARDWARE UPGRADES

Martin Pieck†, Dolores Baros, Chris Hatch, Pilar S. Marroquin, Peter D. Olivas,
Fred E. Shelley Jr., David S. Warren, and William W. Winton
Los Alamos National Laboratory, NM 87544, USA.

Abstract

The Los Alamos Neutron Science Center (LANSCE) linear accelerator drives user facilities for isotope production, proton radiography, ultra-cold neutrons, weapons neutron research and various sciences using neutron scattering. The LANSCE Control System which is in part more than 40 years old provides control and data monitoring for most devices in the linac and for some of its associated experimental-area beam lines.

In Fiscal Year 2011, the control system went through an upgrade process that affected different areas of the LANSCE Control System. We improved our network infrastructure and we converted part of our front-end control system hardware to Allen Bradley ControlsLogix 5000 and National Instruments Compact RIO programmable automation controller (PAC). In this paper, we will discuss what we have done, what we have learned about upgrading the existing control system and how this will affect our future plans.

BACKGROUND

LANSCE is the proposed site for Los Alamos National Laboratory's (LANL) future signature facility Matter-Radiation Interactions in Extremes (MaRIE). This experimental facility will be the first in a proposed new generation of scientific facilities for the materials community to meet 21st century national security and energy security challenges [1].

Currently different efforts are under way to prepare the facility for its future mission. One effort is based on the LANSCE Linac-Risk Mitigation (LL-RM) project that focuses on risk mitigation of programmatic equipment — components and equipment directly related to the acceleration of the particle beam. Other efforts are focused on parts of the facility that are not directly related to the acceleration of the particle beam.

Despite these different efforts that are mostly driven by different funding sources, there is an overarching strategy for the instrumentation and controls system:

- Replacement of obsolete Controls Hardware
- Installation of new Timing System (in 2013)
- Improvement of Controls Infrastructure

The scope of the work ranges from integration of commercial-off-the-shelf components to complete substitution of obsolete and non-maintainable systems and equipment. For the most part, the projects are self-performed by LANL's Accelerator Operations and Technology - Instrumentation and Controls (AOT-IC) group, which provides maintenance and support of the injector, accelerator, beam transport, and target control system (CS) at the LANSCE User Facility (LUF).

†pieck@lanl.gov

PROJECT EXECUTION CONSTRAINTS

To execute any scope of work, while maintaining 3000h/year beam operation requires the integration of the upgrade projects into the (LUF) operation schedule [2].

The LUF operates cyclically. It typically operates for several months a year to meet commitments to programmatic customers. Run cycles are interspersed with intra-cycle maintenance breaks of a few days to a week for the purpose of recycling the H- ion source and conducting emergent or time-sensitive maintenance. Run cycles are followed by months-long outage; during which scheduled and more extensive maintenance is conducted.

The LANSCE Control System (LCS) which is based on the Experimental Physics and Industrial Control System (EPICS) is critical to operations. Even during intra-cycle maintenance breaks the CS is often needed. Any major upgrade or modification needs to be addressed during the months-long outages. Traditionally this annual outage starts in January and ends in April. During the four month outage in 2011 AOT-IC executed several major projects:

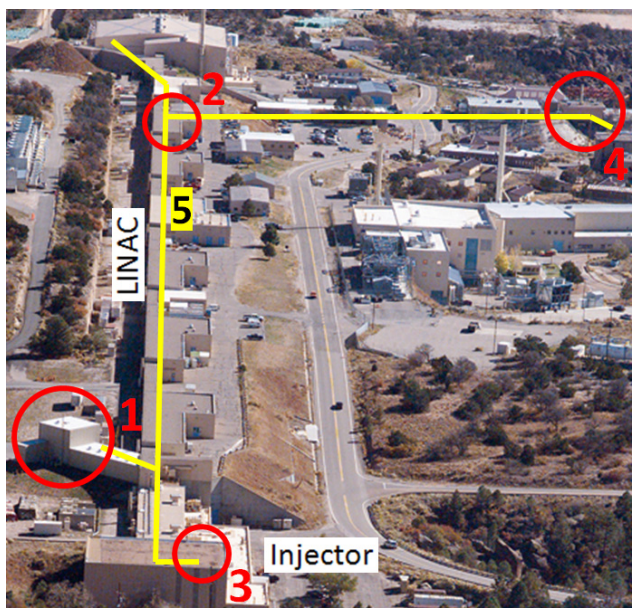

Figure 1: LANSCE User Facility.

1. Isotope Production Facility: Proprietary Control System changed over to an Allen Bradley based Control System
2. LINAC – Sector H: One module of the original "RICE" (Remote Instrumentation and Control Equipment) system was changed over to a National

Instruments cRIO based Control System at the end of the 800MeV Linac
3. PSR – Mechanical Equipment Building: Two CAMAC crates were changed over to a National Instrument cRIO based Control System.
4. H- Injector: CAMAC changed over to an Allen Bradley based Control System
5. Network: Installation of a Fiber Optics back bone communication infrastructure that connects the major areas of the LANSCE Accelerator Facility

These projects will be discussed in turn blow.

ISOTOPE PRODUCTION FACILITY

The Isotope Production Facility (IPF) which produces medical isotopes is part of the LUF. The original IPF Target CS was a stand alone system utilizing non-LCS standardized controls software and hardware components. Due to the fact that the CS was designed, installed and maintained by a non LANL, out of state contractor any maintenance or repair event was time consuming and costly. As a result, IPF management decided to replace the proprietary IPF CS with LCS standardized technology.

The stringent IPF production schedule, as well as the pre and post production requirements, limited the CS upgrade work to 2 1/2 weeks. This included time to take the old CS hardware out, to install the new one, and to test and commission the CS system. In order to accomplish such a daunting task the controls team had to prepare and optimize their approach.

In a process which started 3 months before the actual upgrade work, the old CS was examined during the inter-cycle maintenance breaks. In combination with old CS requirements documentation the system was re-engineered and a suite of process control charts that reflected the operational behavior were developed. These process control charts went through a rigorous review process where operators and expert users verified and validated the new design documentation with requirements and their experience of the old CS. Furthermore, a full CS prototype was developed and tested prior to installation.

For this application an Allen Bradley (AB) ControlLogix 5000 PLC was chosen since the previous system was a PLC as well, though from a different brand. An "EtherIP" driver/device support module interfaces to the AB ControlLogix 5000 PLCs via Ethernet to EPICS IOCs under EPICS R3.13 or R3.14. The software driver (EtherIP) is available through the EPICS collaboration [3].

To accommodate the required Input/Ouput (I/O) points we installed two PLC chassis in the Master-Slave configuration. This saved the project one controller module on the slave side. The Master chassis hosts the AB 1756-L61 ControlLogix 2MB 5561 Processor with an onboard flash memory card that holds the ladder logic program for cases when the internal memory could lose its process application. That same chassis holds all Analog I/O modules of types Spectrum Controls 1756sc-IF8u and AB 1756-OF8. The slave hosts all digital modules of type AB 1756-IB32 and AB 1756-OW16I. The AB's 1756-ENBT ControlLogix EtherNet/IP Module serves as interface between the AB control chassis as well as interface between the EPICS IOC and the AB Master P

The installation and commissioning were successful. However, despite many design reviews, a prototype, and our best effort, some of the requirements surfaced just after the system was installed.

LINAC – SECTOR H

The CS for the 201.25 MHz and 805 MHz linac is based on RICE (Remote Instrumentation and Control Equipment) which was installed in the early 1970's when the facility was built. With more than thirty year old technology come many problems. Many of the discrete components in RICE electronics can no longer be purchased, supplies of spares are dwindling and plastic connectors are becoming brittle. Calibration capabilities were not built-in, raising questions about year-to-year comparability of settings. Lack of any vendor support means all maintenance and repair must be done in-house. Non-standard electronics means all in-house maintenance people must receive extensive RICE-specific training on technology that was installed 40 years ago. The current architecture and implementation is shown below [4].

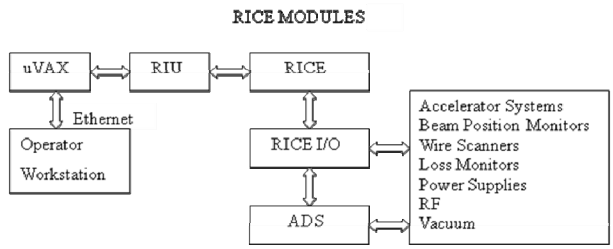

Figure 2: Block Diagram of the RICE System.

RICE controls can be divided into two main categories.

- Industrial Controls: Consists of command and readback of two-state devices, along set-point generation and analog readback of devices.
- Timed-and-Flavored Data: Consists of data taken with a specific relationship to the beam-type (flavor) and timing.

As part of the LL-RM project, a design has been developed to replace the Industrial Controls of the RICE system. The major component of this system are Programmable Automated Controllers (PACs) built by National Instruments. The controller is called CompactRIO (cRIO) and is a reconfigurable control and acquisition system. – An architecture already supported by EPICS [5].

The controller is a cRIO–9024 a Real-Time Controller: 800MHz, 512MB DRAM, and 4GB of Storage. The removable cRIO controller sits in an NI cRIO-9118 chassis with additional 8-slots, Virtex-5 LX110 reconfigurable chassis. The most noticeable advantage is

its high performance and reliability, high performance FPGA, and hot swappable modules. For our application the cRIO is hosted in a commercial BiRIO rack mount chassis which interfaces to commercial BiRIO interface boards that in turn provides interfaces to the device field wiring. This configuration promises in many cases a simple chassis swap during 24-7, on-call operations support while the diagnostic and repair would occur in the electronics laboratory setting.

Figure 3: cRIO in BIRO chassis.

For our analog signals we use the NI cRIO-9205, 16-Bit Analog Input module. The NI cRIO-9474 Digital Output Module is used to create 5 V, 50us wide pulses for stepper motors. For our digital signals we use the NI cRIO-9425 Input Module and the NI cRIO-9477 Digital Output module. A block diagram of the new system is shown below:

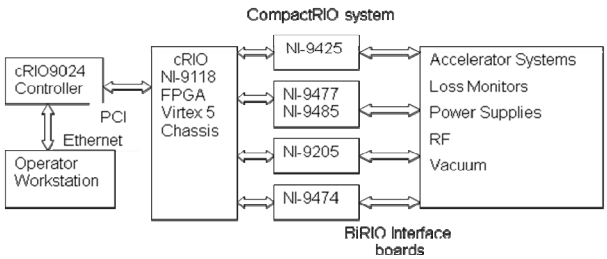

Figure 4: Block Diagram of the cRIO System.

While the controls replacement work was a success the new control wiring needs improvement. Since we replaced only the Industrial Controls I/O of the Rice system the rewiring of the intermixed signals created an eye sour. For the future, any controls rewiring will be done for both the time flavored and industrial control data at the same time. This will minimize any rewiring of the time flavored system when it will be installed in 2013.

H- INJECTOR

The former H- injector CS was based on 1980's Computer Automated Measurement And Control, (CAMAC) technology. It is a modular data handling system and its primary application is data acquisition. Individual crates are controlled by slave or intelligent controllers. The controllers are tied together with a parallel Branch Highway that ends in a Branch Driver. The Branch Driver is interfaced directly to a data acquisition computer; in our case an EPICS VME IOC.

With technology that was installed in the 1980's comes a host of problems. Often the documentation for individual modules is unavailable, spare inventory is limited, many modules are not available anymore and repair of modules is difficult or impossible due to lack of suitable spare parts.

Modern Ethernet enabled data acquisition technology is capable of replacing the CAMAC functionality. Based on our positive experience with AB we did choose the rugged Control Logix5000 PLC for this job in which 80kV arc downs are part of the daily routine.

For this project we did install 2 AB PLC systems, one for the 670kV another for the 80kV section of the Injector. Despite the fact that these PLC were only about 6 feet apart from each other, due to the voltage difference and the required process control communication, a fiber optics network link between the PLCs had to be installed.

The information exchange was implemented through AB ControlLogix producer and consumer tags. Unfortunately, AB's PLC consumer tags do not recognize if the communication to the producer has failed. It just keeps the last know state. Since the communication link between the two PLCs is critical for Run Permit and interlocks, we installed a watch-dog timer that alerts the system and operator if the information link is broken.

The AB PLC is basically the same that we used for the IPF system upgrade with one exception. We introduced an AMCI 5274 High Speed Inspection Module that operates as a stand-alone module with continuous reporting of status information to the AB 1756 system. It can take analog samples at known points; defined by position, time, or digital input, and compare the measured values to a programmed profile and determine the pass/fail of the inspection. We used the AMCI module as a triggered ADC to read the pulsed signals that were previously read by a sample and hold chassis to measure two current monitor signals as well as the current signals of High Voltage and Arc Power Supply.

Unfortunately, operations of the AMCI modules within the arc prone environment caused the module to lock up. Attempts to improve the situation within the high voltage H- Injector Dome environment failed. Even with good vendor costumer support we were unable to find a solution to reset the module without having to reboot the whole PLC.

Since this was not practical solution to this problem we installed the PLC AMCI module in Injector Control Room and connected the signal to the AMCI through fiber optics cables. This solution has proven to be reliable even though it was not our preferred solution.

MECHANICAL EQUIPMENT BLDG

The Mechanical Equipment Building (MEB) hosts a variety of beam line control devices that help transport and diagnose the beam to the different experimental areas (1L and WNR). Part of the in 1980's installed CAMAC system was replaced by a NI cRIO system of the same type as used for the LINAC Sector-H. Leveraging the development and prototyping effort that was done for the LL-RM, project the controls team was able to replace 2 out of 4 CAMAC crates at minimal incremental cost.

For the maintenance outage in 2012 we do expect to replace the remaining two CAMAC systems freeing up more spares for other CAMAC systems still in use.

NETWORK UPGRADE

The communication network upgrade is the first LL-RM scope element that has been delivered. The new network is the foundation for most other system upgrades that will be installed over the next 5 years.

Since the early 1980's, our old LCS network has grown in a piece-by-piece fashion from no network at all to network in many areas. At its core it has a 100Megabit switch and some of the edge switches have only 10Megabit. In many cases we have unmanaged switches in place which makes maintenance, troubleshooting, and performance monitoring inefficient or impossible. Furthermore, the historically grown structure has little to do with modern network topologies. In fact it consists of a multi star configuration where one edge switch functions as a "core switch" for many other new edge switches. Many of these switches were connected via single or multi-mode fiber or CAT5 twisted pair cables.

Our new installed fiber optics network has 10 gigabit (Gb) capabilities at the core switches and 1 Gb at the edge switches. Near the Central Control Room (CCR) we installed five Nortel-5530 core switches. Each switch has 12x1Gb fiber optics ports, 24 x 1Gb twisted pair, and 2x10Gb fiber ports (Note: After installation we learned that 12 of the 1Gb fiber ports and 12 of the 1Gb twisted pair ports are using overlapping resources. The use of one fiber optics port reduces the availability of one twisted pair port.

The new communication network is a true star configuration. In total, 451 fiber optic strands all originating near the CCR were installed. Each of our 42 primary drop off locations has anywhere from 12 to 24 fiber strands. In total 12,800 feet of single mode fiber was installed throughout the accelerator facilities. At each primary drop off location either a Nortel-5510 or 5520 edge switch was installed. Both have 24x1Gigabit twisted pair ports and 2 or 4x1GBit fiber ports respectively. (Note: The Nortel-5520 switch has Power over Ethernet). Near these switches we ran between 12 to 48 CAT6A twisted pair patch cords to secondary drop off locations. These patch cables can be connected back to the edge switch as needed. Under this regime 21,000 feet CAT6A twisted pair cable was installed for this project.

Currently we are in the process of developing a centralized configuration and monitoring schema. The related work including the transition from the old to the new network will start during our next planned maintenance outage in 2012.

CONCLUSION

Commercial off-the-shelf hardware can replace purpose-built hardware with a customized I/O system that interfaces directly with modern standardized control software. RICE controls for two accelerator modules and, a few CAMAC crates in one beam line and injector have been successfully replaced with 8 cRIO Industrial I/O and Allen Bradley systems with more to follow.

PROGRESS IN THE CONVERSION OF THE IN-HOUSE DEVELOPED CONTROL SYSTEM TO EPICS AND RELATED TECHNOLOGIES AT ITHEMBA LABS*

Ivan Kohler, Mogamad Amien Crombie, Cheslin Ellis, Mike Hogan, Hendrik Mostert, Maria Mvungi, Camelia Oliva, John V. Pilcher, Nieldane Stodart, iThemba LABS, Faure, South Africa

Abstract

This paper highlights challenges associated with the upgrading of the iThemba LABS control system. Issues include maintaining an ageing control system which is based on a LAN of PCs running OS/2, using in-house developed C-code, hardware interfacing consisting of elderly CAMAC and locally manufactured SABUS[1] modules. The developments around integrating the local hardware into EPICS, running both systems in parallel during the transition period, and the inclusion of other environments like Labview are discussed. It is concluded that it was a good decision to base the underlying intercommunications on channel access and to move the majority of process variables over to EPICS given that it is at least an international standard, less dependant on a handful of local developers, and enjoys the support from a very active world community.

INTRODUCTION

The cyclotrons of the iThemba Laboratory for Accelerator-Based Sciences have been in operation for approximately 25 years, and provide particle beams for basic and applied research, hadron radiotherapy and the production of radioactive isotopes.

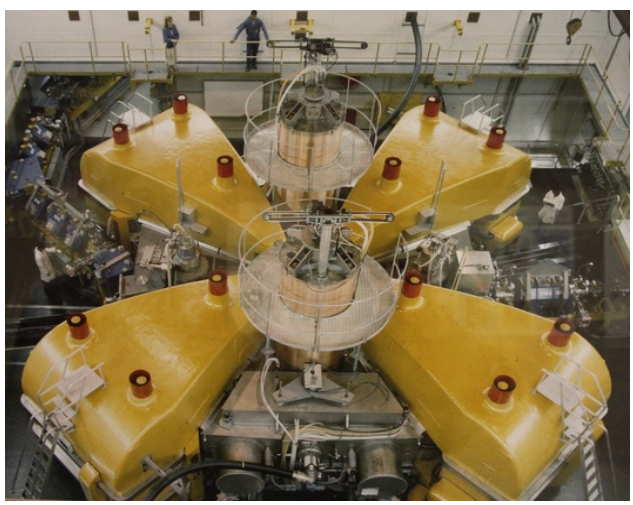

Figure 1: The Separated Sector Cyclotron commissioned 1987.

The laboratory is also responsible for two 6MV Van de Graaff accelerators (a single and a tandem).

*Work supported by National Research Foundation of South Africa

The Control System in Brief

To meet the operational requirements of the facility, the current control system has evolved into a number of subsystems largely based on an Ethernet LAN of low cost PCs running various operating systems with customised application code.

There are +/- 3000 devices that need to be controlled resulting in about 30000 process variables. A distributed database was developed in-house with different parts of the database being housed in node PCs near to the equipment and which communicate to console PCs in various control areas manned by operators. There are approximately 100 OS/2 based PCs 10 if them providing MMI[2] to operators and about 90 acting as local controllers providing I/O to the various devices, each maintaining tables of variables making up parts of the distributed database. The operator interface is presented by an in-house developed console program that displays lists of variables.

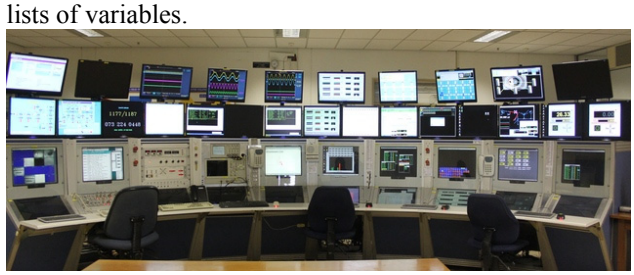

Figure 2: The renovated Control Desk.

Problems with the Current System

The OS/2 operating system is no longer supported by IBM. A generic called eComStation[3] has been used in the interim, though it cannot compete with the support and advances made in systems like Linux and Labview. The CAMAC hardware is difficult to find and expensive to maintain. Software maintainability has become an issue as the developers who wrote the original code retire or move on.

Constraints

It was decided to implement the new system within a number of constraints. A local area network of low cost standard personal computers would be used. An open source Linux operating system and open source EPICS tool-kit would be used wherever practical. The extensive infrastructure linking devices to crates, both CAMAC and SABUS via an 8-bit parallel differential bus would remain on account of the large amount of re-cableing that would have to be done if this was changed. The CAMAC crates

would slowly be replaced by SABUS crates as the new control system developed.

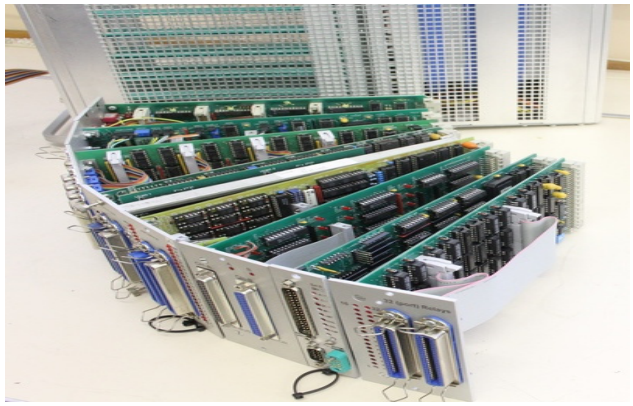

Figure 3: A variety of SABUS cards and a crate, most connectors compatible with CAMAC modules.

Challenges

The first challenge was to develop an understanding of EPICS and then to write an interface to the locally developed PC ISA and PCI master differential bus driver cards through the ASYN layer. The next was upgrading the SABUS interface cards, designing them to operate with EPICS and currently available ICs. Given the availability of limited manpower, and the continuous operation of the facility, a major challenge was to provide for both old and new control systems to operate simultaneously. A further challenge was finding out every aspect of the old system.

PROGRESS SO FAR

Currently the range of devices controllable by the new PC-based EPICS IOCs using SABUS cards, include power supplies (also RS232 serial), stepping motors, pneumatic actuators, all aspects of vacuum system control, slits, scanners and a terminal stabilizing unit for a van de Graaff accelerator. A .NET-based Windows program has been developed to capture harp wire currents and display beam profiles. Labview is used in the logging and monitoring of the charge integrating system of the target stations and in both water and Helium target cooling systems. A software bridge operating in both directions between old and new systems has been developed so that channel access is provided to the old OS/2 variables and the older OS/2 console programs can interact with the newer EPICS based process variables.

EPICS IOCs

A Linux device driver for PC-based differential bus cards was developed followed by a C++ intermediate program which makes calls through the EPICS ASYN layer to this driver. EPICS record based template files were developed for each of the SABUS IO cards, which include a power supply controller, a stepping motor controller, an actuator driver card, a 32 way relay card, an 80 bit opto isolated input card, an 8 channel 16 bit ADC card and an equivalent of a CAMAC IGOR[4] card. DAC functions are handled by the power supply controller card.

A script file (ioc-install) was written so that an IOC can be assembled with little effort. To build an IOC from scratch a user:

- installs Ubuntu 10.04, chosen as it has LTS[5] status for the next three years,
- runs the script file, which will install EPICS base, ASYN, MEDM and configure an IOC based on makebaseapp.pl to include record template files and make everything,
- edits st.cmd and db/substitution files to customise the IOC thus setting up for the number and types of process variables controlled by the IOC.

Start up script files are also generated by the ioc-install script which allows the IOC to start executing on PC power up.

Before After

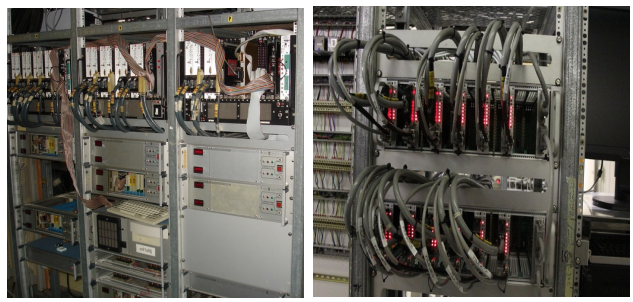

Figure 4: 3 CAMAC crates plus driver boxes reduced to 2 SABUS crates and 12 modules.

The Vacuum Control System

The EPICS vacuum control system is meant to be a direct replacement of the old OS/2 software control system, but with the flexibility to adapt in an easier way to changing I/O hardware, electronic interface equipment and beam-line configurations in the future.

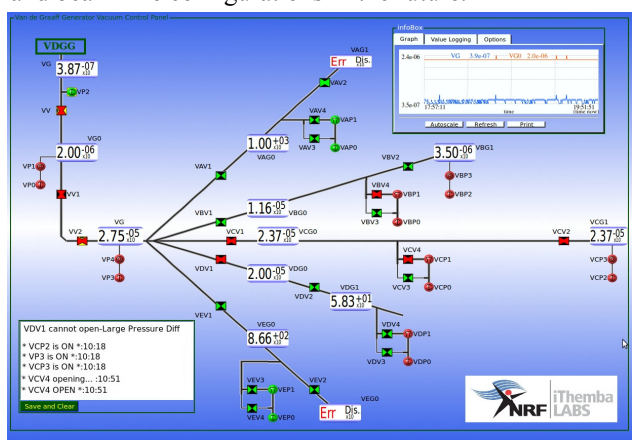

Figure 5: Display of the Van de Graaff Vacuum panel, similar designs will be implemented on the cyclotrons and related beam lines.

The old vacuum system had to remain in operation and having been proven to be conceptually sound, the new vacuum system was modelled on the old.

New EPICS-friendly 32-bit Relay-Output cards were designed. These units provide 32 individually addressed bits whereas the previous modules were byte addressed.

The way the new system is set up is meant to facilitate quick and easy switching between the old and the new vacuum systems during the installation and initial live testing phase.

For the GUI, customised EPICS-capable plug-in widgets/GUI components were created. Using Qt Designer, these GUI-objects can be dragged and dropped into a display and those with EPICS functionality can have their Process Variable names entered. Customised Signals and Slots easily link and transfer information between customised components and standard ones.

With the decision to move to EPICS, the control logic and electronics interfacing is abstracted away from the GUI which affords developers the opportunity to keep up with GUI trends.

The Harp System

The new Harp System consists of the following subsystems: a soft-IOC holding "soft channel" waveform records of harp data, a Harp server application that updates the waveform records and any number of EPICS clients accessing data from the soft-IOC.

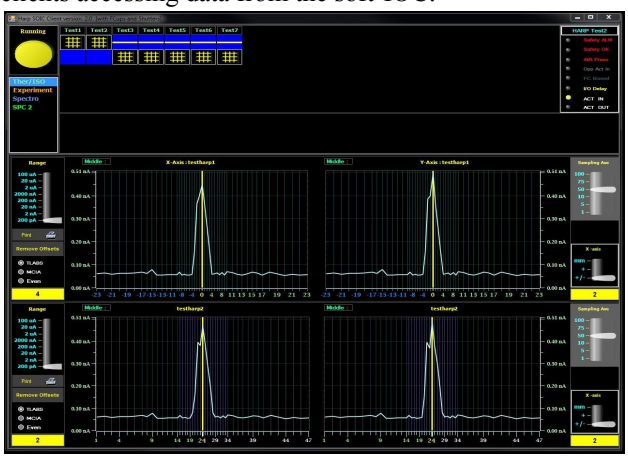

Figure 6: A display for 2 harps and actuators on beam-lines.

The Harp server is the interface between the harp hardware and the soft-IOC. The server monitors actuator process variables and as soon as any client moves a harp into the beam, the server connects to the harp hardware and starts reading ADC values (2 X 48 channels) into the soft-IOC. An EPICS client reads and displays (Fig 6) the ADC values. It also control other pneumatic devices like faraday cups, neutron shutters and attenuators.

The Harp server has been developed on Microsoft.NET Framework 3.5 (using C#) and National Instruments Measurement Studio in VS 2010.

The harp hardware is controlled by a Rabbit[6] (8-bit) micro-controller (programmed with Dynamic-C) that sends TCP/IP packets from the harp's hardware, to the Harp server. PSI's DOTNET library (C#), is used for updating the soft-IOC.

Labview Systems

Labview is used at iThemba as a rapid development system where post digital signal processing and interfacing to off the shelf hardware are a requirement. The ease of use of the Labview interface to existing EPICS IOCs has been a great help. Labview was chosen for the upgrade of the isotope production target stations control system.

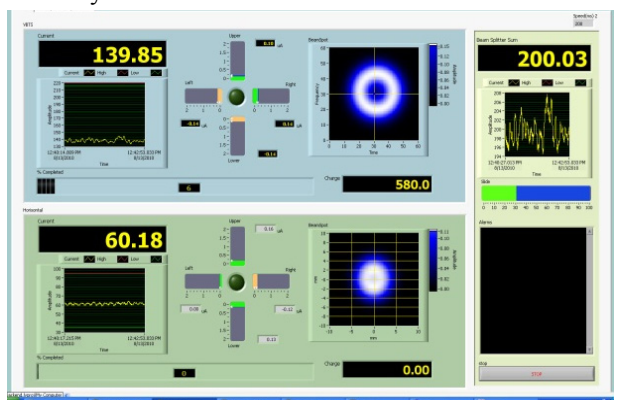

Figure 7: Display of the operator interface to the vertical and horizontal target stations with 200uA split beam.

Currently Labview is used for the logging and monitoring of the charge integrating systems of the horizontal and the high intensity vertical target stations(Fig 7). The software is configured as a main hardware client which stores data to a logging server and Labview shared variable clients for local and remote-control and viewing of target current, collimator currents, beam sweep parameters and collected charge.

The water target cooling system and the Helium target cooling system have been ported from old MSDOS Pascal systems to National Instruments compact RIO FPGA using Labview as the programming interface.

The Scanner System

The program scanner provides a display for National Electronics beam profile monitors. Up to 16 scanners may be connected to National Instruments cards managed by an EPICS IOC. The IOC must be configured with a custom EPICS ASYN driver, developed at iThemba LABS for this purpose.

The program interfaces to the IOC through Channel Access. Clients can be run on different desktops for the same set of scanners. More than one copy of the program can be run on the same desktop to display different sets of scanners, these sets need not be located on the same IOC, since access is only through the process variable names. This program uses Qt Open Source Edition version 4.5.0. by Nokia

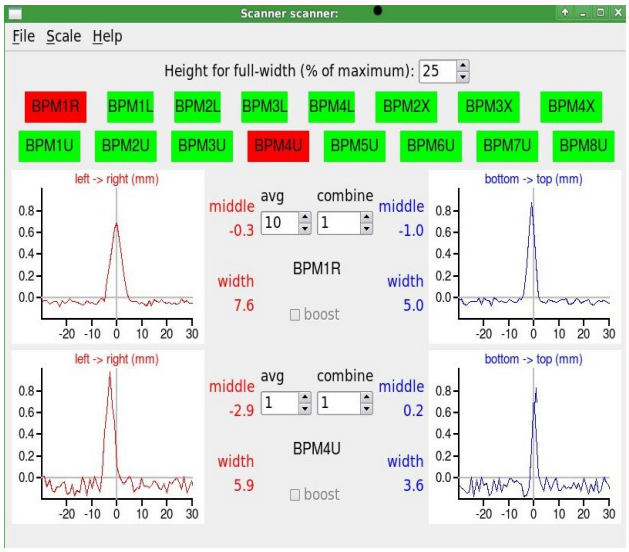

Figure 8: A display showing X and Y profiles of 2 scanners.

Bridging Between Old and New Systems

The old control system [7] is still in use while the new EPICS system is being slowly deployed. It was found necessary for new EPICS programs to communicate with the old system. This was achieved by writing software that acts as a bridge between the systems. The bridging software consists of two programs. The first program uses EPICS channel access server software to get requests for process variables. The program then communicates with the second program, using TCP/IP, that runs on the old control system. The old control system variables appear as EPICS process variables that new programs can handle.

A Switching Program Between Therapy and Isotope Production Beamlines

An IOC is used to control switching of the beam between Therapy and Isotope lines. This is used for beam sharing between radio therapy treatment and radioisotope production. The algorithm, written with EPICS records, goes through a list of checks when setting up the individual lines and aborts the process if any of these fail.

An Energy Table Machine Set Up Program

A Java based program has been developed to allow sections of the accelerators and beam-lines to be speedily and efficiently set up for different beam energies. The program uses a MYSQL relational database. Energy settings are easily managed and after process variables are written to, they are checked for proximity to their set values and alerts given where necessary.

EPICS Clients Currently Being Used

The Archive System is based on the newer Control System Studio (CSS). An Archive Engine takes mainly Vacuum Pump PV data samples via Channel Access and places them in a MySQL Relational Database (RDB). Besides the CSS Data Browser, a JSP-based web report of data is also used to view archived data and allows such data to be plotted and/or exported.

IRMIS, Gateway and Alarm Handler programs will only become fully operational when more systems have been upgraded to EPICS.

The Terminal Potential Stabilizing Unit

A terminal potential stabilizing system including electronic interfacing hardware, EPICS process variables and MEDM control screen was developed for the single ended 6MV van de Graaff accelerator which has greatly lead to improved stability of the beam.

CONCLUSION

The split of implementation is about 90% non-commercial (EPICS and in-house cards) to 10% commercial (Labview, .NET and NI[8] cards). Where there is a large number of I/O cards required (for example about 150 dual power supply controllers) it is cost effective to go in-house. To date about a third of the process variables have been transferred to EPICS on Ubuntu Linux, using off-the-shelf personal computers and in-house interface cards. They are proving to be stable. A consequence of a non-commercial solution is that a fair amount of time has had to be allowed for the development of the software drivers for the I/O cards as well as manufacture and debugging of the I/O cards. This has removed the reliance on commercial suppliers though and the flexibility of the local designs has allowed tailoring of interfacing to match any equipment already installed. Once the design phase is complete the cost per system is low. However on the commercial side when it has been determined that smaller quantities of more specialized interface cards are required Labview in conjunction with these cards has proven to be a very convenient tool with excellent graphics, ready-made drivers and a wide range of I/O cards available. Cognisance also has to be taken of the available skills within the development team. Some developers prefer the Microsoft .NET environment and having experience in this technology allows for rapid development of their assignment, an example being the harp and faraday cup system, successfully deployed.

GSI OPERATION SOFTWARE: MIGRATION FROM OpenVMS TO Linux

Ralf Huhmann, Günther Fröhlich, Susanne Jülicher, V. R.W Schaa, GSI, Darmstadt, Germany

Abstract

The current operation software at GSI, controlling the linac, beam transfer lines, synchrotron and storage ring, has been developed over a period of more than two decades using OpenVMS on Alpha-Workstations. The GSI accelerator facilities will serve as an injector chain for the new FAIR accelerator complex for which a control system is currently developed. To enable reuse and integration of parts of the distributed GSI software system, in particular the linac operation software, within the FAIR control system, the corresponding software components must be migrated to Linux. Interoperability with FAIR controls applications is achieved by adding a generic middleware interface accessible from Java applications. For porting applications to Linux a set of libraries and tools has been developed covering the necessary OpenVMS system functionality. Currently, core applications and services are already ported or rewritten and functionally tested but not in operational usage. This paper presents the current status of the project and concepts for putting the migrated software into operation.

MISSION

Presently, the operation software at GSI runs on a cluster of DEC-Alpha[1] machines. The computers' OS is OpenVMS. The user interface is realized by X-Window and Motif based clients. There are some hardware display and control units, i.e. proprietary interfaced LED and LCD displays, knobs, analog gauges, etc. The software modules for operation of the linear accelerator (LINAC), the transfer lines, and common services are mainly written in Fortran77. The central software components for operation of the synchrotron (SIS) and the storage ring (ESR) are written in Pascal. All programming languages use specific DEC extensions and a lot of OpenVMS specific system calls. The X11 and Motif implementations embed the X11 events into the OpenVMS system's event scheme. We aim to get rid of OpenVMS but to reuse the main parts of the GSI operational software's source code base by porting the software to Linux. Additionally, the migration shall enable interoperability with current or future developments, e.g. in Java on Linux. It showed up that most of the operation applications written in Fortran77 could be ported to Linux with minimal modification effort utilizing the techniques, libraries, and tools described in [1]. Some other Fortran components, especially system oriented services were rewritten in C/C++/Java on Linux. The components for SIS and ESR written in Pascal could not be ported, mostly because no suitable compiler is available which handles the DEC language extensions.

[1] Alpha is today a brand of Hewlett-Packard.

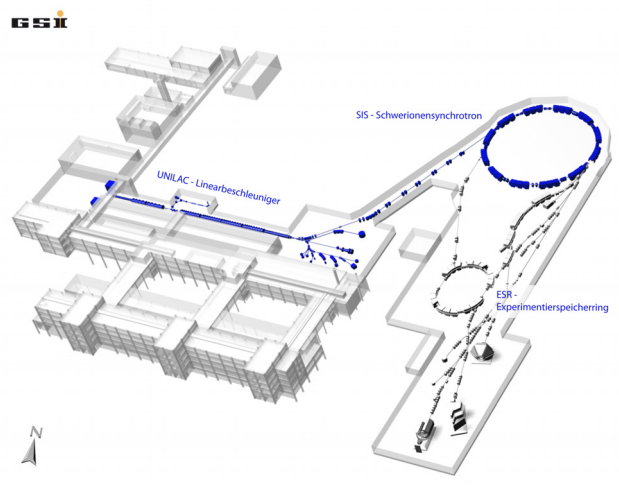

Figure 1: GSI accelerator overview.

ISLANDS

Fortunately, software components for operation of the SIS and ESR on one hand, and the LINAC and transfer lines on the other hand, are only minimally coupled (Fig. 2). Therefore, in step 1 a gateway mechanism was developed to bridge these islands. The SIS and ESR operation software will remain unchanged on OpenVMS and will be excluded from migration in step 1. In a second step those components will completely be replaced by the LSA framework [2] with new Java applications.

New operation applications for the LINAC and transfer lines are developed in Java on Linux and can be bridged with the island of ported Fortran software.

BRIDGES

Fortran@Linux – Fortran@OpenVMS

On OpenVMS, the coupling between SIS/ESR operation software and the LINAC software is realized by a service which sends binary messages from one application to another. It utilizes VMS mailboxes and raw ethernet communication. Actually, for the ported applications on Linux this API was implemented utilizing peer to peer TCP/IP communication and a nameservice (Fig. 4 shows a GUI monitoring the nameservice) to resolve the IP-address and IP-port by the application name. In order to connect from VMS to this framework a proxyservice was developed on

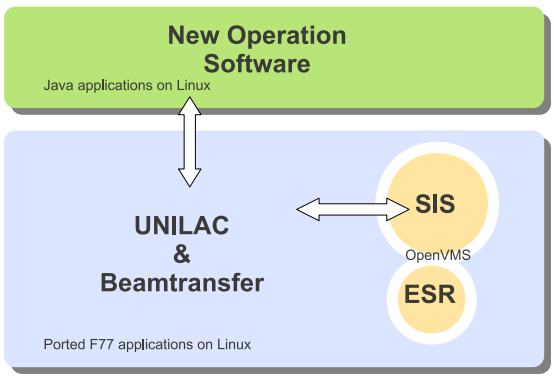

Figure 2: Groups of operation software components in step 1 of migration.

Linux. In Fig. 3 you see as an example two OpenVMS applications `V1` and `V3` which connect via TCP/IP to a service on Linux acting as a proxy for `V1` and `V3` and registering those in the nameservice with the proxy's address and port. Messages from `V1` or `V3` to `L1` or `L2` on Linux are sent to

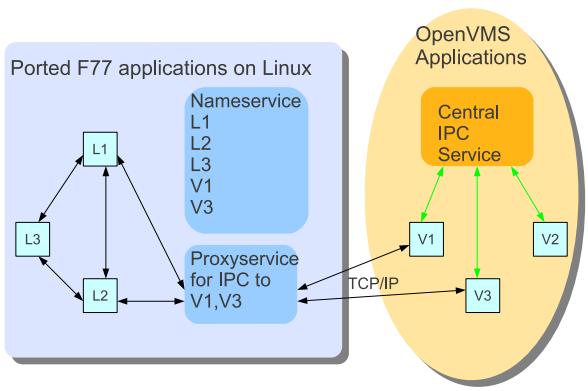

Figure 3: Binary data exchange between Linux and OpenVMS.

the proxy which transmits the packet to its destination application using the name service resolution on Linux. Vice versa, a message from `L1` or `L2` to `V1` or `V3` is received by the proxy since it registered `V1` and `V3` with the proxy's address and port in the nameservice. The proxy forwards the message to OpenVMS via the corresponding TCP/IP socket connection.

Fortran@Linux – Java@Linux

By the *uv*-architecture (Fig. 5) which is described in more detail in [1] an observer pattern is realized to connect Java applications to Fortran applications for data exchange. Fortran applications serve as publisher, Java applications subscribe to data objects. Requests, replies, and notifications are serialized over XML-streams.

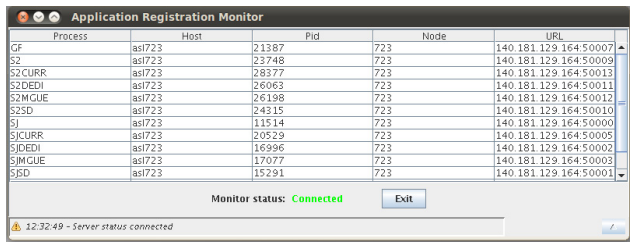

Figure 4: GUI monitor of nameservice.

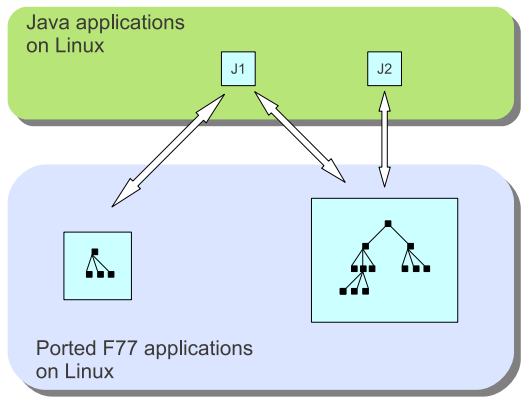

Figure 5: *uv*-architecture for data object exchange between Fortran and Java applications.

Publisher The simple server-API for the Fortran application allows to create and change at runtime a value tree-structure (like adding files and folders to a file-system), to change locally the numerical values of the leaf-nodes, and to put data objects (i.e. arbitrary *uv*-trees) in event-queues. Services like tree transfer of a read result, value changes by clients, sending value change notifications to clients, processing structure changes and subscriptions are hidden in the implementation of the API and are transparent for the application. Value changes initiated by a *uv*-client are notified to the application via callback.

Subscriber The client-API for the Java application is to read the value tree structure or subtree structures. It subscribes to folders for receiving structure changes or to leaf-nodes for receiving numerical value changes or to event-queues for receiving complex data objects. It allows setting values of leaf-nodes of an *uv*-server. Figure 6 shows as an example the value tree of a application seen by a generic value browser utilizing the Java client-API.

CURRENT STATUS

Currently (middle of 2011), the main operation applications for the LINAC and transfer lines are ported to Linux using the VMS system emulation libraries [1]. Some services have been reimplemented, e.g. a central alarm service, a service to launch and monitor applications on selected beam lines, communication modules for dedicated

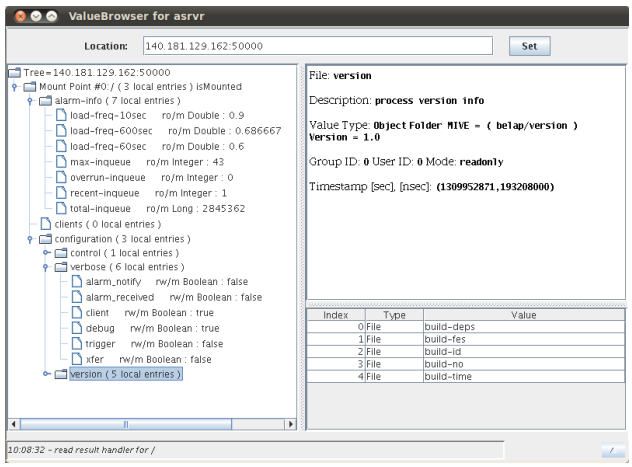

Figure 6: Value tree browser.

hardware control units in the main control room, and a library for accelerator device access. A framework to build the complete software stack from a tagged subversion repository was developed. The above mentioned services and APIs to bridge to remaining VMS software and to new Java applications are implemented and tested.

MIGRATION PATH

Still missing are full integration tests of all operation software components, a production run time environment on Linux, deployment to the production system, performance tests under production conditions, and control room tests without and with beam.

Currently, a test console is set up which will serve as a test site outside the main control room for integration tests and run time environment. In order to switch the operation software to Linux it will be necessary to perform several temporary integration tests in the main control room (Fig. 7), first without beam, later with beam. Hence, to sustain normal operation in the meantime, a procedure has to be defined to enable switching between operation on Linux and back to OpenVMS till the final quality standards are reached. This switching procedure must cover the access to the hardware control units of the consoles, and the interoperation with the left OpenVMS software components. Figure 8 shows the scheduled time scale of the remaining migration path.

Figure 7: Main Control Room at GSI.

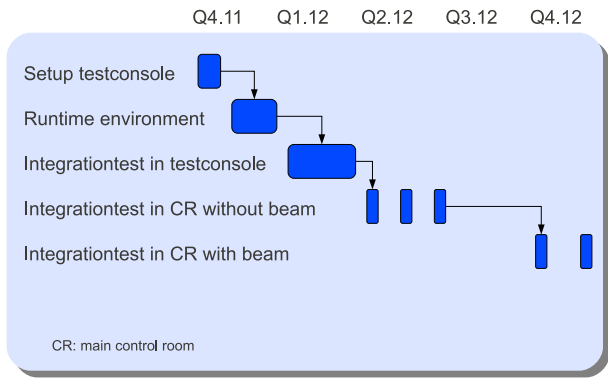

Figure 8: Schedule for migration of operation software.

CONCLUSION

Now, the feasibility studies and most of the implementation, porting, and unit testing has been completed. However, integration and launching in production environment demand further efforts.

THE CONTROL SYSTEM OF CERN ACCELERATORS VACUUM [CURRENT STATUS & RECENT IMPROVEMENTS]

P. Gomes, F. Antoniotti, S. Blanchard, M. Boccioli, G. Girardot, H. Vestergard;
CERN, Geneva, Switzerland
L. Kopylov, M. Mikheev; IHEP, Protvino, Moscow, Russia

Abstract

The vacuum control system of most of the CERN accelerators is based on Siemens PLCs and on PVSS SCADA. After the transition from the LHC commissioning phase to its regular operation, there has been a number of additions and improvements to the vacuum control system. They were driven by new technical requirements and by feedback from the accelerator operators and vacuum specialists.

New control functions have been implemented in the PLCs; new tools have been developed for the SCADA, while its ergonomics and navigation have been enhanced.

INTRODUCTION

The CERN Accelerator Chain

To minimise the interactions between the accelerating beams and the residual gases, and thus maximise the beam lifetime, the beam pipes of all accelerators must be pumped down to a suitable vacuum level.

The Large Hadron Collider (**LHC**) at CERN is a 27 km proton accelerator-collider, with two separate beam pipes that merge at the interaction points. The static vacuum pressure is of about 10^{-11} mbar; due to beam dynamic effects, it can rise up to 10^{-8} mbar.

In order to achieve high fields for accelerating and guiding the proton beams, superconducting materials are used. Therefore, magnets and RF cavities are operated at temperatures down to 4.5 or 1.9 K; they are fed by a separated cryogenic distribution line (QRL).

For thermal insulation, both the superconducting magnets and the QRL are immersed in vacuum below 10^{-5} mbar, often reaching 10^{-7} mbar. The beam and insulation vacuum systems of the LHC totalise some 109 km.

Feeding the LHC, the Super Proton Synchrotron (**SPS**) and its transfer lines add 16 km of beam pipe vacuum [10^{-7}..10^{-9} mbar]. Going back through the chain, the Proton Synchrotron (**PS**), its Booster (**PSB**) and the Linacs (**L2**, **L3**) add a further 2 km.

Vacuum Gauges

To read pressures from atmospheric down to 1 mbar, simple membrane gauges (**VGM**) are used. Thermal conductivity (or Pirani) gauges (**VGR**) are linear in the range 1..10^{-3} mbar. Cold cathode ionisation (or Penning) gauges (**VGP**) reach further down [10^{-5}..10^{-11} mbar].

To cover a wide pressure range, a pair of Pirani and Penning are assembled together and read by common electronics, becoming a "full-range" gauge (**VGF**).

Hot cathode ionisation (Bayard Alpert) gauges (**VGI**) are used in the range 10^{-7}..10^{-12} mbar.

Vacuum Pumps

Primary pumps (also called “roughing pumps”) are used to evacuate from atmosphere down to 10^{-3} mbar; they are also used as a backing pump for Turbo Molecular pumps (TMP), who are effective in the range 10^{-3}..10^{-10} mbar. Often they are both assembled and controlled together as a Pumping Group. If their usage is temporary, they can be are embarked in a mobile trolley (**VPGM**), together with the powering and control electronics. For long-term pumping (**VPGF**), only the pumps and powering circuitry are left close the accelerator, while all the radiation-sensitive electronics is kept in safe areas.

When needed to reach ultra-high, vacuum sputter-ion pumps (**VPI**) are added [10^{-5}..10^{-11} mbar]; as a bonus, their current consumption is a good measurement of the pressure.

Sublimation pumps (**VPS**) are used in the range 10^{-9}.. 10^{-12} mbar. Cryogenic pumps are used in particular cases.

Vacuum Valves

To isolate a pumping group from the pumped volume (vacuum sector), roughing valves are used (**VVR**). Sector gate valves (**VVS**) provide isolation between vacuum sectors, to prevent leak propagation, or to allow for a mechanical intervention. There are also window valves (**VVW**) and fast shutter valves (**VVF**).

Instrument Count in Accelerators Vacuum

All in all, (Table 1) there are more than 6 000 instruments to be controlled and monitored, distributed along 128 km of vacuum, in the range of 10^{-4}..10^{-11} mbar. The mobile pumping groups are not counted here; nor are the gauges and valves in the fixed pumping groups.

Table 1: Vacuum Equipment in CERN Accelerators

VACUUM CONTROLS ARCHITECTURE

The CERN accelerator complex has a history rich of several decades; vacuum controls architecture and equipment have been evolving, with the construction of every new accelerator machine and with the availability of new technologies.

Given the different evolution paths of each machine, managed by different entities, and depending on the funding availability, it was not obvious to always enforce homogeneity of architectures, equipment and naming. It is common to find several versions of the same equipment, from different generations, coexisting in the same machine. In order to increase the efficiency in debugging and repairing and to simplify the stock management, a considerable effort is being put into analysing the existing versions of each equipment and selecting only a couple of them, that would comply with most of the requirements.

Stand-alone Locally Operated Vacuum Controls

In the early times, a central control room near the accelerator concentrated all electromechanical actuators and displays; they were directly cabled to the machine and were not accessible from elsewhere.

That is still the case of some experimental facilities around the PS Complex, where the electromechanical equipment has been replaced by electronic front-ends, but continues to be accessed only locally.

VME & X-Windows / JAVA

In the 90's [1,2], the vacuum controls of the PS Complex and SPS were renovated: for each facility, a VME crate (DSC - Device Stub Controller) collected the data through an RS232/X25 interface; either directly, from industrial controllers equipped with a RS232 port (VGR, VGP, TMP), or through G64 concentrators, for custom-made equipment (VVS, VPI, VPS). The DSC was remotely accessible through Ethernet, on Unix workstations running X-Windows and MOTIF as graphical user interface. The pumping groups, however, were kept running in stand-alone mode.

Until the next wave of renovation, this is still the case of the PS Ring, AD (Antiproton Decelerator) and CTF3 (CLIC Test Facility), although with new graphics provided by Java ("Working Sets").

PLC & PVSS

Since 2000, the SPS, then the LHC (Fig. 1) and part of the Complex PS have been upgraded to a PLC-based architecture [3,4], using the Siemens™ S7-400 series. The human-machine interface is a SCADA (Supervisory Control And Data Acquisition), built with PVSS®.

The application software for both PLC and PVSS started to be custom-made by the vacuum group. With time, it included a growing number of building blocks from the UNICOS framework [5].

Geographically limited accelerators or installations are controlled by a single PLC. Wider machines have one PLC at each underground service area (Complex PS: 5, SPS: 7; LHC: 28). Independently of the number of PLCs used, there is only one PVSS Data-Server (DS) per accelerator complex.

The PLCs and the DS communicate through Ethernet in a protected and restricted "Technical Network"; consoles in the "Office Network" can have access limited to monitoring the evolution of vacuum variables.

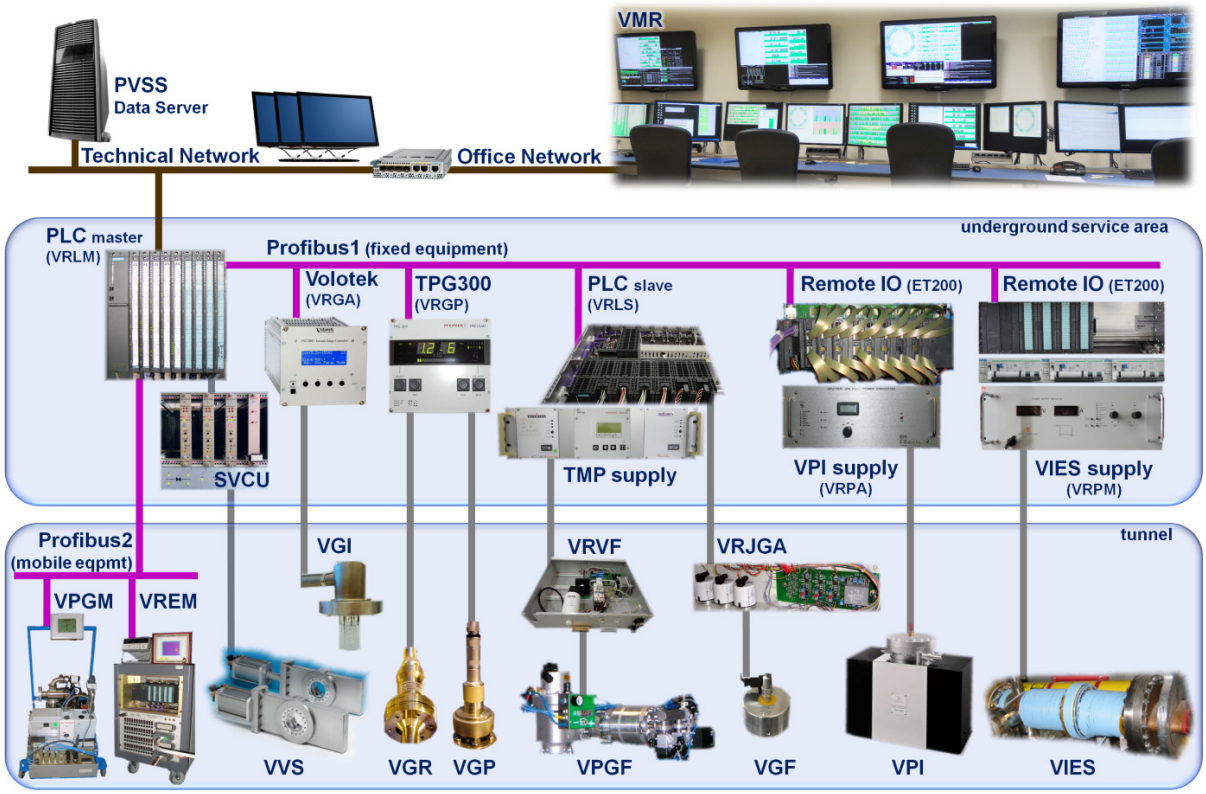

Figure 1: LHC vacuum controls architecture.

Equipment in the Underground Service Areas

A PLC accesses the field equipment (gauges and pumps) through controllers or power supplies; the modern ones are often intelligent, as they have an embarked microprocessor or other programmable device, like an FPGA; when equipped with the corresponding interface, they can communicate with the PLC via Profibus® (a serial communication link for field equipment); this minimises the complexity and price of cabling and also allows for a wider exchange of information and configuration parameters. This is the case of the controllers for VGI (Volotek), for the VGR and VGP (TPG300), and for the power supplies of the recently added "anti-electron-cloud solenoids" (VIES); also, the fixed pumping groups (VPGF) and their TMP controller are managed by a small "Slave" PLC (S7-300), connected to the "Master" PLC by Profibus.

On the other hand, the controllers for the VVS are directly connected to individual IO channels on the PLC; the power supplies for the VPI are connected to remote-IO stations (Siemens-ET200).

While the PVSS-DS reside on centralised surface buildings, the PLCs, controllers and power supplies are kept in underground service areas, away from the accelerator tunnels where radiation could damage them.

Equipment in the Tunnel

In the accelerator areas where the estimated radiation was considered as acceptably low, and where the distance to a service area was quite large, "active" gauges were installed. These consist of a VGF (pair of VGR+VGP) with its front-end electronics nearby. Individual VGR and VGP ("passive" gauges) that are closer to the radiation-protected areas can be directly accessed by a remote TPG.

A dedicated dynamically-configured Profibus network connects the Master PLC to the "mobile" equipment; although sensitive to radiation, they only come to the tunnel when the machine is shut-down. Examples are the mobile pumping groups (VPGM), managed by another "Slave" PLC (S7-200), and the mobile bake-out stations (**VREM**) handled by an S7-300.

Interlocks, Alarms & Warnings

To restrict potential leaks, if several pressure readings (VGP, VPI) in the same vacuum sector rise above a given threshold, an interlock is sent to the VVS controller; the neighbouring sector valves will then close, confining the vacuum sector. To limit its sensitivity to noise or spurious variations of pressure, this interlock is a voting combination of the relay outputs of TPG and VPI_supply: if a majority of the readings is OK, no interlock is produced. However, if at least one relay is not-OK while the neighbouring valves had been closed for some reason, the valves cannot be opened again until all relays are OK. The details of the voting logic are machine-dependent.

As the automatic closure of the VVS would interfere with the beam circulation, when a pressure interlock is going to close the valves, an interlock is also sent to the beam control system (BIC), in order to previously dump the beam. Conversely, the "beam ON" information from the BIC prevents the manual closure of the VVS.

Hardware interlocks are also sent to the control systems of cryogenics, RF, MKI and MKD, in case of degradation of the respective isolation vacuum.

Devices like the VPI, VGP and VGI may be degraded or even damaged if operated at too high pressure; their controllers have internal protection interlocks to power them off in case their pressure reading rises above a given threshold; for the VGP, the interlock can also be derived from the associated VGR within the same TPG.

Less critical situations, but nevertheless important to other control systems, are sent from PVSS to the LHC Alarms Service (**LASER**), to be handled by the accelerator operators.

Vacuum issues demanding the attention or intervention of an expert generate also an alarm in PVSS, which will send a mail or SMS to the corresponding list of experts.

The PVSS application provides a wide set of visual warnings, in terms of colours and widget animations, to draw the attention of the operators in case of unusual conditions.

Communication with Other Systems

Process status and values are published by PVSS, to the other control systems, through the middleware interfaces **CMW** or **DIP**. Also, PVSS can get data from CMW and DIP. Alarms for the accelerator operators are published to LASER. The corresponding configuration comes from **CCDB** (the Controls Configuration database).

The PVSS own local archives are limited in size, and therefore in time-depth, depending on local disk capacity; therefore, the historical data is periodically sent to a central repository - the **LOGGING** database.

Databases & Software Generation

A set of ORACLE databases contain the information necessary to automatically generate the equipment description for the PLCs and for PVSS.

The **Master DB** contains the parameters common to all the machines. This includes the definition of **equipment types** according to the physical characteristics. In addition, equipment is also classified by **control types**, with a set of attributes required to interface the equipment with the control system. Often, equipment of the same type are controlled in the same way.

The **Machine specific DBs** (LHC DB, SPS DB, CPS DB) contain information about each machine, such as the definition of all vacuum sectors, and the individual attributes of each installed equipment. The information about the geographical distribution of all vacuum equipment is imported from the Layout and Survey databases. A user-friendly Java application (**DB_editor**) allows the manual entering or modification of any individual attribute.

The **DB_export_tool** combines the information from the above data bases and produces the configuration files for both PLC (DataBlocks) and PVSS (DataPoints, CMW and DIP servers, LHC Logging, LASER, etc.).

NEW FEATURES

PLC

The control of the pumps and valves in a pumping group is the result from a simple logic combination of several status inputs, including pressure levels, together with some timers. After a power failure, some of the status inputs are lost and the group has to be restarted manually. This is particularly annoying if a thunderstorm causes a power cut in a large region of an accelerator.

A palliative solution was implemented, that includes the cyclic memorisation of the status inputs; when the function detects that the power of the group was off and back again, it tries to automatically restart it, taking into account the memorised status inputs.

In parallel, a completely new approach is under development, using the concept of sequential state machine. Here, the outputs of the function depend only on the current state of the machine, not on the input values. The state is the memorised resultant of the sequence of previous states and inputs. At any time it will be easy to restart from the memorised state.

In order to reduce the electron-cloud effects in the beam vacuum, several solenoids have been installed around critical parts of the LHC. A new function was developed to control this new type of equipment and allow the operators to manually pilot their current from PVSS.

To fight unexpected leaks in the insulation vacuum, it became necessary to quickly install a pumping group with the electronics kept in radiation-free zones. The automatic recognition and integration of slave PLCs into the mobile Profibus has been extended for this purpose.

PVSS

In order to improve the ergonomics and efficiency of diagnostics, several improvements were made on the existing PVSS tools. The users can now define and save the full details of their own email/SMS notifications, one by one or globally in a table. Also the historical trends can now be configured and saved by the users. The query for device list has been improved and merged with the query for state/value history, within a given time frame.

To increase security, the PVSS application now starts with user "monitor", who has no rights to manipulate anything. This way, the user ID is not anymore inherited from the current Operating System session. Only when the operator actually needs to perform any action, he will log into PVSS to gain his access rights; after a period of inactivity he will be automatically logged off. This way, we minimise the time a console can remain unattended with a full-rights account.

The values of the thresholds for the interlocks produced by the TPGs can be accessed and modified from PVSS. In times of accelerator study and development, those interlock levels may be changed by the experts. In order to keep track of these modifications, a new tool was developed to automatically back-up of the parameters of all the TPG, every day.

In order to improve the diagnosis of the vacuum systems and the organisation of preventive actions, new panels were created and others were enriched (Fig. 2). The equipment of the PS-Ring and AD, although still on the previous generation of control architecture, is now available for monitoring on PVSS, using CMW data.

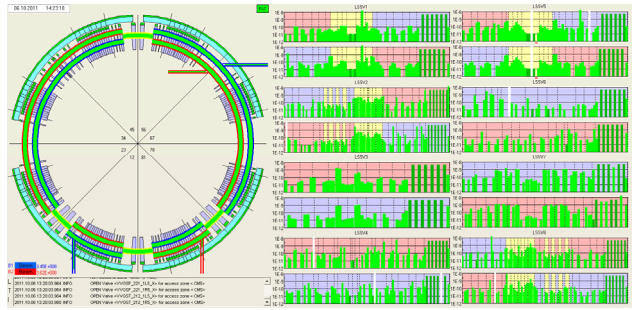

Figure 2: LHC synoptics and pressure bargraphs.

A web server was created, showing PVSS panels that summarise the values and status of the vacuum systems. The function that lists all interlocked valves has been upgraded and exports a list to the web server.

A monitoring room (**VMR**) was set, with 4 stations directly on the technical network and 4 wall-screens running the web summary pages. Soon, all PLCs and DS will be available on **DIAMON**, a tool for remote surveillance and diagnostic of all CERN controls infrastructure.

The PVSS graphical interface for windows clients has been upgraded from the old ActiveX to QT. This finally allows to smoothly move the PVSS servers from Windows to Linux, and also to have client applications on Linux machines.

CONCLUSIONS

New functions have been implemented in the PLC and PVSS. The ergonomics and configurability of the PVSS application have been enhanced.

There is still a long way ahead, regarding the homogenisation of equipment and controls across machines, the convergence towards UNICOS, and the tools for tracking of events, interventions and repairs.

