While this approach may seem complex at first, it has many advantages: the complexity remains in the FESA framework, where it is thoroughly tested. The user only has to write a single implementation of the code which communicates with the hardware, and as a result only has to test one code path.

## TRANSACTIONS ACROSS PROCESS BOUNDARIES

The FESA framework may be used in what is called "split mode". This is meant for highly critical systems, which should always be up and running. In this mode, the real-time part of a FESA deployment is launched in a process, while the server part, responsible for handling client requests, runs in a separate process. This can be seen as a way to sandbox the real-time process.

The two processes communicate using standard IPC methods: shared memory, message queues, shared mutexes and condition variables. From a user point of view, nothing changes feature-wise, but there are a few restrictions, mainly due to the fact that pointers are not valid across process boundaries.

In order to implement the transactions feature in FESA, these considerations had to be taken into account. As a result, the transaction buffer, allocated when a transaction is opened, is a dynamic structure which cannot contain pointers. The devices and their settings are given unique indices, allowing to identify them across the two processes of a split mode deployment. Every transaction buffer also contains a mutex and a condition variable, which are used to signal the completion of the test, commit, and rollback events.

There is another consequence of running in split mode: the memory allocated for the transaction buffer must be contiguous, as it is mapped between the two FESA processes using the *mmap* system call, which takes an address and a size. However, it is not possible to know in advance how much memory will be needed for the transaction buffer: the client opens the transaction sequentially on an unpredictable number of devices. Furthermore, it is allowed to add devices to the transaction as long as the test request has not been sent.

To solve this problem, a naive solution would be to allocate all the memory potentially needed immediately, by computing the maximum size of the transaction, which corresponds to the size of all the settings of all the devices in the server, plus the size required for the transaction's bookkeeping structure. However, many FESA processes operate on machines which have a low amount of memory, without enough memory left to do this. This means that it would be impossible to conduct a transaction on such a server, even if it would affect a single device.

The solution is to take advantage of the MMU of the CPU, and the capabilities of the operating system: it is possible to reserve a chunk of contiguous memory in a process, without actually mapping it to any physical memory. This works even with memory shared between processes, by using the appropriate flags in the call to *mmap*: with `PROT_NONE` as protection together with the `MAP_PRIVATE` and `MAP_ANONYMOUS` flags, the memory is marked as inaccessible, causing the operating system to not allocate any physical memory, but to still reserve the address space in the process, guaranteeing a contiguous memory block. When the buffer needs to be extended, and some actual physical memory allocated, *mmap* is called again, allowing to allocate an arbitrary amount of the reserved memory. This time, we pass `PROT_READ` and `PROT_WRITE` to make the memory readable and writable, together with the flags `MAP_FIXED` and `MAP_SHARED`, ensuring respectively that the address of the reserved memory is not changed, and the memory is visible in other processes.

Tests on multiple Linux platforms have shown that this works as expected. On Windows platforms, the same effect can be obtained by calling *VirtualAlloc* with the flag `MEM_RESERVE`, and then `MEM_COMMIT`.

## CONCLUSION

The design and implementation of distributed transactions in CERN's accelerator control system have been described. During the design process and for simplicity reasons, a choice was made to not make it resilient to hardware errors, but instead to allow the detection of errors until as late as possible before the commit happens. The reason is that, unlike a database, if a hardware error occurs, rolling back to the previous state is not necessarily possible, nor desirable.

Because of this, implementing a strong guarantee on the atomicity of transaction commits is not possible. Any attempt at doing so would be much more complex than the presented implementation and would require compromising on other aspects, such as the time needed to process a commit. In addition, keeping the distributed transaction design relatively simple ensures that it is possible to implement on any device. In practice, this allows to offer in FESA both a "transparent mode", allowing users to enable transactions on their devices without having to write a single line of code, and an "advanced mode", where users can fully benefit from the flexibility of the 2-phase commit.

Nevertheless, given the nature of the commit and rollback events, a logical next step is to implement a system of feedback to allow clients to know immediately if a commit failed, and why. Since the commit and rollback events are broadcast by the timing system, this requires an extension of the protocol to allow clients to be notified when that happens.

# DEVELOPMENT OF AN AUTOMATED HIGH TEMPERATURE SUPER-CONDUCTOR COIL WINDING MACHINE AT CERN

H. Reymond, M. Dam, H. Felice, A. Haziot, P. Jankowski, P. Koziol, T.H. Nes, F.O. Pincot, S.C. Richter, CERN, Geneva, Switzerland

## Abstract

Within the framework of technology studies on future accelerators, CERN has initiated a five-year R&D project aimed at the evaluation of REBCO (Rare Earth Barium Copper Oxide) High Temperature Superconductors (HTS). The study covers a number of areas from material science to electromechanical properties. The REBCO high-field tape will be tested on different HTS magnet prototypes, such as HDMS (HTS Demonstrator Magnet for Space), GaToroid (hadron therapy Gantry based on a toroidal magnetic field) and other smaller coils that will be fabricated to study the tape's potential. To assemble the HTS coils, a new automatic winding station has been designed and constructed at CERN. A touch panel combined with embedded controller, running software developed in-house provides a sophisticated, yet intuitive and user-friendly system aimed at maintaining perfect coil winding conditions. In this paper, we describe the mechanical choices and techniques used to control the seven HTS spool tapes and the winding machine. We also present the analysis of several coils already produced.

## INTRODUCTION

Whether for the next generation of high energy particle accelerators, or for the development of new equipment dedicated to physics or medical research, one of the main decisive factors in the future will be the industry's ability to produce superconducting magnets with a field of at least 20 T [1].

Being one of the world leaders on superconducting magnet technology, CERN has been given responsibility of work-package 10 (WP10) "Future Magnets" as part of their contribution to the EuCARD-2 project [2], supported by the European Commission's Seventh Framework Programme (FP7). WP10's main goal was to manufacture and qualify an HTS cable, within real demonstrator coils and magnets, having useful characteristics for accelerator magnets (dipole field of 20 T, industrialized production, affordable cable, ...).

After studying several possible candidates, the REBCO tape was chosen as an appropriate candidate, mainly because of its mechanical properties, but also due to its availability through many different suppliers, and finally because it doesn't require any further treatment before assembly [3].

In 2017, the ARIES European program was launched with the objective of improving the REBCO tape current density [4]. In parallel, CERN initiated a 10-year research program (CERN HTS program) to study and develop dipole magnets with magnetic fields beyond 20 T [5].

## The Prototypes and Demonstrators

To test and evaluate the new requirements, several R&D studies were launched, each focusing on different technologies.

- The HTS demonstrator magnet for space (HDMS) aims at validating the feasibility of a new generation of magnet to be used for a spatial spectrometer [6].
- The 20 T HTS Clover Leaf End Coils magnet to study the mechanical and magnetic aspects of so-called overpass / underpass coil end assembly [7].
- The 8.2 T toroidal coils, which would be the basis of the GaToroid CERN proposal, for a new gantry design in the field of Hadron cancer treatment [8].
- The small coils program as a general study of high-field accelerator magnets for Hadrons and Muons (solenoid, undulator) [9].

## The Coil Winding Machine

In order to co-wind stacks of REBCO tapes, dedicated tools and custom machinery is needed for its assembly. It was therefore decided that the coil-winding machine would be built in-house, at CERN. As a result, different teams involved in anything from magnets design, mechanical studies to control system development, joined forces to manufacture and assemble the machine in just a few months [10].

## THE WINDING MACHINE DESIGN

One of the main requirements of the machine design was the semi-automation of the winding process to be capable of working with up to 7 tapes simultaneously. An important request was the ability to set up and control in a closed loop the tension on the spools, with added monitoring and storage of the results.

The winding station was built as a long table made of aluminium profiles with 7 spools, each connected via a clutch to a dedicated motor (Fig. 1). Next to the spool holder, custom-made tape routing equipment was installed, both guiding and measuring the tension applied to the tapes. In addition, tape alignment tooling with a built-in length encoder was incorporated into the machine to merge and adjust the tape position before winding the coil.

Figure 1: Winding station 3D model.

## THE CONTROL SYSTEM

After assembling the winding station, the decision was made to build and develop a control system using a CompactRIO [11] controller from National Instruments, taking advantage of its combined RT-FPGA nature, and also because some machines hosted in the workshop had already been successfully renewed with this solution. To allow easy and intuitive human-machine interfacing, a Windows based touch panel was added to the system, allowing the user to constantly monitor the winding process parameters, as well as reconfigure regulation coefficients.

Early in the control system design phase we realized that even minor abnormalities in the operation might have critical impact on the components and the winding process product itself. It was clear that maintaining perfect tension conditions (7 – 100 N) of REBCO tapes would be key to the performance of the manufactured coil.

During the initial design, three important aspects were identified. First, the controller is supplied with quarter bridge strain gage inputs and AO voltage modules. Second, gage signals are used as process variables of the PID regulation loops, running on the embedded FPGA, while the outputs operate as a source (0 – 10 V range) to control the clutches. Third, the cRIO controller also handles DIO signals, connected to the motor relays, safety system buttons and encoders (Fig. 2).

A logging option was added to keep track of parameter changes. These are stored in a file referenced to the manufactured coil for future quality insurance assessment.

### Mechanical Control of the Spools

When the machine is running, only the clutch is actively controlled, while both the gear and the motor are statically configured. This makes it possible to control the final torque, speed and cable tension by regulating the clutch. Due to safety-related aspects, the station is designed to disengage power transmission when idle. The

clutch is controlled proportionally with a current between 0 and 2A, allowing active control of the spool.

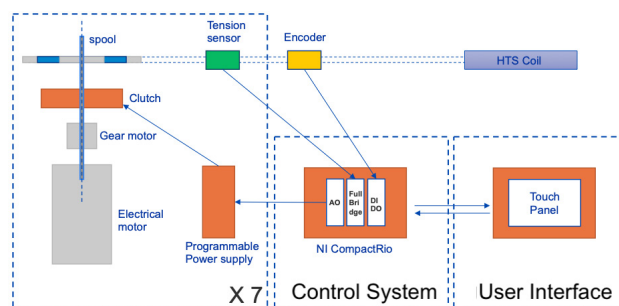

Figure 2: Mechanical diagram of the machine.

### Sensors

One important factor when choosing suitable tension sensors is their readout range. Those selected for the assembly have slightly higher limits than required (200N), but one must consider their location in reference to the spools. As the point of contact between the cable and the strain gage pulley is rotated by 45° relative to the pull direction, the real maximum value of the tension that can be read on the tape is closer to 140N. This value can be adapted by orienting the sensor differently.

### The Embedded Controller

The cRIO-9053 controller used for the project has proven to be a good choice in terms of its price/capability ratio. Our optimizations, such as pipelining and reduction of critical paths, allowed us to implement the software in a relatively small FPGA.

### Software Architecture

Since the final implementation of the winding machine was not completely defined when the project started, we had to choose a flexible yet scalable software architecture that could easily be adapted to changing project requirements.

The software was developed using an optimized QMH (Queued Message Handler) software architecture. By offloading most resource-consuming tasks such as PID calculation to the FPGA, and by running the GUI on an external Windows based touchscreen-enabled computer, we managed to fit the application on the RT controller.

### The FPGA Application

An FPGA-based firmware executes the most critical and time-consuming calculations related to the PID algorithm as well as direct hardware interfacing. Of seven parallel processes, three of them are related to regulation. Even if coil winding is a relatively slow process, the stable clocks of the FPGA tasks allow them to react very quickly to any change in the tape's tension by running the main loop with a cycle time of a few milliseconds.

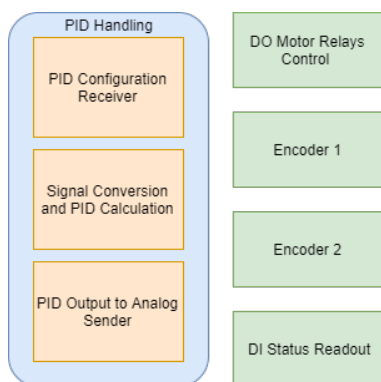

Figure 3: FPGA application parallel processes.

The FPGA implementation is divided into 3 main processes (Fig. 3). The First process is mainly dedicated to configuration management and parameter updates. The second process performs low-level signal calibration and conversions and stores calculated PID outputs into memory blocks. Finally, the third process reads control variables from memory and writes to the analogue and digital output modules.

Thanks to this modularized approach, the code is compartmentalized and simplified, preserving high configurability (fragments of program logic can be disabled or supplied with simulated parameters instead of real ones).

### GUI and User Interaction

The main challenge when implementing a graphical user interface for the project was to keep it simple enough to ensure clear understanding of the machine status, yet deliver a fully functional tool to the operators. This was made even more difficult considering the low resolution and relatively small size of the touch-panel (Fig. 4). Ultimately, close cooperation with the operators and an iterative approach to development paid off with satisfactory results. The user interface is split into three panels (Fig. 5): Operator settings, runtime monitoring view and expert settings.

Figure 4: Winding machine with touch-panel user HMI.

The first panel consists of elementary winding process configuration, where the user needs only to specify

tapes and tension to be used, in addition to optional informational values like operator or coil name.

The second tab provides run-time information and controls. In the central part, the application plots the current tension on a graph while on the left there is an adjustable set point indicator. This way, the user can perform slight tension adjustments during the winding process. The lower part of the GUI is reserved for the encoder readings (they are used to track used tape length and coil layers achieved). Two registers are kept for each encoder: temporary and total reading. The former resets on operator request and the latter is cleared only on winding process start-up. From this panel, the operator can start and stop regulation.

The “Expert Settings” panel is meant to be used only by experienced engineers to modify PID, sensor calibration and debug functionality. This tab is also password protected as because using these options by non-qualified users could damage the coil and REBCO tapes. A final feature from this panel is the live monitoring of some key electrical elements, like the power supplies, the safety stop relay and the motor contactors.

Figure 5: Application GUI.

### PID Regulation

The coefficients of the PID regulations were first estimated, based on a theoretical approach. Then by using a spool of a few meters of copper tape, we adjusted them by executing dozens of tests of the regulation loop. During this process, some mechanical changes were made for the position of the strain gages and the pulleys. Following the final acceptance of the mechanical assembly of the machine, a test campaign was executed with 7 spools of copper tape during which the complete regulation loop was fine-tuned (mechanical, electrical and software parts).

### COIL PRODUCTION RESULTS

Since 2020, the winding machine was used to produce HTS small solenoid, Undulator, HDMS, and Gatoroid coil prototypes. The currently produced pieces have been evaluated and mechanical parameters were assessed to improve the winding processes. Many trials were performed with partial winding of these coils and iterations of the assembly protocol, conducted to validate most of the coil prototypes production steps.

#### The Solenoid Coil

The first prototype (Fig. 6) was made using copper tape. It allowed us to validate some steps of the coil assembly:

- The tape tension (30 N)

- The soldering process of the first turn on the copper ring support (before the winding)
- Soldering paste and heater device ( $T = 176^\circ \text{C}$ ) between each turn

Then the next prototypes were wound on another machine, as the seven spools winding machine was occupied by other projects (HDMS/Gatoroid).

Figure 6: a) Solenoid coil winding, b) Soldering paste deposit.

### The Undulator Coil

The winding machine was used to produce the very first vertical racetrack (VR) coil prototype [12], with two 4 mm copper tapes (Fig. 7). The simultaneous winding of two tapes was validated, but the distribution of the solder in between tapes was not uniformly distributed as needed. It was decided to wind the following prototypes in a vertical winding orientation, which was possible on another winding machine already present in the workshop, which was adapted for this purpose.

Figure 7: a) Winding of the first VR coil, b) The final coil after the soldering process.

### The HDMS Coil

Five coils were made with the winding machine. Only the third and the fifth did not have geometrical errors. Finally, only the fifth one was retained to validate the winding process, using three copper tapes 12 x 01 mm, with an applied strain of 20 N on each. Several steps of the HDMS coil assembly (Fig. 8) still need to be tested (last turn fixing method, ...) or studied (external copper ring to maintain the coil) but this is beyond the scope of the winding machine.

Figure 8: a) The winding machine with the 3 tapes, b) The HDMS coil winding, c) The complete coil.

### The Gatoroid Coil

A first trial was done with this assembly scheme: six copper spools installed on the winding machine (1 x 0.5 mm, 4 x 0.1 mm, 1 x 0.5 mm). Several winding iterations permitted to get the optimal strain to apply on the tapes (50 N on 0.5 mm, 30 N on 0.1 mm). A second trial, using an S-2 fiberglass sleeve, was done to validate the insulation between the layers (Fig. 9). This also confirmed the tension and trench geometry for the coil support. A new mount for the fiberglass sleeve was added to remove friction at the entry point. The assembly process of the second layer spools was also validated by adding a second winding station, made of one axis and six spools. The six tapes were passed through the insulations and were again separated into six independent spools in the winding machine.

Figure 9: a) The winding machine with the 6 tapes, b) The S-2 Fiberglass stored on the tapes path, c) The Gatoroid coil.

## CONCLUSION

The production of the first batches of coils showed that the winding machine works properly. Considering our broad experience with the NI ecosystem, time-constraints, and the robustness of FPGA based solutions, a CompactRIO controller was a clear choice as a basis for the control system. The complete control loop, from the strain sensors, the FPGA running the PIDs, up to the clutches is now set up with very good accuracy. Some mechanical parts have been reengineered during the test and validation campaign (position of pulleys in the merged tapes area, space between pulleys, orientation of the strain sensors). The GUI has been improved to offer more features during operation (easy control settings from the RUN panel, logging of all the commands for future support cases investigation). The winding machine now provides

an efficient service for the production of HTS coil prototypes at CERN. The possibility to wind and unwind a coil gives freedom in using copper tapes (less expensive), for process validation purposes.

### FUTURE PLANS

The validation and initial tests of some winding processes have uncovered needs for mechanical improvements. Several new modules are being designed for some specific phases of the coil winding, such as new fiberglass sleeve storage and mounting system, a thermoforming device for the polyimide insulation thin film layer, and a new dimensional measurement control system for the respooling phase.

On the control and software side of the winding machine, some new features are already planned for better management of the HTS tapes inventory. The idea is to link the GUI with a database to get tape identification and parameters. This will be done by scanning a QR code on the spools to then import automatically the associated properties from the database. This will improve the QA and traceability of the produced coils, by saving tape characteristics with the data generated during the assembly. At the end of the process, this data will be archived in the database. The lengths of used tapes will also be automatically updated to allow an accurate management of available stocks.

# CONTINUOUS INTEGRATION FOR PLC-BASED CONTROL SYSTEM DEVELOPMENT

B. Schofield\*, J. Borrego, E. Blanco, CERN, Geneva, Switzerland

## Abstract

Continuous Integration/Continuous Deployment (CI/CD) is a software engineering methodology which emphasises frequent, small changes committed to a version control system, which are verified by a suite of automatic tests, and which may be deployed to different environments. While CI/CD is well established in software engineering, it is not yet widely used in the development of industrial controls systems. However, the advantages of using CI/CD for such systems are clear. In this paper we describe a complete CI/CD pipeline able to automatically build Siemens Simatic Programmable Logic Controller (PLC) projects from source files, download the program to a PLC, and run a sequence of tests which interact with the PLC via both a Simulation Unit Profibus simulator and an OPC Unified Architecture (OPC UA) interface provided by Simatic NET. To achieve this, a Google Remote Procedure Call (gRPC) service wrapping the Simatic Application Programming Interface (API) was used to provide an interface for interacting with the PLC project from the pipeline. In addition, a Python wrapper was created for the Simulation Unit API, as well as for the OPC UA interface, which allowed the test suite to be implemented in Python. A particle accelerator interlock system based on Siemens S7-300 PLCs has been taken as a use case to demonstrate the concept.

## INTRODUCTION

In software engineering, Continuous Integration (CI) refers to a method of development in which changes are regularly incorporated into a central repository. It is very often associated with the presence of build and test automation, in which code is automatically compiled, and a set of tests run. The objective of the methodology is to provide early detection of bugs introduced by code changes, and to simplify workflows in the case where there are several developers working on a single code base (the alternative is to perform periodic merges of the individual developers' branches, which may be very complex if many changes have been made).

Continuous Deployment (CD) is perhaps less well defined, and entails at least the automatic release of some artefact of the automated build process in the CI stage. It may also involve the fully automatic deployment of the artefact in a production environment.

Software for PLC-based control systems traditionally does not follow CI/CD principles, for a number of reasons. Generally, proprietary engineering tools are used as the development environment, in which code is written, compiled and downloaded to the PLC.

In general there is no support for external version control systems to be used for the source code, at least as far as CERN's standard PLC suppliers are concerned (Siemens, Schneider). Instead, often the full project is included in version control as the collection of files and data used by the engineering tools, provided one is using version control at all. Tracking code changes is difficult, and merging branches is effectively impossible with such a workflow. Automation of the building of PLC projects is not trivial, as not all engineering tools provide easy access from scripting languages to these functionalities. Finally, automated testing proves to be cumbersome for a number of reasons that will be elaborated in later sections.

The question addressed in this article is whether it is technically feasible to implement a CI/CD workflow for PLC-based controls development, and if so, whether such a workflow is practicable and useful in a real-world application.

In order to address the first point, set of tools will be introduced which aim to overcome the obstacles preventing the adoption of CI/CD for PLC-based control system development. Tools for automation of the build process are proposed, with the focus on Siemens Simatic applications, although tooling for other engineering tools has also been developed. An approach for implementing automated testing of the complete PLC program is described, consisting of an interface to a fieldbus simulator, as well as an OPC UA interface to the PLC and Supervisory Control And Data Acquisition (SCADA) layers of the control system.

To demonstrate these tools, and illustrate their potential, a use case consisting of an interlock system for the Large Hadron Collider (LHC) is presented. Major updates and refactoring of this control system have been enabled by employing the CI/CD workflow presented in this article.

The article begins with addressing the question of the tooling required to automate the building of PLC projects. After that, automatic testing is addressed. Finally, the use case is explained and details of the proposed workflow are given within the context of that project.

## TOOLS FOR AUTOMATING PLC PROJECT BUILDING

### Intended Workflow

In order to implement CI/CD for PLC-based applications, it is necessary to adopt a similar underlying development workflow to that used elsewhere in software engineering. Fundamentally, this means adopting the use of version control for all source code. The source code is then compiled to produce some form of output, for example executable programs or libraries, for one or more target systems. These outputs in themselves do not need to be included in version

\* Corresponding Author. E-mail: brad.schofield@cern.ch

control, as they can simply be recreated from a specific state of the versioned source code. The outputs are often referred to as *artefacts*. The CI/CD approach is to automate this process of creation (and subsequent deployment) of artefacts.

In the majority of mainstream programming languages, the source code simply consists of text files. The most widely used version control systems are therefore also based on the use of text files. If it is intended for the complete source of a PLC program to be stored in a version control system, this introduces some restrictions. Of the IEC-61131-3 languages, only the languages which can be represented in text, namely Structured Text (ST) and Instruction List (IL) are suited to this approach. However, the requirement to use non text-based PLC languages does not preclude the use of the proposed approach; it may be the case that a part of the code base is implemented in text-based languages, and other parts in non text-based languages, of which the former are tracked in an external version control tool and the latter kept in the PLC engineering tool.

### PLC Engineering Tools

As previously mentioned, Programmable Logic Controller (PLC) engineering must be performed using the proprietary engineering tools supplied by PLC vendors. The interface for such tools is typically a Graphical User Interface (GUI), in which importation of code from external sources, code editing, compilation, configuration of the target, and downloading of the program are performed. In general, these tools do not have good support for version control systems, meaning that it is difficult to maintain consistency between source code that is maintained in version control, and the resulting compiled version of a project. This is in essence the core problem being treated in this paper. While it is possible to use dedicated version control tools for PLC projects such as *versiondog*<sup>1</sup>, they lack some of the more advanced features of version control systems employed in standard software development like *git*. They also implicitly track all changes to the compiled project, whereas the desired workflow outlined here aims at keeping only the text-based sources in version control, excluding any derived binaries and other non-essential data files. In order to achieve the desired workflow, it is necessary to automate tasks ranging from importation of external sources, to compilation and ultimately downloading of the project to a PLC. If this can be achieved, then the CI/CD workflow will be able to guarantee consistency between source files in the repository and a program running on a PLC, something which is currently not possible with existing tools.

In this work we focus on the engineering tools for Siemens S7-300 PLCs, since these are present in the system at hand. These PLC projects are developed using *Simatic Step 7*, which exposes a C#/Visual Basic API. We developed a C# library which allows us to import source files, build the project and download it to either a test or production PLC. We then designed a simple gRPC service, allowing our C# server to

fulfil requests and interact directly with the *Step7* library, which can be launched from remote clients, implemented in whichever language is convenient. We use a Python client due to its simplicity of use and to match the environment for running the integration test suite. Figure 1 shows the client/server architecture for the proposed S7 gRPC service.

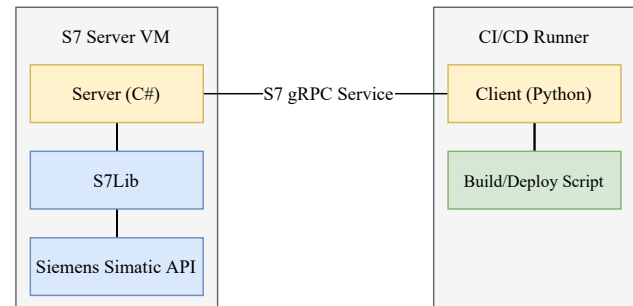

Figure 1: Architecture of the Simatic build tools.

The S7 gRPC service exposes several methods, namely:

- **CreateProject** to create an empty *Simatic* project given the project name and destination path;
- **ImportSource** to import a source file into project;
- **ImportSymbols** to import a symbol table file into project;
- **CompileSources** to build target sources into blocks;
- **CompileAllStations** to build the hardware configuration for each station in the *Simatic* project;
- **StartProgram** to start/restart a specific program on the target CPU;
- **StopsProgram** to stop a specific program on the target CPU;
- **DownloadProgramBlocks** to download a specific program to target CPU.

Finally, we have also developed similar tooling to support newer Siemens S7-1500 and Schneider CPUs, although these are not in the scope of this article.

## AUTOMATED TESTING FOR PLC PROGRAMS

With automated build and deployment tools in place, the last remaining piece required to implement a complete CI/CD workflow is the automated test suite. Automated testing of PLC programs is challenging for several reasons. For the majority of modern programming languages, there are numerous unit testing frameworks available, which make the implementation of unit tests almost trivially simple. In addition, it is generally not difficult to create a build configuration which will create test executables which can be run locally, for example on the developer's machine. This is

<sup>1</sup> <https://auvesy.com/en/versiondog>, as of October 21, 2021

however not the case for PLC programming languages. In order to implement true unit tests for PLC code, frameworks specific to a PLC type would have to be implemented. This topic is explored in [1], in which a unit testing framework for Siemens PLCs is developed. For integration testing, the problem is further complicated by the difficulty of ‘mocking’ the necessary interfaces (for example fieldbuses and supervision systems). Regarding the target on which the test code shall be run, in the case of PLCs this must be either a physical PLC CPU, or a simulator. While the simulator approach may be attractive, currently not all PLC simulators support the functionality required to implement complete test suites.

The approach to PLC program testing proposed here is to generate a PLC program which is either identical, or very close to the final program required in production. This program is then deployed to a physical PLC. The test suite is then implemented externally, and utilises a number of interfaces to interact with the PLC in order to run the tests. The interfaces to the PLC can be summarised as acting on three levels, namely the input-output or fieldbus level, the PLC program level, and the supervision level. These interfaces will be described in detail in the next sections, before describing how they can be combined into a single test suite.

In software development there’s a clear distinction between unit testing, integration testing and system testing. Unit tests focus on verifying the correctness of individual functions or modules in isolation. Integration tests aim at ensuring the module’s interface is correct and it behaves as expected when interacting with other modules. Finally, system testing verifies that a completely integrated system fulfils its requirements. Our proposal cannot be said to consist of unit tests, at least as far as the PLC source code is concerned. Instead we introduce a set of tests which verify that the control system fulfils its task accordingly, which is more strongly aligned with system testing. Even though we use several communication interfaces and thereby implicitly test them, they are not the focus of the test, so they cannot be considered integration tests. Nevertheless, we still mock the PLC inputs and evaluate outputs at both the PLC and SCADA layers.

### Fieldbus Simulators

A PLC application will almost invariably need to interact with the physical world via sensors and actuators. The input-output (IO) hardware required to do this may be installed locally to the PLC CPU, but is more generally installed in a distributed manner, and connected with the PLC via a fieldbus. The fact that this interface is standardised can be exploited for testing purposes, if simulators for such fieldbuses are available. In this article, the focus is on Siemens PLCs, and therefore Profibus and Profinet fieldbus simulators will be taken as examples. Siemens provides hardware which allows the simulation of arbitrary hardware configurations for both Profinet and Profibus. The units are controlled via an Ethernet interface, and a C API is available. For the

purposes of automatic testing, such a simulator can be connected to a test PLC, and a CI/CD pipeline could be used to configure the simulator (by loading a specific hardware configuration), and control IO values, both via the API. In order to more easily access the functionality of the simulation unit from the automated build and test suite, a Python wrapper `py-simulation-unit` was created.

### PLC Interaction via OPC UA

While the fieldbus simulator provides a way to mock field level input to the PLC, from the point of view of writing tests it may be valuable to access the internal state of the PLC program. This is fairly straightforward to achieve provided the target PLC can expose tagged variables in an OPC UA server. In the case of Siemens PLC, Siemens Simatic NET software provides such an OPC UA server, which runs in a separate workstation. Newer generations of PLCs also have onboard OPC UA servers, further simplifying the setup.

In [2], OPC UA was used as the exclusive interface for testing PLC applications. This was possible because the applications under test were all created with the UNICOS framework [3], the structure of which provides a simple way to ‘override’ the hardware IO interface with values written over OPC UA. This effectively means you can mock the IO at the PLC program level. Depending on the way in which an application is written, it may not always be possible to do this, and IO simulation may be necessary.

In this work, the OPC UA client API from the open source LGPL Pure Python OPC UA<sup>2</sup> package is used.