NEW TIMING SYSTEM DEVELOPMENT AT SNS*

Doug Curry, Xihui Chen, Richard Dickson, Steven Hartman, David H. Thompson,
ORNL, Oak Ridge, TN, USA
Joze Dedic, Cosylab, Ljubljana, Slovenia

Abstract

The timing system at the Spallation Neutron Source (SNS) has recently been updated to support the long range production and availability goals of the facility. A redesign of the hardware and software provided us with an opportunity to significantly reduce the complexity of the system as a whole and consolidate the functionality of multiple cards into single units eliminating almost half of our operating components in the field. It also presented a prime opportunity to integrate new system level diagnostics previously unavailable for experts and operations. These new tools provide us with a clear image of the health of our distribution links and enhance our ability to quickly identify and isolate errors.

INTRODUCTION

The Timing System at SNS is based on the dual timing system architecture used at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven Nation Laboratory (BNL) [1]. The first system is a beam synchronous system that distributes and correlates specific tasks that are used in the production of the beam pulse. It produces a bi-phase mark encoded signal to embed the ring RF clock with the event scheduling data to provide remote platforms with a reference in which local PLLs can lock to and derive references that are synchronized to the ring frequency. This system was altered slightly to meet the specific requirements at SNS to synchronize the 60 Hz operation of the LINAC and neutron choppers to the accumulator ring [2]. The second system or Real Time Data Link (RTDL) serves as a general purpose information distribution network. It globally broadcasts information across a unidirectional link about each beam pulse. The delivery of this data only has to occur within a specified range of time and is not required to be correlated to the ring frequency and is therefore asynchronous to the ring RF source.

The hardware delivered by BNL can no longer be reproduced as many of the components have reached their end of life cycle. This makes it impossible to support the existing architecture for any extended period of time. A hardware redesign is required in order for us to effectively support the long term availability goals of the facility. This has provided us with an ideal opportunity to simplify our system architecture and focus on decreasing our maintenance overhead by integrating the functionality of multiple components into a single units and making system diagnostic capabilities available at each node.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy

TIMING MASTER HARDWARE

The Timing Master Hardware achieved the largest gains in reducing individual component design complexity by integrating both of the RHIC timing systems into a single VME card [3]. The previous platform requires multiple sets of hardware components that span across 2 VME crates using a VME bridge [4].

Event Timing

The RHIC beam synchronous system that generates the machine cycle sequence events across the Event Link (EL) requires 4 Trigger modules that produce reference pulses to 4 Event Input modules that are connected to a single Event Link Encoder module using a special adaptor cable that bridges the user defined pins of the P2 connector. The functionality of these 9 cards now resides within the SNS Timing Master Hardware.

The 4 Event Input modules produce all of the fixed or hard events that are used in the production of the beam pulse. The number of fixed events is limited to 64. This restriction is imposed by the Input modules which are only capable of generating 8 events per node. Special care must be taken when setting up this system to prevent Event Jostle. This occurs when 2 or more of these modules try to fire an event at the same time. The generation of soft or floating events must be held off by the IOC during the period of time when beam events are active to ensure they do not cause additional scheduling conflicts while the fixed events are in the process of being broadcast on the EL.

The SNS design utilizes a local memory to store the hard events. It has a depth of 16k address locations. There are only 255 usable events available in the SNS Timing System; therefore, the majority of the memory locations are unused. The Timing Master hardware maintains a counter that represents the current turn count within the machine cycle production period. A turn is defined as the amount of time it takes for the beam to travel around the SNS ring 1 time. There are approximately just over 17k turns in a given SNS machine cycle. This counter is used as an address pointer to the hard event memory. When a non-zero value is returned from a particular address location soft event requests are queued and held off until a conflict is no longer present. The machine specific event numbers are stored in memory locations that correspond to a given turn in the machine cycle when they are scheduled to be broadcast on the event link. Additional events are allowed to pass through the system at anytime there is not a machine specific event scheduled for production. The

possibility of Event Jostle is completely eliminated in this architecture as there is only a single source of the hard events, and the processing of soft events are postponed and queued by the hardware when the address pointer returns a non-zero value. This also allows the IOC to schedule the soft events at anytime within the machine cycle as it is no longer restricted to non-beam production periods. Mapping the fixed events into memory also allows the new system to define any number of the 255 events as either hard or soft events. It is no longer restricted by the Event Input module limitations.

Data Link Timing

The RHIC RTDL hardware requires a single RTDL Encoder and multiple RTDL Input Modules. Each Input module is only capable of producing 8 frames. The encoder and input modules also require a special adaptor cable to bridge the user defined pins of the P2 connector. The protocol defined for the RDTL restricts the unique number of data packets it is capable of transmitting to 256 frames. The SNS system has been configured to broadcast 128 frames of data. This architecture would require a third VME crate if the SNS requirements where updated by adding additional frames above the current 128 that are presently defined and would require installing a 3rd VME crate as a total of 32 Input modules are needed to populate 256 frames.

The SNS Timing Master design eliminated the need for the encoder and input modules. This was handled in a similar fashion to the EL by mapping these frames into a separate local memory bank; however, unlike event driven timing system, this memory only needs to be large enough to contain all 256 frames. The IOC updates values in the RTDL between machine cycles. The RTDL section is processed by the hardware when it observes and RTDL valid event from the IOC. The hardware then processes the entire RTDL table and only queues the frames that have been updated by the IOC. After the table has been processed, the hardware clears the frame table to prevent stale data from being rebroadcast across the link.

TIMING RECEIVER HARDWARE

The most significant achievement in simplifying the overall system architecture was accomplished in the redesign of the Timing Receiver Hardware [5]. The RHIC Trigger Module [6] and the Utility Module [7] were integrated into a single VME card. This has the highest impact on reducing the total number of supported operating components in the field as a large portion of the subsystems utilize both sets of this hardware platforms.

Trigger Module

The primary function of the Trigger Module is to support the SNS subsystems that are responsible for the production of the beam pulse by producing machine cycle specific reference pulses that are synchronous to the ring RF clock. These cards contain local PLLs that derive reference clocks from the bi-phase mark encoded event link generated by the Timing Master hardware at 32x the ring frequency.

These cards contain 8 front panel trigger reference outputs that can be configured independently to produce reference pulses to any of the 255 predefined SNS events. These pulses can be delayed from the start of an event using 1/64 increments of the ring RF frequency for systems that require alignment with the head or tail of the beam pulse within the accumulator ring.

Utility Module

The Utility Module provides the IOC with cycle to cycle information about each beam pulse that is extracted from the RTDL. The module will interrupt the IOC after receiving an RTDL valid event from the Timing Master on the EL. This notifies the processor that the table has been updated and is ready for any user applications that require this information. It also serves a platform for generating additional interrupts to the IOC when specific events have been observed on the EL or an error was observed on the event or real time data links.

System Diagnostics

One of the major challenges with the previous Timing System is determining the existence of and isolating transmission errors. The modules will notify the processor that an error exists; however, it provides very few details about the error. Additional information must be acquired by adding additional VME cards to the configuration.

The new Timing Receiver Hardware incorporates detailed diagnostics for both of the timing links within the hardware design. It utilizes 2 different memory banks that store the observed events from the EL and the frames from the RTDL for each machine cycle. The processor is interrupted only if this feature has been enabled in the hardware. This allows us to field diagnostic tools with every module without running additional application overhead if the diagnostic tool is not needed.

TIMING DISTRIBUTION NETWORK

The SNS Timing Distribution Network also suffers from component availability issues. This hardware redesign has also been modified from the original equipment that was delivered to SNS. This includes changes that actually complicated the design slightly; however, the functionality remains the same. Special care was taken to ensure the health monitoring equipment does not impact the operation of the distribution network should it experience a failure.

The overall distribution architecture was revisited. The previous distribution method performs multiple media conversions prior to reaching its final destination. This adds additional unnecessary jitter to the distributed signal that is received by the end components in the field making it difficult to perform high resolution beam reference measurements. The new design retains the

information on fiber links until it reaches the end point before converting it into an electrical signal.

The new hardware takes advantage of using hot swappable SFP modules and includes an additional new set of diagnostics that allows us to perform health checks of the links at the fan-out modules. This gives us an opportunity to perform preventative maintenance checks during scheduled maintenance periods.

CONCLUSION

By simplifying the system architecture, the SNS Timing System is easier to manage and has significantly fewer active components that are likely to fail. The addition of diagnostics at each node allows us to isolate and identify failures remotely and more rapidly than before. These changes also allow us to incorporate preventative maintenance routines into our scheduled maintenance periods and provide us with the opportunity to address failures before they impact accelerator operations.

Allowing the hardware to manage more of the overhead task allows a number of the IOC responsibilities to be reduced and simplifies the design of the software as well. A fair number of the tasks have been reduced to simply updating a handful of registers in the timing hardware.

The integration of our hardware components has allowed us to remove 8 different types of VME cards from our inventory and combine their functionality into just 2 cards. The Timing Master VME crate previously spanned across two 11U 21 slot VME crates. It now occupies a single 4U 9 slot crate. We have also managed to eliminate approximately 150 active VME cards from our operating environment.

HIGH INTENSITY PROTON ACCELERATOR CONTROLS NETWORK UPGRADE

R. Krempaska, A. Bertrand, F. Lendzian, H. Lutz,
Paul Scherrer Institute, 5232 Villigen PSI, Switzerland

Abstract

The High Intensity Proton Accelerator (HIPA) control system network is spread through a vast area in PSI and it was grown historically in an unorganized way. The miscellaneous network hardware infrastructure and the lack of the documentation and components overview could no longer guarantee the reliability of the control system and the facility operation.

Therefore, a new network, based on modern network topology, PSI standard hardware with monitoring and detailed documentation and overview was needed. We would like to present how we successfully achieved this goal and the advantages of the clean and well documented network infrastructure.

INITIAL SITUATION

The HIPA control system network components and nodes are located in about six buildings. It expanded during many years, often with ad-hoc requirements. It consisted of about 25 network switches of various manufacturers, 150 computer nodes and 20 operator consoles. Numerous problems started to arise with ever increasing frequency.

The lack of general HIPA control system network overview made the system administration difficult. Problems with performance, such as bottlenecks during data transfer between the private machine network and the PSI office network, led to the situation when no central backup and operating system update, by using the PSI standards, were possible.

Further there were problems, based on the network topology. A cascade topology rather than a star topology had evolved over the years.

Another problem we encountered, related to the maintenance of network components. In particular, switches have been installed from a multitude of suppliers and so it was almost impossible to install replacements from our emergency stock. This was a risky situation for the facility operation.

And finally the network administration was not satisfactory. Central monitoring was not possible at all, because most of the network components did not support management or monitoring.

The original situation can be seen on Fig. 1. It shows switches of various manufacturers, often connected in cascade, in six buildings. This diagram has been created after a detailed analysis of the current situation at the facility during November 2010. Fig. 2 illustrates cascaded production switches from various manufacturers used until the end of 2010.

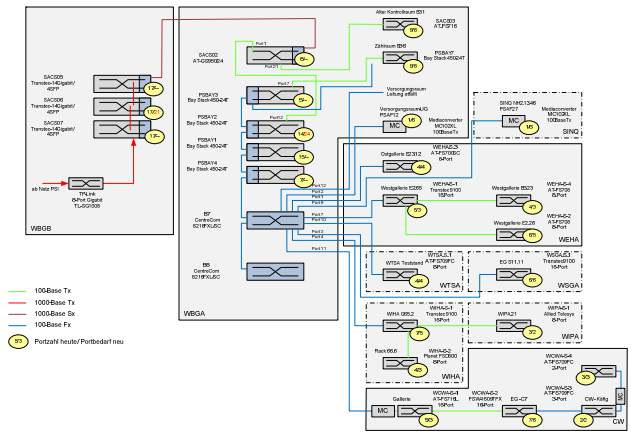

Figure 1: The HIPA network overview after the current status analysis in November, 2010.

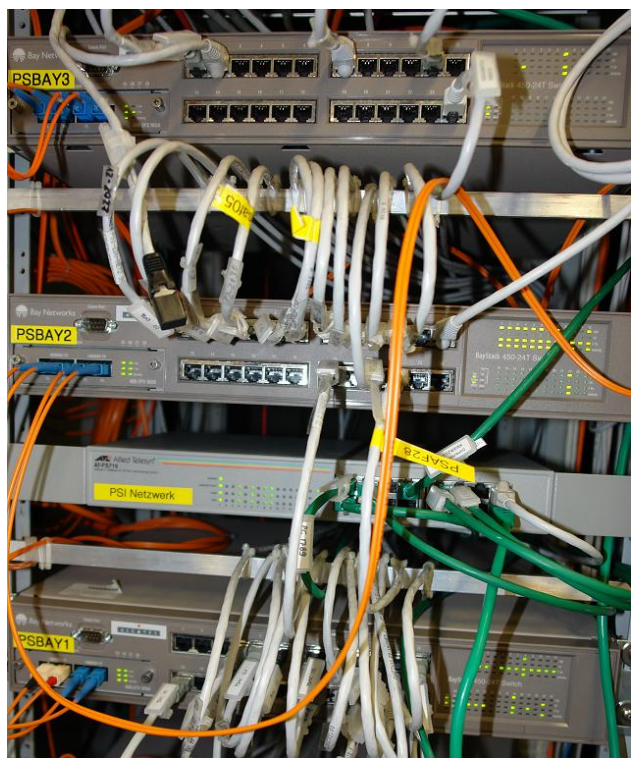

Figure 2: Different flavour of network switches running in HIPA Controls network until the end of 2010.

PROJECT GOALS

The main goal for the HIPA network migration was to build a highly available, stable and scalable network with low complexity and dependencies. This should mainly lead to the improvement of network performance. Furthermore, network administration and hardware maintenance should be more simple and effective. Network design topology should be according the PSI standards with network monitoring. The project should be well documented in order to supply overview and useful information for the facility operation or for people on the on-call service.

PROJECT PLAN AND REALISATION

Three teams collaborated intensively during the project preparation and realisation: At PSI these were the Controls and AIT Network groups and the external company KeyNet Consulting GmbH [1].

Based on the analysis of the current situation, a new design based on the star topology was created, see Fig.3.

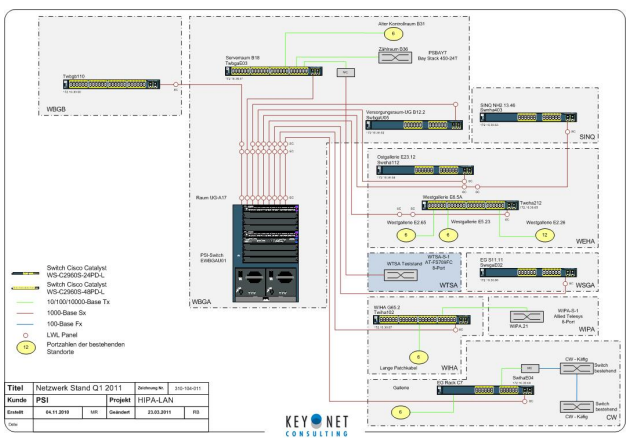

Figure 3: The new network design based on the star topology, PSI standard.

Afterwards, a more detailed project plan was elaborated. This included a schedule for ordering and purchasing of switches and other components; and cabling specification for the Electrical engineering division.

The cleanup of nodes in the new and old server rooms and control rooms has been done. The configuration of operator consoles, servers, and other computing components has been unified. Redundant computers have been removed.

One of the biggest challenges of the network realisation was the tight time scheduling during the HIPA shutdown period. An important part of the project was the cabling realisation. Because of minimal resources, it was difficult to schedule the network recabling to the electrical shutdown plan. All the activities had to be independent of other shutdown activities, such as components and machine tests. And finally, the successful operation start-up schedule had to be guaranteed. Another challenge was the fact that we could enter some locations only for a very short period because of high radiation. This was for example, the building in which the ion source and the Cockcroft-Walton accelerator are located.

RESULTS AND ACHIEVEMENTS

The HIPA proton accelerator control system runs now on a modern scalable and stable PSI standard network.

Network Homogeneity

The number of active components has been reduced from 25 to 9 Cisco Catalyst 24- or 48-port switches. They are the same type as other PSI switches, thus a replacement emergency stock is not an issue anymore.

Performance

We could observe performance improvement, thus the computers can receive the PSI updates and servers are connected to the PSI central backup system.

DHCP and DNS

DHCP and DNS administration has been reorganized by using the PSI standard infrastructure.

Cabling

Cabling and patching work has been done meticulously. Many unused connections have been unplugged and hundreds of meters of cables removed. This led to a better physical overview.

Monitoring

The HIPA network is now monitored by using the PSI standard tool, NeDi (Network Discovery) [2] and the information is visible to the Controls section on the intranet, see Fig. 4.

Documentation

Even the documentation has been written during the each process of the HIPA Network Upgrade, we realized on-line documentation generated directly from the Oracle database. All the information was updated in the Controls Database Inventory [3]. The tool generates various reports in the form of maps and diagrams working directly with the data stored in the database. They can be displayed on the PSI intranet Web, see Fig. 5.

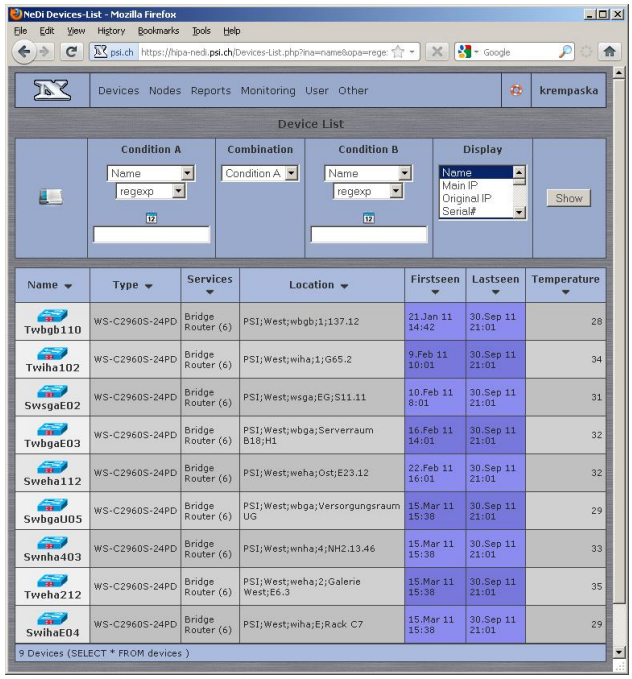

Figure 4: HIPA switches and nodes are monitored by a PSI Network monitoring Web tool NeDi.

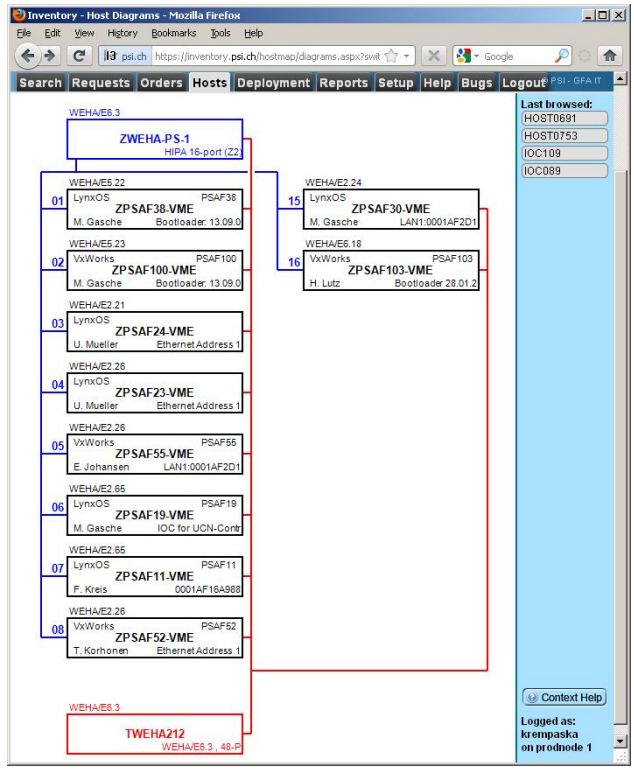

Figure 5: The diagram shows a switch and the nodes connected to it (red lines). These VME IOCs have serial connections to a port server (blue lines).

ACKNOWLEDGMENTS

We want to acknowledge M. Rutz and R. Boesch, KeyNet Consulting GmbH, Luzern, Switzerland for the project management consulting, documentation and technical support. Further, we wish to thank to the colleagues from PSI Infrastructure and Electrical Engineering Divisions for cabling specification and realisation, especially to R. Kaech.

Abstract

To improve tracking robustness and precision of the ATLAS inner tracker, an additional, fourth pixel layer is foreseen, called Insertable B-Layer (IBL). It will be installed between the innermost present Pixel layer and a new, smaller beam pipe and is presently under construction. As, once installed into the experiment, no access is possible, a highly reliable control system is required. It has to supply the detector with all entities required for operation and protect it at all times.

Design constraints are the high power density inside the detector volume, the sensitivity of the sensors against heat-ups, and the protection of the front end electronics against transients. We present the architecture of the control system with an emphasis on the CO_2 cooling system, the power supply system, and protection strategies. As we aim for a common operation of Pixel and IBL detector, the integration of the IBL control system into the Pixel control system will also be discussed.

DETECTOR LAYOUT

The Insertable B-Layer is a pixel detector, which is mounted directly on the LHC beam pipe. Fourteen mechanical support structures, called staves, form a cylindrical shell with an average radius of 33.25 mm and a length of 698 mm. A pseudo-rapidity of $|\eta| < 3$ is covered. Each stave carries sixteen modules. They are composed of the sensor itself and two frontend chips, whose read out cells are bump bonded to the sensor cells. While the inner modules of each stave will be built by planar sensors, the outermost modules of each stave are 3D sensors. In total there are three quarters of planar and one quarter of 3D sensors. For details of the different sensor technologies, see [1]. The frontend readout chips, the FE-I4s, are produced in a 130 nm bulk CMOS process. Its pixel cells are organized in 80 columns with a pitch of 250 µm and 336 rows with 50 µm pitch. Altogether 448 frontend chips provide 12 million readout channels.

Due to the high power dissipation of the detector modules, an efficient cooling system is required. Therefore a cooling pipe is integrated into each stave. An evaporative cooling using CO_2 keeps the detector modules at (-25 to -30) °C. A total power of 1.4 kW can be removed from the detector. Extra cooling power is available to remove the environmental losses of the transfer piping.

The data of the frontend chips are sent to the counting room via optical data transfer. In the other direction configuration, trigger and control signals are sent by the DAQ system to the frontend chips, also using the optical link. The on detector part of the opto-electrical transceivers, the opto boards, are located close to the detector itself, while the off detector part, the Back of Crate (BoC) cards are installed inside the DAQ crates.

DCS REQUIREMENTS

The Detector Control System (DCS) is responsible for the safety of human beings, the detector and other equipment. It must provide tools to control the detector in all operation modes, like normal data taking with colliding beams, as well as calibration and tuning periods. To ensure the success of a command, feedback must be given to the operator. Furthermore the DCS must deliver additional information for debugging the detector and diagnosing its behaviour. Safety, control and diagnostics vary concerning required reliability, availability and granularity. Highest level of reliability is required for the safety system, a high level for all control actions, while the level can be lower for information which is used for diagnostics. Similar levels must be considered concerning the availability of a DCS component. While the safety system must be functional at all times, control units are required as soon as an operation is performed with the detector and diagnostic tools are activated on request. Concerning the modularity the levels are reverse. If the behaviour of the detector must be analysed, detailed information on small units like individual frontend chips must be available. On the other hand, if the detector must be protected against upcoming risks, even larger parts of the detector can be stopped.

A clear user interface, automatic safety and error recovery procedures and archiving of data are tools to fulfill the above listed requirements. Furthermore the integration of the IBL DCS into the Pixel and the ATLAS wide control system [2] must be ensured. These demands have impact on the choice of hardware as well as on the software design of the IBL control system.

DCS HARDWARE

An overview on the IBL DCS hardware is given in Figure 1. The detector modules, the opto boards and the BoC/DAQ crates are subjects to DCS. Furthermore the detector environment must be permanently watched. These are the entities which require monitoring and/or control.

Several power supplies (HV, LV, SC-OL) provide all units with the power they need. On the other side the high power dissipation is compensated by the cooling system.

Various monitoring mechanisms are in place, some of them provide in parallel inputs to the interlock system. This system is responsible for the safety of human being and of the detector and acts directly on the power supplies if an error condition is found. The normal control and monitoring functions are provided by the Cooling and DCS PCs. Most parts of the DCS are located in the counting room which is about 100 m away from the inner detector itself. Just the regulator station and some monitoring units are installed inside the detector cavern.

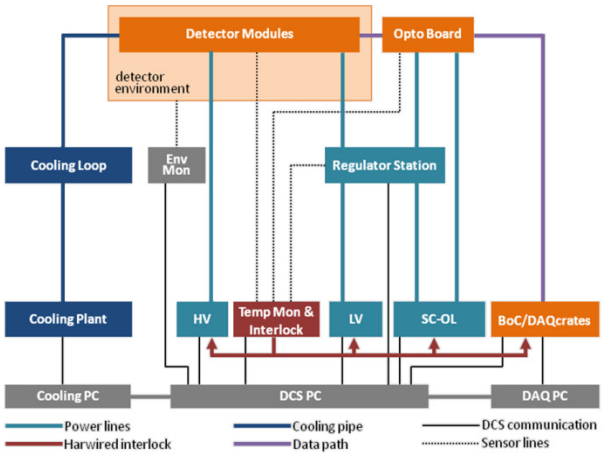

Figure 1: DCS Overview.

Power Supplies

Detector modules and the opto boards require a dedicated powering which is exactly adapted to the needs of the loads. To all components in common is the request of floating supplies. The output voltages must be variable. Concerning safety, over-current protection and interlock inputs are of main importance.

To deplete the sensors a HV power supply is required. While the planar sensors will need up to 1000 V after irradiation, the 3D sensors can be operated with significantly lower voltages of a few hundred Volt.

The frontend chips are powered by the low voltage (LV). Due to the required currents of up to 900 mA per frontend chip the voltage drops on the services are not negligible. The frontend chips themselves require just 1.2-1.5 V, however the LV supply will be able to deliver 10 to 15 V. As on the other side the frontend chips, which are produced in a deep submicron technology, would be destroyed by over voltages of more than 4 - 5 V, a voltage regulation close to the detector is performed. It protects the sensitive chips against transients and is therefore an important safety mechanism. Key components of the regulator station are the regulator LHC4913 and digital trimmers which allow for a remote control. For more details on the regulator station see [3].

The third voltage supply SC-OL (supply and control of the opto link) is responsible for the powering of the opto boards, which require three different low voltages [4]. The VCSEL driver chip and the decoder chip are powered by Vvdc with a maximum voltage of 10 V and 800 mA. As also the chips of the opto link must be protected, Vvdc is routed through the regulator station in the same way as LV. The receiver diodes need a higher voltage of up to 20 V, while 5 V are sufficient for Viset. Viset allows for control of the VCSEL output current. Additionally a reset signal is provided which can be sent to the decoder.

Cooling System

The 14 IBL staves are cooled with 14 parallel cooling loops with evaporative CO_2 of around -40 °C. The 14 cooling loops have manifolds in the muon detector area which is accessible in technical stops. The cooling pipe in the stave has an inner diameter of 1.5 mm and is made of titanium. The in and outlet tubes are both 12 m long and have an increasing diameter in the upstream direction to accommodate the expanding vapour. The inlet is 1 mm and 1.5 mm, the outlet 2 mm and 3 mm.

The cooling plant is located in the USA-15 cavern, the piping distance to the detector is about 100 m. The cooling system is using the 2PACL cooling concept [5] as it was developed for the LHCb-Velo cooling [6]. In a 2PACL system the pressure of boiling is controlled by an accumulator in the plant. The accumulator pressure is controlled by heating or cooling. The pressure in the detector is similar to the plant pressure and thus can the boiling pressure and hence temperature can be controlled from the plant only. With this system no active control and sensing is needed inside the unaccessible detector. The cooling inside is completely passive. Temperature sensors for monitoring are available on each stave in- and outlet. Figure 2 shows a schematic of the IBL CO_2 cooling. Half of the amount of staves will have a flow in the opposite direction so that the outlet flow can cool the inlet flow of the other tubes. This pre-cooling is needed to suppress boiling in the inlet due to parasitic heat. The cooling loops are connected to the transfer line in the junction box located in the muon detector area. The transfer line is a concentric pipe exchanging heat between the in and outlet. This heat exchange conditions the inlet flow to be the right temperature for boiling. As all the pipes are cold, they have to be insulated. Inside the detector there is vacuum insulation, outside the detector there is foam insulation. Two identical cooling units are foreseen for redundancy reasons.

Monitoring

While all power supplies have built-in monitoring units which provide information concerning voltage and current, the temperature monitoring is handled separately. Many temperature sensors are installed and deliver their information into DCS through different paths.

Any equipment which can be damaged by overheat is equipped with an NTC (Negative Temperature Coefficient) sensor, whose value is read by the DCS monitoring units. In parallel its information is fed into the interlock system (see the next section). Further NTCs on the cooling pipes, the cable trays, and elsewhere in the detector environment provide the cooling experts with information which allows for debugging of the system.

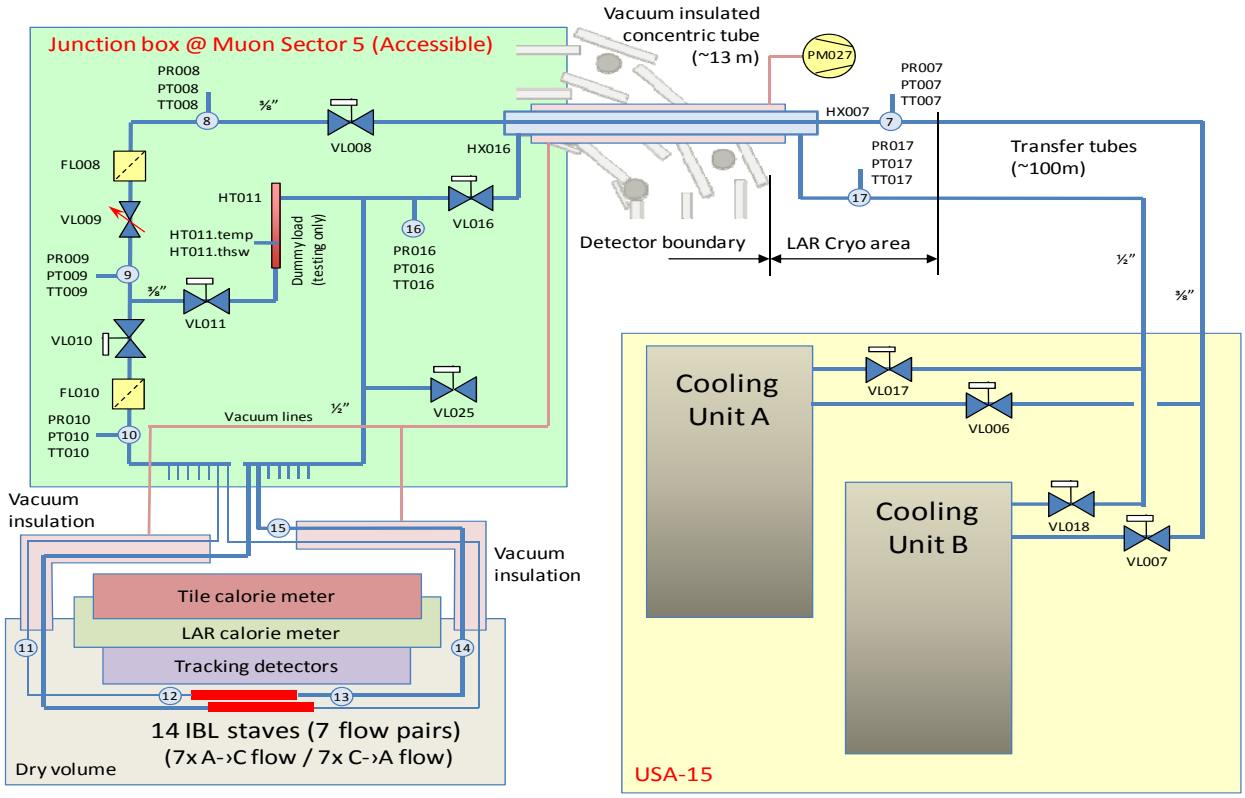

Figure 2: Cooling System.

A further source for detailed debugging of the frontend chips are, among others, temperature sensors (diodes), which are built-in in the frontend chips themselves. In order to control the complex electronics of the FE-I4 [7] and its environment, several voltages and currents are monitored on-chip and digitized for readout. A 10 bit ADC has been designed for this purpose and is associated to an 8 to 1 analog mux in order to select one input among: temperature, power supplies, voltage references, detector leakage current, and other DC analog voltages. On demand these information can be sent through the standard data path. Inside the DAQ dedicated routines extract the DCS information. This monitoring is a promising approach for future Detector Control System developments in order to reduce the material inside the detector volume.

As the monitoring of the DAQ crates and BoC cards is based on standard monitoring tools, it is not described here.

Interlock

As irradiated sensors can be irreparably damaged by overheat, the detector modules are equipped with NTCs which are readout through DCS and in parallel feed their information into the interlock system. A discriminator compares the signal to a threshold which represents the maximum allowed temperature, and creates a logical signal in case of overheat. In the same way, opto boards and the regulator stations are equipped with NTCs.

All signals are collected by the interlock system. It determines which power supply must be switched off and sends out the related signal to the power supply. The core component of the interlock system is a flash FPGA with an internal EEPROM. This avoids the need of a program loading at power-on. A negative logic is implemented, which means that a missing cable or power loss cause automatically an interlock. Additional information from the laser protection system, the cooling system, the LHC or other external systems will be included into the interlock matrix.

As this system is completely hardware based and does not require any software to be running, it provides a maximum of safety.

DCS SOFTWARE

The DCS software splits into three parts, one handling the integration of the hardware into the software, the user interface to operate the detector and connections to the databases plus tools for monitoring.

It is foreseen to purchase the power supplies from the same vendors as they were selected for the Pixel detector and to use the same hardware for custom made devices

(e.g. regulator station, SC-OL). Therefore, the pixel software packages can also be applied to integrate the IBL hardware. Besides the fact that large development work can be avoided, using the same integration software also guarantees an easy integration of the IBL DCS into the pixel frame.

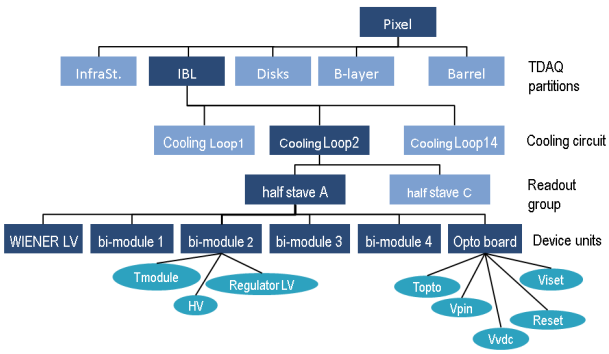

Figure 3: FSM tree of the IBL.

The tool to operate the detector and all its components is the FSM (Finite State Machine). Using the control concept as it is defined by the ATLAS FSM [8] provides the integration of the IBL into the pixel detector and ATLAS. Figure 3 shows the FSM tree of the IBL. The top nodes (TDAQ partitions) are defined by ATLAS. It is also evident that the IBL is a part of the pixel detector. The nodes below IBL reflect the detector's constraints. As done for the pixel detector, a geographical approach is followed.

As the cooling loops can be controlled separately, they define the next level of partitioning. They correspond each to one stave. All modules of a half stave share the same opto board concerning the readout. This defines the next level of partitioning. Besides the opto board, LV and four bi-modules belong to a half stave, respectively readout group.

Due to the services four frontend chips with their two sensors (in case of planar sensors) are the smallest unit which can be separately steered by DCS and are called bi-module.

If the detector behaviour must be studied in more detail the 3D-viewer is a useful tool for experts. It is based on the fw3DViewer package (developed by CERN ITCO [9]) and allows for monitoring of any data available with module granularity. Online as well as historical data can be displayed in any 3D view. Especially 3D views of temperatures or leakage currents can help to diagnose problematic detector regions.

SUMMARY

In 2013 the IBL will be installed as the innermost part of ATLAS. It will complement the existing Pixel detector as a fourth layer. Although being a pixel detector, its sensors and frontend chips are different concerning their qualities and needs.

A complex detector control system is required to supply all required voltages, to keep the detector at an adequate operating temperature, to provide operators and experts with all tools and information they need, and to ensure the safety of the detector at all times.

Key component regarding safety is the interlock system. Furthermore, the sensitive frontend electronics is protected against transients by the regulator station. The standard tool to control the detector will be the finite state machine, which in parallel allows for an easy integration of the IBL DCS into the Atlas wide control system. For debugging the detector and diagnosing its behaviour the built-in sensors of the frontend electronics and the 3D viewer are of special interest.

LHC MAGNET TEST BENCHES CONTROLS RENOVATION

O.O. Andreassen, D. Kudryavtsev, S. Page, A. Raimondo, A. Rijllart, E. Zorin
CERN, Geneva, Switzerland

Abstract

The LHC magnet test benches controls were designed in 1996. They were based on VME data acquisition systems, Siemens PLCs control and interlocks systems. After a review of renovation of superconducting laboratories at CERN in 2009, it was decided to replace the VME systems with a PXI based systems and the obsolete Sun/Solaris workstations with Linux PC's. This paper covers the requirements for the new system and shares the experience of the upgrade of the magnet test benches to these new platforms.

OVERVIEW

A review of superconductors and magnet laboratories took place in May 2009 [1]. It concluded that the removal of the facilities of Block4 to SM18 [2] was desirable to save money, to stop the Block4 refrigeration plant and to increase of efficiency by staff regrouping. Another important reason was related to the FRESCA2 magnet for the superconducting cable test, which was not possible to be installed in Block4 due to the lack of space.

Merging the two facilities allowed the creation of an integrated magnet test facility, adding to the existing horizontal test benches a vertical test station for prototype magnets, a test bench for the existing insertion region magnets, as well as a test station for the new generation inner triplet magnets presently under design.

The ageing infrastructure, the computer systems and the instrumentation needed to be modernised and the controls of the different systems of the two magnet test facilities to be homogenised.

This paper describes the Magnet Test Benches (MTB) controls renovation project. The project targets the Power Converter Controls and the Measurement Systems. A common objective is to bring them as close as possible to the systems presently installed in the LHC to make the MTB look like the "ninth" LHC sector (the LHC has 8 sectors) from the control system point of view. This is important for tests such as the tracking measurements. This effort is complemented by the migration from the General Purpose Network (GPN) to the accelerator Technical Network (TN) and the implementation of the Role-Based Access Control (RBAC) to increase cybersecurity.

THE NEW MTB FACILITY

The new MTB facility (Fig. 1) was created in three main steps.

First, the removal of the vertical test station from the Prévessin site to the SM18 site; second, the modification of one horizontal test bench in order to allow testing the spares of the present inner triplets and other magnets that were produced and tested by two US laboratories; finally the modification of one horizontal test bench to allow the testing of the new inner triplet prototype magnets. These three different parts are independent and can be realized at different times.

The removal was also the opportunity to upgrade the vertical test station. It was equipped with 4 cryostats of different dimensions for different purposes: 3 of them were used in the previous facility and a 4th, the biggest, was procured within the High Field Magnet (HFM) project for the FRESCA2 magnet.

These cryostats allow to test the present LHC corrector magnets, diodes for LHC main dipoles and quadrupoles, new inner triplet correctors, new inner triplet quadrupole model, and the HFM prototypes. With some modification of one cryostat, we should be capable to test also the present LHC HTc current leads.

The vertical test station will also allow the test of Fast Cycled Magnets (FCM) and Superconducting Links (Sc link) for the new inner triplet and FP7 (EUCARD) project.

A 20 kA and 25 V power supply from the former facility have been recovered for the new station together with several 600 A and +/- 12 V power supply to assure the powering of the present LHC and future new inner triplet magnets. The existing commutation switch of 20 kA completes the installation.

This new station profits from the cryogenic installations and He gas recuperation system of the test area.

The FCM and the Sc link, not operating at the same time, will use a common cryogenic distribution box, existing in the hall.

A modification of the liquid distribution, gas recuperation and the control system of the cryogenics of the new station has still to be done.

The former protection and detection systems and the data acquisition system of the vertical test stand were obsolete and could not be integrated into the new system. Therefore a new one had to be developed and installed in the same time with the new station.

The horizontal benches to test the LHC main magnets, such as dipoles and corrector magnets, will now share optimally the resources with the vertical benches.

Figure 1: Part of the merged MTB facility.

Power Converter Control Upgrade

Every power converter is controlled by a Function Generator Controller (FGC) that hosts the control software. Normally a set of FGCs is connected to the Control Middleware (CMW) [3] via a gateway PC through a WorldFIP bus.

The upgrade of the FGC gateways was a relatively simple operation. The operating system needed to be switched from LynxOS to SLC5 Linux, and the start-up sequence had be updated to be identical to the one used in the LHC.

Following the upgrade, commands are sent through the CMW and must be accompanied by a valid Role-Based Access Control token [4]. RBAC rules granting access to the power converters have been defined. A new RBAC role and RBAC location has been created and is populated with the names of the new Linux controls consoles.

The majority of the power converters were controlled by old FGC1 hardware. In order for the FGC1s to work in conjunction with the new version of the gateway, a minor upgrade has been made to their software.

The first step to integrate the MTB power converters into the standard LHC architecture was to connect them and their control console to the Technical Network. This meant upgrading the obsolete network, removing the coaxial cables to be replaced with optical fibres and replacing the old star points. At the same time the objective was to improve the actual network (WiFi covered zones, GPN or TN, additional sockets for the office spaces) and to add new network sockets for the relocation of the test components.

This migration from coax GPN to structured TN network of all the devices has been done in a staged way to avoid stops in the MTB operation.

The upgrade of the building gateways was needed for the LHC software architecture (LSA) to directly control the power converters. LSA can directly control the FGC2 interfaces and with minor changes in the name of the properties the FGC1 interfaces. This additional flexibility will probably be needed in the future.

Once done, the existing direct current readout from the FGC1 used by the old measurement applications would not be available anymore and the control applications had to be upgraded.

The FGC2 interface is requested in order to have the "post mortem" data with the detailed executed current cycle or to investigate eventual problems offline in detail. Both systems (gateway and FGC) are synchronised with the Universal Time (UTC) as foreseen for all the accelerator systems at CERN, with a precision of 1 ms, that is considered necessary and sufficient.

Last but not least, it is worth to have the last electronic version (i.e. FGC2 interface) to control all converters for maintenance reasons and for the ongoing magnet control developments.

Measurement Systems Upgrade

The first step of the upgrade was to replace the existing VME based Data Acquisition (DAQ) system with a new one based on PXI hardware and LabVIEW RT.

Previously each cluster was equipped with an INCAA DAQ system for magnet power tests. These systems were getting old and the SUN Solaris operating system, on which the control consoles were based, has been phased out. Moreover LabVIEW was no longer updated on this operating system. The data acquisition systems used previously had to be renewed as the installations were 20 years old and were not reliable and adapted for the test of the new inner triplet magnets.

Therefore the installations had to be changed, adapted to those used at CERN presently.

A new architecture has been defined in our group (Fig. 2) and a prototype based on PXI has been built with the goal to test it on present LHC magnets and to qualify the solution to be applied on each horizontal bench and the vertical test station.

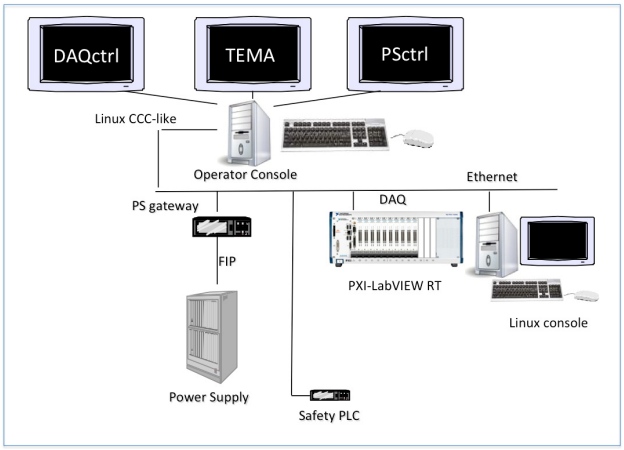

Figure 2: The control architecture.

The second step was to port the actual Test Master, the application that drives the sequence of tests, and Hardware Recognition, the application that allows to configure the electronics, on Linux with the addition of a DAQ control application.

The next step was to port the actual Power application on Linux to access all the Power Converters via the LHC Control Middleware using RADE [5] from the control room. The new control room has become similar to the CERN Control Room.

On the three screen consoles; the middle one shows the Test Master window, which is equivalent to the sequencer for the LHC Hardware Commissioning, and on the left and right screens there are the DAQ and the Power Converter control applications.

CONCLUSIONS

The review of superconductors and magnet laboratories concluded the removal of the facilities of Block4 to SM18 site. Merging the two facilities allowed the creation of an integrated magnet test facility, adding to the existing horizontal test benches a vertical tests station for prototype magnets.

Thanks to the merging we started a renovation program to replace the obsolete VME DAQ and Solaris consoles with modern PXI RT and Linux consoles. In addition the update of the FGCs has made the MTB look like the "ninth" LHC sector from the control system point of view.

The renovation of the control architecture started end of 2009 and involved 3 FTE up to now. The upgrade went in parallel with the standard magnet test benches operations to keep the compatibility between the new and the old systems as they needed to run in parallel.

The upgrade has now been completed and all the test benches are now commissioned.

Further improvements are ongoing until the end of this year.

EVOLUTION OF THE ARGONNE TANDEM LINEAR ACCELERATOR SYSTEM (ATLAS) CONTROL SYSTEM*

M. Power, F. Munson, Argonne National Laboratory, Argonne, IL 60439, U.S.A.

Abstract

Given that the Argonne Tandem Linear Accelerator System (ATLAS) recently celebrated its 25th anniversary, this paper will explore the past, present, and future of the ATLAS Control System, and how it has evolved along with the accelerator and control system technology.

ATLAS as we know it today, originated with a Tandem Van de Graff in the 1960s. With the addition of the Booster section in the late 1970s, came the first computerized control. ATLAS itself was placed into service on June 25, 1985, and was the world's first superconducting linear accelerator for ions. Since its dedication as a National User Facility, more than a thousand experiments by more than 2,000 users world-wide, have taken advantage of the unique capabilities it provides.

Today, ATLAS continues to be a user facility for physicists who study the particles that form the heart of atoms. Its most recent addition, CARIBU (Californium Rare Isotope Breeder Upgrade), creates special beams that feed into ATLAS.

ATLAS is similar to a living organism, changing and responding to new technological challenges and research needs. As it continues to evolve, so does the control system: from the original days using a DEC PDP-11/34 computer and two CAMAC crates, to a DEC Alpha computer running Vsystem software and more than twenty CAMAC crates, to distributed computers and VME systems. Future upgrades are also in the planning stages that will continue to evolve the control system.

ATLAS' FIRST CONTROL SYSTEMS

In 1978 a proposal was submitted to create a super-conducting LINAC using seven groups of independently-phased split ring resonators, and called for a computer based control system. The proposal was to use a Digital Equipment Corporation (DEC) PDP 11/34 to "(1) set and monitor all parameters of resonators and solenoids, and to control long-term drifts, if any; (2) to monitor many sensors such as thermometers; (3) to automate the tuning operations" [1]. Figure 1 shows the original proposed design, using two CAMAC crates, two touch screen panels integrated with knob controls, and a numeric keypad as shown in Figure 2, and a raster display as operator interfaces. Control programs were written mostly in FORTRAN on the RSX/11 operating system. Some of this code is still in use today.

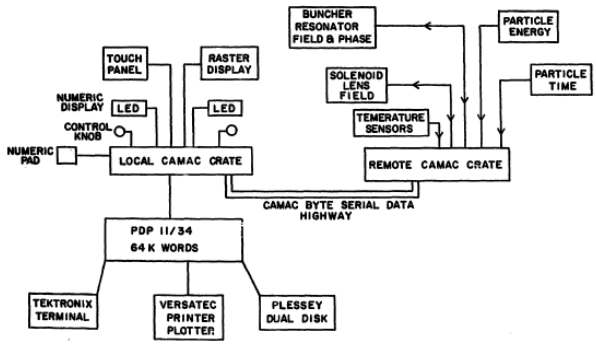

Figure 1: Original computer control system proposal.

Figure 2: Touch screen control board.

As the accelerator continued to expand, so did the control system to include three PDP 11 systems, each controlling part of the accelerator: the newly constructed Positive Ion Injector (PII), the primary accelerator section (Booster and ATLAS), and beamline devices. All three systems contained separate and isolated databases. More CAMAC hardware was added and separated into two serial highways [2]. Figure 3 shows the control room after the expansion.

* This work was supported by the U.S. Department of Energy, Office of Nuclear Physics, under Contract No. DE-AC02-06CH11357.

Figure 3: Control Room circa 1985. The right (grey counter) is the accelerator control system including the original Booster and added ATLAS sections. The left (white counter) is the added beamline control system.

MAJOR UPGRADE

In the early nineties, plans to update the control system to create a more integrated and expandable system using newer technologies began to be discussed. Since there was a significant investment in the existing CAMAC hardware, it was decided to retain it, but the crates were reconfigured into a single serial highway. The multiple PDP 11 computers were replaced with a single DEC MicroVAX running VMS software, and an Ethernet based LAN was installed to interconnect the various display computers with the server. A third party software package, Vista Control Systems Vsystem, was chosen to provide an integrated database, graphical user interface, and hardware support [3]. Figure 4 depicts one of the new Vsystem displays.

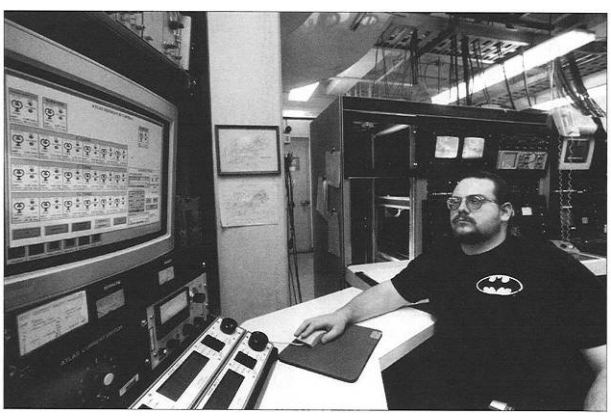

Figure 4: New Vsystem display in the Control Room.

Gradually, new pieces were phased into the system. The software written for the PDP 11 computers was transferred to the MicroVAX. Once the port was complete, a new DEC AlphaServer was purchased and replaced the MicroVAX. The AlphaServer was the core of the control system and contained the single link to the CAMAC serial highway and all the real time databases and displays. Various other Alpha workstations and PCs were used as operator workstations throughout the accelerator site. Figure 5 shows the conceptual layout of the upgraded control system.

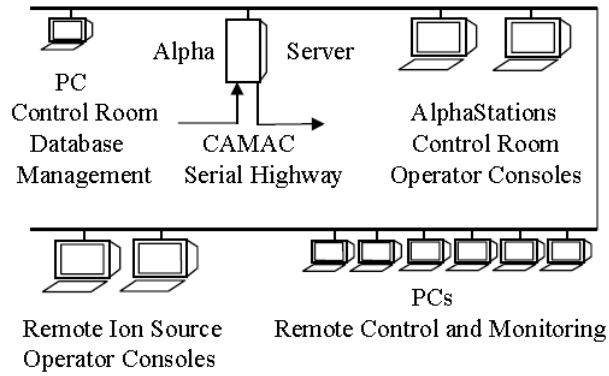

Figure 5: 1990's upgrade configuration.

Additionally, two relational databases were added to provide logging of system parameters and the ability to scale and reload control parameters into the real-time system for similar charge to mass ratios. This was accomplished by storing real-time data on the AlphaServer using Oracle RDB, and periodically transferring the data onto a remote PC located on the LAN. The PC software was written with Corel Paradox to store the data and provide an interface for the operations staff.

Another noteworthy accomplishment of this upgrade was that it was done for the most part online, simultaneous with the operation of the accelerator. The ported software control programs including Resonator and Solenoid Control, Autoscan, and Energy and Time Measurement applications are still in use today.

DISTRIBUTED SYSTEMS

As ATLAS would continue to grow, and with the understanding of the limitations of having a single point of failure with a single server and single CAMAC serial highway, efforts were made to implement a distributed system test case. The Vsystem software already supported distribution, and it was decided to move the cryogenics database to a distributed system. The cryogenics database and its related displays were copied to a PC with the Linux operating system running the Vsystem software. A PCI to CAMAC interface was installed, and the CAMAC crate was removed from the main serial highway and connected directly to the Linux PC. Figure 6 shows the new configuration [4].

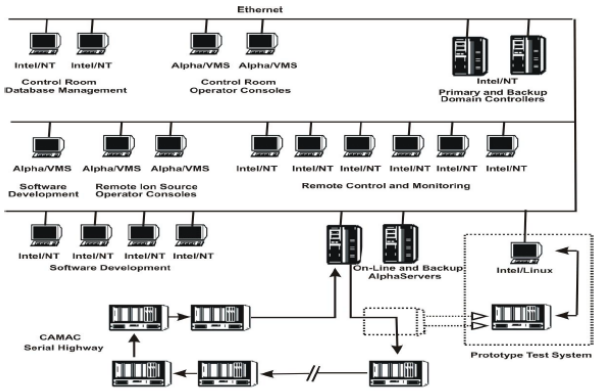

Figure 6: ATLAS control system with distributed I/O.

More recent accelerator upgrades including the new Charge Breeder and the addition of the CARIBU (Californium Rare Isotope Beam Upgrade) Source have increased the use of distributed processing. With increasing prices due to the low demand for CAMAC modules, additional hardware options have also been investigated. Two hardware options using Industry Packs have now been implemented. Four VME crates have been installed, and are controlled using Linux based PCs running the Vsystem software. A second option was initially installed on the source high voltage platforms. Two Hytec 9010 blade I/O controllers [5] were installed using the onboard Industry Pack support. These controllers also run the Vsystem software on Linux, and are excellent in areas where less I/O is needed. Due to problems with the 9010s caused by an occasional electromagnetic pulse due to high voltage arcing in these locations, the 9010s have been replaced with VME systems, but will be repurposed for use in other areas as the system continues to be distributed and offloaded from the DEC AlphaServer. Figure 7 shows the current control system configuration.

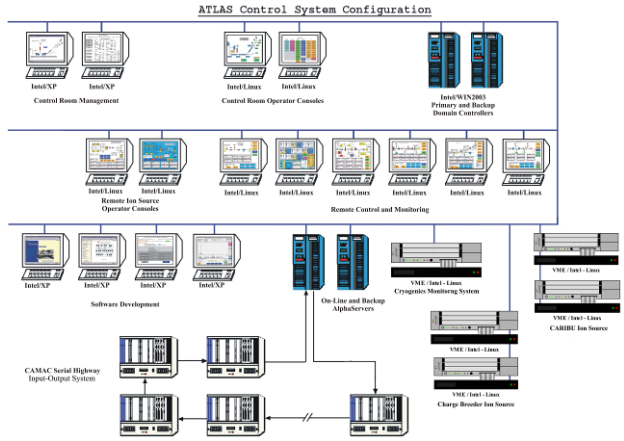

Figure 7: Current ATLAS Control System configuration.

FUTURE PLANS

ATLAS continues to evolve and expand, meeting the future needs of its users. Additional upgrade projects are currently underway and the control system will continue to evolve with the accelerator. Along with supporting additions and updates, future plans include further distribution of I/O processing and databases, and phasing out the DEC AlphaServer.

With the use of well tested and commercially available control system solutions, the ATLAS control system continues to be maintained by a very small staff.

MIGRATION FROM OPC-DA TO OPC-UA

B. Farnham, R. Barillère, CERN, Geneva, Switzerland

Abstract

The OPC-DA specification of OPC has been a highly successful interoperability standard for process automation since 1996, allowing communications between any compliant components regardless of vendor. CERN has a reliance on OPC-DA Server implementations from various 3rd party vendors which provide a standard interface to their hardware. The OPC foundation finalized the OPC-UA specification and OPC-UA implementations are now starting to gather momentum. This paper gives a brief overview of the headline features of OPC-UA and a comparison with OPC-DA and outlines the necessity of migrating from OPC-DA and the motivation for migrating to OPC-UA. Feedback from research into the availability of tools and testing utilities will be presented and a practical overview of what will be required from a computing perspective in order to run OPC-UA clients and servers in the CERN network.

INTRODUCTION: OPC CURRENTLY AT CERN

At CERN, OPC is heavily used to control and monitor a large variety of devices. One commonly used technology stack allowing a human controller to control physical devices is a HMI and SCADA layer provided by Siemens [3] WinCC OA, WinCC OA communicates via its built-in OPC driver (an OPC Client) to an OPC server and the OPC Server communicates with the physical device in question.

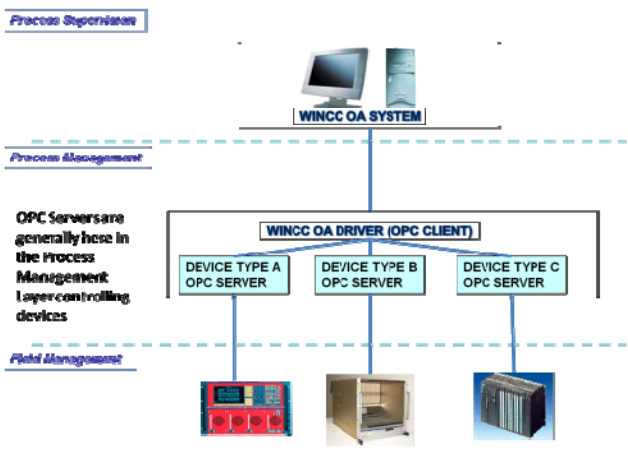

Figure 1: Common current usage of OPC at CERN as device orientated middleware.

The device vendor generally provides hardware plus an OPC Server capable of driving it. Current devices driven by OPC at CERN include:

- PLCs, providing low level control and monitoring of systems.
- High and low voltage power supplies, powering detector tubes and front end electronics.
- VME crates, providing specialist control of peripherals.
- Embedded Local Monitor Boards (ELMBs), a CERN proprietary I/O module for monitor/control of front end equipment.

Prior to OPC-UA, the OPC Foundation produced a series of sibling OPC specifications, amongst which was OPC-DA. These sibling specifications are hereafter referred to as OPC Classic. OPC-UA [1][2] is intended to be the modern successor to OPC Classic. CERN currently has only OPC Classic applications in production systems, however, there are some OPC-UA evaluation projects currently in progress.

OPC-UA HIGHLIGHTS

Platform Independence

OPC Classic is tied to Microsoft platforms by its dependence on COM/DCOM for security and inter-process communication. The OPC-UA specification has a built-in means of security, transmission and message encoding based on modern industry standards. Dropping the COM/DCOM dependency frees OPC-UA client and server implementations from the Microsoft platform.

Embedded Platforms

An important corollary of the point above is that OPC-UA servers can be written for embedded platforms – a device could have its own OPC-UA server built in. For scalability, the full functionality of the OPC-UA specification is chunked into discrete profiles describing subsets of the full feature set: An embedded OPC-UA server need only implement profiles relevant to its operating constraints.

Improved Security

Classic OPC has no intrinsic security; this is delegated to the COM/DCOM layer. OPC-UA has a comprehensive security model built in based on Public Key Infrastructure providing application identity and secure channel client/server communication. The specification also describes a means for exchanging user identity for application specific user authorization and authentication.

Improved Modelling

The OPC-UA standard provides an extensive vocabulary for modelling devices and processes, including being able to type components (allowing clients to establish semantic information) and to express relationships between components (allowing clients easier browsing between related components).

Message Transmission and Encoding Options

An OPC-UA slogan is 'from the device to the enterprise'. OPC-UA has been designed to allow

applications to encode and transmit messages in a manner most suited to their operating environment and constraints. There are two means of transmission: An efficient low level means, based on TCP/IP, called tcp.opc and ubiquitous HTTP. There are two means of encoding messages: UABinary, which is small on the wire and requires less processing overhead than the alternative XML/SOAP encoding which allows for the possibility of OPC-UA messages to be consumed by a wide variety of applications (i.e. not just OPC-UA). OPC-UA applications providing software interfaces to devices are expected to prioritise efficiency, whereas OPC-UA applications providing high level information publication are expected to prioritise support for the widest client base.

MOTIVATION IN MOVING FROM OPC CLASSIC TO OPC-UA

The primary motivation for migrating from OPC Classic is that its message transmission is based Microsoft's proprietary COM/DCOM. COM/DCOM has been de-emphasized in favour of .NET's Windows Communication Framework. OPC-UA on the other hand describes two non proprietary means of message transmission, tcp.opc or HTTP. OPC-UA applications can choose to support one or both transmission types.

Linux compatibility. Some administrators of Detector Control Systems (DCS) have selected Linux as their preferred operating system but are forced to maintain windows machines in order to host OPC Classic applications. Linux compatible OPC-UA replacements would allow administrators to remove these windows nodes thereby reducing maintenance complexity by homogenizing the host operating system, Linux, across the DCS. Devices supplied with embedded OPC-UA servers would further simplify DCS administration: The device hosts its own OPC-UA Server.

OPC-UA security is standards based and easier to configure. Restricting access to OPC Classic applications is possible but experience has shown that setting up DCOM security configuration is error prone and the results fragile to operating system updates and patches. OPC-UA application authenticity is provided by standard x509 certificates which every OPC-UA application is required to uniquely own. OPC-UA applications only accept session requests from other OPC-UA applications proffering trusted certificates. These same certificates are used to provide secure communications channels for client server sessions in which all messages can be signed (preventing message tampering) or signed and encrypted (additionally preventing eavesdropping).

OPC-UA allows for more intuitive server address spaces. As mentioned in OPC-UA highlights above, OPC-UA has some quite considerable changes and enhancements over OPC Classic. OPC Classic provides a simple address space in a tree structure of branch nodes containing branch nodes and leaf nodes. A common idiom in OPC Classic is to have write-only leaf nodes, which, when written to, invoke an action on the OPC server/device. To turn on/off a channel in an industrial power supply, for example, an OPC Classic user often writes true/false to a write only OPC item. The idiom works but to the uninitiated user it is not obvious that this is the standard means of turning a channel on. OPC-UA servers describe their address spaces in objects (as in Object Orientation) whereby objects contain fields, and methods which have an effect on those fields. An OPC-UA server for an industrial power supply could model a channel as an object with fields representing current, voltage etc. and a method, parameterised with a Boolean, to turn the channel on and off. This interface is more self-explanatory. Views are another useful OPC-UA address space enhancement. Similar to database views, OPC-UA views exist to provide subsets of the full address space tuned to a specific perspective. For example, a cooling and ventilating application is more likely to be interested in temperature sensor values of an industrial power supplies than, say, voltage and current read outs. An industrial power supply OPC-UA server could provide views tuned for such perspectives.

OPC-UA IMPLEMENTATION AVAILABILITY

Stacks

The OPC Foundation provides their corporate members with reference OPC-UA implementations, stacks, of the standard. Stacks are available in three languages: ANSI C, .Net and Java. The primary goal of the stacks is providing communications interoperability. At time of writing only the .Net stack supports both transmission means (opc.tcp and HTTP) and both message encodings (UABinary and XML/SOAP). The C stack and Java stack provide only opc.tcp transmission and support for binary encoded messages. In terms of the C stack this is not unreasonable, it is the most likely to be used for embedded or high performance environments where HTTP/SOAP would not be the natural choice. The .Net stack is the most fully featured but is limited to the .Net runtime, essentially limiting it to Microsoft platforms.

Toolkits

These are built on top of the stacks and aim to provide a much more complete SDK to aid and simplify application development (providing programmatic session management for example). The toolkits generally inherit any omissions or limitations in functionality from the stacks upon which they are built, the Java SDKs surveyed, for example, do not currently support HTTP transmission or XML/SOAP encoding.

There are various stack vendors available but the main players are:

- Unified Automation [5] - Have C, C++ and Java toolkits. Applications built with the Java toolkit are naturally cross platform, application hosts require JRE6. The C and C++ toolkits can, on request, be

cross compiled by the vendor to various Windows/Linux platforms including embedded variants and realtime operating systems.