### Supervision Systems

A PLC-based control system most often interacts with a SCADA system, in which operators can observe the status of the system, and send commands to the PLC. In certain cases there may be additional logic implemented in the SCADA system, which provide further inputs to the PLC. Rather than mocking the SCADA interface (which in the use case presented in this article consists of Siemens S7 communication with a CERN-specific protocol built on it), it was decided to instantiate a SCADA system specifically for the test setup, and to interact with it via OPC Unified Architecture (OPC UA). This interaction allows the test suite to ‘force’ operator actions and logic outputs to the PLC, and thus provides a very realistic test setup. An added benefit is that the test suite can be used for manual validation of the graphical features of the SCADA system, as shown in Fig. 2. Effectively, by visual inspection of the SCADA faceplate it is possible to monitor the automated test execution in the lab setup. The SCADA system used here is built with WinCC OA, using features from CERN’s UNICOS framework [3].

<sup>2</sup> <https://github.com/FreeOpcUa/python-opcua>, as of October 21, 2021

Figure 2: Part of the SCADA faceplate for one Powering Interlock Controller PLC. The automated test suite can be used to drive inputs to manually validate the supervision layer.

## USE CASE: LHC POWERING INTERLOCK CONTROLLER

An example of the utilisation of the proposed CI/CD workflow can be found in the Powering Interlock Controller (PIC) of the LHC. This system controls the powering of the superconducting magnets of the LHC, and consists of 36 Siemens S7-319 PLCs, physically distributed around the 27 km circumference of the LHC as shown in Fig. 3. Each PLC is responsible for managing the interlocks for a certain number of electrical circuits powering the magnets. Depending on the types of magnets being controlled, the PIC is required to monitor different types of signals, and perform different interlock actions. All 36 PLCs utilize a common generic code base, which is parameterized in each PLC using source files which determine input-output mappings and circuit types [4].

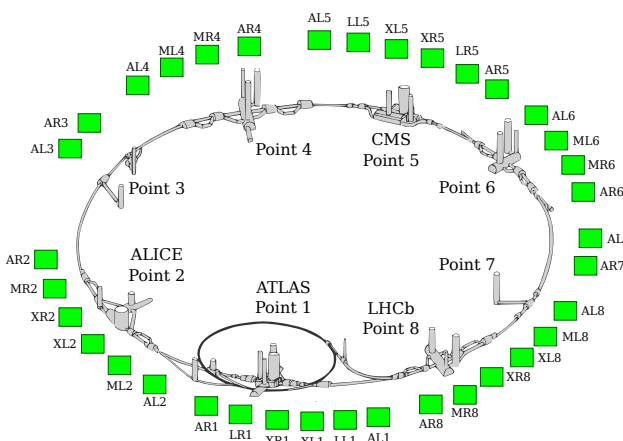

Figure 3: Layout of the LHC showing PIC PLC locations. Each PLC is shown as a green box with the corresponding name.

## Legacy Workflow

Prior to implementing a CI/CD workflow, the method used to update the generic code was to edit it in each Simatic project. This was time-consuming and error prone. Deployed versions of the PLC projects were kept in versiondog, which enabled tracking of changes to each individual Simatic project. Testing was performed manually with a hardware-based lab setup. Consistency between the code depoloyed on the lab setup, and that deployed in the production system had to be handled by the developer.

## CI/CD Workflow

The starting point of the CI/CD workflow was the creation of a GitLab repository containing a set of sources (ST and IL files) for both the generic code (the same for all PLCs) and the configuration code (different files for each PLC). A set of 'base' Simatic projects, containing the hardware configurations of each PLC, are also included in the repository. It should be noted that these projects are only used as inputs to the workflow; that is, the resulting complete Simatic projects are not versioned in git.

**Lab testing workflow** The automated testing is performed in the lab, using an identical PLC to those used in production, connected to a Siemens Profibus Simulation Unit. An additional Simatic project containing the configuration of this PLC is present in the repository; the hardware configuration of which is the basis of the Simulation Unit configuration.

The build stage of the CI/CD workflow uses a Python build script to import the generic sources as well as the specific configuration sources of the configuration to be tested. The resulting program is compiled. Finally, the complete PLC program is downloaded to the lab PLC. In order to update the OPC UA server used for the testing, the script also downloads to the OPC UA station.

With the build stage complete, the test stage can begin. This simply involves calling pytest on the complete test suite. Test fixtures manage the connections to the Simulation Unit, as well as the OPC UA servers for both the PLC and the SCADA. An example of a pytest fixture is as follows (for the PLC client):

```
@pytest.fixture
def plc_client() -> Client:
    """Returns an OPC UA client connected to the PLC"""
    client = Client(CLIENT_PLC_URL)
    client.connect()
    yield client
    client.disconnect()
```

Listing 1: Fixture for OPC UA PLC Client

The SCADA client fixture follows the same pattern. The simulation unit fixture (called simba in this use case) is slightly more complex as the hardware configuration is loaded.

A specific test may use any combination of these fixtures, depending on what needs to be accessed in the test. The following is a very simple test to verify the magnet quench detection status for the main dipole magnet circuit:

```
def test_quench_abort_status_rb(plc_client, simba):
    """Main Dipole Quench Status test"""
    plc = plc_client.get_root()
    status_abort = plc.get_child("7:A_A_1_ST_ABORT")
    quench_status =
        plc.get_child(['7:1_Instance1_Circuit1',
            '7:Quench_Status'])

    simba.write_io_bin('S000I4.1', 1)
    wait()
    assert status_abort.get_value() is True
    assert quench_status.get_value() is False

    simba.write_io_bin('S000I4.1', 0)
    wait()
    assert status_abort.get_value() is False
    assert quench_status.get_value() is True
```

Listing 2: Example Test for the Power Interlock Controller System

It can be seen that the inputs are manipulated using their hardware addresses directly, via the `simba` fixture. If desired, an abstraction layer based on the signal list of a specific project could be implemented to simplify the reading and writing of the tests. The test assertion is based on accessing the instance data block of a specific function block representing a state machine corresponding to the main dipole circuit, and verifying that a particular property is correctly set. This illustrates the usefulness of the OPC UA connection to the PLC, as this information may not necessarily be accessible via other interfaces such as the SCADA.

Naturally, the more complete functionality tests are more complex than the examples reproduced here, but all tests follow the same principles. All three interfaces are used to drive the program to the desired initial state, and then test inputs can be given, representing either field or operator input. The interface to the internal PLC data allows many ‘fine-grained’ assertions to be made, such that if a test fails, it is easy to identify the location in the code that caused the failure.

**LHC build workflow** With the tests passing, it is now possible to build all 36 PLC projects ready for deployment to the LHC. For this build stage, the build script is parameterized by the different subsectors of the LHC, allowing some control over which PLC projects are built. This can be useful as interventions are typically performed on one sector of the LHC at a time, and the complete build pipeline for all 36 projects takes approximately 2 hours to run. Currently, automatic deployment is not performed for the production PLCs although there is no technical barrier for this. Instead, the artefacts of the build pipeline (i.e. the `Simatic` projects) are added as a new version to `versiondog` and downloaded

manually. The complete conceptual workflow is illustrated in Fig. 4.

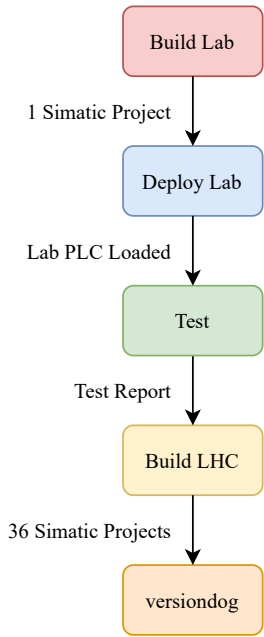

Figure 4: The conceptual CI/CD workflow. Labels by the arrows describe the artefacts produced by the preceding stage.

**Tangible benefits of the CI/CD workflow** In terms of the time saved for simply deploying a code change, the current workflow (with manual download) is estimated to reduce workload by approximately an order of magnitude. Manually updating each project would take at least a day, whereas simply downloading the resultant artefacts can be done in approximately one hour. With automated deployment, no developer input would be required after committing the changes to the repository and triggering the pipeline.

Naturally, the development time saved by having access to a full automated test suite is not as easily estimated, and must also be offset by the time taken to develop and maintain the test suite itself as well as the Continuous Integration/Continuous Deployment (CI/CD) infrastructure. Nevertheless, in the scope of this use case it has been clear that the CI/CD workflow has greatly facilitated development of new features, the refactoring of the code, as well as identification and resolution of bugs.

## CONCLUSION

In this article a complete CI/CD workflow for PLC application development is proposed, along with a set of tools which enable all of the necessary stages of such a workflow. In summary, these tools are:

1. A gRPC service enabling scripting of many operations needed during PLC project engineering, including importation of sources, compilation, and download;

2. A Python wrapper for the Siemens Simulation Unit API, allowing configuration and manipulation of simulated IO from Python;
3. An example of an automated test suite, implemented in Python and taking advantage of existing testing packages (pytest) as well as an open source OPC UA package to interface with the PLC and SCADA.

The complete CI/CD workflow has been illustrated using the Powering Interlock Control system of the LHC.

### Future Work

Currently, our test suite still refers to each simulated Profibus I/O channel by a tag name defined in the Simulation Unit project. A simple yet effective improvement would be to create an additional shallow abstraction layer that maps a meaningful device field to each I/O tag name. This would considerably improve the test readability.

Additionally, it seems feasible to automatically upload the PLC project built by the CI pipeline directly to versiondog, preserving a connection to a tagged commit in version control. This would effectively give us the best of both worlds: being able to quickly deploy to a running PLC while knowing exactly which source code is responsible for that specific version of the program.

Our current proposal still relies on manually creating base projects which include the hardware description. The need for these could be eliminated by just creating an empty project, automatically generating the hardware configuration and importing it as part of the CI/CD workflow.

Finally, one can think of how we can effectively implement unit testing at the PLC source code level by leveraging PLC simulators, namely with support for cycle-by-cycle execution, as is explored in [1].

# AN EVALUATION OF SCHNEIDER M580 HSBY PLC REDUNDANCY IN THE R744 SYSTEM A COOLING UNIT

D. Teixeira<sup>†</sup>, University of Cape Town, Cape Town, South Africa

L. Zwalinski, L. Davoine, W. Hulek, CERN European Organization for Nuclear Research, Geneva, Switzerland

## Abstract

The Detector Technologies group at CERN has developed a 2-stage transcritical R744 cooling system as a service for future detector cooling. This is the first system in operation at CERN where Schneider HSBY (Hot Standby) redundant PLCs are used. This cooling system provides a good opportunity to test the Schneider redundant PLC system and understand the operation, limitations and probability of failure in a controlled environment. The PLC redundancy is achieved by connecting Schneider M580 HSBY redundant PLCs to the system where one is the primary which operates the system and the other is in standby mode. A series of tests have been developed to understand the operation and failure modes of the PLCs by simulating different primary PLC failures and observing whether the standby PLC can seamlessly take over the system operation.

## INTRODUCTION

Previously, most large-scale systems at CERN have made use of multiple small PLCs where there is one running per subsystem and communicating with one leading PLC. The idea behind this is that if one PLC fails, the other subsystems are still able to operate. However, in previous experiences, losing one subsystem can cause erroneous readings fed to the other subsystems or interlocks created in the processes of the other subsystems.

In the context to avoid multiple semi-autonomous PLCs, EP-DT decided to go in the direction of a central powerful PLC connected to the different subsystems which each have communication cards that read and write inputs and outputs. This ensures the centralisation of information inside a single core element. In order to improve the communication availability of such systems the RIO loop was proposed following ring topology. This has been used in the MAUVE system with good results. The ring topology used is shown in Fig 1.

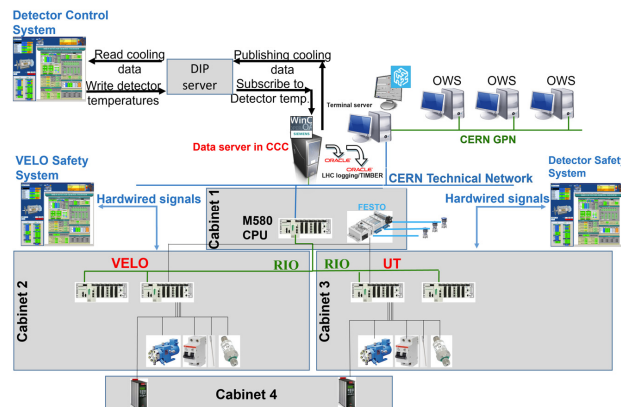

Figure 1: MAUVE control architecture.

For the LHC Phase II upgrade, two different cooling systems, CO<sub>2</sub> based, will be installed, namely the R744 Primary system (2 stages transcritical) [1] and the 2PACL (2 Phase Accumulator Control Loop) system [2], both of which are quite large with a high quantity of inputs and outputs.

The approach of a main core system to control the different remote IO was foreseen to be used in Phase 2. However, following recent technological developments by Schneider, the solution of PLC redundancy was proposed to improve the reliability of the system. Before installing the systems underground, this solution was first implemented on the surface with R744 Primary System A which is currently operational. Following this, it will also be used in the DEMO system which is a 2PACL equivalent currently being installed. The purpose of these surface systems is to gain experience on the process and validate the redundant architecture before installing the final systems underground.

## CONTROLS

### PLC Selection Following Current Solutions Available on the Market

The Schneider M580 HSBY redundant PLC was chosen for these systems due to satisfactory compatibility with the currently used UNICOS (Unified Industrial Control System [3]) framework as well as the simplicity of implementation. CERN makes use of mostly Schneider and Siemens PLCs, with Schneider being the most commonly used PLC in cooling applications. PLC redundancy has previously been implemented at CERN using Siemens PLCs (S7-400). However, the return of experience from our cryogenics colleague experts was giving a global difficulty with implementation and possibility to update code. There is a new type of PLC from Siemens which proposes a redundant

<sup>†</sup> TXRDAN001@myuct.ac.za

functionality. However, these PLCs (1500 generation) use dynamic addressing which is currently not the simplest to implement with UNICOS framework as this last one is establishing a link between PLC and SCADA through fixed addressing. This leads to a need of global update on both SCADA and PLC for any simple operation. The Schneider redundant PLCs used in the new systems are much simpler to maintain and program using the CERN environment.

### From the Electrical System Configuration to the Control System

Following the idea of improving the reliability and availability of the cooling systems, several decisions have been made in terms of electrical distribution and control systems. After performing an analysis of critical equipment, the most important elements are connected to a UPS (uninterrupted power supply) to avoid system failure during loss of power. To ensure circulation of CO<sub>2</sub> for example, the liquid pump creating the flow in the system is under UPS.

It is also critical to keep the 24VDC circuit operational. The approach here is to use two redundant power supplies, interconnected through a redundancy module, with one power supply under UPS. The configuration of the system can be seen in Fig. 2 below.

Figure 2: 24VDC Redundant power supply configuration.

The benefit of this configuration is that the failure of one power supply does not cause a loss of power to the 24VDC components and signals, meaning that we keep the monitoring possibility of the system and can monitor and track the current process even in case of interlock. This is needed for system diagnostic to understand the process state at any time.

Similarly, the use of redundant PLCs aims improve availability by removing the single point of failure found in single PLC applications. The system has two backplanes with two separated PLCs. Each PLC has its own communication card which communicate with the CERN Technical Network. Risk of failure is decreased by powering

each PLC with its own dedicated redundant 24VDC power supplies. The configuration of the redundant PLCs used in the R744 Primary System is shown in Fig 3.

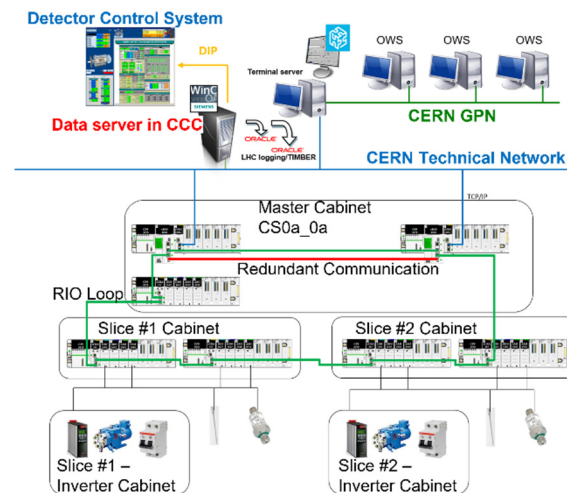

Figure 3: Topology of PLCs in R744 Primary System.

The green connections represent the RIO loop which exchanges data between backplanes. The red connection between the two PLCs represents the Hot Standby link which sends application variables, system status and I/O data from the primary PLC to the standby PLC. It is also used to compare the code program stored in each PLC [4].

The PLCs are named PLC A and PLC B, either one receives the role of primary PLC and standby PLC. This depends on several parameters such as which PLC was loaded first, internal logic comparison, and the state of the PLCs.

Both PLCs run the same program, with one acting as the primary PLC which operates the system and the other acting as the standby, ready to take over should the primary PLC become unavailable.

Additionally, efforts have been made to reduce errors in the system by using automatic code generation [5]. There are many basic and complex functions that are needed several times in each project, such as addition, subtraction, and saturation temperature calculations. Templates are written with the logic for each basic function and are then used to generate multiple similar functions where the PLC developer needs only to specify the names or values of the input variables for each instance. This way, the function is written once and can be used to generate as many iterations of the function as required. This reduces the likelihood of syntax errors which are common when developing code.

### Failure Modes

The Schneider HSBY redundant PLCs have already been installed in the R744 Primary System A and this system was used to test the various failure modes of the PLC, power supply, and communication with the technical network and remote IO backplanes. It is important to understand how the system operates under different combinations of failure modes and whether the system can still run under these circumstances. The results of these tests are summarised in Table 1. In these tests, a PLC failure is

defined as any loss of PLC operation, whether due to a failure on the power supply, a circuit breaker tripped, or a failure within the PLC itself.

Table 1: PLC and System Response to Multiple Failure Modes

Failure mode	PLC A	PLC B	System Response
1. PLC B failure	Primary	Off	Running
2. PLC A failure	Off	Primary	Running
3. Failure of both PLCs	Off	Off	Not running
4. PLC A loss of network communication	Standby	Primary	Running
5. PLC B failure & PLC A loss of network communication	Primary	Off	Running, no network communication
6. PLC B loss of network communication	Primary	Standby	Running
7. PLC A failure & PLC B loss of network communication	Off	Primary	Running, no network communication

In addition to the failure modes shown in Table 1, there are failure modes which result in more complex PLC and system behaviour. These cases are described in detail in Table 2.

Table 2: PLC and System Response to Complex Failure Modes

Failure mode	PLC Behaviour and System Response
8. Logic of PLC A different to PLC B	The PLC which is initially primary remains as such and the other PLC is in wait mode. The system operates without error.
9. Loss of one link between backplanes	The primary and standby PLCs remain as they were, and the system operates as normal
10. Loss of multiple links between backplanes	The primary and standby PLCs remain as they were, but the system runs with loss of functionality. The backplanes which are completely cut off from the PLCs are inoperable.
11. One PLC is completely disconnected from the RIO loop, the other has no connection to the Technical Network, the Hot Standby link is still available	The PLC connected to the Technical Network becomes the primary and the PLC which is still connected to the RIO loop is in standby. In this case the system does not operate as the primary PLC has no communication with the remote backplanes

From the system responses seen in Tables 1 and 2, it is clear that the only failure modes that result in loss of system functionality or full system failure are when both PLCs fail or multiple connections in the RIO loop are lost.

In addition to reducing the likelihood of failure, changing the primary PLC from PLC A to PLC B happens seamlessly with no effect seen in the system.

The switching between primary and standby modes makes use of the default switching logic from UNICOS, however, the developer does have the freedom to define user-specific conditions for this change. For example, the R744 Primary System A will make use of user-defined logic to modify the scenario shown in point 11 of Table 2. In the case that one PLC is disconnected from the RIO loop and the other is disconnected from the technical network, the default logic would keep the PLC connected to the Technical Network as the primary despite its lack of communication with the other remote backplanes. This is not consistent with the reliability definition established for the Phase 2 upgrade. Instead, the system should have the primary PLC connected to the RIO loop while the PLC connected to the Technical Network should be in standby mode. In this case, there is no communication of system information to the network, but the system can still operate.

## CONCLUSION

The Schneider HSBY redundant PLCs are a solution compatible with the Phase 2 cooling upgrade requirements in term of availability and reliability. Its implementation is supported by CERN UNICOS framework and specific automated generation for CO<sub>2</sub> templates developed by EP-DT. The introduction of PLC redundancy is defined as baseline for the LHC detectors' critical CO<sub>2</sub> cooling applications as an additional level of safety.

# MODULAR SOFTWARE ARCHITECTURE FOR THE NEW CERN INJECTOR WIRE-SCANNERS

A. Guerrero<sup>†</sup>, D. Belohrad, J. Emery, S. Jackson, F. Roncarolo,  
European Organization for Nuclear Research (CERN), Geneva, Switzerland

## Abstract

In the scope of the LHC injector upgrade, new wire-scanner devices have been installed in the LHC injector circular accelerators. This paper outlines the software architecture and choices taken in order to provide the scanner experts with comprehensive diagnostics as well as operators with straightforward size measurements. The underlying electronics acquire large amounts of data that need to be accessible for expert and machine development use and need to be processed before being presented for daily operational use, in the shape of a beam profile and its derived size. Data delivery and measurement computation are accomplished by means of a modular structure, using functionally distributed real-time processes that handle the different data views, with minimal interference in the processing, and minimal exchange of data among modules.

## INTRODUCTION

A wire-scanner is generally based on a thin wire traversing at high-speed circulating particle beams. Monitoring turn by turn the distribution of secondary particles generated by the beam-wire interaction (bottom plot in Figure 1) as a function of the wire position (top plot in Figure 1), allows reconstructing the transverse beam profile.

Figure 1: The top plot shows position data for both in and out scan. On the bottom plot beam profile data is displayed.

Such measurements are performed daily by accelerator operators and experts to infer the size of the beam and via the beam optics and beam momentum spread the transverse emittance of the different beams played in the machines.

At CERN a new generation of Beam Wire-Scanners (BWS) has been developed, installed, and recently commissioned [1] in the scope of the LHC injector upgrade (LIU), during the accelerator restart after the long shutdown (LS2). New engineering concepts were applied to build the hardware and electronics of these devices [2] [3] [4] [5], thus giving rise to a new complete software system built and constrained within the available controls infrastructure and underlying standards. In particular, the Front-End Software Architecture (FESA) [6] [7] was chosen as

the framework for the design and development of the system modules.

## SYSTEM DESCRIPTION

The BWS applies key innovations to its kinematic unit: moving parts located only in vacuum, magnetic and optical techniques to power and air vacuum signal exchange. The unit performs trajectory control of the shaft via a solid rotor resolver [8] and provides carbon wire measurement and a high accuracy position measurement using an optical encoder [9]. Electronics driving the system consist of an Intelligent Drive (BWSIDC) in charge of the powering and wire movement and an acquisition crate collecting data from the different actuation parts as well as from the optical encoder measurements. Diagnostics and tests possible in *local mode* at this level include verification of cabling and parts of the kinematic subsystem, powering and scanning procedures without beam interaction for diagnostics, all without tunnel access.

Communication with kinematic control and acquisition electronics is done through Ethernet by means of the IPbus protocol and associated module and libraries for firmware and software development [10]. The IPbus protocol is a simple packet-based control protocol for reading and modifying memory-mapped resources within FPGA-based IP-aware hardware devices which have a virtual A32/D32 bus, thus enabling the replacement of VME control (a usual standard in our operational instrumentation) in our case.

The secondary particle shower detection is performed by a scintillator coupled to four Photo-Multiplier Tubes (PMT) to acquire four signal amplitude ranges with the aim of covering the large dynamic range of beam energies and intensities across the LHC injectors [11]. The PMT devices are powered with a custom board optimised for large pulse mode and fast recharge. The gain of the PMT is set via a high voltage power supply controlled through a 4-channel commercial board accessed through the VME bus. PMT output currents are amplified in two stages and driven into parallel high-speed digitizers, feeding the so called VFC [12]. The VFC is a CERN FPGA-based multipurpose carrier with VME interface, designed to be the new standard acquisition platform for the Beam Instrumentation Group. The VFC wire-scanner application firmware was built in house and adapts to the different accelerator synchronisation. The acquisition takes place asynchronously to the bunched beam at 500MHz and with a 14-bit resolution. Together with the sensor current outputs, the beam revolution frequency and bunch timing are written into a memory bank composed of two 8Gb DDR chips. On request, acquired digitised beam information is integrated on the fly and placed in the VME bus for the CPU to recuperate

<sup>†</sup> ana.guerrero@cern.ch

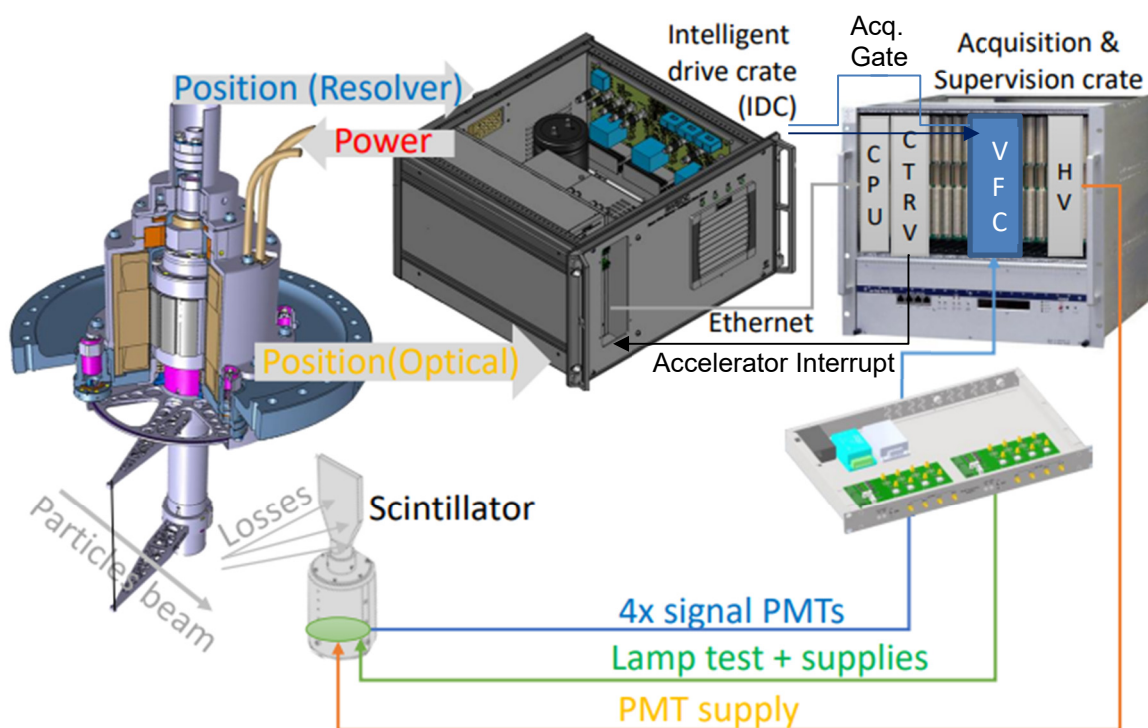

Figure 2: From left to right, mechanics installed in the accelerator, secondary particle detector, IDC, digitisers and VME crate containing the different VME acquisition and control boards.

through VME fast block data transfer. Data transfer is performed using an in-house product called EDGE that automatically generates a driver from a database description. The VFC firmware also controls the amplifier stage and a lamp for test purposes through an UART interface.

The synchronisation to machine timings of the different elements involved in the measurement following a user's request for a specific time in a concrete cycle is achieved by programming an interrupt in a VME timing receiver board (CERN product) that will send a pulse to the BWSIDC. The controller is then triggering the start and end of the acquisition gate in between rotational shaft angles corresponding to the window of measurement provided by the user. These angles can be pre-set using the data derived from a calibration function computed in the laboratory during the pre-installation phase.

Figure 2 shows a diagram of the full hardware system.

The front-end software is running on a MEN-A25 CPU with CENTOS Linux which communicates with the control and acquisition boards either through the VME bus or through Ethernet. It is composed of 5 different FESA classes, each one mostly mimicking the functionality emerging from the hardware design and encapsulating the low-level data corresponding to the main function performed: wire movement across the beam pipe, secondary particle integration for bunch profile construction, PMT working point parametrisation, measurement synchronization and finally operational beam profile measurement.

## FESA

Currently, the standard infrastructure for equipment front-end software in the CERN accelerators, the Front-End Software Architecture (FESA) is a complete environment for equipment specialists to design, develop, deploy, and test their equipment software, which produces as an end product a FESA class and FESA devices. The focus of the instrument developer is set on the structure and the flow control of the application domain, and to standardise the outcome of this analysis into a framework. The framework orchestrates the activity, real-time processes and user interface exchanges calling routines provided by the application developer to apply the equipment-specific behaviour.

The internal real-time functionality can be as modularised and parallelised as allowed by the constraints imposed by the underlying hardware components of the system. The outcome of the different threads or concurrency layers talking to the external hardware is stored in a shared memory accessed also by the defined interface. An operational FESA class receives input parameters from database declared fields for server initialisation and from external sources via a predefined interface using a device-property model. The acquired and processed data is retrieved via the same mechanism.

Thus, all data exchanges are done through one server dealing with all the requests coming from the different user scripts and applications accessing the class. In our case, expected applications accessing the class are hardware expert's Python scripts to retrieve hardware status information and raw data, Java and Python expert applications

to control and display low level information for instrument diagnostics, operational applications to produce measurements and set parameters interesting to operators and accelerator specialists, multipurpose WEB interfaces [13], ad-hoc scripts launched during machine development periods while studying the machine behaviour or the instrument behaviour in test conditions and last but not least, data retrieval for long term storage.

## FUNCTIONAL MODULES

As we have seen in the system description, the hardware and electronics composing the BWS system have two fundamental functional modules controlling and acquiring both sensors and actuators, one handling the movement of the wire and one in charge of the particle distribution acquisition. The only link between them is the hardware signal triggering the acquisition gate. The parameters involved in the generation of this trigger are an essential concern for meaningful profile measurements in cycling machines where the cycle time at which the wire is flying in the beam is precisely requested by the user performing the scan and necessarily synchronised to the played cycling sequence. It is this synchronisation functionality using the timing infrastructure of the accelerator which makes up a third functional module and drives the former two modules. These three quasi-independent modules become integrated with one another by means of a fourth module, the operational bunch profile measurement, dedicated to the construction of the requested measurement. For practical reasons, we decided to split the particle distribution acquisition into two different modules, namely bunch profile acquisition and PMT gain thus making up a total of five functional modules.

More and more specialists and operators want to access system data and beam data at different processing levels. The functionality and type of the exchanged data between the FESA server and the users may be as varied as the type of user looking at and/or actuating them, but we can differentiate three main types: machine operators, accelerator specialists and system specialists. The described functional decomposition of the software enables at the same time an easy encapsulation of the data to provide different data views of the system and different security access depending on the user.

### *Wire Displacement*

Hardware-wise the wire displacement is the most complex functionality of the system, however this is not the case at the software level. This module is in charge of starting a scan with or without external synchronisation and of reading a bulk of registers with acquired data and status. No processing of data is required for publishing. The decision to design this module separately also obeys two particularities at the functional internal level, the introduction of the IPBus protocol for the data transfer on one hand and the handling of critical settings on the other. Whereas in the other modules errors in the parametrisation of the devices do not have consequences other than a wrong measurement, this module includes a few parameters that could

potentially disturb the feedback in the movement or the lifetime of some of the instrument components. The firmware implements all needed protections to avoid any harm to the instrument but nevertheless a strict policy must be applied to the initialisation and modification of critical settings. The access to the module should be confined to the instrument experts.

Regarding the choice of data transfer between the BWSIDC and the software module, the use of a VFC was initially considered to profit from the tools and automatic driver generation from the EDGE register description. Finally, we opted to use ethernet with IPbus as the communication technology to reduce the VME bus data traffic at the same time as allowing parallelising the data transfer of the modules retrieving most of the acquired raw data. In order to maintain the standard register description, the module initialisation required the incorporation of a translation of the current EDGE description into the XML description supported by the UHAL library of IPbus.

### *Bunch Profile Acquisition*

This module deals with the different aspects of the bunch transverse profile construction from the digitised particle shower distribution detected: It prepares the VFC and amplifier stage for acquisition and reads four integrated data streams and the raw data of a non-saturated channel for publication. From the firmware signal level detection facility, it tries to derive the ideally ranged channel. When requested, attempts to compute the bunch phase with respect to the retrieved or produced bunch clock depending on the accelerator concerned for correct integration of the bunch. Both the PS and PSB injector electronics do not have access to the bunch timing but only to the revolution frequency, however the harmonic used is known before-hand. The bunch timing is thus generated by the firmware dividing the turn length by the harmonic. The phase will depend on the type of beam, scan cycle-time requested and radio frequency signal offset.

The main internal requirement for handling the bunch acquisition is high speed data transfer due to the large amount of raw data produced in the four digitalisation channels.

For test purposes a lamp control is also included in its functionality.

### *PMT Gain*

One could argue that this functionality can be integrated in the bunch profile acquisition module since it is an essential working component of the beam signal amplitude. However, it is distinctly decoupled from the hardware point of view and at the same time, needs no dynamic control which is a key point for adding this module. As the system has been conceived, the working point of the PMT filter combination needs tuning only during a commissioning phase to correctly cover the ranges of energy and intensity without neither saturating all channels nor decreasing the signal to noise ratio too much.

There is also a practical reason for this choice as discussed later.

## Machine Timing Synchronisation

Machine synchronisation and timestamp related functionality is handled within this module.

All LHC injectors are cycling machines. The selection of the cycle and time in the cycle to scan is a must for a meaningful size measurement and therefore the actuation has to synchronise with machine events to respect within one or two milliseconds, depending on the accelerator, the wire beam crossing time. When the user requests a certain cycle time an interrupt is programmed taking into account the measured time for the wire to fly to the centre of the vacuum chamber, according to a calibration function assigning a position in the chamber to the angle of the rotating fork. The timestamp generated by the interrupt allows posterior data correlation across modules.

## Operational Bunch Profile Measurement

The transverse size measurement starts from a user request holding a few already mentioned parameters such as cycle, cycle-time, applicable harmonic number in some cases, and others such as speed and acquisition window. This module takes care of the distribution of commands and settings to the other modules for scan preparation. Once the interrupt is programmed, the unit simply awaits the notification from the other modules that the different requested data are available. When the trigger fires, the derived events will start the corresponding sequence of tasks in each of the acquiring modules. Each sequence ends in the notification of the success if the requested data is ready or, error, in case a problem was encountered, so that the error description can be retrieved. When all needed data is rendered, the correlation of the position and amplitude of the integral of each of the acquired turns takes place together with the size computation by fitting the constructed bunch profile to a gaussian.

## ARCHITECTURE

The main purpose of the BWS system is to provide bunch profile and size measurements in accelerator operations. Whereas from an operational perspective the complexity of the system is hidden, the specialized usage and tuning requires access to the large amount of data and status produced while scanning by the different components of the system. Comprehensive diagnostic and testing tools need interfacing to maintain and monitor the system.

Figure 3: BWS software system event-driven architecture. Central unit FESA class with four satellite FESA classes, each representing a functional module.

The high degree of independence of the functional modules emerging from the underlying hardware design and the distinct nature of the data produced, allows the implementation of software modularisation where one coordinating unit, the operational bunch profile measurement module, orchestrates via few operation settings, the other modular components dealing with highly specific tasks. This organisation (Fig. 3) fits an event-driven architecture, using FESA classes as modules, with one central BWSLIU class having the capability of orchestrating the operations and the other satellite classes BWSLIUEXP, BWSACQ, LTIM and BHVVHS4 performing their concrete task and exposing the associated data. Such modularisation takes into account prior existence of two FESA classes, LTIM and BHVVHS4 that could be incorporated without changes only by splitting the bunch acquisition module into two, one dealing with the actual acquisition, the other handling the fine-tuning of the working point.

While FESA is very flexible and the described modular structure could be designed inside the framework, an approach to push the decoupling of the modules by using a class per functional unit adds several advantages:

- Delocalisation of modules not using VME bus, for relaxing the load of the CPU both in memory and processing.
- Interface distribution, the server is not unique anymore with higher capability of absorbing requests from the varied application set, thus, sharing the load of data publication. In this way, each set of functional users also have their encapsulated view of the system.
- Implementation in smaller units which are easier to maintain, modify and use.
- Module additions or substitutions without interference on the other units. This type of modularisation allows easy prototyping, testing, and introduction of simulation blocks when a part of the hardware is not available.
- Facilitates the test procedure. During the prototyping and testing phase multiple procedures were put in place to validate and diagnose the system during hardware commissioning and individual system tests. These can be launched without all the system being in place.

## CONCLUSION

The implementation of FESA classes as building blocks in a functionally modular structure, in this case using an event driven architecture, grants high flexibility to the system in terms of prototyping and testing. It also simplifies coding structures that facilitate maintenance, encapsulates data views with extensive diagnostic possibilities and focuses interfaces adapted to the type of user exploiting them.

Following the restart of the LHC injectors the system has been deployed successfully in each of the accelerators. The commissioning was certainly facilitated by this modularisation due to the formerly described assets.

# A RELIABLE MONITORING AND CONTROL SYSTEM FOR VACUUM SURFACE TREATMENTS

J. Tagg, E. Bez, M. Himmerlich, A. K. Reascos Portilla, CERN, Geneva, Switzerland

## Abstract

Secondary electron yield (SEY) of beam-screens in the LHC puts limits on the performance of the accelerator. To ramp up the luminosity for the HiLumi LHC project, the vacuum surface coatings team are coming up with ways to treat the surfaces to control the electron cloud and bring the SEY down to acceptable levels. These treatments can take days to weeks and need to work reliably to be sure the surfaces are not damaged. An embedded control and monitoring system based on a CompactRIO is being developed to run these processes in a reliable way [1].

This paper describes the techniques used to create a LabVIEW-based real-time embedded system that is reliable as well as easy to read and modify. We will show how simpler approaches can in some situations yield better solutions.

## PROJECT AND BACKGROUND

The objective of the LESS (Laser Engineered Surface Structures) project is the commissioning of an in-situ laser surface treatment conceived to mitigate electron clouds in the Large Hadron Collider (LHC) at CERN. Secondary electrons are multiplied when they interact with the vacuum chamber walls of the accelerator and consequently form electron clouds that can negatively affect its performance.

The secondary electron emission of a surface can be reduced by surface roughening. In this project, pulsed laser processing is applied to generate micro and nanostructures on the inner vacuum chamber surface that surrounds the proton beam. In this way, secondary electrons are captured by the surface geometry. The resulting structures and the performance of the surface strongly depend on the processing parameters, such as the laser power, the scanning speed, and the line distance, as well as on the scanning pattern [2].

The final treatment must be applied in-situ in the already existing accelerator and the system must be capable of treating tens of meters of vacuum pipe autonomously. The dedicated setup to perform this is composed of a picosecond pulsed laser source and a Beam Delivery System (BDS) that shapes and couples the laser beam into an optical fiber, which guides the laser light through an inchworm robot where the beam is decoupled through a rotating nozzle (see figure 1). The translational movements of the robot are driven by a pneumatic clamping system.

Figure 1: Longitudinal view of the inchworm inside a beam screen. The laser nozzle in the center points upwards. a. inchworm, b. nozzle, c. beam screen.

This setup requires a control system that communicates with each component and allows flexible parameter changes. The system must be reliable enough to run for many days unattended. For example, in a spiral treatment format (described later) we would need to treat 16m of beam screen while advancing by 50μm approximately every 5s. This would take up to 3 weeks. Similar times are expected for other sequences.

The system must also manage concurrent communication with all the components which make up the system and ensure that any issue is either resolved, or the system is safely stopped so the treatment can continue once the issue is resolved.

Movement of the inchworm makes up the bulk of the expected issues because of its mechanical nature. The system must be able to manage and identify movement problems and fix them where possible without affecting the overall process.

## HARDWARE

The system consists of multiple hardware components connected to an NI CompactRIO (cRIO) real-time embedded system for control and monitoring. A cRIO was chosen because of successful implementations of cRIO-based control systems for other projects and because it provides a relatively straightforward programming model through LabVIEW.

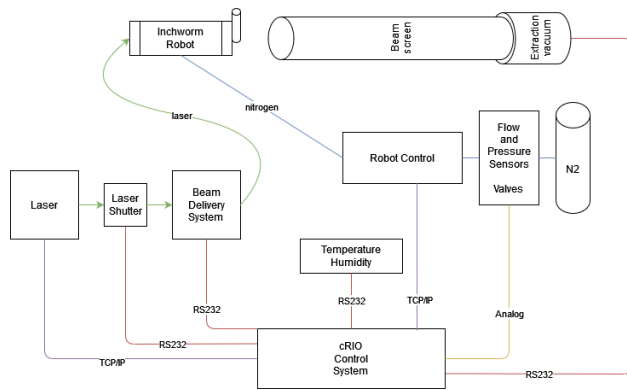

Figure 2: Main hardware topology.

Chief among the devices to control are the laser system and the mechanical robot that moves in the beam screen to distribute the laser to the surface. All hardware is connected to the cRIO through either TCP/IP connections, RS-232 or analog signals (see table 1 and figure 2).

Table 1: Connected Devices

Device	Connection
Robot	TCP/IP
Laser	TCP/IP (Telnet)
Laser shutter	RS-232
Laser BDS	RS-232
Extraction vacuum	RS-232
Temperature / humidity	RS-232
Flow and Pressure	Analog NI 9205
End switches	Analog NI 9205
Nitrogen supply valves	Relay NI 9481

The inchworm robot's movement scheme deserves some further description because it is at the core of how movements are defined in the software.

The robot is designed to move somewhat like a caterpillar and is composed of a fixed frame which contains a mobile internal sled. Both the frame and the sled can be clamped by pushing against the beam screen, which fixes its position. By activating the right clamps and moving the sled in the right direction, we can create a sequence of moves which advances the whole robot longitudinally along the beam screen.

The laser and its distribution, beyond an initial configuration of its settings, mostly turns into an on/off system. Sequences will use this facility to activate and deactivate the laser so that the treatment happens at the right times.

A nitrogen supply is used to pump nitrogen into the beam screen at the treatment point. Previous research has shown nitrogen to be an effective atmosphere for treatment of the surface [3]. Because the nitrogen tanks will run out before the full treatment is done, there are in fact 2 tanks. When the pressure from one tank falls below a defined threshold, the system automatically switches to the other tank and emails the operators so that the inactive tank can be switched out.

## ARCHITECTURE

### Control System Requirements

Control systems typically acquire many data points from various connected sensors and devices. Software control loops then use the acquired data to make decisions, which will affect the software itself as well as control actuators.

We decided early on that an architecture in which data would be at the center was the way to go. This leads to data being shared mostly globally in the application, and while shared data is often regarded as a danger, the small scope of the software implementation led us to accept this as a useful concept so that software procedures could more easily integrate a cross-section of application and hardware functionality.

### Application Architecture

The go-to template for most LabVIEW applications over the past decade is the queued message handler (QMH). While QMHs promote modularity, and, when done properly, encourage code reuse, they can also make some applications needlessly complicated. Debugging and reading such code on embedded systems suffers from the many layers between an action from a GUI and the code that ends up running as a result. This is especially the case when frameworks force or encourage the use of re-entrant VIs, which cannot be debugged using LabVIEW's traditional debug tools, these tools being one of the main benefits of using LabVIEW. Because of this limitation and the small size of the application, it was decided to restrict the use of frameworks and to focus on a more direct and 'simple' approach to programming, in which events and their reactions are closer together.

Table 2 summarizes some of the most widely used LabVIEW frameworks, evaluating them in terms of readability, debuggability, prototyping ease and whether they can be easily instantiated multiple times.

Table 2: Framework Comparison

	Readability	Debuggability	Prototyping	Multiple instances
CVT [4]	yes	yes	yes	No
DCAF [5]	With experience	Not directly	Takes planning	Yes
QMH [6]	Can be	With experience	Nothing built-in	Yes
DQMH [7]	Lots of boilerplate code	Good testing tools	Scripting tools for quick creation of functions	Cloneable modules share some resources
Actor Framework [8]	With experience	Difficult in LabVIEW real-time	Slow to deploy	Yes

The application architecture includes a set of a few main processes (external communication, event handling, writing to file) and a series of monitoring loops which read from all the devices connected to the system. The monitoring loops mostly only read data into the system and make it available to the rest of the processes.

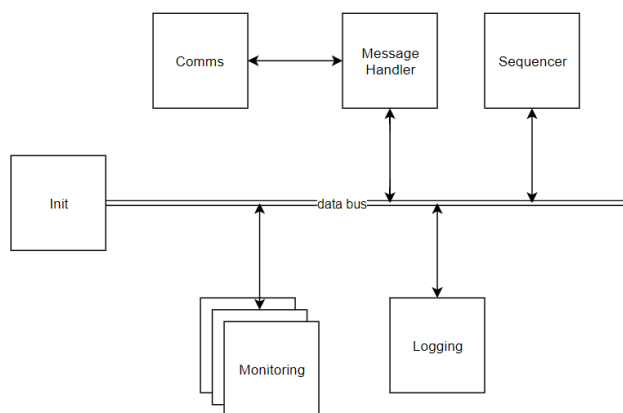

Figure 3: Software architecture.

There are few processes in the application and their roles are described here (see figure 3):

**Message handler:** Handles all incoming messages from the GUI. Any time the operator performs an action on the GUI, it gets sent to this process and for the most part is handled directly.

**Logging:** As its name implies, logs run-time data to file every few seconds so longer processes can be followed-up on in case of issues.

**Monitoring:** Many monitoring loops are implemented, one per device connected to the system. These processes gather all the needed data points from all devices and stores them in the central data storage for use by other processes.

**Sequencer:** The sequencer processes only run on-demand, and only one at a time. They simulate a series of requests and commands from the GUI so that the system can perform treatments over several days or weeks. Sequences are described in more detail further on in this paper.

## IMPLEMENTATION

Because we are not using an established framework, it is important that the required attributes are built in from the beginning. The main components and attributes will be covered in this section.

### Security and Safety

Like all control systems, we need to make sure that the system only does what it is supposed to. Any behavior that is outside of that established explicitly should be caught and the system should be put into a safe state. Indeed, if any behavior has not been explicitly planned for, we assume it is wrong and stop operation.

Because the movement of the robot is purely horizontal, we do not need any special consideration when stopping movement as it will simply stay in its position if we cut power to the drives.

The laser, being the active agent of this system needs to be considered more carefully because it will be damaging

if it does not switch off when needed. There are multiple ways to prevent laser damage in this system. The laser can be powered off by a software command or its integrated shutter can be closed. Since a communication issue with the laser would prevent either of these safety mechanisms to be used, there is also an external laser shutter which can be independently controlled.

The system implements a safe state, which is a series of commands that is run when something unexpected happens. The main job of this routine is to stop all movement and to close all laser shutters. It puts the system into a safe mode from which it will only recover when the operator decides it is safe to do so.

### Error Handling

Error handling is especially important in long-running embedded systems since operators are not monitoring the system 24/7. All errors need to be caught and, unless a recovery procedure is known, they must immediately put the system in a safe state.

Since there are many external hardware elements to be monitored during the whole treatment procedure, we make sure that communication to each device stays open and available at all times. Any communication issue immediately puts the system in its safe state.

### Data Transfer and Communication

Because we wanted to keep a more direct path between events and their reactions, all processes in the application can use the central data store. This enables all processes to act in whichever way they deem necessary but introduces a higher risk of running into race conditions.

To avoid race conditions, we have a good definition of which process writes to which data point. Obviously, for data coming from external devices, only the respective monitoring loop writes that data.

All data in the application can be separated into 3 categories depending on how that data should be handled when restarting the application.

**Configuration data** is read-only data that comes from a configuration file on disk. This represents fixed configurations that do not change and which the application assumes will never change. We find such information as the radius of a beam-screen or the hardware address of an external device to control.

**Settings** represent data that the user can modify, and which can be saved to file. This allows the operator to define the details of the treatment and how the attached devices should run. These values will be remembered at subsequent launches of the application.

**Run-time data** is the collection of all other data the application keeps track of while it is running. Most of the data is contained here. The publishing process saves the relevant data points to a file during operation.

All 3 of these data sets are passed around the application to all processes and constitute what the application calls the data environment.

## Environment

The environment contains all the data needed for the various processes of the application to run properly. It is passed around as a Data Value Reference (DVR) which allows concurrent access throughout the application. One of the reasons for choosing to store this data like this rather than using existing solutions like the CVT (Current Value Table) is that this solution allows us to potentially run multiple instances of the application on the same hardware. We currently only run a single instance, but there were discussions at the beginning to run multiple systems from the same cRIO.

Giving each process access to the full dataset of the application means that each process can be more intelligent in making decisions because it has more context.

Figure 4: Application layers.

## Actions

Each external hardware component is represented in the software by a library which encapsulates the communication with the device. These functions have no knowledge of the application they run in and therefore cannot be relied on to coordinate anything but the communication with that device.

To integrate these devices into a complete system, an extra layer is used above these libraries to coordinate them with each other. The first such layer is called the action layer. Each action takes in the environment data as an input and does something that the system needs to do (Figure 4). This can range from a low-level encapsulation of a single command to a single device, to a more complex one which reads data from multiple devices and coordinates their actions. The processes box represents the processes described at the end of the architecture description (monitoring, logging, communicating processes...). The processes mainly use the aforementioned actions to perform their tasks.

## Sequences

To run the system autonomously, it is necessary to have some controlling process that sequences the steps necessary for a treatment run. Such processes are called sequences and they are only run on-demand when the operator sends the command. In figure 4 they run at the top-level

processes category and have full access to the environment.

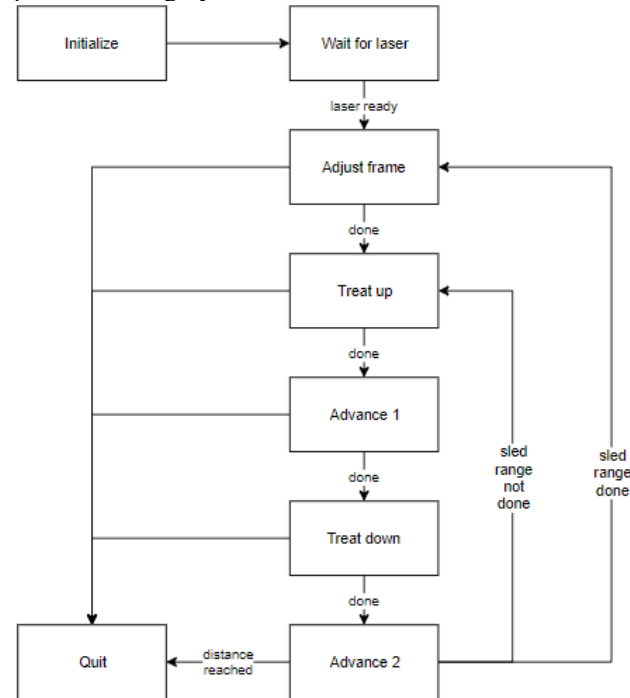

Figure 5: Line sequence logic.

More than one sequence is designed, but only one can ever run at any given time. The sequence takes control of the system and uses the data and actions to run it through the steps as the sequence defines them. When a sequence is started, the communication interface ignores most commands from the GUI because they would otherwise interfere with the sequence. In fact, sequences can be thought of as equivalent to the GUI + operator. They use the same actions as the GUI commands and simply wrap them up into a process which waits for events and reacts to them.

Sequences must also be implemented such that issues with the movement of the inchworm robot are properly handled. At each movement stage of the robot, care is taken to test for various outcomes, like getting stuck, so that it does not continue treatment.

Multiple sequences have been implemented to test their relative treatment effectiveness and are summarized here:

**Spiral**, as its name implies, moves the laser nozzle in a spiral fashion, in which it slowly advances while rotating the nozzle. Settings such as speed or spiral pitch allow the operator to make it more or less loose.

**Line** creates a movement similar to the spiral sequence, but where the forward motion is decoupled from the rotation. In this configuration it rotates with treatment, then advances without treatment, then rotates again to continue the treatment (Figure 5).

**Longitudinal** motion is a variation of the line sequence in which the treatment is done while moving linearly. Once it reaches the length to treat, it rotates slightly and starts treatment again.

**Zigzag** is a spiral sequence variation in which it does not spiral out in a single rotational direction. The rotation goes back and forth while advancing the linear stage.

**Move** does a simple linear move of the robot to a new position and does not involve any treatment. It is useful for movements longer than the range of the robot sled because it sequences the necessary clamping and move details.

### User Interface

The user interface runs on a separate PC connected to the same network as the other devices of the system. It connects to the ‘event handler’ process on the cRIO to send commands to the system. The event handler simply executes the commands as they are received if no sequence is running.

Communication between the PC and the cRIO is made with the AMC (Asynchronous Messaging Communication) library [9], which allows multiple systems to send messages to each other using a UDP connection.

Commands are sent from the PC to the cRIO to execute the above-mentioned actions and sequences. All data from the environment is constantly sent from the cRIO to the PC once it is connected so that it can display the current state of the system and help the operator understand what is currently happening.

### Reliability

Because the system needs to run for days at a time with minimal intervention, it is extremely important that it performs reliably. Several features of the software implementation facilitate this and were mentioned throughout the paper. The main points are summarized here for convenience.

The GUI can be connected and disconnected from the device without affecting it, thus keeping it out of the loop for the core functionality.

A safe state has been implemented which sets all hardware to a desired state. Any unplanned error puts the system in this state so that an operator or expert can check the system before running again.

Because there are so few layers of software, actions are closely linked to triggering events, leading to fewer chances for errors and mistakes to appear.

Preliminary reliability tests in the absence of full hardware integration have shown that it is able to run a sequence reliably for 2 days, after which it was stopped because it performed dozens of cycles of the sequence without issue, as indicated by the event log file. As long as the laser isn’t present, a longer test won’t yield more useful results at this time. Further tests are planned when the full system will be assembled.

## CONCLUSION

We described the architecture and implementation choices used for the project. A custom-made data and communication structure helped simplify the overall complexity of the software so that we could focus more on direct readability and benefit from LabVIEW’s built-in debugging tools.

While the system is not yet operational (not all components are ready for integration), we have benefitted from the structure of the code, allowing for quick debugging while testing integration and sequences. Because of the smaller code footprint, it is also much faster to deploy and test variations of the software while fine-tuning behavior.

It is also important to note that while this structure is used successfully in this project, we must stress that it is very likely to show its limits if functionality were to get bigger and more complex. Its application in this project was made possible by the fact that no added complexity is foreseen. Another reason why we could safely rely on a simpler architecture is that if the needs do arise, we can quite easily replace this simple structure with something more complex.

## FUTURE IMPROVEMENTS

As it stands, the project is ready for integration of final components, and it is not expected that anything big will need to change. Future improvements to the system will likely be in the details and timing of the sequences, which we’ve modularized to a simple state machine architecture.

# A PYTHON PACKAGE FOR GENERATING MOTOR HOMING ROUTINES

A. S. Palaha, T. Cobb, G. Knap, Diamond Light Source, Didcot, UK

## Abstract

Diamond Light Source uses hundreds of Delta Tau Turbo PMAC2 based motion controllers that control motors with precision and repeatability. Homing is critical to these requirements; it safely moves axes to a well-known position using a high-precision device for detection, leaving the overall system in a well-known state and ready for use. A python package called “pmac\_motorhome” has been developed to generate homing routines for multiple motors across multiple motion controllers, allowing the user to write a script that is terse for standard/typical routines but allows for customisation and flexibility where required. The project uses jinja templates as ‘snippets’ to generate the homing routine code written in Delta Tau PLC notation (PLC is the name for logic programs in Delta Tau motion controllers). The snippets can be re-ordered and grouped together, supporting the design of homing routines for multi-axis systems with mechanical limitations that require an orchestrated approach to safely home the axes. The python script using the package is kept terse using a context manager and can group axes together to the same homing group easily.

## WHAT IS “HOMING” A MOTOR/AXIS?

Motors, sometimes referred to as “axes”, typically turn rotational movement into moving some load. In the operation of an x-ray synchrotron and its associated beamline laboratories, there are many motors used on scales that require precise and repeatable movements.

The position of axes is typically tracked with an encoder that produces signals as the axis turns; these signals are monitored by the motion controller and converted into positions. Assuming no power loss or miscounting of encoder signals (e.g. due to speed or slippage) then the position will remain accurate. However, the counting must start from a known position, and this must be recoverable in the event of power loss or miscounting. This is where homing procedures are critical.

The known position can be provided either by a dedicated home switch, activated when the axis reaches a certain position, or one of the end-of-travel limit switches that are usually present. The manner of activation is also important; sometimes requiring moving to the switch and then in a particular direction to release the switch, or to approach the switch from a particular direction.

Another method of creating a homing signal can be to drive against a hard stop which may generate a following error (the difference between the demanded move and measured move). This is generally used for small axes that can tolerate driving into a hard stop.

Consideration must be made for axes that are coupled; that is when movement in one axis will affect another such as when they are attached to the same load. Such scenarios require homing routines that can act on multiple axes. With the possibility of many different combinations of axis types and multi-axis systems, the ability to create tailored homing routines for each axis or group of axes is a necessity.

## WHY IS PMAC\_MOTORHOME NECESSARY?

The first homing routine generator written in python for Diamond Light Source (DLS) was called motorhome.py. It generated homing routines as PLC code for Delta Tau motion controllers and started as a single script. As different homing scenarios became necessary, this script grew into a large monolith that was difficult to maintain and became inflexible in some scenarios. The python interface to motorhome.py could not be used to add a custom piece of PLC code that might be used for unique or rare homing scenarios.

## PROJECT REQUIREMENTS

The new homing routine generator had to satisfy the following requirements to be a viable replacement for motorhome.py, and to ensure minimal disruption/effort in converting the original generator scripts into the new style:

### *Maintain the EPICS interface*

The EPICS Input Output Controller (IOC) used to control and monitor the Delta Tau motion controller device also monitors the status of the homing routines by polling the program variables, or “p-variables”. For instance, the State, Status and Group number of homing routines are accessed through \$(PLC)00, \$(PLC)01 and \$(PLC)02 respectively; where \$(PLC) is the number of the PLC program (there can be up to 32 programs stored on the motion controller). So, for the homing routine stored in PLC9, the Status of the routine would be held in p-variable 0901.

The State and Status are enumerations that indicate if a routine is operating, has completed, failed, or been aborted. The Group number indicates whether a particular axis in a group is being homed, or all axes in the group are being homed. The group is configured in the python script that imports the generator module.

## *Have a Python File/Script per Motion Controller or Group of Motion Controllers*

The PLC code generated and stored for motion controllers at DLS is organised firstly by domain (either beamline laboratories or storage ring areas), and then by motion controller device. For example, there is a directory for a particular beamline laboratory (BLxxI) inside which there is a directory for each motion controller. The domain level directory typically contains the python script that imports the generator python module. This script configures which axes will be grouped together and how they will be homed.

Some domains have a python script per motion controller, so this must also be achieved by `pmac_motorhome`.

## *Home up to 16 Axes at once*

The original homing routine generator allowed the grouping and homing of 16 axes together from one motion controller. Although rarely used in practice, this must be achievable with the new generator to maintain compatibility.

## *Allow Insertion of Custom Routines*

Some motion setups require a specific set of homing instructions that are uniquely used, and therefore not worth adding to the generator module as a pre-defined homing type. Originally this was achieved by generating the closest matching homing routine and then modifying it manually. Though this worked, and was stored under version control, it was not automatically repeatable when the generator script was run.

The `pmac_motorhome` module should allow the insertion of text strings into the generated homing routine. As the typically used pre-defined homing routines would be a list of actions that would apply to motor axes, users of the python configuration script should be able to define custom sequences of actions to make a new homing routine, with custom code inserted where required.

## *User Friendly Python Interface*

The structure of the python configuration script using the original generator, `motorhome.py`, was arguably simple but did not make an easily human-readable layout. Because the python configuration script is called once for each motion controller using a Makefile system, the configuration script is set out in blocks according to the name of the homing PLC to be generated, so there may be multiple blocks per motion controller. As a homing PLC is configured by adding motors to the PLC object when using `motorhome.py`, the configuration and grouping is done per added motor, so it is not clear which motor axes are grouped together without studying the assigned group numbers.

The `pmac_motorhome` generator will make use of context managers to structure the configuration script. This should group motor axes together and has all the groups

for a particular PLC object listed under it, with the required python indentation providing a visually easy to understand structure. This also allows changes or configurations to be applied to motor axes, groups, or to the overall homing PLC explicitly.