- Softing [4] - Have a .Net (requiring the .Net 3.5 runtime) and C++ toolkit available. On request the vendor can compile the C++ toolkit for Windows or Linux.
- Prosys [6] - Have a Java toolkit, application hosts require JRE6.

Diagnostic Tools

An important tool for OPC deployment is a simple, visual OPC client, allowing verification and problem diagnosis of server installations. Unified Automation, provide UaExpert: A free, stable and sufficiently fully featured OPC-UA client available on Linux and Windows. For low level diagnosis, ascolab [8] provide a Wireshark [7] plugin allowing an engineer to view client/server messages (for unencrypted client/server sessions).

FUNCTIONALITY TESTS

The following tests were carried out using available implementations from various vendors. In all cases only UABinary message encoding was used and opc.tcp transmission.

Cross Stack and Cross Platform Interoperability

In every attempted permutation (see table below) of client/server toolkit and platform the connecting client was able to connect to, and browse, the server without problems:

Table 1: Permutations Tested for Cross Platform and Toolkit Client/Server Interoperability: All Succeeded

Client Description	Server Description	Server Description	Server Description
Java on Windows	Java on Windows	C++ on Windows	C++ on Linux
C++ on Windows	C++ on Windows	C++ on Linux	Java on Windows
C++ on Linux	C++ on Linux	C++ on Windows	Java on Windows
Java on Linux	C++ on Linux	C++ on Windows	Java on Windows

OPC-UA as Device Middleware

OPC Classic is heavily used at CERN as device middleware (see figure 1), OPC-UA's applicability for device middleware was tested. The test stack consisted of a WinCC OA HMI and SCADA layer, using its built-in OPC-UA driver to communicate with a custom made OPC-UA server providing control and monitoring of simulated hardware.

The WinCC OA system (version 3.10) and its OPC-UA driver ran on Windows 7. The OPC-UA server was built using Softing's C++ toolkit, the OPC-UA server and hardware simulation processes ran on Scientific Linux 5.

Table 2: Test Results of OPC-UA Functionality for Device Middleware

Functionality	Results/Notes
OPC Classic Functionality in OPC-UA	
Create a simple, browseable address space for device.	The OPC-UA server builds an address space to represent the device, browseable from WinCC OA.
WinCC OA datapoints could be mapped to server variables.	WinCC OA datapoints have a 'peripheral address' configuration, allowing mapping between them and OPC-UA server address space elements.
WinCC OA Datapoints updated as hardware values change.	WinCC OA defines subscriptions on the OPC-UA server, with publishing intervals. The OPC-UA server sends cyclic notifications to WinCC OA, updating the datapoints.
Can write values to server variables	WinCC OA's dpSet() command uses peripheral address mappings to send write commands to the OPC-UA Server, on receipt, the server writes hardware values.
OPC-UA Enhancements	
Server object methods can be browsed and invoked	The OPC-UA Server can provide methods on objects. These can be invoked using the UaExpert client. Siemens confirmed this is not available in WinCC OA version 3.10.
Server views can be browsed and datapoints mapped to view fields	As above, the OPC-UA server can provide views, browseable from UaExpert. Siemens confirmed this is not available in WinCC OA version 3.10.
OPC-UA Security	
OPC-UA applications only communicate with trusted applications	The OPC-UA Server only communicates with trusted clients however it was possible to initiate communications between WinCC OA and untrusted servers. The vendor is investigating this.
OPC-UA client/server traffic can be signed or signed and encrypted.	The OPC-UA Server supports this, tested in session with UaExpert, however attempts to create secure sessions between the server and WinCC OA failed. The vendor is investigating this.

Overall, OPC-UA analogs of OPC Classic functionality, essential for device control and monitoring, work in the surveyed OPC-UA implementations. Nice-to-have OPC-

UA device modelling enhancements were not present in the WinCC OA version used. WinCC OA security issues are being investigated by the vendor.

INFRASTRUCTURE REQUIREMENTS OF OPC-UA APPLICATIONS AT CERN

The main difference for system administrators is adapting to OPC-UA's security requirements.

Firewall Settings

OPC-UA has been designed to be firewall friendly. For tcp.opc traffic the administrator need only open the port required by each endpoint. Endpoints using HTTP transport require port 80 open.

Application Certificates

CERN already has infrastructure in place for generating and managing the type of signed certificates OPC-UA applications require: The CERN CA (Certificate Authority). The CERN CA is visible from both CERN's technical and general purpose networks. Currently, obtaining a CERN signed certificate requires non-trivial manual interaction with the CERN CA website. This effort would be required on each application installation and additional effort to renew certificates before they expire (CERN certificates generally expire after one year). Planned CERN CA enhancements include provision for programmatic certificate generation and renewal. Once in place, OPC-UA applications could be delivered with a module which communicates with the CERN CA interface to automate (as far as security policy allows) the process of obtaining signed certificates as part of the installation procedure and certificate renewal.

OPC AS HIGH LEVEL MIDDLEWARE

OPC-UA's features make it an interesting candidate for high-level middleware providing a means of inter-system communication and publication of enterprise level summary data (fig. 2).

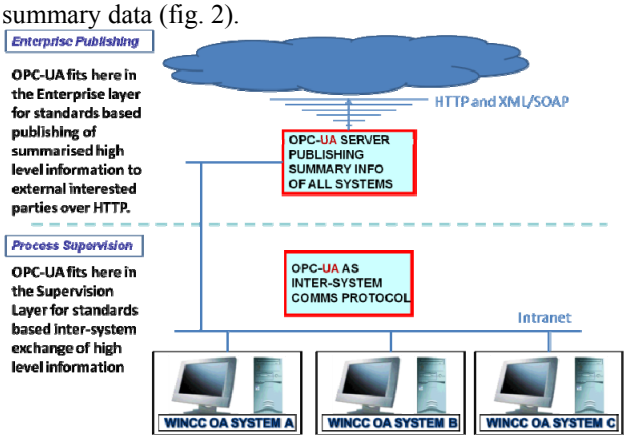

Figure 2: OPC-UA in high level middleware roles.

- OPC-UA is a common standard, compatible with a range of 'off the shelf' components.
- OPC-UA provides secure client/server sessions, with message integrity and confidentiality.
- opc.tcp transmission and UABinary encoding are designed for bandwidth and processing efficiency.
- HTTP transmission and XML/SOAP encoding opens the possibility of delivering messages to a broad base of non OCP-UA specific clients.
- Toolkit interoperability allows for creating a communications system between applications dispersed over heterogeneous platforms.
- Service discovery via OPC-UA discovery servers.

Whilst the features above are very promising facets of OPC-UA for high level middleware, the technology is, at time of writing, insufficiently mature for the purpose for three main reasons:

- During the evaluation, secure sessions failed to work between WinCC OA and an OPC-UA server. The vendor is investigating.
- HTTP transmission and XML/SOAP encoded messages are only currently available in the windows centric .Net tools.
- The final 'Discovery Server' section of the specification is currently in draft; however it is expected to be released this year.

CONCLUSION

OPC-UA is clearly a most compelling candidate for control and monitoring middleware between SCADA systems and device layers. OPC Classic, the incumbent CERN middleware, is based on deprecated COM/DCOM technology and OPC-UA is its successor, based on modern industry standards. The full functionality described in the specification was not found to be available using the current technology and tools surveyed. Despite this, however, current OPC-UA tooling would be sufficient (once security issues are resolved) to provide applications to match and exceed functionality currently provided by OPC Classic applications, most notably in that existing OPC-UA tools allow for interoperable cross platform implementations. Features described in the OPC-UA specification make it an interesting candidate technology for standards based, inter-system communications. However, implementations of some of these features (e.g. server discovery) were absent in the tools surveyed. The evolving OPC UA toolset will be monitored for implementations of these features and verified to ensure they fully cover these expectations.

Abstract

The J-PARC accelerator complex comprises proton LINAC, 3-GeV RCS, and 30-GeV MR. The J-PARC is a joint project between JAEA and KEK. Two control systems, one for LINAC and RCS and another for MR, were developed by two institutes. Both control systems use the EPICS toolkit, thus, inter-operation between two systems is possible. After the first beam in 2006, beam commissioning and operation have been successful.

The current status of J-PARC control structure is given. Components are introduced and reviewed with reliability issues: A plan to develop new GUI applications for operators is given.

INTRODUCTION

A high-intensity proton accelerator complex, J-PARC (Japan Proton Accelerator Research Complex), consists of three accelerators: a) 180-MeV LINAC (energy upgrade to 400 MeV is underway), b) 3-GeV RCS (Rapid Cycling Synchrotron), and 30-GeV MR (Main Ring). J-PARC is a joint project between two institutes: JAEA in Tokai-mura and KEK in Tsukuba.

The construction of J-PARC facilities started in 2002 in Toka-mura. The first proton beam to LINAC was in 2006, followed by RCS (MR) in 2007 (2008), respectively. In March, 2011, we have achieved stable beam operation at the power of 220 kW for neutron productions, and of 140 kW for neutrino productions.

In the very early phase of the project, a decision was made that JAEA is in charge of LINAC and RCS, and KEK is of MR. Discussions on J-PARC controls were also made around 2001. As a result, we decided to have two independent control groups. However we had some agreements: a) both use the EPICS toolkit, b) three accelerators must be controlled from a single control room, c) have single personnel protection system (PPS), and so on. Even after the beam operation started, we still keep two control groups.

The above history has made our control structure very difficult to understand. In the past, general design views of J-PARC controls were reported in [1,2]. System and infrastructure of JAEA was given in [3]. Control overview was presented in [4]. In this report, our control structure is reviewed, with discussions on reliability issues.

CONTROL SYSTEMS OVERVIEW

Components Overview

A brief summary of control components is given in Fig. 1. It is apparent that JAEA (LINAC and RCS) and KEK (MR) have different policies.

Accelerator	OPI Application Basic	OPI Application High-Lvl.	IOC(VME) OS,H/W	Drivers
Linac	Java +MEDM	XAL /JCE	VxWorks PowerPC	- VME I/O Modules - TeraDev for PLC
RCS	Java +MEDM	SAD	VxWorks PowerPC	- VME I/O Modules - TeraDev for PLC
MR	MEDM or EDM	SAD Python ROOT	Linux Intel-based (+PLC/F3RP 61-Linux)	Network devices -NetDev for PLC -WE7000 drivers

Figure 1: Overview of control components at J-PARC.

OPI (GUI) Applications

JAEA has developed stand-alone Java applications for basic GUI applications. In the early phase, JCA libraries, which handle Java to EPICS connections, had small bug. JAEA modified the library to avoid problems [5]. For high-level applications used in beam commissioning studies, XAL was introduced from SNS [6]. Later JCE, simulating SAD script using Java [5], was developed and used by JAEA[7].

KEK introduced MEDM and EDM as basic GUI tools. SAD script, Python script, and ROOT, were used for high-level applications.

The key idea of JAEA is that Java should be the primary platform for all applications. In addition, JAEA developed tools by themselves, except for XAL. However, rack of rapid development tool allowed some MEDM applications in LINAC and RCS.

In turn, KEK introduced EPICS standard tools, based on experiences of KEKB controls. This selection saved start-up man-powers, and enabled rapid developments of GUI applications for MR. Up to now, number of applications registered to the MR launcher is about 270.

IO Controller and Signal Front-end

Both groups selected VME-bus computer as a default IO controller. JAEA selected a Power-PC based CPU board with real-time operating system (vxWorks). There are about 120 (30) pieces of CPU boards for LINAC (RCS), respectively. Standard IO boards of VME-bus are used to handle signal cables. In addition, pieces of Yokogawa PLC (Programmable Logic Controller) with ladder logic were introduced as local controllers of various power-supplies.

In KEK, an Intel-based CPU board and Linux operating system were selected. They are used as disk-less Linux computers. KEK enhanced to use network-based devices, such as Yokogawa PLC and WE7000 measuring station [8,9]. In 2011, we have about 90 pieces of CPU boards for MR, however, 60 of 90 CPU boards do not have any IO boards (see Fig. 2).

In 2008, a new CPU module for Yokogawa PLC (F3RP61-2L) appeared. It can be a Linux-based IO controller with PLC IO modules [10]. In 2011, there are about 30 pieces in MR.

Selections by JAEA were traditionally safe for 25Hz machines. This is because decision was made around 2002. Before the decision by KEK in 2007, we had much discussion whether we chose the same operating system (vxWorks) as JAEA or not. Finally KEK selected Linux. Use of Linux allows easy maintenance and customization of control software. It is worth noting that MR is a slow-cycle machine (a few seconds), thus, real-time features of vxWorks are not needed.

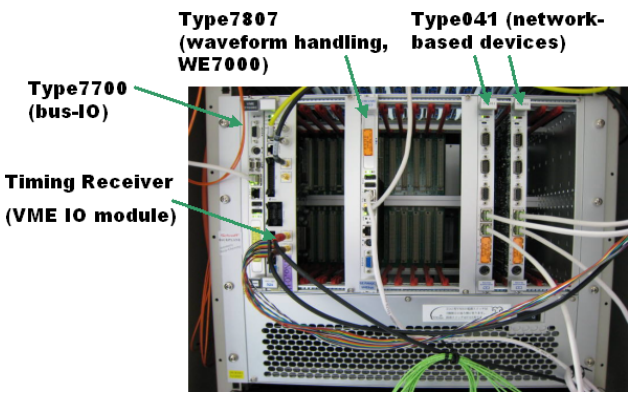

Figure 2: Typical IO Controllers for MR.

Network System

Network system for J-PARC accelerators was introduced around 2004 by JAEA. The system has intelligent core loops to ensure high redundancy [3]. Later in 2006, KEK joined to use the system together. In 2011, we have 80 edge switches for LINAC, 24 for RCS, and 5 for MR. The bandwidth between buildings has been 1 Gbps, partly upgraded to 10Gbps in the summer, 2011.

The network system is logically divided into sub-networks (vlan), which correspond to accelerators (LINAC, RCS, MR) and other facilities. Thus, most of network traffics are localized within single sub-network. For EPICS protocol, we put a few gateways (CA gateway) to enable communication between sub-networks.

Basic services of TCP/IP networks (DNS, NTP) are managed by JAEA, while user authentication service (LDAP) is by KEK. A web server has been operated by KEK to indicate accelerator status and information.

Computers and Storage Disks

JAEA has used rack-mount servers for disk storage. In 2011, total amount is around 16 TB. Standard desktop PCs, running RHEL, have been used as operator's consoles as well as platforms to run control applications.

KEK started to use a dedicated disk storage system and blade-type servers in 2007. In 2011, total amount of disks is around 20 TB, and more than 20 pieces of blade-type servers, running Scientific Linux, are used in operation. Control applications run on blade-type servers, while GUI screens are displayed on thin client terminals [11].

RDB (Relational Database) and Data Archive

Both JAEA and KEK have been using PostgreSQL RDB engines. JAEA has used RDB features for: a) automatic generation of configuration files for EPICS IO Controllers, and b) handling operation parameters (for example, timing-signal settings [12]). In addition, data archive system has been developed using RDB [13].

KEK has used RDB for backup purposes. Databases for a) IP addresses and EPICS record names in MR, b) copies of GUI screens on operator consoles, have been managed using RDB. One can search them through Web-based interfaces. For data archive, channel archiver, a standard tool of EPICS, was introduced and has been used since the beginning of MR beam commissioning [14].

ISSUE FOR RELIABLE OPERATION

Control Room

In J-PARC, all accelerators (LI, RCS, and MR) are controlled from a single control room. We have arranged console desks to form a rectangular shape, in order to force people stay inside (Fig. 3). Two workspaces and one meeting desk are nearby. This structure encourages tight communication between operators, a shit leader, and commissioning staff. In addition, people from experimental facilities (MLF, HD, NU in Fig. 2) can stay in the control room for communication. We believe that this idea is essential to improve reliability.

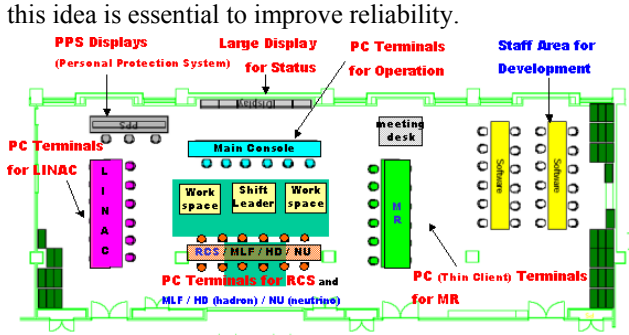

Figure 3: Schematic view of control room for J-PARC.

Safety System (PPS)

The safety is fundamental for high power proton machines like J-PARC. The PPS is to protect personnel from the radiation and other hazards caused by accelerator operations. In order to avoid confusions originated from different policies of JAEA and KEK, we assigned a single person for design and construction for whole of the PPS.

The PPS must be highly reliable and fail-safe. The system was developed using PLC with ladder logic, but no usual computer with operating system. Moreover, we asked two companies to develop PLC ladder logic independently. Thus, having two PLC-based sequences makes the PPS system extremely redundant. More detailed description of PPS is given in [15].

United Sub-Systems

Some sub-systems were introduced for LINAC and RCS by JAEA first, later KEK disagree to extend it to MR, but developed a different system with a link to the JAEA system. The examples of "united" sub-systems are: a) MPS (Machine Protection System) and b) timing system.

The MPS for LINAC and RCS was developed by JAEA [3]. The system has a simple tree-type topology. Because the MPS system for MR was requested to have links to downstream experimental facilities, more complicated logic scheme was needed. As a result, KEK developed a new MPS using FPGA-based logic controllers [16].

The studies of timing system for J-PARC were made in very early phase. NIM modules for signal distribution to all buildings and VME-bus timing IO modules were developed in 2002-2003 by JAEA [3,17]. However, software strategy by JAEA was designed only for 25Hz machines. As a result, KEK decided to use the same hardware (NIM and VME modules) to link to the JAEA timing system, but developed another software framework to fit slow machine cycle of MR (a few seconds) [18].

Electric Logbook

An electric logbook, Zlog, was developed using RDB and Python script by KEKB [19]. We decided to use Zlog for all J-PARC accelerators since early phase of its operation. Operators are responsible to insert machine events. One can watch at them remotely by a Web interface.

Since Zlog is RDB-based, it has advanced features as: a) search entries to search for past events, b) automatic generation of machine study report, c) recalling a shift summary, and so on. In addition, automatic insertion mechanism of machine faults has been developed. It has been in evaluation in operation.

PLAN FOR NEW GUI FOR OPERATORS

Up to now, we already experienced three-year beam operation for experimental facilities. However, operation experience shows that two control systems often make operators distressed. For example, different GUI look-and-feels, separated MPS screens, independent data archive systems, and so on. In addition, we do not have an alarm system, which informs pre-critical events of devices before a severe fault. Moreover, many of GUI applications for MR were developed for accelerator experts, not for operators. A miss-operation by operator would cause a serious machine stop.

Considering demands of further power upgrade and longer beam delivery times in the future, we need a new GUI system for operators. We, two control groups, have started to discuss to develop common GUI screens of status and alarms, and an interface to connect to both data archive systems. Recently we have interested in CSS (Control-System Studio) [20], which has been widely introduced in EPICS-based control systems. An idea is that we add a CSS layer over existing control systems. As shown in Fig. 4, the CSS layer will contain: a) new GUI applications common for all three accelerators, b) a single alarm system for all three accelerators, and c) an archive viewer for two different archive systems.

In the summer, 2011, we succeeded to introduce CSS package with helps of CSS experts [21]. Three components of CSS (GUI, Alarm, Archive viewer) worked well. Evaluation and development will start soon.

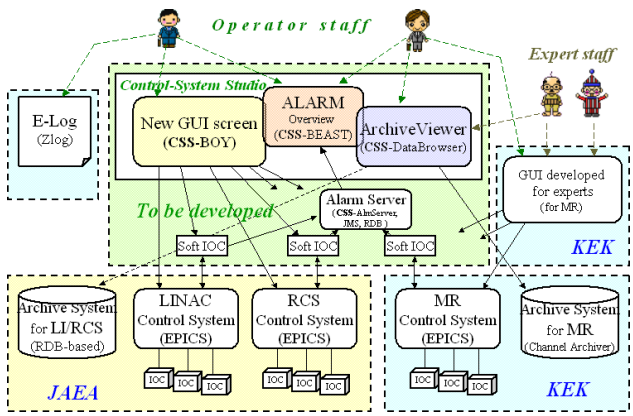

Figure 4: Relations of CSS layer and control systems.

ACKNOWLEDGEMENT

The components of control systems for J-PARC have been highly relied on fruitful products of EPICS toolkit. In addition, we thank EPICS collaborators for various discussions during construction and development. Thanks are also to operators and support staff members who have concern accelerator operation and system maintenance.

FAST BEAM CURRENT TRANSFORMER SOFTWARE FOR THE CERN INJECTOR COMPLEX

M. Andersen*, L. Jensen. CERN, Geneva, Switzerland

ABSTRACT

The fast transfer-line Beam Current Transformers (BCTs) in the CERN injector complex are undergoing a complete consolidation to eradicate obsolete, maintenance intensive hardware. The corresponding low-level software has been designed to minimise the effect of identified error sources while allowing remote diagnostics and calibration facilities. This paper will present the front-end and expert application software with the results obtained.

INTRODUCTION

The Transformer Integrator Card (TRIC) a new digital acquisition module, was designed to replace obsolete analogue integrators used to acquire the beam intensity from the Fast Beam Current Transformers (FBCT) in the CERN Proton Synchrotron Booster (PSB) and CERN Proton Synchrotron (PS) transfer lines.

The older Fast BCT acquisition electronics was, for the most part, analogue and provided poor facilities for remote adjustment and diagnostics. The output of the older FBCT system was essentially limited to a single value corresponding to a beam's total intensity. While the sample-to-sample reproducibility was within the 1% required for normal operation, the absolute errors could be considerable due to time-variations in the analogue electronics. Maintaining this system often required cumbersome expert interventions at the site of the installed hardware. This approach is outlined in Figure 1.

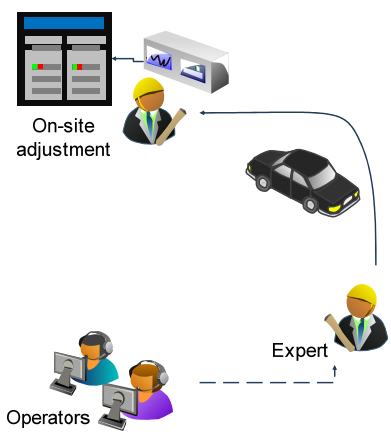

Figure 1: Interaction with old system.

The following outlines the main drawbacks of the old system:

- No ability to precisely time the acquisition to the beam signal, leading to the integration of additional noise in the measurement
- No ability to perform remote calibration or any remote diagnostics
- No possibility to discern and measure multiple isolated beam bunches and beams of multiple injections
- Parameters such as measurement gains had to be changed on-site via analogue potentiometers using a screwdriver
- The DC measurement offset had to be subtracted by the software. This made it impossible to compare the results from two distinct FBCT's in hardware and prevents the implementation of a hardware-only Beam Loss Watchdog. Reliability is therefore reduced due to this dependence on software and its associated complexity.

The new system was designed to address the above issues while maintaining or improving the satisfactory relative measurement accuracy.

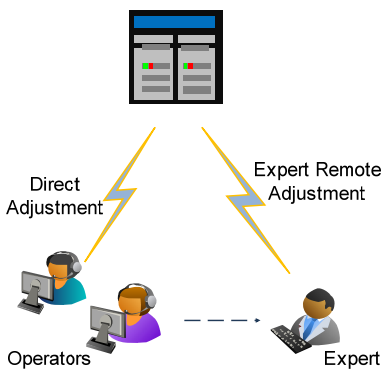

Figure 2: Interaction logistics for the new system.

TRIC HARDWARE SOLUTION

The TRIC is a VME-based acquisition module equipped with two analogue inputs each sampled at 200 MHz and subsequently processed by a large FPGA [1]. The TRIC card incorporates all the required functional elements for making reliable beam intensity acquisitions. The flexible and modular nature of the FPGA digital platform allows multiple data integration schemes which are explained below:

Parallel integrator – uses single window beam capture scheme with an accompanying offset capture. This integration is the most commonly used type for ordinary PS and PSB transfer line measurements. The

DC offset measurement can be specified to be performed at any time interval when there is no beam in the line.

Calibration integrator – single calibration window with accompanying DC offset capture as in the Parallel integrator above.

Bunch integrator – allows up to 32 possibly overlapping measurement gates to be defined and acquired using a single trigger signal. Each measurement has its own delay and capture length.

Multigate integrator – stores its values as a set of 1024 back-to-back capture gates with the same programmable gate duration. This mode provides an "oscilloscope" type overview and is extensively used in setting up timing parameters for the "single shot" integrators described above [2].

SOFTWARE ARCHITECHTURE

The software architecture for the new Fast BCT acquisition system is displayed in Figure 3. It consists of:

1. *BCTFPS*, a FESA acquisition server running locally on the Linux or LynxOS VME front end computers.

2. *BCTFPS_Monitor*, a Java based expert GUI application used for adjusting measurement parameters and validating acquired results.

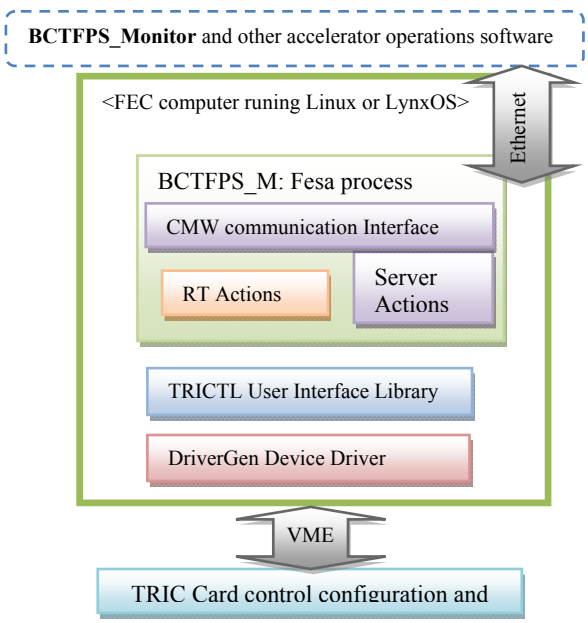

Figure 3: Software structure.

The *BCTFPS* is based on the FESA framework [3] allowing it to benefit from features such as real-time scheduling, beam-cycle synchronisation, user-notifications and use of a shared memory model.

Communication with the TRIC card is provided by a *TRICTL User Interface Library* where the register access to the TRIC hardware is made and data is decoded and pre-processed [4]. The low level hardware access is implemented using CERN's new standardized DriverGen driver platform.

The real-time part of the BCTFPS acquisition server consists of Prepare and *Acquire* actions triggered by PS or PS Booster central timing events linked to active elementary cycles. The following table summarises various steps taken during real-time actions.

Table 1: Functions Performed in Corresponding Real-Time Part of the BCTFPS Code

Real time SW Action	*Main functionality*
Prepare	✓ Reset integrators ✓ Configure each of the hardware integrators for the new cycle ✓ Select calibration scheme ✓ Setup cycle specific calibration parameters
Acquire	✓ Read timestamps, beam destinations and measurement status ✓ Read and store intensity measurements ✓ Scale *multigate* integrator values ✓ Compute intensity from raw data for verification ✓ Compute long term current statistics for the beam

INSTRUMENTATION EXPERT SOFTWARE

The *BCTFPS_Monitor* application (Fig. 4) is built for the adjustment of the timing as well as electrical and logical parameters for the low level *BCTFPS* acquisition server. It is coded using *Expert GUI* framework Java libraries developed by the CERN Beam Instrumentation Software Section [5]. The settings that can be applied are grouped into those applied for specific acceleration cycles and those that are common for all cycles. The integration gate length and its delay from the start trigger are, for example, settings which vary greatly from one accelerator cycle to another.

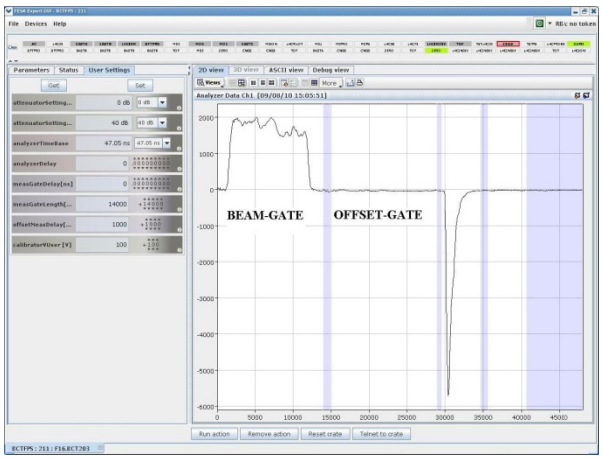

Figure 4: BCTFPS_Monitor GUI screenshot showing the beam intensity and negative calibration pulse with respect to the various integration gates.

The main part of the GUI is a large graph showing acquisition data from the 1024 data points of the *multi-gate* integration. The graph refreshes with every beam pulse passing in the transfer line. The beam acquisition and calibration pulse are superimposed on the acquisition gates using background colour cursors. The time base for the multigate integrator can be varied, achieving a 10ns resolution at its minimum setting. Figure 5 shows some of the shortest beam pulses extracted. The individual bunches of the *SFTPRO* beam cycle, ejected from the PSB, are <200ns long and spaced by ~300ns, and can easily be resolved using the smallest multigate integration time window.

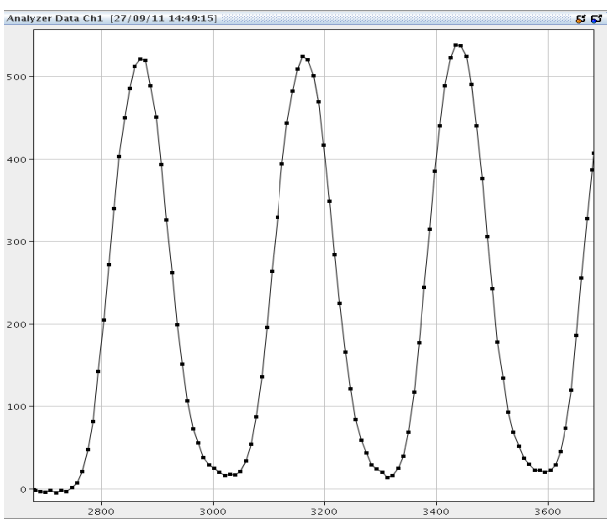

Figure 5: PBS ejected *SFTPRO* beam with *multigate* integration time increment of 10ns.

Increasing the increment acquisition time to tens, and even hundreds of ns, allows the expert to see the full picture for beams of longer duration. Figure 6 displays the same *SFTPRO* cycle at ejection from the PS, with the full 10μs beam pulse now visible.

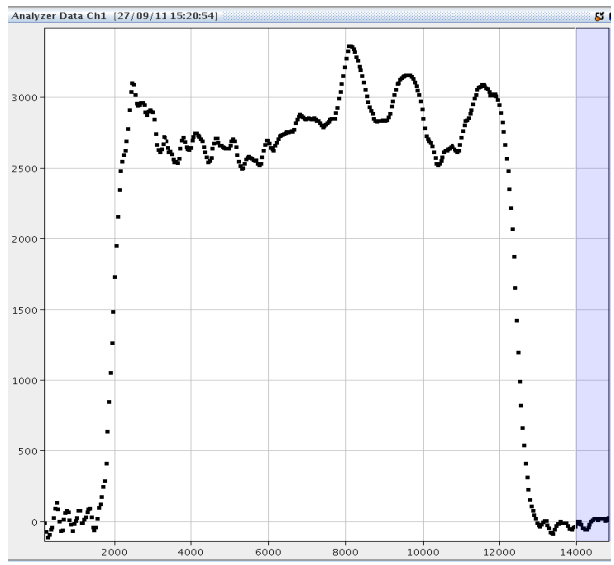

Figure 6: PS ejected *SFTPRO* beam with multigate integration time increment of 38ns.

MEASUREMENT REPRODUCIBILITY

The quality of the measurement data acquired by the new BCTFPS server was inspected with respect to different acquisition scenarios and compared to the old Fast BCT acquisition system. The first parameter studied was the relative error of the new system in the PSB transfer line compared to the intensity measured in the ring itself.

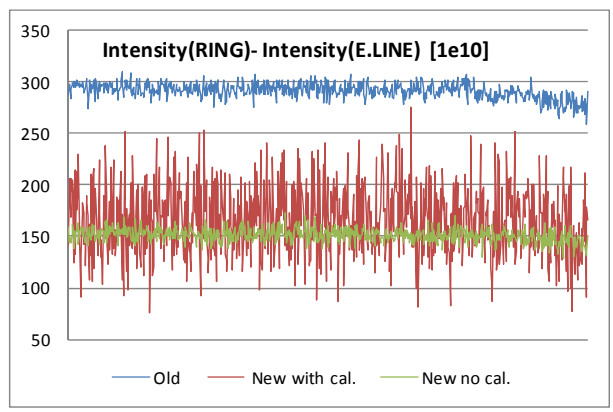

Figure 7: Comparison of the reproducibility for the old and new system. Using shot by shot calibration increases the noise on the measurement.

For the measurement in Figure 7, the average beam intensity was around 3e14 charges. The absolute value of the error is not important for the variation analysis, since the acquisition systems are not cross calibrated. It was seen that when the calibration was applied on a cycle by cycle basis additional noise was added to the final intensity result. This was found to come from the non-reproducibility of the calibration pulse. It was thus decided that rather than perform the calibration for each new measurement it was better to use a single

constant calibration factor. This factor was to be determined and applied by the expert in the instrument setup phase by taking the mean value from many calibration pulses. Once the calibration factor was fixed the remaining errors in the intensity measurement came from the front-end electronics and reproducibility of the beam injection process. The drawback of the "fixed calibration factor" scheme is that the system is not 100% autonomous and maintenance free.

Unique calibration factors have to be maintained for each of the two acquisition channels and each of the three attenuation levels (0dB, 20dB and 40dB). To set-up these factors, the expert uses a dedicated feature of the *BCTFPS_Monitor* GUI (Figure 8). The steps are the following:

1. Enable active calibration routine after every beam measurement
2. Unselect the "Freeze" radio-button in current attenuation level.

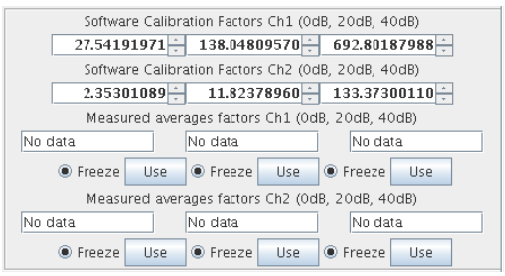

Figure 8: GUI panel for the calibration factor setup.

The system then starts acquiring calibration factors computed from the applied physical calibration pulses. The running sum of the 16 last measurements is displayed in the field.

3. Once the average is accumulated the Expert presses the "Use" button to subsequently set this value in a firmware register.
4. Disable active calibration and start using the new fixed calibration factor.

The quantitative improvement in the measurement reproducibility (i.e. less shot-to-shot variation) by using a "fixed" calibration factor has been significant. The following table displays the relative error of the total measured intensity for two distinct Fast BCTs [2].

Table 2: Reproducibility Error of old and new Fast BCT Acquisition Systems

Measurement System	BCT.BTTRA	BTY.TRA325
Original System	0.63%	0.23%
New system with Active Calib.	0.65%	1.2%
New system Const. Calib. factor	0.08%	0.22%

The last column showing BTY.TRA325 corresponds to the graph in Figure 8 above and shows how the relative pulse-to-pulse error was initially dominated in the new system by the shot-to-shot reproducibility of the calibration, returning to that of the old system once a constant calibration factor was applied. The downside of this solution is the fact that the new TRIC based system did not become totally maintenance free, as originally envisioned, since a periodic adjustment of the fixed calibration factor is now needed to correct for long term drifts in the acquisition electronics.

CONCLUSION

The new Fast BCT acquisition system has been significantly improved by new hardware and software. A highly modular digital integration module allows experts to cover many possible measurement scenarios by means of multiple integrator implementations keeping configuration settings limited and uncluttered. The additions of the on-board calibration circuit, as well as 1024 data point acquisition graph view, have greatly simplified instrument expert setup and maintenance procedures. The software solutions for both the front-end FESA server and the Expert GUI enable a seamless acquisition service to accelerator operations and a convenient parameter adjustment interface for the experts.

CSNS TIMING SYSTEM PROTOTYPE

G.L. Xu, G. Lei, Y.L. Zhang, P. Zhu, L. Wang, IHEP, Beijing, China

Abstract

Timing system is important part of CSNS. Timing system prototype developments are based on the Event System 230 series. We use two debug platforms, one is EPICS base 3.14.8. IOC uses the MVME5100, running vxworks5.5 version; the other is EPICS base 3.13, using vxworks5.4 version. Prototype work included driver debugging, EVG/EVR-230 experimental new features, such as CML output signals using high-frequency step size of the signal cycle delay, the use of interlocking modules, CML, and TTL's Output to achieve interconnection function, data transmission functions. Finally, we programed the database with the new features and in order to achieve OPI.

INTRODUCTION

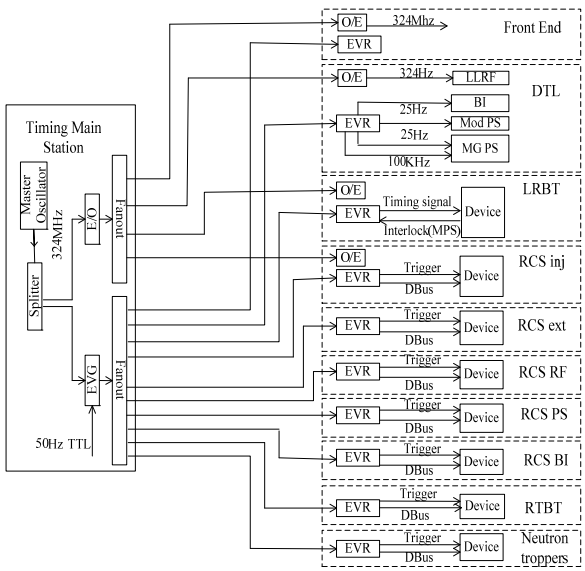

Figure 1: Timing System Outline.

The timing system using an Event system, that the event generator (EVG) and event receivers (EVR) as the main structures of a multi-level star structure(see Fig. 1), the core is EVG. The basic principle is, EVG distributed generation 8-bit parallel bus clock signal and 8-bit event codes, with 4 of 20 after a check code and / strings encoded as a stream of events, through the electro-optical conversion, optical fan-out module by and fiber (or cable) will be sent to a series of event streams EVR.EVR to receive the flow from the EVG's event to restore the 8-bit distributed bus clock signal and the 8-bit event code, and phase-locked clock generation and clock events EVG, EVR as a variety of operating reference clock. EVR can specify the port output clock signal; in the default event code EVR arrives, you can also specify the port in the pulse trigger signal output, and can produce a soft interrupt, the event code and time stamp stored in the FIFO memory with the memory can be read via the VME bus.

In BEPCII, event system has been successfully used to build a timing system, and long-term stable operation. CSNS timing system also intend to continue to use the event system[1]. Since 2004, the event system has also been upgrading , added a lot of features, the prototype of these new features was attempted. The CSNS timing system prototype provide the necessary basis for the construction of CSNS.

PLATFORMS AND DRIVER DEBUGGING

The software and hardware platforms of this experiment is as follows:

- Solaris2.8 of UNIX, mvme5100 CPU board, EPICS 3.13.8, Tornado2.1, VxWorks 5.4.2 .
- Red Hat Enterprise Linux 4, Kernel 2.6.9.Tornado 2.2.1, VxWorks 5.5.1, mvme5100 CPU board, EPICS BASE 3.14.8.2.

Modify some files of the driver，such as the routine ErCMLPat in the file drvMrfEr.c. Modify the souce code and the Db file.

HIGH-FREQUENCY STEP CYCLE DELAY

The control of the trigger delay is based on the RF cycle step (event clock = RF cycle * divide factor, of which divide factor can be 4, 5, 6, 8, 10, 12). As usual, the signal delay will be 12ns (see Fig. 2).This prototype utilize the CML output character of EVR230, of which up to 16 20-bit pattern configure register achieve the trigger delay control based on RF cycle step[2]. In fact, the maximum accuracy can be 1/(81MHz * 20)=617ps (see Fig. 3).

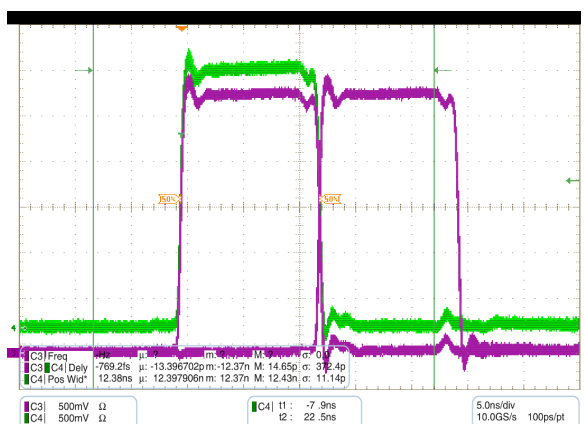

Figure 2: Delay is 12ns use common output.

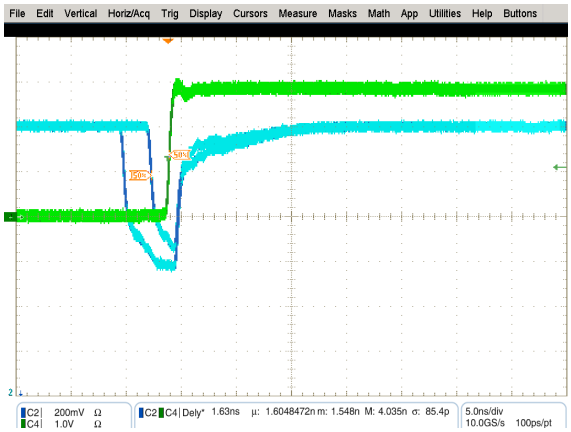

Figure 3: Delay is 600ps use CML output.

INTERLOCK FUNCTION

The event system of 230 series has interlock function. This function controls system can be used to participate and achieve with the machine protection system (MPS) of the interface. Using interface module UNIV-TTLIN, to receive electrical signals from the machine protection system, when the change occurs, the interlock signal level will become high level (see Fig. 5) from low level (see Fig. 4), the yellow signal will be closed .

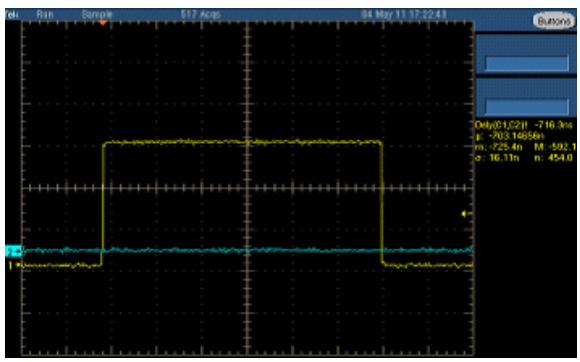

Figure 4: The blue signal is the input signal of interlock, its level is low when there are no interlocks. The yellow signal is the output of EVR.

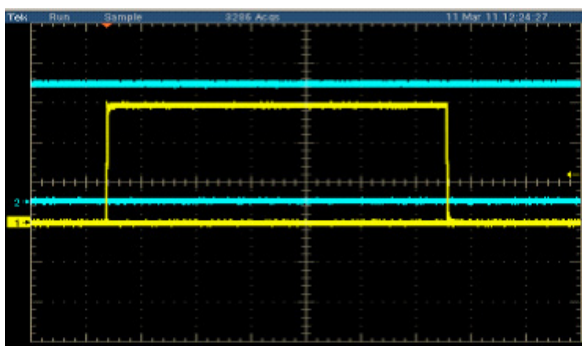

Figure 5: When the blue signal needs to realize the interlock function, it becomes high level, and the yellow signal is shutdown it just becomes low level.

DATA TRANSMISSION FUNCTIONS

The timing system prototype also considered the data transfer function, such as time-stamping, machine run mode data adn so on. EPICS-based control system can be used NTP (Network Time Protocol) to synchronize the time of each IOC. If the time granularity is the repetition period (such as J-PARC is 50Hz, U.S. SNS is 60Hz), then the timing system can be used to give each IOC to provide such high-precision time synchronization[3]. If the accelerator beam need to define some of the machine transfer mode and beam mode, in a different mode, some devices have different time charged action. We therefore need a model before the start of the model number will be sent to the running time of each site. Each time the site received mode information, to register the corresponding with different parameters, in order to achieve this mode of timing.

Data transfer operation mode is the accelerator data and time stamp and other information through the timing system to send and receive, this study we use the Swiss light source driver to Achieved. The driver contains four EPICS application: mrfApp, mrfDataBufferApp, regDevApp and generalTimeApp[4].

The four EPICS application to achieve three main functions: (1) mrfApp timing system to achieve the basic functions, which provides the trigger signal and clock signal; (2) mrfDataBufferApp and regDevApp accelerator operating mode to achieve data transmission;(3) generalTimeApp achieve timestamp (Timestamp) transmission.

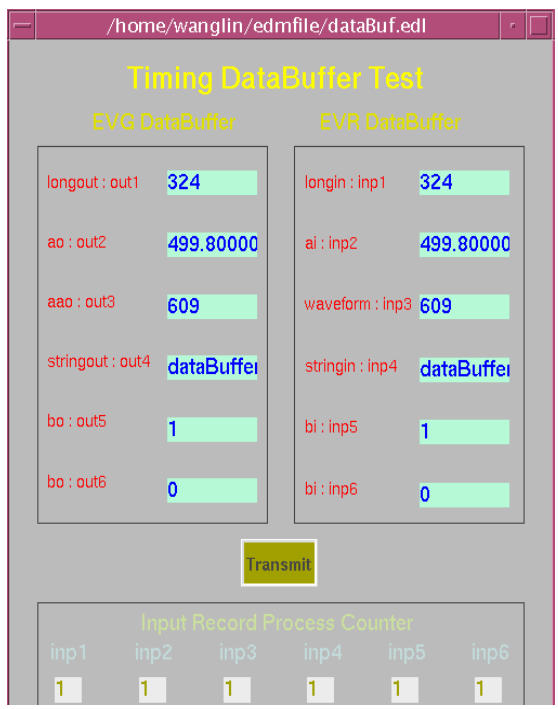

Figure 6: Data transfer test.

OPI

To facilitate the operation, in particular, produced a man-machine interface.The OPI has 4 part as shown in Figure 6 [5]. The first part is distribute bus&pulse output. The second part is CML output which showed in Figure 3. The 3rd is interlock function which showed in Figure 4. Last part is data transmission function. For the different mode, the right area will show different place which is correspond the left area.

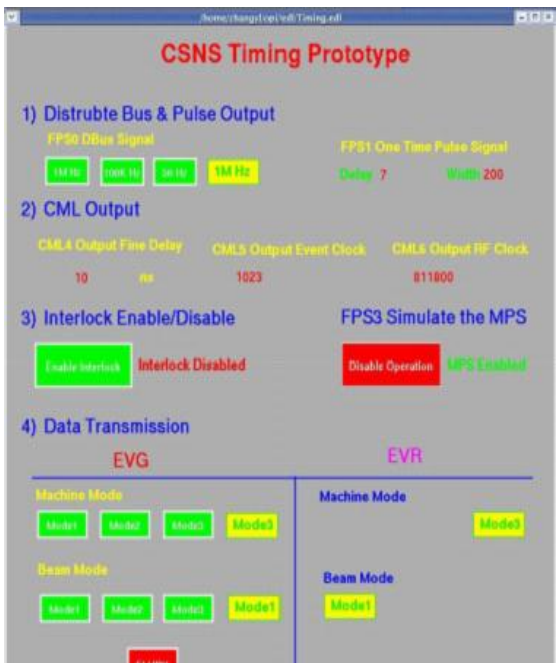

Figure 7: OPI of the prototype.

FOLLOW-UP

In CSNS,timing system is designed to provide triggers and clocks to the following systems,such as Front end, linac RF, injection, beam instrumentation, magnet power supply, RCS RF, extraction, spectrameter and target.Detailed discussions with the above systems have been done, while there are still some points need to be studied further.

THE BPM DAQ SYSTEM UPGRADE FOR SUPERKEKB INJECTOR LINAC

Abstract

The KEK electron/positron linac is a 600-m-long injector that provides the beams with different energy to four independent storage rings. The non-destructive beam position monitor (BPM) is an indispensable diagnostic tool for a long-term stable beam operation. In the KEK linac, about one hundred BPMs with the four strip-line type electrodes are utilized for the beam orbit and charge measurement. The measured beam orbit data is used for the beam orbit and energy feedback loops. The current data acquisition (DAQ) system for BPM comprises 24 fast digital oscilloscopes. They can work as a WindowsXP-based EPICS IOC.

Toward the SuperKEKB project, the upgrade of injector linac is going on for increasing the beam intensity and reducing the emittance. For the SuperKEKB injector linac, the electron beam emittance will be reduced one-fifth smaller than that of former KEKB project by using a new RF gun. For this reason, the measurement precision of BPM is strongly required to be increased. In this paper, we present the upgrade plan and status of DAQ system for BPM towards SuperKEKB project in detail.

INTRODUCTION

The KEK linac sequentially provides the electron and positron beams with different energies and intensities for four independent storage rings as shown in Table 1. For increasing the integrated luminosity and stored current stability, the simultaneous injection between KEKB electron and positron rings has been strongly required. In addition, the PF top-up injection has been also strongly demanded even during the KEKB injection. For these reasons, the injector upgrade project started in 2004 so that the simultaneous top-up of KEKB electron/positron and PF rings. This upgrade was completed in April 2009, and the simultaneous top-up injection among three independent rings was successfully achieved [1, 2, 3, 4].

Whereas the KEKB project has completed in the summer of 2010, the Super KEKB project has started for aiming at the peak luminosity of 40 times higher than that of former KEKB project. For this purpose, the injector linac upgrade is going on for increasing the beam intensity and reducing the emittance. In this linac upgrade, main issues are the construction of positron damping ring, the development of the new positron capture system for increasing the positron charge of four times present, and the installation of a low emittance electron gun as shown in Fig. 1. The performance required of beam position measurement is a higher precision of ten micro meters or less since the emittance of electron and positron beams are less than 20 mm·mrad.

LOW EMITTANCE ELECTRON BEAM DELIVERY

For the SuperKEKB project, the emittance of positron beam will be reduced 10 mm·mrad from 2100 mm·mrad by using the damping ring newly constructed. The

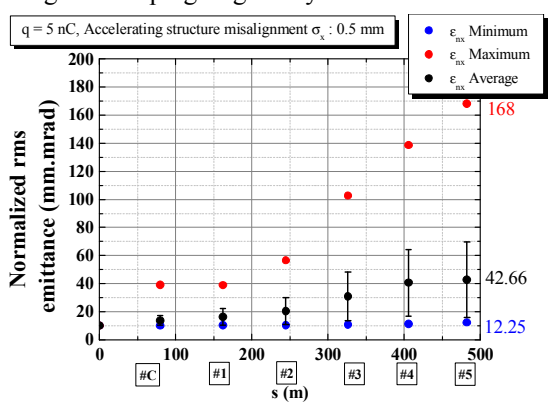

Figure 2: Simulation result of horizontal emittance growth in the KEK injector linac from Sector C to Sector 5.

emittance of electron beam will be reduced 20 mm·mrad from 100 by a low emittance rf gun. The low emittance electron beam should be delivered to the ring without damping ring due to cost reduction. In the high intensity electron linacs, emittance growth can be caused by the misalignment of accelerating structures and magnets.

Figure 2 shows the simulation result of horizontal emittance growth in the KEK linac. Here, it is assumed that the KEK injector linac configuration from Sector C to Sector 5, bunch charge of 5 nC and initial normalized rms emittance of 10 mm·mrad, and the accelerating structure misalignment of 0.5 mm with standard deviation. In this simulation, the emittance calculations were carried out by using simulation code elegant and 100 different error seeds. The simulation result shows that the average and maximum emittances at the end of Sector 5 are 42.66 mm·mrad and 168 mm·mrad, respectively. The final emittance strongly depends on the seeds of error.

On the other hand, the fine control of beam orbit can cure the emittance deterioration. Figure 3 shows the simulation result of emittance growth compensation by using the fine control of initial beam offset and angle. In this simulation, we used the seed of alignment error corresponding to the maximum emittance growth of 168 mm·mrad. The simulation result shows that the final emittance can be reduced 11.5 mm·mrad from 168 mm·mrad by adjusting of initial beam angle and offset. The control values of initial beam angle and offset are 100 μrad and 10 μm, respectively. From these simulation results, the high precision beam position measurement is strongly required for the fine beam orbit control of SuperKEKB injector linac.

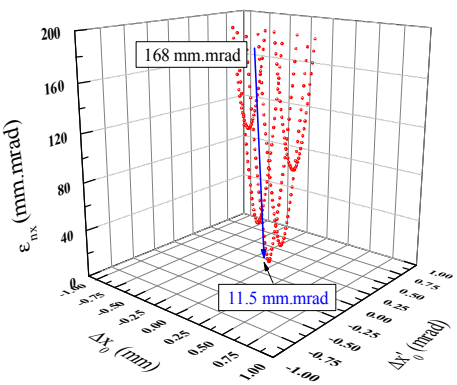

Figure 3: Simulation result of emittance growth compensation by using beam orbit control.

BPM DAQ SYSTEM

Present System

In the KEK linac, many kinds of feedback loops have been developed and utilized to stabilize the beam orbit, energy, and energy spread [5, 6, 7]. These feedback loops make use of the beam position information acquired by the non-destructive BPMs [8]. About one hundred stripline-type BPMs have been installed in the KEK linac.

The twenty four front-end systems have been installed in the linac klystron gallery at a nearly equal interval along the beam line. The each DAQ system deals with the analogue signals of 3 to 6 BPMs. A schematic drawing the present DAQ system is shown in Fig. 4. It comprises a fast digital oscilloscope (Tektronix DPO7104; 10 GSa/s, 4 channels, 8 bits, CPU P4/3.4 GHz, Gigabit-Ethernet) and a cable combiner box.

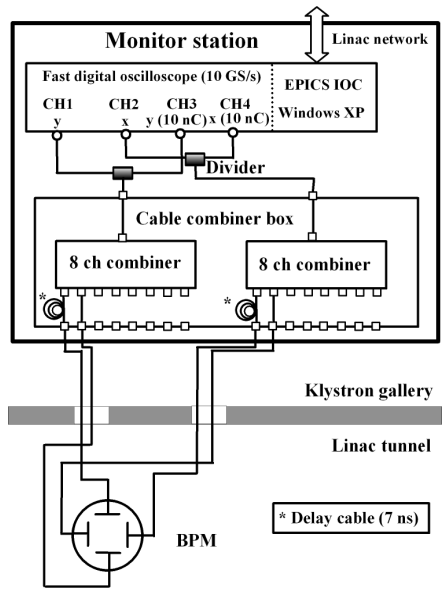

Figure 4: Schematic drawing of the present BPM DAQ system.

The four signals coming from one BPM are fed to two signal combiners (vertical and horizontal) together with the signals from other BPMs. The delay cables corresponding to a 7 ns time delay are used to avoid waveform overlaps at the signal combiners. The each output of combiner box is divided again into two signals. Since it is impossible to change the vertical scale of oscilloscope in every 50 Hz, CH1/CH2 and CH3/CH4 are used for the low charge and the high charge modes, respectively. The waveforms digitized at a sampling rate of 10 GSa/s are analyzed and converted into the beam parameters (beam charge, horizontal position, vertical position), taking into account the calibration coefficients. The DAQ software has been developed by using Microsoft Visual Studio 2005 C++, TekVisa, and EPICS R3.14.8.2 libraries. The DAQ software is running on the fast oscilloscope, and each DAQ can work as an EPICS IOC [9]. The similar DAQ system is also utilized for the KEKB and PF-AR beam transport lines [10].

The beam position measurement precision of the present system is listed in Table 2. These figures show the experimental results measured by three BPMs method [5]. The result of 1 nC shows worse precision than that of 0.1

nC since the same vertical scale settings are used for the measurements of 1 nC and 7 nC. There, the maximum ADC counts of 1 nC are smaller than the case of test with 0.1 nC electron. From these experimental results, it is difficult for the present DAQ system to achieve the beam position measurement precision of 10 μm or better. Toward Super KEKB linac, a new BPM DAQ system should be implemented since the ADC resolution of 8 bits limits the position measurement precision in the present system.

Table 2: BPM Precision of the Present DAQ System

Beam charge (nC)	Measurement precision (mm)
0.1	0.06626
1	0.10645
7	0.05052

New System

For the new DAQ system, the measurement precision of about 10 μm or better is one of key requirement. In addition, all beam position should be measured in every 20 ms interval. The SuperKEKB injector linac should perform the simultaneous injection to four independent rings since the beam lifetime of SuperKEKB is much shorter than that of KEKB rings. In the current design, it is estimated to be around 10 minutes. Figure 5 shows the beam operation scheme of SuperKEKB injector linac. The electron/positron beams with different energies and amounts of charges are delivered in every 20 ms. For this reason, the fast and precise attenuation control is also key requirement for the new system.

We adopt Libera Brilliance Single Pass unit as a candidate of the new system [11]. It is a commercial product of Instrumentation Technologies. It is a module dedicated for BPM DAQ and widely used at many recent accelerator facilities. Libera Brilliance Single Pass unit comprises four 16-bits ADCs of 125 MHz sampling frequency, two pass band saw filters in each analogue channel, a single-board computer (SBC), a field-programmable gate array (FPGA), and so on. It has also the variable attenuator with maximum attenuation of 31 dB. The attenuation level can be adjusted in 1 dB step.

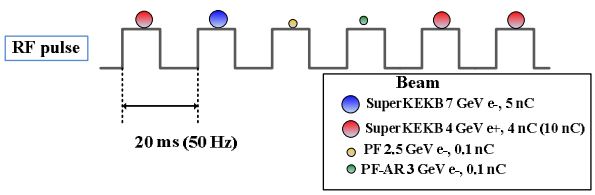

Figure 5: Schematics drawing of SuperKEKB injector linac beam operation. The beams with four different energies and amounts of charges should be managed.

The typical analogue signal shape from BPM electrode is a bipolar of 3 ns in width. Applying double saw filters, the signal is stretched to around 100 ns as shown in Fig. 6. After about 10 data points are sampled, the sum of squares of them is used as signal amplitude from each electrode. The data processing of digitized waveform is carried out on the FPGA side. The calculated beam position and other data are transferred to SBC side which is the embedded Linux operation system with fast Gigabit Ethernet. A client software like beam orbit display can retrieve the information of beam position and amount of charge via EPICS CA protocol.

EVALUATION OF DAQ PERFORMANCE

We evaluate the basic performance of Libera Brilliance Single Pass unit. Figure 7 shows the result of data acquisition defect by using test pulse of 50 Hz while four hours of continuous measurement. In this graph, the timestamp intervals between previous and current acquisitions are plotted as a function of test pulse number. From this result, all beam pulse can be measured up to 50 Hz since all timestamp differences are less than 40 ms. The more long-term experiment will be also carried out soon.

Figure 8 shows the precision of beam position measurement by using 1000 successive pulses of 0.1 nC electron beam. In this experiment, we used the eleven different steering settings and three LIBERAs connected to different BPMs. These results include the beam position fluctuation. The result of vertical direction at steering setting #5 of BPM#1 shows the standard deviation of 15 mm. The measurement precision of

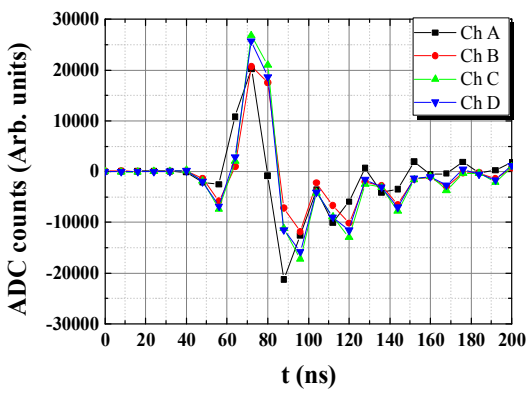

Figure 6: Raw waveform data measured by LIBERA Brilliance Single Pass unit.

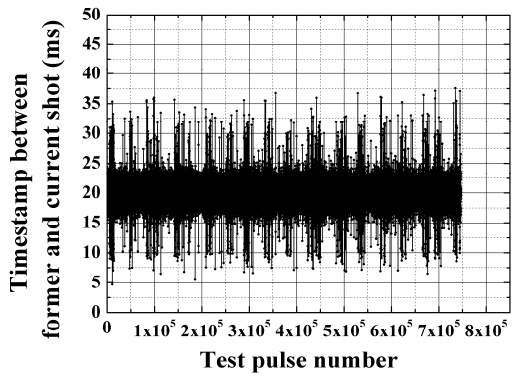

Figure 7: Result of data acquisition defect by using test pulse of 50 Hz while four hours of continuous test.

LIBERA Single Pass unit could be less than 15 mm when the effect of beam fluctuation is subtracted from this result. From these results, it is convinced that LIBERA Single Pass unit is feasible for our purpose.

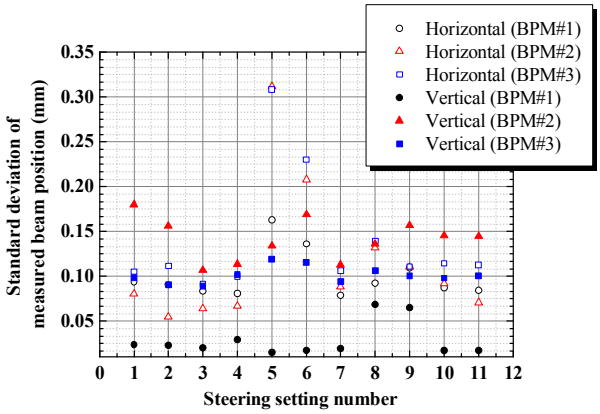

Figure 8: Precision of position measurement by using 0.1 nC beam and eleven different steering settings.

SUMMARY AND FUTURE PLAN

Toward the SuperKEKB project, the injector linac upgrade is going on for increasing the beam intensity and reducing the beam emittance. For the low emittance electron beam transport without damping ring, high precision beam position measurement and control are strongly required. For this purpose, the current BPM DAQ system should be replaced by new one with higher measurement precision. Recently, we preliminary evaluate the performance of a candidate Libera Brilliance Single Pass unit of Instrumentation Technologies.

In this performance test, we measured the speed performance of BPM signal detection and the precision of beam position measurement by using the KEK linac beam of 0.1 nC. The test result shows the speed performance is enough high for our application of 50 Hz beam measurement. The possibility of position measurement precision less than about 15 μm is also confirmed by the beam test.

The functionality of fast and precise attenuation control will be implemented soon. The complete test of position measurement precision by three BPMs method will also be carried out by using the KEK linac beam in the near future. At the same time, other schemes for getting the higher precision are also under consideration.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Rok Hrovatin, Mr. Matjaz Znidarcic, Mr. Peter Leban of Instrumentation Technologies for their fruitful discussions.

IMPROVEMENT OF THE ORACLE SETUP AND DATABASE DESIGN AT THE HEIDELBERG ION THERAPY CENTER

K. Höppner*, Th. Haberer, J. M. Mosthaf, A. Peters,
HIT, Heidelberg Ion Therapy Center, University Hospital, Heidelberg, Germany
M. Thomas, A. Welde, Eckelmann AG, Wiesbaden, Germany
G. Fröhlich, S. Jülicher, V. RW Schaa, W. Schiebel, S. Steinmetz,
GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany

Abstract

The HIT (Heidelberg Ion Therapy) center is an accelerator facility for cancer therapy using both carbon ions and protons, located at the university hospital in Heidelberg. It provides three therapy treatment rooms: two with fixed beam exit (both in clinical use), and a unique gantry with a rotating beam head, currently under commissioning. The backbone of the proprietary accelerator control system consists of an Oracle database running on a Windows server, storing and delivering data of beam cycles, error logging, measured values, and the device parameters and beam settings for about 100,000 combinations of energy, beam size and particle rate used in treatment plans. Since going operational, we found some performance problems with the current database setup. Thus, we started an analysis in cooperation with the industrial supplier of the control system (Eckelmann AG) and the GSI Helmholtzzentrum für Schwerionenforschung. It focused on the following topics: hardware resources of the DB server, configuration of the Oracle instance, and a review of the database design that underwent several changes since its original design. The analysis revealed issues on all fields. The outdated server will be replaced by a state-of-the-art machine soon. We will present improvements of the Oracle configuration, the optimization of SQL statements, and the performance tuning of database design by adding new indexes which proved directly visible in accelerator operation, while data integrity was improved by additional foreign key constraints.