Additionally, it should be possible to explicitly define a homing routine as a sequence of actions for a particular group or motor axis. For repeated sequences, such a list of actions can be defined as a separate function. The most commonly used homing sequences are provided in `pmac_motorhome` as pre-defined functions.

During most of Diamond's operation, it was the controls engineer's responsibility to create and maintain the PLC code for homing routines. Moving forward, this responsibility will be shared between the controls and motion engineers, combining experience and expertise in motor control and operation. This should also assist in the commissioning process of new motion axes. Having a more user-friendly interface will help the creation and maintenance of the homing routines between the two groups of engineers.

The new generator tool and interface should use python3, instead of python2 like the original generator. This should bring the tool into line with currently supported python versions and allows the use of some of the new features in the underlying `pmac_motorhome` code.

## *Can Reproduce Existing Homing Routines*

To have as minimal disruption as possible during the replacement of the original homing routine generator with `pmac_motorhome`, a tool should be provided to convert an existing python script that imports the original generator into a `pmac_motorhome` style python script. This should automate the majority of the conversion process, to simplify the adoption of the new generator by controls engineers and provide confidence that existing and working homing routines will not be changed in the process. This should be demonstrated during the conversion process by comparing the outputs of the old and new generators when run for a particular beamline or domain of motion controllers.

## *Enforce DLS Homing Conventions*

Conventions for homing PLC code at DLS includes only using PLC numbers above 8 for homing routines (1-7 are reserved for specific non-homing functions) and having all axes in the same group home with the same homing sequence.

## **PYTHON INTERFACE**

The user interface of the `pmac_motorhome` generator is a python3 configuration script that imports the `pmac_motorhome` package. This python3 script will configure PLC objects that will render a homing routine PLC file.

The python interface uses context managers to specify the configuration of the different layers of the PLC file; the top-level object is the PLC, within this there are

groups, and within those are axes. Even solitary axes need to be defined in a group, as the group number is used to monitor homing progress and state.

In python, a context is created using the key word “with” followed by the instantiation of the object, and finally a colon; and then the next indented lines are now within the created context. Context managers allow the allocation and release of resources as needed. Boiler plate actions such as inserting a tidy-up snippet of PLC code or writing a PLC code to file can be implemented in the PLC object class. These boiler plate actions are necessary for every homing PLC, and would be executed implicitly without including it in the user level configuration script.

A simple example of a configuration script is shown in Figure 1. The editor used in the example, and in the development of this package, is Visual Studio Code.

```
from pmac_motorhome.commands import group, motor, plc
from pmac_motorhome.sequences import home_hsw

with plc(
    plc_num=12,
    controller="GeoBrick",
    filepath="/tmp/PLC12_SLITS1_HM.pmc",
):
    with group(group_num=3):
        motor(axis=1)
        motor(axis=2)

    home_hsw()
```

Figure 1: simple configuration script for a homing PLC

The use of the python language lends itself to defining custom routines that are repeatedly called. Such routines can be called inside a group to operate on some given axes, and can make use of pre-defined functions that insert blocks of code, e.g. “drive\_to\_limit(direction)” or “jog\_if\_on\_limit(direction, limits)”. An example of a custom routine for a group of four axes is shown in Figure 2.

```
from pmac_motorhome.commands import PostHomeMove, group, motor, only_axes, plc
from pmac_motorhome.sequences import home_hsw
from pmac_motorhome.snippets import drive_to_limit

def custom_slits_hsw(posx, negx, posy, negy):
    drive_to_limit(homing_direction=False) # drive all slits to limit away from home

    with only_axes(posx, posy): # home and return to limit only positive slits
        home_hsw()
        drive_to_limit(homing_direction=False)

    with only_axes(negx, negy): # home and return to limit only negative slits
        home_hsw()
        drive_to_limit(homing_direction=False)

with plc(
    plc_num=12,
    controller="GeoBrick",
    filepath="/tmp/PLC12_CUSTOM_SLITS_HM.pmc",
):
    initial = PostHomeMove.initial_position
    with group(group_num=2, post_home=initial):
        motor(axis=1, jdist=-400)
        motor(axis=2, jdist=-400)
        motor(axis=3, jdist=-400)
        motor(axis=4, jdist=-400)

    custom_slits_hsw(posx=1, negx=2, posy=3, negy=4)
```

Figure 2: example of custom homing routine definition

Custom code snippets can also be introduced, and with the control of the sequence of pre-defined and custom

blocks even more control of the customisability of homing sequence generation is possible.

Finally, the layout and indentation due to the use of context managers creates a more readable configuration script; where groups of axes are visually one block of code. The naming of the snippet functions and routines aims to be as descriptive as possible, while the availability of pre-defined homing sequences for the most typical and simple of homing scenarios will allow for terse and concise configuration scripts for most homing scenarios.

## GENERATING PLC CODE

The python configuration script creates a PLC object that contains groups of axes, and all these objects are instances of classes that contain data members detailing the homing sequence to be performed. These PLC objects are fed to the homing sequence PLC generator.

The pmac\_motorhome generator compiles the homing routine PLC code by piecing together blocks of code formed from code templates. The Jinja engine is used to interpret and fill in the templates. The templates contain special place-holders allowing python-like code to be inserted and eventually rendered into text strings. These templates are referred to as “snippets” in the pmac\_motorhome package, and generally correspond to functional blocks of code, such as the “drive\_to\_limit(direction)” function, among others.

The interpreted code in the templates allows loops to be performed, and more snippets to be invoked and inserted in place, such as for multiple motors in the same group. It also provides conditional logic, allowing for snippets to be included if, for example, an option to perform a move after homing is supplied. When invoking a particular snippet with this option, the corresponding code would be rendered, otherwise it would be omitted. The snippet shown in Figure 3 shows the post home action snippet, using an if-statement to control whether the code template is rendered or not. If the python class member group.post contains a non-empty string, the template will render.

```
{% if group.post and group.post != "" %}
{% include "debug_pause.pmc.jinja" %}

;---- PostHomeMove State ----
if (HomingStatus = StatusHoming or HomingStatus = StatusDebugHoming)
    HomingStatus=StatePostHomeMove
    ; Execute the move commands
    if (HomingStatus = StatusHoming or HomingStatus = StatusDebugHoming)
        {{ group.post }}
    endif
endif

{% endif %}
```

Figure 3: snippet inserting code for post home actions

The snippets are structured in such a way as to represent simple and broadly singular functions, for the benefit of developers and maintainers of the code and to correspond to the required structure of the homing PLC code that already exists at DLS for its Delta Tau motion controllers. A particular snippet will usually perform one function, however there is a base snippet that includes all the beginning and ending boiler plate, and contains loops for all the groups and axes contained in the PLC.

The final step is writing the rendered code into a file, the path for which is specified in the configuration of the PLC object.

## CONVERTING TO THE PMAC\_MOTORHOME GENERATOR

A converter tool is provided in the package to convert the original python configuration scripts in the DLS motion directories to the new style of python script using the `pmac_motorhome` package. This is to facilitate the adoption of the new style of homing code generation with as little intervention as possible, and to check that the new generator can produce the same homing PLC code as that which already exists.

The converter tool (written in python3) operates on a domain level or motion controller level directory and creates two copies of these directory structures in a temporary location: old and new. The old copy has the original generator script called through a subprocess call in a python2 shell (as the original generator is a python2 tool).

The new copy is also run through a python2 shell with the original generator script, but the generator code is “shimmed” (or substituted) with code that records the data structures produced without creating a file on disk. These data structures are the PLC objects that contain group and axis objects and are required in order to create a `pmac_motorhome` style configuration script. As the converter tool is run in python3 and the shimmed `motorhome.py` generator is run in a separate python2 shell, the PLC data object must be loaded in some way into the python3 instance of the converter tool. This is achieved by creating a FIFO (First-In-First-Out) pipe file from inside the python3 converter tool. Then the shimmed `motorhome.py` generator in python2 will write to that FIFO file a copy of the PLC data objects it creates.

To ensure the data is compatible between python2 and python3, the PLC data object is first serialized into a byte stream using the pickle package before being encoded using the struct package into a packed form. This encoded byte stream is written to the FIFO file, where it is read out by the converter tool in python3 that is monitoring it. The byte stream is unpacked and then un-pickled to extract the native python data structure of the PLC object. Using this PLC object, the configuration script using `pmac_motorhome` can be generated in python3 and run in its own python3 shell to create the homing sequence PLCs in the new copy of the motion directories.

The final step of the conversion process is to compare the homing PLCs created using `motorhome.py` with those created using `pmac_motorhome`; this is done with a call to the “diff” command with options to ignore blank lines and space changes. The result is then reported to the terminal indicating whether any comparisons or conversions failed, and provides a short, generated script to copy the new python3 configuration script to the original motion directory for the beamline or motion controller, if the user chooses to do so.

It is expected that not all conversions will be successful, however enough development has been done to ensure that about 85% of existing DLS motion homing directories will convert successfully, and of the remaining directories the majority of individual homing PLC files will be successfully converted. The remaining homing PLCs that were not converted can then be investigated manually, the expectation being that most will be custom PLCs or edge cases that will require some tweaking of the configuration script.

## CONCLUSION

The `pmac_motorhome` package has been specified, designed and developed with the aim of improving the tool to generate critical motion homing routines at DLS, and other institutions that use Delta Tau motion controllers. The improvements include a more friendly and readable user interface, a better structured code base that is more maintainable and a testing framework with continuous integration built in. Documentation is generated in a web page format with explanations, how-to guides, tutorials and references; this will be beneficial to developers who want to add another defined homing routine or new snippets. Consideration has been given to the roll-out and adoption of the new tool, with effort put into removing any barriers to adoption and creating a conversion process that is as simple and confidence inspiring as possible for the controls engineers as the targeted users.

This tool provides the means to create customised homing sequences where required, and always be able to re-create it without manual intervention or editing. Finally, it will and allow better collaboration between motion and controls engineers through its more readable user interface and documentation.

It is hoped that `pmac_motorhome` may prove useful to other institutions using many Delta Tau motion controllers that require homing routines.

# COLLISION AVOIDANCE SYSTEMS IN SYNCHROTRON SOLEIL

C. Engblom<sup>†</sup>, S. Zhang, S. Bouvel<sup>1</sup>, D. Corruble, G. Thibaux, S. Akinotcho, P. Monteiro, L. Munoz, B. Pilliaud<sup>2</sup>, L. Amelineau, Synchrotron SOLEIL, St. Aubin, France

<sup>1</sup>also at EFOR, Paris, France

<sup>2</sup>also at Mediane Systems, Paris, France

## Abstract

Beamlines at Synchrotron SOLEIL are finding that their experimental setups (in respect to their respective sample environments, mechanical systems, and detectors) are getting more constrained when it comes to motorized manoeuvrability - an increasing number of mechanical instruments are being actuated within the same workspace hence increasing the risk of collision. We will in this paper outline setups with two types of Collision Avoidance Systems (CAS): (1) Static-CAS applications, currently being employed at the PUMA and NANOSCOPIUM beamlines, that use physical or contactless sensors coupled with PLC- and motion control- systems; (2) Dynamic-CAS applications, that use dynamic anti-collision algorithms combining encoder feedback and 3D-models of the system environment, implemented at the ANTARES and MARS beamlines but applied using two different strategies.

## INTRODUCTION

System actuation in small or limited workspaces can be a delicate matter when taking the risk of collision into consideration. Synchrotron multi-techniques experimental environments are becoming more difficult in this matter as they combine complex beam-focusing setups, sample stages, and detectors - each section often actuated in many Degrees-Of-Freedom (DOF), sometimes with overlapping workspaces, and each section often very fragile and expensive/time-consuming to repair.

The traditional (and most direct) approach to this problem is to introduce workspace limitations (with mechanical hard-stops and/or limit switches to the various actuators) to different subsections, hence assuring non-overlapping workspaces and thus eliminating the risk of collision. This method is however only limited to static (e.g. unchanging) and less constrained environments in the sense that the setup is set in a fixed configuration and no additional systems should be introduced into the workspaces, nor that the different workspaces should ever overlap.

This paper will outline four motorised Collision-Avoidance-Systems (CAS) at SOLEIL that have been adapted to *dynamic or complex workspaces*, particularly where overlapping workspaces are being used. The CAS applications are here classified as:

1. **Static-CAS:** Systems that use proximity- or touch-based sensors coupled with PLC- and motion control-systems.
2. **Dynamic-CAS:** Systems that use motion controllers with integrated dynamic anti-collision algorithms

<sup>†</sup> christer.engblom@synchrotron-soleil.fr

combining encoder feedback and 3D-models of the system environment to avoid collisions.

## STATIC-CAS AT THE PUMA BEAMLINE

PUMA [1] is an ancient materials analysis beamline optimised for 2D- imaging with hard X-rays in the 4-23 keV range. The beamline offers its users a range of analytical tools in the form of X-Ray fluorescence (XRF), absorption spectroscopy (XANES), and powder diffraction (XRD). A second experimental stage will be added in the future for 3D imaging with up to 60 keV X-ray beam energy.

This section will focus on the setup situated in the CX-hutch where its beam-focusing section, sample-stage, and detector-support all move in collision-range of each other.

### PUMA Experimental Station Overview

The PUMA CX Environment system consists of two motorised table platforms: one holds the Kirkpatrick-Baez (KB) mirror subsystem, its sample goniometer stage, microscope and XRF detectors, while the other table supports the 2D X-ray camera detector. Figure 1 illustrates the overall setup, here each subsystem annotated with the DOF used in the CAS. In total, the complete system holds 41 motorised axes - with overlapping workspaces over 16 DOF for the mirror-chamber, sample stage, and detectors.

Figure 1: PUMA CX environment overview to be controlled with a CAS, here portraying the five subsystems with a total of 16 degrees of freedom (DOF) used in the CAS.

## PUMA Experimental Station Control & CAS Architecture

Figure 2 shows the control architecture for the complete system implemented in the CAS: low-level control is applied via a SOLEIL-standardised 4-controller(ControlBox)-driver(DriverBox) setup [2] and a PLC system, and high-level control is done via the TANGO framework [3].

The CAS framework is introduced at the low-level, with proximity-sensors and a safety light curtain sensor strategically installed at collision risk-zones. A PLC continually monitor and filter these sensor states and blocks (via dedicated PLC-controller TTL signals, here marked 'Inhibition' in Fig. 2) specific axis movements if it deems a collision is imminent. All controllers contain application-specific microcode to take the appropriate action based on these PLC-signals. To 'unblock' motors, the user can apply an 'Acknowledge'-command to the PLC via the TANGO framework, which then transfers it to the controllers via TTL-signals and hence unblocks the motor movements in the appropriate direction. The *Inhibition* and *Acknowledge* signals have been made active so that if connectivity or power-loss issue arise, the motors are blocked by their controller.

Figure 2: PUMA CX CAS control architecture, the SOLEIL standard controllers (ControlBox [1]) here complemented with PLC-treated signals from proximity- and safety light curtain sensors.

Each anti-collision sensor outputs two states (collision/no-collision) to the PLC system: the safety light curtain sensor simply does this by detecting laser-breaks in the visible path, the proximity sensors must however be pre-configured to output their collision-states if the measured distance falls within certain thresholds. The output from the proximity sensors can however give off false activations (in the form of ON/OFF flickering) and are therefore filtered in the PLC system for more robust use. The PLC then blocks/unblocks specific axis movements using the

combined sensor data using pre-filled table-data for reference.

The whole CAS can be deactivated via the TANGO device server with a password protection.

## STATIC-CAS AT THE NANOSCOPIUM BEAMLINE

The NANOSCOPIUM beamline [4] is dedicated to hard X-rays (5-20 keV) fast scanning multimodal and multiscale (35 nm to 1  $\mu$ m) 2D- and 3D imaging with high spatial resolution (nanometric). The beamline offers cutting-edge X-ray nanoprobe imaging and tomography techniques. It provides a wide range of complementary imaging and spectroscopy modalities, to which coherent diffraction imaging is associated.

The NANOSCOPIUM CX2 and CX3 nanoprobe stations are in exploitation in sequential mode: CX2 is based on FZP and CX3 is based on KB nanofocusing optics. CX2 offers Ptychography with highest spatial resolution down to 35 nm and full field X-ray microtomography in absorption and phase contrast modes. For which many different types of motorized detectors and optical elements are installed in a very compact space, each can be inserted or extracted to build a specified station environment according to the experimental requirements. However, the risk of collision between different elements is increasing and needs to be treated for its safe operation.

### NANOSCOPIUM CX2 Overview

The general setup of the CX2 environment is shown in Fig. 3, where the sample stage and most of the detector sections are installed in close proximity to each other. In addition, the Fresnel Zone Plate (FZP) and Central-Stop (CS) optical stages may also approach the same area and possibly collide with the vertical support marble during their displacement, which complicates the issue even further.

The risk of collision doesn't only present itself from the motorised elements: users should be able to manually displace certain sections (e.g.: the XRF stations along a circular rail) and possibly install/uninstall beam transfer tubes that approach the sample environment.

The first CAS control has been implemented to take care the collision risks between the optics stage, 3 detector stages, the support marble and the CX3 beam transfer tube. It will be completed by an evolution study in the future to take account collision risks with the sample stage and XRF detector stages.

Figure 3: NANOSCOPIUM CX2 environment overview to be controlled with a CAS system, here portraying the five subsystems with a total of 18 degrees of freedom (DOF). Note that the two XRF-stations and Sample Stage are not yet included in the CAS.

### NANOSCOPIUM CX2 Control & CAS Architecture

Figure 4 shows the general architecture that is currently in place: low-level control is using a high-performing SOLEIL-standardised 4-controller (Powerbrick LV [2][5] & Controller+Piezo driver) setup [2] and a PLC system. All the controllers (1 master and 3 slaves) are synchronized by a fibre-optic ring network (MACRO ring). High-level control is exerted via the TANGO framework [3].

The NANOSCOPIUM-CAS operates primarily in the PLC system and continually receives: the states of all the CAS-limit switches, each controller state (ex: running/not-running), and the general locations of the subsystems (based on encoder feedback). The PLC system also relies on user-specified (via TANGO devices) experimental configurations – where each configuration defines a set of optical stages and detectors to be used in the workspace. The PLC then authorizes/refuse stage movements depending on the combined sensor- and user-configuration- data with pre-filled reference tables.

All controllers contain specifically written microcode to transfer its running state to the PLC – only the master controller has additional CAS programs to take the appropriate action based on commands from the PLC. In addition, the master controller also holds automated scripts to safely insert/extract the subsystems into use.

Currently under investigation, the PLC-Controller-GPIO communication could be replaced by a serial communication bus (ex: EtherCAT) – which would significantly simplify the communication architecture.

Figure 4: NANOSCOPIUM beamline CAS control architecture, the SOLEIL standard high-performance controllers (Powerbrick LV [2][5]) here complemented with a PLC-system and CAS limit switches (green arrows indicate control signals, blue arrows are encoder feedback signals, black are state/command data).

### DYNAMIC-CAS AT THE MARS BEAMLINE

The MARS beamline [6] seeks to research radioactive matter in the fields of biology, chemistry, and physics. The beamline provides users amongst other things with characterizations with transmission and high-resolution X-ray powder-diffraction (XRD), Wide Angle X-ray Scattering (WAXS), and Small Angle X-ray scattering (SAXS).

The MARS Detector Support was installed in 2020 in the CX3 experimental station to actuate heavy detectors (< 50kg) for SAXS experiments and would be doing so using relatively large movements in the sample stage vicinity (and would therefore induce risk of system-collisions).

#### MARS Detector Support: Overview, Control- and CAS Architecture

Figure 5 shows the overall system overview annotated with its DOF. The system only contains 5 motorised axes, of which the three axes ( $TS$ ,  $TX$ ,  $RX$ ) are the ones running the risk of system-collision with its surrounding environment. As is seen in the same figure, the control- & CAS architecture is relatively simple and direct; a single high-performing SOLEIL controller [2][5] is used which is connected to a high-powered (> 1 kW) motor amplifier for the rotational axis. The CAS algorithm here is generated from the system 3D-models and is entirely implemented in the controller which will dynamically calculate the ( $TS$ ,  $TX$ ,  $RX$ ) motor *software limits* in function of their respective encoder values to prevent their entries in collision areas. This constant re-calculation of the motor software limits allows for a more complex and detailed workspace - assuring that movements on the ( $TS$ ,  $TX$ ,  $RX$ )-axes would never cause a system-collision with a perceived virtual object in its vicinity.

These virtual objects are the core of the MARS dynamic-CAS algorithm and it is essential that they mirror the real environment.

Figure 5: MARS Detector Support overview and control architecture - here using a SOLEIL standard high-performance controller (Powerbrick LV [2][5]) matched with a high-powered driver for the rotational axis.

### MARS Detector Support: dynamic-CAS algorithm

Figure 6 illustrates the five-step approach in which the MARS dynamic-CAS was implemented – starting here with system 3D-models (and its environment), extracting the necessary kinematic- & spatial data, identifying collision points (using MatLab simulations), and then generating and implementing the CAS-algorithm. We will in this paper focus on the second and third point: *Simulations & Collision Detections*, and *Anticollision equation generation*.

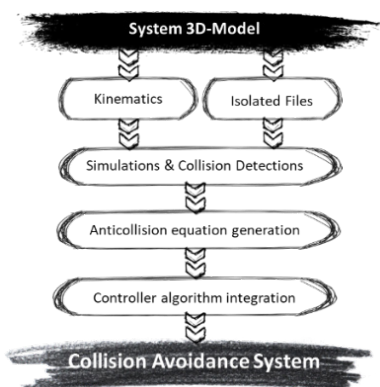

Figure 6: The five-step approach used in implementing the MARS Detector Support dynamic-CAS.

### Dynamic-CAS: Finding Collision Points & Generating the Algorithm

Figure 7 shows the approach taken to generate the CAS algorithm. The 3D-models of the Detector Support system and its environment were implemented (with the system kinematics) into Matlab where a batch of simulations would move the system axes to find all collision points with its environment. These simulation-movements would virtually test all points (and map them) in the  $(TS, TX, RX)$ -space (with pre-defined small step increments) for collisions.

To further condense the collision point data (which is in this case 3-dimensional), and make it more suitable for controller implementations, linear collision boundaries were calculated - thus grouping together collision data-points using linear equations.

The line equations (depicting the collision boundaries) could then all be transformed into a set of geometrical closed half-space equations (see Fig. 7). This set of equations (each equation stretching over  $n$  dimensions, where  $n$  is the number of actuators used), would essentially contain as many equations as there were boundaries – making it scalable and simple enough to implement in the controller.

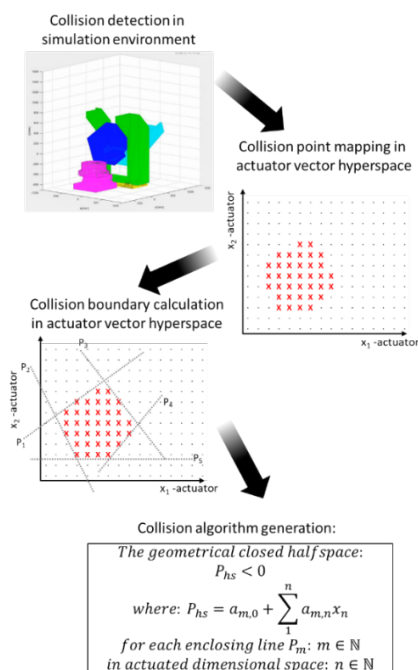

Figure 7: Finding collision point data and generating the dynamic-CAS algorithm on the MARS beamline.

### DYNAMIC-CAS AT THE ANTARES BEAMLINE

The ANTARES beamline offers its users a spectroscopic non-destructive nanoprobe (k-space nanoscope) that is used to study materials using Angle Resolved PhotoEmission Spectroscopy with nanoscale lateral resolution (nanoARPES) [7].

The ANTARES experimental station (see Fig. 8) is set in a vacuum chamber and contain several piezo-driven stages. Three of these stages: the Order-Sorting-Aperture (OSA), the Fresnel-Zone-Plate (FZP), and the Sample Stage have their workspaces overlap and run the risk of collision when in use.

Figure 8: ANTARES Experimental Station overview, here showing the 11DOF that are used in the CAS.

### ANTARES Experimental Station: Overview, Control- and CAS Architecture

The experimental station makes use of a two-controller configuration (see Fig. 9): two synchronized Delta Tau Controllers [2], both using Piezo- and stepper-drivers to interface with the motors and actuators. The control-CAS system controls 11 DOF in total.

The ANTARES beamline makes use of a dynamic-CAS – here essentially blocking/unblocking motor axes in function of the system encoders. It does this by identifying what specific region each subsection finds itself and blocks other stages from entering the same space.

## CONCLUSION

The trend towards multi-techniques & multimodal beamlines makes for more densely packed experimental stations with overlapping (or more complex) workspaces – this makes Collision Avoidance Systems a more pertinent addition to control-systems. As is shown in this paper, the CAS-architecture and approach differ somewhat between applications but the common thread in CAS would indicate a closer collaboration between metrology, mechanical design, and electronics- & control- architecture.

Advanced-CAS development is a part of the roadmap for the SOLEIL electronics group to address future synchrotron beamline needs in respect to: workspace limitations, and experiment automatization (in particular integrating industrial arm robots in the mechatronic architecture).

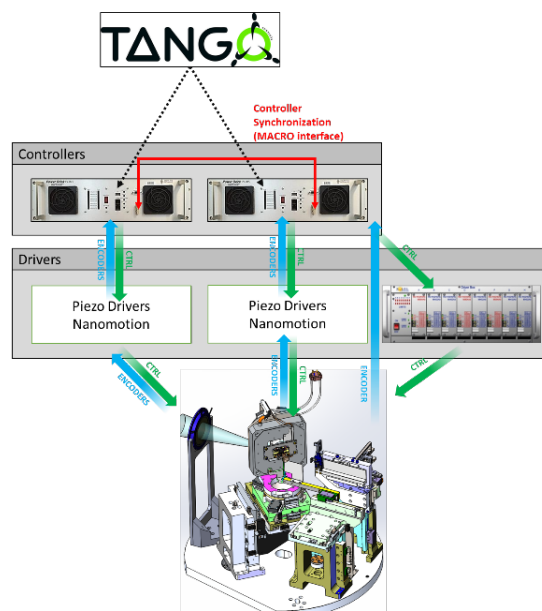

Figure 9: ANTARES Experimental Station Control- & CAS architecture, here with two synchronized SOLEIL standard high-performance controllers (Powerbrick LV [2][5]) using piezo- & stepper- drivers to control the 11 DOF. The Controllers contain the anti-collision algorithm.

## ACKNOWLEDGEMENTS

The authors would like to thank: the beamline teams, mechanical engineers and metrologists who were involved in these developments, as well as all SOLEIL staff who have aided or participated in any way to the development of the CAS systems.

# MODIFICATION OF DATA ACQUISITION SYSTEM IN HLS-II EXPERIMENTAL STATION\*

Zhen Zhang<sup>†</sup>, Gongfa Liu

University of Science and Technology of  
China National Synchrotron Radiation Laboratory, Hefei, China

## Abstract

With the proposal of the concept of super-facility in recent years, users of experimental stations only need to pay attention to data with scientific significance, and the management of massive experimental data are assisted by the super-facility technical support platform to effectively improve user efficiency [1]. Based on this theory, we modified the data acquisition system of the XMCD experimental station in HLS-II. We continue to use LabVIEW software to reduce development workload. Meanwhile, we have added the interaction program with the high-level application in the original data acquisition process under the principle of keeping the user habits of XMCD experimental station. We have modularized the XMCD experimental software and redesigned the experimental architecture into 4 modules: Swiping Card Module, Experimental Equipment Control Module, Storage System Interaction Module and Data Management System Interaction Module. In this way, we have completed the collection of rawdata and metadata, the docking of the data persistent storage system, and the docking of data centralized management.

## INTRODUCTION

As a synchrotron radiation light source, Hefei Light Source (HLS-II) provides a basic research platform for collection system will obtain the management metadata related to the user (management metadata) on the HLS-II user platform. The experimental equipment control module is the process control module of the XMCD experiment. This module will record the original experimental data (scientific rawdata) of XMCD and the metadata related to the experiment generated during the experiment (scientific metadata), and transmit them to the data processing module in the form of a data stream. The scientific rawdata and scientific metadata are encapsulated into the standardized format of HDF5 and uploaded to the file storage system through storage system interaction module. The management metadata and scientific metadata are encapsulated into the standardized format of JSON and uploaded to the data management system through data management system interaction module.

multi-disciplinary research on cutting-edge topics [2]. Under the important trend of informatization construction [3-5] of large scientific equipment at home and abroad, we have upgraded the data acquisition system of the HLS-II XMCD experimental station.

## ARCHITECTURE

Based on LabVIEW experimental system, the data acquisition system (DAQ) of HLS-II XMCD experimental station can accomplish the mission of scientific data acquisition. However, under the information construction trend of centralized data management, experimental data needs to be uploaded to the experimental data management system together with experimental metadata. At the same time, in order to facilitate the management of data, relevant information of the experimenters also needs to be collected. Therefore, based on the development of the existing XMCD experimental station data acquisition system, we upgraded it to meet the above requirements. The acquisition system architecture is shown in the Fig. 1 below.

The data acquisition system is divided into four modules: swiping card module, experimental equipment control module, storage system interaction module and data management system interaction module. After the user swipes the ID card, the data

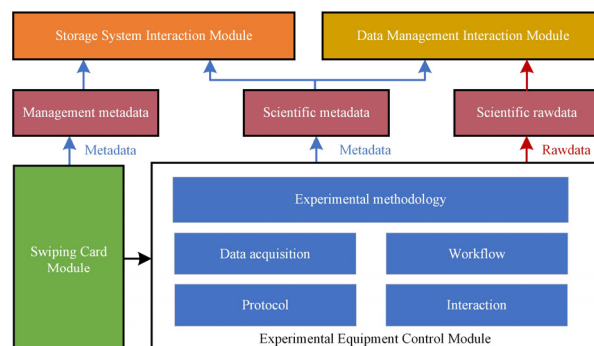

Figure 1: The architecture of DAQ system.

## DATA ACQUISITION

### User Management Metadata Acquisition

The User management metadata is collected from the HLS-II user platform. The process is shown in Fig. 2: (1)User needs to swipe the ID card at the card reader; (2)The user authentication module sends the collected ID number to the HLS-II user platform via RESTful API, and waits for the HLS-II user platform to return the verification result; (3)If the verification is successful, it means that

\* Work supported by Key R & D Project of Hefei Science Center, Chinese Academy of Sciences (No.2019HSC-KPRD003)

<sup>†</sup>zzsrl@mail.ustc.edu.cn

when the user has applied for the current experimental machine of the experimental station, scientific experiments can be carried out, otherwise the card needs to be swiped again; (4)After the user checks the information, the management metadata will be output.