THE HIT MEDICAL ACCELERATOR

The heavy ion accelerator at HIT is used for raster-scanning radiation of cancer patients (cf. [1, 2] for an overview) with different types of ions from two sources (upgrade to three sources in progress [3,4]) in several treatment rooms, two with horizontal fixed beam exit and the heavy ion gantry with rotatable beam exit (under comissioning [5]), and a beam exit for experiments (see Fig. 1). Each combination of source and destination may be used for medical treatment, represented within the Accelerator Control System (ACS) by the so-callled *virtual accelerator* number. A radiation plan consists of a series of beam pulses chosen from a catalogue of 255 different energy values (88–430 MeV/u for carbon, 48–220 MeV/u for protons), 6 focus sizes, 15 intensity values (2×10^6–5×10^8 particles per second for carbon, 8×10^7–2×10^{10} pps for protons), and 36 exit angles in case of the gantry. These tuples of beam settings are named the MEFI combinations. Both the virtual accelerator as the MEFI combination may be changed from beam pulse to beam pulse (multi-plexed operation).

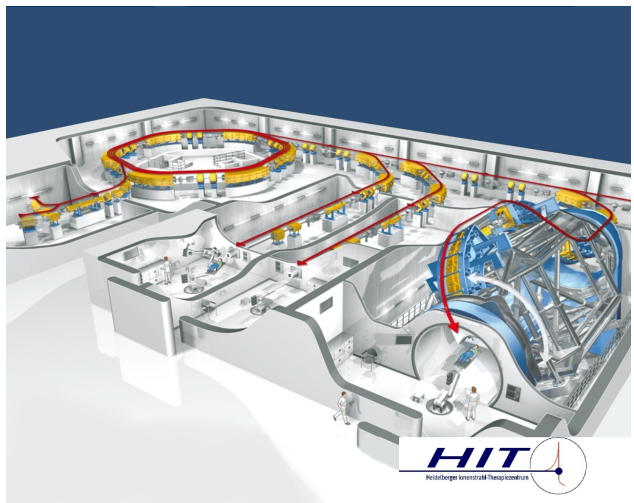

Figure 1: HIT accelerator facility with two ion sources, linear accelerator, synchroton, two horizontal beam exits and gantry for medical treatment. The experimental area is not shown.

DATABASE AS PART OF THE ACCELERATOR CONTROL SYSTEM

The database is a core part of the accelerator control system. It is used for

- a list of executed beam cycles for about 6 weeks together with measured values for e. g. currents of power supplies, data beam instrumentation (like ionization chambers), vacuum pressure, ...
- list of devices that are active for a virtual accelerator,
- settings for all accelerator devices to be written into the device controllers,
- alarm and log messages,

* klaus.hoeppner@med.uni-heidelberg.de

- users and access rights,
- computers and applications.

The device settings are generated as binary large objects (BLOBs) by the DSM, the data supply module, from the physical beam properties optimized for a representative number of MEFI values and interpolation over the full MEFI range. Finally, the device blob per MEFI is stored within the Oracle database.

There exist three kinds of device blobs to combine the need for adjusting the accelerator settings and test of different beam optics with the quality requirements for stable settings needed for medical treatment:

- flash blobs that are stored in non-volatile memory of the device controllers after verification for therapy,
- online blobs stored in the RAM of the device controllers that are changed during accelerator adjustment (without affecting the verified flash data), and
- offline blobs to save old device data, present in the database, only.

The checksums of the blobs stored in the device controllers are checked against the blob checksums stored in database on any beam request to ensure the integrity of the settings.

DATABASE PROBLEMS

Since about 2010 the existing Oracle database (Oracle 9i running on a server with a dual core Xeon CPU and 2 GB of RAM under Windows 2003) showed performance problems. This was both visible during therapy (when checking the blob checksums, writing measured values) as during accelerator adjustment (when writing generated online blobs into database, copying online blobs into flash blobs after verification).

Obviously, a major reason was the outdated hardware, that was upgraded to a modern blade center during summer 2011 (as presented in [6]), but also issues beyond hardware should be addressed. Thus, we established a working group consisting of HIT controls group, Eckelmann AG (as supplier of the proprietary control system) and the database experts from the accelerator controls department of the GSI Helmholzzentrum für Schwerionenforschung in Darmstadt, Germany.

The workgroup analyzed both the setup of the current Oracle installation (e. g. by statspack[1] reports of usual operating tasks) as well as the structural design of the database (tables, indexes, constraints).

RESULTS, RECOMMENDATIONS, AND REALIZATION

Hardware and Oracle Setup

As expected, both the CPU speed and the memory of the database server were considered insufficient. It was recommended to upgrade the Oracle installation to version 11g and use Oracle's Automatic Storage Manager (ASM) as file system which is optimized for the data storage of an Oracle instance. RMAN[2] should be used as backup tool instead of the previous daily tablespace exports.

With the installation of the new blade servers during the summer shutdown period, these proposals were put into practise.

Number of Commits

The statspack analysis showed a high number of about 20 commits per second. This is caused by several data gateway processes that insert measured values from the devices into the database. In the current realization of the control system, a commit command is sent per insert statement. It was proposed to decrease the number of commits per second.

Eckelmann AG was checking the impact of grouping several insert statements per commit on the overall performance of the ACS. Obviously, the longer the delay between insert and commit, the slower the GUIs will present state changes and measured values to the operator. Thus, a compromise had to be found. Additionally, since several applications are writing into the database, the effort to implement and test a better commit mechanism was rather high.

Finally, the changes will be installed at HIT in October.

Structure of Tables

Many requirements for accelerator operation changed until or even since the accelerator facility became operational for medical treatment, inspired by the lessons learnt during commissioning. Thus, there was an evolution of the ACS from its original design until its current state. The database design reflects this evolution.

It was the overall impression that the database design for rather static data (like definition of ion types, beamlines, list of devices and their assignment to beamlines) was good, with appropriate relations between tables defined by foreign key constraints. But in some cases, data columns with dynamic, volatile data were added into these "static" tables due to changing or adding new features for accelerator controls. Tables for dynamic data (beam cycle data, measured values, messages) were often lacking foreign key constraints.

The recommendations for an improvement of the database design were as follows:

- Separate tablespaces for static (configuration) data and dynamic (measured) data,
- avoid to mix columns with static and volatile data in tables,
- define proper relations between tables by adding foreign key constraints where missing,

[1] statspack is a performance monitoring and reporting tool provided by Oracle starting from version 8i, cf. `http://www.oracle.com` or `http://www.orafaq.com/wiki/Statspack`.

[2] RMAN is a tool provided by Oracle to backup, restore and recover Oracle databases, cf. `http://www.oracle.com`

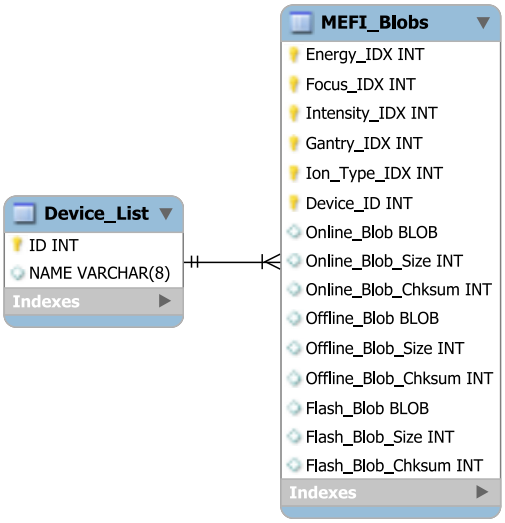

Figure 2: Current design of the table with MEFI device blobs, with three blobs per record.

- add indexes to optimize database queries,
- redesign "wide" tables to achieve a better in-memory-caching of data records within the Oracle database instance.

A good example for the last item is the table of device blobs per MEFI combination. As mentioned above, there exist online, offline and flash blobs. In the current table design, the table for MEFI device blobs has three blob columns (as shown in Fig. 2), one per blob type, i. e. when loading the data record for a MEFI combination and a device, three blobs are read and have to be cached in memory. Consider the workflow during accelerator adjustment, when online blobs are generated and written into database for all MEFI combinations and all devices. For downloading the new online blobs into the RAM of the device controllers, many records from the table with MEFI device blobs have to be read, and though only the online blobs are needed, the offline and flash blobs are read as well, consuming I/O ressources and memory of the database cache.

It was recommended to keep the blobs itself in an own table and replace the blob columns in the MEFI blob table by references. This would increase the number of tables itself, but keep the MEFI blob table compact. By appropriate joins between the MEFI blob table and the table(s) keeping the "real" blobs, the set of blobs that are read by Oracle would be reduced to those that are really needed. Figure 3 shows a possible redesign, where the blob columns are replaced by references to another table. Since changes to the table structure have impacts on the whole ACS, a redesign needs to be thorougly planned and tested. This process will be done until the end of this year.

Other recommendations listed above are already implemented or will be installed during the next ACS update in October 2011 (like adding foreign key constraints). The separation of static and volatile data in different tablespaces was realized during the migration from Oracle 9i to 11g.

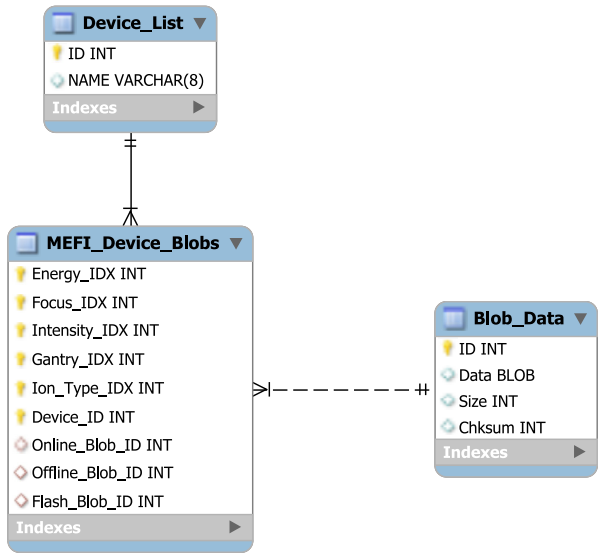

Figure 3: Possible change of table structure for MEFI device blobs by replacing the blob columns with a reference to another table keeping the blobs.

Several missing indexes were pointed out by the working group, that were added in the meantime, and some indexes were reorganized to achieve unique indexes as unique index scans are more efficient than normal index scans.

FIRST RESULTS

In combination with the new hardware platform, the changes to the Oracle database show already a positive performance effect.

Figure 4 compares the time between the stop and start broadcast signals (as sent by the central timing system), i. e. the dead time between beam cycles needed to prepare and setup the next cycle, for a week of therapy in September 2010 and September 2011, respectively. While the time

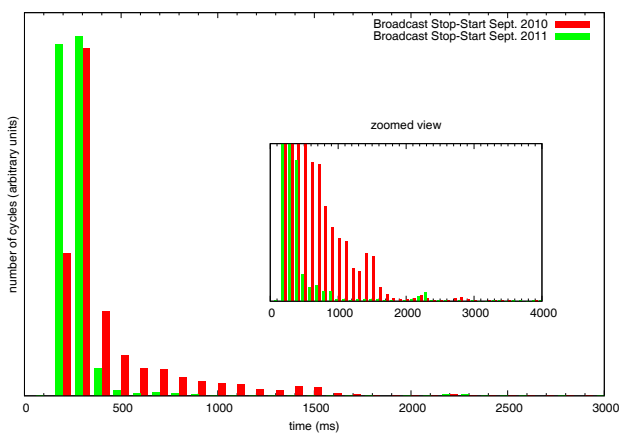

Figure 4: Comparison of dead time between beam cycles needed for preparation of the next beam pulse: September 2010 (red) and September 2011 (green).

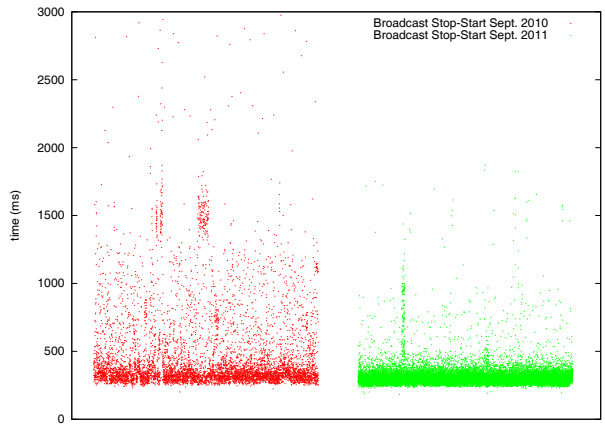

Figure 5: Scatter plot of dead time between beam cycles needed for preparation of the next beam pulse: September 2010 (red) and September 2011 (green).

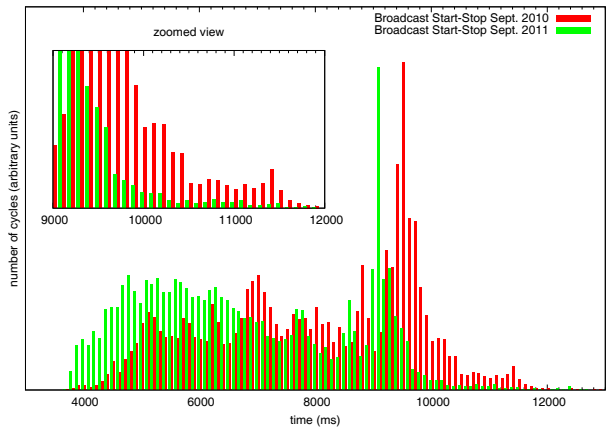

Figure 6: Comparison of beam cycle time (for up to 5 s tumor radiation): September 2010 (red) and September 2011 (green).

needed to prepare the next beam cycle after the end of the previous cycle is about 250 ms for most of the cycles, the average dead time was spoiled by many cycles with a much longer preparation time before the start broadcast signal was sent. The analysis of traces of servers and device controllers showed, that this effect was mainly caused by

- a delay in the Oracle database when creating the database record for the upcoming cycle and querying the list of devices that are active for the cycle,
- a read delay in the flash memory of the device controllers when checking the MEFI blob checksums.

After both problems were solved this year, it is immediately visible from the plot that most delayed cycles were eliminated, with the effect that the average preparation time was decreased from 490 ms in September 2010 to 390 ms in September 2011. The scatter plot in Fig. 5 also shows, that the number of cycles with preparation time above about 400 ms is decreased dramatically.

We compared also the times between the broadcast signals for cycle start and stop during therapy (based on medical treatment with up to 5 s radiation of the tumor per beam cycle) for September 2010 and 2011. As seen in Fig. 6 the cycle performance increased a lot, caused both by improvements in the therapy control system (TCS) and the communication between ACS and TCS, as well as the performance tuning of the database. The analysis of the traces showed that the time needed for updating the cycle status in the database was sometimes up to 200 ms.

CONCLUSION

As presented in the previous section, the accelerator performance was increased a lot during the last year. This is due to many efforts to optimize the ACS, both by hardware as well as by improvements to the database.

The improvements are also visible in GUIs for the operator that profit from better database querying performance, and time consuming tasks during accelerator adjustments, like interpolating and generating MEFI blobs or flashing are much faster than before. E. g., an interpolation of all devices for the gantry needs about 1.5 hours per ion type, instead of 6 hrs. before.

The recommendations didn't just address database performance, but data integrity, too. The realization of proper relations between the tables, as it is currently in progress or preparation, will help to avoid both redundant or even invalid data within the database.

Abstract

The ALICE Detector Control System (DCS) is in charge of control and operation of one of the large high energy physics experiments at CERN in Geneva. The DCS design which started in 2000 was partly inspired by the control systems of the previous generation of HEP experiments at the LEP accelerator at CERN. However, the scale of the LHC experiments and the use of modern, "intelligent" hardware and the harsh operational environment led to an innovative system design. The overall architecture has been largely based on commercial products like PVSS SCADA system and OPC servers extended by frameworks. Windows has been chosen as the operating system platform for the core systems and Linux for the front-end devices. The concept of finite state machines has been deeply integrated into the system design and the design principles have been optimized and adapted to the expected operational needs. The ALICE DCS was designed, prototyped, and developed at a time when no experience with systems of similar scale and complexity existed. At the time of its implementation the detector hardware was not yet available and tests were performed only with partial detector installations. In this paper we analyse how well the original requirements and expectations set ten years ago comply with the real experiment needs after two years of operation. We provide an overview of system performance, reliability and scalability. Based on this experience we assess the need for future system enhancements to take place during the LHC technical stop in 2013.

INTRODUCTION

The design of the ALICE DCS started late 2000. In its initial phase the project was able to profit from already advanced developments in other LHC experiments and from tools and guidelines provided by the Joint Controls Project (JCOP) [1]. The existing concepts were compared with ALICE detector needs and from this the first ALICE DCS architecture was designed [2]. The first presentation given to the ALICE Technical Board in 2001 defined the roadmap for the whole DCS. In the following chapters we will review the presented key concepts and compare them with the current system implementation.

ALICE DCS SYSTEM CONTEXT

The architecture of the ALICE DCS is strictly hierarchical. The top level is formed by the central DCS which coordinates the individual detector systems. Each detector system is then divided into sub-systems which group devices with similar functionality. Subsystems are then further partitioned into devices, modules, and channels according to individual detector architectures. Each component of this hierarchy is modelled as a finite state machine (FSM) with standardized states and recognized commands. The commands are propagated through the hierarchy from parent to child, while the states are reported by children back to parents. The global status of the DCS takes always into account the states of all children in the hierarchy, with exception of any which have been masked (excluded) by the experts. This approach has been implemented using the SMI++ toolkit, which proved to be an extremely powerful, flexible and reliable component.

The core of the ALICE DCS is based on a commercial SCADA system – PVSS II [3] – which is extended by frameworks developed at CERN. Individual PVSS systems are grouped by detector and supervised by central DCS system.

The whole system is configured using data stored in the central ORACLE database. Up to 6GB of configuration data is uploaded to detectors before a physics run can be started.

Acquired data is compared with predefined operational limits and automatic or operator driven actions are taken in case of an anomaly. A subset of the acquired data is stored in the ORACLE database for further use in offline analysis or by detector experts.

A large amount of data is being exchanged between the central DCS and external systems such as electricity, magnet control, gas systems, cooling, etc. Data exchange between ALICE and the LHC is provided within the DCS context and currently represents one of the major data processing challenges.

Finally, the DCS communicates with all components of the ALICE online and offline system. The information exchange is mostly based on the FSM states and commands, but a large amount of data also flows via dedicated data publishers and file exchange servers.

COHERENT AND HOMOGENOUS SYSTEM

The DCS covers a large number and variety of devices, systems and components, which are developed by various groups in parallel. The role of the central team is the coordination and monitoring of these developments. Standards and recommendations are issued and reviewed regularly. Whenever possible, common solutions are recommended and deployed both in the hardware and software domains [4].

In the original concept, the DCS backend, consisting currently of about 170 computers, was based on the Windows platform, with a very limited number of Linux installations. With the growing complexity of the overall DCS systems, the number of Linux services increased to about 30% of all installed systems. Another increase in Linux installations is related to the front-end boards, which contain embedded operating systems. In the full configuration there will be ~800 of such boards installed in ALICE, making Linux the main OS platform.

In the ALICE DCS the operating system flavours and software versions are defined centrally. The developers are then requested to follow these requirements. Due to continuous system evolution, the number of required software packages is increasing and there are several justified deviations from the standards. The central team carefully monitors the exceptions and updates standards as needed. The software upgrades are usually carried out during the longer LHC breaks in the winter period.

FLEXIBLE AND SCALABLE SYSTEM

The control system has been operational since the first device installations. It follows detector evolution with the goal to cover the lifetime of the experiment. The system architecture has to be flexible to accommodate future detector developments and operational procedures. At the same time, the system needs to be scalable to cope with the experiment's growth.

Keeping these requirements in mind, the DCS has been designed to accommodate possible future extensions. The first architectural principle was to build a modular system and avoid a monolithic architecture. Separate and independent control systems have been built for each detector, avoiding cross-detector dependencies. The individual detector systems consist of one or several sub-systems which control devices with similar functionality. All detector systems are then integrated into the global controls system, using the distribution features of PVSS.

On the lowest level, the device access has been strictly separated from the control tasks, which are implemented in PVSS. Modules communicating with devices recognize simple commands, but do not implement any control logic. On the supervision level, the operator is presented with a set of tools which allow for experiment operation. The tools are executed on computers separated from the machines in charge of the device control. The clear advantage of the modular approach is the possibility to distribute the individual parts across several computers. This allows for better resource sharing and assures scalability. Separation of operator tasks from the controls functionality helps to prevent a possible critical system overload, triggered, for example, by an excessive request – like conditions data retrieval for a long time period which could overload the operator machine, but will leave the controls functionality intact.

OPERATIONAL MODES AND CONCURRENT OPERATION

One main difference between DCS and other online systems is that the DCS needs to remain operational during all phases of the experiment. Full DCS functionality is expected also during the periods without data taking – shutdown periods, upgrades, etc. The requirements during the different periods vary; the DCS is designed to cope with them, successfully providing its services 365 days a year.

When experiment conditions allow for it, the detectors are able to get some autonomy in the operation of their hardware. Using the SMI tools, whole detectors, or their parts, can be excluded from the central DCS and released to local operators. Such systems do not receive commands from the central operator, but the alerts are still propagated and followed in a standard way.

The operational experience revealed one potentially weak point of this approach: the devices under the local control do not report their status to the central operator and ignore commands. This might be dangerous during the critical phases of the experiment – for example during the magnet ramp or injection of particles to the LHC. In such periods, the detector settings, such as high voltage or frontend configuration, must be compatible with the intended operation. For these reasons a new technique has been developed and deployed in parallel to the standard SMI tools. A set of software probes controls all critical settings and read back values, independent of the FSM status. Thanks to this, the safety of excluded devices can be assessed and taken into account regardless of their ownership within the hierarchy and assure the correct execution of DCS procedures.

The original hierarchical approach and the FSM standardization across all detectors as defined 10 years ago proved to be valid and successful. However, with the knowledge gained during the operation with LHC, many extensions were implemented and the whole system became too complex to be efficiently exploited by the shift crew. A set of tools were then developed to group several functionalities and to allow the operator to execute complex tasks without the in-depth knowledge of the underlying FSM processes.

USER FRIENDLY AND INTUITIVE OPERATION

During normal operation, only a small shift crew of 2-6 people control the whole experiment from the central workspace. Since the operators are not necessarily detector experts, special attention is given to the presentation of the system.

A dedicated component, ALICE DCS UI, has been developed and deployed in all detector systems. It allows for standardized presentation of the systems to operators; it provides a uniform look and feel and is easy to use. Experience has shown that the operators have a tendency to cover the monitor screens with many windows. The philosophy adopted in ALICE has therefore been to aggregate the information and to provide a summary to the operator who then can decide to browse the hierarchy for more details.

All critical operations which require operator action are executed from dedicated interfaces. These contain all the buttons and indicators gathered from other components which are required for the current task. The operator can therefore fully focus on the action, without the need for browsing the system to get information.

Although lots of attention has been given to intuitive operation, human errors were responsible for the majority of the operational incidents, which led to data taking delays. After careful analysis of all events, the tools were redesigned and simplified, with most of the actions automated. In 2010 we started to deploy expert systems which monitor the critical operations and inform the operator about all anomalies, with clear troubleshooting instructions. These instructions are displayed directly on the interface related to the executed task along with all indicators and buttons required for the problem resolution. Unlike the alert system, which typically informs about exceeded thresholds for a monitored value, the expert system proactively follows the operation and is able to detect events such as an incorrect sequence of commands that did not yet trigger an anomaly.

AVAILABLE, SAFE AND RELIABLE SYSTEM

Whereas the safety of the personnel is the task of the CERN Safety System, ensuring the integrity of the detector equipment is largely the task of the DCS. The control system allows for hardwired or software actions in case of hazardous situations. The system must be reliable and available; where needed, the equipment is running on safe power.

The current operational performance proves that the ALICE DCS reached this goal. While during the start-up phase of the experiment the shift crew required daily assistance of the central team, in 2011 we reached a stable state where the shift crew does not need to consult the expert for several weeks in a row. Besides the stability of the deployed software and hardware, a large contribution to the reliability and smooth operation comes from comprehensive training provided to the shifters.

SYSTEM MAINTAINABILITY

The complexity of the ALICE experiments clearly exceeds the capabilities of a small central team. The expertise related to individual detector operation is maintained in the various institutes that developed the detectors. By using well defined interfaces and standards it is possible to integrate individual developments into the overall DCS, however long term support and maintainability becomes a major concern.

The overall culture of the academic environment expects exploration and deployment of latest tools and technologies. A small central team is not able to certify all the proposed components and is therefore forced to insist on conservative solutions, providing the required functionality.

In the lifetime of a large experiment such as ALICE, the migration of experts is an inevitable fact which has to be taken into account. It is not uncommon that the major developments are carried out by graduate or PhD. students who leave and continue their career in other fields. The developed systems are transferred to new colleagues. The transfer procedure usually does not explain all the background and context, and the developers tend to focus on the solution without taking into account the overall system architecture. The role of the central team is to monitor this evolution and ensure that the takeover will respect the agreed rules and principles.

The key to a maintainable system lays in the standardization. The ALICE DCS project team imposed rules and common solutions whenever possible. From the very beginning, the detector requirements were carefully reviewed and standard solutions were proposed. Thanks to this approach, despite the large differences in detector architectures, we were able to limit the variety of devices used; only three brands of power supplies are used in ALICE, for example. The uniformity of the hardware has clear benefits for the support provided by the central team.

Operational experience gained in past years has also proven the success of the deployment of common solutions also in other subsystems, such as gas or cooling. One exception to this model is however the front-end and readout electronics (FERO). By the time of the DCS design, the individual FERO architectures were already significantly advanced, with most of the modules already produced. The DCS had to cope with a large variety of architectures based on completely different solutions. A perfect example is the deployment of field buses. While in the power system we were able to restrict this layer to CANbus and Ethernet, the FERO access is based on JTAG, RS-232, VME, CANbus, Ethernet and a number of non-standard solutions developed in the institutes. To cope with this diversity the concept of Front-end Device (FED) was developed [5].

The FED architecture is inspired by the commercial OPC technology. The low level layer of the FED software is responsible for the communication with the FERO. Its

development requires deep expertise provided by detector designers, but once deployed it remains a relatively stable component, with changes linked mostly to hardware updates. The upper FED layer is based on the standard communication protocol DIM. Similar to OPC, it is implemented as a server that reacts to standardized commands sent by the clients and reports back the status. Several devices require a middle layer which translates the general commands into device specific actions. In most cases, the functionality of this layer focuses on sequencing and synchronizing commands transmitted directly to device channels, formatting and compression of data and low level error handling. The FED clients are implemented in PVSS. The FED concept provides a hardware abstraction layer, which allows for communication with the different FERO architectures in a unified way.

In the past few years, the FED concept has been used for other non-standard devices and subsystems in ALICE. Despite the obtained unified operation, FED remains one of the major challenges in ALICE DCS due to the complex functionality of its low-level layers.

OUTLOOK FOR SYSTEM EVOLUTION

During the long LHC technical stop planned for 2013, the DCS will profit from the gained experience and the system will be modernized.

As a first step, the standards are already being reviewed and new solutions will be proposed and made available to the detectors. All exceptions accumulated during the past years of operation will be removed and the system uniformity will be restored.

The plan is also to update all software components and to deploy the latest operating systems and tools. This is very delicate process as many commercial components do not follow the same evolution. Validation of the new systems has therefore already started in order to give sufficient time for finding satisfactory solutions.

The design of the detector hardware, including the computer interfaces, was launched more than 10 years ago. Stable operation of the experiment does not allow for regular upgrades. As a consequence, the DCS needs to operate a large fraction of obsolete hardware which in turn triggers a necessity to maintain a stock of spares. In some cases – like PCI interfaces, it is not possible to support the existing solution long-term. Therefore, new standards are being tested and prepared for deployment during the long technical stop.

CONCLUSIONS

The ALICE DCS project was launched 10 years ago. The construction, testing and operation phase of the system proved that the original assumptions and design principles were correct and efficient. The hierarchical approach and deployment of standards and common solutions contributed to the successful DCS operation.

The experience with the production system revealed many additional aspects that were not originally anticipated. One of the most visible examples is the front-end electronics with all its complexity and diversity. The DCS had to adopt already developed systems and build abstraction layers to allow for smooth integration and operation.

Interaction with systems external to DCS, increased data flow, and synchronization issues led to a need to create new unforeseen tools and procedures.

Comparing the original plans with the existing system it can be concluded that the system became more complex than anticipated, but the design principles have been well validated by operational experience. The main goal – to have a stable, reliable and safe system – has been reached. So, we got what we aimed for ten years ago.

RE-ENGINEERING OF THE SPRING-8 RADIATION MONITOR DATA ACQUISITION SYSTEM

T. Masuda#, M. Ishii, K. Kawata, T. Matsushita, C. Saji, JASRI/SPring-8, Hyogo, Japan

Abstract

We have re-engineered the data acquisition system for SPring-8 radiation monitors. The previous system consisted of dedicated digital indicator/controller modules (DICMs) optically linked with radiation monitors, embedded PCs for data acquisition, and programmable logic controllers (PLCs) for 1-h integrated dose surveillance. The embedded PCs periodically collected radiation data from the DICMs through GPIB. The DICMs and the dose surveillance PLCs were interfaced with an accelerator radiation safety interlock system (ARSIS). These components were dedicated, black-boxed, and complicated for operations. The GPIB interface was legacy and not reliable enough for the critical system. Therefore, we re-engineered the previous system by adopting PLCs and FL-net. Local PLCs were deployed as substitutes for all the previous embedded PC-based components. Another PLC was installed to enable centralized management of all 81 monitors. All the new PLCs and a VME computer for data acquisition were connected via FL-net networks. In this paper, the new system and a method for upgrading this system within the short shutdown interval of the accelerator operations are described.

INTRODUCTION

SPring-8 is the electron beam accelerator complex used in experiments that require a high-brilliance synchrotron radiation beam. According to the act on prevention of radiation disease, the radiation dose from the accelerator complex must be controlled. Therefore, it is mandatory for a radiation monitoring system to always monitor the radiation dose, and when the dose exceeds the alert level, it should immediately interrupt the accelerator operation through an accelerator radiation safety interlock system (ARSIS) [1]. A total of 81 radiation monitors including the 17 monitors used for the interlock system are deployed around the SPring-8 site.

The radiation monitoring system was very complicated because of the patched update one after another. It comprised two independent systems, namely a main system for 79 radiation monitors and a subsystem for two monitoring posts. The main system consisted of radiation monitors, optical transmitters with local controllers, optical converters to electrical serial communications, 79 digital indicator/controller modules (DICMs), 11 embedded PCs with GPIB and Ethernet interfaces, 3 programmable logic controllers (PLCs) to evaluate the 1-h integrated dose for the 17 interlock radiation monitors, and 3 PLCs for the interface with ARSIS. All the DICMs were mounted on eleven 19-inch racks scattered around the site. The DICMs monitored the radiation data on the basis of the three established alert/warning thresholds (low, high, and high-high). It also checked the normal operation of the radiation monitors and communication devices.

*masuda@spring8.or.jp

Although the radiation data were very important for the accelerator operation, these data could not be accessed in the same manner as other data related to the accelerator, because the radiation monitoring system was developed as the completely independent system with the accelerator control system. Therefore, we built the data acquisition system three years ago for the radiation monitors by installing a server PC that communicated with all the embedded PCs. We used the data acquisition software of message and database oriented control architecture (MADOCA) [2] to accumulate all the radiation data into the common database used for the accelerator control system. Figure 1 shows the previous data acquisition system used for the SPring-8 radiation monitors.

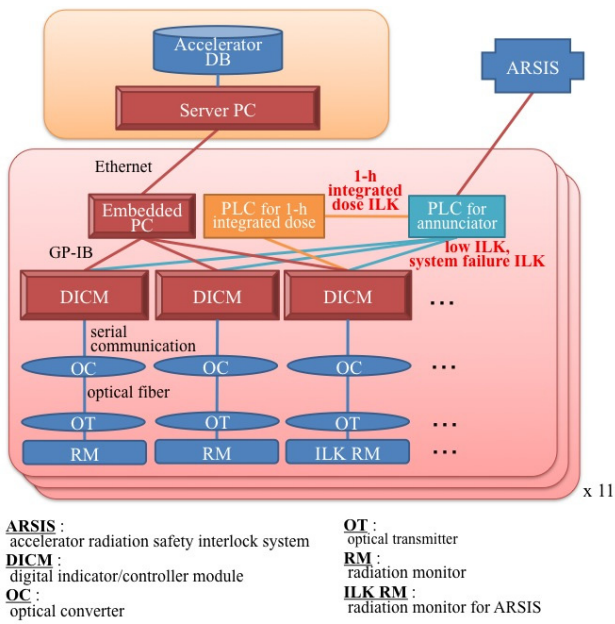

Figure 1: Previous data acquisition system for the SPring-8 radiation monitors.

PROBLEMS WITH PREVIOUS SYSTEM

Development of the previous data acquisition system enabled the accelerator operators to browse and investigate the status of the radiation monitors in the same manner as that used for the accelerators' data. The previous system, however, had the following problems.

- The GPIB interface employed in the previous system was not reliable enough for continuous use.
- The software that periodically collected data from the radiation monitors via the GPIB in the embedded

PCs was black-boxed. It was not practical to radically modify the software. However, it was necessary to improve the software because there was no way of knowing whether or not the software was running normally.

- Accelerator operators were unable to access the 1 h-integrated dose data used for radiation control, because these data were integrated by PLCs using the analogue outputs of the DICMS. These PLCs were patched at a later date and were independent from the data acquisition system.

Therefore, we radically re-engineered the data acquisition system to solve these problems.

NEW SYSTEM DESIGN

The new data acquisition system was designed in the following manner.

- We deployed local PLCs instead of the DICMs, embedded PCs, and GPIB interface to enhance the system reliability and to reduce the number of black boxes as much as possible.
- We integrated the independent subsystem for two monitoring posts into the new system.
- We assigned the integration function for dose data to the newly installed local PLCs.
- All the local PLCs were equipped with touch panels to enable user-friendly operations.
- We introduced a central PLC to centrally manage all the monitors near the central control room.
- We adopted FL-net [3], which was widely used in the SPring-8 and SPring-8 angstrom compact free electron laser (SACLA) control system, to connect all the local PLCs and the central PLC.

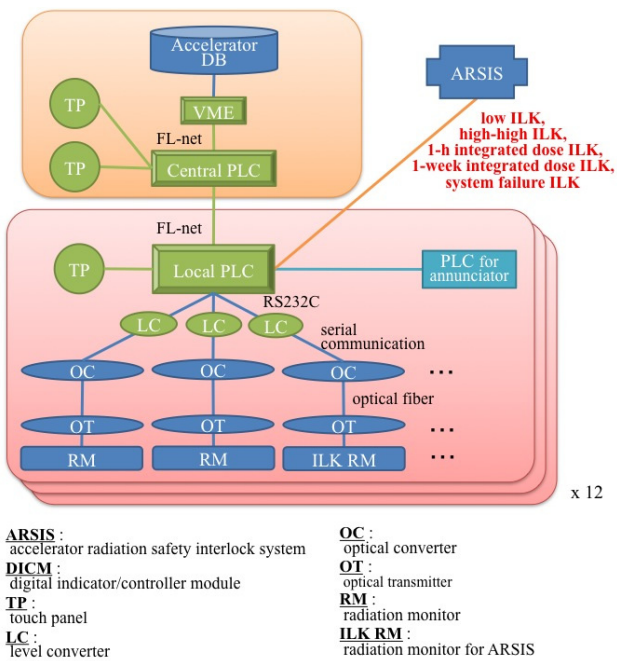

Figure 2: Schematic diagram of the new data acquisition system for the SPring-8 radiation monitors.

- The central PLC was provided with an additional FL-net module to enable connection with a VME computer that was linked to the accelerator control network. The VME computer collects all radiation data and incorporates them into the common database of the accelerator control system using the MADOCA framework.
- All the critical processes concerned with ARSIS are carried out by the local PLCs. The central PLC is not used for ARSIS.
- The interlock signals originating from the local PLC are sent directly to ARSIS. The existing PLCs are not used for interlock processing to simplify the system.

The new data acquisition system is shown in Figure 2. The new system consists of 12 local PLCs with touch panels, 1 central PLC with 2 touch panels, 2 FL-net networks, and 1 VME computer.

Local PLC Units

We simply replaced one embedded PC and its corresponding DICMs with a new local PLC because of the time and space limitations for our upgrade. We adopted a MELSEC Q-series controller [4], equipped with a 12-inch V812iS touch panel with 800 × 600 resolution as the local PLC [5]. Figure 3 shows the local PLC unit mounted on the existing 19-inch rack.

The local PLC uses an RS-232C module to interface with the optical converters that use serial communication with a different signal level than the local PLC. The local PLC is equipped with several two-channel RS-232C modules and communicates with the optical converter through a newly prepared external circuit that converts the signal level to that of the optical converter.

We give integration and evaluation roles for the 1-h integrated dose and the newly introduced 1-week integrated dose to the local PLC instead of the existing PLCs. The local PLC outputs interlock signals to ARSIS when the following conditions are satisfied.

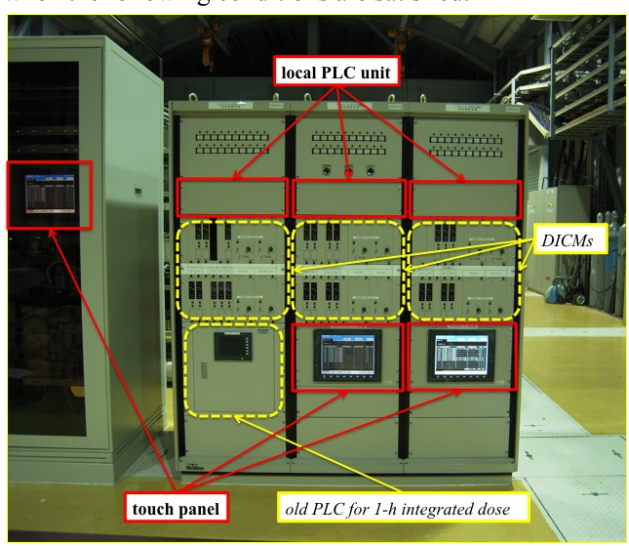

Figure 3: Photograph of the local PLC unit.

- The radiation value is lower than the low threshold level during the 3 s when the interlock by low alert is enabled.
- The radiation value is higher than the high-high threshold level during the 3 s when the interlock by high-high alert is enabled.
- The 1-h integrated dose becomes larger than its threshold level when the interlock by 1-h integrated dose is enabled.
- The 1-week integrated dose becomes larger than its threshold level when the interlock by 1-week integrated dose is enabled.
- The radiation monitor or the communication device encounters an error when the interlock by system failure is enabled.

These thresholds can be changed using the local touch panels. Alert histories encountered on the local PLC can be viewed on the touch panel.

We have incorporated the data-logging function into the local PLC unit. An 8-GB compact flash drive installed into the local touch panel stores sampling data for 7 days. This function ensures continuous data logging even when data acquisition into the accelerator database is stopped for some reasons.

Central PLC Unit

The new central PLC unit has been deployed in the radiation monitoring room near the central control room to enable centralized management of all the radiation monitors. The central PLC unit is equipped with two FL-net interface modules. One module communicates with the twelve local PLCs, while the other module communicates with the VME computer. We have also adopted the MELSEC Q-series PLC with two touch panels.

The central PLC unit simply oversees the entire system management; that is, it does not play critical roles related with ARSIS. The central PLC unit provides the following functions.

- Browse the current radiation data and status of all the radiation monitors.
- Browse 1-h and 1-week integrated dose data for the interlock monitors.
- Browse the alert histories occurring in all the radiation monitors.
- Change the alert/warning thresholds of low/high/high-high/1-h integrated dose/1-week integrated dose of all the radiation monitors.
- Enable/disable each interlock function of high-high/1-h integrated dose/1-week integrated dose.
- Attach/detach the radiation monitors to/from the surveillance system.
- Change the system times of all the PLC units.
- Change the common password to enable privileged accesses to the all the PLC units.

To enable the VME computer to collect the data, the central PLC copies almost all the data from the local PLC on the FL-net for the VME computers.

UPGRADE

We faced several difficulties during upgrade. The biggest problem was insufficient time for upgrade. Although the work had to be completed by 18th March 2011, it started after the SPring-8 operation was stopped in the end of February. Furthermore, we were not able to start the detailed designing work with the contractor until November 2010, even though we had already finished the ground design.

The restriction that the old devices such as the DICMs had to be kept in 19-inch racks made the work troublesome. On the other hand, this restriction enabled the old system to be restored immediately even when the new system did not work well. However, there was not enough space left to install the new system in the existing 19-inch racks.

In order to overcome these difficulties, we carried out the upgrade following a well-defined process.

- We prepared a ladder program and a level conversion circuit for the communication test held in the winter shutdown period of 3 weeks that was the unique opportunity for the test before the end of the February. The preparation of the ladder program and the level conversion circuit was carried out according to the specifications.
- During the winter shutdown, we investigated the communication protocols between the DICMs and the radiation monitors, and we tested the prepared program and circuit with the actual system.
- After the winter shutdown, we prioritized the design of touch panels because they made clear the necessary functions of both local and central PLCs. We discussed the design with the safety office, the main user of the new system.
- The PLC units were designed simultaneously. The units had to be as compact as possible because of shortage of installation space in the 19-inch racks. All the level conversion circuits and terminal blocks for external signals were put together in the units.

Consequently, we successfully upgraded the system before the deadline. The remaining minor troubles were fixed during a short shutdown period from 28th April 2011 to 9th May 2011.

SUMMARY AND FUTURE PLAN

We have re-designed the data acquisition system for the SPring-8 radiation monitors. The new system is a PLC-based system and is simpler, more comprehensible, and is more reliable than to the previous system. The new system consists of 12 local PLCs and 1 central PLC. The introduction of the central PLC enables the centralized monitoring and management of all the radiation monitors. All the local and central PLCs are equipped with touch panels to facilitate ease in operation for the radiation monitors.

The new system has been employed in the practical use since the end of March 2011 and has been working well

without any issues after a minor problem was fixed in May 2011.

In August 2011, we succeeded in adding the same setup functions to the radiation monitors as those employed in the DICMs. These functions are mainly used for maintenance work during long shutdown intervals. The new system was successfully applied for the practical maintenance work, in August 2011. This proved that the new system was realistic enough for maintenance work. This will enable us to eliminate DICMs from the radiation monitoring system and rearrange the 19-inch racks to enhance maintainability by eliminating the dispensable devices.

STATUS, RECENT DEVELOPMENTS AND PERSPECTIVE OF TINE-POWERED VIDEO SYSTEM, RELEASE 3

Stefan Weisse, David Melkumyan (DESY, Zeuthen, Germany),

Philip Duval (DESY, Hamburg, Germany)

Abstract

Experience has shown that imaging software and hardware installations at accelerator facilities needs to be changed, adapted and updated on a semi-permanent basis. On this premise the component-based core architecture of Video System 3 was founded. In design and implementation, emphasis was, is, and will be put on flexibility, performance, low latency, modularity, interoperability, use of open source, ease of use as well as reuse, good documentation and multi-platform capability. In the past year, a milestone was reached as Video System 3 entered production-level at PITZ, Hasylab and PETRA III. Since then, the development path has been more strongly influenced by production-level experience and customer feedback. In this contribution, we describe the current status, layout, recent developments and perspective of the Video System. Focus will be put on integration of recording and playback of video sequences to Archive/DAQ, a standalone installation of the Video System on a notebook as well as experiences running on Windows 7-64bit. In addition, new client-side multi-platform GUI/application developments using Java are about to hit the surface. Last but not least it must be mentioned that although the implementation of Release 3 is integrated into the TINE control system [1], it is modular enough so that integration into other control systems can be considered.

OVERVIEW

The Video System explained further on originates at the Photo Injector Test Facility Zeuthen (PITZ). This is a test facility at DESY for research and development on laser driven electron sources for Free Electron Lasers (FEL) and linear colliders [2, 3]. A vital diagnostic used to observe and measure the electron beam is the Video System at PITZ. As the facility has been constantly upgraded over the last decade, the video system was enlarged and easily outgrew its initial specifications.

Based on the acceptance and extension at PITZ, the Video System has been exported over the years to PETRA at DESY and its pre-accelerators [4], EMBL Hamburg and PETRA III user beamlines at Hasylab [5], where the requirements for a Video System at these facilities admittedly were substantially different compared to PITZ. In addition, remarkably small installations have been realised as well, such as providing video stream of a high-voltage power supply display installed at a remote location.

During the years of evolvement, the Video System underwent constant extension and upgrading. Naturally, it quickly outgrew its original specifications which made any further extension or upgrading cumbersome. A redesign towards a component-based approach, where individual elements are easy to change, adapt, upgrade etc., has been completed [6]. Due to this well-defined and flexible approach, a lifetime of more than a decade is expected. This fits to lifetimes of existing and coming accelerators and other experiments close to basic physics research.

Some of the many new available features include:

- flexible image source interface, focused to AVT Prosilica and JAI Gigabit Ethernet cameras, other interfaces available, new interfaces easy to implement
- raw grayscale images up to 16 bits per pixel
- raw colour images (RGB24)
- integrated JPEG compression/decompression (grey and colour)
- focused but not limited to Gigabit Ethernet, GigE Vision, gen<i>cam cameras
- loss-less acquisition, transport and analysis
- high-bandwidth (tens of megabytes per second)
- low latency (tens of milliseconds range)
- well-defined image data type, integrated in TINE data transport
- up to 30 frames per second are easily achievable
- lightweight shared memory interconnection for video stream handover across video system components
- multicasting of video images via TINE
- interface to Matlab
- well-defined, documented and flexible XML configuration files
- integrated native Java-based universal slow control solution (puts up a pretty good show on its own)
- native components (MS Windows) are based on platform-independent source code easy to port
- client-side is native Java code

It needs to be mentioned here that the system has been kept very flexible beneath the surface. Use-cases that require more frames per second, integration of other cameras, higher resolutions or bit-depths than mentioned above can certainly be considered. If there is demand, a test installation to verify special requirements should be easy to provide.

STATUS

At the moment, the current release of the Video System has been installed and is used in production level at PITZ, Petra III (pre-accelerators, diagnostic beamline, synchrotron radiation interferometer, user-beamlines of Hasylab, …) and since April 2011 at the Relativistic Electron Gun for Atomic Exploration (REGAE) accelerator. In the past, the European Molecular Biology Laboratory (EMBL)

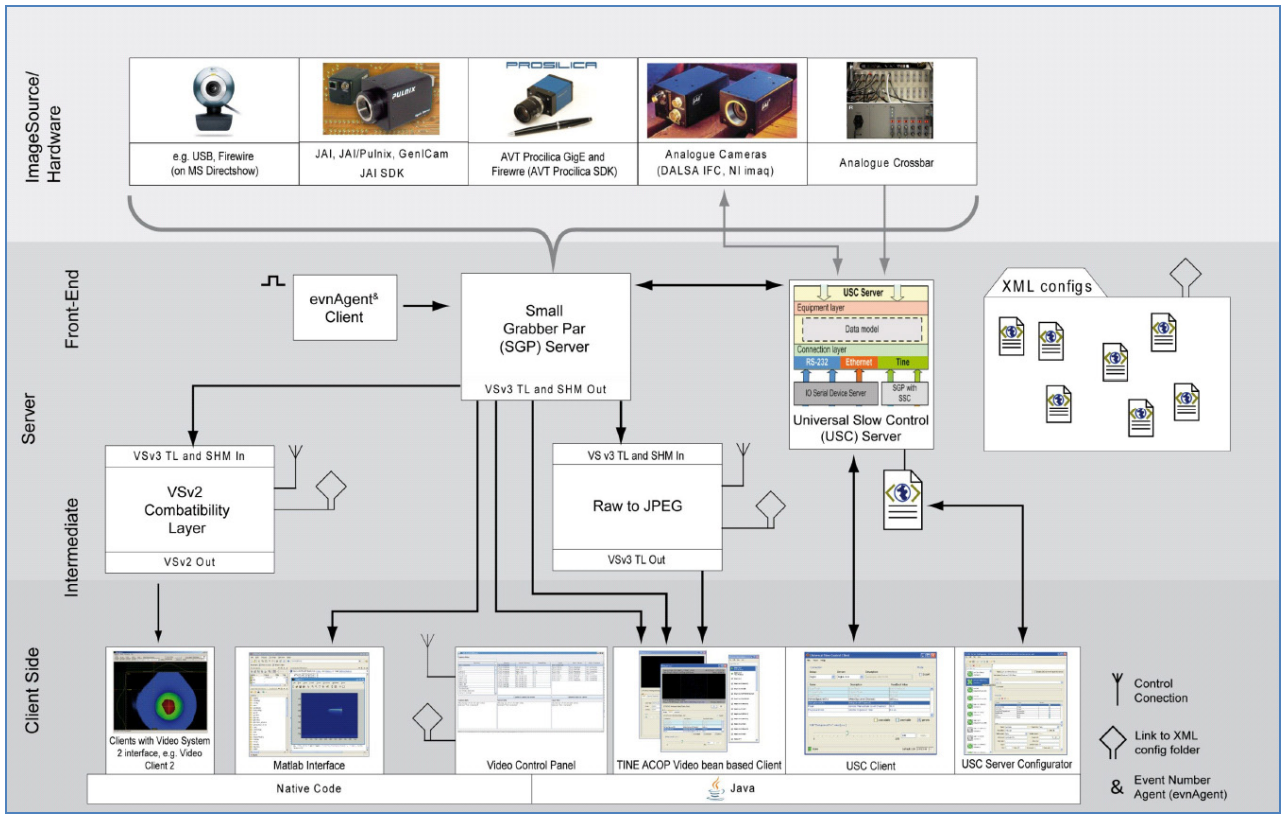

Figure 1: Simplified layout of VSv3 components and their interaction.

Hamburg has used the Video System 2 (VSv2) [7] for sample changer monitoring and control to great satisfaction. As step by step EMBL user beam-lines are commissioned at PETRA III, VSv3 components are foreseen to be installed there. The simplified layout of the VSv3 components can be seen in Fig 1.

PITZ

In the past year, PITZ has finished its current gun conditioning cycle and is currently experiencing a hardware upgrade of the accelerator. The video system is set up in a heterogeneous way. Various types of cameras (analogue JAI, digital JAI, JAI/Pulnix and Prosilica GigE) coexist next to each other, each one where its characteristic fits best. All cameras are snapshot-triggered by central timing (mainly 10 Hz) and are in general delivering frames at this rate. Legacy VSv2 technology is still used on the client side, while back-end/infrastructure has been fully upgraded to the current release level. Matlab interfaces keep growing as to satisfy demands of physicists.

PETRA III

Upgrading VSv2 legacy installations to VSv3 was one of the main tasks performed during the past year. Now as everything is VSv3-based, a Raw to JPEG component has been introduced almost anywhere to reduce video transmission usage on the controls network. For many raw video feeds to the controls network there is now an additional JPEG feed which provides the same stream, only JPEG-compressed (using compression ratios of about 1:10 to 1:50). In addition, a synchrotron radiation interferometer has been commissioned and the diagnostics beam-line has been upgraded to JAI BM141 camera. Matlab interfaces have been introduced and extended in the last months. The synchrotron radiation interferometer measurement applet is based on this.

PETRA III client-side at Hasylab

In the past year, the already existing pure VSv3 installation at client-side of Petra III has constantly been extended. Currently there are various types of Prosilica GigE cameras (about 90 pieces) running in parallel at slow non-triggered update rates. As many server processes as cameras, distributed across three server hosts running Windows XP SP3, provide control of the cameras and a standard VSv3 video interface via TINE to the control system.

REGAE

A new linear accelerator is currently being set-up at DESY. For the diagnostics of the electron bunches at REGAE [8], an installation of the Video System has been done. For initial operation phase, three cameras of JAI BM 141 have been installed at the accelerator. One server

PC is used for control and readout of these cameras. First beam images have been taken.

RECENT DEVELOPMENTS

Transition from former technology (Video System 2) to the state-of-the-art Video System is still ongoing. At PITZ, step by step important legacy client applications such as the PITZ Video Control Panel and Video Client 2 are going to be exchanged to new native Java-based applications.

Foreseen as a successor to Video Client 2, the Java Video Client application is a component-based client-side application, which encapsulates the functionality needed to provide a single high-level user interface to display video streams including image analysis (ACOP Video component) and controlling camera settings (USC component) as well as providing a consistent view of all available cameras across a VSv3 installation.

Matlab Interface

In 2010, the first interface from VSv3 to Matlab was created and used enthusiastically by the physicists, who immediately began requesting more features. Thus, as time passed, the Matlab interface grew. Using the multi-platform-available MEX-functions, one is able to get a single video image from the server, load in proprietary Video System 2 images and image sequences from file and is able to grab a sequence of video images from server. The MEX functions have been carefully designed for cross-platform compatibility and have been made available on a wide range of Matlab versions (v7 to 2011a) on Win 32, Linux and Win 64. Our aim here is again to provide the user with a wide range of tools, so that he can use his favourite working environment. As our development cycle regarding the Matlab interfaces is maturing and the physicists are providing feedback, more external functions can be expected to be implemented.

Video System on a Notebook

In the last year demand rose for having a standalone Video System installation on a notebook, where one is able to use the benefits of a known on-site video system installation for both on- and off-site use. This allows temporary local installations at any laboratory, where hands-on experience can be gained by sites interested in joining the video system collaboration For example, the Cherenkov Telescope Array (CTA) test facility to be built in Berlin is interested in having such a local installation on a notebook for first hands-on outdoor measurements on and at the dish.

Some local installations on notebooks have been used, primarily at REGAE and CTA. Each has in common a server as well as client applications which can be run on the notebook locally (see Fig 2). A local Ethernet interface is used to connect a GigE camera. As a bonus, the software was set up in such way that if a network connection to a site-network exists, video system components located therein can be accessed if necessary. As Windows XP SP3 Professional workstation-type machines are used for video server environment on site, installation on Windows XP notebook was fairly straightforward. In contrast, a CTA notebook was already equipped with Windows 7 / 64 bit. Although this was new territory, the installation and usage of native Windows (Win32) software under 7/64 was easier than expected. However, significant attention needed to be paid to the Start Menu and shortcuts, WOW64 and Networking Firewall.

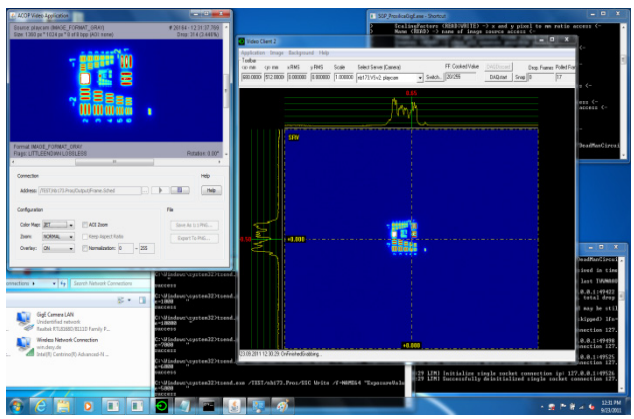

Figure 2: Video System 3 and 2 (client-side) running in parallel on a notebook using Windows 7/64 bit.

Attaching Event Numbers to Video Frames

Up to now, a neglected part of the Video System has been the integration to Archive/DAQ systems. As an important step in this direction, attaching event numbers to newly acquired video frames has been implemented (see Fig 3). An important criterion for exact correlation of a beam image at a facility using triggered acquisition like PITZ is a so-called general event number. Each shot of the accelerator gets a unique event number assigned, which in general is transported to individual controls subsystems and experiment's properties are tagged with that event number. Afterwards, the data is transferred to the DAQ system. Later on, the physicist will require the event number to collect data that belong to an individual shot of the accelerator. A lightweight solution has been developed and installed at PITZ, which makes use of multicasting the event number from a central timing source throughout the controls network. On the server level, the SGP component with the help of an 'event number Agent' component (evnAgent), tags each freshly acquired video image with the event number.

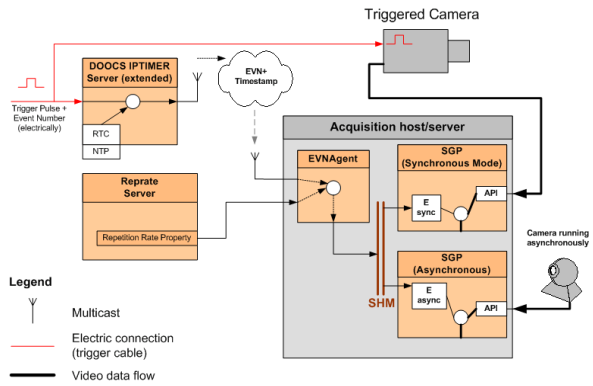

Figure 3: Distribution of Event Number.

The integration of image data into the TINE event archive system is well underway. Generic tools such as the TINE Event Archive Viewer are now able to store and retrieve video sequences, either frame-by-frame or movie style. Streaming these stored image data into specific dedicated video analysis tools will provide the physicist with the ultimate comfort in rapid browsing and searching of stored events coupled with the precision analysis found in the live video tools.

Online Documentation

The Video System website (an important element of the TINE website) has likewise matured over the past year [9]. General information, technical aspects, reference documentation, conference submissions and contact persons are now available world-wide. Readers are kindly asked to provide feedback.

PERSPECTIVE

At REGAE, integration of Andor iXon scientific detector into the Video System is currently being considered. By using a plain C-API which Andor provides to interface with the detector, a proof-of-concept application has been successfully implemented. A SGP component may be introduced later on.

A big point for PITZ in the coming year is the removal of Video System 2 support on the client side. Necessary for this is the availability of comparable tools using Video System 3 interface. Most tools will follow the paradigm of using native Java on the client side, to provide freedom of client platform for the operator. Also, effort will be spent to move legacy native measuring clients with VSv2 interface to the new release level. The Emittance Measurement Wizard (EMWiz) and Momentum and Momentum Analysis tool (MAMA) are two central applications there.

Furthermore, investigations and implementations of native releases of some Video System components on Windows 7/64 bit und possibly Linux platform, implementation of Image Source Profiles, creation and extensions of client VSv3 APIs, fine tuning of server-side to make it easier to set-up, maintain and use, are certainly worth mentioning.

ACKNOWLEDGEMENTS

We would like to thank Kathrin Pflaum, Markus Degenhardt and Peter Walter at Hasylab for administration and growth of the Video System at their site, Gero Kube for substantial interest and feedback, providing of sample cameras and beta-testing and Hossein Delsim-Hashemi for pushing things forward at Regae site.

SOFTWARE RENOVATION OF THE CERN EXPERIMENTAL AREAS

J. Fullerton, L. Jensen, J. Spanggaard, CERN, Geneva, Switzerland

Abstract

The Experimental Areas at CERN's Antiproton Decelerator (AD), Proton Synchrotron (PS) and Super Proton Synchrotron (SPS) have recently undergone a wide-spread electronics and software consolidation based on modern techniques. This paper will describe the scale of the software renovation and how the issues were overcome in order to ensure a complete integration into their respective control systems.

INTRODUCTION

The CERN Experimental Areas include 7km of beam lines (Figure 1) with just over 400 detectors used by about 2400 experimental physicist and covering three different locations: the North Area (SPS), the East Area (PS) and the Antiproton Decelerator (AD). This instrumentation allows the observation of particle beams via 7 families of detectors (Table 1). The main requirement for the consolidation was to reduce down-time for physics and to reduce the required man-power for CERN to maintain and operate the beam instrumentation in these lines.

Table 1: Detector Families

Detector family	Number in the Areas
Scintillation Counters [1]	50
Filament Scintillators	65
Cerenkov counters	8
Delay wire chambers[2]	36
Analog wire chambers	65
Gas electron multipliers[3,4]	4
Scaler-counters.	190

HARDWARE SOLUTION

Until recently the hardware to control the beam instrumentation was implemented with CAMAC and NIM modules that had become obsolete and were generating frequent faults. In order to make the hardware more reliable and simpler to troubleshoot, new equipment-oriented hardware was developed in VME [1]. About 30 such VME crates are now controlling all the beam instrumentation equipment in CERN's experimental areas.

Figure 1: A beam line in the North Experimental Area.

SOFTWARE SOLUTION

The software structure chosen to accompany this hardware renovation is based on a classic three tier structure (Figure 2). The operational user GUI connects to the **C**ERN **E**xperimental area **S**oftw**A**re **R**enovation (CESAR) [5] J2EE server from where the Controls Middle Ware (CMW) [6] grants access to the Front End Software Architecture (FESA) server [7] and configuration databases.

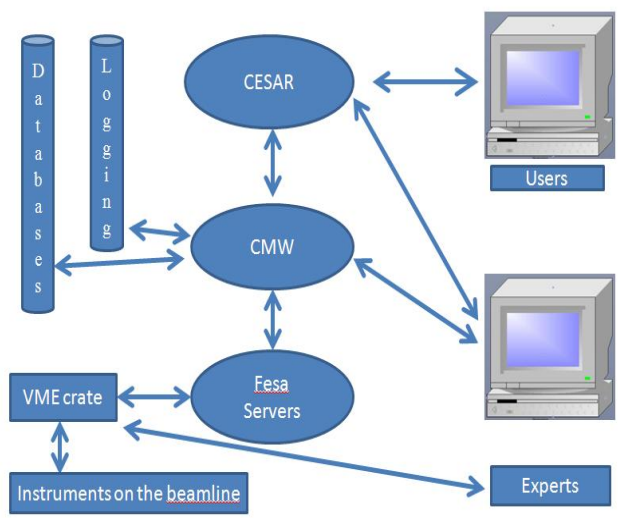

Figure 2: The three tier Software structure used.

CESAR

This tier allows a high level of abstraction. From the controls point of view the VME crates access detectors on many different beam lines whereas the end-user only wants to see equipment on the beam line on which he/she is working. This extra level of abstraction enables all the access rights, beam line configuration and display code to be separated from the hardware server code.

CMW

An object oriented device model implementation middleware with extensions to cover accelerator control created for the demands of LHC.

FESA

An environment for developing, deploying and maintaining front-end software. This enforces CERN accelerator control standards.

The equipment specialist can access hardware on four levels:

- CESAR GUI's where they have the same functionality as the users, which often allows simple misunderstandings to be ironed out.
- Expert GUI's (Figure 3) providing extra, potentially dangerous functionality, where processes such as pressure scans can be carried out. A separate expert GUI shows the status of all equipment of a single type (shown in Figure 4), which is useful as the equipment specialist often tests by instrument type and not by beam-line.
- FESA navigator which is a data driven GUI program for setting and getting all parameters defined in the front-end FESA class.
- Locally run programs on the VME front-end with no complex communications software involved.

These separate possibilities are important as they allow each level of the structure to be tested separately in case of doubts whether an issue is related to hardware or a software tier.

All computers, VME crates and the various servers running on them are constantly monitored by the CERN Controls Group "DIAMON" tool, a universal tool for diagnostics on the controls infrastructure across all CERN accelerators.