Figure 2: User authentication process.

### Scientific Rawdata Acquisition

The original experimental data of the XMCD experimental station comes from the KEITHLEY 6517B electrometer. It contains two parts of data: the electrometer data at the gold mesh in front of the sample and the electrometer data at the sample. Combined with the energy point data, the three together form the the scientific rawdata. These data will be packaged into HDF5 format files together with the scientific metadata. The HDF5 file is shown in Fig. 3.

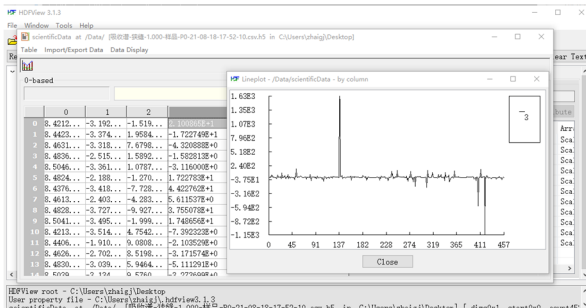

Figure 3: Scientific rawdata.

### Scientific Metadata Acquisition

Combined with the management requirements of the experiment management platform and XMCD experiment station, we have compiled the relevant metadata of the XMCD experiment which is shown in Table 1.

Table 1: Scientific Metadata

## DATA MANAGEMENT

### Storage System Interaction

HDF5 [6] is a common cross-platform data storage file, which can store different types of images and digital data, and can be transmitted on different types of machines. At the same time, there is also a function library for unified processing of this file format. HDF5 files generally contain two parts: groups and datasets. Groups are similar to folders and serve as the root directory of datasets. Datasets contain rawdata and metadata. Rawdata is the core data of HDF5 files, and metadata is used to store attribute values related to the rawdata. In Hefei light source, the original data of HDF5 files are mainly used for the preservation of experimental data, such as photoelectron spectroscopy.

After storage system interaction module gets the scientific rawdata and the scientific metadata transferred from the experimental equipment control module, it encapsulates them in HDF5 format. The scientific rawdata is the rawdata of HDF5 file and the scientific metadata is the metadata of HDF5file. Then the module generates the md5 checksum file of the hdf5 file. Through the API provided by the storage system, these files will be uploaded to the specified directory of the storage system

### Data Management System Interaction

JSON [7] is a lightweight data exchange format. It is based on a subset of ECMAScript [8] (the js specification formulated by the European Computer Association), and uses a text format completely independent of the programming language to store and represent data. The concise and clear hierarchical structure makes JSON easy to read and write, easy to parse and generate by machine, and effectively improve network transmission efficiency.

According to the requirements of the scientific data management system, the management metadata and experimental metadata collected during the experiment need to be filtered and flattened by the data management system interaction module, and packaged into a single-layer JSON file which is shown in Fig. 4.

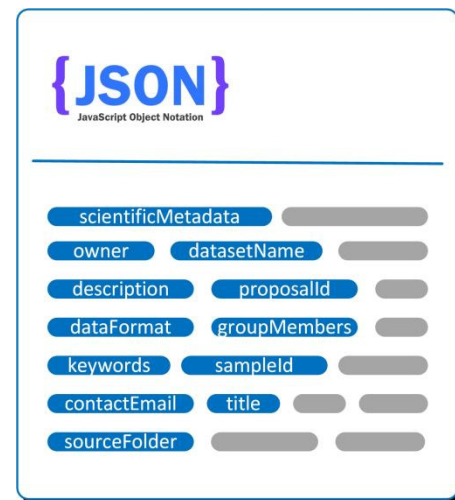

Figure 4: JSON file of metadata.

## CONCLUSION

In response to the need for centralized data management, we upgraded the data acquisition system of the XMCD experimental station in Hefei light source. The upgraded data acquisition system can better realize the collection of scientific rawdata, scientific metadata and management metadata. At the same time, the data acquisition uploads the collected experimental data to the storage system and the experimental data management system to provide a basis for future experimental reproduction and high-level software data processing.

## ACKNOWLEDGEMENTS

Thanks to Hefei Light Source BL12B beamline station for cooperating with the upgrade of data acquisition system.

# CONTROLLING THE CERN EXPERIMENTAL AREA BEAMS

B. Rae\*, V. Baggiolini, D. Banerjee, J. Bernhard, M. Brugger, N. Charitonidis, M. Gabriel, L. Gatignon, A. Gerbershagen, R. Gorbonosov, M. Hrabia, M. Peryt, G. Romagnoli, C. Roderick  
CERN, 1211 Geneve 23, Switzerland

## Abstract

The CERN fixed target experimental areas are composed of more than 8 km of beam lines with around 800 devices used to define and monitor the beam parameters. Each year more than 140 groups of users come to perform experiments in these areas, with a need to control and access the data from these devices. The software to allow this therefore has to be simple and robust, and be able to control and read out all types of beam devices. This contribution describes the functionality of the beam line control system, CESAR, and its evolution. This includes all the features that can be used by the beam line physicists, operators, and device experts that work in the experimental areas. It also underlines the flexibility that the software provides to the experimental users for control of their beam line, allowing them to manage this in a very easy and independent way. This contribution also covers the on-going work of providing MAD-X support to CESAR to achieve an easier way of integrating beam optics. An overview of the on-going software migration of the Experimental Areas is also given.

## INTRODUCTION

The CERN experimental areas are a complex system of beam lines and beam intercepting devices that are able to provide a large variety of different particle beams to different experiments and detector assemblies. They serve both fixed target experiments and test beams [1]. The most important aspect of these unique experimental facilities is the possibility for experimental users to control and to monitor beam parameters from dedicated terminals installed in their respective control rooms. Such parameters include the access to the experimental zones, the beam intensity via collimator settings, the magnet currents, which are defining the beam trajectory and focal properties, the particle species via the use of targets, converters and absorbers, and the instrumentation for monitoring. The beam control system is called CESAR [2], which is an acronym for CERN Experimental areas Software Renovation. Through the past 10 years, CESAR has been continuously developed with new features and devices types being added. With the new secondary beams software migration project, the CESAR scope will be extended to accept optics calculations through MAD-X connectivity, and ideally also with automatic layout updates through the CERN Layout database.

The particularity of CESAR with respect to other control systems of the CERN accelerators is that it is designed to be operated by non-experts, as well. Many of the experimental users are not accelerator physicists and do not know all

details of the beam line and its equipment. Therefore the system is made easy and intuitive, yet safe, in order to avoid any unintentional damage to the beam lines and experimental equipment. CESAR is based on Java and constructed around an ORACLE database. It acquires and sets so-called equipment knobs, mainly by subscribing to the Front-End Software Architecture FESA [3] device. In addition, it receives information from other services such as from the access system database (Access-DB), via DIP (Data Interchange Protocol), and the data logging system NXCALs [4]. All devices are identified in the CESAR database together with their parameters, such as FESA name, element type, beam line, and others. This allows flexible modifications as often needed in secondary beam lines. The architecture of CESAR is shown in Fig. 1.

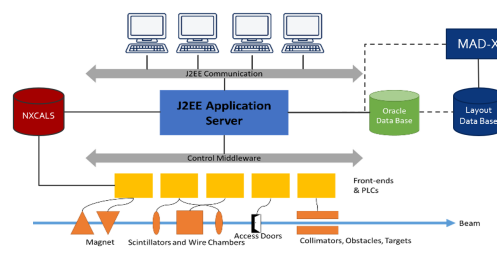

Figure 1: CESAR Architecture and Foreseen Connectivity.

## USER TYPES

For both safety and simplicity reasons, there are three user types defined in the database: (1) *Super Users* are allowed to see and change any parameters of all devices in all beam lines. This group is composed of the responsible beam physicists, accelerator operators, and selected equipment specialists. (2) *Main Users* are associated with specific consoles in an experimental control room and are allowed to change most non-safety relevant settings in their beam line up to their experiment. They are set by the super users according to the experiment schedule, which is provided by the SPS/PS Physics Coordinator. (3) *Standard Users* are treated similarly as main users, however they see only their assigned experimental area, for instance to initiate an access procedure. Standard users are able to monitor their beam parameters, but are not allowed to control any devices other than the ones in their assigned user zone.

## INTERFACE

The CESAR interface is composed of three main panels, as depicted in Fig. 2: the top menu, the devices panel and the beam line selection tab. The latter is used to change the

\* Bastien.Rae@cern.ch

the so-called rectifier status, from which the power supplies can be switched on/off or moved to standby, for instance if a magnet is not in use for the currently loaded optics. It allows also resetting the power supply for certain fault types.

## Collimators

For collimator settings, each of the motors moving individual jaws is controlled. Collimators with four jaws are considered as two different entities, one vertical and one horizontal, for a better overview. They are used for changing intensity, shape, and energy spread of a beam. Similar to the magnet settings, one can set reference values for each of them, as can be seen in Fig. 3.

In the magnets status panel (see Fig. 4), all magnets of the selected beam line are displayed together with their main parameters. There is the possibility to set and read the applied current values for each of the magnets and reference values can be defined in addition. This reference allows to go back to previous configurations, e.g. when steering the beam. CESAR also displays magnet faults together with the specific fault type, e.g. overheating. Another functionality is

## BEAM INSTRUMENTATION

### Scintillators and Scalers

The trigger status displays counts from each scintillator along the selected beam line, as depicted in Fig. 6. In addition, it calculates ‘normalised counts’, which are normalised to the beam intensity on the upstream primary target in order to avoid fluctuations coming from the primary beam. As they are motorised, scintillators can be moved out of beam on demand, e.g. to reduce absorption for low-momentum electrons. Furthermore, in each control room, users can connect their discriminated NIM detector signals to scaler units, which are then displayed on CESAR and allow beam operators to scan and set the beam position for a maximum number of counts.

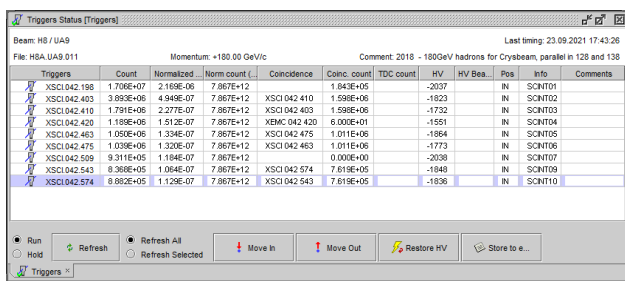

Figure 6: Scintillator Status.

### Profile Monitors

As shown in Fig. 7, CESAR displays beam profiles along the beam lines independent of the type of monitors that are used. Typical monitor types are analogue MWPCs, delay wire chambers and scintillating fibre monitors (XBPF). CESAR provides count rates from each monitor as well as calculated mean values of the profile distribution. As for the scintillators, some of the monitors can be moved out of the beam. Voltage settings can be adjusted by the operators for an optimal dynamic range.

Figure 7: Profile Monitors.

### Other Instrumentation

In addition to the above, CESAR offers displaying a variety of other beam instrumentation types specific to the selected beam line. Such detectors include the FISC scintillating wire scanners, for which CESAR reads counts versus the selected fibre position, and Cherenkov detectors for beam

particle identification, for which users can set the gas pressure and even make pressure scans besides the readout of the counting rate.

## IMPROVED OPERATIONAL FEATURES

### Scans

CESAR offers the possibility to perform scans on any beam device and instrumentation. One can select the control element (e.g. magnet or collimator) and the instrumentation to perform a scan between certain values in selected steps. The scan will go through all preset values and plot the detector reading as a function of scanned parameter, e.g. a magnet current as depicted in Fig.8. This needed allows to maximise transmission through a beam line or to find the position of a user detector without the need of survey in the zone. FISC scans can be performed in different modes, i.e. one position per extraction or in a fast mode for a complete scan during one extraction. There are different expert modes in addition, for instance to scan the beam divergence between two FISC monitors.

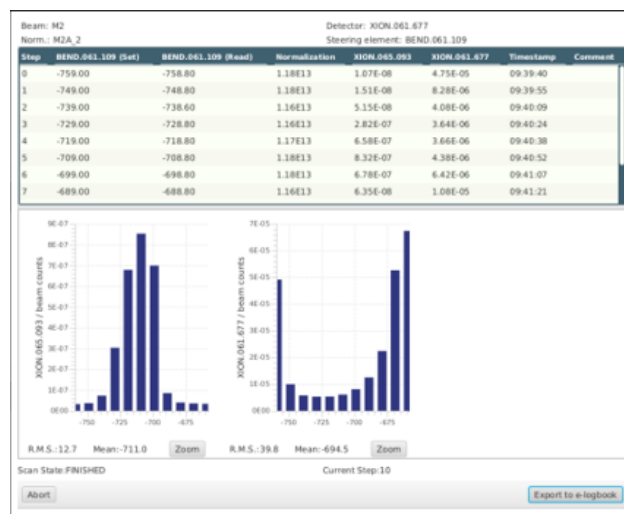

Figure 8: Scan Result.

### Beam Files

Users of experimental areas may want different beam parameters and desire different particle types, energies, and intensities. The beam files of CESAR contain all beam reference values for the selected beam lines that have been set and saved after commissioning of the specific optics and beam. This allows users to switch easily between configurations as needed by simply loading a beam file without the need of constant help of the beam operators and physicists. In addition, each file can be extrapolated to different energies, taking into account energy changes in the line as needed for tertiary beams.

### Access System

Users of secondary beams typically often need access to their respective experimental areas, in particular for test

beam users. It is therefore important to allow quick access to their setups without having to ask operators constantly. Hence, an access system control has been implemented in CESAR. All users can see the access status of their experimental area. The main user can both ask for access in their respective zone and turn on the beam for all users in the beam line. For safety reasons, CESAR receives information from the access system and commands the safety devices only if allowed and not prohibited by the beam interlocks. In order to make sure that no erroneous command can be sent to a device protected by the access system hardware loop, the access system matrix including all safety elements is duplicated in CESAR and verified before sending the signal. In this way, it is ensured that all conditions are fulfilled before opening a zone or turning on the beam.

### *Radiation Monitors*

Reading of radiation monitors has been implemented in CESAR for each beam line, in order to check the ambient radiation levels as well as to display information about the alarm thresholds. If the warning threshold is passed, the respective line will turn orange in the display window. The colour changes to red if the alarm threshold is passed. This allows a quick follow-up in case radiation alarms occur. Note that the radiation safety system is completely independent and CESAR only displays information for convenience.

### *Beam Layout*

The beam layout panel displays all devices that are registered in the CESAR DB for the selected beam line. In the experimental areas, the beam lines change regularly depending on user requests. If some equipment is removed from the line, the super users can hide devices that are not needed. Those devices then are not shown in the regular status panel anymore in order to keep the overview concise. In addition, super users can “protect” any device, which means that any other user is inhibited from operating it anymore. Finally, Super users can add comments to any device that will be displayed in their corresponding panel, e.g. for better explanation of the device function or to highlight important features of the device setting.

## **SOFTWARE MIGRATION PROJECT**

The Software Migration project has been initiated with the goal of modernisation of the offline software used for the description and design of the secondary beam lines at CERN. The situation at the beginning of the project in 2017, the reasons for undertaking the migration, and the baseline software after the completion of the migration by the time of the restart of the Experimental Areas beam lines after the Long Shutdown 2 have been described in [5]. The present contribution summarises the project status and puts a particular emphasis on the coupling of the software used for the beam optics calculations (MADX and AppLE.py) with CESAR.

### *Project Status*

A migration of the complete software chain used for the design of the secondary beam lines in both CERN North and East Areas has been performed. The new baseline consists of MADX [6] for beam optics and survey calculations, the in-house developed software AppLE.py for graphical output and matching, as well as FLUKA [7–9], BDSIM [10] and Geant4 [11], respectively Geant4-based derivatives, for beam-matter interactions. The solution has been validated with the help of benchmark studies and a test of the complete software chain. It is planned to use the software in a highly integrated way, utilising the modern online database tools available at CERN, such as Layout Database and GitLab.

The new software has become the baseline for Run 3 (2021 - 2025), which is expected to allow the final validation of its practicality and to reveal some aspects requiring improvement. While the major migration work has been completed according to the initial project plan, the work on the adaptation of the software chain to the evolving software infrastructure at CERN as well as the integration of the beam lines into the Layout Database, the benchmarking studies and work on further automatisation are foreseen to continue during Run 3 and beyond.

### *Layout Database*

The Layout Database [12] is a CERN-wide database, designed to contain integration and installation layout data, a naming portal, photographs and drawings of the beam lines, tunnels, areas, as well as tables with all parameters relevant for the beam line description for the CERN accelerator complex. The secondary beamlines are currently being included in the database in the framework of the CERN-wide Configuration Management. It is planned to import beam line parameters such as magnet names, magnetic lengths, apertures, mapping of magnetic field strength to currents and vice versa as well as others from the CESAR database into the Layout Database and vice versa. For the latter, there exists a function of automatic generation of MADX input files from the Layout Database, which has been adapted to match the format and naming convention as required. This application takes various parameters from the database and constructs the MADX input in form of a sequence file the given beam line. This tool has been successfully tested with the K12 beam line and the sequence file has been validated successfully with the help of the previously used software. Many of the use cases for the new software chain will be tested now thanks to the restart of beams after LS2. A large share of the North Area beam lines has still to be implemented into the Layout Database, which is planned to be completed by the end of 2021.

### *Envisaged Future Steps*

Continuing the integration of the North Area beam lines into the Layout Data Base and the MADX sequence file generation for each of them. In the medium-term, it is envisaged to create an interface between AppLE.py and CESAR. The

first steps for such an integration have been taken already, allowing beam files from the CESAR database to be read by AppLE.py. That way the beam optics for any specific beam file can be calculated and visualised, allowing for instance to predict losses at collimator apertures. It is also planned to feed back newly generated and modified optics settings from AppLE.py to CESAR beam files

## CESAR FUTURE

The most important aspect from the configuration management point-of-view will be the connection of CESAR to the newly commissioned beam software. The project is on a good track and several new features for CESAR have been already developed, such as the Apple.py-to-CESAR conversion and the automatic layout update with the Layout Data Base. We are thankful for the plenitude of ideas reaching us from the user community and from the recently established North Area Consolidation Project, which are evaluated at the moment. A frequently wished for item is establishing an Application Programming Interface (API) for CESAR, permitting Super Users to access the CESAR functionality from within scripts. This would allow to automatise even complicated steps for beam tuning with direct feedback from the beam instrumentation. In addition, connecting CESAR to the NXCALs logging service will allow users to retrieve recorded values of any device in convenient way. Thinking further ahead, integrating fault reporting into CESAR, e.g. with the already existing Automatic Fault System AFT [14], will improve reliability analyses and save time of the operators.

In addition, the new CERN GUI Strategy working group currently reviews the existing GUI systems with the aim of streamlining and easier maintainability. This is a good opportunity to improve the graphical interface and to explore possible synergies with the other control systems of CERN, for instance by adding some useful features that have been developed for accelerator controls.

## CONCLUSION

CESAR is a versatile and flexible control software that is used in the experimental areas of CERN allowing users the operation of all beam devices in the secondary beam lines. It features personalised settings, such as beam configuration files, which enables quick changes of beam parameters up to a complete change of particle species and beam momentum. CESAR is being improved continuously with new features becoming available and following the evolution of users requirements. Recently, in the framework of the secondary beam software migration project, a first interface to beam simulations has been established that will allow visualisation of models, currently loaded optics and direct feedback from beam instrumentation. In the future, further upgrades are envisaged, reaching the full capabilities due to the software migration project, the North Area Consolidation Project, and the new CERN GUI Strategy.

## ACKNOWLEDGEMENTS

The authors warmly thank G.L. D'Allesandro, D. Walter, I. Perez, M. van Dijk, M. Rosenthal, and E. Montbarbon for their important contributions to the software migration and the CERN management for their continuous support of these activities.

# UPDATES AND REMOTE CHALLENGES FOR IBEX, BEAMLINE CONTROL AT ISIS PULSED NEUTRON AND MUON SOURCE

F. A. Akeroyd, K. V. L. Baker, L. Cole, J. R. Harper, D. Keymer, J. C. King, T. Lohnert, A. J. Long, C. Moreton-Smith, D. Oram, B. Rai, Science and Technology Facilities Council, Rutherford Appleton Laboratory, Chilton, UK

## Abstract

IBEX is the EPICS based experiment control system now running on most of the beamlines at the ISIS Neutron and Muon Source, with plans to deploy to all remaining beamlines by the end of the upcoming long shutdown.

Over the last couple of years we have added support for reflectometry and muon instruments, developed a script generator, moved from Python 2 to Python 3, and continued to build on our suite of device emulators and tests. The reflectometry inclusions required the development of a framework to maintain the complex motion control requirements for that science technique.

Whilst it is desirable that IBEX is easily configurable, not all operations should be available to all users, so we have implemented functionality to manage such access.

The COVID-19 pandemic has meant we have also had to adapt to greater amounts of remote experiment access, for which we developed systems covering both IBEX and the old SECI control system.

This presentation will aim to provide a brief update on the recent changes to IBEX, as well as outlining the remote operation solutions employed.

## INTRODUCTION

The ISIS pulsed neutron and muon source [1] is a world-leading centre for research in the physical and life sciences and currently has over thirty beamline instruments. The IBEX control system [2, 3] is currently replacing the previous control system, called SECI, and to date about two thirds of instruments have been converted. IBEX is a client-server based system composed of EPICS [4] for the server part, Eclipse/RCP/Control System Studio [5] for the client GUI (see Fig. 1), and utilising Python for scripting.

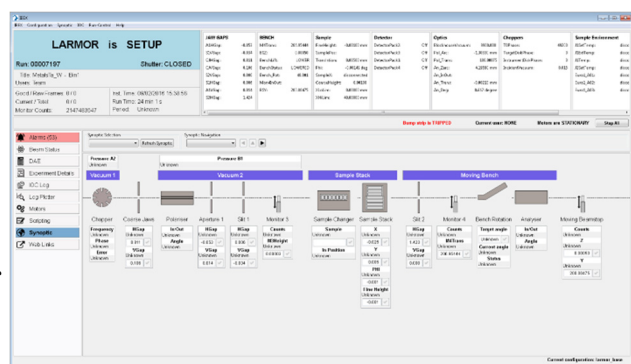

Figure 1: The IBEX user interface.

## REMOTE EXPERIMENT ACCESS

Lockdowns and subsequent travel restrictions, social distancing and new safety measures brought about by the COVID-19 pandemic caused disruption to planned operation of the ISIS facility. When systems were put in place to allow the accelerator and instruments (beamlines) to operate again, it was still impossible for most external facility users to travel to ISIS to perform an experiment.

### Gathering Requirements

A consultation was undertaken with instrument scientists and technicians, initially with a questionnaire and then follow up meetings with group leaders. The aim was to determine how they foresaw operations with "user not present" experiments and to look for common themes of where best to concentrate our resources. We also needed to cover both IBEX and non-IBEX (SECI) instruments with our solutions.

There were quite a range of levels of user engagement proposed, these were often determined by safety or equipment damage considerations with remote control. Only one instrument group, the muon beamlines, wished their users to have full access. Other instrument groups wished various degrees of read-only access so the user could monitor the experiment remotely, liaising with the local contact when necessary. The support technicians also wished for enhanced remote monitoring, which would allow them to better optimise timing and resourcing of general equipment tasks on site.

### Full Remote Experiment Access

For the muon beamlines it was practical to allow remote users full access to the experiment equipment. We were able to achieve this by using the cloud connectivity solution provided by the commercial RealVNC package [6], effectively putting the user in the instrument cabin. The muon beamlines were not fully running IBEX at this point, so this solution also avoided having to modify the old SECI control system.

A dedicated control computer in each instrument cabin was configured for cloud VNC access, instrument scientists then added users to the relevant VNC group granting access only for the duration of their scheduled experiment. Remote users were required to use Two-Factor Authentication (2FA) [7] for access to the VNC system.

In addition the VNC system has proved useful for more than just remote user experiments. An engineer from an overseas external company was also able to take part in commissioning a new chopper system along with local staff.

Though VNC was primarily used for read/write access, it can be used to grant read-only access to a computer. Such access, however, does not even let you change which window you are viewing, so is only useful if there is a particularly relevant screen that could be left visible on the system

## Remote Monitoring via Web

ISIS has a “web dashboard” (see Fig. 2) for both old and new control systems, this gives a very brief snapshot of the instrument state and key values (blocks), but is more suited to quickly checking the instrument is still working or what stage an experiment has reached. To monitor progress in sufficient detail, the ability to see historical values is required.

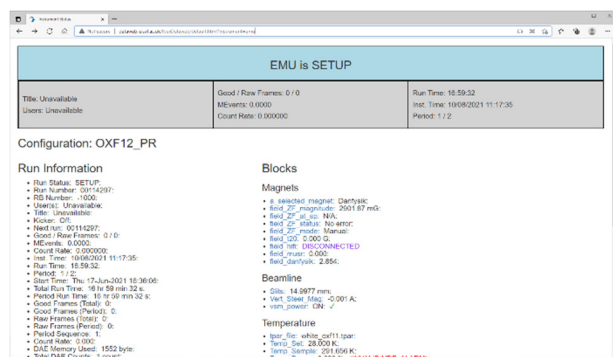

Figure 2: Instrument web dashboard.

Developing a solution applicable for both the IBEX and the SECI control system made use of a common component of both systems, the ISISICP program. This manages the fast data acquisition system, but also has access to all the sample environment data as it is responsible for writing the final NeXus HDF5 [8] experiment data file.

We chose to use Grafana [9] to provide the graphs of experiment parameters. The system is stationed behind an Apache web server proxy and uses a FreeRADIUS plugin

to interact with the user office system to authenticate users and check they were part of the appropriate “virtual visit”.

To provide the data for Grafana, we chose to make use of the Prometheus [10] monitoring tool as an intermediary. The common control program component was instrumented to allow it to be scraped by the Prometheus system, which then stored the values (metrics) in its time series database. A data retention period of two weeks was applied in Prometheus to the scraped data. As Prometheus is a full monitoring system it also supports defining rule-based alerts, but as we already had an existing system for this it was not something we investigated.

Figure 3: Plot of a block from the web dashboard.

A simple single value plot from following a link to a block on the web dashboard is shown in Fig. 3. A more complex interaction can be obtained via the Grafana explorer interface as shown in Fig. 4. Items monitored via Prometheus conveniently appear in the metrics dropdown list and multiple queries can be added to the same graph and then stored in the query history for use at another time.

The Grafana data view proved very popular with the various groups. The technicians also created their own cross-instrument dashboard to help with coordinating work.

Figure 4: Grafana explorer view.

## Remote Monitoring via IBEX Client GUI

Many ISIS users were already making use of IDAaaS (ISIS Data Analysis as a Service) [11] for carrying out data analysis using software such as Mantid [12]. The IDAaaS system allows authenticated users to provision a new pre-configured Linux virtual machine which has appropriate resources and pre-installed software for a particular data analysis technique.

Though the IBEX control system primarily runs on Microsoft Windows, this is only (currently) a requirement for the server part of the system. The IBEX client is Java based, making use of Control System Studio and Eclipse/RCP, so is cross platform. By providing the IBEX client on the IDAaaS system we were able to give users an enhanced read-only view of the experiment, they were able to open all equipment panels from the synoptic and plot values in the data browser window, even access the live detector view served via channel access through EPICS areaDetector [13]. Users were, however, not able to change values via this interface, this access was enforced via EPICS CA gateways.

The IBEX GUI did not require extensive work to be packaged and deployed to the linux IDAaaS system. Most issues were related to accidental use of \ rather than / in pathnames and mis-matching of upper/lower case between on disk and in software filenames. These issues were corrected and automated checks added to our system.

## BUILDING AND DEPLOYING SYSTEMS

The IBEX control system runs on Windows virtual machines, which provides a good business fit with the other IT infrastructure on site. We have been looking to improve the way we deploy and upgrade the system, both the IBEX applications and the Windows operating system.

Over time the performance of an operating system can suffer from repeated installation/removal/upgrade of applications and security patches; in additional different instruments can diverge in the type and version of software installed. Ideally, we would like to refresh the operating system while preserving the rest of the system.

Our new Windows 10 instrument system is generated by using the Microsoft Deployment Toolkit (MDT) [14] to build a system image with relevant applications installed, and then to attach the remaining parts of the IBEX control system as separate Virtual Hard Disks (VHDs) that have been separately created elsewhere. Applications that make use of the windows registry are installed as part of the base Windows system image, however IBEX and most of its associated utilities are purely file based and can be deployed on the non-operating system VHDs. Besides the main Windows system VHD, we have four others that are attached to the virtual machine:

- APPS: main applications minus any instrument specific settings e.g. EPICS Input/Output Controllers (IOCs)
- SETTINGS: instrument specific details and configuration information, referenced by IOCs on APPS VHD
- SCRATCH: temporary storage, raw data cache
- VAR: MySQL database files, other dynamic settings

By using MDT we have embedded the knowledge of building and configuring the control system computer into version controlled scripts. Performing a major windows and applications upgrade would now be easier and involve generating a new windows base image, mounting an updated APPS VHD, mounting the other existing VHDs, and running the upgrade script provided on the new APPS VHD which will make any required changes to files on the SETTINGS and VAR VHDs.

## REFLECTOMETRY SERVER

One of the most complicated scientific techniques from the controls perspective is reflectometry. These beamlines have many axes of motion and require precise alignment as well as coordinated motion of components. Items commonly found on other beamlines, such as slits, often have an additional degree of motion on reflectometers, and super mirrors can alter the beam direction, requiring downstream components to compensate. To handle this, we developed an additional abstraction above the EPICS motor layer called the reflectometry server [15], the GUI for this is shown in Fig. 5

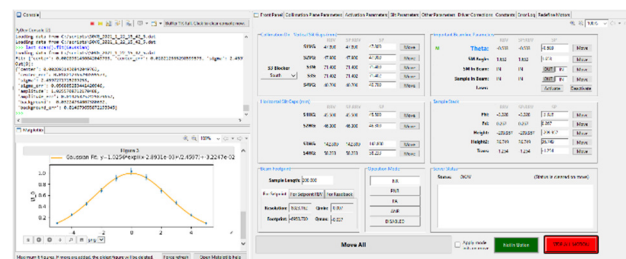

Figure 5: The reflectometry GUI.