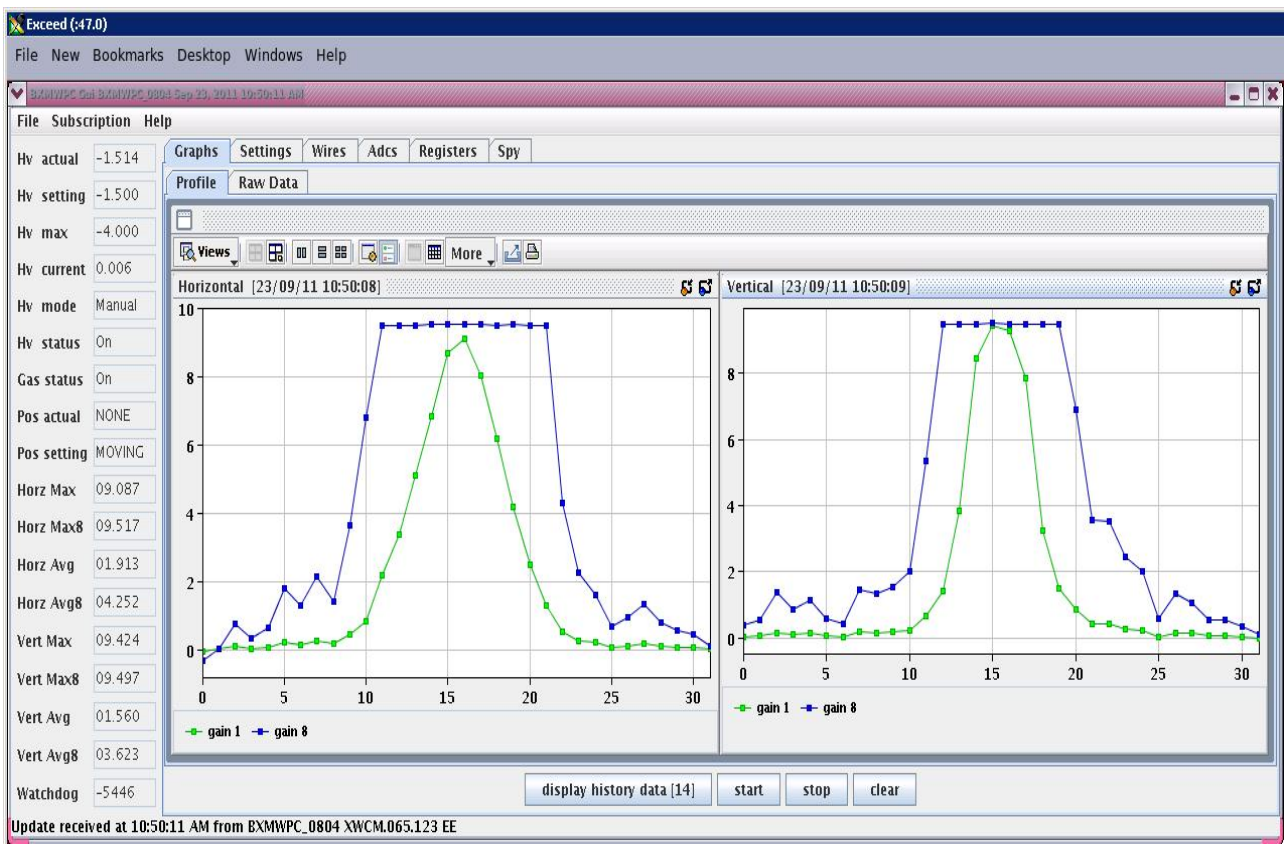

Figure 3: Example of an expert GUI, this one is for the control of an Analog wire chamber.

Figure 4: A display of all the Cerenkov counters of the North Area.

STATUS

FESA Servers and Expert GUI`s have been developed for all new equipment-oriented hardware modules and we are now in the process of introducing new detector families, requiring similar solutions. In parallel existing hardware modules are being used to control new instrument-types with only minor changes to the servers. An example of this is for the East Area target telescopes that will benefit from the existing VME module and server of the Scintillation Counter. The target telescope is an intensity measuring device based on scintillation that observes the particle production through a 5 meter long pipe perpendicular to the beam axis.

VME front-end crate controllers are currently changing from LynxOS to Linux. This move was in parts caused by modern software being memory hungry. The increase in speed of the new controllers has made the need for a specific real-time operating system an unnecessary overhead. The switch of operating system and controller card has used more manpower than expected due to the requirements/exploitation of current standards e.g. C to ANSI C and missing features in the new compilers which were used unknowingly in our old code.

CONCLUSION

As a result of this hardware and software renovation CERN's Beam Instrumentation Group has been able to support more experimental users, with fewer CERN staff dedicated to these areas. The instrumentation of the experimental areas is now based on modern, maintainable software tools and on the hardware side the new equipment-oriented approach has increased the reliability of the electronics. Both of these consolidations have made the overall maintenance load significantly smaller. From a user point of view the control system has changed from a command line to a more intuitive GUI based interface that provides better displays. A further side effect of using CERN standard software solutions has been to enable other software experts to remedy issues where formerly only the author of the code had the needed knowhow.

A BEAM PROFILER AND EMITTANCE METER FOR THE SPES PROJECT AT INFN-LNL

G. Bassato, A. Andrighetto, N. Conforto, M. Giacchini, J. A.Montano, M. Poggi, J.A. Vásquez
INFN-LNL, Legnaro (PD), Italy

Abstract

New beam diagnostics tools have been developed for the SPES [1] project in the perspective of reusing them to upgrade the system currently in operation at LNL in the superconducting Linac ALPI.

The goal is providing the new R.I.B. facility, that will use ALPI as re-accelerator, with an homogenous set of tools and a common user interface to support beam transport over the future accelerators complex. This paper focuses on the realization of a new emittance meter and on design of control software that has been written using EPICS.

OVERVIEW

The Spes Project and the New Ion Source.

SPES is a new facility under construction at LNL whose aim is the production of radioactive nuclei beams that will be injected into the Linac ALPI. The production of unstable nuclei is accomplished by impinging a proton beam delivered by a commercial cyclotron (energy range 40-70 Mev) into a UCx target. The diagnostics on proton beam will be part of cyclotron delivery and will not be presented in this paper; instead, we shall discuss the diagnostics on secondary beam with particular emphasis on devices that have been realized to characterize the new ion source currently under test in the SPES Target laboratory.

The Beam Diagnostics at LNL

The Linac ALPI, together with its injector PIAVE, has about 80 QWR resonators in operation. Beam transport is carried out by observing its profile and measuring its current by means of 48 diagnostic boxes installed along the machine. Each diagnostic box contains a faraday cup and a couple of grids (horizontal and vertical), each one made of 40 wires. Current signals are converted to voltage by an analogue board closely installed on top of box, in order to minimize the noise induced by cables; the conversion factor is selectable by software and covers four decades. Grid signals are multiplexed and serialized before being transferred, over coaxial cables, to the data acquisition system. Serialization strongly simplifies the overall wiring: in fact, only one coaxial cable is required for a 40 wire grid The multiplexer is driven by a counter whose clock is generated by the ADC itself, to have the signal transmission synchronized with the conversion.

DEVICES FOR BEAM DIAGNOSTICS

Figure 1 shows the faraday cup designed for beam current measurement. Behind this device it is possible to notice the grid based profiler. The faraday cup is inserted or removed by means of a pneumatic actuator while the grids are moved by a stepper motor.

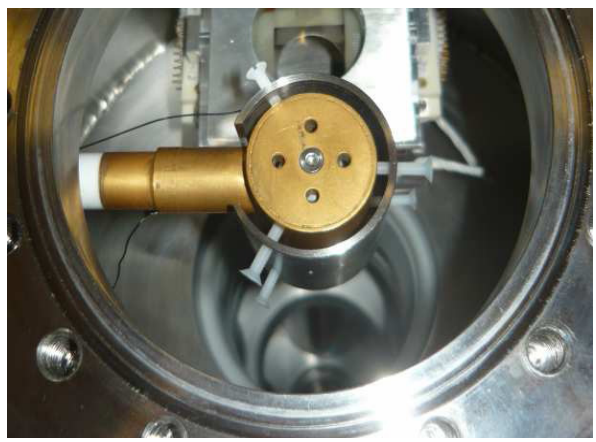

Figure 1: Faraday cup and beam profiler.

The Data Acquisition System

Signals from beam profilers and faraday cups are acquired by ADC cards installed in VME crates. The boards are XVME566 produced by XYCOM; they have 12 bit resolution and support a conversion rate of 100 KHz in streaming mode. Although higher performance products are available today we decided to continue using these modules, already installed in ALPI diagnostics system, because of the on board timer chip we use to generate the clock for the external multiplexer.

The stepper motor controllers are VME cards, designed in house, together with the associated power drivers; one controller manages 8 motors. The crate controller is an Emerson MVME3100, based on the PowerPC8540 processor and including 256MB RAM. The need of keeping the stream of serialized analogue signals coming from front-end electronics synchronized with the A/D conversion cycle imposes strict constraints in terms of response time. Because of this, the data acquisition software runs under the real time operating system Vxworks; the release currently in use is 6.8. The OS image has been tailored to support all features required to host an EPICS IOC using Wind River Workbench 3.2.

THE EMITTANCE METER

Measuring the emittance is of essential importance to evaluate the quality of beam produced by an ion source. The emittance meter designed for SPES [2] is based on two identical moveable slits (collimators) placed in front of a couple of horizontal and vertical grids. The slits have an aperture of 0.3 mm. and the distance from grids is 300 mm. By moving the collimators up and down (or right to left and acquiring data from vertical grids) it is possible to scan the whole beam area and evaluate the beam divergence by measuring the grid currents for different collimator's positions (the position is obtained by reading the output voltage of a linear encoder). Figure 2 illustrates the measurement scheme, while figure 3 shows the mechanical realization.

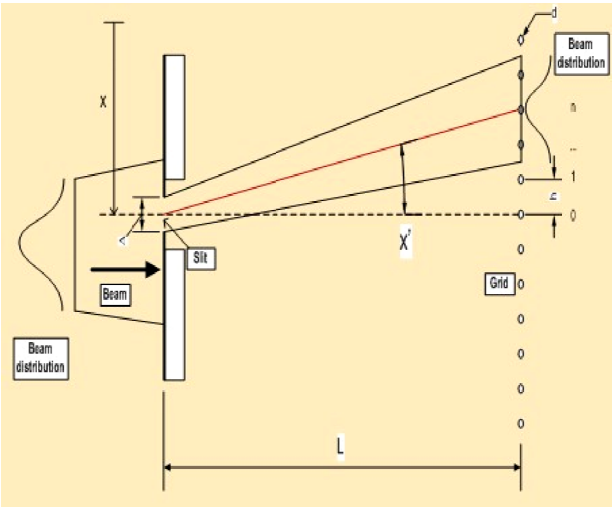

Figure 2: Scheme of emittance measurement.

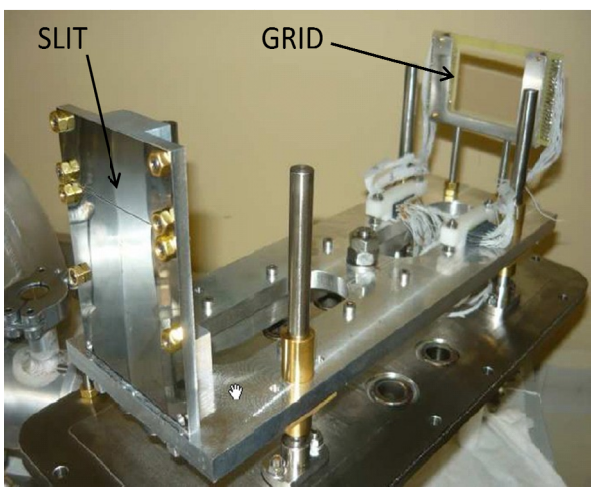

Figure 3: Instrument mechanics.

SOFTWARE DEVELOPMENT

One key point of SPES new diagnostics system – and in perspective of ALPI diagnostics renovation – is the complete remake of control software. The choice of software tools for beam diagnostics development was coherent with our previous decision of using EPICS as general framework for SPES controls. It will allow us to take advantage of a plenty of utilities developed by the user community other than the great performance of data distribution system offered by Channel Access architecture.

This choice also fits naturally with our plan of ALPI diagnostics upgrade: reusing the rather large amount of legacy hardware installed in ALPI will be not a problem since the XYCOM I/O boards and the operating system Vxworks are supported by EPICS since its origin. Some modifications were required on drivers available from the community but the overall cost of migration will be strongly reduced.

The Emittance Measurement Software

According to EPICS terminology, the VME processor implements an IOC (Input Output Controller) providing the following functions:

- acquisition of grid signals, an array of integers configured as an instance of waveform record
- acquisition of collimator position from the linear encoder
- control of stepper motors, to synchronize the collimator motion with the grid signals acquisition

The database loaded in the IOC is relatively simple and provides minimal processing on raw data, mainly using C-sub records. Most calculations are performed on the client side, which is a Linux PC also used to run the graphic interface. The program is written in C++; it reads through the Channel Access the grid current arrays acquired by subsequent samples together with collimator position and stores all information in its disk, until the number of programmed steps is reached. At the end of the acquisition cycle it calculates the emittance and displays the result.

Data used for emittance analysis can also be stored in an EPICS Archiver for off-line review. The Archiver version currently in use is configured to work in conjunction with mySQL running on a Linux server. Replacement by a higher performance installation based on Hypertable [3] is planned for the near future.

The user interface has been realized using CSS (Control System Studio)[4], the new Java based graphic environment that provides a seamless integration of EPICS records management and high level supervisor functions (i.e. alarm handling, interface to the Archiver, etc.). Figure 4 is a snapshot of user interface, showing in a unique panel the raw beam profile as collected by grids, the faraday cup current and the phase space distribution.

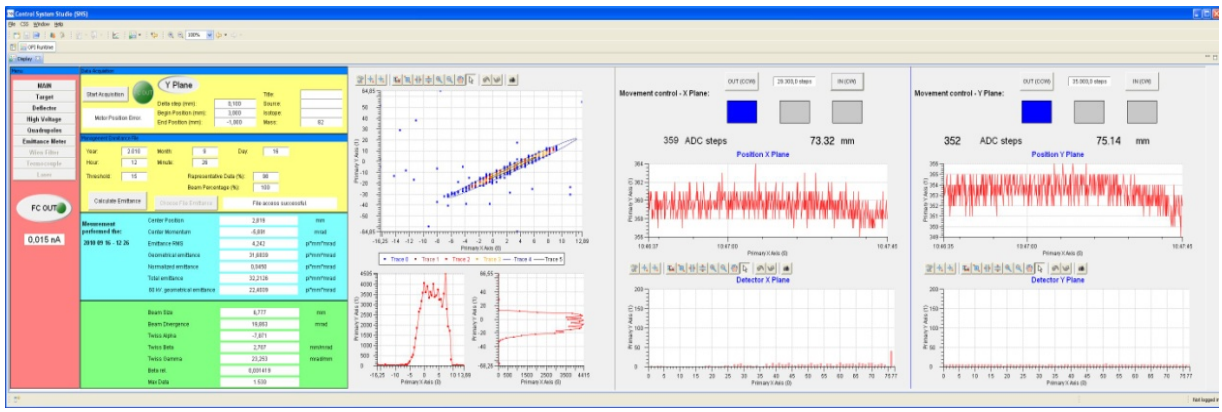

Figure 4: Snapshot of user interface based on CSS.

CONCLUSION

New diagnostics instruments were developed for SPES and are today in use in the Ion Source and Target Laboratory. The emittance meter has proven to be a very sensitive tool for the characterization of beams generated by the ion source prototype. The software migration to EPICS resulted in a significant increase of flexibility and performance of overall system. The software developed for SPES is being ported with minimal adaption to ALPI, in order to have an unique interface for the diagnostic systems of both facilities.

ACKNOWLEDGMENTS

We are grateful for their valuable help to M. Davidsaver (BNL) for rewriting the XYCOM566 driver and to D. Chabot (BNL) for developing the EPICS driver for our stepper motor controller.

UPGRADE OF THE NUCLOTRON EXTRACTED BEAM DIAGNOSTIC SUBSYSTEM.

Evgeny V. Gorbachev, Nicolay Lebedev, Nicolay Pilyar, Sergey Romanov, Tatyana Vladimirovna Rukoyatkina, Valery Volkov, JINR, Dubna, Russia

Abstract

The subsystem is intended for the Nuclotron extracted beam parameters measurements. Multiwire proportional chambers are used for transversal beam profiles measurements in four points of the beam transfer line. Gas amplification values are tuned by high voltage power supplies adjustments. The extracted beam intensity is measured by means of ionization chamber, variable gain current amplifier DDPCA-300 and voltage-to-frequency converter. The data is processed by industrial PC with National Instruments DAQ modules. The client-server distributed application written in LabView environment allows operators to control hardware and obtain measurement results over TCP/IP network.

THE PROBLEM STATEMENT

The project to construct a new accelerator complex NICA (Nuclotron-based Ion Collider fAcility) on the basis of the modernized existing Nuclotron accelerating facility is under active development at JINR. The modernization of the Nuclotron set the task to develop and put into operation a modern data acquisition and control systems. It is important to keep the existing functionality during accelerator runs while improving the graphic user interface, hardware control convenience, operation speed and stability. Fundamental principles of the control system organization are as follows:

- the client-server distributed model of data exchange,
- equipment operation reliability,
- applications operation stability in the long accelerator run.

The wide range of the acquisition electronics and software produced by National Instruments is quite satisfactory to solve the above tasks. A wide range of functions available in NI multifunction data acquisition modules allows to use only a few hardware modules to realize all necessary tasks. The software is based on .NET Framework, NI-DAQmx universal driver set and powerful graphics.

THE SUBSYSTEM STRUCTURE

The extracted beam diagnostics subsystem is intended to realize three features:

- to provide acquisition and remote observation of the extracted beam transversal profiles in four points of the transportation channel by means of proportional chambers;
- to measure the beam intensity using an ionization chamber;
- to control the gain of proportional chambers by means of their high voltage power supplies adjustment.

The equipment of the primary signal registration from the detectors is located on the beam transfer channel. The server computer and data acquisition modules are placed in the accelerator control room at about 400m distance from the detectors.

The subsystem structure is shown on Figure 1. The subsystem hardware has been made on the basis of Advantech industrial PC, multifunctional modules NI USB-6259 BNC, NI PCI-6703, NI SCB-68 produced by National Instruments [1], HV power supplies N1130-4 produced by WENZEL Elektronik and FEMTO variable gain sub femto ampere amplifier DDPCA-300 [3] with trans-impedance gain from 10^{+4} to 10^{+13} V/A. Additional custom voltage-to-frequency converter hardware to convert a voltage level signal from current amplifier to a frequency signal suitable for transfer of the data into the NI USB-6259 integration counter has been built.

HARDWARE OPERATION PRINCIPLES

Extracted beam intensity is calculated from measured ionization chamber current. The measured current is amplified by DDPCA-300 current amplifier and then converted to frequency signal by voltage-to-frequency converter. The signal is transferred over the long coaxial cable to 32-bit counter of USB-6259, synchronized by signal of extraction gate. The software allows to measure the cycle intensity and integral intensity of the extracted beam. The DDPCA-300 gain is controlled by 4 bit wide digital port of the USB-6259.

Beam transversal profiles are obtained by multiwire (32x32) proportional chambers. Signals from all 64 wires are multiplexed into a single analog line. Four ADC channels of USB-6259 are used to measure the analog signals from each proportional chamber. All ADCs are clocked by external clock signal formed by multiplexer thus allow deriving signals of each wire from the single line.

Proportional chambers gas amplification can be adjusted by means of high voltage power supplies which are controlled by NI PCI-6703 DACs. Adjusted high voltages are measured by four channels of USB-6259 ADCs.

SOFTWARE COMPLEX

The software complex consist of server application running on the server computer and few identical client applications which retrieve measurements data, visualize

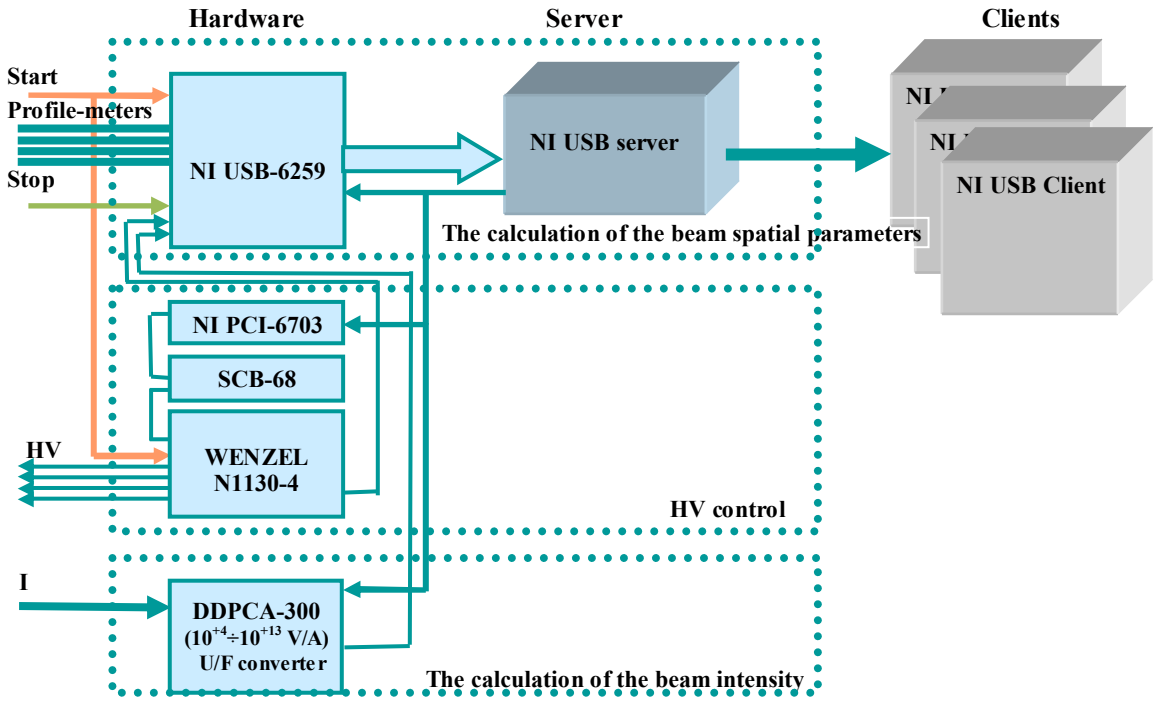

Figure 1: Extracted beam diagnostics subsystem structure.

it and allow an operator to control the hardware via TCP/IP network.

The server and clients applications are written in LabView development system for Windows. The data exchange between server and client applications are realized using LabView DataSocket server (DSS) running on the server computer. It realizes the application-layer DSTP transport protocol [2] operations and simplifies the task of organizing simultaneous interchange of data with many client applications connections in one cycle of the Server program. The publishing and subscribing of the data, located in the DSS URL-named memory, are preformed via a simple low-level interface of DataSocket Read and Write functions. These functions allow getting rid of the low-level TCP/IP programming and greatly simplify the server and client applications code. Besides, DataSocket server allows arranging data access permissions (write or read permissions) based on clients IP addresses. One of the client programs can be allowed to control the hardware, other are used only for the data visualization.

The server application consists of two continuously working cycles While and a Timed Loop cycle. In the first cycle, measurements of the beam spatial characteristics from proportional chambers and their power supplies voltages are acquired from NI USB-6259 module. The external ADC clock ensures correct timing of wires signals measurements. The second cycle reads-out the remote control DSS variables and makes a decision about hardware controls source - the server application or the controlling Client via DSS variables. The Timed Loop cycle is purposed to organize the start of the beam intensity measurements in a precisely given moment of time: 32-bit counter of the NI USB-6259 module counts the number of pulses of the voltage-frequency converter between the signals of the beginning and end of the slow extraction gate. At the moment when the counting is finished, the value on the counter is read-out, summed up with stored integral value and sent to DataSocket server together with time stamp and other measurements and calculations of the beam intensity. The integral intensity and the number of completed measurements cycles can be reset remotely.

The client application is intended for on-line and off-line processing of the measured data, its visualisation and remote hardware control. It consists of the two program loops: the Event structure and a continuous working cycle While.

The first cycle treats the events from all application controls such as buttons, sliders, drop lists and xcontrols. According to controls values, it sets the operation regime (online processing or visualisation of the offline data collected before), proportional chambers and current amplifier parameters, graphics scales and colors. The working cycle While connects to DataSocket server in online mode or open a file with previously stored data in offline mode and read the acquisition data. The obtained data is then processed to calculate instantaneous and integral beam profiles spatial statistical parameters such as beam position and dispersion taking into account the chosen distance between the wires in each profile-meter. 32 instantaneous beam profile shots for chosen point of the transfer line allowing to see the beam profile time progression and the integral beam profile are displayed in the «Profiles» tab for both transversal coordinates. The tab «Integral profiles» shows the integral profiles of all

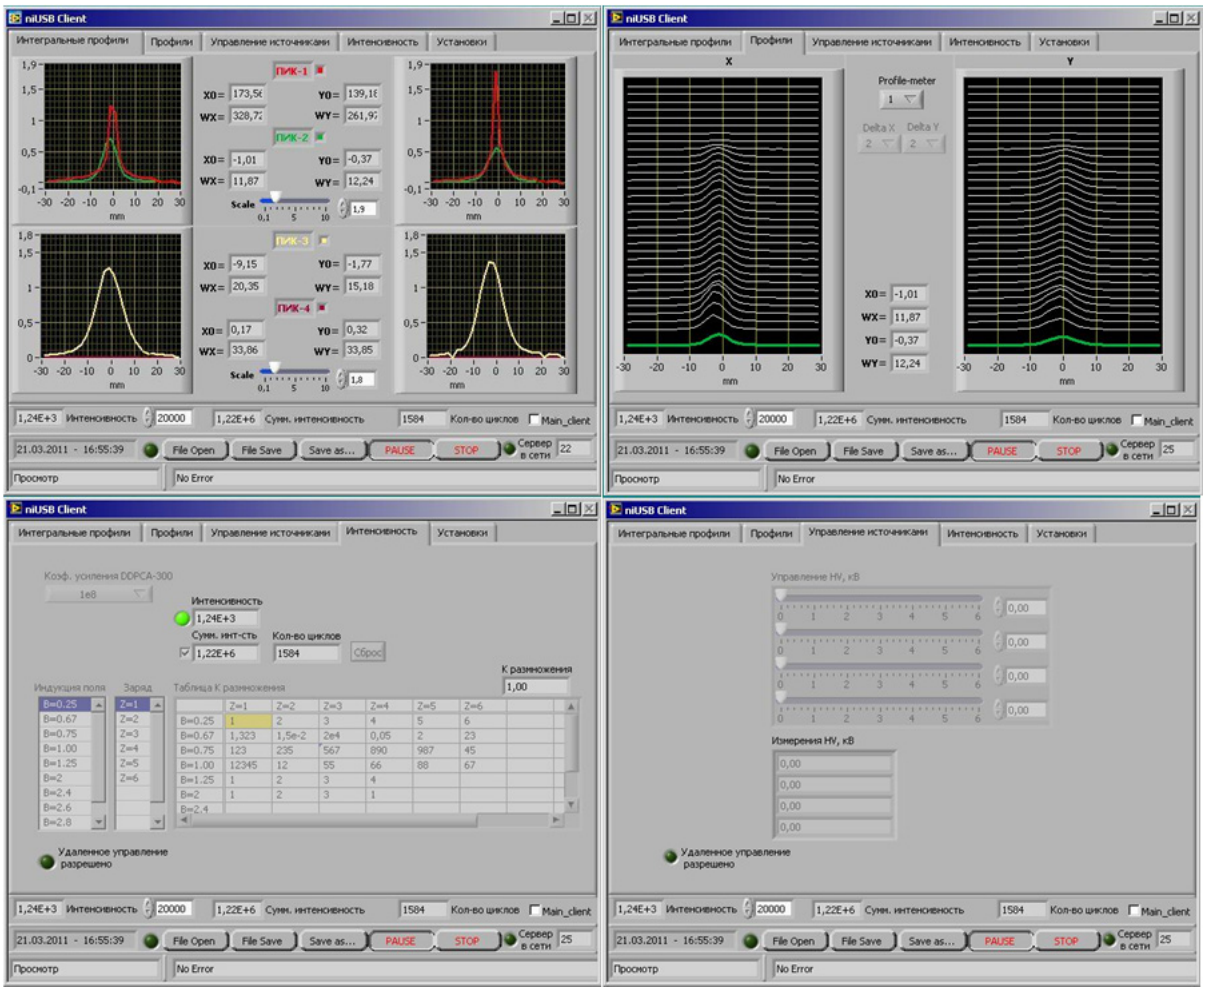

Figure 2: The beam tests of the subsystem to control extracted beam parameters (21.03.2011– 16:55). The Client window tabs: a) “Integral profiles”, b) “Profiles”, c) “Intensity”. d) “HV supply control”

profile-meters simultaneously. Intensity and high voltage measurements are visualised as well on corresponding application tabs.

The client software allows operator to control remote hardware such as current amplifier and proportional chambers high voltage power supplies if it is allowed by server. Otherwise the corresponding controls are disabled.

EXTRACTED BEAM DIAGNOSTIC SUBSYSTEM BEAM TESTS

The beam diagnostics subsystem was tested on the extracted beam during March 2011 Nuclotron run. Figure 2 shows window tabs of the client application. The “Integral profiles” tab illustrates integral transversal beam profiles while “Profiles” tab shows 32 momentary profiles shots from the selected multiwire detector in both X and Y coordinates. The “Intensity” tab shows extracted cycle intensity and integral intensity over 1584 cycles. Since the screen tab with the integral profile values must be watched permanently, the values of the intensities are given also below all the screen tabs. The last tab “HV supply control” contains HV power supplies controls and measurements. Hardware controls are disabled on all application window tabs as remote control was not allowed by the server.

CONCLUSIONS

The distributed subsystem to control parameters of the Nuclotron extracted beam was developed on client-server technology using National instruments acquisition modules, FEMTO current amplifier and LabView development system. Beam tests during March 2011 Nuclotron run showed the correct approach to the hardware-software selection and stable complex operation.

A CUSTOMIZABLE PLATFORM FOR HIGH-AVAILABILITY MONITORING, CONTROL AND DATA DISTRIBUTION AT CERN

M. Braeger, M. Brightwell, A. Lang and A. Suwalska, CERN, Geneva, Switzerland*

Abstract

In complex operational environments, monitoring and control systems are asked to satisfy ever more stringent requirements. In addition to reliability, the availability of the system has become crucial to accommodate for tight planning schedules and increased dependencies to other systems. In this context, adapting a monitoring system to changes in its environment and meeting requests for new functionalities are increasingly challenging. Combining maintainability and high-availability within a portable architecture is the focus of this work. To meet these increased requirements, we present a new modular system developed at CERN. Using the experience gained from previous implementations, the new platform uses a multi-server architecture to allow running patches and updates to the application without affecting its availability. The data acquisition can also be reconfigured without any downtime or potential data loss. The modular architecture builds on a core system that aims to be reusable for multiple monitoring scenarios, while keeping each instance as lightweight as possible. Both for cost and future maintenance concerns, open and customizable technologies have been preferred.

INTRODUCTION

The context of this work is the required replacement of an existing monitoring and control system at CERN: the Technical Infrastructure Monitoring system (TIM) takes part in the supervision of infrastructure surrounding the accelerator complex and is mainly used within the CERN Control Centre [1][2]. It has been in place for the last 5 years (TIM) and is now at an advanced stage of maturity. However, due to the use of now obsolete technologies, a new implementation was required, and this was an occasion to reassess the current and future use of the system, and update the design to meet these new challenges.

The services provided by TIM have evolved over the years. In addition to the direct monitoring of hardware, the software also provides real-time control of access systems and transmission of video signals. Such real-time services impose strict time constraints on the transmission of selected data. Moreover, due to the proven reliability of the service, an increasing number of external systems have come to rely on it: data re-distribution over various protocols is now one of the principal tasks of the system. The data is then being used in making critical decisions elsewhere.

With the evolutions described above, the availability of the system has become increasingly important, imposing strict constraints on any maintenance stops. This is accentuated by the variety of the data transiting through the system, since it cannot be linked to any particular phase of accelerator operation. One of the main aims during the redesign was to improve the availability of the old system – although already very high – and facilitate maintenance procedures.

The re-designed TIM system is based on the new CERN Control and Monitoring Platform (C^2MON*). The aim is to provide a generic platform that can be reused in multiple monitoring scenarios. A second service at CERN will also be based on C^2MON in the near future (the Diagnostic and Monitoring service or DIAMON [3]). More generally, a shared platform should help in harmonizing monitoring solutions used at CERN, optimizing costs, maintenance and system compatibility.

CONSTRAINTS ON MODERN MONITORING SYSTEMS

Modern monitoring systems are asked to meet ever more stringent requirements. Reliability has always been a key demand, as for all systems used on a 24/7 basis for operational monitoring: data should pass reliably through the system and be reliably correct! On the other hand, the handling of critical data can result in new availability constraints: external operational decisions may rely on this data. Moreover, these actions may even be triggered in an automatic way, with processes gathering data from the monitoring system through some external protocol. In addition to these availability constraints, performance in terms of data throughput and delivery speed must often be guaranteed. Any transmission of signals used for human interactions impose tight constraints on the time needed for data to pass through the system, including during data avalanches. A good example of this is data used for access control, when operators will expect a rapid response (typically under 1s). Finally, while satisfying these additional constraints, it is expected that the product will provide good maintainability qualities, in particular in terms of applying patches at short notice and the introduction of new features to satisfy evolving demands.

In view of the discussion above, the C^2MON platform aims to increase the availability and maintainability of the systems it is replacing, while maintaining the reliability of the older systems.

SYSTEM ARCHITECTURE: A GENERIC-PURPOSE MONITORING PLATFORM MAXIMISING AVAILABILITY

Having covered the background to this project and discussed current monitoring requirements in general, we now focus on the design of the C^2MON platform, and

* Further details from mark.brightwell@cern.ch

how the design choices have helped achieve the goals outlined above.

Generic: in what sense?

Many monitoring scenarios have similar requirements: acquiring data using a variety of protocols, managing the data (temporary storage, logging, distribution for instance), and displaying it for human visualization. Using a modular architecture, the C²MON platform was designed from the start to fit multiple monitoring scenarios: at CERN, it will be used as the basis for two distinct monitoring systems TIM and DIAMON.

The DAQ design allows modules to be written for new protocols and underlying hardware. The server architecture builds on a core part, to which optional modules can be added for custom behaviour. A client API is provided and can easily be reused in external GUIs for displaying C²MON data (an actual GUI implementation is also available). The only genuine constraint when using the C²MON platform is the data structures involved: for instance, internal data points correspond to single primitive values and need configuring as such in the database. Adding new data structures to the system remains possible, but requires a good understanding of the core design of the platform.

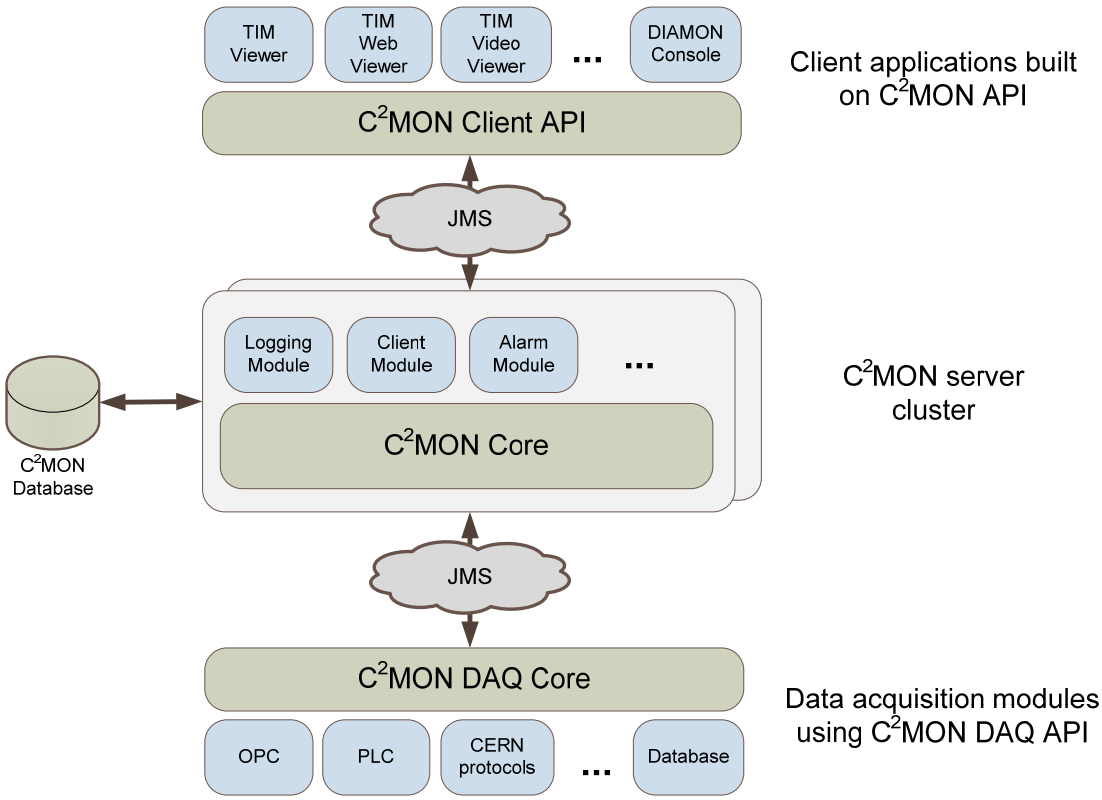

Figure 1: C²MON architecture overview

Architecture Overview

The C²MON platform follows a traditional 3-tier architecture, with data acquisition (DAQ), business logic (server) and client layers. An overview of the architecture is provided in figure 1 above. The DAQ layer is made up of any number of separate processes acquiring data through a variety of protocols. A DAQ implementation makes use of a common provided Core API for communicating with the business layer. The server layer itself consists in a cluster of servers. The server architecture is made up of a core part and a number of optional modules providing additional functionalities. The client layer provides a complete API to communicate effectively with the server. A number of client applications have been built on top of this API (e.g. the TIM Viewer). The various layers are linked with each other through messaging middleware.

The system is designed to run both in a single-server and multi-server configuration. In the multi-server configuration, data is shared between the servers in a distributed cache. Servers can be started on the fly and join an existing cluster. The multi-server configuration improves the availability of the overall system by adding failover support: in case of a single server failure, the remaining cluster is able to take over its workload. It also improves the maintainability of the system, since patches can often be rolled out across the servers without bringing down the whole cluster. The cache is regularly persisted

to the DB and can be recovered even after a complete cluster restart.

As already explained, running in a multi-server mode improves the availability of the C²MON platform. On the other hand, it comes at the cost of a more complicated design, and involves the use of more advanced/specialized software for the cache distribution (see the section below on technological choices). For this reason, the option of running in a single-server mode is of interest, particularly when occasional short downtimes are possible. This mode also remains as an emergency fallback scenario, rapidly deployable with minimum configuration settings.

Runtime System Data Configuration

As already mentioned, adding/removing or reconfiguring the monitored data is a frequent use-case for most monitoring systems. To maintain a high availability, the design must allow for these to be applied with minimal disruption to the service. To achieve this, the C²MON platform uses a flexible approach, allowing each data acquisition module to decide whether it is able to apply the changes with or without a restart of the particular acquisition process. Before providing some details, let us briefly review the C2MON re-configuration process.

All the configuration details for the monitored data points are held in an *offline* database. Before submitting this data to the online C²MON system, it must pass a strict data validation process. This process has proven as important as the system design to the long-term success of the service, but will not be discussed further in this paper. Once the data is correctly configured offline, it can be passed to the C²MON system for online configuration. On reception of a configuration request, the C²MON server loads the details from the offline database. The changes are applied internally, persisted in the online DB and made available in the distributed cache. These changes are applied immediately across all servers in the cluster. Moreover, any changes affecting the data acquisition layer will be propagated down to the appropriate DAQ modules. The functionality available at this level will then depend on the particular DAQ module implementation (specific to the protocol or hardware): if any changes cannot be applied at runtime by the module, the server will be informed that a DAQ process restart is necessary for the changes to take effect.

Using Real-time Filtering on the DAQ Layer

Guaranteeing the availability of a monitoring system also involves protecting it from overload during data avalanches. The C²MON system already greatly restricts the amount of data sent through the system by filtering out redundant values at the DAQ layer (these are forwarded to a separate statistics-gathering process for system administration purposes). However, to help protect the system further, the DAQ layer provides a *dynamic-filtering* option, whereby time dead bands are imposed on individual points detected as feeding too much data to the C²MON server cluster (various strategies on measuring the data throughput are provided).

Technological Choices

The platform is implemented in Java. Based on previous experience, the technological choices were guided by the following principals:

- Stick to proven technologies, facilitating project maintenance and stability.
- Where possible, use open-source resources, facilitating the reuse of the software in other projects. If justified by performance, use other 3rd party products, but provide a basic open-source fallback option.

With these principals in mind, the following choices were made:

- Spring is used as the basic framework wiring together the various components.
- Concerning the JMS middleware, implementations of the various C²MON layers are available for ActiveMQ only.
- The system was designed against an Oracle database, but should run with other databases (this has not been tested so far; some transaction support is required).
- Database persistence is done using the iBatis Java library.
- The cache library used is Ehcache, an open-source Java cache.
- To run in a multi-server configuration, the cache is distributed using the Terracotta technology, which involves running a separate Terracotta server (same company as Ehcache). This technology remains free when run in a basic configuration (sufficient for most purposes).

CONCLUSION

The C²MON platform has been designed over the last year with a view of reusing it in multiple monitoring scenarios. With this in mind, care was taken to provide a flexible core, with convenient hooks for adding custom functionalities. Together with the essential reliability of such a system, the design has attempted to maximize its availability, without affecting maintainability. We list the important design choices made in achieving this:

- The option of running a cluster of servers using a distributed cache, providing a failover mechanism and allowing rolling application of software patches.
- Runtime configuration of the monitored points/ hardware (so without server/acquisition process restarts).
- No operational database dependencies (only required for reconfiguration functionality).

All core parts of the system rely solely on open-source & free technologies.

The C^{2}MON platform is currently in the testing phase, with a planned rollout into production in December 2011.

SOFTWARE AND CAPABILITIES OF THE BEAM POSITION MEASUREMENT SYSTEM FOR NOVOSIBIRSK FREE ELECTRON LASER

E.N. Dementyev, A.S. Medvedko, S.S. Serednyakov, E.N. Shubin, V.G. Tcheskidov N.A.Vinokurov.
BINP SB RAS, Novosibirsk, Russia

Abstract

The system that measures the electron beam position in Novosibirsk free electron laser with the application of electrostatic pick-up electrodes is described. The measurement hardware and main principles of the measurement are considered. The capabilities and different operation modes of this system are described. In particular, the option of simultaneous detection of accelerated and decelerated electron beams at one pick-up station is considered. Besides, the operational features of this system at different modes of FEL performance (the 1st, 2nd, and 3rd stages) are mentioned.

INTRODUCTION

A high-power free electron laser (FEL) based on the accelerator-recuperator [1] is under construction now at Budker Institute of Nuclear Physics. The first and second phases of the project were commissioned recently. The beam position measurement system is one of the important diagnostic systems of the FEL. The system consists of a large amount of electrostatic pick-up electrodes installed on the vacuum chamber of the microtron-recuperator and special measuring devices located outside the accelerator hall. The main characteristics, measurement algorithm and capabilities of this system are described in this paper.

SYSTEM STRUCTURE

As mentioned above, the main part of the system is a number of pick-up electrodes (BPM stations) installed in different parts of the vacuum chamber of the microtron-recuperator. Each BPM station has four buttons with a clear aperture diameter of about 80 mm. Signals from the plates of all BPMs are transmitted by cables outside the shielded hall to the site of location of the measurement electronics. The beam position is determined via simultaneous measurement of the amplitudes of signals induced on the buttons by the beam field. It is done with the use of the following linear approximation formula:

$$x = k \frac{U_+ - U_-}{U_+ + U_-},$$

where k is a factor with the dimension of length. It is obtained from electromagnetic measurements (in the case of a circular tube, $k \cong a/4$, where a is the tube radius); U_+ and U_- are the amplitudes of signals from a pair of opposite (left and right) plates.

Due to the principle of operation of the microtron-recuperator, there are simultaneously several electron beams at some places of beam propagation. For example, accelerated and decelerated beams are moving simultaneously in the accelerating RF section. The total number of different beams in the RF section depends on the number of beam turns and equals *2*N* (where *N* is the number of turns). Owing to this feature, the task of separated measurement of the positions of different beams at the same BPM station arises. This task influenced the choice of the measurement hardware and the measurement algorithm.

The main devices used in this system are as follows:

- a 4-channel analog-to-digital converter with a 32k-memory cell per each channel and external start,
- a 4-channel delay line with a step of time delay adjustment of 250 psec, and
- a 5-channel multiplexer

All these devices are manufactured in the CAMAC standard. A more detailed description can be found in [2].

The principle of measurement is shown in Fig. 1.

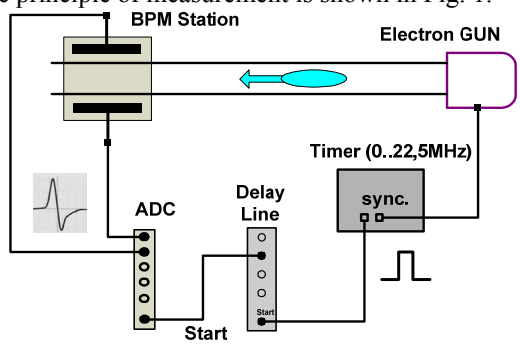

Figure 1: Scheme of beam position measurement.

The measurement is performed bythe 4-channel ADC, to which 4 cables from the BPM plates are connected. The moment of measurement is determined by an external "Start" signal. This signal is generated by the Timer – a device that also sends a control signal to the electron gun modulator. Thus the frequency of the "Start" signal is equal to the frequency of the movement of the electron beams. For compensation of the difference in the time of movement of all these signals and time of beam movement in the vacuum chamber, the "Start" signal is passed through the adjustable delay line. A precise adjustment of the time delay value allows one to select the time of measurement, tune the measurement moment to the pulse maximum, and also to tune the measurement to different beams, moving one after another. Since the number of BPM stations is rather large, the measurement devices are grouped in units. Each unit contains one ADC and five multiplexers, so it is possible to connect five BPMs. Besides, each unit uses one channel of the delay line. So, since a CAMAC crate can hold up to three units, there should be one delay line in each CAMAC crate. The entire scheme of this system, connections of the BPM electrodes and measurement devices are presented in Fig.2.

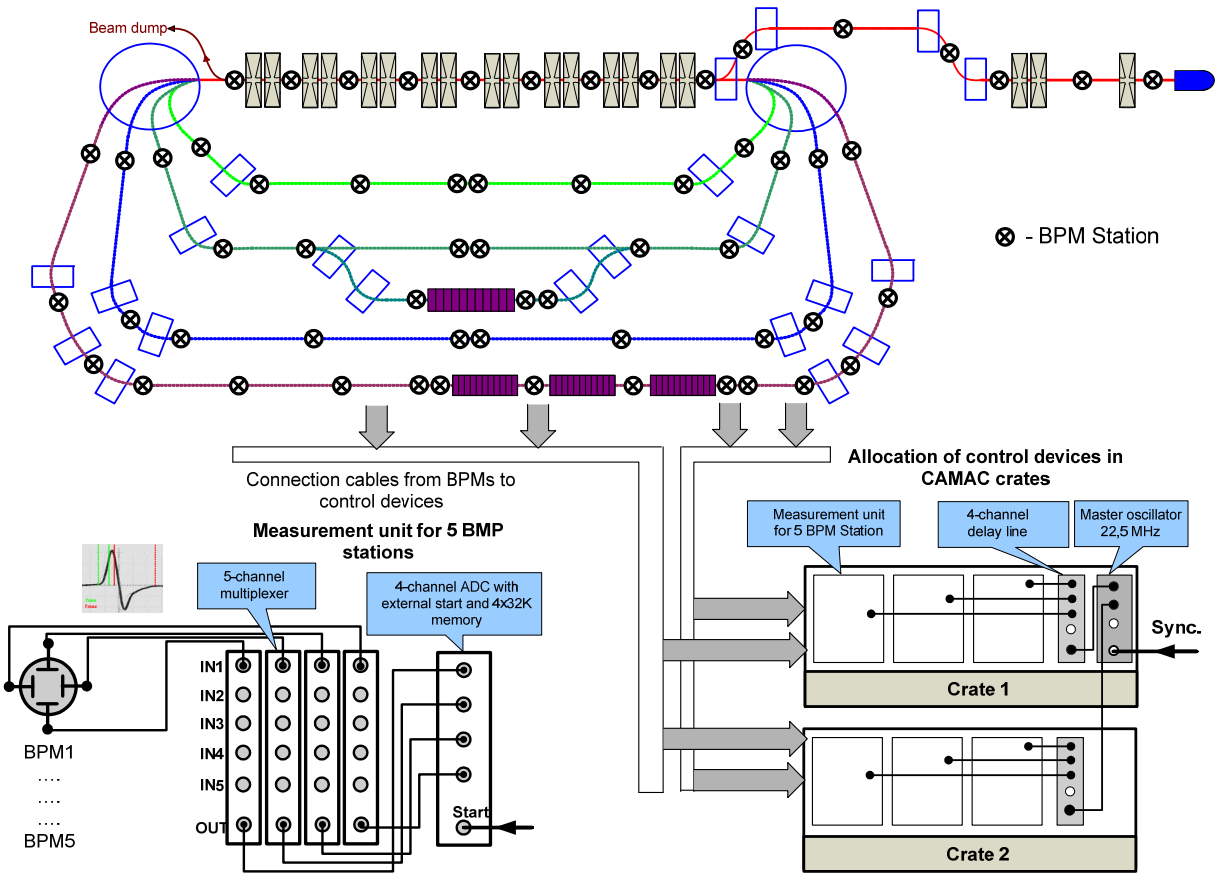

Figure 2: Main scheme of the beam position measurement system.

SOFTWARE

The control software for this system is a single application running on the IBM-PC computer. Communication with the CAMAC crates is realized with the help of the ISP controller, developed at Budker INP. The application can operate in several different regimes.

The first regime is a serial poll of all the BPM stations for the purpose of determination of the transverse coordinates of the beam (the main operating regime). In this regime, the application is subsequently polling all BPM stations. Measurement at each BPM station is executed in a specified delay time range assigned to the delay line. After running throughout the range, the program finds the maximum of signals from each button, computes the transverse coordinates, and displays it either as the beam trajectory or as the beam positions at each station (see Fig.3). In this case, measurement of one point requires ~15 CAMAC NAF instructions and a time of approximately 1 millisecond. Usually, each BPM station has a range of about 10-15 time delay points. So, for the FEL 1st stage with 37 measurement points in total, the overall time of measurement of the entire beam trajectory is 400-600 msec.

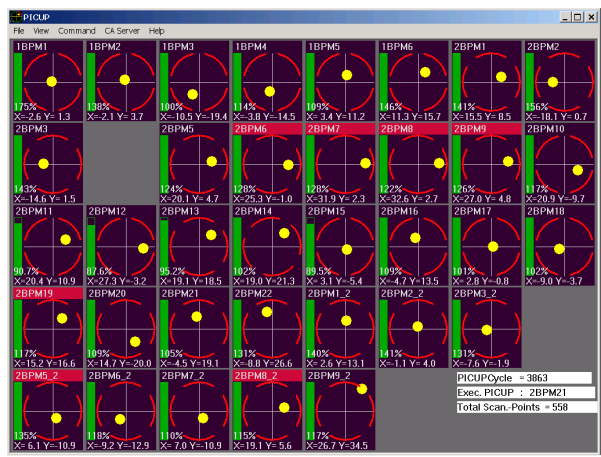

Figure 3: Window of a serial poll of the BPM stations.

Besides the calculation of transverse coordinates, in this regime the application calculates the sum of all maximum measured signals since this value is proportional to the value of electron beam current. The user can select any BPM station, and the application will calculate the beam current value in percents relative to this value on the selected BPM. The "relative" beam current value is drawn in the main window with green vertical bars. With this feature it is very easy to find areas of the accelerator track with beam current losses.

The second operation regime is a scanning throughout the delay time range of one of the BPM stations. While

executing this cycle, the program plots the time dependence graph of the beam-generated pulse. If there are several different beams at a selected BPM station, the user can view them in the same graph. The resulting plots of this regime are shown in Fig. 4. This regime is mainly used for specification of the time delay limits for scanning in the main, first regime. The user can manually select the time delay range as narrow as possible to reduce the time of processing of this BPM station. At the same time, this range should include all the four maximums of signals from the BPM buttons.

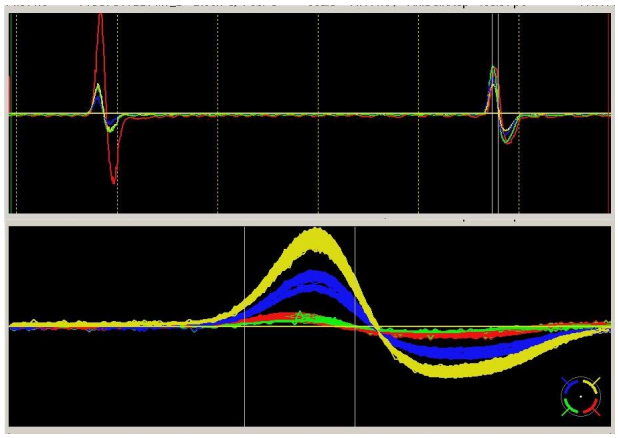

Figure 4: Graphs of the scanning cycle throughout the time delay range.

Another application of this regime is the study of the time stability of electron beam. The user can specify the scanning range as small as possible, containing only pulses from the buttons (see the lower part of Fig.4.). It is also possible to run this scanning cycle infinitely, without erasing the previous graphs. In this case, if there are some oscillations of beam position or beam current, the BPM button pulse graphs will cover the whole area of these oscillations.

The third and very useful regime is a poll of the waveform of the BPM button pulses with the frequency of the beam movement and a constant time delay value. As in the previous regimes, measurement is triggered by an external signal. However, in this case, measurement data are stored in the internal ADC. The ADC has a memory of 32 K of 12-digit words for each channel and can perform measurements with a frequency as high as 50 MHz. When the whole memory is filled, the application reads all the measurement data from it and plots them (see Fig. 5). Measurements in this regime being executed with the beam movement frequency, the amplitude, frequency, and shape of beam pulse oscillations, if any, can be found. Besides, modifying the beam pulse area where these measurements will be performed, one can easily study the nature of oscillations of beam positions or current.

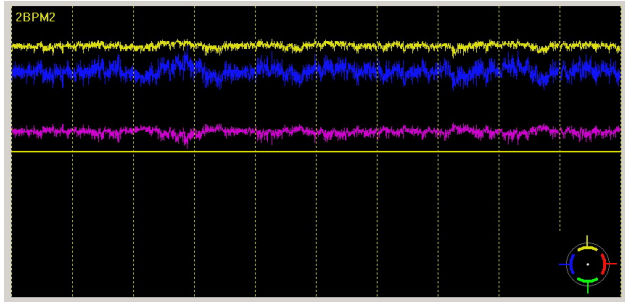

Figure 5: Plots of measurements with a constant time delay value and beam movement frequency.

Another useful feature of this application is the ability to transfer all measured data (the x and y coordinates and beam current) to another application in the FEL control LAN. For this purpose, a portable Epics Channel Access server is built-in inside the application. Every measured value is presented by one process variable.

CONCLUSION

The above-described system has been operating for about 8 years, demonstrating high reliability. The features of the measurement equipment allow observing simultaneously the accelerated and decelerated beams in the accelerator-recuperator beam-line. The interface and capabilities of the control software allow analyzing the behavior and time characteristics of the electron beam. The existence of the Epics Channel Access server in the program allows archiving all measured data and using them in other applications.

Abstract

The Taiwan Photon Source (TPS) is a low-emittance 3-GeV synchrotron light source which being in construction at National Synchrotron Radiation Research Center (NSRRC) campus. Control system for the TPS is based on EPICS framework. Standard hardware and software components were defined. Prototypes of various subsystems are in implementation. Event based timing system was adopted. Power supply control interface accompany with orbit feedback support are also defined. Machine protection system is in design phase. Integration with the linear accelerator system which are installed and commissioned at the temporary site for acceptance test was already done. Interface to various system are still in negotiate stage. Development of the infrastructure of high level and low level software are on going. Progress will be summarized in the report.

INTRODUCTION

The TPS [1] is a latest generation of high brightness synchrotron light source which is being in construction at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan. It consists of a 150 MeV electron linac, a booster synchrotron, a 3 GeV storage ring, and experimental beam lines. Civil construction has started from February 2010. The construction works are scheduled to finish in later 2102. Accelerator system installation and system integration will be proceeding in the year of 2013. Commissioning with beam is scheduled in the first quarter of 2014. Control environment should be ready in 2013 to support subsystem integration test and hardware commissioning without beam. Control system for the TPS is based on the EPICS framework [2]. The EPICS toolkit provides standard tools for display creation, archiving, alarm handling and etc. If users have found these tools inadequate, development of in-house alternatives is feasible and compatible. The big success of EPICS is based on the definition of a standard IOC structure together with an extensive library of driver software for a wide range of I/O cards. Many users of the system report a steep learning curve and the need for significant development resources, but this is balanced by the large installation base and proven ability of this approach. The EPICS toolkits which have various functionalities will be employed to monitor and to control accelerator system. The control system consists of more than a hundred of EPICS IOCs. The CompactPCI (cPCI) IOC will be equipped with input/output modules to control subsystems as standard IOC or the TPS control system. The power supply and fan module of the cPCI crate will be hot-swapped. Adopting cPCI platform for EPICS IOCs provides us a chance to take advantages of local IT industry products with better supports and low cost. The other kinds of IOCs are also supported by the TPS control system, such as BPM IOC, PLC IOC, various soft-IOC and etc. Consoles and servers are PCs or blades PC running Linux. To achieve high availability of the control system, emphasis has been put on software engineering and relational database for system configurations. Data channels in the order of 10^5 will be serviced by the control system. Accessibility of all machine parameters through control system in a consistent and easy manner contributes to the fast and successful commissioning of the machine. High reliability and availability of TPS control system with reasonable cost and performance are expected.

CURRENT STATUS

Major procurement is scheduled in 2011 to 2012. The design for the control system environment is already frozen in the hardware part. The software environment will be completed in 2012. Control related applications are started and expected to a preliminary form before subsystem ready in early 2013. Define TPS control system standard processed during the last couple of years. Efforts of the control system development status are summarized in following paragraphs. Progress on various issues is summarized in following paragraph.

Networking

Mixed of 1/10 Gbps switched Ethernet will be deployed for the TPS control system [3]. The Gigbit Ethernet connection will be delivered at edge switches installed at control and instruments area (CIA). One CIA corresponding to one cell of the storage ring, there are 24 CIAs total. The control network backbone will be 10 Gigabit link to the control system computer room and redundancy network installation site in the specific CIA #24. Private Ethernet is used for Ethernet based devices access which will support fast Ethernet and GbE. Adequate isolation and routing topology will balance between network security and needed flexibility. The file and database servers are connected to the control and intranet network, allowing the exchange of data among them. Availability, reliability and cyber security, and network management are focus in the design phase.

Equipment Interface Layer

There are several different kinds of IOC at equipment interface layer to satisfy various functionality requirements, convenient, and cost consideration. Most of the devices and equipments will connect to cPCI IOCs crates running EPICS directly. The 6U cPCI platform was chosen for the EPICS IOC platform. Local company manufactured crate and CPU module providing an economic solution is the major reason. To simplify various developments at construction phase, only 6U modules will be supported for the machine control system. The cPCI EPICS IOC equipped with the latest generation CPU board will be standardized as ADLINK cPCI-6510 CPU module [4]. The CPU module equipped with Intel Core i7 CPU running Linux delivery high performance to meet various applications. The latest releases version of Fedora core Linux distribution is adopted at IOC level. The cPCI-7452 128 bits DI/DO module will be used for BI, BO solution, this high density version in 6U form factor will save crate slots and satisfy most of applications. Industry pack (IP) carrier board in 6U cPCI form factor can equip up to 4 IP modules. Various IP modules are adopted for necessary applications. ADC and DAC modules in IP module form factor will be used for smaller channel count application, such as insertion devices control. Event system modules are in 6U cPCI form factor. Private Ethernet will be heavily used as field-bus to connect many devices. Power supplies of all magnets except for correctors are equipped with Ethernet to the EPICS IOC communication. Multi-axis motion controller with Ethernet interface will be the standard support for the control system.

Ethernet attached devices will connect to the EPICS IOC via private Ethernet. Some network attached devices might cannot work properly when the network traffic busy due to its simply TCP/IP stack implementation. Private network ensure lower traffic to ensure the reliability and performance of the links. Devices support VXI-11, LXI, Raw ASCII, Modbus/TCP protocol can connect to the EPICS IOC via TCP/IP interface directly. Devices of this category include power supply, temperature acquisition (RTD or thermocouple), digital multi-meters, oscilloscopes, signal generator, and other instruments.

High resolution ADC module embedded with EPICS IOC from D-tAcq [5] will be used for the analogue signal reading, it provides 10 Hz rate reading and has transient capture buffer up to 100 Ksample/sec sampling rate.

All corrector power supply will interface by the corrector power supply controller (CPSC) module. The CPSC equip with 20 bits DAC and 24 bits ADC. Corrector power supplies will be driven by the output of this module. Two SFP ports supported by the on board FPGA (Spatan 6), these SFP ports will receive correction setting (Autora and Gigabit Ethernet by using UDP/IP protocol) from fast orbit feedback FPGAs ot slow orbit feedback PC, feed-forward correction computer and IOC. Setting command received by these SFP ports will be added with the slow setting from EPICS CA setting.

Power Supply System Control

TPS power supplies control interface are divided into three categories rather than a unified solution [6]. All of the power supplies will be provided by three different vendors. The reason of this choice is to meet the practical situation from budget and available vendors and manpower.

The small power supply for corrector magnets, skew quadrupoles in the range of ±10 Amp categories. This category power supply will be in module form factor. Each power supply subrack can accommodate up to 8 power supply modules. A custom design CPSC module will be installed at control slot of the sub-rack. The CPSC will be embedded with EPICS IOC and provide fast setting SFP ports to support orbit feedback functionality. Power supply modules installed at the same sub-rack will interface to this CPSC module. The CPSC installed 20 bit DAC and 24 bit ADC to ensure necessary performance for the orbit control especially in vertical plane of the storage ring. To simplify the type of power supply, this category power supply will be used for the corrector of LTB/BTS/Booster Synchrotron, and storage ring as well as skew quadrupole magnet power supply. The CPSC modules support waveform capability which can support corrector ramping for the booster synchrotron if necessary.

The intermediate power supply with current rating 250 Amp will be equipped with Ethernet interface. Power-supplies are expected to have internal data buffer with post-mortem capability. Output current of the power supply will output at rear plane BNC connector, which can connect to the cPCI ADC module also. There are two versions of power supply in this category, sextupole power supply with 16 bits resolution and quadrupole power supply with 18 bits resolution DAC. Both kinds of power supply can meet the 50 ppm and 10 ppm performance specifications for long-term drift. Both kinds of power supply noise level are in the 10 ppm range of the full scale

The storage ring dipole DC power supply and power supplies for the dipole and quadrupole power supply of the booster synchrotron had already contracted to the IE Power (Acquired by Eaton in 2011). The control interface will be a serial interface. It is expected that a serial and Ethernet adapter enable directly Ethernet connection. Control resolution of these power supplies will be 18 effective number of bits, noise and drift will be better than 10 ppm of these power supplies. The dipole and quadrupole power supply of the booster synchrotron have built in waveform support with external trigger capability. This functionality is essential for energy ramping of the booster synchrotron. All of these power supplies will interface with the EPICS IOCs directly.

Timing System

The event system consists of event generator (EVG), event receivers (EVRs) and a timing distribution fiber network [7, 8]. EVG and EVRs can be installed with various universal I/O mezzanine modules to meet different input/output requirements. The mechanical form factor of EVG and EVRs is in 6U cPCI module. The 125 MHz event rate will deliver 8 nsec coarse timing resolution. Fine delay is also supported by UNIV Output module with fine delay and special EVR which can generate gun trigger signal. Its high resolution and low timing jitter allow accurate synchronization of hardware and software across the TPS control system. Its usage simplifies the operation of the machine and allows complex sequences of events to be carried out by changing very few parameters. Prototype system was delivered in March 2011 already and applied to the TPS linac system commissioning at the temporary site successful. Consideration for the injection sequence control is also in intensive study.