The reflectometry server is a Python program based on the PCASpy [16] package and is configured via a Python file that defines the beamline layout. The beamline is assembled out of building blocks called components, which represent a node of interaction with the beam (either passively tracking it or actively affecting it). These components are linked to low level motors, but a management layer can provide service such as altering motor velocities to enable synchronisation of component motion and calculating a beam footprint.

The reflectometry server has recently been extended to support a bench component, which transforms three linear motion axes to motion on an arc around the sample. This has been successfully deployed to the ISIS POLREF instrument. Other improvements to the system have included:

- Allowing components multiple parking positions to choose from, these can depend on beam angle so ensuring they do not block the neutron beam
- Parking components in a sequence of multiple moves to avoid collisions
- Components can now have a variable rather than fixed Z (along beam) position, and this can be scanned.

## SCRIPT GENERATOR AND SERVER

Automated control of user experiments is achieved via scripts written in Python, which while powerful can be error prone. Users' scripts loaded into the system are checked with Pylint [17], which spots some errors and python 2/3 incompatibilities, but will still miss issues like referring to non-existent equipment or waiting for too much time or beam current. Other problems can occur if a user creates two scripting windows and accidentally launches two competing scripts. Running a script in a dry-run or simulation mode can spot some additional problems, but this requires the script to have been written following a set of strict rules (i.e. only accessing devices via certain APIs) or else the modes will either fail or have undesired effects.

### Script Generator

The IBEX script generator aims to provide a simpler table like interface for users to script the instrument. Rows are populated in a table where the columns refer to parameters that affect the control of the experiment. The parameters available and functions used to validate parameters and run scripts are configured via a local *script definition* file. More details of this system are presented in another paper at this conference [18].

### Script Server

The script server is based on NICOS [19], it takes its input from the script generator and its role is to queue up scripts and provide a mechanism for interacting with the running scripts. A script server perspective is provided in the IBEX GUI; however, a future goal is to provide more dynamic interaction between the script generator and script server.

## CONTROLLING USER ACCESS

The IBEX control system has several classes of user: visiting scientists, instrument scientists and technicians. Each of these groups may wish to see a slightly different view of the available information, and the ability to change specific parameters may need to be restricted by user group type.

A hierarchy of screens can be created that allows “drilling down” from a synoptic to greater details, or an “advanced” tab is sometimes used instead. Often we wish to restrict access to a screen or values on a screen, for this we have defined a system called *manager mode* that must be enabled (via entering a password in the GUI) to allow such access.

*Manager mode* makes use of EPICS channel access security at its heart. Process variables that require protection are placed in an EPICS access security group that only allows write access when the *manager mode* EPICS process variable is set. In addition, scripts attached to GUI panels can show/hide or enable/disable widgets based on the status of *manager mode*.

## AUTOMATED TESTING

The development of IBEX utilises modern software engineering techniques, such as Continuous Integration [20],

and we make extensive use of automated testing. We have developed a framework for testing our software against device emulators [21], the latter usually developed using the LeWIS package [22]. We also use Squish [23] for user interface testing.

This approach has continued to be useful to us, allowing us to spot issues and incompatibilities early when software or packages are changed.

## CONCLUSIONS

The rollout of the IBEX control system to new instruments has been partly interrupted by the COVID-19 pandemic, but this also gave us the opportunity to explore and develop new remote access mechanisms that will be useful in future. The various systems and procedures that have been put in place to develop IBEX, such as extensive testing and use of emulators, taken together with the systematic creation of the instrument virtual machine system via MDT, should provide us with a good platform for future longevity and reliability.

# THE IBEX SCRIPT GENERATOR

James King, Jack Harper, Thomas Löhnert, Aaron Long, Dominic Oram,  
STFC/RAL/ISIS, Chilton, Didcot, Oxon, UK

## Abstract

Experiment scripting is a key element of maximising utilisation of beam time at the ISIS Neutron and Muon Source, but can be prone to typing and logic errors. The IBEX Script Generator enables collaboration between instrument scientists and users to remove the need to write a script for many experiments, so improving reliability and control.

For maximum applicability, the script generator needs to be easily configurable which is achieved by instrument scientists creating script definitions. Script definitions are Python classes that contain the parameters a user can fill in for each action in the script, and functions to execute, validate and provide a time estimation for each action.

A user organises a table of actions and fills in their values to create their experiment, these action values are validated in real time. With a valid table of actions a user can generate a Python script which can be executed via the IBEX scripting tools.

A key requirement of the script generator is for it to integrate the pre-existing Java based IBEX client. Py4J is used as a bridge between Java and the Python script definitions. An iterative, user-focused approach has been employed with quality assurance techniques such as user interface (UI) testing to achieve a behaviour-driven development workflow.

Further planned development includes dynamically controlling the execution and values of actions whilst the script is running, action iteration and user experience improvement.

## INTRODUCTION

IBEX [1] is an EPICS based control system developed and used at the ISIS Neutron and Muon Source to control beamline equipment and experiments. A key feature of IBEX is the Python-based control and scripting library known as genie python [2]. This library provides functions to control experiments in an automated manner, beginning and ending data collection, writing to EPICS process variables (PVs) to control equipment amongst a host of other functionality.

Scripting is an integral part of how ISIS runs experiments, both in IBEX and the previous control system SECI. Giving users the power to write scripts allows them to control and automate experiments in a very customisable and expressive fashion. It also helps improve the reproducibility of experiments and enables maximum utilisation of beam time.

However, there are a few pitfalls when it comes to using scripting extensively. To script an experiment a user needs to understand how to code in Python, this places a steep

learning curve ahead of users who have little or no experience in coding. This learning curve distracts user focus away from the science of an experiment. Furthermore, even if a user is proficient in coding they are not familiar with genie python and IBEX, so they must learn a new complex set of commands and logic in order to correctly run their experiment. For users that are familiar with the environment it is certainly easier, but writing scripts is still prone to logic errors and mistyping of commands.

There are attempts to mitigate many of these issues within genie python, such as checking of scripts for programming errors at load time, providing a reduced command set for specific instruments and providing autocomplete for PVs of interest. One of the main roles of the script generator is to mitigate the pitfalls surrounding scripting as well as enhancing the experience of a user at the facility by enabling them to focus on the experiment.

There are a number of script generators in use at ISIS with varying degrees of functionality - some that work with the previous control system SECI. The aim of the IBEX script generator, produced by the experiment controls group [3], is to provide a unified tool – taking inspiration from other script generators currently in use at ISIS – for generating scripts without having to write code for specific experiments.

## WORKFLOWS AND FUNCTIONALITY

Many experiments at ISIS follow a regular pattern. Users and scientists often customise previous scripts that follow a similar pattern to the experiment they are creating. The script generator targets this workflow by allowing instrument scientists to create script definitions – which define the parameters an experiment can take and the logic to run the experiment – and users to input experiment parameters. Using these two inputs the script generator can then generate a script (see Fig. 1).

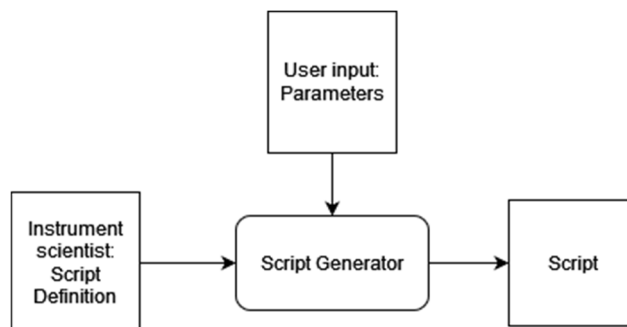

Figure 1: Script Generator inputs and outputs.

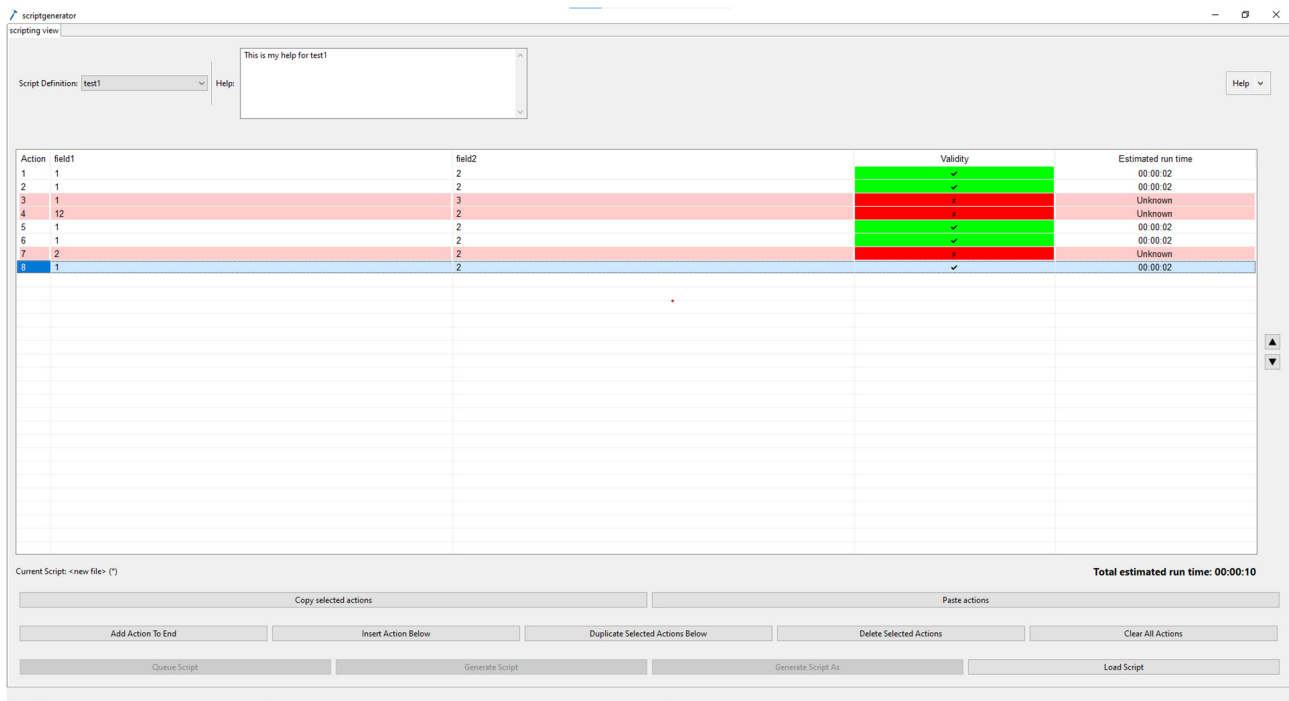

Figure 2: Script Generator User Interface.

To create their experiment the user must select the script definition (see Fig. 3) that contains the logic to run it and input their parameters into a table (see Fig. 2). In the table rows are individual actions for the script to run and columns are the experiment parameters to run each action with.

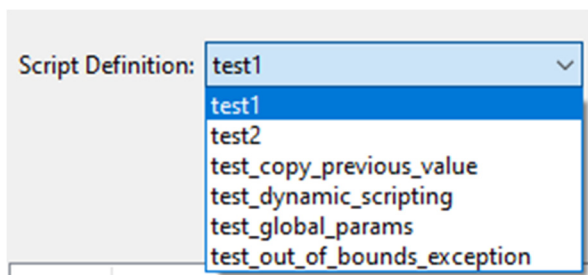

Figure 3: Script Definition selector.

There are a number of gestures (user actions) to control the order and values of actions. These include copy/paste, insert, append, delete and duplicate gestures, as well as the ability to tab between cells and reorder actions.

A user can generate a script and save it to file. This script can be executed in the IBEX scripting console. Alternatively a script can be previewed and sent to the script server [4] – a server that runs queues of Python scripts separately to the scripting console.

One requirement of the script generator is to be able to reload a script back into the script generator and edit it. To achieve this, when generating a script the parameters entered by the user are also saved to a separate json file. This file can then be reloaded into the script generator for use at a later point.

Script generator parameters are validated in real time. The validation aims to ensure incorrect values and mistyping do not end in generated scripts executing incorrectly or failing to run.

Scientists provide a validation function in a script definition. This function is arbitrary Python code which validates individual actions' parameter values. If invalid this function provides a string containing a message to display to the user as a tooltip when hovering over the action. The validity of actions are displayed through colouring an actions row.

Another feature which adds an output (read-only) column is time estimation. A script definition defines a time estimation function, which takes an actions parameter values and returns a number of seconds that this action will take to run. The time estimation column then displays this time to run in hours, minutes and seconds for each action. A total time to run is also calculated and displayed.

There are two types of parameters in the script generator, action parameters and global parameters. The previously mentioned parameters that are contained in the table are action parameters and only apply to one action. Global parameters are only set once for the whole script. For example, a script definition may use a global parameter to select a temperature controller for the whole experiment, and then individual actions may have a parameter to specify the temperature to set on that temperature controller for that action.

Global parameters are also validated individually, and can be used in the validation, time estimation and execution functions for individual actions (see Fig. 4). All these features are subject to refinement and additional functionality. This future work is discussed in the future work section.

Action	to_print	Validity	Estimated run time
1	hello	✓	Unknown
2	1	✓	Unknown
3	hello	✓	Unknown

Figure 4: Global Parameters.

## ARCHITECTURE

The IBEX control system uses a client-server architecture. The client provides a variety of perspectives for instrument control including the scripting console and script server. The client is developed using Java and the Eclipse RCP framework [5] and as such follows object-oriented design patterns to form the software architecture [6].

As there is a requirement to include the script generator as part of the IBEX client, it has also been written in Java using the Eclipse RCP framework.

Python was chosen as the scripting language for IBEX because it is an easy to learn language and is widely used in the sciences. Because Python is used for IBEX scripting, scientists have experience writing Python scripts, and the `genie_python` library has functions for instrument control, it makes sense for script definitions to also be written in Python.

Py4J [7] is a Python and Java library that enables code from each language to access objects from the other language. We are utilising Py4J as a bridge between the Java model and script definitions.

The architecture follows the Model-View-ViewModel (MVVM) architectural pattern [8] (see Fig. 5). The Java model talks via the Py4J bridge to the script definitions.

Figure 5: The Script Generator Architecture.

Python is the main language we target to generate scripts for. However, there is a requirement to be able to add new languages to generate scripts in. We have made the generation mechanism extensible using the strategy design pattern (see Fig. 7). This pattern will allow us to add extra generator languages by extending the `AbstractGenerator` class.

The `PythonInterface` class that a `GeneratorPython` object makes calls to is a façade on the communications over the Py4J bridge. The Python side is made up of a number of script definitions provided by instrument scientists and a number of classes providing helper methods to facilitate communication across the Py4J bridge (see Fig. 6).

## Python Code

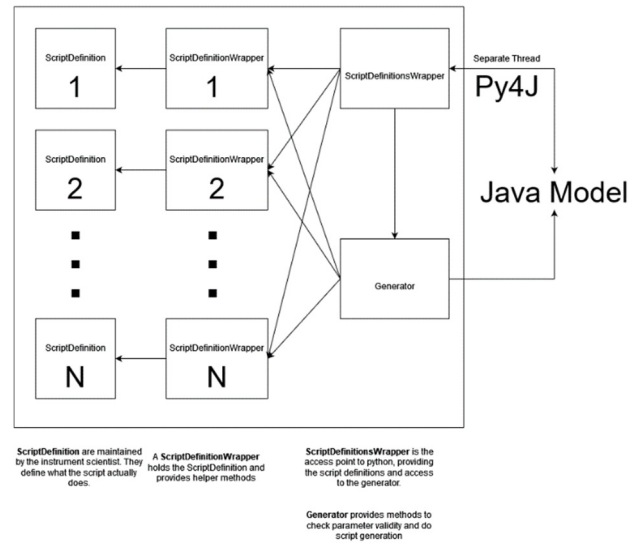

Figure 6: Python Utilities to access Script Definitions.

To compensate for the brittle and slow communication over the bridge, all communications are handled in separate threads via the Java `CompletableFuture` mechanism [9]. The `CompletableFuture` mechanism avoids blocking on the UI thread, keeping the UI responsive. However, it does mean we cannot simply set and get values from the Python side. We have thus had to develop a mechanism where the Java Model listens for the `CompletableFuture`s to complete and passes these values back up through chain of listeners to the ViewModel from the Model.

## QUALITY ASSURANCE

There are 2 forms of automated testing used to ensure the quality and behaviour of the script generator: unit testing, and system UI testing. Unit testing is carried out in Java using the JUnit framework [10] and in Python `unittest` [11] is used.

Both the JUnit and `unittest` tests are run as part of the build process, which is regularly executed on a Jenkins [12] continuous integration pipeline.

Our system UI testing is run using a separate continuous integration pipeline. These tests are written and executed with the Squish UI testing tool [13]. Squish supports a Behaviour-Driven Development (BDD) [14] approach. Tests can be laid out in the Gherkin [15] ubiquitous language. These tests reference steps that are defined as functions which carry out actions such as press buttons, fill in table cells and verify the presence and state of UI elements.

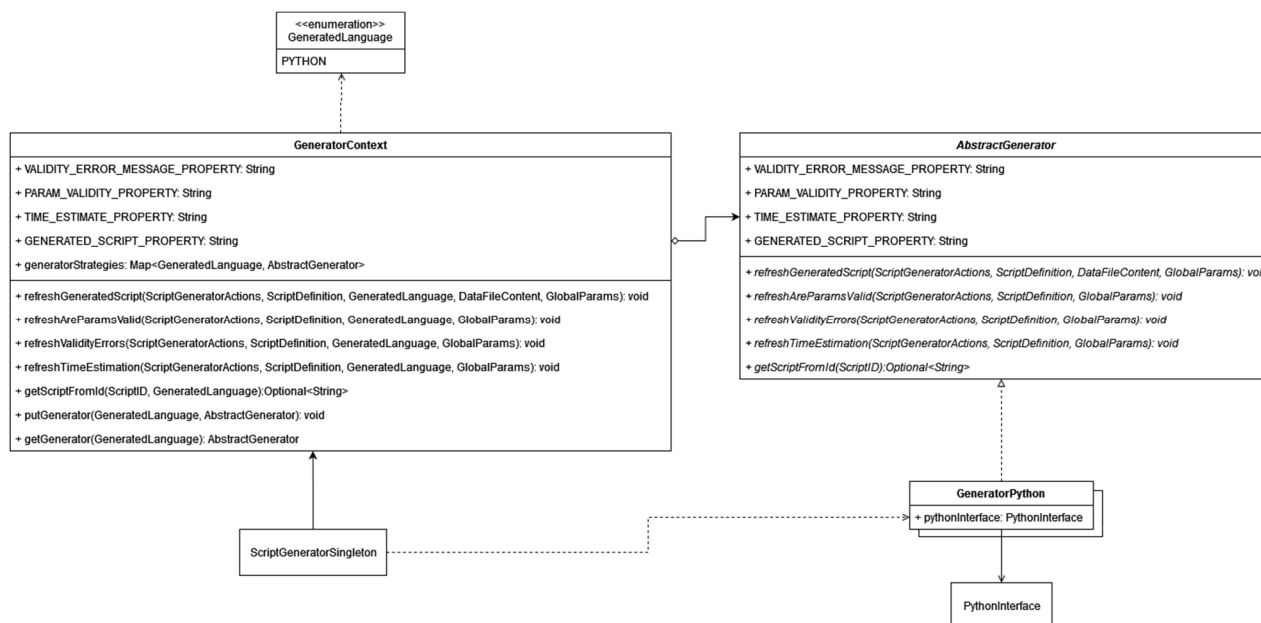

Figure 7: Strategy pattern used for generator extensibility.

We have used the Squish BDD tools [16] to describe behaviours of the script generator and verify their presence. Our suite of UI tests have caught regressions and deviations in behaviour prior to releases on multiple occasions. For example, when duplicating an action and changing the contents of one of the actions, these changes were also visible to the test on the other action revealing a shallow copy issue on the duplication mechanism.

During the release creation process we also carry out some manual system tests. These manual tests include smoke tests and tests that are difficult or impossible to automate using our current tools.

Further to testing, all code for the script generator is subject to review. These reviews help to minimise mistakes, share knowledge and techniques. Reviews also ensure consistency is practiced throughout the system, and requirements and quality standards are met. These reviews are an integral part of our quality assurance and often lead to reworks which drastically improve software quality and functionality, and the underlying code.

We run the static code analysis tool Checkstyle [17] on our Java code to identify programming flaws and enforce consistent coding standards, improving the correctness and maintainability of our codebase [18].

## FUTURE OF THE SCRIPT GENERATOR

Although the script generator can be installed on any machine [19] we are current only deploying releases to two muon instruments [20] [21], for which we have met the requirements.

We are now looking at expanding the script generator functionality to make it useful to other instruments [22]. The project is being managed as a subproject of the IBEX project and fits into the scrum methodology used for the IBEX project [23]. Scrum requires work packages to be split into manageable chunks taken from requirements.

A new requirements document is being created to cover all interested parties. These requirements are being split into milestones in order to provide a roadmap to scientists and developers. The roadmap can then be used when planning work for the project.

The requirements are also split into the following categories: dynamic scripting, estimation, generated scripts, actions and parameters, gestures, script definitions, usability and miscellaneous.

Dynamic scripting captures behaviours which interact with the script server to run and control scripts directly from the script generator. Eventually a user will be able to start, stop and pause execution of the script, edit actions whilst the script is running, and execute dry runs.

Dry runs will not interact with any hardware but use a simulated version of genie python to test scripts act as expected. The script generator will display feedback from the running script to ensure the user knows the status of their running script.

Time estimation of a script is achievable with the current script generator, but scientists would also like to be able to estimate other values. For example, muon instrument scientists want to display estimated events. This is captured in the estimation category as well as displaying an estimate of when the script would finish if run at the current time.

There is some debate as to the best method of saving and reloading parameters into the script generator. Using a second file to store the parameters is confusing to users. Work to hide or remove the second file, as well as improving the readability of generated scripts and reloading of global parameters is captured by the generated scripts category.

Currently, the script generator only accepts values in the table as strings. We plan to define types for action parameters. This will enable script definitions to configure displays such as having drop downs for enumerated types and only accepting numbers as inputs for integers. This typing system is captured in the actions and parameters category.

Also captured in this category is the ability to select different script definitions for each action in the table and creation of configurable objects. These objects are passed a bit like global parameters through the entire script but are decoupled from script definitions so can be used in different types of actions. Both the configurable objects and ability to select different script definitions for each action are inspired by another script generator currently in development at ISIS.

The gestures category captures the ability to export and import parameters to and from excel spreadsheets and looping more intelligently over actions.

We want to enable ease of development for script definitions to make the script generator a tool of choice for instrument scientists. Instrument scientists may not have experience in tools to manage code bases and so we have devised a workflow for managing them easily which is captured in the script definitions category.

The usability category defines work to improve the user experience, such as displaying more helpful errors when a script definition is invalid, improving the visibility of problems on the loading screen, and a UI review and subsequent redesign.

Finally, the miscellaneous category captures a few smaller work packets that do not fit into the categories listed previously, such as bugs to fix, some reorganising of where we store our script generator python code and reducing the size of the built script generator.

## CONCLUSION

The IBEX script generator fulfils many of the required behaviours to improve the reliability of scripting experiments and is well on the way to being a useful tool for beamlines at the ISIS Neutron and Muon Source. However, more work is required to fulfil the requirements of those beamlines and improve the usability of the script generator.

Developing the script generator has come with a number of challenges including using a bridge between Java and Python. These challenges and the object-oriented design techniques employed have helped form the software architecture of the script generator.

We utilise several quality assurance measures to give us confidence in the functionality of the script generator. Although these measures have not caught all bugs and usability issues they have caught a number of significant problems. Our iterative approach and close working with a small number of early users have allowed us to pre-emptively identify issues and refine the script generator to improve its robustness.

Development work will continue to run within the IBEX project. A renewed focus to work with a wider user base will help us to develop a roadmap to fulfil the requirements of more beamlines at ISIS and drive future work on the script generator.

# CONTROL SYSTEM UPGRADE OF THE HIGH-PRESSURE CELL FOR PRESSURE-JUMP X-RAY DIFFRACTION

R. Mercado\*, N. Griffin, S. Lay, P. Holloway and P. Roberts  
Diamond Light Source, Oxfordshire, UK

## Abstract

This paper reports on the upgrade of the control system of a sample environment used to pressurise samples to 500 MPa at temperatures between  $-20^{\circ}\text{C}$  and  $120^{\circ}\text{C}$ . The equipment can achieve millisecond pressure jumps for use in X-ray scattering experiments. It has been routinely available in beamline I22 at Diamond. The millisecond pressure-jump capability is unique. Example applications were the demonstration of pressure-induced formation of super crystals from PEGylated gold nano-particles and the study of controlled assembly and disassembly of nano-scale protein cages.

The project goal was to migrate the control system for improved integration to EPICS and the GDA data acquisition software. The original control system was based on National Instruments hardware controlled from LabView. The project looked at mapping the old control system hardware to alternatives in use at Diamond and migrating the control software. The paper discusses the choice of equipment used for ADC acquisition and equipment protection, using Omron PLCs and Beckhoff EtherCAT modules, a custom jump-trigger circuit, the calibration of the system and the next steps for testing the system.

## INTRODUCTION

Beamline I22 and Imperial College London built and developed a sample environment [1] used to pressurise samples for diffraction experiments. This end-station equipment has been available for several years [2].

This end-station was built using a control system based on Compact DAQ measurement and control modules (National Instruments). Its associated control was realised by the collaborators using LabView.

An initial attempt was made to integrate with EPICS but the integration was not maintained, due to LabView not being an actively supported platform for the controls group at Diamond. User feedback indicated that direct control from GDA and EPICS would make operations less prone to user error.

## SYSTEM DESCRIPTION

The high pressure cell has these components (as shown in Fig. 1):

- Pressure generator. This is a motor driven high pressure pump which can generate pressures up to 700 MPa. The drive motor is a high power DC servo operated with a custom built motor controller.

\* ronaldo.mercado@diamond.ac.uk

Figure 1: Detail of the pressure cell [1].

- Two remotely operated, normally closed pressure valves.
- Two remotely operated, normally open fast pressure jump valves.
- Three pressure transducers monitoring three sections of the pressure network. The sensors are 700 MPa strain gauge based transducers excited with 10 V and reading 10 mV at full scale.

The pressure network comprises three sections:

- the first section with the pressure generator,
- the second that includes an optional additional tank that can be used particularly for pressure jumps and
- the third section where the pressure cell is installed.

The control system opens and closes valves, allows the syringe pump motor to pressurise and de-pressurise the pressure network.

The pressure network has to be protected from overpressure. Valve operations are inhibited if the pressure differential is larger than 5 MPa (50 bar) between sections, with the exception of pressure jumps.

There are two jump valves, one dedicated to jumps up in pressure and another for jumps down in pressure.

## HARDWARE USED IN THE UPGRADE

Diamond standardises on electronics hardware (as shown in Table 1) where possible [3, 4]. A benefit to the facility is the maintainability and support by standardising on a limited set of components.

The majority of the digital I/O signals for the system can be mapped one to one as they are standard and are based

Table 1: Hardware Module Types and Replacements

Function	Original module	Replacement

Figure 2: Electronics cabinet of the upgraded control system.

on 24 V on/off, a PT100 temperature sensor and analogue 0-10 V I/O.

Reading the strain gauge is a more specialised operation that originally used the NI-9237 module. A strain gauge amplifier was selected based on prior experience: the RDP Electronics (Wolverhampton, UK) DR7DC. The amplifier converts the millivolt strain gauge signal to the usual control range of 0-10 V. The signal is read by ADCs in parallel.

The most recent standard set of components (as shown in Fig. 2) includes a strain gauge EtherCAT module (Beckhoff EL3356), but its acquisition speed was not adequate to capture a pressure jump.

The PLC system controls the system protection, arms the pressure jumps and controls the motor for the pressure generation. The supervisory control uses EPICS. The fast EtherCAT ADC signals are captured using the ADEthercat area detector plug-in described below.

One important requirement was the desire to acquire the pressure signal during the pressure jump. An in-house electronics module was created to trigger a pressure jump on a hardware trigger signal from the beamline acquisition system. This replaced the NI-9401 high speed digital I/O mod-

ule. The design was based around an inexpensive flip flop and current driver that opens a valve for a pressure jump using a TTL signal in order to synchronise with the image acquisition with the x-ray detectors. For a pressure jump acquisition the valve is “armed” so that it opens on the trigger.

During early testing the simplistic electronic design turned out to be vulnerable to noise when operating real solenoids. It took careful diagnosing and re-work of the circuit to improve the pressure jump circuit noise immunity by adding filters.

Other difficulty was signal noise from the transducers. The solution was to modify the cabling between the transducers and the strain gauge amplifiers with improved shielding and grounding.

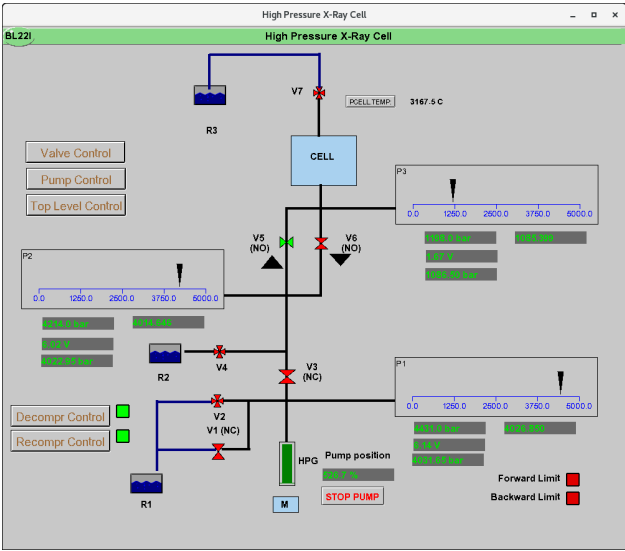

Figure 3: Top level EPICS control screen showing the pressure network.

ADETHERCAT

The pressure signals are captured at 10 kHz using the DLS EtherCAT EPICS scanner (as shown in Fig. 3). The

ADethercat area detector plug-in was used to capture the signal. ADetherCAT is a variety of driver to read ADC to area detector. It was inspired by prior experience with the D-TACQ ADC (Glasgow, UK) and beam position monitor devices (e.g. quadEM [5]) that use the EPICS area detector framework to operate on 1-D signals. ADethercat converts ADC signals from the EtherCAT master used in the Diamond ethercat EPICS driver [6] to 'image' frames. The two dimensions of the 'image' are the number of signals and 'n' samples. For the pressure cell application there are four signals captured, three for the pressures in the network and a fourth signal of the trigger value.