Insertion Devices Control Interface

Insertion devices (ID) control for the phase I project include one set of EPU46, two sets of EPU48 and seven sets of in-vacuum insertion devices (two sets of 2 meter long IU22, three set of 3 meter long IU22, and one set of 3 meter long IU 22 with taper functionality). The driven mechanism of EPU46 and EPU48 are drive by servo motors. All IU22 drive by stepping motors. The motion controller is Galil DMC-404x Etherent/Series Accelera motion controller. Preliminary version of EPICS devices supports for this motion controller is in use. Improve is under way. The cPCI EPICS IOC equips with AI/AO/BI/BO I/O modules will serve each ID. All IDs will equip with SSI optical encoder. All encoder are connected to the motion controller. All parameters of motion controller will map to EPICS PV. Update rate up to 200 Hz is feasible. This might useful for feed-forward compensation which need to know the encoder value as fast as possible.

Diagnostic System Interface

New generation digital BPM electronics [9] is equipped with Ethernet interface for configuration and served as EPICS CA server with 10 Hz data rate. Another multi-gigabit interface will deliver beam position for fast orbit feedback purpose at rate up to 10 kHz. The BPM electronics will also provide post-mortem buffer for orbit analysis during specific event happened like beam loss. Post-mortem analysis can help to find the weakest point and provide information to improve system reliability.

High precision beam current reading and lifetime calculation will be done at a dedicated IOC. This IOC will install EVR to received booster cycle timing signals and high resolution IP ADC modules to digitize the DCCT signal and perform beam lifetime calculation.

The GigE Vision digital cameras will capture images for diagnostic purposes and other applications.

Counting type and integrating type beam loss monitors will be connected to the control system by counter or ADC modules installed at IOCs.

Feedbacks and Feed-forward Plans

Since the TPS adopt aluminium chamber with 4 mm in thickness. Eddy current effects prevent the standard corrector from fast corrector. Four fast correctors will be installed at bellows site for each cell. So, the global orbit feedback system by using slow and fast correctors in the same feedback loop is the baseline design [9]. A counter rotate multi-gigabit links will circulate 10 kHz rate orbit data among all BPM platforms. The FPGA module embedded in the BPM platforms will be configured as distributed fast orbit feedback engines. All of these platforms will be installed with EPICS interface for various feedback supports such as PID parameters, and matrix download. The correction command from FPGAs will be sent to the CPSC module located at the power supply sub-rack via Aurora links. The data buffer in the FPGA module can be used to capture fast orbit data up to 100 sec at 10 kHz rate for feedback system diagnostic and performance study. The capture can be triggered either software or hardware with post-mortem capability.

The slow orbit feedback is planned to use one dedicated EPICS IOC for each plane (maybe one aTCA compute blade for each plane). The orbit data can be acquired by the EPICS CA access or from the BPM grouping data directly by UDP/IP link. The slow orbit feedback will used the slow transfer matrix to calculate the correction values. The slow feedback loop will read the DC value of the fast corrector regularly (1 ~ 10 times/sec), multiply the inverse of the fast response matrix to get the orbit distortion which cause due to the DC setting of fast correctors. The same orbit distortion will transfer to the setting value by the slow correctors. This scheme can ensure the setting of the fast corrector always around zero. This will keep the maximum dynamic range of the fast corrector to suppress fast perturbation. The corrector setting for the slow orbit feedback loop is via UDP/IP packet. All setting value of the correctors are packed in one UDP/IP package. Each CPSC module extract their setting form specific offset within the packet. One packet can serve for all slow corrector in one plane for the whole ring.

The bunch-by-bunch feedback system will adopt signal processor based on the latest generation FPGA processor with embedded EPICS IOC and build-in diagnostics.

Turnkey System Solution

Turnkey systems such as linear accelerator and RF transmitters were delivered by industry as turnkey contracts and EPICS control environment. Work on EPICS support for the turnkey system with proprietary control environment is also not a problem. It is expected

that the turnkey systems delivered no matter with or without EPICS control system can integrate with the TPS control system. The linac system delivered in June 2011 and done acceptance at accelerator test site. It will move to the TPS linac site in later 2012 after civil construction of the TPS building is completed. Two RF transmitters were received in 2010. EPICS ready interface of these delivered system proved that the integration is not a big problem.

PLC and Interlock Solution

Current TPS control system will support Siemens S7-300 or compatible model from VIPA PLC which are delivered from the turn-key vendors. Yokogawa FM3R PLC will be used for most of control system related interlock system. FM3R with embedded EPICS IOC will be used for some applications also. Each subsystem is responsible to build their own interlock and protection system based on their requirement and preference. The global machine interlock system will collect various interlock signals from local interlock subsystem of orbit, vacuums, front-ends, radiation dosage monitors and etc. The beam disable commands to trip beam or inhibit injection can be distributed to the specific devices or subsystem by the global machine interlock system or uplink functionality of the event system.

Operator Interface

The operator interface level consists of Linux PCs for consoles and servers for various purposes. Various EPICS OPI tools and Matlab will be adopted for OPI development [10, 11]. It is planned currently that most of the GUIs will be implemented by EDM and Matlab. Consoles in the control room have multiple LCD screens. The OPI computer will be installed at the equipment area of control room with optical PCIe extension to remote display unit at control room. This can provide better cooling for the computer, reduce loudness at control room and provide clean control consoles. Large screen format displays hang on the roof at control room will be available for display of important parameters likes beam current, lifetime, vacuum distribution, synchrotron radiation image and etc.

Control Applications

Generic applications provided by the EPICS toolkit will be used for all kinds of applications. Standard tools such as the archiver, alarm handler and save/restore tools are supported. Channel Access (CA) is used as an interface for machine process variables (PVs) access. Simple tasks such as monitoring, alarm handling, display and setting of PVs are performed using EDM panels and strip tools. Cold start, warm up and shutdown process will done by Matlab scripts.

Physics Applications Interface

The accelerator physics tools for TPS include extensively adopted Matlab Middle Layer (MML) and Accelerator Toolbox (AT) software packages. It enables various developed applications of different machines to be directly adopted for TPS applications. The MML has also provided a systematic way of managing machine data, and is easily extended to separate data from transfer lines, booster and storage ring. The Middle Layer communicates with the machine from within MATLAB using LabCA. To enable early testing of the physics tools through the control system, a virtual accelerator has been implemented to give simulation of the accelerators through the EPICS PV interface. It was developed by provided EPICS device support to interface the model using the AT and MML.

SUMMARY

Implementation of the TPS control system is in on going. Major procurement is in proceeding. Assembly and system integration is scheduled in 2012-2013. The TPS control system will take advantages of the latest hardware and software technology to deliver better performance and functionality, avoid quickly obsolesce and more economic. There are many issues required further efforts and focus including relational data base, system configuration and operational management, various application programs. Identify priority and find an adequate measure to deal with various issues is current efforts.

Abstract

Spiral2 whose construction physically started by the beginning of this year at Ganil (Caen, France) will be a new Radioactive Ion Beams facility to extend scientific knowledge in nuclear physics, astrophysics and interdisciplinary researches. The project consists of a high intensity multi-ion accelerator driver delivering beams to a high power production system to generate the Radioactive Ion Beams being then post-accelerated and used within the existing Ganil complex. Resulting from the collaboration between several laboratories, Epics has been adopted as the standard framework for the control command system. At the lower level, pieces of equipment are handled through VME/VxWorks chassis or directly interfaced using the Modbus/TCP protocol; also, Siemens programmable logic controllers are tightly coupled to the control system, being in charge of specific devices or hardware safety systems. The graphical user interface layer integrates both some standard Epics client tools (EDM, CSS under evaluation, etc …) and specific high level applications written in Java, also deriving developments from the Xal framework. Relational databases are involved into the control system for equipment configuration (foreseen), machine representation and configuration, CSS archivers (under evaluation) and Irmis (mainly for process variable description). The first components of the Spiral2 control system are now used in operation within the context of the ion and deuteron sources test platforms. The paper also describes how software development and sharing is managed within the collaboration.

THE SPIRAL2 PROJECT

Ganil is one of the major facilities producing stable or rare ions beams (RIB) for nuclear physics, astrophysics and interdisciplinary research. In order to extend both the range and mass of exotic nuclei able to be provided, the Spiral2 project [1] at Ganil will deliver RIB at intensities never reached before and is built within two phases:

- The first one is the primary beam acceleration process consisting of deuterons and heavy ions sources, a warm RFQ and a superconducting linac. It also includes the S3 (Super Separator Spectrometer) and NFS (Neutrons for Science) stable experimental areas. Construction of the buildings is under way so that the installation should start in fall 2012 with the first beams expected in 2013. To anticipate the commissioning phases, the deuteron and heavy ions sources with their associated low energy beam lines are already in test respectively at CEA-IRFU (Saclay) and CNRS-LPSC (Grenoble).

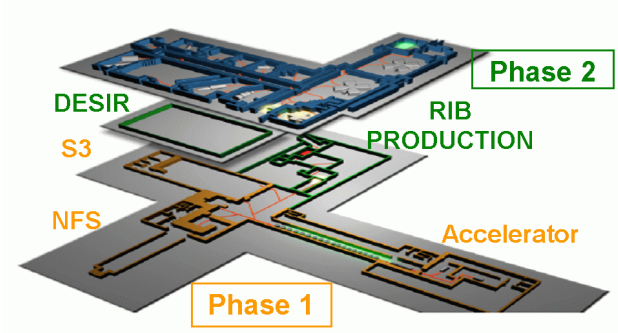

Figure 1: The Spiral2 general layout.

- Phase two concerns the RIB production complex, a new DESIR experimental room and the link to the existing Ganil facility for post acceleration and reuse of the experimental switchyard.

CONTROL SYSTEM CONTEXT

Software Development Around Epics

Since the preliminary design phase study, it has been decided to build the Spiral2 control system upon the Epics framework.

For the phase 1 control system, a collaboration between CEA-IRFU (Saclay), CNRS-IPHC (Strasbourg) and Ganil (Caen) has been set within a specific organisation so that these three laboratories share their developments [2] according to the work packages they are in charge of.

The phase 2 control system will be also based within the same Epics technical pattern, being still under design for its detailed conception. Nevertheless, it is clear that a specific point will have to be addressed as this part of the facility as it will be the recovery domain of the new Spiral2 and the legacy Ganil control systems, this last one resulting of an home-made Ada design formerly defined in the beginning of the 90's.

Main Technical Options

Most of the technical options result from the Epics environment (currently 3.14.12) which was adopted and the main choices were presented previously [3], [4].

IOC servers will be either VME crates running VxWorks (currently 6.8 release) or Linux PCs. Equipment will be addressed either directly from VME chassis or through field buses (mainly Modbus/TCP). Also Siemens S7 PLCs will be used, being in charge of specific devices or handling safety processes.

On the client side, GUIs will be, depending on the context and needs, either standard Epics tools or Java applications being developed within an adaptation to our project of the Xal framework [5].

Basic Infrastructure

In order to integrate the future needs brought by Spiral2 and to cope with the needs of the existing Ganil facility, a consequent upgrade of the Ganil central servers was performed during the yearly Ganil winter shutdown by the beginning of this year.

The new environment consists of two Dell Power Edge servers equipped with Intel Xeon E5620 processors at 2.4 GHz. SAN disks are configured as Raid10 (3 Tb) and Raid 5 (4 Tb) within iSCSI storage units. The operating system is the Red Hat Linux 6 distribution with the high availability features provided by the cluster suite package.

Shared by both the Ganil and Spiral2 control systems, this set of replicated servers is in charge of all the basic system services as well as the relational database management servers (Ingres for Ganil and Spiral2, in addition MySql envisioned for Spiral2).

Beside of these infrastructure servers, application program servers dedicated to each of the Ganil and Spiral2 machines run on specific applicative servers.

EQUIPMENT LAYER

First, linked to the equipment management (fig. 2), a development is in parallel under way for providing an environment to integrate the equipment into the control system by the end users themselves, even not Epics aware people [6]. It relies on the standard Epics template database files, the substitution mechanisms and the so-called "generation" consists of generating the starting boot file, the Epics substitutions files and (if required) the sequencer scripting files. This has been prototyped up to now within the context of quite simple equipment such as beam slits or power supplies; to be compliant with this process, developments have to respect configuration, programming rules and codification recommendations.

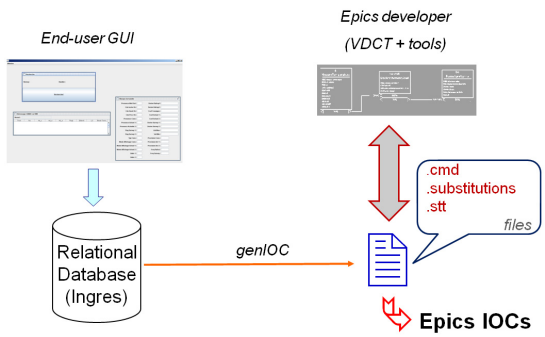

Figure 2: Equipment management work flow.

Table 1 summarizes most of the equipment to be integrated within the accelerator control system; according to the current status development, items are highlighted from green (tested during the first beam tests at Saclay and Grenoble), orange (work in progress) or red (standby).

Table 1: Equipment Integration

Equipment	Interface	Comments
Power supplies [6]	Modbus/TCP	Alarms handling still to be implemented. Various implementations according to providers.
PLCs	Modbus/TCP	Siemens S7 serie.
Faraday Cups & ACCT - DCCT Current transformers [7]	VME	Slow acquisition to get average value and fast acquisition for peak value as well as pulse display.
Slits	Modbus/RTU	Step by step motors. Temperature measurement and beam current acquisition through VME.
Fast Faraday Cup	Digital oscilloscope	Preliminary tests performed using the SCPI protocol (packet length).
Time of flight	Modbus/TCP (phase)	Specific Ganil design.
Fast current transformer	Digital oscilloscope Modbus/TCP (phase)	Preliminary tests performed using the SCPI protocol (packet length).
Transversal emittance	VME	Complex system with HT settings, Brushless motors and Faraday cups. Validated for the Low Energy Beam Transfer Lines.
Profilers	Modbus/RTU	Specific Ganil design.
Beam Position Monitors	VME64x	Specific BARC design.
Beam Losses Monitors	VME	Complex system with NIM chassis, HT modules. Specific IFIN-HH design.
Beam Energy Monitors	?	Detector not yet defined
RF amplifiers [8]	Modbus/TCP	Different for the RFQ and the Linac cavities.
LLRF control	VME64x	Specific IRFU design.
q/a=1/3 ions source [9]	VME	Complex system tested at LPSC Grenoble. Uses LabView &Epics.
Deuterons source	VME	Complex system tested at IRFU Saclay.
Timing system	Modbus/TCP	Handled by a PLC and an electronic system to tune the beam pulse shape by setting the sources, RFQ, and chopper pulsations.
Hall probe magnetic field	Modbus/TCP	Specific Ganil design.
NMR probe magnetic field	?	To be specified according to the system to be used.
Buncher, RFQ and Linac cavities	RF systems	Linked with the LLRF, RF PLCs and a private network.
Machine Protection System	?	GUIs, alarms, thresholds handling to be specified upstream the system.

Conventional facilities, cryogenic distribution and the personal access control system are out of the scope of the control system.

OPERATION INTEGRATION

Operator Interfaces and Tools

First, the EDM standard Epics editor is used for supervision applications, CSS/BOY being presently in evaluation with a specific care for its use in operation.

The archiving system is planned to be implemented with archive engines upstream a MySql database and performance tests started recently (400 values at 10 Hz monitored), jointly with the CSS client operator interface.

The alarm handling system will be a home made one (Java development), being able to process both the alarms coming from the legacy Ganil and new Spiral2 control systems. Alarms are stored in an Ingres relational database up to 330 per second for the global throughput.

Software Organisation and Standardisation

From the very beginning, to cope with the collaboration needs, a dedicated organisation was set to share developments. A Spiral2 repository was adopted both for the Epics and Java developments, including naming rules and conventions for files, directories. Also codification rules were defined for equipment.

Later, it turned out for better interactions to propose a standardized interface between IOCs and the GUI applications by defining a generic way to access equipment [10]. First, deeper codification rules were extended for Process Variable naming to handle settings, readbacks and measurements. Then, a specific database pattern consisting of dedicated records is introduced within IOC developments. It presents to any Channel Access client Process Variables to read the status word, read the default word, provide the list of all available commands to be applied, provide the list of all defaults able to be raised, get the meaning of each status bit …

High Level Applications and Machine Description

After having decided to write high level applications in Java, an investigation was done to adopt or define a framework able to fulfill our needs and requirements. Therefore, the Xal environment was evaluated within our context and, with the help of the Xal collaboration, tests were carried out successfully so that a Spiral2 derived version is now available [11]. It uses all the Xal approach and concepts and integrates some specificities coming from the new machine itself or inheriting from our previous Ganil approach.

According to the Xal schema, the facility is defined along an accelerator tree whose final leaves are the accelerator components. This description is stored in a relational Ingres database from which data are extracted to generate the Xal .xdxf compliant file. A gateway with the simulation CEA TraceWin program was added to generate theoretical values for the beam to be produced.

The first Xal based application was a general one to manage beam parameters; others under development are the beam profiles display, an optimization on-line program (using Xal algorithms), the buncher tuning and a general purpose handling tool. Many others are planned. Also standard Xal applications will be used such as the scanning programs and the magnet cycling one.

NEXT STEPS

Taking benefit of the ions and deuterons test platforms at Grenoble and Saclay, some components of the control system were tested within a quite operational context.

Nevertheless, a lot of work has still to be done with the development of the Linac control system. Also, providing more operational tools and high level applications is an issue. Lastly, the scalability of the system in a more loaded environment has to be checked carefully.

The installation is planned from summer 2012 while, in parallel, the phase 2 control system is under design.

ACKNOWLEDGEMENTS

Other contributors from the Ganil control group are: J.C. Deroy (LabView), P. Duneau and J.M. Loyant (real time), P. Lermine (databases), J.F. Rozé (PLCs infrastructure). PLCs development is managed by C. Berthe (Ganil) and R. Touzery (IRFU).

The basic hardware and software infrastructure and the network architecture are managed and provided by the Ganil Computing Infrastructure group.

THE COMMISSIONING OF THE CONTROL SYSTEM OF THE ACCELERATORS AND BEAMLINES AT THE ALBA SYNCHROTRON

D. Fernández-Carreiras, F. Becheri, S. Blanch, A. Camps, T. Coutinho, G. Cuní, J. Gigante, J. Klora, J. Lidón, O. Matilla, J. Metge, A. Milán, J. Moldes, R. Montaño, M. Niegowski, C. Pascual-Izarra, S. Pusó, J. Jamroz, Z. Reszela, A. Rubio, S. Rubio-Manrique, A. Ruz, CELLS, Cerdanyola del Vallès, Barcelona, Spain

Abstract

Alba [1] is a third generation synchrotron located near Barcelona in Spain. The installation of the Control System for the Accelerators (Booster, Storage Ring, Transfer lines and Front-Ends) finished at the end of 2010. The final functional tests took place during the first weeks of 2011, right before the commissioning of the Storage Ring, which started the 8th of March. Currently we are carrying out the final stages of the installation and commissioning of the seven experimental stations of the phase 1 (known as Beamlines at Alba). The control system is based on the middle layer provided by TANGO combined with open source SCADA, Sardana [2][3][4]. It is highly distributed relying extensively on Ethernet as a Field Bus. It combines diskless machines running Tango on Linux and Windows, with distributed PLCs connected to remote peripheries. In several cases, application specific hardware has been produced in house. This paper describes the design, requirements, challenges and the lessons learnt during the installation and commissioning of the control system.

THE CONTROL SYSTEM

The infrastructure implicated in controls includes more than 350 racks, 6300 equipments and 17000 cables. The controls architecture is highly distributed, comprising about 2500 network devices. The central Tango Installation for the Control and data acquisition of the accelerators has today 5680 devices and 1480 processes running.

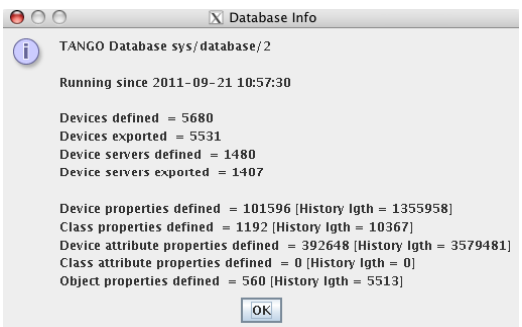

Figure 1: Summary of the Tango database for the control system of the Accelerators.

Besides the controls for the Accelerators, there is one control system per Beamline, implementing the same architecture, running on industrial PCs installed in the Beamline and virtual machines in the computing room. Each Beamline has an independent Tango installation, controls hardware and disk space in the central storage. The networks between machine controls and Beamline controls are separated, having a firewall in between. Thus the interfaces between Machine and Beamlines are implemented via virtual machines acting as gateways, and PLC direct connections.

In this first deploy of the control system for the accelerators comprises about 84 cPCI, and 22 industrial PCs distributed in the service area, all diskless running Linux openSUSE11.1 with a kernel 2.6.27 (known as Input/Output controllers or IOCs in our naming convention). The central services run in multicore servers or virtual machines in the computing room. We extensively use Nagios for monitoring controls IOCs, workstations, services and servers. Nagios combined with the Alarm system [5] has been of a great utility during the commissioning and operation.

INSTALLATION

The installation of the control system started with a prototype for the control system of the Linac-to-Booster transfer line (LTB), which was installed at the end of 2007. That installation served to test our management tools, external contractors, and to tune the project planning and execution. The year 2008 was mainly focused on the mechanical installation of the equipments of the Accelerator. In 2009 the booster was carried out and in 2010 the Storage Ring. The installation of the controls for the Beamlines was more spread in time. It has mostly occurred between 2010 and 2011.

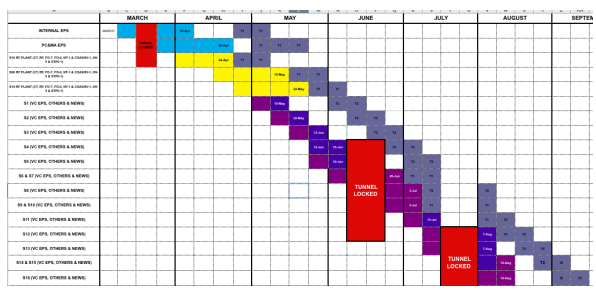

Figure 2: Cabling installation and verification, sequenced over the 16 sectors.

One of the biggest challenges was the coordination of the cabling in the different sectors combined with the check of the different subsystems, in particular EPS. The installation of the cabling for the Accelerators has been accomplished roughly in thirteen months, four months for

installing about 1200 cables of the booster and nine months for installing the 9000 of the storage ring.

MANAGEMENT TOOLS

During the installation and commissioning, a detailed plan, the commitment of many people including external contractors, and the assistance of a number software applications have been determinant for success. The most important are the cabling database [6], the request tracker (RT), the timeDB and the project management tool.

Cabling Database

A central database manages all the definitions, names and plug information related to equipments and cables. This is the central repository where types of equipments, cables and connectors are declared allowing later managing instances of every item. The types of equipment, connectors, cables and "cable configurations" are defined and inventoried as the first step. Next, instances of equipments, cables and connections between equipments are defined. Once this was completed, the cable lengths have been calculated and the manufacturing order has been determined. After the cables have been received they were installed in the final position, labelled and verified. The cable database plays a key role in all phases. Reports for manufacturing, labels, and diagnosis of the tests are generated from the database. In order to do this, the information must be consistent at any time. This has been a great challenge and an important key for the success.

Having a consistent and up-to-date central repository of the equipments and cables for the control system opens many new possibilities from the installation and operation point of view. During the pre-installation phase, the equipments were assembled, mounted and tested in the warehouse, and the record of those tests was kept in the database. Also valuable information like MAC addresses, IP addresses, boot servers, etc. was added during this phase. This made possible to create from the cabling database, configuration files for several network services, such as DNS, DHCP, Radius.

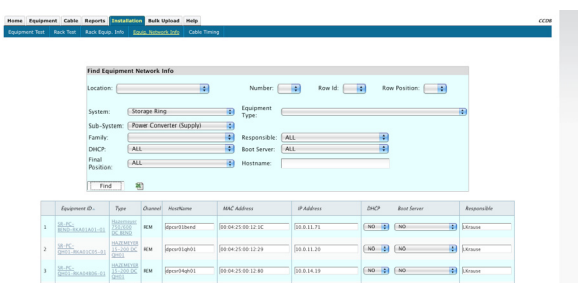

Figure 3: Snapshot of the web interface of the Equipment and Cabling database.

Many components of programs running in the PLCs of the Equipment Protection System are generated automatically from the database. The huge effort done for keeping the database up-to-date and consistent pays back here, when software components are generated automatically, reducing errors and increasing the efficiency. A Visual Basic Script running in excel creates files containing the declaration of variables, data structures, software tasks, Modbus mapping and documentation. The Logic is still programmed manually due to the difficulty managing the large number of exceptions to the standard interlock rules. In addition, Tango attribute names and the expert GUIs are also generated from the controls equipment and cabling database.

RT

RT (Best Practical Solutions LCC), has been intensively used in the computing division. It is a great tool for implementing ITIL [7] practices. Tickets are distinguished between Incidents, problems, User Requests and Request for changes. After their creation they are assigned to Unit services and to a responsible.

TimeDB and the Project Management Tool

The time spent in projects, services, problems or any other task is logged and managed by another web application, the timeDB.

Projects are managed following the PRINCE2 methodology [8], and assisted by the Computing Project Management tool, another application developed by th Management Information System group (MIS), and extensively used by the entire Computing division. It handles Business Cases, Plans, Risks, Communication management, etc. up to Project Initiation, Highlight and Exception Reports.

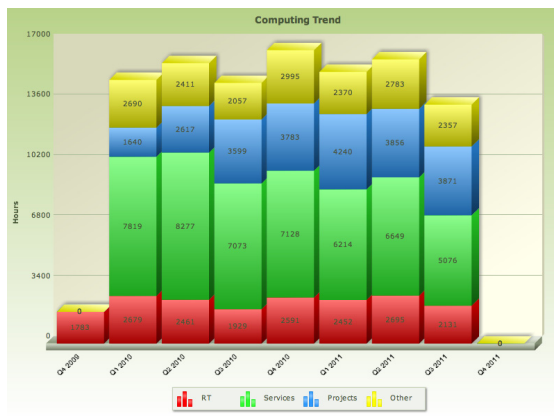

Figure 4: Trend chart of the time allocated in the computing division in the years 2010 and 2011. Green corresponds to Services, Blue to projects and Red to RT.

COMMISSIONING

The commissioning of the control system started at the beginning of 2008. A prototype of served to both test the concept and do commissioning of the LINAC and the transfer line. Later, at the end of 2009 the commissioning of the Booster started. It took place during few days in

2009 and the first weeks of 2010. At that time, RT was setup and tuned, adding the concept of services (as described in ITIL best practices), combined with incidences, problems and different type of requests. We also improved the project management tool and the timeDB.

In November 2010, the control system for the machine was ready for operation, but unfortunately, due to a delay in the authorization permit issued by the local authorities, we started only few weeks later, the eight of March 2011. In the meanwhile, we changed the schedule and we installed 3 (out of 6) insertion devices. The 16th March 2011 we had the first accumulated beam and the 18th we opened the first Front-End (BL09: a Beamline on a Bending magnet). In June the Front-Ends corresponding to the two helicoidal undulators and the conventional wiggler were open. The Machine was shutdown the tenth of June, to allow the installation of the remaining insertion devices.

During the summer we installed two in-vacuum undulators and one superconducting wiggler. We setup the cabling, electronics and the control system and we restarted the machine at the end of August.

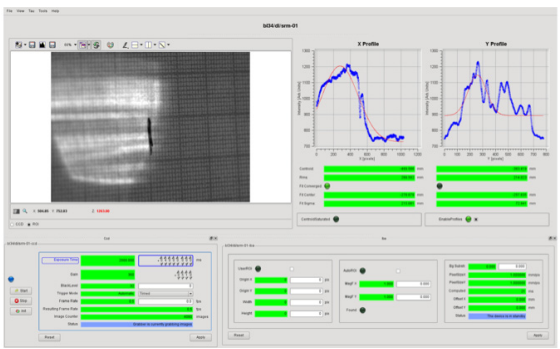

Figure 5: Snapshot of the first beam seen as visible light from a bending magnet taken the diagnostics Beamline.

During the commissioning, the management tools and the on-call service were fully operational. The computing division had a total of four persons on-call simultaneously, two controls engineers, one Electronics engineer and one system administrator. In the RT's controls queue, there were 192 standard requests and 49 tickets directed to the on-call service. These tickets were about half incidents half request for changes.

There were few looses of the beam due to the control system. Most of these unjustified interruptions of the service, have been due to Interlocks, either provoked by the Personnel Safety System (false intrusions or errors in the logic activating the beam killer) or by the Equipment Protection system (Interlock boards, water cooling, Ethernet Powerlink communications). Both are particular sensitive to any issue because they operate in many cases directly stopping the accelerators. After the first days where the issues were identified and fixed in the case of the EPS and avoided in the case of the PSS, the number unexpected interlocks was remarkably reduced. The PSS was fixed on the 23rd of June, and is already accepted and certified by TÜV.

CONCLUSION

The commissioning of the control system is an important and time-consuming task, which shall be planned, and considered accordingly in the time schedule. It is particularly tricky, because it is the last one before the commissioning of the accelerators, and it has dependencies with all the predecessors, hardware installation, equipments, fluids, sensors, cables, etc. It is necessary to break it down in parts, typically divided in subsystems, and always regarding the progress of the installation of the equipments. The equipment protection system is a particularly complex example, because it is spread all over the place, counting more than eight thousand signals installed at different times in different places. It always required three phases; checking of the cables, functional tests of the subsystem or sector and finally the general functional test.

Having a pre-installation campaign was crucial for speeding up the final installation. Most racks were preinstalled in 2007 and 2008, including equipments and internal cables, which resulted in a significant workload advanced in time.

The management tools, in particular the cabling database was crucial for maintaining the consistency and reducing the tests and early maintenance costs.

Although for a new installation like Alba, apparently operation and installation do not interfere, it was not the case. During the installation, there were quite a few "routine" operations, like Factory and Site acceptance tests of equipments, Bake-outs of vacuum chambers and equipments, etc. which implicated the different support groups in Computing, having an important impact in the final workforce for development and commissioning.

CONTRIBUTIONS

Many people have worked in this project. This is a work achieved with the effort of the whole computing division. The whole controls, electronics, network system administration groups actively participated in the design, installation and tests of the control system. Among them, the persons in charge of the network, M. Díaz, R. Escriba, had an important role. Furthermore, the help of the Management Information System group, in particular, O. Sánchez, I. Costa, A. Nardella, A. Klora, D. Salvat and V. Prat, who developed and maintained the cabling database, the TimeDB and the Project Management system has been crucial.

ISHN ION SOURCE CONTROL SYSTEM OVERVIEW

M. Eguiraun*, I. Arredondo, M. Campo, J. Feuchtwanger, G. Harper, S. Varnasseri,
ESS Bilbao Consortium, Spain
J. Jugo
University of Basque Country, Spain

Abstract

ISHN project consists on a Penning ion source, which will deliver up to 65 mA of H- beam pulsed at 50 Hz, with a diagnostics vessel for beam testing purposes. The present work summarizes the control system of this research facility. ISHN consists of several power supplies for plasma generation and beam extraction, including auxiliary equipment and several diagnostics elements. The control system implemented with LabVIEW is based on PXI systems from National Instruments, using two chassis connected through a dedicated fiber optic link between the HV platform and ground. Source operation is managed by a real time processor, while additional tasks are performed by means of an FPGA. In addition, the control system uses EPICS Archiver and Hypertable database for data logging. The integration of EPICS into the control system is done by deploying a Channel Access Server in the PXI Controller,.

INTRODUCTION

The ESS-Bilbao (ESSB) light ion linear accelerator has been conceived as a multi-purpose machine, useful as the core of a new standalone accelerator facility in southern Europe [1]. The project aims to develop significant capabilities needed to support the country participation in a good number of accelerator projects worldwide. In this context, the designed accelerator should serve as a benchmark for components and subsystems relevant for the ESS project as well as to provide experience on power accelerators science and technology.

In this context, the development of a front-end test stand for ion sources will allow ESSB to test, develop and optimize ion sources and their working parameters. Currently, a modified penning ion source on loan from ISIS is being tested [2]. This project serves several goals. It generates experimental data that can be contrasted with simulations and it serves as test stand for control systems and hardware (data acquisition, diagnostics, etc.).

A penning type ion source is operated applying a pulsed discharge periodically ($800\mu sec.$, $30A$) to source's cathode, generating a mixed plasma of Hydrogen gas and Caesium vapor. Hydrogen is delivered applying a pulsed voltage to a piezovalve for $250\mu sec.$, and its voltage is automatically controlled for maintaining a constant pressure in the plasma chamber. Once the plasma is stabilized ($\sim 500\mu sec$ later), a pulsed extraction voltage is applied ($300\mu sec.$, $12kVolt$) generating an H^- beam. This pulse diagram is repeated at $50Hz$, see Figure 1. In order to accelerate the beam, the platform high voltage power supply usually runs at $35kVolt$. In addition, a continuos power supply ($600V$ and $2A$) is needed for conditioning ion source's electrodes. This power supply is only used in the beginning of the operation. The main devices required for source operation are listed in Table 1

*meguiraun@essbilbao.org

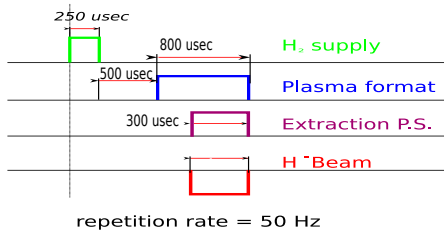

Figure 1: Pulse diagram for beam generation.

Table 1: Main Devices for Ion Source Operation.

Utilities	*Plasma creation*
Cs Heaters	DC Power Supply
H_2O Refrigeration	Pulsed Power Supply
Air Refrigeration	H_2 Piezovalve
Vacuum pumps and sensors	
Beam Extraction	
Extraction Power Supply	
High Voltage Platform Power Supply	

Once the beam is extracted, it goes through the so called diagnostics vessel, Figure 2 picture. The first diagnostics are the current transformers (ACCT and DCCT). Then, a quadrupole focuses the beam and a dipole is used for obtaining information about the degree of stripping and beam species components. The least beam diagnostics are a Faraday Cup for measurement of beam current, a Retarding Energy Analyzer for energy spread analysis, and, finally, a pepperpot device for obtaining emittance values. These devices, cannot be activated simultaneously and are also used as beam stoppers.

The control system is in charge of all of these elements, ensuring its correct operation and granting safety for both personnel and machine. In the following section, the architecture of the system will be explained, extending the information of [3].

CONTROL SYSTEM OVERVIEW

The control system architecture can be observed in Figure 3. Due to the high voltage in the platform, the main

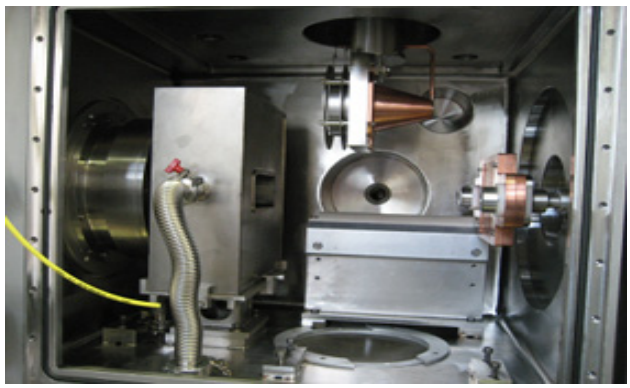

Figure 2: Diagnostic devices: from left to right, ACCT and DCCT (not visible), Quadrupole, Dipole, Faraday Cup, RPA (behind) and Pepperpot grid.

system is divided into two control subsystems, located at ground and at the platform, respectively. Each area has its own operator panel, allowing the operation of the ion source from both control desks, but not simultaneously. However, continuos monitorization and data logging of the status of the system is always active in the both panels.

The control system architecture for source operation and data acquisition is mainly based on hardware from National Instruments. Two PXI (PXI-1042Q and PXIe-1065) chassis are used, one at ground and other at platform. They are linked with a dedicated MXI fiber optic card from same vendor, and therefore, the two-chassis system can be treated as a single element from the point of view of the control designer.

The chassis located at ground contains a Real Time controller programmed in LabVIEW. It manages Cesium boilers' and pressure's control loops, some data acquisition through other PXI cards and the FPGA and communication with the operator's control desk using shared variables. It also communicates with some power supplies by Modbus/TCP and GPIB and pressure sensor by serial protocol link. In addition, the EPICS server is deployed in this device.

On the other hand, the FPGA located on the HV platform controls diverse elements. It manages the pulse signals for plasma power supplies and H_2 supply, generating the pulse diagram of Figure 1. In addition, it manages some safety signals from and to plasma power supplies and controls several electrovalves for gas supply and refrigeration of the ion source. Being the only card with signal acquisition capabilities in platform, it is in charge of acquiring voltage and current waveforms from plasma generation power supplies. Furthermore, it also measures gas flow rate, temperatures of the ion source and some other standard parameters.

As there are two operator panels, the code should avoid data overwriting between both monitorization applications. Therefore, two mode of operation are defined: local and remote.

All the code has been programmed in LabVIEW: the Real Time application, the FPGA and both monitorization programs.The main operator panel runs in a Linux environment. This is recommendable since the necessity of the EPICS archive engine.

In addition to the main controllers, a Twido PLC manages the operation of the vacuum system, which consists of two mechanical and two turbomolecular pumps. The advantage of this modular solution is to have the ability of performing stops and upgrades of the main control system without disturbing vacuum operation. This is very important in the commissioning phase, where adjustments of diverse elements and minor changes of the control system are usual. Moreover, a modular control approach leads to the possibility of reuse code and proposed control solution in other projects.

Two safety PLCs from PILZ located in both cabinets ensures safety during operation. The one located at ground handles several safety sensors (doors, grounding arm status, ...) and ensures that power supplies only receive electrical supply if safety environment is guaranteed. The safety PLC located in the platform handles the signals related to the H_2 supply and the electrical power supply of the Cs heaters. If any problem is detected or if the emergency stop is pressed, safety system shutdowns high voltage power supplies.

The fiber optic link is used for ethernet communication, and the real time controller, both monitor panels, plasma power supplies, PLCs and some other noncritical devices are attached to this network.

The following sections will briefly explain the main changes that have been implemented in the last upgrade. The most important one is the addition of an EPICS server to system, along with a new data logging system, based also in EPICS. Finally, the timing system is explained.

EPICS Integration

With additional minor improvements and modifications in current control system, an EPICS server has been implemented. It is based on the implementation by National Instruments (LabVIEW DSC module), and runs on the real time system in the PXI controller. As the first version of the program was a pure Labview implementation, some parameters of the control system are left out from EPICS server, for example some PID gains. The parameters that are published via EPICS are mainly for system configuration and machine operation, along with data acquisition variables, resulting in 65 Process Variables. The current implementation lacks of several critical capabilities of PVs such as alarm handling and extended field support. For that reason, EPICS server is used just to communication, without the full functionality that an IOC provides.

The Real Time controller publishes those PVs taking data from LabVIEW's Shared Variables, but since the main operator panel runs on Linux (there is not support for SV on Linux), this program must read and write data directly

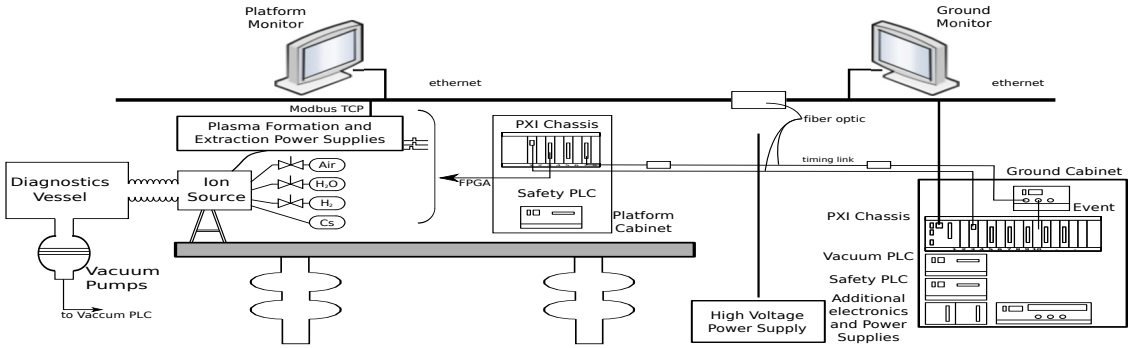

Figure 3: Control System Architecture.

from and to EPICS PVs. For that purpose CA Lab LabVIEW library is used [4]. It provides some vi-s for interfacing EPICS and LabVIEW and can be compiled for a Linux environment.

An alternative to NI approach is the one presented in [5], a pure CA server implementation in LabVIEW. It is under development but once released it will be tested to check if it fulfills the control requirements as presented in this work.

Data Archiving

As far as the database architecture is concerned, it was decided to keep the MySQL schema provided by the ArchiveEngine utility [6], an EPICS ChannelAccess client. Using this client, any channel served by any ChannelAccess server can automatically saved to a relational database, like MySQL or Oracle. In present case, Hyperachiver, a customized version of the RDB Archiver, and HyperTable, as an alternative database to MySQL or Oracle, are used. This has been developed at INFN laboratories at Legnaro (Italy) and modified in ESSB to fulfills ISHN project requirements. Since this database choice requires a linux environment, the current implementations is running on Fedora14.

PVs of array type are stored every $5sec$, the rest of the variables at $1sec$ except the ones that are recorded only on changes. This gives a total amount of data around $100MB/hour$. A graphical user interface was developed in python at ESS-Bilbao in order to have at disposal a simple data visualization tool, lighter than CSS and, as it was proved by the tests' results, faster than CSS Data Browser, which had already been used by people at INFN/LNL.

Timing System

An independent high resolution synchronization system has been designed to generate timing for triggers of plasma generation and extraction as well as data acquisition for beam diagnostics. The current design is based on commercial devices. A master event generator located at ground cabinet produces two event signals at $50Hz$. One needed in ground PXI to trigger data acquisition for beam current transformers and Faraday Cup, and the other one to trigger the generation of pulses for the plasma formation power supplies, passing through electrical-optical converters. On each chassis there is a stable and precise dedicated timing card (PXIe-6672 and PXI-6651) which receives the event signal and routes it to a PXI Trigger line. Then, a DAQ card at ground and the FPGA inside the chassis of platform starts data acquisition and pulse generation, respectively. The approximate delay of the signal due to the optical-electrical converters and the difference in cable length is around $100nsec.$, which is compensated in the event generator configuration.

FUTURE WORK

The ISNH control system is under development in various aspects, as for example the timing system. Some delay cards (Green Field technology GFT-9404) are being tested in the laboratory, but the lack of LabVEW Real Time support prevents for its usage in the facility.

In addition, full features of EPICS will be implemented, by means of a different implementation, or by deploying an extra IOC in the host computer. The most interesting features are first, the alarm handling through the so called alarm server and its operation in Control System Studio. Even if it is not required at this development stage, the EPICS gateway and nameserver are also interesting features to be implemented.

SOLARIS PROJECT STATUS AND CHALLENGES*

P. P. Goryl#, C. J. Bocchetta, K. Królas, M. Młynarczyk, R. Nietubyć, M. J. Stankiewicz, P. Tracz, Ł. Walczak, A. I. Wawrzyniak, National Synchrotron Radiation Centre Solaris at the Jagiellonian University, Krakow, Poland
K. Larsson, D. Spruce, MAX IV Laboratories, Lund, Sweden

Abstract

The Polish synchrotron radiation facility, Solaris, is being built in Krakow. The project is strongly linked to the MAX-IV project and the 1.5 GeV storage ring. An overview will be given of activities and of the control system and will outline the similarities and differences between the two machines.

INTRODUCTION

The first synchrotron light source in Poland will be built in Krakow. It will be located at the III Campus of the Jagiellonian University. The project is hosted by the Jagiellonian University and funded with EU regional development funds of 143 MPLN. The contract for the establishment of the National Synchrotron Radiation Centre Solaris was signed between the Jagiellonian University and the Polish State on March 9th, 2010.

MAX IV Collaboration

The agreement between the Jagiellonian University and Lund University in Sweden is crucial for the success of the Solaris project. It was signed in November, 2010 following earlier Memorandum of Understanding. According to the agreement between these institutions, the Solaris facility will be built based on the MAX IV design. The project is based on a close cooperation with the MAX IV project. MAX IV provides not only design but also expertise, support and training for the Solaris team.

Machine Description

Machine will consist of a 1.5 GeV ring and a 550 MeV linac injector (see Fig. 1). The ring will be an exact copy of the smaller ring of the MAX IV project but with differences in beamlines, insertion devices and general infra-structure.

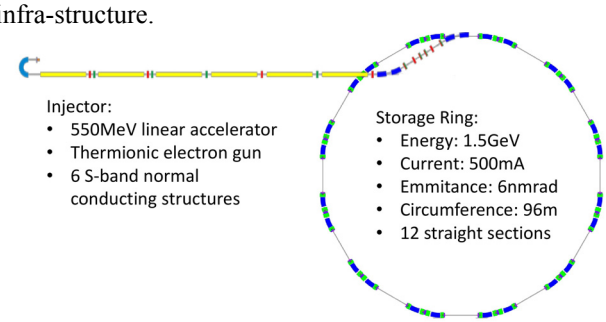

Figure 1: Layout of the machine.

* Work supported by the European Regional Development Fund within the frame of the Innovative Economy Operational Program: POIG.02.01.00-12-213/09
#piotr.goryl@uj.edu.pl

A thermionic electron gun will be used as the source of electrons. The beam will then be accelerated by an S-band normal conducting linac. The linac injector will be built with the same components of MAX IV incorporating similar design concepts. Since at the first stage of solaris the linac will not provide full energy injection, a ramping procedure will be implemented. Infra-structure and the design of the accelerators will permit a future implementation of top-up [2].

CURRENT STATUS AND ACTIVITIES

The status of Solaris has been reported in [1]. In this paper the control system status and IT related issues will be emphasized.

Since the machine will be a replica of the MAX IV 1.5 GeV ring it is reasonable to have the same control system solutions. Therefore most of the control system concepts for Solaris follow relevant ones for MAX IV.

The TANGO [4] control system and its dedicated tools have been chosen for the integration layer. TANGO has been implemented at several laboratories in Europe and found to be both reliable and mature. Close collaboration between laboratories involved in TANGO projects provides plenty of software tools, components and support.

From the tools the TANGO community provides several have been chosen. As an example Sardana developed at ALBA will be used for sequencing purposes. Graphic user interfaces will be built with different tools like Taurus, Jddd, JDraw and the ATK library. Among them Taurus and Python scripting language is preferred.

Development

Subversion and the Redmine server for a source code sharing and projects' tracking have been adopted.

There are several on-going software developments at MAX-lab. Some of them are directly connected to the new facility. Others are for maintaining the current laboratory in operation. All new development at MAX-lab, however, is using the TANGO control system and may be regarded as preparation and proof of the system.

Developments related to future control system include: the pre-injector test stand control system, the Virtual Accelerator and the Allan Bradley PLC device server.

MAX IV is cooperating with Soleil to adopt their motion control standard and evaluate a new standard in the future.

Evaluation

Many of activities are on going to find and evaluate solutions to be implemented for both MAX IV and Solaris. The MAX III ring has been integrated into TANGO using channel access device servers. TANGO historical and temporary archiving is in operation at MAX-lab for more than one year and several beamlines are using TANGO at the facility.

Network Reflective Memory based on the FERMI@Elettra solution is being evaluated and adjusted in cooperation with Fermi [3]. It is likely that MAX IV will use the image acquisition and processing system developed at Fermi too.

Procurements

There are several procurements at MAX IV related to the control system. Recently, two framework agreements have been awarded:

- For control system services and support
- For PLC's hardware and support

All of them include the option for Solaris. According to the agreement between the Jagiellonian and Lund Universities, Solaris may purchase specific hardware or services using a single source procurement procedure to ensure compatibility amongst the two machines.

In parallel to the above activities, the construction of the building infra-structure is on-going in Krakow. It includes power, water and heating, air conditioning, the security system and computer network.

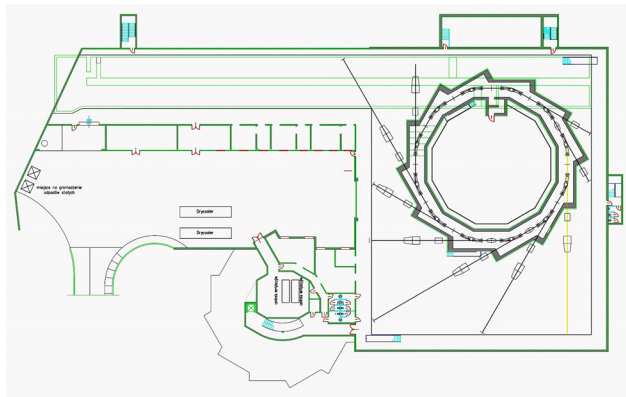

Figure 2: Concept layout of the facility.

Network

The computer network will be connected to the Jagiellonian University campus network. However, it will be operated independently from the rest of University network at least for the accelerator control systems. The general layout has already been designed along with some technological solutions to be used. Separation between the control network, the office network and the campus network will be implemented with VLANs and an on-site firewall. Additionally it is planned to use stackable switches in a main distribution point with the office network and control system network connected to separate similar units (see Fig. 3).

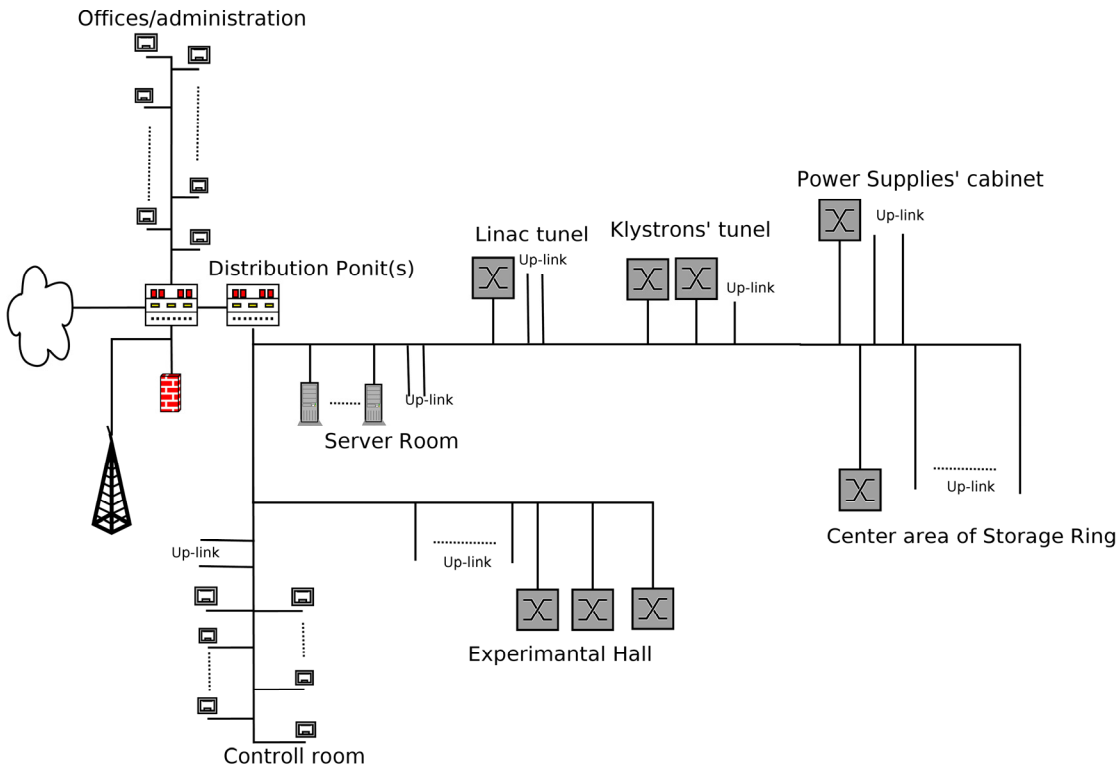

Figure 3: Concept network diagram.

Offices will be equipped with a 1GbE network whereas the accelerator control system will be provided with 10GbE fibre access points in specified locations. At these locations switches will be installed according to needs. Redundancy will be implemented through the provision of backup uplink connections between neighbouring switches, assuming a spanning tree protocol will be used.

This has been found to be a cost effective solution and flexible enough for future upgrades. Compatibility with Network Reflective Memory should be achieved, too.

DIFFERENCES TO MAX IV

In general, the Solaris control system will be identical to MAX IV. The main goal is to have both systems as similar as possible. If there is any dissimilarity at least the same tools (software, protocols etc.) should be used.

Differences between Solaris and MAX IV come mainly from project physical and logical dimensions (scale) and location. The scale of the Solaris project means there is no need to implement all the features of the MAX IV control system. The Solaris team will handle location and environmental differences.

Most of the work resulting from these differences may be related to configuration but it depends on a design of affected element. Configuration may be regarded as a part of installation and not as additional work. However, it may require pre steps like re-designing.

Differences Between Solaris and MAX IV

Listed below are the identified differences grouped by source and in brackets the consequent work.

Location:

- Network (design, configuration)
- Server and equipment location (installation)
- Cable trays (installation)
- Racks (installation)
- Geographical GUIs (design and development)

Equipment differences:

- Beamline (design, development, configuration, installation)
- EPS (configuration, re-development)
- Standard servers and workstation hardware (no impact)

Project scale:

- One mode linac operation
  - Triggering system (configuration)
  - GUIs (simplification, configuration, development)
- No need for Network Reflective Memory or equivalent
- Shorter linac, no bunch compressor
  - GUIs (simplification, configuration, development)
- Ramping (development, configuration)
  - GUIs (configuration, design, development)
  - Operation logic (development, configuration)
- Number of signals
  - Less archiving space
  - Less network load

Environment:

- Staff size (management)
- Office infrastructure and services
- PSS (development, purchase)
- Schedule (management)

Schedule Impacts

MAX IV and Solaris schedules are compatible in terms of purchasing and installation. Commissioning of the Solaris ring will, however, occur before that of the MAX IV rings. This means that Solaris should actively participate and follow work in Lund in preparation of a rapid systems start-up. In the area of the control system this is especially important in regard to eventual debugging of the system during the commissioning phase.

Collaboration

Collaborations with other institutes will be established to cope with differences and to handle additional work. In this respect Memorandums of Understanding with Elettra and ALBA have already been signed. This will provide additional expertise and support too.

CONCLUSION

As outlined in the paper, the Solaris project is progressing. Due to the linking to the MAX IV project the most demanding part of activities is in management. Almost all design and development is being done in Lund by MAX IV team with support being provided by the Solaris group. Work is being undertaken to design, develop and put into operation the Solaris facility and its control system. Solaris will reply on tight cooperation between the Jagiellonian and Lund Universities and on collaboration within the TANGO community. The facility will be built on limited resources and within a short time schedule through shared knowledge, shared expertise, shared workload and rapid training .

THE DIAMOND CONTROL SYSTEM: FIVE YEARS OF OPERATIONS

M. T. Heron, on behalf of the Diamond Control Systems Group, Diamond Light Source, Oxfordshire, UK.

Abstract

Commissioning of the Diamond Light Source accelerators began in the 2005, with routine operation of the storage ring commencing in 2006, and photon beamline operation in January 2007. Since then, the Diamond control system has provided a single interface and abstraction to (nearly) all the equipment required to operate the accelerators and beamlines. It now supports the three accelerators and a suite of twenty photon beamlines and experiment stations. This paper presents an analysis of the operation of the control system and further considers the developments that have taken place in the light of operational experience over this period.

INTRODUCTION

Diamond Light Source [1], is a third-generation 3 GeV synchrotron light source based on a 24-cell double-bend achromatic lattice of 561m circumference. The photon output is optimised for high brightness from undulators and high flux from multi-pole wigglers.

Storage Ring (SR) commissioning was completed in two phases during 2006. An initial phase of commissioning, to establish accumulated beam at 700 MeV in the SR, took place during April and May 2006. This was followed by installation of the insertion devices for the first eight beamlines and a second phase of commissioning to establish operational conditions and undertake photon beamline commissioning. Routine user operation for the first seven photon beamlines began in January 2007.

Since January 2007 there has been an aggressive programming of photon beamline design, installation and commissioning, such that as of September 2011 there are twenty beamlines in operation, four beamlines in advanced construction or commissioning, and eight in various stages of design. During this period there have also been a number of developments of the accelerators to improve the performance and operational reliability. The operational photon beamlines have been developed with increased automation of samples and of data analysis, and the use of new detectors.

All of the above developments have required ongoing development and support from the control system. In addition, the control system has been managed to improve reliability and to prevent the onset of obsolescence.

RECAP ON THE DIAMOND CONTROL SYSTEM

The Diamond Control System [2] uses the EPICS toolkit [3] and provides a high degree of integration of the underlying technical systems. These include all power converters, most diagnostics, vacuum systems, the machine protection system, insertion devices, RF amplifiers, girder alignment, front-ends, photon beamlines, experiment stations, instrumentation and detectors.

Most of this equipment is interfaced through a range of generic VME I/O based on VME IP carriers, IP modules, transition cards and plant interface modules. For motion control, the OMS VME58 is used for straightforward applications; however, for synchronous control, the Delta Tau PMAC controller is used. Programmable Logic Controllers (PLCs) from Omron are used for interlocking and control, e.g. for vacuum valves, whilst for high-end process control applications, such as the Linac, the RF cavities and the cryo-plant controls, the Siemens S7 series of PLCs are used. The control system interfaces to the accelerator technical systems at 32 control and instrumentation areas (CIAs) and to photon beamlines at one or two CIA(s) for each beamline. The CIAs are air-conditioned rooms that maintain a clean and temperature-stabilised environment for the instrumentation.

A fibre optic infrastructure is installed from each of the CIAs back to the Control System Computer Room and from there to the Control Room. The fibres provide two computer networks, a control system network and a secondary computer network, and are also used for the timing systems, for the Machine Protection System and for the beam position feedback system.

A global Machine Protection System (MPS) [4] manages global equipment protection for vacuum vessels and series-connected magnets (SR dipoles, booster dipoles and booster quadrupoles). Whilst water and temperature are managed using PLC-based solutions local to each cell, some of the global interlocks, notably mis-steered beam, require a fast response and are therefore managed by bespoke MPS modules. The timing system uses a central event generator, with receiver modules located in each EPICS IOC.

Development and operational client platforms for the control system are PCs running RedHat Enterprise Linux.

Diamond has standardised on a combination of EPICS and GDA [5] for the control of photon beamlines, experimental stations and detectors. EPICS provides the low-level interface to the hardware and user interface functionality for engineering type operations, whilst GDA provides the science-based interface for the station scientists and visiting users of Diamond. The exception to this is where commercial instrumentation forms the basis of the experimental station.

CONTROL SYSTEM RELIABILITY

From day one of operation of Diamond, every beam loss has been recorded and analysed, along with non-

beam-loss faults, to understand failures. During the period 2007 to 2011 the number of operating hours per year has increased from 3048 hrs to 4848 hrs and the MTBF for the year has increased from 10 hrs to 53 hrs. Over this period, the number of beam loss faults caused by the control system (software, hardware and machine protection system induced) has fallen, as shown in Figure 1.

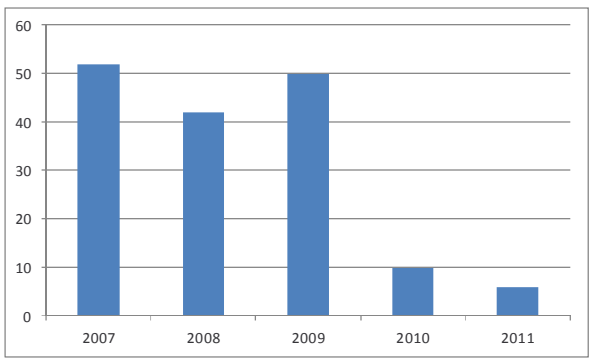

Figure 1: Number of control system faults by year to dump stored beam. For 2011, only 3648 hours have been operated out of 4848 scheduled hours.

The control system faults in 2007 were caused by a series of MPS faults related to the MPS logic for front ends, enabling beamline faults to propagate through the front ends and so causing the electron beam to be dumped. The requirements for the protection were reviewed and new logic applied to minimise these trips. This highlighted the need to take input from operations into account in the hazard analysis and assessment process.

In 2008 the faults were dominated by a series of faults in the global MPS system. These were difficult to diagnose as the beam loss causes all electron beam position monitors (BPMs) to indicate an orbit excursion interlock, within the sample time of the clock latching on the first interlock. The cause of the MPS fault was diagnosed to be a failure of optical transmitters and insufficient optical budget. In the first place the local MPS module transmitters were modified, and subsequently the global MPS module was redesigned to provide a post mortem capability. This problem highlighted the difficulties in diagnosing faults which are effectively in a feedback loop with the beam system and are beam critical.

In 2009 the faults were dominated by a failure of the Fast Orbit Feedback (FOFB), which despite traps in the software to shutdown the FOFB gracefully, still dumped the beam. It was again an intermittent fault and was due to a fault on the VME back plane on the bus grant acknowledge chain in one of the 24 VME crate controllers used for orbit feedback (possibly as a result of a tin whisker). This was again difficult to diagnose as it was intermittent and in the feedback so that it dumped the electron beam.

Whilst the underlying EPICS base software is very stable and the large deployed base quickly highlights any significant problems in new releases, each control system also includes many in-house-developed components (device drivers, database and configuration). Work has been performed on a number of tools to automate the building of EPICS databases [6] thereby minimising configuration errors, and on building unit tests for all in-house support modules. However, so far the unit tests have only been developed for a fraction of the total number of modules used.

MAJOR DEVELOPMENTS SINCE FIRST OPERATIONS

Since first operation, Diamond has installed fifteen photon beamlines, experimental stations and associated front ends. These have required in-vacuum, ex-vacuum, and cryo-cooled permanent-magnet insertion devices and two superconducting multi-pole wigglers. These have required two significant lattice modifications [7] for routine operation, adding additional quadrupoles to the SR, and a new lattice tuning for low-alpha operation to deliver electron bunch lengths of a few picoseconds. All of these have been supported by the control system. The following presents some key developments of the accelerator and beamlines involving the control system.

Control System

The machine control system was predominantly deployed with EPICS 3.13.9, (3.14.6 for Libera and soft simulations) as this was the stable version of EPICS in 2003 and so provided a stable platform for in-house work and for external suppliers delivering turn-key systems. The beamline control systems which started in development in 2005 adopted EPICS version 3.14.8.2. During the period 2008 to 2011, the machine control system was upgraded to 3.14.8.2. The difference in process and environment meant that the changes were involved and so required considerable testing. All the control systems are now in the process of being upgraded to EPICS version 3.14.11, and the policy is to try and keep all systems on a common version of EPICS base, core components and modules.

All development and operational client systems are Linux-based, whilst servers predominantly run under Linux or VxWorks, with a few Windows systems where only Windows drivers are available for a given piece of hardware. The version of Linux has been steadily upgraded such that it is currently Enterprise Linux 5, with a move to Enterprise 6 and 64 bit platforms in progress. In order to ensure quality of deployment, all applications are built on a build- and deployment-server, thereby ensuring consistency of the tool chain for the build of all operational systems.

Fast Orbit Feed Back

Diamond commenced operation running a client application to correct the orbit manually, after injection,

then once per second during stored beam. This addressed issues from long term drift but did not suppress a range of disturbance induced from changing ID gap or from the environment. During 2007 the Diamond FOFB [8] was commissioned. It takes the data, at a 10 kHz update rate, from the 172 electron BPMs to 24 VME processor cards, which carry out the feedback processing to update the 344 corrector PSUs. It uses a low-latency high-bandwidth data path which is realised by connecting the Libera units and the computation nodes using the high-speed serial interconnections available on the Xilinx FPGAs. The interconnection is realised over a fibre optic link using the Diamond Communication Controller designed and implemented in VHDL. It provides excellent rejection of disturbances from ID scanning and environmental effects up to ~100Hz.

The data path further feeds an on-line spectral analysis application, and since 2010 this data is being recorded in a short-term archiver [9], storing the most recent three days of data to enable subsequent analysis of reported disturbances. Measurements of the forward and reflected powers and phases into each of the RF cavities have also been included by using the Libera electronics as RF power meters, and from that data, disturbances originating from the RF amplifiers were identified. Current work has included the design of an interface from the communication network to photon BPMs, to incorporate BPM data into the fast archive.

Whilst FOFB achieves the desired electron beam stability of better than 10% in beam dimensions, it is foreseen that improvements in this performance are likely to be required in the future. In preparation for this, the booster synchrotron is being operated as a storage ring at 100 MeV to develop and test new control algorithms for improved FOFB operation on the SR [10].

Top-up Operation

The initial design of Diamond made provision for top-up operation in the accelerator technical systems including the control system and Personnel Safety System (PSS). As part of the implementation of top-up [11], a hazard analysis was undertaken to define a safe operating regime. This defined limits on the integrated radiation losses and transfer efficiencies, and PSS logic for injection with shutters open, such that excursions outside these constraints would cause the electron beam to be dumped by the PSS. Critical parameters must stay within the safe operating window to avoid unnecessary beam dumps and ensure reliable operation. When a problem develops, it must therefore be detected before the PSS dumps the beam, causing machine operation to drop back to decay mode and so preventing beam loss. This supervision of top-up is managed by a client application implemented in Python and Qt which ensures that these requirements are met. It further generates and compiles statistics on the operation of the technical systems required, e.g. transfer efficiencies through each of the accelerators. These are produced for the last shot, the last 10 shots, the last hour, the last six hours and the last 24 hours and so give visibility to developing problems.

Top-up operation also required the provision of additional timing signals to each of the experimental stations, as both hardware signals and EPICS PVs, to gate data acquisition during the injection when the photon beam is disturbed by the effect of the injection kickers on the stored beam.

Archiving

Diamond has tried to archive as much information as possible about the environment, accelerators and beamlines. This is valuable in diagnosing beam losses and also in understanding and characterising long-term behaviour. By 2010 there were 12.5 TB of data on line, and the system was reaching the storage capacity; further, the storage rate was approaching the limits of the hardware, and the retrieval time had become unacceptable for both very wide (in terms of number of process variables) queries and for very deep (going back in time) queries. Despite segregation of indices by technical area, the 2 GB index limit was being reached. To address these problems, new hardware consisting of 36 TB of disk in a RAID 5 configuration has been installed. The 2 GB index limit has been eliminated from the code by moving from 32-bit file addressing to 64-bit, allowing a single master index to be implemented. The XMLRPC query interface has been extended to return structured arrays of data in one query. However, it is recognised that this solution is still close to what is achievable in terms of performance from the current architecture [12]. Increases in the amount of data archived or further improvements in retrieval times will require a new storage architecture.

Motion Control

Motion is realised through a variety of motion controllers which all use the EPICS Motor record to give a common interface. As part of this we have developed a system for co-ordinated motion over multiple axes [13]. Traditionally a sample has been scanned in a stop-start way, with acceleration time limiting the rate of acquisition. To address this, trajectory scanning has been developed, whereby complex motion is pre-programmed in to the motion controller, and a hardware trigger is used to take the data on the fly. The result has been a reduction in the time taken by a data scan for EXAFS from 50 minutes to 60 seconds [14].

Video Cameras

Support for video cameras was initially standardised on a range of cameras using the Firewire interface. These were interfaced with PMC Firewire interfaces located on VME processor boards and a commercial, (binary only) Firewire stack running under VxWorks. With limited numbers of cameras per bus and limited bus length these worked reasonably reliably, but the interface failed to support the specified maximum number of cameras per bus, and so it was migrated to use PCs and Linux. Again this failed to support reliably multiple cameras per bus.

Only on detailed investigation did it become clear that the Firewire stacks under both VxWorks and Linux were not full implementations of the standard. The most complete implementation tested was under that running under Windows XP. With Firewire declining in popularity, cameras are now being interfaced using Ethernet and the GigE protocol [15].

Excalibur Detector

A 2D position-sensitive detector is currently being developed for a range of imaging experiments. It is based on Medipix3 device, a 256 x 256 pixel photon-counting detector. The hardware to interface an array of these devices is being developed jointly with STFC [16]. The detector control, calibration and readout will use EPICS and the EPICS area detector module.

Transverse Multibunch Feedback (TMBF)

To damp coupled-bunch instabilities up to 250 MHz, a TMBF system was developed [17]. It consists of a detector in the form of a set of pick-up buttons, an in-house-developed RF front end, a commercial digital FPGA- based feedback electronic module called Libera Bunch-By-Bunch from Instrumentation Technologies, and stripline kickers. The FPGA functionality and the EPICS interface were developed in house. It provides good suppression of horizontal and vertical instabilities at 250mA beam currents with zero chromaticity, together with a range of operational diagnostic functionalities including continuous measurements of the betatron tune and chromaticity

Future Interface Standards

With a third phase of ten photon beamlines approved in 2010 it was considered timely to review the choice of control system interface platform. A decision was taken to move away from VME and to use network-attached I/O for all new beamlines and photon front ends. The resulting solution uses Ethernet-attached motion controllers, PLCs, cameras and serial devices through terminal servers, and ADCs, DACs and Digital I/O through Ethernet and the Ethercat protocol [18]. The IOC servers are 1U PCs running Linux with a real-time extension, where required.

CONCLUSION

The Diamond control system has met its initial objectives and gone beyond them, particularly in the control of experiment stations, and detectors. The overall contribution to beam losses has been at an acceptable level and early issues contributing to unreliability have been identified and addressed. Nevertheless, control system reliability is an area that continues to receive attention.

However, there remain areas for further improvement, including documentation of the installed system and in provision of unit tests for all mo dules. Both of these activities are limited by the available effort and priority. The latter is likely to be of significant value when a major change in the EPICS base software components is made.

Looking to the immediate future, most of the control system hardware is now six years old. Whilst it is not showing signs of increased failure rates, a number of hardware systems have been subject to end-of-life notifications by manufacturers. In all the cases to date, this obsolescence has been readily managed. Nevertheless, all areas need to be continually assessed such that the risk level from obsolescence presented to the overall project is limited to an acceptable level..

The main EPICS client applications (EDM, Alarm handler) are X11- and Motif-based, and somewhat dated, and so a move away from these applications is now being considered.

Abstract

To meet the increasing demand from user community, China decided to build a world-class spallation neutron source, called CSNS(China Spallation Neutron Source). It can provide users a neutron scattering platform with high flux, wide wavelength range and high efficiency. CSNS construction is expected to start in 2011 and will last 6.5 years. The control system of CSNS is divided into accelerator control system and experimental control system. CSNS Experimental Control System is based on EPICS architecture, offering device operation and device debug interface, communication between devices, environment monitor, machine and personnel protection, interface to accelerator control system, overall system monitor and database service. The control system is divided into 4 parts, such as front control layer, local and global control layer based on EPICS, database and network service and the others. The front control layer is based on YOKOGAWA PLC and other controllers. EPICS includes local and global control layer provides all system control and information exchange. Embedded PLC YOKOGAWA RP61 and others is to be used as communication node between front layer and EPICS. Database service provides system configuration and historical data. From the experience of BESIII, MySQL is an option. The system will be developed in Dongguan, Guangdong province and Beijing. So VPN will be used to help development. Now, total 9 persons are working on this system.

INTRODUCTION TO CONTROL SYSTEM OF TARGET AND INSTRUMENTS

Neutron scattering becomes a more and more important method probe the structure of the microscopic world. In physics, chemistry, biology, life science, material science, new energy, as well as in other applications, Neutron scattering is the widely used as a complementary way to X-ray in advance research.

To meet the increasing demand from user community, China decided to build a world-class spallation neutron source, called CSNS(China Spallation Neutron Source) [1] [2]. It can provide users a neutron scattering platform with high flux, wide wavelength range and high efficiency. CSNS construction is expected to start in 2011 and will last 6.5 years.

The control system of CSNS is divided into accelerator control system and experimental control system. This paper introduces the design and some test work of the experimental control system.

OVERALL TASKS AND SYSTEM ARCHITECTURE

The main tasks of experimental control system includes: providing the global communication platform for the whole target station and instruments; providing global monitoring and database service; providing TPS(Target station Protection System); providing interface to the front end controls ; fan-out of T0 related signals to where needed; interface with the accelerator control system with their cooperation; coordinating the PPS work for the target station and instruments; local control tasks as required.

CSNS Experimental Control System is divided into global control layer (GCL), local control layer (LCL) and front end layer (FEL), as shown in Figure 1. Global control layer and local control layer are based on EPICS.

In Global control layer, network and database service are main task. Device control and TPS are dominated works for front control layer. Sub-system control is the main task of local control layer. All these are integrated in EPICS system.

KEY ISSUES AND TECHNICAL DIFFICULTIES

In Target and Instruments control system, some difficulties and key issues are focused on.

Stability and Reliability of the Key Path and Devices

Stability and reliability is the most important issue of control system. Control on key path is related to the whole system safety and availability.

To achieve this, system self-check is must. All sub system is required to have self-check ability, and the result of self check can be displayed on the central control room. All the status must be stored in database for historical display and trouble shooting in the future.

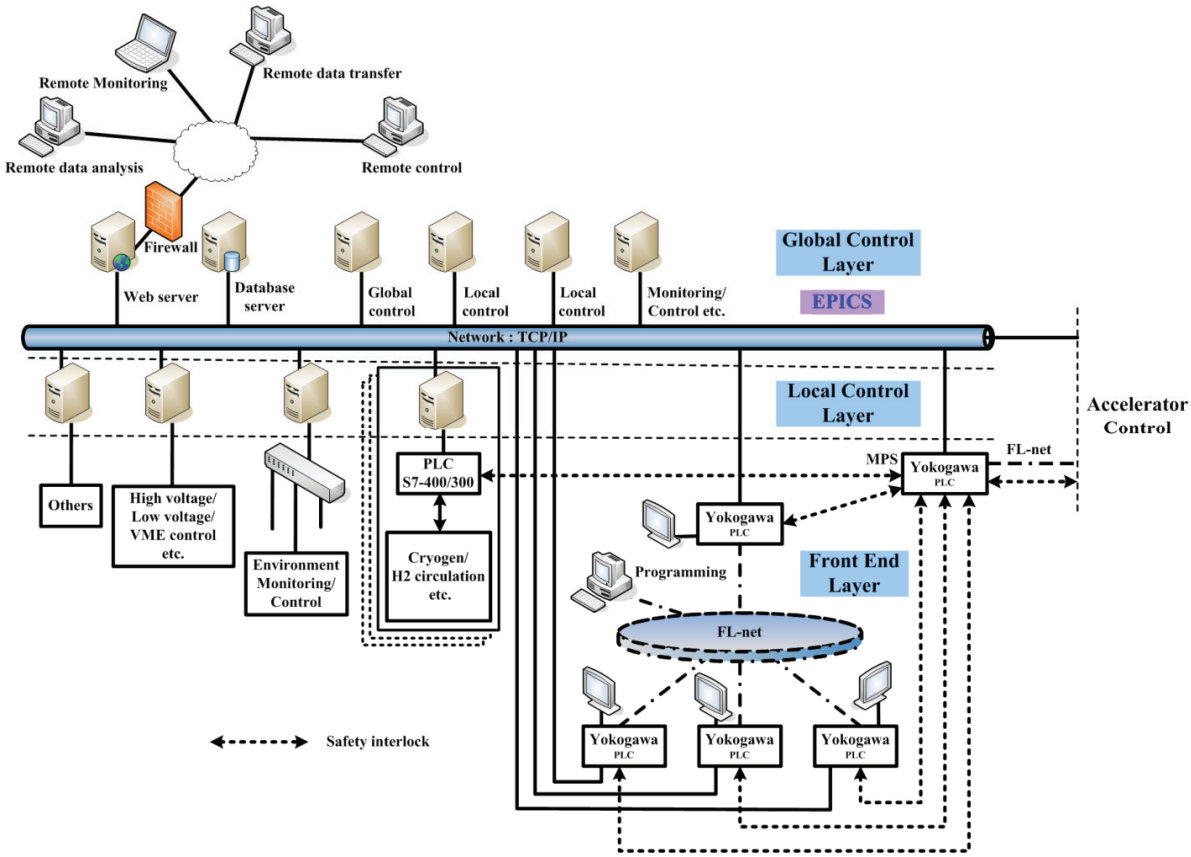

Figure 1: System Architecture.

System Scalability, Maintainability and Configurability

The experimental control system will run for several decades. For long term running, system scalability, maintainability and configurability are main issues that we should be focused on.

Budget

For any system, budget is always an important issue.

Interface with the Front End Control

In instruments, there are always many types of devices for different purpose. So, how to integrate all these devices to the whole control system is a big issue for us.

DESIGN AND TEST STATUS

Epics

CSNS experimental control system is integrated by EPICS control system. To guarantee the Stability and reliability of the system, software version control should be adopted. A software package called CCSP(Control Core Software Package) is created. CCSP includes some selected software, such as EPICS base 3.14.12, Control System Studio 3.0, and some other software. All these software are tested in the function test system to avoid bugs in software version mismatching as shown in Figure 3.

Three kind of IOC is considered to be used in CSNS experimental control system.

The embedded PLC F3RP61 from YOKOGAWA will be used as information exchange and control node in local control layer, between global and front control layer. A lot of test is done on F3RP61. Its performance and role in system is clear.

ARM based IOC will be used in environment monitoring for its low cost as shown in Figure 2. EPICS IOC test is done on a low cost ARM board based on S3C2440 CPU. The results show that illustrates the net performance of this kind board is limited. Graphical interface Qt is developed on this board. This IOC may be used in some device control, and information display.

Blade server or industrial PC is considered to be used as soft IOC to integrate other front layer device into system. Blade server can provide some virtual computers by virtualization software to achieve high reliability, availability and scalability. Soft IOC in virtual computers can provide high reliability data exchange between device and global layer.

Figure 2: IOC based on ARM.

A CA Gateway computer will be placed between experimental control net and accelerator control net to avoid net broadcast storm and increase security of whole system. The test of CA Gateway is also done in function test system, and the policy is decided.

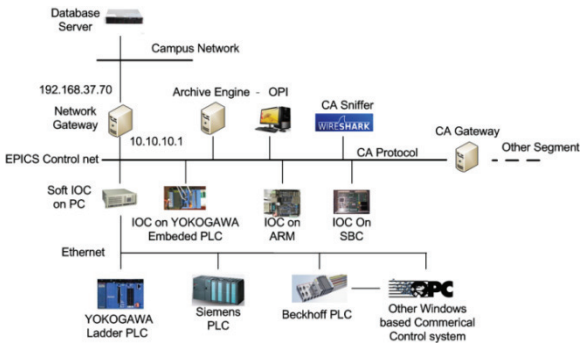

Figure 3: EPICS system architecture. In this figure, all components integrated into EPICS are shown.

Database and Network

MySQL is a choice for the experimental control system, according to its successful application in BESIII. The main advantage of MySQL is free. It can be easily to be developed in distributed environment to achieve database expansion, backup and accessing speed speedup.

Now, MySQL has been integrated into EPICS. Its functions and performance tested is in progress. A long term test and further study will be done next.

The control net spread in 80m x 80m experiment hall. Cables are routed in bridge along the wall. Fibers are used to avoided length limit and interferences Figure 4 shows the topology of the whole control net. Two redundant core switches in control room provide reliable net service. Access switches are placed closed to front device

Front Control

PLC from YOKOGAWA in Japan and Control system from Beckhoff in German are used in front control layer.

The two systems are also test in function test system, and have been integrated into EPICS system.

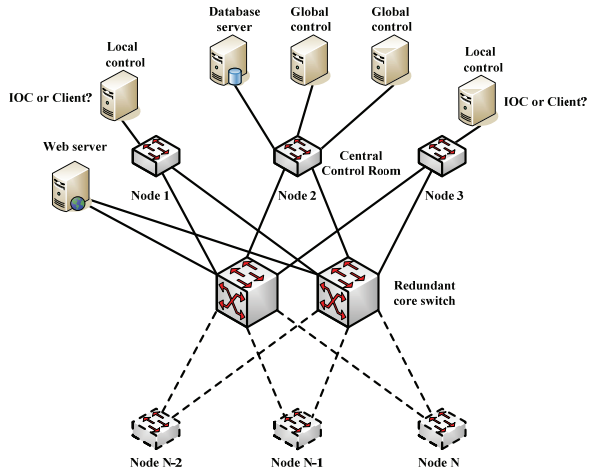

Figure 4: Global control net. The core switch is redundant to avoid shutdown of whole system. And links to core switch is also redundant. The failure of other switch only impact local sub-system.

TPS and PPS

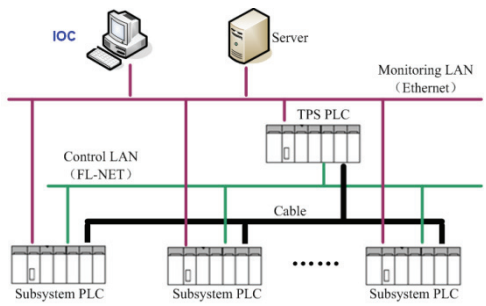

Figure 5: TPS architecture.

Design and technical study of TPS are nearly finished. Figure 5 shows the architecture of TPS. Key interlock signal is routed by hardware, and less important signals are communicated in FL_NET.

A function test system has been established with the heavy water control simulation involved in. A New developing system will setup in Beijing and Dongguan to fulfil the whole system development. Function test system will be upgraded to Beijing segment of the developing system. This function test system is shown in Figure 6.

EPICS software, network, database, archiving and others have all been tested in function test system.VNC, DNS and VPN are also tested which will help integrate the system in two locations into one system.

Function Test System

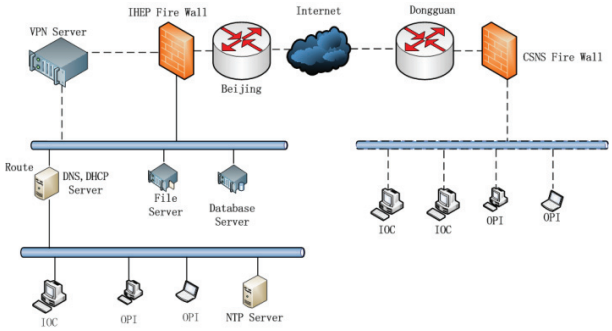

Figure 6: Structure of function test system now and future upgrade. Solid line means what we have already implemented. Dash line means the segment will be build when lab in Dongguan is ready.

Device Control

Some device level control is implemented by control group, which will be help the upper layer test and development. Figure 7 shows the sample platform in HIPD instrument. The platform is driven by 4 servo motors. Servo motors will be controlled by Beckhoff control system through 2 servo amplifier.

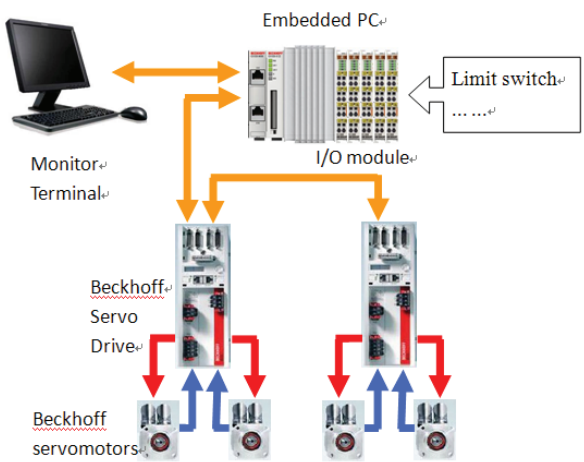

Figure 7: Architecture of sample of HIPD.

Sequence of Events Recording

For control system, sequence of event monitoring is useful for system self-check. On the other hand, sequence of events recording enables rapid root cause analysis after multiple events occurred. Sequence of events is therefore utilized as a diagnostic tool for trouble shooting and minimizing overall downtime. The system structure is shown in Figure 8.

XFC (eXtreme Fast Control Technology) modules from Beckhoff Company are used to build the sequence recording. A test result in Figure 9 shows that this system has a 1us time resolution with some dead time. Next, further study of sequence recording system to achieve higher time resolution to meet the requirements from T0 monitoring will be done.

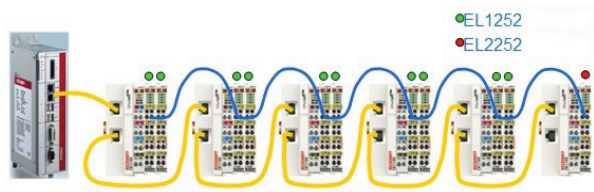

Figure 8: Time resolution test. EL1252 module sends a pulse and all EL2252 measure this pulse and takes a timestamp. The difference of these timestamp is the time resolution of the system.

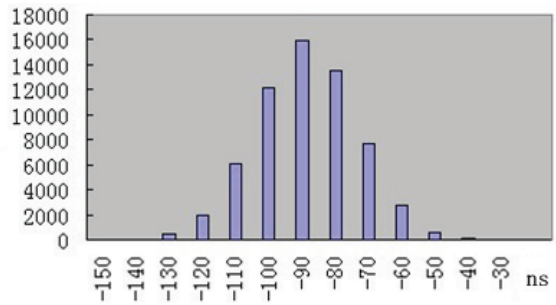

Figure 9: The time resolution of XFC module. X axis means the time difference measured on the same signal. Y axis delegates the sample numbers. The total sample numbers is more than 60,000. And this test also shows there is no big impaction of length of cable and sequence of modules.

NEXT TO DO

In the next two years, setup of the development system, a prototype system of entire CSNS experimental control system is key work. In this system, long-term stability and speed of MySQL; study of CSS and other tools in EPICS further; integration the device into EPICS; design of self-check and alarm system; design of fan-out system of T0 related signals; implementation of TPS and PPS will be done

SUMMARY

In the past, global control layer and some local layer design are finished. Some devices control is under developing now. The function test system is established. EPICS, front controllers and many other techniques have tested.

THE LOCAL CONTROL SYSTEM OF AN UNDULATOR CELL FOR THE EUROPEAN XFEL

S. Karabekyan, R. Pannier, J. Pflüger, European XFEL GmbH, Hamburg, Germany
N. Burandt, J. Kuhn, Beckhoff Automation GmbH, Verl, Germany
A. Schöps, DESY, Hamburg, Germany

Abstract

The European XFEL project is a 4th generation light source. The first beam will be delivered in the beginning of 2015 and will produce spatially coherent ≤80fs short photon pulses with a peak brilliance of 10^{32}-10^{34} photons/s/mm^2/mrad^2/0.1% BW in the energy range from 0.26 to 29 keV at electron beam energies 10.5 GeV, 14 GeV or 17.5 GeV [1, 2]. Three undulator systems SASE 1, SASE 2 and SASE 3 are used to produce photon beams. Each undulator system consists of an array of undulator cells installed in a row along the electron beam. A single undulator cell itself consists of a planar undulator, a phase shifter, magnetic field correction coils and a quadrupole mover. The local control system of the undulator cell is based on industrial components produced by Beckhoff Automation GmbH and a PLC implemented in the TwinCAT system. Four servo motors control the gap between the girders on each undulator with micrometer accuracy. One stepper motor is used for phase shifter control, and two other stepper motors control the position of the quadrupole magnet. The current of magnetic field correction coils as well as the gap of the phase shifter are adjustable as a function of the undulator gap. The high level of synchronization (<<1μs) for the complete undulator system (for instance SASE 2 with 35 undulator cells in total) can be achieved due to implementation of a fast EtherCAT fieldbus system in the local control.

SYSTEM OVERVIEW

At the project start-up stage three undulator systems SASE1, SASE2 and SASE3 will be used to produce photon beams (see Figure 1). The electron bunch train is distributed into two branches by a flattop kicker magnet into SASE1 and SASE2 beam lines, where hard X-ray beams are generated. After passing through SASE1 the electron bunches are used a second time by passing through the SASE3 undulator system to create additional soft X-ray beam.

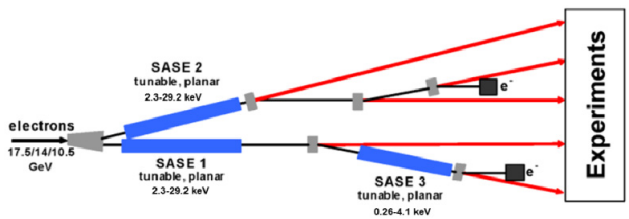

Figure 1: Schematic layout of the electron and photon beam distribution.

The parameters of the undulator systems relevant to the control system are shown in the Table 1 [1-3].

Requirements

The tolerance requirements for the undulator systems relevant to the control system are following [1-6]:

Table 1: Parameters of the Undulator Systems Relevant to the Control System

Photon Beamline	Electron energy GeV	Photon energy keV	Wavelength Å	Gap mm	Magnetic period mm	Quantity of Undulators
SASE 1	10.5	2.3 – 14.9	5.4 – 0.83	10 – 24		
&	14	4.1 – 18.7	3.0 – 0.66	10 – 20	40	35
SASE 2	17.5	6.4 – 29.2	1.9 – 0.43	10 – 20		
	10.5	0.26 – 2.2	47.7 – 5.6	10 – 28		
SASE 3	14	0.47 – 2.6	26.6 – 4.8	10 – 24	68	21
	17.5	0.73 – 4.1	16.9 – 3.0	10 – 24		
						Total: 91

- Undulator gap control accuracy ±1 μm.
- Quadrupole mover positioning repeatability ±1 μm.
- Phase shifter gap control accuracy ± 10 μm.
- Max. Steering Power for Air Coil Correctors ±0.6 Tmm.
- Accuracy of the temperature measurement of magnet structures ± 0.03 K.

The functional requirements to the local undulator cell control are:

- Gap control with low following error (<±10μm).

- Local temperature measurement and appropriate undulator gap correction.
- Undulator gap dependent air coil correction.
- Undulator gap dependent phase shifter control.
- Motion control for quadrupole movers.
- 3 way mixing valve control for the beam pipe temperature stability.
- Safe operation, damage prevention, proper and precise movement limitation, failure detection.

An undulator cell consists of a 5m long undulator segment and a 1.1m long intersection segment (see Figure 2). Four servo motors are used on each undulator to control the gap between girders with micrometer accuracy. One stepper motor is used for phase shifter control, and two other stepper motors control the position of the quadrupole magnet. The current of magnetic field correction coils as well as the gap of the phase shifter are adjustable as a function of the undulator gap.

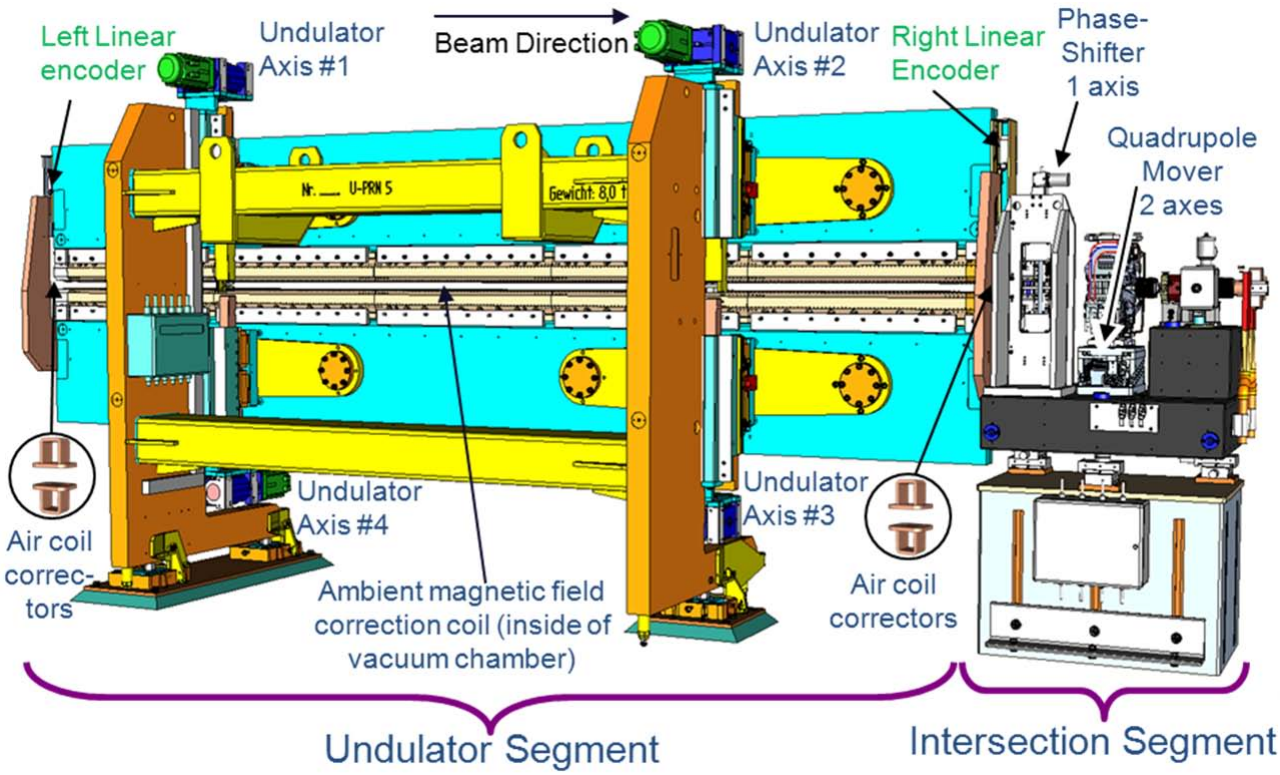

Figure 2: Undulator cell. Undulator and intersection segments in array.

UNDULATOR CELL CONTROL

Control of the Undulator Gap

Each of the four undulator motors is equipped with a rotary multiturn absolute encoder, flanged directly on the axis. In addition to those four encoders each undulator is equipped with two absolute linear encoders, which are installed on both ends of the undulator girders. These linear encoders directly measure the right and left gap between the girders. The undulator can be operated either using rotary encoders or linear encoders as a feedback for the servo drivers. At small gaps the strong magnetic forces cause a deformation of the undulator support frame and thus cause deviations between the linear and the rotary encoder readings. To compensate the influence of these deformations the gap is measured with high precision external gauges during commissioning. The results of these measurements are used to generate curves (see Figure 3) which are implemented as feed forward corrections farther in the PLC program.

If the rotary encoders are used for the gap control, then these correction curves are applied to all four axes.

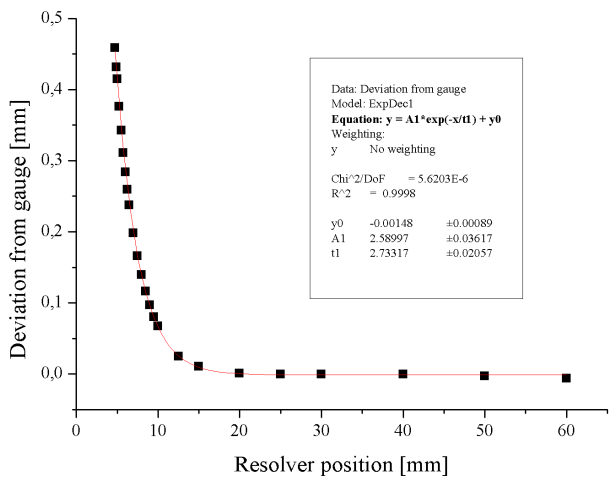

Figure 3: Evaluation of the correction curves for one axis.

In case of using the linear encoders as feedback, the lower two axes are using the corrected value of the rotary encoders as a feedback, while the position of the upper two axes is controlled according to the readings of the linear encoders.

Temperature Drift Compensation

The NdFeB permanent magnet material, which is used to create the magnetic field in the undulator, has a temperature coefficient for its remanent field. These temperature coefficient for the relative magnetic fields $(\Delta B/B)/\Delta T$ in the air gap of the NdFeB dipole magnets is $\sim -1.1\cdot10^{-3}$ K^{-1}. To compensate for magnetic field changes due to temperature variations the gap correction method is used [4]. The required gap correction is calculated in the PLC program. The correction is done according to equation 1:

$$\Delta g_{Loc} = \frac{\lambda_U \eta}{b + 2cg / \lambda_U} \Delta T_{Loc} \qquad (1)$$

where $\Delta T_{\mathrm{Loc}} = T_{\mathrm{Nom}} - T_{\mathrm{Loc}}$, T_{Loc}, is the local temperature, T_{Nom} is the nominal operating temperature of the undulator system, λ_U is the undulator period length, g the undulator gap, η is the reversible temperature coefficient of NdFeB ($-1.1\cdot10^{-3}$ K^{-1}), b and c are empirical constants describing the gap dependence of the peak field.

At 10mm gap, for instance, the temperature dependence for SASE 1 and SASE 2 is ~9.17µm/K, for SASE 3 this dependence is ~15.7µm/K [5].

To provide accurate temperature data three PT100-3 sensors are mounted inside the magnetic structures, one in the middle of the upper structure and two on both edges of the lower structure. The temperature is measured by Almemo 8590-9 Delta-sigma, 24-bit A/D converter.

Control of the Temperature of Vacuum Chamber

In order to avoid bending of the magnet girders by temperature gradients the temperature of the vacuum chamber should not differ from that of the girders. Thermal stabilization is achieved through the cooling water by appropriate mixing of warm (27°C) and cold (18°C) water with 3-way valve. The actual water temperature of the 3-way valve outflow is measured by PT100-3 sensor, which is connected to the same Almemo 8590-9 temperature measuring device, and provides feedback to the PLC program. In the PLC program the water temperature and the temperature of magnetic structure are compared and 3-way valve is controlled to eliminate any deviation.

Magnetic Field Corrections by Means of Air Coils

On each undulator segment two horizontal and vertical air coil correctors are used.

- to compensate residual gap dependent steering errors of the undulator (~ ± 0.1 Tmm),
- to compensate residual gap dependent steering errors of the phase shifter (~ ± 0.05 Tmm),
- for beam ballistic steering of ± 0.45 Tmm

The maximal steering power in horizontal and vertical direction is therefore ±0.6 Tmm.

During operation the air coil correctors are controlled using look up tables. These look-up tables contain the steering strengths as a function of the undulator gap, which are required to compensate 1st and 2nd field integral errors. They need to be derived from magnetic measurements. The required correction currents are calculated from the conversion constants which are in the range 0.4 to 0.67 Tmm/A.

An ambient magnetic field correction coil consisting of just two parallel wires is fitted inside two bores of the vacuum chamber. It's called Two Wire Corrector (TWC). It can be used for compensation of an ambient magnetic field of up to 150µT.

The current for each air coil and the TWC is regulated by means of constant current power supplies controlled via analog output terminals. Direction of the magnetic field is changed by means of polarity reversal relay, which is changing the current direction supplied to the air coil.

Phase Shifter Control

For gap adjustable undulator systems phase shifters are need to adjust the phase between electrons and photons field. The phase shifter for European XFEL is based on permanent magnet technology. The magnet structure consists from four magnetic arrays, two in the top and two in the bottom. The phase is adjusted by changing the gap between upper and lower magnetic arrays. Figure 4 shows the dependence of the phase shifter gap value on the undulator gap value for SASE 2 and SASE 3 at different harmonic numbers [6]. The basic control requirement is that the phase shifter gap has to follow the undulator gap.

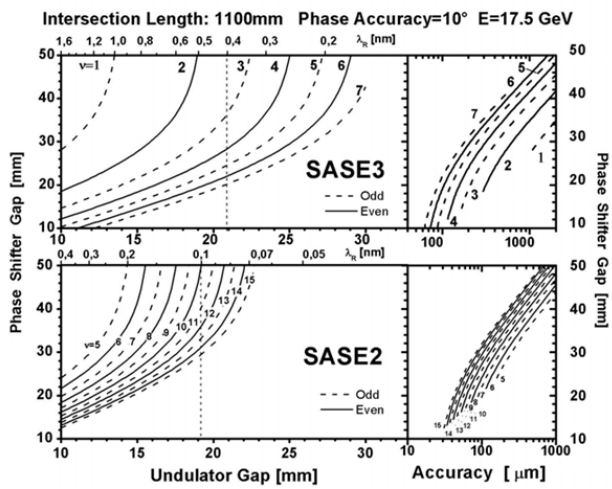

Figure 4: Tuning curves for the phase shifter. The right-hand side graphs show the required gap precision of the phase shifter for to control the phase within ±10°.

The phase shifter is controlled by means of a look up table, which is evaluated from the magnetic tuning curves. Both motion controls, undulator and phase shifter, are synchronized with a following error of ≤10µm.

Motion control for the phase shifter consists of a five-phase stepper motor, a self-locking gearbox with a ratio of i=50, a spindle with right- and left-handed thread with 5 mm pitch, and an incremental linear encoder for position feedback (see Figure 5).

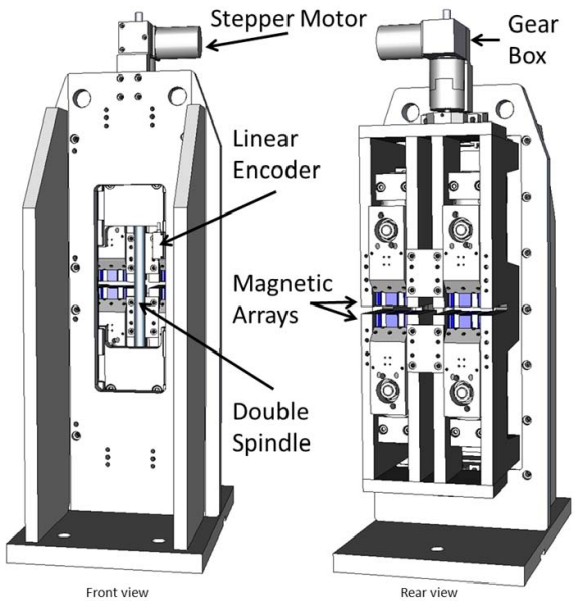

Figure 5: Motion control components of the phase shifter.

Quadrupole Mover Control

The control of the quadrupole magnet movers that are situated between undulator segments is a part of the local undulator control system as well. Information about the quadrupole magnet corrections or the set values in horizontal and vertical directions is obtained from the beam positioning system. This information is received by undulator local control from the accelerator control via the global undulator control system. The requirements to the quadrupole mover control are the following:

- Movement range in horizontal and vertical directions: ±1.5 mm.
- Positioning repeatability in both directions: ±1µm.
- Maximal movement speed in both directions: 1mm/sec.
- Maximum load: 75kg

The quadrupole mover control consists of two actuators for horizontal and vertical movement, driven by five-phase stepper motors and two LVDT sensors as feedback for each motor.

Implementation

The local control system of undulator cell is completely implemented in Beckhoff's PLC and TwinCAT system manager.

The graphical user interface (GUI) consists of following windows:

- Main control window.
- Intersection control.
- Alarm display.
- Axes status.
- System information.

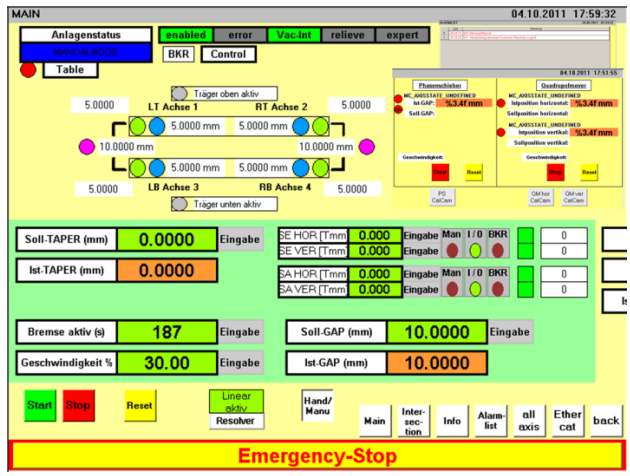

Figure 6: GUI widows of the local control for the undulator cell.

The local control system provides all possibilities for control, monitor and error tracing of each undulator cell. It also provides the interfaces to integrate the local control system into the global undulator control system.

Canadian Light Source, University of Saskatchewan, Saskatoon, Canada

Abstract

The Canadian Light Source is nearing the completion of its suite of Phase II Beamlines and in detailed design of its Phase III Beamlines. The paper presents an overview of the overall approach adopted by CLS in the development of beamline control and data acquisition systems. Building on the experience of our first phase of beamlines the CLS has continued to make extensive use of EPICS with EDM and QT based user interfaces. Increasing interpretive languages such as Python are finding a place in the beamline control systems. Web based environment such as ScienceStudio have also found a prominent place in the control system architecture as we move to tighter integration between data acquisition, visualization and data analysis.

PHASE II AND III BEAMLINES

The Canadian Light Source (CLS) is a 2.9 GeV Synchrotron facility[1] that contains six phase I beamlines in operation, an additional seven phase II beamlines in various stages of development (as listed in Table 1) and an additional seven Phase 3 beamlines under construction. Table 2 provides a comparison of underlying technology used across all of the CLS beamlines.

Table 1: Phase II Beamlines

Name	Application	State
BMIT-BM	Biomedical Imaging	Operational
BMIT-ID	Biomedical Imaging	Commissioning
CMCF2	Protein Crystallography	Operational
REIXS	Emission Spectroscopy Resonant X-ray Scattering	Operational Commissioning
SXRMB	XAFS Micro-Probe	Operational Commissioning
SyLMAND	Lithography	Commissioning
VESPERS	Spectroscopy & Micro-Probe	Operational

To minimise project risk and ensure the cost effective delivery of the beamline control systems the underlying architecture developed for the first phase of beamlines[2] was to a large extent applied again to the Phase II and Phase III development.

EPICS was again used as the underlying platform of the development of CLS new round of beamlines. This permitted us to leverage significant earlier development.

COMMON ELEMENTS

Operating Systems

Linux continued to be the primary operating system platform used at CLS. This was augmented with a more limited number of MS-Windows based data acquisition computers required to support specific commercial off-the shelf (COTS) software.

Though CLS has extensive experience with the use of RTEMS, we have continued to find the need for hard-real real-time applications limited to certain accelerator applications. We continue to evaluate the potential application of RTEMS to our beamlines.

Hardware Platform

We find the use of the Moxa MIPS based controllers (Model UC-7408-LX and DA-662-16-LX) compelling[3]. Over the past four years CLS have deployed 120 of Moxa computers in the facility and has yet to experience any significant hardware failure. The Moxas are used as full fledged EPICS IOCs primarily interfacing Ethernet, USB and Serial devices into the control system.

Modicon Momentum PLCs continue to be used primarily for machine protection. These are interfaced into the CLS control system through Modbus over TCP/IP.

VME64x is primarily used for motion control and data acquisition applications. The Prodex MaxV is used with a combination of drivers [4]. Data acquisition is primarily accomplished with the use of SIS3820 scalar boards.

Network Setup

Each beamline has its own VLAN, with all of the beamline specific IOC and OPI computers located on the VLAN. Any computers that a user brings in to control a user-furnished end-station are also added to this VLAN.

EPICS IOC applications, home directories, applications and users data storage areas are accessed by NFS from a central SAN.

For added security, Ethernet devices are normally connected directly on a secondary network port on a Moxa and are not directly accessible on the VLAN. Beamline specific PLCs are also normally placed on the

accelerator VLAN and accessed through EPICS Gateway software.

Centrify is used to provide unified cross-platform user authentication for access to networked resources such as password authentication and networked file access. This ensures account information is the same on all workstations in the facility, and changes to account information are available immediately.

Virtual Machines

CLS now has two years of experience in the use of VMware ESX based virtual machines in the control system[5]. A common ESX cluster is used for the control system across the accelerator and all of the beamlines. softIOC applications and data analysis applications that do not require specific hardware access are deployed on virtual machines.

EPICS

EPICS continues to be used as the common software platform for integrations of the various sub-systems. The EPICS Gateway provides access to storage ring devices, such as insertion devices.

From the synApps toolkit [6], developed at APS, CLS makes use of asyn and areaDetector libraries. These two libraries are used to interface most of the serial devices found and detectors found on the beamlines.

CLS Extensions to EPICS

The base EPICS software is supplemented by the use of locally developed scanning libraries and experiment specific higher level beamline applications [7].

CLS makes extensive use of the Qt toolkit in building custom extensions. The CLS-IDA and Aquaman are two example of such applications.

Increasingly Python has started to play a more significant role in the development of user applications. The CMCF 1&2 beamlines operator interface software is based on Python and work is underway on the development of an EDM compatible display tool based on Python.

Relational Databases

Predomently mySQL is used for relational databases. MxLIVE, MxDC, and ScienceStudio all make use of mySQL.

BEAMLINE SPECIFIC ELEMENTS

BMIT

The BMIT beamlines use standard CLS motor controls (EPICS, VME, MaxV) for operation of the beamline equipment installed in the optics hutches (including monochromators, filters, slits, shutters etc.). High-level software for device control and beamline monitoring has also been developed using EPICS and EDM screens. Wherever possible, high-level beamline software used by researchers provides an abstraction layer to hide the details of operation of physical beamline components from the user, allowing them to instead specify and achieve their end goal.

Standard CLS control software is supplemented on BMIT with the use of additional software products. LabView programs are used to operate smaller positioning devices within the experimental hutches. Use of this equipment varies widely for different experiment types and sample sizes, and LabView provides beamline staff with the ability to quickly adapt to various experimental configurations. The three large positioning systems on BMIT use Bosch servo motors with low level control functionality provided by Bosch Rexroth IndraMotion MLD drive-integrated PLC programs developed using IndraWorks software. Data acquisition on BMIT is primarily via vendor software particular to the detectors in use on the beamline.

CMCF2

The phase 1 and phase 2 Protein Crystallography beam lines have two major components, the local data collection software, and a web interface. The data collection software, called MxDC [8], was written in house by Michel Fodje, in python using GTK+ (Glib) (reference) as the main application framework with Twisted and Avahi. Access to the beam line for control is accomplished through Epics Channel Access for Python (reference). MxDC was deployed onto the beam line for production use in 2007 and has seen extensive feature additions through constant use and testing as well as user feedback. Using python as the development language has made it easier to interface the data collected locally by users at the beam line with the web based interface MxLIVE.

MxLIVE allows users to describe their samples, submit their experiments, approve strategies, and review results over the web. Developed on the django web framework (Python), MxLIVE is independent of the data collection software, as all communication is through a relational database (MySQL, json). Users may view results as soon as they are collected, and download individual images as well as full datasets directly from MxLIVE. MxLIVE is very popular with both “mail-in” users and users who are coming to the CLS to collect their own data. It was first made available to users in May 2011.

Some sophisticated users who prefer not to travel to the CLS are also enabled to use the data collection software remotely, via a NoMachine interface.

REIXS

REIXS beamline control was based on CLS standard EPICS controls including MAXv motor control and an EPICS based energy application originally developed for the Spectro Microscopy (SM) beamline. The energy application allows simultaneous setting of the monochromator mirror and grating and the gap and girders of one or two elliptically polarizing undulators (epus). Energy scans can be accomplished with one epu or two epus in conjunction with a chopper. Spec is used for RSXS data acquisition and “Aquaman”[9] software developed in a collaboration between the University of Saskatchewan and CLS for XAS and XES data acquisition.

REXIS also contains a limited amounted of SPEC to meet some user specific requirements.

SXRMB

The success of the controls at SXRMB is a reflection of the greater success of software standards at the CLS. Commonality of drivers allows quick reuse of software at both the driver and GUI levels. The initial XAFS commissioning experiments used the HXMA beamline’s C++/Qt IDA application, as well as a number of EDM support screens. This was followed by a customized version of the XAFS software (C++/Qt) used at the SGM beamline, which gives a more integrated data acquisition environment. The microprobe endstation is near

completion, and will be able to use the multi-dimensional scanning and acquisition software (C++/Qt/Root) in use at the VESPERS and HXMA beamlines.

SyLMAND

SyLMAND is also an EPICS based beamline. The Endstation is a pre-pacakged scanner with vendor furnished software running on an MS-Windows platform. To facilitate integration with the beamline, the vendor was provided with EPICS interface libraries for Visual Studio C++.

VESPERS

VESPERS makes use of two different high-level experiment management frameworks: (1) Aquaman and (2) ScienceStudio, Both system are the same underlying EPICS IOC applications and frameworks for device control permitting rapid switching between the two systems.

Acquaman [9] is an experiment-centred framework that encapsulates low level control into coherent objects and exposes, to the end user, only what is necessary to run scientific experiments on the beamline. This enables users with varying levels of synchrotron experience to take data effectively without the need for extensive software training. The primary benefits are three-fold. First, the process of switching between experiment settings is presented in obvious ways without the need of exposing low level hardware. As well, where only the pertinent pieces of the beamline are exposed to users, the chances of a user accidentally accessing part of the beamline that they should not are minimized. The Acquaman framework has been applied on VESPERS to create a tailored user interface capable of seamlessly supporting XRF and XAS. Lastly, all data that is collected using the Acquaman framework is automatically saved into a database to ensure that no data that is collected can be inadvertently lost and can be exported at the leisure of the user.

Currently, the user interface handles all general features of the beamline, such as photon shutters, slits, sample position, and positions for all detectors. The Acquaman framework allows for easy control of the beamilne while enforcing logic that prevents users from entering situations that may damage the beamline (ie: colliding detectors together). The user interface also configures the silicon drift detectors (SDD) for setting up X-Ray Fluorescence (XRF) 2D maps and allows easy access to configuring regions of interest which provides tools to quickly assess the elemental composition of the samples.

Finally, encapsulation of all necessary controls to perform X-ray Absorption Spectroscopy (XAS) while still hiding low level control that will enable users to concentrate on their experiment, rather than compromising their data with low level software.

Science Studio [10] is a web portal, and framework, that provides scientists with a platform to collaborate in distributed teams on research projects, and to remotely access scientific resources. Like Aquaman ScienceStudio only exposes the aspects of the beamline that are pertinent to the user experience. The core component of Science Studio is a web-based experiment management system which allows users to organize and share their sample information, experimental data and analysis results. The VESPERS beamline has been integrated into Science Studio to provide remote control and data acquisition capabilities. ScienceStudio has been extended to provide on-line realtime analysis of both XRF and XRD data, while using high performance computing to process the XRD data.

DEVELOPMENT OF DISTRIBUTED DATA ACQUISITION AND CONTROL SYSTEM FOR RADIOACTIVE ION BEAM FACILITY AT VARIABLE ENERGY CYCLOTRON CENTRE, KOLKATA

K. Datta#, C. Datta, D. P. Dutta, D. Sarkar, H. K. Pandey, T. K. Mandi, VECC, Kolkata, India
A. Balasubramanian, K. Mourougayane, R. Anitha, SAMEER, Chennai, India

Abstract

To facilitate frontline nuclear physics research, an ISOL (Isotope Separator On Line) type Radioactive Ion Beam (RIB) facility is being constructed at Variable Energy Cyclotron Centre (VECC), Kolkata. The RIB facility at VECC consists of various subsystems like Electron Cyclotron Resonance (ECR) Ion source, analysing magnet, Radio Frequency Quadrupole Linear Accelerator (RFQ linac), Rebunchers, Inter-digital H-mode Linear Accelerators (IH linacs) etc which are required to produce and accelerate radioactive ions for different experiments. To facilitate the smooth operation of this RIB facility by way of monitoring, supervision and control of all the important parameters associated with its various sub-systems, a "Distributed Data Acquisition and Control System (DDACS)" is being developed at this Centre. This paper briefly describes the design philosophy, basic architecture and various functional components of the DDACS.

INTRODUCTION TO RIB FACILITY

The RIB facility (Fig. 1) at VECC is an ISOL type RIB facility. Radioactive isotopes are first produced in a target from nuclear reaction with the primary beam coming from K-130 Cyclotron operational at this Centre. Radioactive atoms diffusing from the target are ionized initially in an integrated 1^+ ion-source and then in a 6.4 GHz Electron Cyclotron Resonance Ion source (ECRIS). After mass separation, the low energy RIB is accelerated from 1.75 KeV/u to about 100 KeV/u in Radio Frequency Quadrupole Linear Accelerator (RFQ linac). Three Inter-digital H-mode Linear Accelerator (IH linacs) modules raise the energy up to around 415 keV/u. Subsequent linac modules are to be used to achieve the final beam energy of 1.3 MeV/u [1].

DESIGN PHILOSOPHY OF DDACS

The DDACS for RIB facility, like any other control systems of large accelerators, is not only a vital means of monitoring the status of the machine at any point of time during operation, but also a tool for achieving desired beam. A detailed requirement analysis was done for the design of the control system. Following are some of the guidelines which are followed in global stages and have also been appropriately adopted in the design of DDACS.

- The control system should have multi-layered architecture. Entire task of data acquisition and control would be shared by different control modules distributed in all layers [2].
- The control system must be modular, incrementally upgradeable and extendable to fulfil the future requirements as machine grows in scale [3].
- The modules of the control system must be individually usable in case of testing, installation and commissioning of a subsystem.
- The control system must have provision to accommodate various kinds of heterogeneous equipments manufactured by different companies and hence characterised by different operational requirements.
- Variation in design of individual control modules should be minimized. Homogeneous design of control modules must be of paramount importance for the ease of maintenance and replacement.
- Use of state-of-the-art technology.
- The control system should be expandable in terms of addition of similar modules for similar subsystems.

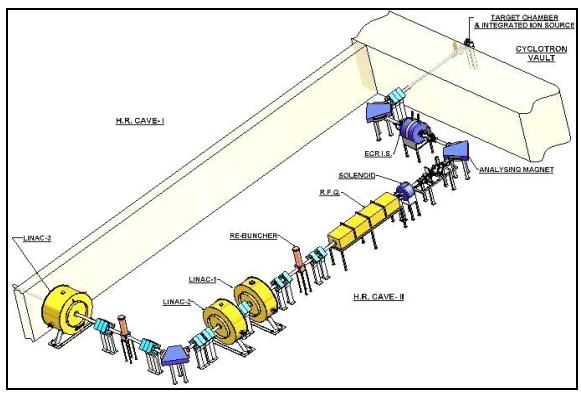

Figure 1: Layout of RIB facility (up to LINAC-3).

ARCHITECTURE OF DDACS

Based on the above design philosophy, RIB control system is being developed using 3-layer architecture: a) Equipment Interface Layer b) Supervisory Control Layer and c) Operator Interface Layer. The control system is composed of a number of functional modules distributed over these layers which are connected through suitable communication network and protocol.

The Equipment interface layer consists of different Equipment Interface Modules (EIMs) which are directly connected to the accelerator equipments through various interfaces. Each EIM is a microcomputer based intelligent unit with front-end analog/ digital electronics. Each of the EIMs is separately connected to the supervisory computer through fibre optic link in a star topology.

kaushikdatta@vecc.gov.in

The Supervisory layer has been realised using Embedded Controllers (EC) designed around Single-Board-Computer (SBC) with Embedded XP operating system. This controller, interfaced with EIMs through fibre optic cables, performs supervisory task of continuously sending command and acquiring data from lower level EIMs and reporting to the operator interface layer as and when requested.

Operator interface layer consists of operator console formed with another embedded controller and high performance PCs/ Workstations for controlling and monitoring machine parameters. The data acquired and analysed at the supervisory layer can be displayed at the operator console and operators can control the whole facility from the user friendly graphical interfaces.

A schematic diagram of the architecture is shown in Figure 2.

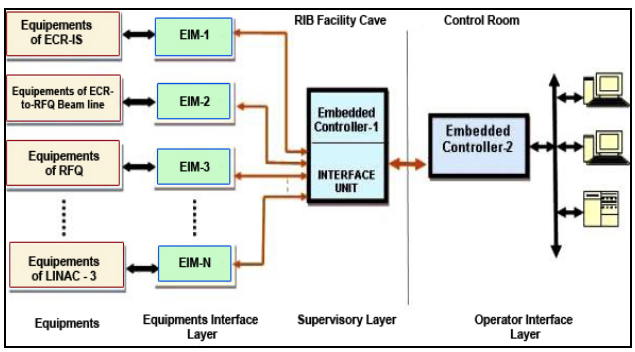

Figure 2: Schematic diagram of DDACS.

DESCRIPTION OF DDACS

For the development of data acquisition and control system, entire RIB facility has been viewed as a composition of following subsystems and their interconnected beam lines (as per present status of RIB facility).

a) Electron Cyclotron Resonance Ion source (ECRIS)
b) ECRIS to RFQ Beam Line
c) Radio Frequency Quadrupole (RFQ)
d) RFQ to Rebuncher Beam Line
e) Rebuncher
f) Rebuncher to Linac-1 Beam Line
g) Linac-1
h) Linac -1 to Linac-2 Beam Line
i) Linac -2
j) Linac -2 to Linac -3 Beam Line
k) Linac -3

These subsystems and their interconnected beam lines are associated with various kinds of equipments like High Current Magnet Power Supplies, High Voltage Power Supplies, Klystron High Power Amplifier (KHPA), RF Transmitters, Vacuum Pump Controllers, Vacuum Gauges, Gate Valves, Faraday Cups etc. DDACS is intended to monitor and control important parameters of these equipments and thus help smooth operation of machine.

The three layers of DDACS are detailed in the following sections.

Equipment Interface Layer (Layer-1)

The Equipment Interface Layer is the lowest level of control system which is directly interconnected to the accelerator equipments. It consists of multiple microcomputer based modules named as "Equipment Interface Module" (EIM) (Fig. 3) which form the basic foundation of this data acquisition and control system. The multiple equipments associated with each subsystem are physically connected to their respective EIM module through a variety of interfaces which actually governs the design of the EIM. Wide range of computer/remote interfaces available with the equipments from different manufacturers has been extensively studied and EIMs are finally designed to support multiple analog/ digital input/ output channels and RS-232/ RS-485 ports suitable for connecting all the equipments. Following a generalised hardware architecture, EIMs are indigenously developed around 32-bit ARM controller with analog/ digital front-end electronics (ADCs, DACs, Opto-isolators, Multiplexers etc.) and RS232/ RS-485 level translator. It also consists of a touch-screen display (Fig. 4) using which, equipments, connected to it, can be locally controlled and monitored. This feature immensely helps in tuning of the control system during installation and also in testing and commissioning of many subsystems.

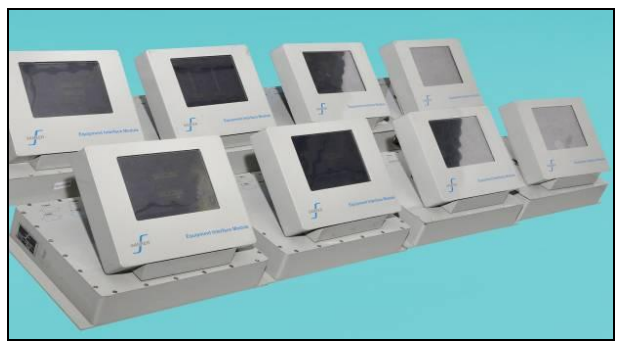

Figure 3: Snapshot of Equipment Interface Modules (EIMs).

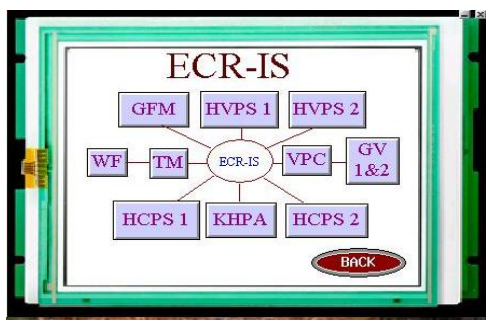

Figure 4: Snapshot of a typical touch-screen based local display panel of EIMs.

Some of the equipments such as RF transmitters, Faraday cups and Slit controller do not have compatible

remote interface to connect them to EIM. Hence, suitable interface units are introduced to enable them to get connected to their respective EIM.

Each of the EIMs is individually connected to the Supervisory Layer computer through fiber optic link in a star topology which has helped in reducing the overhead of address checking.

Software in EIM performs predetermined tasks either on request or on regular basis and confines to a group of instruments. For getting access to the equipment parameters, various proprietary command-response based communication protocols of different equipments have been implemented in EIM software. It periodically scans all equipments, connected to it, to read the status of their parameters and stores parameter values in its local buffer. It finally sends these values to the upper layer on demand. It also issues required control commands to the individual equipment for changing value of their parameters as desired by the operators. The task of handling data exchange between EIM and Supervisory Computer (SC) is performed following a customised protocol. The message received from SC is parsed and appropriate action is taken according to the command. Thus, dedicated software at this layer in coordination with upper layer provides total accessibility of equipment at remote control location.

Each EIM also handles safety interlocks associated with the subsystems it deals with and informs the interlock status to the upper layer.

The software for this layer is written in C language and after cross-compilation, the executable code is downloaded to the EIM controller.

Supervisory Layer (Layer-2)

The Supervisory Layer of DDACS has been realised by a system, developed using single board computer with Embedded XP operating system (OS) and named as Embedded Controller-1 (EC-1). The EC-1 (Fig. 5) is physically located at the cave of RIB facility, but away from the machine and interfaced with all the EIMs through fibre optic link to ensure necessary isolation and noise immunity. EC-1 performs the task of supervision by way of delivering the operator commands to the EIMs for controlling field equipments and receiving status information from them to report to the operators.

The Embedded Controller is built around a VIA processor operating at 800 MHz. However, the processor architecture is optimized for low power operation and reliable performance to meet the requirements of industrial applications. The embedded controller board supports operation over a wide temperature range of -20 to 70 deg. The controller runs on Embedded XP operating system which is built with minimum kernel resources, drivers and occupies minimum foot print when compared to the conventional Windows XP operating system. The OS, drivers and application software are embedded in a Flash memory. The board supports 512 MB of SDRAM and 512 MB of Flash memory. The controller board is operated from a DC supply of 5 - 28V DC. All the secondary DC supplies and the power management circuitry are built on-board. The Controller module has been tested and qualified for the environmental standard as per JS 55555 and Electromagnetic Compatibility (EMC) standard as per MIL STD 461.

The EC-1 system rack contains a Data Interface Unit (DIU) which physically connects EC-1 to all the EIMs. This unit mainly converts the fibre optic signals to the appropriate electrical signals and vice versa.

Main functions of this supervisory level controller are:

- To acquire data from EIMs (Layer-1), process the same and communicate the relevant data to control console at Layer-3.
- To receive the control messages from the control console, parse the same and distribute those to related EIMs to make effective on the equipments.

The application software, running in EC-1, is developed using Labwindows™/CVI and continuously sends commands to and acquires data from lower level EIMs. A customised command-response based protocol with 16 bit Cyclic Redundancy Check (CRC) has been adopted for reliable data communication between EC-1 and EIMs. Each equipment attached to an EIM is identified by unique "Instrument ID". This instrument id along with specific "Function Code" in a command message issued by the EC-1 uniquely define a particular operation (such as setting a voltage, reading a voltage, making a power supply on/off etc.) on a piece of equipment connected to a particular EIM.

Figure 5: Snapshot of Embedded Controller-1 System Module.

The EC-1 is connected upward to an Operator Interface Layer controller, named as Embedded Controller-2 (EC-2) through a pair of optical link. It receives operator commands and provides corresponding responses like transmitting a block of data or initiating the action to change the status or set the values of parameters of different equipments.

Operator Interface Layer (Layer-3)

Operator Interface layer handles operator interaction and provides a means of communication between operators and the accelerator machine. It mainly deals

with data representation and responds to each of the user actions. This layer has been realised by another embedded controller named as EC-2 and multiple PCs/ Workstations. These all are physically located in the RIB control room and form user friendly operator console.

EC-2 is similar to EC-1 in respect of hardware, but is functionally different. EC-2 is interconnected with different monitoring units (PCs/ Workstations) through a Local Area Network (LAN). All the status information of different equipments received from all EIMs by EC-1 are sent to EC-2 and finally displayed at PC/ Workstations. Any control action (for changing status of equipments) initiated at this layer finally reaches to the intended equipment through EC-1 and respective EIM. The response to user interaction has been kept within the human acceptable limits (500 milliseconds to 1 second).