An immediate benefit was the ability to use a software plug-in 'NDReframe' that allows triggering on a 1-D signal as it is streamed. This solves a limitation of EtherCAT hardware that does not otherwise provide a method of triggering for data capture. The framework also adds for free the ability to write the signal to HDF5 files, which are the standard for data acquisition.

A custom pressure scaling plug-in was developed that applies the calibration method described below (Fig. 4).

Figure 4: Plot of example pressure jump. Optimized fast valve achieves jump time of approx. 5 ms. The traces shown are the trigger (red) and pressure measurement (blue). The data capture uses the ADethercat driver. The data scaled using a custom scaling plug-in and written to an HDF5 file using the area detector file writer plug-in.

## AUTOMATED OPERATIONS

There is a mode of operation implemented at the PLC level to achieve a target pressure or a target position. It was implemented at the PLC level because it allows closer control at shorter cycle times than the supervisory control in EPICS.

There are modes of operation of higher abstraction that are implemented using a python soft IOC [7]. The operations allow setting up a pressure and setting a pressure jump.

The volume and stroke of the pressure generator are not large enough to achieve an arbitrary pressure in a single operation. Two examples are that to reach certain higher

pressures the network needs to be refilled and to reach lower pressures sometimes water needs to be removed from the pressure network.

The logic allows the composition of sequences of operations to liberate the user from potentially tedious operations of pressurising the network to reach high pressures. This is more important when using the expansion tank option in the middle section of the pressure network. In tests a filling in operation needed to follow the steps to fill in and pressurise in steps for about 10 minutes with several dozen operations.

## CALIBRATION

A significant hurdle to realising the project was also the calibration of the pressure signals. Calibration facilities use a calibration rig where a special oil is pressurised with known weights to reach high pressures. It was not practical or possible to operate the equipment with its full upgraded electronics read-out next to the calibrator.

Instead of this, the beamline obtained calibration certificates from ASCO Instruments (Châteaufort, France). The calibration points were linearised based on the eleven data pairs of pressure vs strain gauge voltage obtained at the calibration facility. To calibrate the electronics, the millivolt signals were input to the electronics components using a precision millivolt source (Time Electronics 1006 DC Millivolt Source Model 404S).

At lower pressures, below 50 MPa (500 bar), the calibration was changed to reflect that when opening the valves to atmospheric pressure the linearised calibration did not read zero as expected.

The result is a custom scaling mode where there are two linearisations above and below the 50 MPa threshold. This was reflected in a custom area detector pressure scaling plug-in prepared for the pressure cell and also in the PLC software.

The use of ADCs reading the amplifier signal in parallel for fast ADC capture and machine protection resulted in different voltage readings by a few millivolts after amplification. A calibration correction was adopted to account for this discrepancy that was attributed to impedance mismatch of the ADCs [8, 9].

## CURRENT STATUS AND IDEAS FOR IMPROVEMENT

The system is being tested in an off-line laboratory and integration with the beamline will follow.

The project was conceived nearly five years ago. More recently it has become possible for Omron PLCs to also support EtherCAT modules that can capture ADC signals at 100 kHz. Using a higher speed CPU and the NX range of PLCs it should be possible to get the required ADC acquisition speed. The missing component is a software layer to 'stream' the ADC waveforms to area detector. This would be a welcome improvement over the current state in which limited developer effort is available to support adding more module types using the Diamond ethercat EPICS driver.

The use of a single ADC instead of two sets of ADCs reading in parallel would also simplify the calibration.

## ACKNOWLEDGEMENTS

Thanks to Nick Brooks for helpful guidance and discussion. Also thanks to Andy Smith for the support setting up the equipment and for obtaining the sensor calibration. We would like to thank colleagues who have contributed to the project in the past and have since left Diamond: John Emmins, Chris Roper (Engineering) and Brian Willis (Detector Group).

Integrated Computer Control System, National Ignition Facility, Computational Engineering  
Division, Lawrence Livermore National Laboratory, Livermore, CA 94551, USA

## Abstract

Characterizing plasmas generated in the world's largest and most energetic laser facility, the National Ignition Facility (NIF), is an important capability for experimentalists working to achieve fusion ignition in a laboratory setting. The optical Thomson scattering (OTS) laser has been developed to understand the target implosion physics, especially for under-dense plasma conditions. A 5w probe beams can be set up for diagnosing various plasma densities. Just as the NIF laser with 192 laser beams are precisely aligned, the OTS system also requires precision alignment using a series of automated closed loop control steps. CCD images from the OTS laser (OTSL) beams are analyzed using a suite of image processing algorithms. The algorithms provide beam position measurements that are used to control motorized mirrors that steer beams to their defined desired location. In this paper, several alignment algorithms will be discussed with details on how they utilize various types of fiducials such as diffraction rings, contrasting squares and circles, octagons and very faint 5w laser beams.

## INTRODUCTION

The National Ignition Facility (NIF) has made tremendous progress in our understanding of inertial confinement fusion [1]. Recent breakthroughs in fusion performance have attracted worldwide attention to NIF. In NIF, 192 precisely aligned laser beams [2] are designed to irradiate a mm scale fusion target to achieve ignition and produce a net energy gain in a laboratory setting. To achieve this goal, NIF employs several tools to diagnose the plasma condition. The optical Thomson scattering (OTS) laser [3] is such a tool which can deliver a 1 Joule, 5 $\omega$  (211 nm) probe beam with a 1 ns flat-in-time pulse-shape, for diagnosing the plasma temperature at a user-specified time during the plasma evolution in a NIF experiment.

Experiments on NIF can be designed to utilize all 192 or any subset of laser beams. In every case, accurate beam alignment is essential. Beam positions are monitored in the NIF facility using hundreds of CCD cameras distributed throughout each of the 192 beams path. Feedback control loops form the main engine for the NIF automated alignment control system [2]. Position estimates are generated by image analysis algorithms, which are used to align motorized mirror pairs and other optics to direct NIF beams to their desired locations. Starting from the beam source, or Master oscillator, these alignment loops are responsible for

aligning the beams along the complete beam path and finally to the mm size targets located in the target chamber center. In this paper, we will discuss several alignment loops in the OTS laser.

## OTSL ALIGNMENT

A total of eight mirror pairs are closed-loop controlled using more than 14 distinct alignment loops to complete the full alignment of the OTS laser. These alignment points are divided into five main sections as shown in Fig. 1. Starting from the pre-amplifier module (PAM) and through the intermediate amplifier, the beam is taken to the Final Optics Assembly (FOA) via an imaging transport telescope section. The FOA contains frequency conversion crystals to convert the beam to the fifth harmonic and motorized, 5 $\omega$  high-reflecting mirrors to point it to the diagnostic load package (DLP) located in the NIF Target Chamber. Obtaining good OTS data requires precisely overlapping the plasma volume illuminated by the fifth-harmonic probe laser and the plasma-volume imaged by the DLP OTS spectrometer.

The transport vacuum relay telescope (VRT) is used to deliver the conjugate-image of the regen apodization-aperture to the plane of the fifth-harmonic generating crystal; the associated alignment mirror pair ensures the fundamental beam is correctly pointed and centered to the FOA converter line-of-sight for optimum harmonic conversion. Two of the alignment loops discussed here align the ISP laser to the transport telescope input aperture (ISP\_TTI\_PL loop) and the second one aligns the output of the transport telescope to the input of the FOA (OTS\_TTO\_FOA\_PL). Alignment images for both loops are acquired with the same far-field (FF) alignment camera in the FOA but alignment is completed for each loop using different reference fiducials. Specifically, the physical alignment reference for the OTS\_ISP\_TTI\_PL loop is a pair of precision tooling spheres (pinheads) installed in the output optical aperture of the VRT whereas the OTS\_TTO\_FOA\_PL loop is referenced to a commissioned pixel on the FOA FF alignment camera.

2-D and 3-D images for the OTS\_TTO\_FOA\_PL pointing loop are shown in Figure 2. The beam has a dragonfly-shaped appearance with a distinct head and a tail. The coma-like aberrations seen in this image is caused by diffraction since the alignment beam over-fills the aperture of the intermediate amplifier rod and clips on its edge. The alignment feature for this image is the center of the head of the dragonfly-shaped beam. It was determined that a

centroid based algorithm [4] position detection scheme can accurately detect this feature, enabling the VRT output mirrors to be repeatably aligned. The higher brightness of the

head compared to the tail, allows a high-threshold background subtraction-based centroiding, to detect the center of the head of the dragonfly.

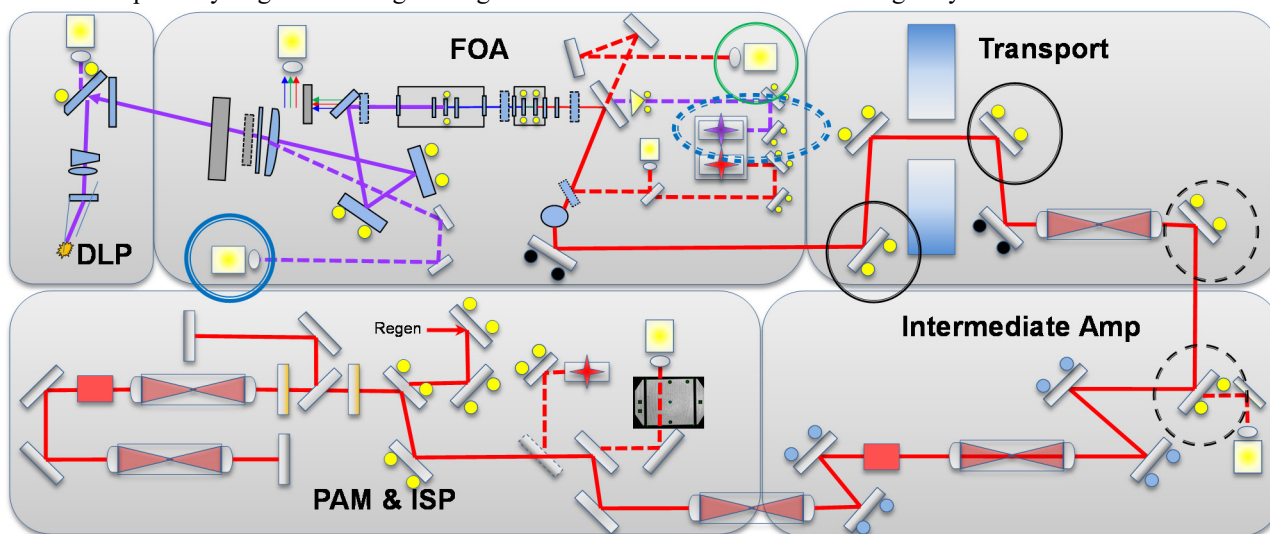

Figure 1: Alignment loops within the OTSL cover 5 sections starting from the Pre-amplifier module (PAM) and Input sensor package (ISP) through the final optics assembly (FOA) which converts the beam to the fifth harmonic and points it to the diagnostic load package (DLP). The mirror-pairs used for the OTS\_IST\_TTI\_PL are circled with dashed black rings whereas the those used for the OTS\_TTO\_FOA\_PL are solid black rings. Both loops align to the same camera in the FOA circled with a green ring.

Performance of the centroid approach was tested for more than a year and was found to be satisfactory [4]. However, if there is a beam deflection with a magnitude similar to the central spot and period on the order of the image integration time, then the consequent smearing makes the centroid-approach unstable. Consider the cases of motion blur in image 59 and 229 in figure 2, where the position is shifted as the peak is shifted. Comparing the two consecutive images 58 and 59, image 58 shows a single peak with maximum at the head location. The 3-D plot of image 59 shows lowering of the intensity of the head and elevation of the first side lobe of the tail indicative of image smearing. Other images exhibit smearing and displacement in the vertical direction, where multiple heads as well as two tails are visible, as shown in image 91 of Fig. 3.

Figure 2: A typical OTSL camera image of OTS\_TTO\_FOA\_PL loop, where OTS is the OTS laser, TTO indicates transport telescope output, (FOA --final optics assembly. PL -- pointing loop). Smearing of images causes a 19 pixel shift in centroid. The surface plot of images 58 and 59 shows the shift of the location of the maximum from the head to the tail.

This weakness in the centroid algorithm prompts us to develop an alternate algorithm.

### Alternate Algorithm to Mitigate Smearing

Matched filtering is well known for its ability to track an object in a complex scene. The dragonfly shape of the OTSL pointing beam makes it a good candidate for using pattern recognition tools based on matched filtering. NIF uses matched filtering techniques [5] to provide robustness and position stability in the presence of illumination gradients, time varying signals, and unpredictable background noise. In comparison, centroid based techniques are affected by all these variables.

To test this approach, we randomly chose a nominal image as a template. Applying the same template to images 59 and 229 resulted in consistent position estimates as shown in Fig. 3. The centroid technique does not produce such a result, as observed above.

Figure 3: The result of matched filtering on the smeared image shows a sensible result.

### Template Selection

When a beam is aligned, the beam may appear initially in any location within the image. To test possible variations, beam image was the shifted from the nominally aligned

position in four directions (left, right, up and down). 100 images were captured in each position. For comparison purposes, we apply the weighted-centroid approach to the sets of images in the nominally aligned position. The result

Figure 4: For a 100-image-set of an aligned beam, the scatter plot on the left is generated by the centroid approach where 99% of the spots are within a 7-pixel radius. The scatter plot on the right is generated with a template (image65). The 99% encompassing radius is reduced to a tight cluster with a span of 0.3 pixels.

Variations in intensity within the head of the dragonfly image, from image to image, produces variations in the centroid based beam position estimate.

Moving the position of the beam can cause the shape to change. However, in practice, the measurement will be for a consistent spot when it is in the fixed aligned position, for that reason the align65 template was deployed. Next, we look at the second OTSL alignment loop.

## ALIGNING DIFFRACTION RING

Alignment fiducials in the beam image are often used to help locate the beam or reference position. One of the OTSL alignment loops, ISP\_TTI\_PL, uses out of focus imaging of a spherical object connected to a shaft as a fiducial. These fiducials are positioned at the edge of the optical aperture of the circularly formatted alignment laser beam. The alignment camera is focused to image the NF relay plane which is about 40 meters away from the pointing reference fiducials. The beam leading to a clipped diffraction pattern. The out-of-focus imaging produces a pair of diffraction rings at the top and bottom of the alignment image as shown in Figure 5. Both rings are present with partially missing portion. The objective of this alignment algorithm is to detect the center of the diffraction rings under various imaging conditions.

Figure 5: (a) A typical OTSL camera image ISP\_TTI\_PL loop, where ISP is the ISP laser, TTI indicates transport telescope input, and PL stands for pointing loop. Every beam is aligned using a pointing and centering move (b) The diffraction rings may appear in the top and bottom, note that the left ring was moved to the top.

## Algorithm

The diffraction rings intensity levels are very similar to the background making a threshold-based approach centroid approach not possible for meeting alignment requirements. Since the diffraction ring has a distinct pattern however, pattern recognition techniques based on matched filtering [5] is a viable option. As a first approximation, the template is considered to be a circular ring, with a fraction missing to resemble the missing part of the diffraction as shown in Fig. 6. The parameters inner radius,  $r_{est\_left}$ , ring thickness,  $\delta$ , percentage of the ring missing from one side, missing fraction defines the template. If missing fraction is 50% then half of the ring is missing.

Figure 6: The template showing 4 parameters defining it: estimated radius for left ( $R_{est\_left}$ ), radius of inner spot ( $\gamma$ ), width of the ring ( $\delta$ ) and missing fraction (left fraction). The new template design instead of a full circular ring use half circle with linear extension (on the right).

To avoid spurious correlation peaks, two rings are initially segmented using the angular location from a global centroid [6]. During alignment, the missing fraction for both rings changes. It was found that if the missing fraction of both rings remained same, the template in Fig. 6 performed well, however, as the image moved in four directions the template was unable to detect the center accurately. To correct an incorrect position using angular position and distance, one must be certain which of the two position is correct.

### Certainty Detector

As inspired by a bipolar binary associative memory [7] single computational neuron, is used to evaluate the quality of the location detected. The function of the neuron is to generate a high score when there is a match of the stored pattern with the input pattern and a low score when there is no match. Here the stored pattern is the cross-section of the template in bipolar binary. When the position is correct, high score of above 80 is obtained. For a totally incorrect position, the score is highly negative. These scores are used to generate the uncertainty of the position as well as correct an incorrect position.

### Template Design II

A simulation of the Nfiducial diffraction pattern reveals that the ideal diffraction pattern may not actually contain a complete circular ring, rather it is partially circular and partly linear. Therefore, the template was redesigned as depicted in the right side of Fig. 6, where a half circular ring is extended by the straight edge of the template in a linear fashion up to an extent defined by the missing fraction. The weight of the linear extension was 50% compared to the weight of the right half, to reduce the effect of the high intensity near the edges which has biased the previous centering position.

### Optimization

During alignment, the rings do move relative to the large disc, and as such the rings appear with different missing fraction as shown in Fig. 7. To capture the possible variations of the alignment images, the nominally aligned position image (used in Phase I) was moved in four directions

to the left, right, up, and down and 100 images were captured in each position. One image from the set is shown in Fig. 7.

To choose the optimized parameters defining the template, the position detection program is executed in a loop with varying four parameters: inner radius, width of the ring, radius of the inner disc, and missing fraction on single image for both left and right rings in the aligned set of 100 images. Solution which gives minimum divergence of each position in terms of standard deviation is chosen after visual verification. Then process of stability check is then applied to the remaining 400 image sets at all the other positions above. After that the solution is applied to a data set taken from the images archived in the NIF for the previous 6 months. Using this data set, a variety of templates was applied until a solution was found that worked robustly on the entire set of NIF images.

Figure 7: The variation of the diffraction rings as it moves left right and up and down with respect to the aligned position.

Figure 8 shows the difference between templates I and II design. The left results show, the phase I template introduce bias in the lower position. In phase II, the result is improved significantly with lower incidence of bias towards any specific direction as shown in the right onset.

Figure 8: The variation of the diffraction rings as it moves left right and up and down with respect to the aligned position.

The optimized parameters are, top template radius = 77, width = 48, missing fraction = 0.3 and gamma = 12 and the bottom template radius = 73 width = 45, missing fraction = 0.6 and gamma = 12. After position estimation, the missing fraction is re-calculated. If the supplied missing fraction was very different from the re-estimation of the same, and it also had a negative score, only then was the algorithm allowed to recalculate the predicted second spot. Most of the time, the new missing fraction calculated online was used to stop predicting the second spot and avoid oscillation, which could make the alignment in a closed loop very difficult. Correlation-based approaches must be guarded against spurious detection. After the two rings are located, the position data obtained is subjected to several spacing tests. Such spacing tests with certain tolerance help us to eliminate spurious spots from the solution.

Next, we look at an alignment loop algorithm for centering the OTSL 5w laser.

## OTSL SQUARE BEAM ALIGNMENT

One of the more challenging image processing loops in OTSL is the AA\_OTSL\_PILOT\_CL loop. The image processing algorithm for this loop uses multiple, superimposed image features to locate the beam reference and the beam center to enable proper laser alignment. The features consist of parallel opposing beam edges (reference location) and parallel opposing lines or dark bands (beam location) to estimate the 5w beam centering offsets. The images for this loop tend to have high noise within the image as well as near desired beam edge features. In addition, image illumination is often poor and can have undesired gradients near the beam edges. A typical image example is shown in Fig. 9.

Figure 9: A typical OTSL 5w camera image for the AA\_OTSL\_PILOT\_CL loop (left). The Crosshairs algorithm is used to determine the left and right parallel opposing edges as well as the top and bottom parallel opposing lines or dark bands in the image. The center of the line and edge positions are returned as the beam and reference center locations. The output mask of the adaptive beam location algorithm is shown on the right.

The beam edges and reference lines are found initially using the adaptive beam location algorithm and then further refined with the crosshairs algorithm. The crosshairs algorithm has been used with great success in many loops in the NIF automated alignment control system [8-10]. Crosshairs has proven to be tolerant to object rotations, noise, changes in illumination and target object properties such as line thickness.

All images initially undergo a process to quickly identify unacceptable or 'off-normal' images. The off-normal processor is an image analysis routine that contains a suite of selectable tests each of which analyze the image and classify it as a good or bad image. The tests are limited to basic or common image errors such as an image that is unacceptably dim or blank, missing the beam, all-white, etc.

## Adaptive Beam Estimator Algorithm

After successful off-normal processing, an initial beam location estimate mask is found with the adaptive beam location algorithm. This algorithm employs an iterative intensity level process to create an optimize mask for the desired image object(s) [11]. To begin, the image is filtered with a non-linear edge preserving filter[12]. All objects at each intensity level are identified and tested for a set of criteria, for example: size, ranging, signal to noise of objects found, and object location in the image.

The resulting mask created is seen in Fig. 9. The edges of the mask are used to identify the initial, general locations of the beam and reference features. The edges are used to identify sub-image areas to locate initial reference lines or beam edge locations. Sub-image boundaries can be seen outlined in green in the lower right plot in Fig. 10.

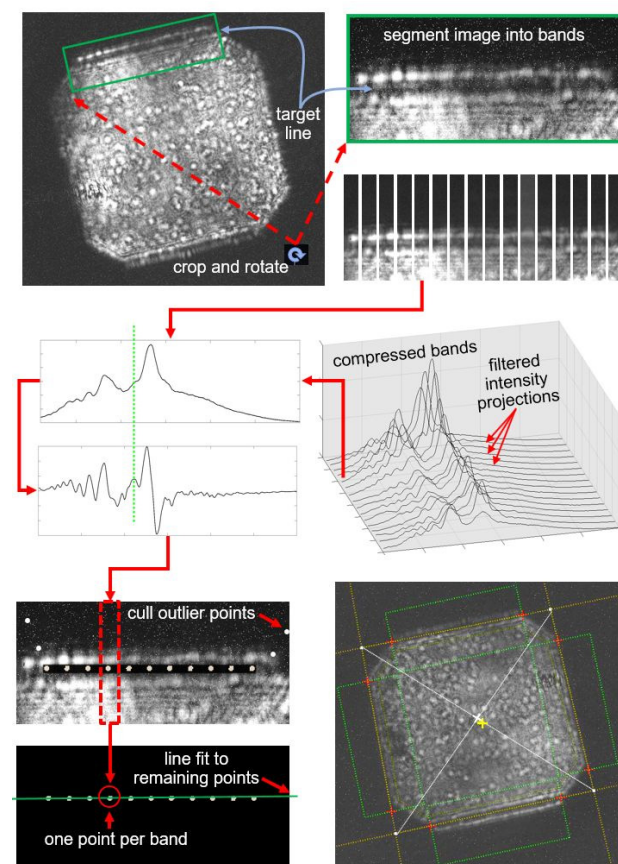

Figure 10: Crosshairs is executed by first rotating the sub-image to orient the target line or edge (top). The image is then segmented into orthogonal slices or 'detection bands' (lower top right). The bands are transformed into a set of intensity vectors by calculating the mean projection for each band (middle). The intensity vectors are then

processed and filtered individually to identify the edge or line center location for that band (middle left). This results in a set of points, one point per band (bottom left). A series of tests on the resulting set of points is performed to remove outliers. Finally, a least squares linear fit of the remaining points is used to determine the optimal target feature fit (green lines). Final beam location is seen as the yellow + and the reference as the white x and are used to guide beam alignment.

### Crosshairs Algorithm

Resulting edge and line locations are then processed and refined with the crosshairs algorithm. A diagram of an example of the complete crosshairs process is illustrated in Fig. 10. Crosshairs is executed by first rotating the sub-image to orient the target line or edge. The image is then segmented into orthogonal slices or 'detection bands'. The bands are transformed into a set of intensity vectors by calculating the mean projection for each band. The intensity vectors are then processed and filtered individually to identify the edge or line center location for that band. This results in a set of points, one point per band. A series of tests on the resulting set of points is performed to remove outliers. Finally, a least squares linear fit of the remaining points is used to determine the optimal target feature fit. Uncertainty for any given line estimate is calculated and reported using the mean deviation of the points used in the line fit. The uncertainty is used to abort the alignment if the deviation does not meet the loop requirements. Final beam and reference locations can be seen in Fig. 10 as the yellow + and the reference as the white x and are used to guide beam alignment. Optics adjustments are made until they are co-located and thus alignment for the AA\_OTSL\_PILOT\_CL loop is complete.

### CONCLUSION

This paper describes the image processing associated with several OTSL alignment loops. In the first two examples, template-based matched-filtering approach was utilized. The last algorithm uses an adaptive beam location algorithm and then is further refined with the crosshairs algorithm.

# A FRAMEWORK FOR HIGH LEVEL MACHINE AUTOMATION BASED ON BEHAVIOR TREES

G. Gaio†, P. Cinquegrana, S. Krecic, G. Scalamera, G. Strangolino, F. Tripaldi, M. Trovò, L. Zambon, Elettra-Sincrotrone Trieste S.C.p.A., Trieste, Italy

## Abstract

In order to carry out complex tasks on particle accelerators, physicists and operators need to know the correct sequence of actions usually performed through a large number of graphical panels. The automation logics often embedded in the GUIs prevents its reuse by other programs, thus limiting the level of automation a control system can achieve. In order to overcome this limit, we have introduced a new automation framework for shifting the logics from GUIs to server side, where simple tasks can be easily organized, inspected and stacked up to build more complex actions. This tool is based on Behavior Trees (BT) which has been recently adopted in the gaming industry for in-game AI player opponents. They are able to create very complex tasks composed by simple decoupled self-contained tasks (nodes), regardless how they are implemented. The automation framework has been deployed in the Tango-based control systems of Elettra and FERMI to implement autonomous operations. A dedicated Qt GUI and a web interface allow to inspect the BTs and dynamically go through a tree, visualize the dependencies, monitor the execution and display any running action.

## INTRODUCTION

In Elettra and FERMI, a synchrotron light source and a free electron laser located in Italy, it is usual for control room operators or physicists to manually perform long sequences of operations to configure the accelerators in the desired state. These procedures are prone to errors and heavily dependent on the skills of the operators. Over time, many institutes have developed frameworks to automate these lengthy procedures [1,2,3,4]. Therefore, the framework we are going to present in this article is not an absolute novelty.

To be successful a framework must be easy to use, robust and adopted by as many people as possible. These concepts were the basis for the development of this new framework. The originality lies in inheriting the modularity, flexibility and robustness of the Behavior Trees (BT).

## Behavior Trees

BTs are very efficient in modelling what an Artificial Intelligence (AI) algorithm can do. They allow designers to define very low-level tasks and combine them to create the set of high-level tasks that the developer wants available to the AI application.

The Behavior Tree is a directed rooted node tree where the internal nodes are called “control flow nodes” and leaf nodes are called “execution nodes” (see Fig. 1). Briefly, the execution flow starts from a root node and go through the tree down to the leaves. The main control flow node is the *sequence node* that can run in parallel or in series to other *sequence nodes* or *action nodes*. An *action node* executes a task and returns to its parent a *success*, *running* or *failure* state. The *sequence node* returns *success* to its own parent if all its children return *success*. The *sequence node* can be configured as *fallback node* to return *success* when at least one of its children return *success*. A *condition node* returns *success* or *failure* depending on the evaluating condition. A *decorator node* can invert a *failure* state into *success* and vice-versa.

There is no canonical implementation of BTs. They are very flexible and suitable to be customized for any application, whether it is an AI algorithm in a computer game [5] or in an Unmanned Aerial Vehicle [6].

Each node executes an instruction after receiving a tick from its parent. In our implementation this aspect has been neglected. The *Action node* start to executes the task at the first tick and completes procedure detached from any external timing signal.

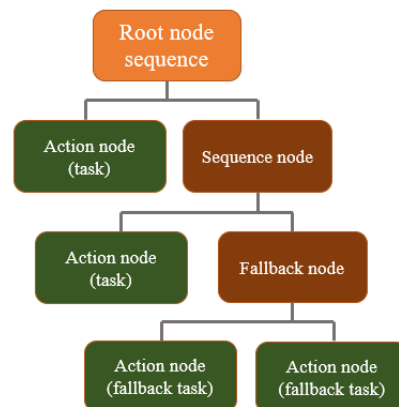

Figure 1: Example of Behavior Tree structure.

## THE SEQUENCER

A sequencer (corresponding to a node of the BT) is a Tango device. The core of the sequencer is the sequence which is written in a basic homemade language that has to implement the operations that are performed manually by operators. The language implements macros containing *if/else* conditions and *read/set* instructions, and support basic arithmetic and bitwise operations.

† email: giulio.gaio@elettra.eu

The sequence is stored in the sequencer Tango device property or in a text file (see Fig.2). The loading of the sequence is carried out during the Tango device initialization. After that, the sequencer device executes the sequence immediately or when a *start* command is received.

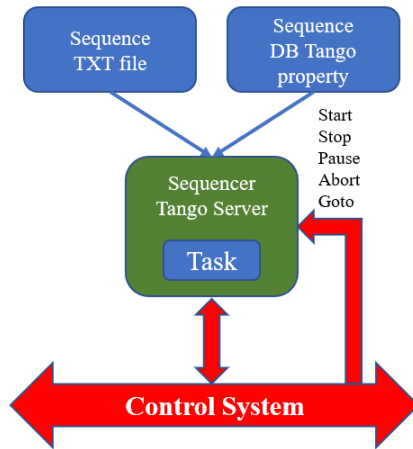

Figure 2: Sequencer device architecture.

The Tango server executes the sequence instructions (commands and read/write attributes) row by row. Each row is identified by a step number (see Fig. 3). For each step a mandatory *goto* statement specifies the next step to execute. The sequence ends after evaluating the last step or can last forever.

The sequencer states are:

- OFF: sequencer is not running (success state)
- RUNNING: sequencer is executing the sequence code
- FAULT: sequencer has terminated due to an exception
- WARNING: sequence parsing error
- STANDBY: the sequence is paused

### Internal Variables

The sequence can instantiate internal variables (ex: a loop counter, a threshold, ...) which are dynamically mapped into read/write attributes. For simplicity the attribute types are *bool*, *int32*, *int64* and *double*, and can support vectors and images.