Application software in EC-2 communicates with the supervisory layer embedded controller i.e EC-1 for data acquisition and control initiation. It communicates with the monitoring units using UDP protocol for displaying machine information in user friendly Graphical User Interface (GUI) (Fig. 6).

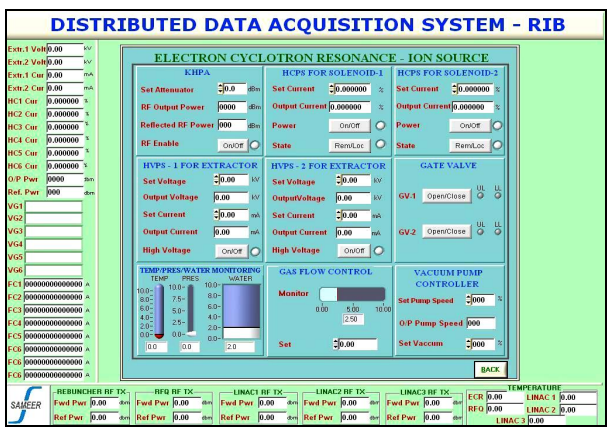

Figure 6: A typical GUI for ECR-IS Subsystem.

PRESENT STATUS

All the data acquisition and control modules have undergone functional performance check and EMI/ EMC qualification tests at Society for Applied Microwave Electronics Engineering & Research (SAMEER), Chennai before installation at RIB facility at VECC. Functional performance of the modules has been checked using a simulator system developed indigenously. Radiated Susceptibility test, Conducted RF Immunity test and Power Frequency Magnetic Immunity test have been carried out as per IEC 61000 standards on the modules to qualify them to be used in an accelerator environment. Presently, all the EIMs are installed and rigorous testing of the modules with the different sub-system has been carried out successfully at the RIB site. Embedded Controllers are also installed and thorough testing of those with EIMs produced expected results.

CONCLUSION

The RIB facility at VECC is under development and it is growing step-by-step towards its complete shape. The multilayer architecture of this data acquisition and control system is ideally suited for the RIB facility growing in phases. It has been envisaged to deploy a database server to be connected to the LAN at operator interface layer for data archival and off-line analysis.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to Dr. R. K. Bhandari, Director, VECC and Dr. A. L. Das, Director, SAMEER for their constant support and encouragement for this activity. The authors also thankfully acknowledge the overall guidance and useful suggestions received from Dr. Alok Chakraborti, Head, Radioactive Ion Beam Facilities (RIBF) Group, VECC. All the officers and staff members of RIBF Group of VECC and SAMEER who are involved in this project deserve special thanks for their sincere efforts towards achieving the goal.

Abstract

FERMI@Elettra is a single-pass Free Electron Laser (FEL) user-facility covering the wavelength range from 100 nm to 4 nm. The facility is located in Trieste, Italy, nearby the third-generation synchrotron light source Elettra. Three experimental stations (Fig. 1), dedicated to different scientific areas, have been installed in 2011: Low Density Matter (LDM), Elastic and Inelastic Scattering (EIS) and Diffraction and Projection Imaging (DiProI). The experiment control and data acquisition system is the natural extension of the machine control system. It integrates a shot-by-shot data acquisition framework with a centralized data storage and analysis system. Low-level applications for data acquisition and online processing have been developed using the Tango framework on Linux platforms. High-level experimental applications can be developed on both Linux and Windows platforms using C/C++, Python, LabView, IDL or Matlab. The Elettra scientific computing portal allows remote access to the experiment and to the data storage system.

INTRODUCTION

The newly-built free-electron laser FERMI@Elettra generated its first flashes of coherent light in the far ultraviolet in December 2010. A second phase of commissioning started in January 2011, with the goal of providing optimized FEL light to the experimental chambers [1]. The "first-shots" experimental activities, held in March and in July 2011, were mainly devoted to the commissioning and tuning of the three existing end-stations: LDM, EIS and DiProI.

The FERMI@Elettra fast data acquisition (DAQ) system is used to acquire, store and correlate multiple data sources. Based on the estimated scientific data throughput, the DAQ system has been designed in order to guarantee a data acquisition rate up to 1400 Gbyte/hour. During the experiment, scientific data is saved on a centralized storage system using a 10Gb ethernet connection.

Once stored, experimental data are available for offline data processing using the Elettra high performance computing clusters. Besides this, experimental data and local computing infrastructures can be remotely accessed through the Elettra scientific computing portal.

DATA ACQUISITION FRAMEWORK

FERMI@Elettra DAQ framework inherits from two years of experience gained during the machine commissioning and has been thought as the natural extension of the machine control system [2]. For every single laser pulse, at 50 Hz repetition rate, the DAQ system acquires, stores and links data coming from scientific instrumentation and machine diagnostics.

Control System Hardware Architecture

Dedicated scientific instrumentation apart, a uniform hardware architecture has been adopted for all the FERMI@Elettra experimental stations. According to Fig 2, at top there is a workstation dedicated to application software. Via a private VLAN, it accesses two low-level machines for interfacing instrumentation and a PLC dedicated to protection of the equipment.

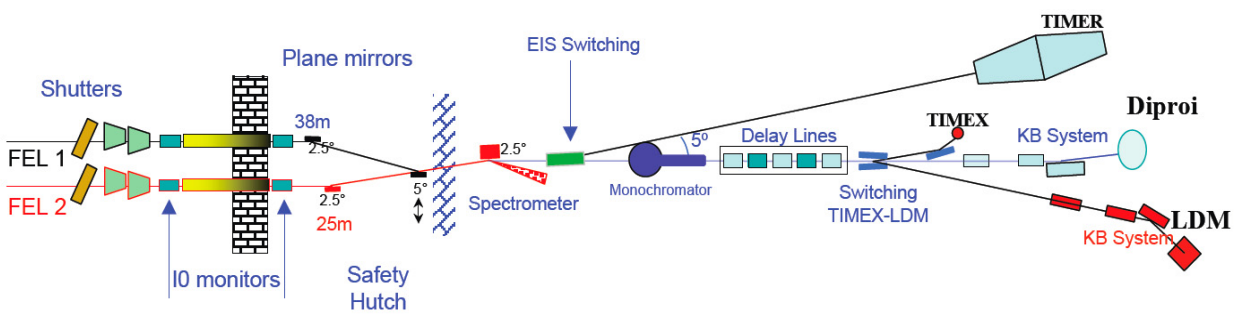

Figure 1: FERMI@Elettra beamlines layout.

*Work supported by the Italian Ministry of University and Research under grants FIRB-RBAP045JF2 and FIRB-RBAP06AWK3

The workstation is an Intel Core i7-950 multi-screen desktop computer running either Linux or Windows.

Standard instrumentation is controlled by a VME system equipped with an Emerson MVME-7100 PowerPC board (Equipment Controller – EC). The EC also hosts the Event Receiver (EVR) by Micro-Research, that receives the machine bunch trigger via a fiber optics infrastructure. The EVR board can generate software interrupts and digital signals with a maximum jitter of 20ps. Instruments requiring special hardware interfaces or proprietary software are controlled and acquired by an Intel-based rack-mount server (Pentium XEON Quad Core). Both PowerPc and rack-mount Intel server are directly involved in real-time data acquisition. They are based on Linux (Kubuntu 10.04) with the Xenomai real-time extension [3].

Machine real-time diagnostics data are transparently shared among data acquisition computers using a network software application called Network Reflective Memory (NRM) [4]. The NRM system has been deeply tested during the commissioning period. It works on a fully dedicated, private network that covers the whole machine from the electron gun to the experimental hall.

Finally, a Siemens S7 series 300 PLC is used for the interlock system in order to protect equipment and devices from damage.

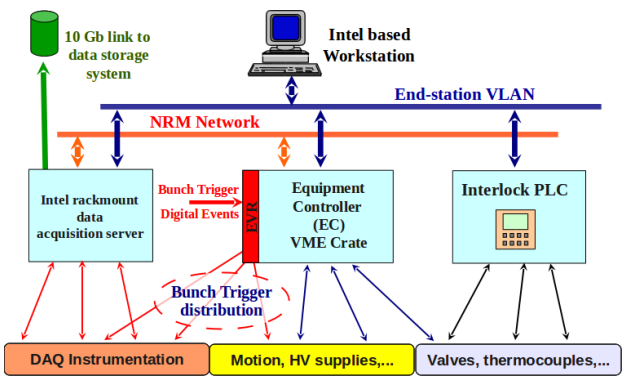

Figure 2: DAQ system hardware architecture.

Control System Software Platform

The DAQ system of the experimental stations is based on the Tango framework [5]. Low-level instrumentation control, scan implementation, data acquisition and analysis is done through Tango device servers. The low level device servers have been developed using C++, while the higher level ones have been written in Python and C++.

Each experimental station control system uses a private Tango database running on a virtual machine in the central system main server. Communication with the machine control system is made possible by special Tango devices that act as gateways. These are configurable servers that export specific attributes and commands between control system running on different VLANs.

As a general rule, automation and complex data acquisition operations are performed at Tango device server level, while client-side GUIs are used only for visualization purposes.

Graphical interfaces can be developed by beamline staff on Linux and Windows platforms using common frameworks like Labview, IDL, Python or Matlab. Applications developed by controls specialists have been written using QTango [6], a Qt based framework developed in house.

SCIENTIFIC DATA PIPELINE

Each laser pulse produced by FERMI@Elettra is unique in terms of spatial position, photon flux and energy spectrum. It is crucial to acquire and store *shot by shot* not only experimental data coming from the beamline detectors but also photon beam diagnostics data.

Every acquisition device server maintains and updates a circular memory buffer in which the acquired data are tagged with an increasing counter named *bunch number*. These low level devices export tagged data to the higher level storage device servers that organize experimental data in HDF5 (Hierarchical Data Format) [7] archives.

A challenging task in terms of data throughput is the acquisition of scientific detectors: until now only 1Mpixel detectors have been used but in the near future these will be upgraded to 4 Mpixel.

Table 1: Estimated Experimental Data Throughput

Endstation	FEL @ 10Hz	FEL @ 50Hz
DIPROI	140 Gbyte/hour	700 Gbyte/hour
LDM	280 Gbyte/hour	1400 Gbyte/hour
EIS	66 Gbyte/hour	330 Gbyte/hour

Data Storage and Analysis Resources

For each experiment a specialized Tango DAQ device performs data collection, online data reduction and storage in the HDF5 format.

Data archives are directly saved through the NFS protocol on a high speed centralized storage via a 10Gb ethernet connection.

The present centralized storage system is based on a 70 TB EMC Storage Area Network (SAN). Its next planned upgrade will provide FERMI users with a 1 PB distributed filesystem that will grant a data throughput of 1600 MB/sec.

Experimental data can be consequently analysed using the Elettra scientific computing infrastructure that currently includes:

- two state-of-the-art High Performance Computing Clusters equipped with InfiniBand and over 250 processor cores;
- an interactive computing cluster with about 40 processor cores;
- a cloud system, with a growing number of cores (presently 30).

The above resources can be remotely accessible through a specialized web portal: the Virtual Control Room (VCR) [8].

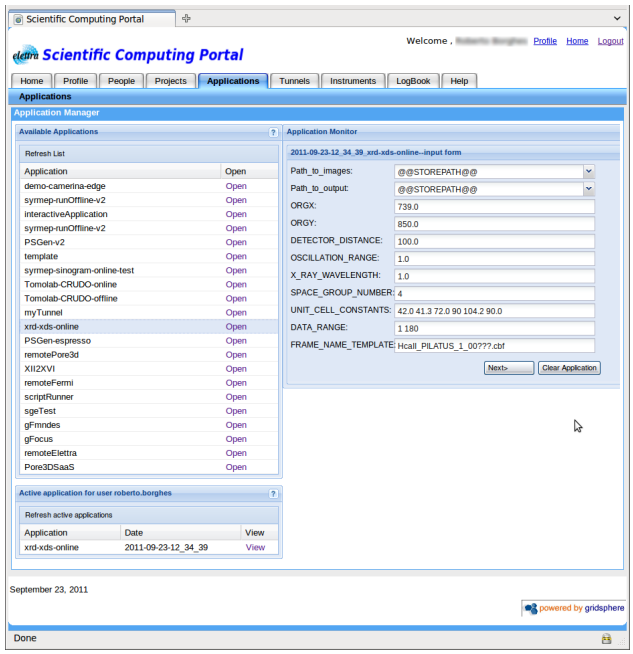

Figure 3: Elettra VCR web portal.

Virtual Control Room

The VCR is an open source web portal based on the GridSphere framework and Web 2.0 technologies. It is a highly configurable tool, designed for easy development and deployment of custom applications with transparent access to the underlying infrastructure. Among its main features are a safe tunnelling tool and an application manager (Fig. 3) that integrates a Jython-based scripting environment. The VCR acts as a front-end to the gLite-based Grids and to grid-enabled remote instrumentation via Instrument Element [9]. A number of tools like e-logbook, help-system and users-browser, make it a collaborative environment.

The portal provides secure remote operations of beamlines and experimental stations. It allows access to raw datasets and enables initiation of data processing during the acquisition phase. As such, the VCR is virtually suitable for any kind of scientific or business application and for the associated user communities.

CONCLUSIONS AND OUTLOOK

The FERMI@Elettra fast DAQ system has been tested during "first-shots" experimental activities held in March and July 2011. Working with a source of 10Hz repetition rate it has proven to be reliable, stable and dynamic enough for an experimental environment.

Further hardware and software upgrades will be carried out in the next months in order to handle a 50Hz repetition rate and 4Mpixel scientific detectors.

The efforts will be in accordance to the PANDATA ODI[10] related activities that include data policy, format standardisation, automatic metadata association and data management.

TRIUMF'S ARIEL PROJECT

J. Richards, D. Dale, K. Ezawa, M. Leross, K. Negishi, R. Nussbaumer, D. Morris, S. Rapaz, E.Tikhomolov, G. Waters

TRIUMF, Vancouver, Canada

Abstract

The Advanced Rare Isotope Laboratory (ARIEL) will expand TRIUMF's capabilities in rare-isotope beam physics by doubling the size of the current ISAC facility. Two simultaneous radioactive beams will be available in addition to the present ISAC beam. ARIEL will consist of a 50 MeV, 10 mA CW superconducting electron linear accelerator (e-Linac), an additional proton beam-line from the 520MeV cyclotron, two new target stations, a beam-line connecting to the existing ISAC superconducting linac, and a beam-line to the ISAC low-energy experimental facility. Construction will begin in 2012 with commissioning to start in 2014. The ARIEL Control System will be implemented using EPICS allowing seamless integration with the EPICS based ISAC Control System. The ARIEL control system conceptual design and initial results from a prototype injector control system will be discussed

INTRODUCTION

Commencing in 2012, with staged installations, the TRIUMF ARIEL project will triple TRIUMF's Rare Isotope Beam (RIB) program by providing two new radioactive beam sources. Combined with the existing beam from ISAC, TRIUMF will have three simultaneous radioactive beams available for experiments or beam development. The ARIEL project consists of a superconducting electron linac, a new proton beam line from the TRIUMF cyclotron, 2 new target stations, 2 new mass separators and a low-energy beam line switchyard feeding into the existing ISAC accelerators (Figure 1). The project implementation will extend over 10 years.

ARIEL Phase I, to be completed by 2015, consists of the construction of a RIB Factory comprised of a new RIB driver, an electron beam line, and a temporary production target. The driver, a CW superconducting electron linac with 250 kW beam power operating at 2 K will use a demonstration dump. ARIEL Phase II will complete that factory with RIB production targets, a linac energy upgrade, and the addition of a proton-driven RIB production line.

The Phase 1 electron linear accelerator (e-linac) will be comprised of a 300 keV Thermionic gun (e-gun), an injector cryo-module with a single 9-cell cavity and one accelerator cryo-module with two 9-cell cavities. The injector provides a 5-10MeV beam current of 10 mA, i.e a beam power of up to 100kW. The accelerator cryo-module will boost beam energy to 25 MeV. The division into injector and main linac accelerator allows a possible future expansion for energy recovery or energy doubling.

The ARIEL project is aided by collaboration between TRIUMF and VECC of Kolkata, India, which is planning a RIB facility with an e-linac similar to ARIEL. The injector cryo-modules are being jointly developed and one module each will be built for VECC and ARIEL. A beam test for the VECC module is scheduled at TRIUMF in 2012. This presents an opportunity to prototype many elements of the ARIEL control system.

Figure 1 shows the layout of TRIUMF's RIB facility indicating the additions by the ARIEL project.

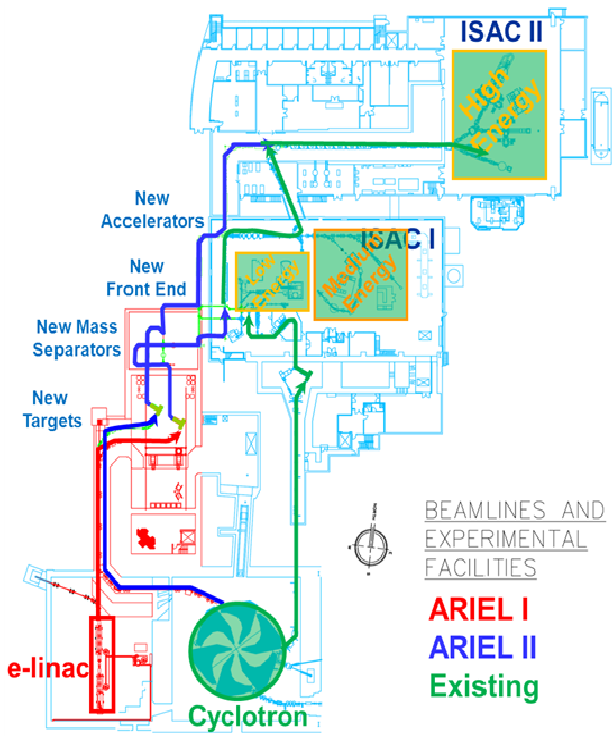

Figure 1: TRIUMF's ARIEL Project.

CONTROL SYSTEM: CONCEPTUAL DESIGN

The ARIEL Control System (ACS) will be implemented using the EPICS toolkit relying on established technologies and productivity tools of the ISAC Control System [1] wherever possible:

- The IOC software will be designed using the tdct [2] EPICS database configuration tool using the "object-like" device and component hierarchy developed for ISAC
- The ISAC device relational database web tools [3] will be used to:

- capture device information and interlock specifications
- instantiate devices in tdct schematics.
- validate interlock implementation in PLCs against the specification.
- auto-generate device control panels with interlock visualization [4],[5]

Evolution of the ISAC standards will be driven by the fact that high power beams are controlled and the need to further optimize resource usage in the control group.

In order to reduce the knowledge base to be maintained within the controls group, Linux will be used as the sole operating system on all IOC target architectures, servers and operator interface stations [6].

Integrated operation of the Cyclotron, ARIEL and ISAC control systems is not needed until after 2015 – when the proton beam line 4North comes on line. For this, a relocation of the Cyclotron and ISAC control rooms together with the ARIEL controls into one operations centre is being considered.

Machine Protection System

With a Phase 2 capability of 500 kW C.W. of beam power, the e-linac has been referred to as an electron blow torch. Therefore – in addition to the ISAC model - a fast machine protection system (MPS) will be required which is intended to prevent the high power beam from damaging the ARIEL accelerator and electron beam line. The MPS conceptual design is based on the JLAB implementation and intends to use JLAB–designed hardware that interface with photomultiplier tubes and ionization chambers [7]. The MPS will consist of a reactive fast shutdown system, a beam loss monitor system in support of the fast shutdown, and a preventive status monitoring and veto system. The MPS has unrestricted control of the e-gun grid modulation and HVPS with reaction time < 10 μsec in event of a full point loss. The MPS independently monitors devices deemed critical to the MPS function.

The MPS will use a modal view of facility operation. An e-linac Operating Mode is a configuration of beam characteristics (current, energy) and machine destination modes that permit such beam (low energy beam dump, high energy beam dump, etc). The desired operating mode is selected by the operator, but may be "downgraded" by the MPS based on events or operating conditions. The MPS will inform the control system of the actual Operating Mode which will form part of the control system interlocks for critical devices. Once a valid beam mode is established, the MPS system will automatically configure itself to monitor only those inputs which are required for beam operation to the designated beam dump.

An MPS trip will result in a hardware distributed event signalling the control system to acquire a time-stamped, beam-mode relevant, device snapshot. This will allow MPS trip post mortem analysis.

Operator interface to the MPS will be through the EPICS control system. Operator screens will be used to select machine configuration, monitor system status and reset trips. Additional screens may be used to set up beam loss monitors, initiate built in self-tests of fast abort components, and analyse trip data sets.

RF

EPICS will communicate with HPRF systems for control and to obtain device status, diagnostic values and interlock status. Interlocks for the HPRF systems will be directly supplied by the control system PLCs. The power supply for the 30 kW Inductive Output Tube that feeds the injector cryo-module will be controlled using the unit's RS232 interface and Streamdevice.

The 1.3 GHz, 300 kW klystron needed for the accelerator cryo-module has now been ordered from CPI. Tendering for all hardware and software to control the operation of the five required HV power supplies is underway. The contract stipulates PLC control for voltage regulation and protection of both the supplies and the klystron. The control module will present a Man-Machine Interface (MMI), a state machine for implementing the sequences required for proper operation of the power supplies for the klystron, and a latching interlock system that provides time-stamped fault logging. An interface layer for EPICS command and readback is stipulated since remote control of the HPRF sources via the control system is required.

Integration of the klystron power supply system and the klystron RF system is included in the scope of work as an option of the tender. If not provided by the vendor, this integration which encompasses interlocks, control, and monitoring of the complete RF system will be implemented in-house. The RF system includes the klystron, circulator with waveguide directional couplers, high power dummy loads with associated cooling and temperature monitoring systems, and a window arc detector. The operating parameters of the klystron for achieving 300 kW CW RF power at the dummy load are yet to be established. The response time of the interlock system must ensure protection of the klystron and other system components under any fault condition. Interlock trips must be time-stamped at a resolution of 1 ms or better. This precludes the use of a slow PLC scan. The status of all signals at the time of fault must be readable via MMIs and EPICS interface.

Figure 2 shows the e-linac RF components as they will exist for Phase 1 in 2014.

Low level RF is controlled by a dedicated RF control system [8] running on PCs running Windows. This local control subsystem is integrated into the EPICS control system using a shared memory interface with a "soft" IOC [9].

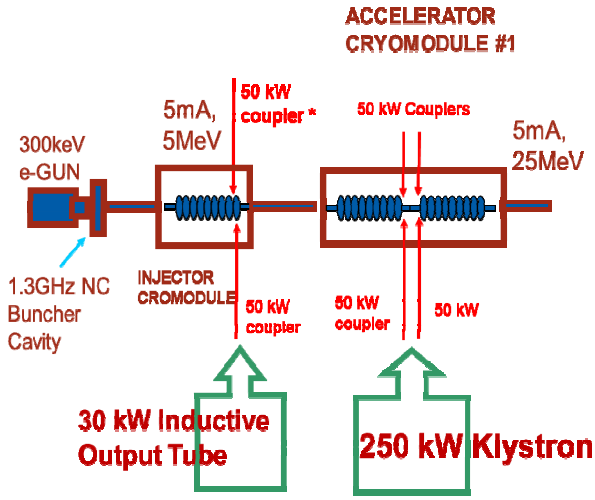

Figure 2: E-linac RF – Phase 1.

Beam Diagnostics

The E-Linac Diagnostic design has already been the subject of an International Review. Expected prompt radiation effects near the beam line would require all electronics to be rad-hard. No electronics will be installed in the E-linac hall, except in select shielded areas. This imposes restrictions on the type of instruments and bus lengths used since a 50 meter cabling path will be required.

The majority of e-linac diagnostic devices are slated to use VME for analog control and read back using 16 bits precision. The response time requirement of the control system is 10 Hz with a 5 Hz rate for updates on the operator consoles. Diagnostics that have data acquisition rates faster than 10 Hz will be handled by specialized hardware which will provide a first order processing. Data communication to the control system may then follow shared memory methods established in the ISAC control system for "soft" IOC data acquisition [9].

Diagnostic elements include button-type beam position monitors (BPM), ring capacitive pickups, DC current transformers, camera screen devices and wire scanners. The control of screen devices is being provided by the University of Victoria, a joint partner in the E-Linac project.

Device actuation into the beam line will be interlocked by the MPS subject to a proper facility operation mode (beam energy, beam intensity) for the device. Device trips, under conditions in which the device should be protected from the beam power, must be dealt with using "upstream" protection since the diagnostic devices cannot move fast enough to protect themselves. Device radiation dosage history will affect the performance of some units. Hence records must be kept by the control system and alerts issued when designated thresholds are reached.

Beam Optics

In ISAC, the supplies powering electrostatic or magnetic beam optics devices were controlled by individual TRIUMF-developed microcontroller cards and supervised from the IOCs via CAN field-bus [10]. This solution, while cost-effective and low maintenance at ISAC, may not be propagated to the electron beam optics control because of a different cost situation and concerns over reliability in the high power beam environment. At present, different approaches for low current and high current power supplies are being evaluated.

For optics devices requiring no more than 10V/5A, the Matsusada R4K-80L is a strong candidate for its cost effectiveness (150+ units are required). A control solution where small R4K-80L clusters are controlled from an EPICS IOC using ASYN/Streamdevice via RS232, with interlocking and external polarity switching provided by PCI digital I/O cards, will be evaluated during the VECC test phase using x-86 IOC targets. [6].

For optics devices requiring more powerful controllers, three possible methods of control are being considered: RS232, CANbus, or PLC. The criteria for instrumentation bus selection includes how fast the PS can be controlled, reliability of power supply shut off, and cost. In each of the following control scenarios, PLC interlocks on magnet temperature switches will cut power to the device. For an RS232 controlled supply, it is estimated that a polling rate of 10 Hz could be maintained from a Linux IOC. If the unit failed to respond, a method to remotely turn off the supply could be implemented using PCI digital I/O driving a relay which removes the power. The design of existing TRIUMF CAN-bus microcontrollers provides for a maximum update rate of 10 Hz and uses a beacon to determine communication health, resulting in a power supply being shut off on beacon loss. PLC control of direct analog/digital supplies is already a feature of the ISAC control system for units at elevated potential. The PLC response rate, reliability, and precision are satisfactory – however price factors may limit this choice.

Source E-GUN

Tests using a 100 keV electron gun have already been performed on a prototype using the standard ISAC Controls model: PLC, VME, and CANbus. Additional tests will be conducted using this source before it is replaced with a 300keV e-gun for VECC injector cryo-module tests.

Vacuum System

As in ISAC, control and interlocking for vacuum devices will be implemented using PLCs and the interlock implementation will be automatically verified against the specification [4]. Schneider/Modicon PLCs of the Quantum and M340 series are currently being commissioned in the VECC injector beam line test. The PLCs are supervised by EPICS using a TRIUMF developed Ethernet driver with the Modbus over IP protocol.

A major departure from the ISAC vacuum system design is the use of movable pumping stations for the ARIEL vacuum system. This translates into large cost

savings as turbo and scroll pumps are mounted on carts and connected to sequential vacuum volumes as required. Ion pumps maintain the attained vacuum in the beam line when the pumping cart is detached.

Cryogenics

The cryogenic plant for the e-Linac is currently in the tendering process. The Helium cryogenic system has three components: 4K liquid He in a closed re-liquefaction – refrigeration loop, 2K liquid He produced within the cryo-module by sub-atmospheric pumping, and room temperature gaseous He. A 77K liquid Nitrogen system provides for pre-cooling of He gas. The design places strong emphasis on monitoring and maintaining the helium purity. The scope of work mandates a PLC implementation with a documented TCP/IP interface to EPICS. The existing cryogenic system in ISAC has EPICS controls implemented in-house [11].

High Level Applications

E-linac tuning will require Control System High Level Applications (HLA) based on physics models. The XAL [11] framework, which integrates with the EPICS control system and provides for accelerator models, was chosen as a platform for HLA development, testing, and execution. XAL uses XML descriptions of the beam transport model that include specific optic and beam monitor control system process variables. TRIUMF XAL developments have thus far focused on low energy beam transport models. An empirical model has been created which has been proven to perform correctly at 300 keV [13].

HVAC

The buildings that house the ARIEL project will have a commercial building control system supporting the BACnet standard. In many situations the need to monitor such parameters as room temperature or air flow for correlations with beam or machine behaviour is required. BACnet/Ethernet is the physical and datalink layer that is proposed for the ARIEL facility. The building controls data can be accessed using BACnet support for EPICS [14].

UPDATE ON THE CENTRAL CONTROL SYSTEM OF TRIUMF'S 500 MeV CYCLOTRON

M.M. Mouat, E. Klassen, K.S. Lee, J.J. Pon, P.J. Yogendran, TRIUMF, Vancouver, Canada

Abstract

The Central Control System of TRIUMF's 500 MeV cyclotron was initially commissioned in the early 1970s. In 1987 a four year project to upgrade the control system was planned and commenced. By 1997 this upgrade was complete and the new system was operating with increased reliability, functionality and maintainability. Since 1997 an evolution of incremental change has existed. Functionality, reliability and maintainability have continued to improve. This paper provides an update on the present control system situation (2011) and possible future directions.

INTRODUCTION

The Central Control System (CCS) has been running almost continuously since 1974 when the first beam was extracted. Since those early days, and still ongoing, there has been a constant, incremental evolution of the CCS. These advances are punctuated periodically by more major changes. Even during major changes of the control system, which may occur during multi-month shutdown periods for the cyclotron, the scheduled off time for the CCS has been limited to durations of not more than a few days because many groups on site require CCS functionality even when beam is not being delivered. Instances of shutting down the CCS rarely occur now.

Evolution of the CCS has been shaped in part by constraints such as the need for availability and accommodating these constraints has presented interesting challenges. An example of this evolution is the emergence of two, symmetric, computer clusters, one for software development (and diagnostics) and one for production operation. The Development Cluster can provide all of the functionality of the Production Cluster. During a major, multi-month, site shutdown, disruptive upgrades such as that of the fibre channel storage system on the Production Cluster can proceed while the CCS software runs with full functionality in the Development Cluster. This is an important redundancy.

Almost all applications in the CCS use the X Window protocol to display their output. Two more clusters of computers (the Display Clusters) are dedicated for display purposes. Within the Display Clusters, 16 multi-headed workstations are used simply to receive output from the servers, display the X window on monitors, and allow keyboard and mouse input from the user. These workstations do not run applications.

During the life of the CCS, its computers have evolved from the initial 16 bit processors, through 32 bits to the present blend including multi-core, multi-processor 64 bit computers. Disk storage changed from the original fixed head devices, through removable cartridge styles, to multi-access DSSI drives, to early fibre channel, and now virtualized fibre channel is being installed. There was a time with no network, then the network started with collision-based 10 Mb/sec simplex thickwire, and moved through thinwire, to FDDI, to 10/100 Mb/sec switched Ethernet, and presently to the 1 Gb/sec configuration.

There are a number of general goals that most controls systems will strive to meet, characteristics such as reliable operation (low downtime), ease of new developments and maintenance, a high level of functionality, longevity while providing the required functionality, simplicity of use, and the like. The experience of TRIUMF's Cyclotron Controls Group is that to identify and understand the goals takes a cooperative approach with the end users, within the Controls Group itself, and with management. The end users are typically cyclotron sub-system groups (Vacuum, RF, Magnets, etc) and especially the Cyclotron Operations Group, but include a number of other groups such as Beam Development and ISAC Operations.

HARDWARE STRUCTURE

The present hardware configuration is a natural evolution from the initial design, which was destined to be very effective. This design employed CAMAC as a data acquisition and control bus with multiple, hardware arbitrated, computer connections (the GEC Elliott Executive crate). The configuration is referred to at TRIUMF as multiporting. This concept of multiporting continues to be a major characteristic and powerful advantage within the CCS architecture. Having multiple computers able to independently, efficiently, and (effectively) simultaneously have access to almost all CCS device channels, largely eliminates the need, overhead and complexity of passing commands and data between computers (IOCs and servers). The CCS does not have IOCs. There are only servers and these servers are capable of quickly accessing parameters across the breadth of the cyclotron from the ion source to the beam dump. This allows functionality such as quick, high level interlocks that otherwise would be difficult to provide.

CAMAC is a set of well defined, open, standards with many useful features such as a simple inter-crate bus system, interrupt handling, multiple topologies, locally arbitrated intelligence in a crate, etc. CAMAC is now seen by many people as an old technology (of approximately the same age as VME). At TRIUMF the CAMAC continues to function very well. The CCS's CAMAC was incrementally expanded to the present configuration, which has multiple, independent systems running in parallel, with each system capable of supporting up to seven parallel or serial branches. Each of these systems is capable of interfacing multiple computer connections, presently providing between three and eight computer connections.

The electronics in the CAMAC varies from the original (1970s), to the very recent (2011). Many of the new CAMAC modules (ADCs, DACs, etc.) are newer in fabrication, of a more recent design, of better function, higher resolution, and of better performance than our new PLCs, and at a lower cost per channel. Although design and fabrication of CAMAC electronics is easy by today's standards and witnessed by recent modules, industry support of CAMAC is in sharp decline.

Other data acquisition and control connections are also supported, including links such as Ethernet to PLCs, Ethernet to other processors, Ethernet to terminal servers (for serial ASCII), Ethernet to specific devices (such as an arbitrary waveform generator), Ethernet to web servers (such as a weather station), and VME.

PLCs are being increasingly used in the CCS because of their ease in interlock implementation, modularity, and widespread acceptance. There are still more than 10, old, microprocessor-based, local control and interlock systems that communicate with the CCS and are in need of replacement. Refurbishing each of these systems represents a significant amount of monetary, staff and time resources, all of which are in short supply. Projects such as replacing the main tank vacuum microprocessor system continue to be deferred. The original systems run with remarkable reliability, although two years ago a microprocessor failed and integrated circuit chips were found with chip leads corroded away.

The CCS network expansion has a variety of characteristics including aspects such as in the number of connections, in bandwidth and latency performance, in functionality, in complexity of management, in the resources required for maintenance and development, and in the resources required for security. To help address security, a security-in-depth (layered) approach is taken. This includes items such as firewalls, multiple VLANs, individualized computer security filtering, and monitoring. Diagnostic devices such as the Fluke OptiView Series III network probe has proven to be particularly useful in characterizing network activity and in diagnosing network problems (such as to identify multiple use of an IP address).

Hardware diagnostics have increased significantly, especially in specifically targeted areas. Each CAMAC crate is now equipped with a specially designed diagnostic module (60 in all), which is queried every six seconds to identify early signs of power supply issues, temperature issues (ambient and fan failure), and in the future other potential problems will be monitored.

The widespread expansion of Uninterruptible Power Systems (UPS) within the CCS has boosted reliability and uptime. Although various sub-systems suffer during power issues, normally the CCS now runs through these events and helps to identify and analyze the consequences. This is particularly helpful for Operations.

The main console has been tailored to work efficiently for the Operations Group. Approximately 35 dedicated CCS monitors of varying sizes from 18 to 42 inch are driven by two clusters of multi-headed workstations. Twelve of the workstations are in the main console.

In addition to workstations, the console still provides knobs, buttons, and analogue meters to enhance the tuning ergonomics. These devices come in both dedicated and assignable instances and the underlying software support provides a number of enhanced features such as configurable beam current run-up characteristics to take a beam-off situation to the desired beam current.

SOFTWARE (DEVELOPMENT & PRODUCTION) ENVIRONMENTS AND FRAMEWORK

The Central Control System software was first created (early 1970s) using the recently developed NATS (Nova Asynchronous Tasking Supervisor) realtime operating system. The control system software was written in assembler and distributed across a number of Data General Nova computers. These Nova computers ran, with daily reboots due to application bugs, for many years until the completion of an upgrade project that was initiated in 1987. The choice was made to move to Digital Equipment Corporation VAX computers running the VMS (also called OpenVMS) operating system but to maintain the data acquisition hardware infrastructure, which was predicated on CAMAC. Due to the constraints of the upgrade, the conversion was not completed until December 1996. Although the Cyclotron Controls Group also supports Linux, Microsoft Windows, and Solaris, VMS is the operating system underlying the cyclotron's production software. VMS runs efficiently and reliably. As the computer hardware evolved from 32 bit VAXes to 64 bit Alphas and then Itaniums, the necessity arose to simultaneously support applications and software infrastructure on multiple hardware architectures. The OpenVMS development and runtime environments make this issue straightforward. There is only one code base for the CCS and users are unaware of the hardware they are running on. Now, only Alphas and Itaniums are supported but adding another architecture should be simple.

Programming, debugging and software testing is done on the Development Cluster. When the software is deemed to be running correctly it is moved to the Production Cluster for deployment.

A master Oracle database is used to maintain device and acquisition information. From the master database a single, static, runtime database with all necessary device and acquisition information is extracted and normally moved to each of the computers doing data acquisition and control. Configuration management is effectively eliminated because there is only one current configuration and normally all of the computers have it. A new version of the runtime database can be installed on the fly, without needing to reboot or stopping any applications that are running. Only newly started applications will dynamically link to the new version, thus multiple versions may simultaneously be active in each computer.

This flexibility allows new versions to be tested while the latest commissioned version continues to run.

OpenVMS, like Linux and Unix, employs the X Window protocol for display purposes. The vast majority of display processes use X Windows but web based applications are supported. Web based programs such as Oracle forms and a Safety System program for testing gamma and neutron monitors are frequently used.

The main Operations console hardware is tied into the CCS via interrupt driven CAMAC signals that go to the OpenVMS servers. Software detects device selection and parameter modification (such as an increment via button press) so that dedicated applications can quickly and appropriately adjust the accelerator equipment and the X window displays. Input via X windows is also available.

The CCS framework has mostly been developed in house but there are some commercial products such as the graph widgets and message bus infrastructure.

A communications link exists between the CCS and the Central Safety System (CSS). In the CCS a touch panel and associated monitor provide Operations and others an interface with the CSS. This system has 39 display pages. In addition, there are a number of other display pages showing CSS data, such as neutron monitor levels displayed as vectors, which change colour depending on their value as compared to the trip and warning levels.

A recent addition to the Cyclotron's control system is the implementation of EPICS for a part of the ion source and injection line's vacuum equipment. This work has been structured to follow the standard EPICS implementation as used in ISAC, a radioactive ion beam (RIB) facility at TRIUMF. The Cyclotron Controls Group has previously been involved in implementing and supporting EPICS on secondary beamlines for experimental facilities.

Access directly from an application in a server to production equipment connected to the CAMAC takes approximately twenty microseconds (depending on computer, command, and location of the equipment). The hardware component varies between three and eleven microseconds (with an average of five uS). A new hardware interface, which is in design, should lower the access times in both hardware and software. The effective bandwidth is also increased because there are multiple CAMAC systems and computers running in parallel.

Graphical displays in the Main Control Room that are generated from CCS applications can be roughly placed into one of two categories, displays that run continuously in a specific location for all operational shifts (the vast majority), and displays that change from shift to shift and are started and used dynamically as the need arises. Many LCD monitors have multiple application displays of the first category running on them. All of these applications normally run on just one server and if a full startup is requested, approximately 180 applications (and displays) are created during the startup period. A full startup has been slowed down (to about five minutes) to provide programmed delays for sequencing the window startups. The displays are positioned and sized to nicely tile the monitors' screens. If the Controls Group wants to shutdown the active display server, with one command executed on another server all of the applications/displays can be started and run simultaneously to those on the first server. The previously existing displays will be covered over by a new copy of the application's output and the first server can be shut off without Ops losing any displays. The configuration of displays is handled by Ops.

APPLICATIONS

The CCS has five primary applications that play major roles in cyclotron operation: XTpages, Xstrip, Histograms, Scans, and Elog. The key application is called XTpage (originally for X window Terminal Pages). This is more a framework with a common user interface for what is currently 325 display pages. Each display page is an application on its own. Emittance scans, target scans, control of probes, individual device control, loading injection line tunes, viewing and controlling sub-system parameters, bypassing PLC interlocks, control system diagnostics, and many other activities are interfaced via XTpages. In addition, each page has a user customizable help page. XTpages follows the CCS colour rules and provides a standardized user interface.

Xstrip is a heavily used strip chart tool. On each instance, the user can retrieve up to ten years worth of logged data on up to twenty parameters and plot the data. The tool will let the user then go into active mode and append current data in realtime at up to 20 hertz. Xstrip has received, and continues to receive, a significant amount of ongoing development to add features. Many users and especially Operations have contributed to its characteristics and success. By right clicking on an active parameter on an XTpage, you can start an Xstrip application, automatically retrieve/plot that parameter's logged data, and then start gathering active data.

The Histograms are a family of vector plot applications. Plothist, Plotcross, Complex Plot, etc will allow users to represent parameters as vectors in realtime.

The Scans is a server based package of event handling software that loads pre-defined scripts and then runs in realtime. There are two basic forms, event handling that provides messages only, and event handling that provides messages and device interlocking. Because of the CCS architecture, the Scans can quickly read parameters across the breadth of the CCS, draw conclusions and take actions. The Scans are modelled on PLC operation but provide the power and flexibility expected in a server.

The Elog is a web based, database backed, electronic log application. Other CCS applications have been modified to support saving graphical displays for inclusion in the Elog.

NEW/INCREASED FUNCTIONALITY

Only a few of the developments since the last Status Report [1] will be mentioned here. The targets in RIB facilities are important and need stable incident beams. Because beam over current and position errors may cause

machine protection issues, beam trips are periodically initiated. To enhance beam stability, beam current (amplitude) feedback, and beam position feedback loops have been implemented [2]. The feedback loops have significantly reduced these trips. In addition, a procedure referred to as "soft trips" is now used [2], which allows the beam current to be quickly and iteratively reduced to avoid the trip situation as opposed to just turning the beam off. This "soft trip" is much easier on the targets, and probably other equipment such as extraction foils. In another ISAC related development, an application was setup to rotate the proton beam in a circle on the RIB target to assist in beam and target development.

There have been a variety of enhancements to existing applications (XTpage, Xstrip, Scans, and Histograms). In the cases of emittance and target scans, isolated applications were incorporated into XTpages. Online diagnostics have been enhanced. One major step forward, as described earlier, was the deployment of a specially designed diagnostic module and initial software support. In what is an ongoing project, the Oracle X window based forms are being replaced by web based forms.

RELIABILITY, PERFORMANCE, MAINTAINABILITY

The Central Control System runs reliably. Figure 1 shows that since the upgrade was started in 1987, the control system downtime has been decreasing to the point now where it varies according to the (small) number of hardware failures. Equipment is normally spared at an appropriate level, which helps maintainability. And most failures can be analyzed rather quickly with the aid of improved diagnostics. Online diagnostics and daily checks often show problems before downtime occurs.

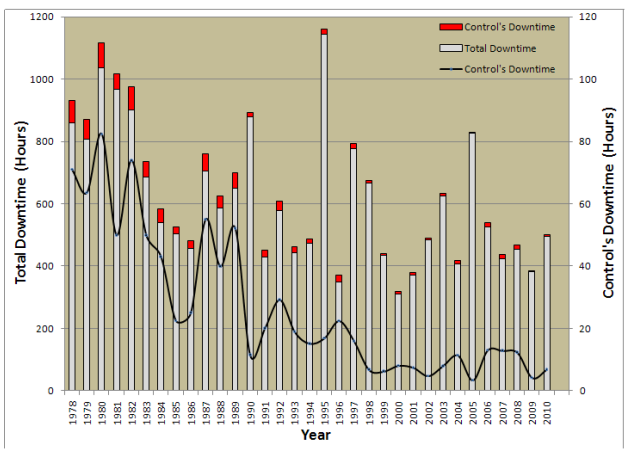

Figure 1: Cyclotron Total and CCS Downtime.

Reliability, performance and maintainability have all benefited from new designs and new electronics. New DACs and ADCs have been deployed in the last few years and new digital I/O is being prepared.

PROJECTS DONE, PROJECTS TO DO

The Cyclotron Controls Group inherited responsibility for the hardware of more than twenty old microprocessors. Some of these systems are obsolete and do not need replacement. Two systems, the Solid Target Facility and Beamline 2C's vacuum system were each replaced by a PLC. There are still more than ten microprocessors, involving major systems such as the main tank vacuum and ISAC target protection, which need to be replaced. The scope of this work is daunting.

A large project involving a major upgrade of the vertical section of the ion source and injection system was recently completed. Control of the vacuum component of this work was done using a PLC and EPICS.

FUTURE

The future will continue to bring the incremental changes as seen in the past. Changes to the fibre channel storage arrays are now underway. The site network is almost always being upgraded, with significant redundancy plans established. Enhanced Scans are also underway. These changes will provide better efficiency, clarity, and flexibility. Upgrades of the microprocessor systems will occur but firm plans are still to be made, although almost certainly PLCs will be used.

SUMMARY

In summary, the Central Control System is running well, providing good functionality, performance, and reliability, while remaining efficient to support. Many of the lessons learned must be viewed knowing that TRIUMF is a lightly funded facility relative to many similar sites. The CCS has done well to stay with technologies that are reliable and that have an evolutionary path. The VMS, CAMAC and multi-access disk storage systems are good examples. The effort to recognize and remove less reliable/harder to support technologies has been rewarded. Investing in diagnostics and tools to detect problems early on before downtime occurs or more serious consequences follow, has been worth the effort. The perspective of taking ownership of the core infrastructure, to maintain adequate spares, and to follow the philosophy of don't change for change's sake, change to gain something, has worked well.

THE GATEWAYS OF FACILITY CONTROL FOR SPRING-8 ACCELERATORS

M. Ishii#, T. Masuda, R. Tanaka, A. Yamashita
JASRI/SPring-8, Hyogo, Japan

Abstract

Utilities data such as the air temperature in a machine tunnel, power line voltage, and temperature of machine-cooling water are managed by the facility management system. Previously, the accelerator control system could not obtain most of the required utilities data because the accelerator control system and facility management system were independent systems without an interconnection. In 2010, we updated the old facility management system. In order to facilitate data acquisition, we constructed gateways between the MADOCA-based accelerator control system and the new facility management system, installing the BACnet protocol. The data acquisition requirements were as follows: to monitor utilities data with the required sampling rate and resolution, to store all of the acquired data in the accelerator database, to maintain independence between the accelerator control system and the facility management system, to ensure a future expandability to control the facility equipment from the accelerator control system. We outsourced the gateway construction, including the MADOCA-based data acquisition software, to solve the problems of limited manpower and short work period. In this paper, we describe the system design and the outsourcing approach.

INTRODUCTION

Utilities data such as the air temperature in a machine tunnel, power line voltage, and temperature of machine-cooling water assist accelerator specialists in studies on the correlation between beam stability and environmental conditions. In SPring-8, the accelerator control system, which used a Message And Database Oriented Control Architecture (MADOCA) framework [1], and the facility management system, which used the old MELBAS (Mitsubishi Electric Building Automation System), were independent systems with no interconnection. For over 15 years, the accelerator control system had no provision for obtaining most of the utilities data handled by the facility management system, except for that from legacy and offline devices such as paper records, floppy disks, and USB memories.

We started to implement an update of the old facility management system in June 2010, and we completed the project in March 2011. The new facility management system employs BACnet [2] as the underlying protocol. BACnet is an open protocol of data communication for building automation and control networks, and it has been standardized by an ASHRAE, ANSI, and ISO. The BACnet protocol defines a number of data link/physical layers, including Ethernet and ARCNET. BACnet is widely used in the building management market. We built the gateways to facilitate communication between the MADOCA-based accelerator control system and the new facility management system.

To implement these gateways, we had to overcome the problems of limited manpower and short work period. We outsourced the construction of the gateways, including the data acquisition software of MADOCA framework. We describe the system design and outsourcing approach below.

SYSTEM DESIGN

In this project, our objective was to make a provision for the accelerator control to acquire the utilities data handled by the new facility management system. The RF conditions are very sensitive to the facility equipment and environmental conditions such as the air temperature of machine tunnel and temperature of the machine-cooling water. We focused only these utilities data and constructed a utilities data acquisition system (utilities DAQ system). The requirements for the system were as follows:

- The utilities DAQ system can acquire the utilities data for the facility equipment with the required precision and sampling rate.
- Accelerator specialists can easily refer to the utilities data.
- The acquired utilities data can be stored in a database for the accelerator control.
- The facility management system cannot access to the accelerator control system.
- The accelerator control system and facility management system must remain independent from each other. This is because the facility management system does not have a shutdown period. Even if the utilities DAQ system or the accelerator control system is stopped during a shutdown period for the maintenance, it will not affect the facility management system and facility operations.
- The utilities DAQ system can provide a future option to control the facility equipment from the accelerator control system without a large modification. We anticipate a future need to control the facility equipment from the accelerator control system to achieve more precise beam control for SPring-8 II [3].

Configuration

Generally, a facility management system using the BACnet protocol does not need a fast DAQ. In the facility

#ishii@spring8.or.jp

management system for SPring-8, it takes 12 minutes to update all of the analog signals. There are about 16,000 points, including analog and digital signals, in the entire facility management system. At the SPring-8 storage ring, accelerator specialists found that the preservation of thermal equilibrium in the machine tunnel and precise cooling water temperature control for the magnets and vacuum chambers contributed to beam orbit stability [4]. They also reported that one of the sources of beam kick was the expansion and contraction of the floor and base girders caused by the variation in the air temperature in the machine tunnel, and that the source of this variation was the variation in the air velocity caused by the fluctuation in the power voltage of the fan coil units [5]. The machine-cooling system must acquire precise values for the temperature, resistivity, flow, and pressure of the machine-cooling water with a high sampling rate (2 s) over a long period of observation. Data acquisition via BACnet cannot satisfy a fast DAQ.

Figure 1 shows a schematic diagram of the connection between the accelerator control system and the facility management system. The red background shows the accelerator control system with the MADOCA framework. The blue background shows the facility management system with the BACnet protocol. The green areas show the FL-net [6], and purple areas show a MELSECNET [7], which is the data link protocol for the programmable logic controllers (PLCs) of Mitsubishi Electric Co., Ltd. An iCONT is an intelligent controller connecting a local device to the BACnet backbone. The dashed line shows the gateways of the fast DAQ.

We built three types of gateways as the key devices for the utilities DAQ system. The first is a MADOCA/FL-net gateway that consists of a VME computer with an FL-net interface board for the MADOCA data acquisition software (MADOCA/FL-net GW). Second is a BACnet/FL-net gateway that consists of PLC modules with both BACnet and FL-net interfaces (BACnet/FL-net GW). The acquisition cycle from the MADOCA framework via the BACnet/FL-net GW is 60 s. Third is a MELSECNET/FL-net gateway that consists of PLC modules with both MELSECNET and FL-net interfaces for the fast DAQ (MELSECNET/FL-net GW). The acquisition cycle via the MELSECNET/FL-net GW is 2 s. An iCONT translates the data of the facility equipment data such as the electric and air conditioning utilities with a local controller to the BACnet protocol. A BACnet/FL-net GW translates the data to the FL-net protocol. A MADOCA/FL-net GW translates the data into MADOCA messages. Finally, the data are stored in the database for accelerator control. The data of the machine-cooling utilities are also stored in the database via the MELSECNET/FL-net GW and MADOCA/FL-net GW. In all, there are a BACnet/FL-net GW, four MELSECNET/FL-net GWs, and five MADOCA/FL-net GWs in the utilities DAQ system. FL-net is an Ethernet-based open standard protocol on UDP/IP for a factory floor network. We previously introduced control systems that use the FL-net such as the linac interlock system [8] in SPring-8, and the radiation monitoring system and

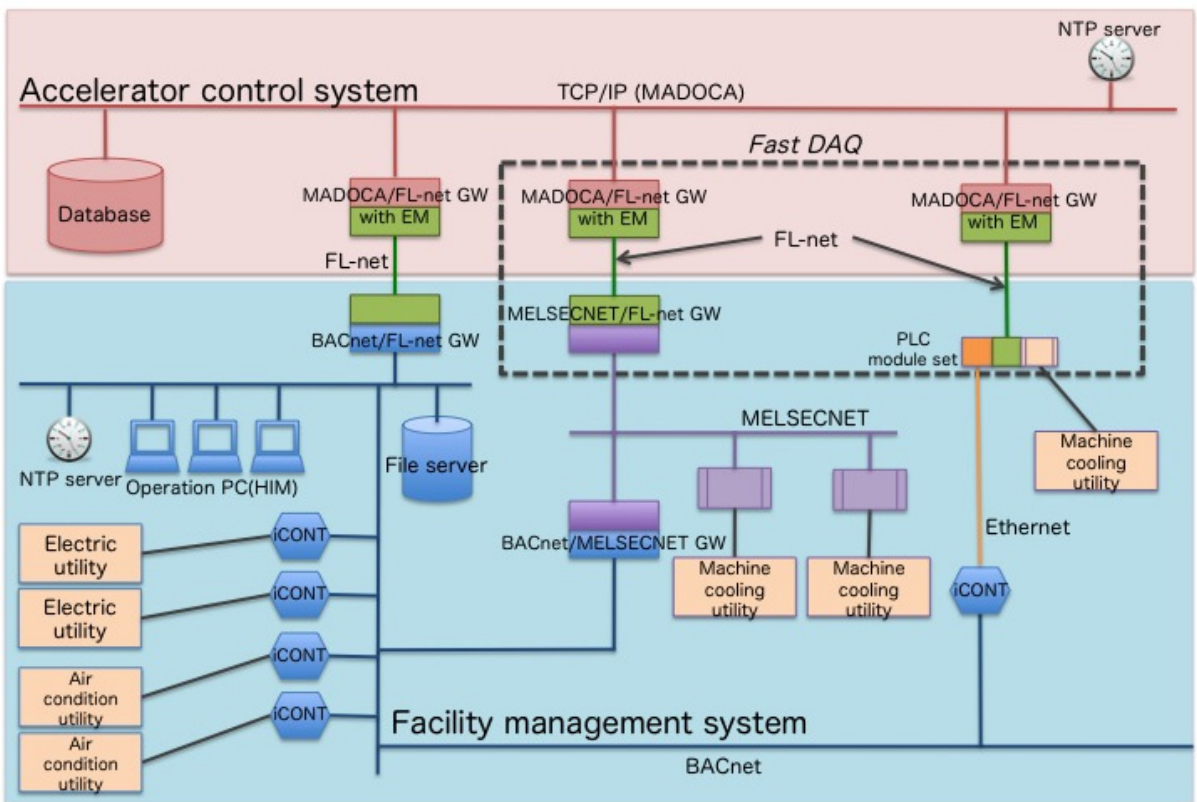

Figure 1: Schematic diagram of connection between accelerator control system and facility management system.

facility control system [9] in the XFEL facility, SACLA. These systems continue to operate stably.

A firewall is not needed for access control between the accelerator control network and facility management network when implementing the FL-net protocol. This is because a VME-based FL-net interface board implementing a MADOCA/FL-net GW can control front-end devices through the VME bus system and has a function to execute the FL-net protocol using the firmware. The FL-net board reads and writes 8 k words and 8 k bits of cyclic data transferred by the BACnet/FL-net (MELSECNET/FL-net) GW.

Future Option

The current system has been providing only data acquisition from the facility equipment. We have the option of controlling the facility equipment such as the machine-cooling utilities directly from the accelerator control system. We can achieve only minor software modification of a MADOCA/FL-net GW and a BACnet/FL-net GW. With this option, the flow of control commands would have only one path via a BACnet/FL-net GW. At the facility management system, the commands sent from the operator PCs in the central monitoring room are executed via BACnet. In the same way, the commands from the accelerator control can be sent directly to the facility equipment through a BACnet/FL-net GW with this option.

IMPLEMENTATION

We had to accomplish this large project over a short period of time. Additionally, we had limited manpower when constructing the utilities DAQ system. To solve these problems, we outsourced the construction of all the GWs to Mitsubishi Electric Building Techno Service Co., Ltd. [10] in June 2010 and Hitachi Zosen Corporation [11] in February 2011. In particular, it was a first trial of the development of Equip Management (EM) and poller, which were applications of a MADOCA framework and were run on Solaris 10 in a VME bus system. We provided a development tool that allowed MADOCA to set up configuration tables for the contractors. This development tool used OpenOffice.org [12]. It was very helpful at decreasing careless mistakes and saved work. The contractors did not need to develop a new C language function for EM and poller because they could use our prepared C libraries for FL-net device access.

As a test environment, we set up a test-database and a test-LAN using dark optical fiber cables. This test environment simulated the accelerator control system and was completely independent from any system at SPring-8. Even during the SPring-8 user time period, the contractors could confirm the capabilities of the utilities DAQ system in the test environment. Additionally, the contractors did not need to change the installation location and network configuration of all the GWs for the test environment. After the confirmation, we could smoothly install the GWs into the accelerator control system from the test environment in only one day. During this work, we frequently verified the progress.

SUMMARY

We designed and constructed a utilities DAQ system composed of three types of gateways: a VME-based MADOCA/FL-net GW, PLC-based BACnet/FL-net GW, and MELSECNET/FL-net GW between the accelerator control system and facility management system. This system can acquire the utilities data from the facility equipment with the required precision and sampling rate and can store the data in a database for the accelerator control. We also provide the future option of controlling the facility equipment from the accelerator control system. For the implementation, we outsourced the construction of the gateways, including data acquisition software of the MADOCA framework, to overcome the problems imposed by our limited manpower and short construction period. We were able to smoothly install the GWs in the accelerator control system by effectively using a test environment. The number of acquired signals is 678 signals with a slow sampling rate and 382 signals with a fast sampling rate.

Figure 2 shows the correlation between the delay of the trigger jitter at a linac M6 thyratron and the receiving voltage in July 2011. One of the sources of instability for the linac RF output is the jitter delay of a thyratron. As can be seen in figure 2, when the receiving voltage increases, the jitter delay decreases. Accelerator specialists installed an automatic voltage regulator (AVR) in the power supply of an M6 thyratron in August 2011. They are considering the installation of AVRs into other thyratrons. It is now possible to easily obtain and refer to the utilities data from the database because of the construction of the utilities DAQ system.

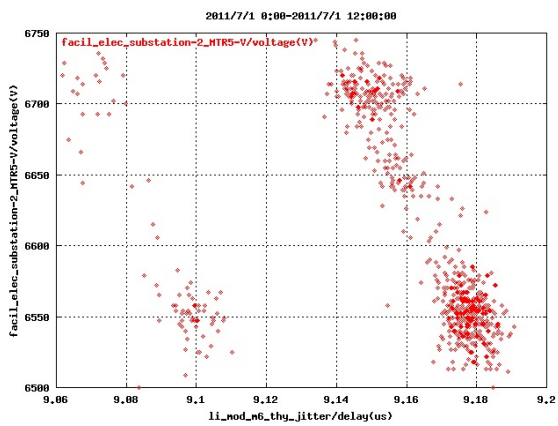

Figure 2: Correlation between delay of trigger jitter at linac M6 thyratron and receiving voltage.

Abstract

The Neutron instrument BIODIFF is a single crystal diffractometer for biological macromolecules that has been built in a cooperation of Forschungszentrum Juelich and the Technical University of Munich. It is located at the research reactor FRM-II in Garching, Germany, and is in its commissioning phase now. The control and data acquisition system of BIODIFF is based on the so-called "Juelich-Munich Standard", a set of standards and technologies commonly accepted at FRM-II, which is based on the TACO control system developed by the ESRF. In future, it is intended to introduce TANGO at the FRM-II. The Neutron Image Plate detector system of BIODIFF is already equipped with a TANGO subsystem that was integrated into the overall TACO instrument control system.

INTRODUCTION

In protein crystallography X-ray diffraction is a successful tool for structure analysis. Neutron diffraction is a complementary method, since it can provide detailed information on hydrogen atom locations [1]. A further advantage is the possibility to differentiate between hydrogen and deuterium atoms. The development of Neutron Image Plate (NIP) detectors was a big advance for neutron protein crystallography leading to the developments of several instruments, e.g. the BIX-3 at the Japan Atomic Energy Research Institute and LADI-III at the Institute Laue-Langevin [2]. Also at the German research reactor FRM-II in Garching a single crystal diffractometer for biological macromolecules called BIODIFF has been developed as a joint project of Forschungszentrum Jülich and Technische Universität München (TUM). BIODIFF is a monochromatic instrument using a cylindrical NIP as its main detector. For adjustment purposes it is equipped with a CCD camera looking at a ZnS:Li scintillator as an auxiliary detector [3]. The complex mechanics of BIODIFF includes about 20 movement axes, mainly equipped with stepper motors. Additional control tasks are related to beam shutter control and sample environment. The control and data acquisition system of BIODIFF is based on the "Juelich-Munich Standard". This is a joint effort of ZEL (Central Institute for Electronics of Forschungszentrum Jülich) and TUM to define a common framework for the electronics and software of neutron instruments that is followed by most instruments at the FRM-II [4]. It is based on the TACO control system developed by the ESRF and the extensive use of industrial type front-end equipment, e.g. PLCs, fieldbus systems or remote I/Os.

OVERVIEW OF THE BIODIFF INSTRUMENT AT FRM-II

According to Fig. 1 the BIODIFF consists of two subsystems, the monochromator with its outer shielding and the detector housing.

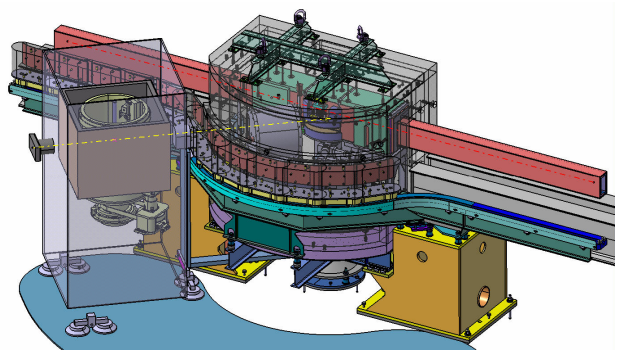

Figure 1: Schematic view of the BIODIFF instrument.

The incoming neutron beam is monochromated by a graphite crystal, which is movable in 6 degrees of freedom. An additional velocity selector from ASTRIUM removes the higher order wavelength contaminations of the monochromatic beam. By movement of graphite crystal, selector and detector housing a neutron wavelength between 2.4 Å and 5.6 Å can be selected. For the interruption of neutron beam and γ-radiation two shutters are foreseen.

The detector housing contains the cylindrical NIP as well as the CCD camera (icon-L series from company ANDOR), which both can be moved in and out by several mechanical axes. The NIP detector system is commercially available from company "Maatel". It contains the PMT-based reading head as well as the erasing system. Control of NIP drum movement, erasing and readout is implemented by Maatel as a self-contained system including an operating PC. On this PC a complete TANGO system is implemented, providing interactive local control as well as remote control via the CORBA-based TANGO protocol.

The NIP detector provides a solid angle of almost 2π, with the sample in the centre. Sample environments can be mounted on the sample table above the NIP detector, which is movable in three degrees of freedom. Additional fine positioning of the sample can be done with piezo-driven manipulators from company "attocube systems".

THE "JUELICH-MUNICH STANDARD"

The "Jülich-Munich standard" is a framework for the selection of technologies and components at each level of the control system. The definition of this framework was motivated by synergy effects and the reduction of spare parts on the shelf. A guiding principle for the framework was to minimize the development efforts and to acquire as much from the market as possible. A key component of the framework is the consistent use of industrial technologies like PLCs, fieldbus systems or decentral periphery in the front end. Main motivations are:

- low prices induced by mass market,
- inherent robustness
- long term availability and support from manufacturer
- powerful development tools

A control system according to the Jülich-Munich Standard is organized hierarchically into the following levels:

Field level: The field level is the lowest level, at which devices that are not freely programmable reside, like motor controllers, SSI controllers, PID controllers, analogue and digital I/O modules, or measurement equipment. For all industrial type of I/O modules PROFIBUS DP based decentral periphery is recommended. Siemens ET200S is the preferred one. Jülich Centre of Neutron Science (JCNS, Neutron science institute of Forschungszentrum Jülich with outstation at FRM-II) predominantly uses the stepper motor controller 1STEP from Siemens.

Control level: The control level resides on top of the process level. Devices at the control level are freely programmable. They must meet real time requirements and guarantee robust operation in a harsh environment. At the control level Siemens S7 PLCs, mainly from the S7-300 family, are used, because they dominate the European market.