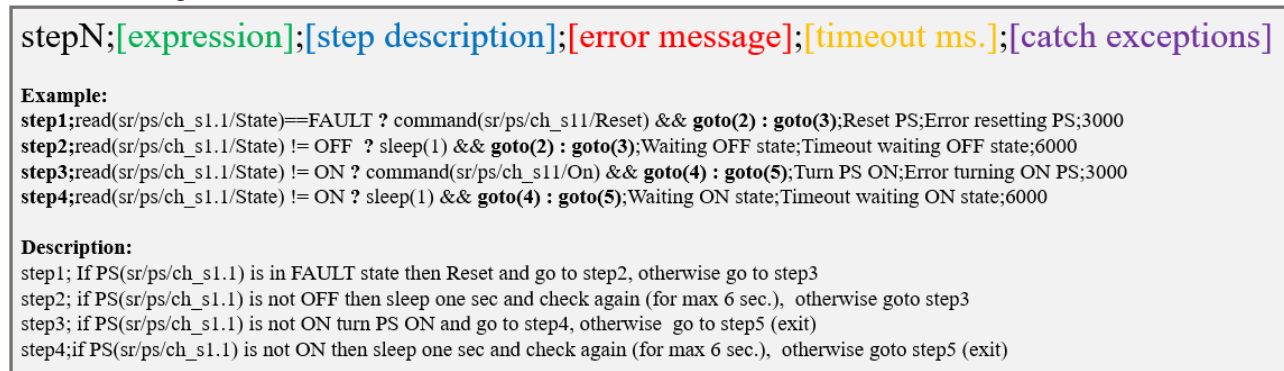

Figure 3: Description of the sequencer scripting language. Each code line is composed at least by 5 fields: step index, logical expression, step description, error message and timeout. The catch exception field is optional. The if/else statement is implemented with the ternary conditional operator (? :).

### Stop Conditions and Exceptions

The sequence stops after receiving an *abort* or *stop* command. While the *abort* command halts the sequence immediately, the *stop* command lets the sequence terminate the running step. In both cases the sequence ends in OFF state, which means *success*.

The sequence can be paused upon receipt of the *pause* command or can execute a single step specified in the *goto* command.

The instruction *goto(-1)* generates an internal exception that stops the sequence in FAULT state. The *goto(N+1)* instruction, where N is the last step number, terminates the sequence in OFF state.

There are four types of exceptions.

- *syntax exception*: it occurs during the sequence loading process in case of a syntax error. The sequencer state turns into ALARM and it cannot be restarted. The status attribute returns the part of the sequence containing the syntax error.
- *global timeout exception*: the sequence execution time takes more than the global timeout; the sequence ends and the device state is set to FAULT.
- *step timeout exception*: the step execution time takes more than its timeout; the sequence stops and the Tango device state changes to FAULT.
- *Tango exception*: when a Tango exception occurs in a command or read/write attribute, the sequence is immediately stopped and the sequence state is set to FAULT. Tango exceptions can be ignored; in this case all *if/else* statements involving Tango read attributes are evaluated as true.

Tango and step timeout exceptions can be caught and the execution flow redirected to a specific step. Similarly, the *Stop* command can be intercepted by the sequencer engine that, instead of ending the sequence, jumps to a predefined “exit” step.

The sequencer can be configured to have its error recognized by the operator. In this case the sequencer requires an *acknowledge* command before receiving a new *start* command.

## Logging

The sequencer device implements data logging on two levels:

- *high resolution buffer*: a circular buffer of 10000 entries records every instruction executed inside the sequence, any value read or set, and any error or conditional jump with microsecond resolution. It is mostly used by developers during the sequence debugging and, in the near future, analysed by software bots for malfunction prediction.
- *Long-term buffer*: in order to record any modification on machine parameters, each sequencer can store all executed Tango commands and written attributes in a circular buffer of 100000 entries.

The description and error messages encoded in each sequence step are also stored in the long-term buffer.

Currently both buffers are reset after device reinitialization.

## Additional Info

In the header of the sequence code it is possible to specify a description of the sequence, the author and the release date.

The sequence device returns the last execution time, the elapsed time from the start, the remaining time till the global timeout and, in case of exception, the last faulty step. Moreover, during sequence execution, the description of the running step is pushed by the sequencer to any event subscriber.

In order to trace dependency between sequence devices, each device returns separately the list of the sequence devices and the list of other Tango devices to which it is connected. This information is useful for monitoring, at a higher (client) level, that the BT respects a Directed Acyclic Graphs (DAG) structure. In fact, no loops are allowed between parent nodes (ex: the root node) and the child nodes.

## Templates

In order reuse the same sequence, the concept of template has been introduced. After loading the template from file and before checking its syntax, the Tango sequencer engine replaces keywords with the strings specified in a device property called *wildcards*. The replacing strings are usually Tango device names or constant values.

About fifty templates are available for sequencer developers. Some of them execute specific tasks (ex. recovering a faulty plant), other implement BT flow control, generic algorithms as scans/ramps, basic optimization algorithms (Extremum Seeking, Golden Search) or save/restore procedures. The most used template is the *launcher*. It is the main building block of the BT as it implements both a sequencer and fallback node.

The *launcher* can start up to 64 sub-sequences. Through the use of bit-masks (r/w attributes) it can select groups of sub-sequences:

- to be launched in series and/or parallel.

- to be restarted after a fault for a maximum number of times.
- to be ignored if producing errors and continue in launching the remaining sub-sequences.
- to be stopped at the first fault and abort the launch of the remaining sub-sequences.

Furthermore, a per sequence boolean attribute enables/disable its execution at runtime.

After all sub-sequences have been executed successfully, the *launcher* stops in OFF (or FAULT in case of errors) and its state is acquired by the parent node. When a *launcher* is going to terminate in FAULT state, it is possible to execute, as the last running sequence, a rollback sub-sequence.

Sometimes it is useful to stop, pause or abort the execution of an entire BT. In order to do so, the *launcher* sequencer, if explicitly enabled, can propagate all received commands directly to all child nodes.

## Naming and Database Configuration

In the Tango database the naming of the sequences follows the rule:

*seq/[action]/[detailed\_description]\_[where]*

As example, the naming of a sequence which performs the power-cycling and communication recovery with a CCD in the Elettra booster is:

*seq/reset/ccd\_b1.1*

Similarly, the sequence calculating the global orbit feedback response matrix in the storage ring is:

*seq/calc/gof\_rm\_sr*

A global free property in the Tango database called *sequencer* contains several sub-properties, each one containing a list of root sequence devices grouped by usage. For the Elettra storage ring the sub-property list names are Feedback, InsertionDevices, PowerSupplies, MSCR, Optimization, Recover, BeamOFF.

Another sub-property contained in the *sequencer* global free property called *SuperList* contains the name of all the sub-properties listed above. This information is used by graphical applications to dynamically build up the GUIs for configuration, monitoring and control of the sequence-based operations.

## Executing External Programs

The sequencer language supports a restricted group of Tango APIs. For more complex tasks it is possible to execute in the sequence, by means of a c-style “exec” system call, Python, Matlab, Bash and any other type of script.

## GRAPHICAL INTERFACE

One of the main problems of automation is making the operator aware of the operations involved in a procedure and understand what is the cause of an error. Both in FERMI and Elettra BTs are made of up to a few hundreds of sub-sequences and the number is constantly growing. In order to provide the operators with flexible command and control tools two graphical panels based on Qt-Cumbia libraries [7] have been developed.

## Sequencer GUI

The panel loads a list of predefined root sequences or, by means of Tango wildcards (ex: seq/\*/\* selects all sequences in Tango database), composes a dynamic list of all the sequences matching the search criteria. Thanks to the information gathered from the devices and the Tango database, the panel identifies the BT dependencies and builds the BT in a hierarchical list format. The user can inspect the entire BT from the root sequence node down to the leaf nodes (see Fig. 4). A tree structure view is also available. By browsing the hierarchical list, the user gets the description, the state (Tango *state* attribute), the last execution time and the last execution elapsed time of each sequence. In the hierarchical list the states of all non-sequence Tango devices logically connected to the BT are also reported.

The user can start/stop an entire BT or just a part of it. The source code of each sequence can be displayed in a read-only format.

A textual search can be performed simultaneously on the logging buffers of all the sequences belonging to a BT. Furthermore, the panel not only displays live, thanks to the Tango events, the list of errors and settings performed by one BT, but can also collect any action performed by all the sequencers configured in a Tango database.

## SeqLauncher GUI

This panel reads the *SuperList* free property from the Tango database and creates as many tabs as the number of lists found inside the *SuperList* property. Each tab contains

all the root sequences belonging to the corresponding list (see Fig. 5). For each sequence an “OpenGUI” button starts preconfigured legacy applications that ease the monitoring of the BT execution. Similarly, the “CloseGUI” button kills all applications started by the OpenGUI button. This is the panel used by the operators in control room to access directly the sequencers.

## WEB interface

A web interface (see Fig. 6) based on PUMA [8] allows listing all sequence devices installed in FERMI and Elettra. Sequences can be remotely started by users after LDAP authentication.

## APPLICATIONS

There are 958 sequencer devices installed in the Elettra Tango database and 995 in the FERMI Tango database.

In Elettra, most of the high-level applications used for the accelerator automation have been replaced by sequencers. There are two main sequencers, the first for recovering the machine from a faulty state, the second for injecting the beam into the storage ring and performing optimizations and orbit correction until a stable beam can be delivered to the beamlines. Thanks to the BT modularity both of them have been embedded in larger sequencer that is able to run the machine autonomously. The work to refine especially the recovery sequencers is ongoing with the goal to face any anomalous situation from which the machine could be automatically recovered.

Device	State	Enable	Block	Executed	Last Exec	Elapsed	Description
seq/on/injection_2gev	OFF	✓		YES	5h 5m	1906	Injection @2GeV operations

seq/off/injection s	OFF	✓	YES	YES	5h 9m	0	Stop Injection (kiser, siser, gun grid at 0V)

Figure 4: Overview of the BT used for the Elettra storage ring injection at 2GeV. The Root node launches 31 sub-sequences over a total of 219. The total procedure lasted 1906 seconds. Excluding the “waiting tasks”, the longest ones during the injection are: automatic optimizations (338 sec.), orbit correction (116 sec.), undulator gaps closing (56 sec.).

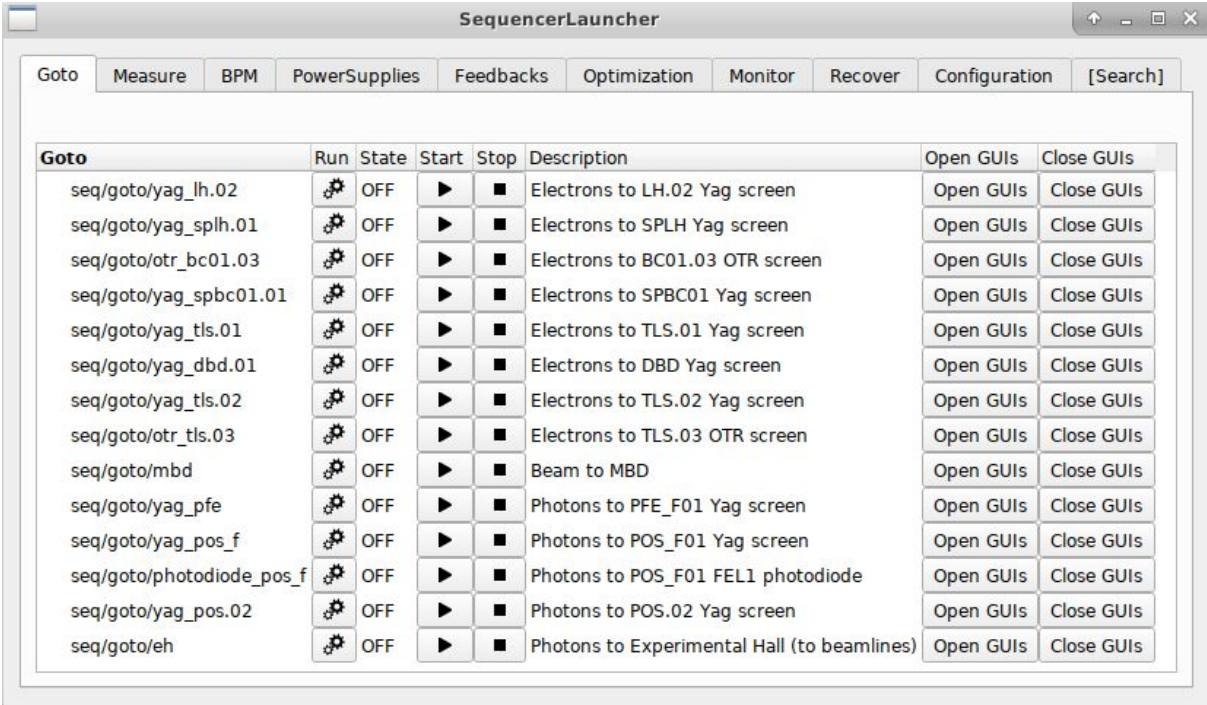

Figure 5: Control panel for driving electron and photon beams to diagnostic stations and beamlines in FERMI.

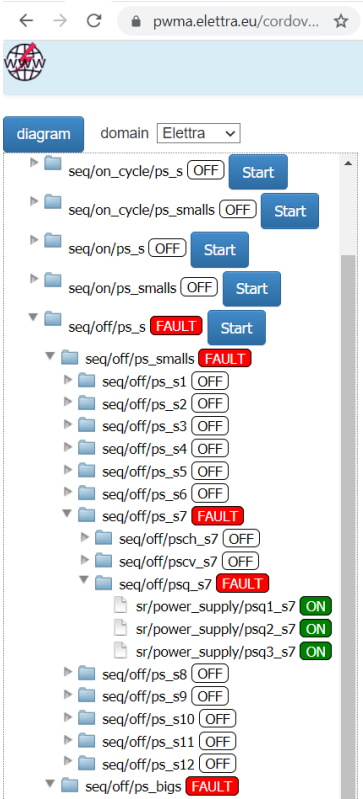

Figure 6: Web based sequence browser.

In FERMI the sequencers have been introduced quite recently. They supervise the online the FEL automatic optimizers and reconfigure the machine for delivering the electron and photon beams to diagnostic stations and beamlines.

## CONCLUSION

With the adoption of sequencers, developing automation applications with very complex logics has become much easier than in the past. More people, even non-professional programmers, are actually working on automation, bringing machine autonomous operations to unprecedented levels of complexity.

Thanks to the sequencers, moving logics from GUIs to server applications is possible and convenient: the server-side logics can be recalled by any client in the control system without caring of its implementation. Moreover, encoding in a sequencer a procedure that is normally written in an operator manual or, even worse, known by just one expert, is a clear advantage. Once the optimal sequence is defined and encoded, everyone can perform that task at expert level.

Another advantage in the present Machine Learning era is that, by using sequencers, the machine operations become more deterministic. Machine settings are not polluted by the randomness of the human actions. As a consequence, any Machine Learning algorithm designed to learn from logs any insight of malfunctions or weird behavior of the machine, will benefit from processing cleaner data.

To start playing with the sequences there is no need of external software except the sequencer Tango server and the Tango control system. For building up more complex applications, the use of the *Launcher* template and the Qt GUIs are strongly suggested.

## Abstract

The new fast orbit feedback (FOFB) system, a typical multiple-input and multiple-output (MIMO) system, is essential for the storage ring of High Energy Photon Source (HEPS). In order to reduce overall latency and achieve more than 500Hz bandwidth, the FOFB system adopt 16 sub-stations with the same hardware and software function to obtain bias-data from the beam position monitors (BPMs) data using 2.38Gbps in the SFPs and send correct-data to the fast corrector power supplies using a serial point-to-point link around the storage ring, and each sub-station share BPMs data with daisy-chained using of 10Gbps in the SFPs. It is optimized to calculate the large matrix based on the singular value decomposition (SVD) taking the digital signal processing (DSP) modules of V7 field programmable gate array (FPGA) with parallel pipeline. For performance tuning and additional flexibility when adding or removing BPMs and fast corrector power supplies, or downloading new matrix, we implement an independent ethernet controller for remote operation. This article presents details on the design and implementation of the FOFB system, and also the future improvements.

## INTRODUCTION

High Energy Photon Source (HEPS), a high-performance and high-energy synchrotron radiation source, is one of the major national scientific and technological infrastructures, mainly composing of accelerators, beam lines and experimental stations, supporting facilities, etc, such as show in Figure 1. HEPS will be an original and breakthrough in the fields of basic science and innovative research.

Figure 1: Layout of HEPS.

The size of modern light sources is getting smaller and smaller, and the brightness is getting higher and higher. The performance of the synchrotron radiation photons that

finally reach the sample is closely related to the orbital stability of the electron beam. According to the practice of major international laboratories, the stability of the position should be about 10% of the bunch size. For HEPS, the brightest fourth-generation synchrotron radiation source in the world, the bunch vertical emittance should be on the level of 10pm.rad, which corresponds to the vertical bunch size about less than 3μm. Therefore, at the short straight section, the stability of the beam position should be better than 0.3μm.

## REQUIREMENT

There are many factors that affect the stability of the beam orbit, including the stability of the magnet power supply, ground vibration, temperature effects, etc. According to ring accelerator physical design and requirements, there are many beam position monitors (BPMs) to monitor the orbit and many correctors to correct the orbit in the storage ring. In order to suppress interference and keep the beam orbit stable, it is we adopt a high-intensity and high-speed orbit feedback system, a typical multiple-input and multiple-output (MIMO) system, to achieve long-term stable operation of the light source based on singular value decomposition (SVD) commonly [1]. The correction algorithm is based on an SVD of the orbit response matrix:

$$\Delta \bar{X} = R \Delta \bar{\theta} \quad \text{and} \quad R = USV^T$$

$$\Delta \bar{\theta} = VS^{(-1)}U^T \Delta \bar{X}. \quad (1)$$

Where  $\Delta \bar{X}$  is error that the current orbit is compared to the golden orbit, U and V are matrices whose columns form an orthogonal basis in BPM(X) and corrector magnet  $\theta$  space, S is the diagonal matrix of singular values. The proportional-integrator (PI) control algorithm operates in this diagonal space and the relevant parameters can be adjusted for each mode separately [2]. All multiplication and calculations stages are done for all eigenmodes at one cycle. Therefore, it is necessary to comprehensively consider the whole time consuming, including the speed of BPMs data acquisition, the delay of global BPMs data distribution and calculation, and other factors. According to accelerator physical design and requirements, the fast orbit feedback system should optimize strategies to achieve the low latency response with BPMs and fast corrector power supplies, which is essential to achieve a certain effective bandwidth range for the stable orbit.

<sup>†</sup> zhup@ihep.ac.cn

## ARCHITECTURE

The main part of the HEPS is an ultra-low emission electron storage ring, composing of 48 identical hybrid 7BAs cell. According to the accelerator design, there are 12 BPMs and 8 fast corrector power supplies in each cell.

Figure 2: Layout of FOFB architecture.

The storage ring of HEPS, a kilometre scale ring, in order to reduce overall latency and consider feasibility study, we adopt the architecture of daisy-chain based on 16 sub-stations, each sub-station is responsible to interact with local BPMs and fast corrector power supplies. Figure 2 and Figure 3 are shown the layout of FOFB architecture and connection between sub-stations.

Figure 3: Layout of connection between sub-stations.

Detailed, each sub-station is design and implement to obtain bias-data from BPMs using 2.38Gbps in the SFPs and send correct-data to the fast corrector power supplies using a serial point-to-point link, and each sub-station share BPMs bias-data using of 10Gbps in the SFPs. In order to ensure synchronization with the global beam, all the above working sequence is strictly in accordance with the global clock. For performance tuning and additional flexibility when adding or removing BPMs and fast corrector power supplies, or downloading new matrix, an embedded Ethernet controller is designed as a full hardwired TCP / IP providing internet connectivity to sub-station by using Serial Peripheral Interface (SPI). Figure 4 is shown the hardware architecture of FOFB sub-station.

Figure 4: The hardware architecture of FOFB sub-station.

As show in Figure 4, in pursuit of the stable performance with high-speed data transmission, the hardware system of sub-station is only based on ATCA mechanical architecture, but custom the main logic backplane board and the front boards. Furthermore, the sub-station hardware mainly includes:

- 1 main logic backplane board;
- 4 front boards for local BPMs, one of which is reserved for XBPM for beam line;
- 1 front boards for global BPMs;
- 4 front boards for local fast corrector power supplies;
- 1 front boards for global Timing;

The main logic backplane board and the front boards use high-speed TE signal connectors to interact mutually, and providing the front board power supply.

## HARDWARE DESIGN

### Main Logic Backplane Board

The self-developed main logic backplane board followed the ATCA mechanical size is one of the core board of FOFB. Considering the stability and reliability for long-term operation and future upgrade, the backplane of FOFB is adopt a large-capacity, high-density architecture, as

## Front Board

Figure 9 is shown the diagram of signal and function of the front board.

The fast corrector power supply front board is mainly responsible for outputting current settings for power supply substations, and the data transmission rate is about 50Mb/s.

The local BPMs data front board is mainly responsible for collecting 3\*12 groups of 32bit effective data, the rate is about 2.38Gb/s. The global BPMs data front board is mainly responsible for transmitting the BPMs data collected by this substation to the global BPMs data

transmission link, and where is obtained other FOFB substations, and the rate is about 9.5Gb/s.

The local BPMs data front board and the global BPMs data front board adopt the same hardware based on the ATCA standard (322mm\*280mm).

The dedicated timing front board is mainly responsible to receive the timing trigger signal and reference clock signal from global timing and sent to the main logic backplane board. The FOFB system is controlled by the 22kHz timing signal, reset signal, system synchronization start signal, system synchronization stop signal, and loop injection signal sent by the timing system.

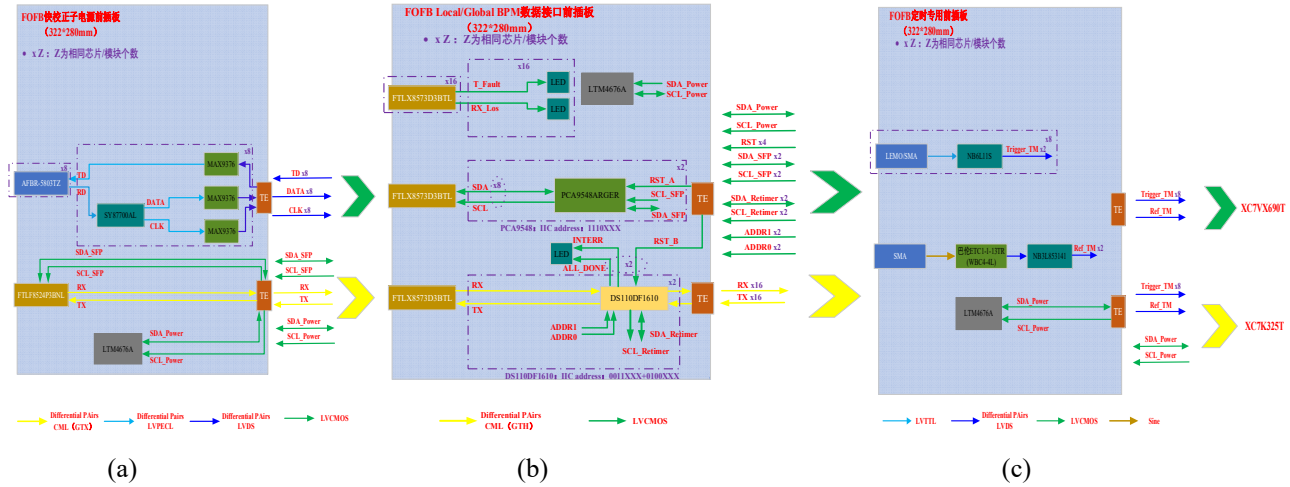

Figure 9: The diagram of signal and function of the front boards.

## LOGIC DEVELOPMENT

### Data Calculation Module

The data arithmetic module adopts a pipeline design, which is advantage that it can accurately control the data to reach a certain position at a certain time and reduce the delay at the same time, as shown in Figure 10.

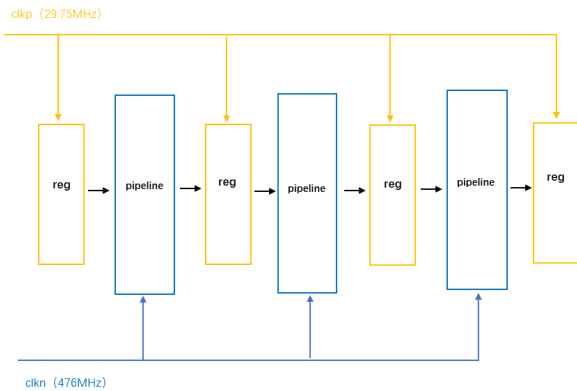

Figure 10: The diagram of pipeline design.

### Data Storage Module

Because the amount of parameter data that the system needs to store is very large, so it is necessary to call the Block Memory resource in the FPGA for data storage.

Considering the design goal of FOFB low latency, BRAM is used in the memory module design to ensure that the data is written and read in one clock cycle to reduce latency.

## CONCLUSION

In order to reduce the system response time as much as possible and improve the effective feedback bandwidth of the FOFB system, we propose a new hardware architecture that can quickly obtain all BPMs data in the storage ring, and quickly complete large data calculations, and send the setting to the fast corrector power supply in real-time. It is shown that the architecture can achieve an effective bandwidth of more than 500 Hz, which also meets the main requirements of the HEPS project.

## ACKNOWLEDGEMENTS

Thank you for all the leaders, teachers and colleagues of the research group of HEPS, especial members of FOFB.

## Abstract

The Tango Controls collaboration has continued to grow since ICALEPCS 2019. Multiple new releases were made of the stable release V9. The new versions include support for new compiler versions, new features and bug fixes. The collaboration has adopted a sustainable approach to kernel development to cope with changes in the community. New projects have adopted Tango Controls while others have completed commissioning of challenging new facilities. This paper will present the status of the Tango-Controls collaboration since 2019 and how it is helping new and old sites to maintain a modern control system.

## INTRODUCTION

Tango Controls is a software toolkit for building object oriented control systems. It has been adopted at a large number of sites around the world either as the main toolkit for their control system or for a sub-system or commercially acquired systems. A growing number of commercial products and control systems are now based on Tango Controls. A few commercial companies offer paying support for anyone needing help in integrating Tango Controls into their system.

The main objectives of kernel developments for Tango Controls since 2017 has been to consolidate the continuous integration for all major platforms, maintain the Long Term Support version V9, i.e. bug fixing and add features which are strongly needed by the community but do not break compatibility with V9 release, improve the web development platform, continue to improve the documentation and website, and prepare the next major release of Tango (V10). This paper summarises these developments.

## COLLABORATION

The Tango Controls Collaboration is in charge of ensuring the sustainability of Tango Controls. It currently has 11 members who contribute financially and in-kind to the maintenance of Tango Controls as a modern reliable controls toolkit for small and large facilities. In addition to the collaboration members a number of individuals and some companies contribute new developments to the ecosystem e.g. see section Rust binding below.

The Tango Controls Collaboration contract has been in operation since 5 years. The initial collaboration contract ended in 2020. All partners agreed the collaboration was fulfilling an essential role for the sustainability of Tango and should be continued for another 5 years. All partners signed the new contract running from 2021 to 2025. The new contract maintains the objectives and missions of the previous one i.e. all members provide the same financial contribution to maintaining the kernel, while some partners contribute in-kind resources too. The ESRF is in charge of sub-contacting tasks on behalf of the other members. A major change in sub-contracting took place in 2021 with a Call For Tender for sub-contractors who could provide services to Tango for the next 3 to 5 years. After a selection process 4 companies were chosen based on their competence and knowledge of the Tango kernel. Setting up contracts for 3-5 years will help ensure the sustainability of Tango controls. The new collaboration contract foresees a rotation of the role of coordinator amongst the members every year.

## New Projects

New projects continue to adopt Tango as their controls toolkit. Some examples of major new projects are the LOFAR 2.0 project (see [1]), the JINR 200 MeV LINAC (see [2]), the PEPC plasma electrode Pockels cell (see [3]) to mention a few. Some of the large projects which are based on Tango have completed successfully, for example the ESRF-EBS, the first 4th generation storage ring (see [4] and [5]). Other large projects like the SKA are ramping up to full speed and are already well advanced in their developments and will soon start construction (see [6]). A number of other 4th generation storage rings which will be based on Tango (e.g. ELETTRA, SOLEIL and CELLS) are in the planning phase. The above projects are only a small subset of projects using Tango: due to the way open source code can be downloaded by everyone without registering not all projects are declared or known to the community. They illustrate how vibrant the Tango Controls community is and the strong need to sustain and continue developing the Tango Controls toolkit for the coming decades.

## KERNEL DEVELOPMENT

### *Migrating from GitHub to GitLab*

The tango-controls GitHub organization [7] had been used since 2016 for hosting the various tango source code repositories as well as for managing issues and code review. The Continuous Integration was based on Travis-CI [8], also integrated in GitHub. A change in the terms of use of Travis-CI in December 2020 prompted the migration of the whole tango-controls organization to the GitLab platform. GitLab was found better suited to the open source nature of the Tango collaboration, offered more support for Continuous Integration and the fact that its Open Source version can be installed on-premises (as it is the case in many of the facilities involved in the Tango Collaboration). GitLab therefore offers better protection against potential vendor lock-in. The GitLab.com organisation graciously accepted to host the tango-controls project with gold status free of charge. Gold status allows up to 100 seats for developers of which currently 62 are in use.

The migration is being done on a per-project basis (at the moment of writing, 49 have been migrated, out of 67 originally in the tango-controls organization), and the main code review, continuous integration and issue handling is already done in GitLab.com. In terms of implementation, the migration has been relatively simple thanks to the automated import of GitHub projects provided by GitLab. The only aspects that needed some manual intervention were adapting the CI configuration from Travis-CI to GitLab-CI and the coordination to ensure that the contributors had linked their GitLab and GitHub accounts in order to preserve the cross-references and contribution statistics.

See paper [9] for more details.

### *C++ Core Library*

Part of the TANGO C++ core library development is being subcontracted to Byte Physics and S2Innovation for the TANGO collaboration. The Tango C++ Kernel library cppTango [10] is actively maintained with the excellent expert help of these companies.

Since the last ICALEPCS conference, cppTango 9.3.4 [11] has been released and a new Tango Source Distribution Release [12] has been prepared. This new cppTango release provides several bug fixes for race conditions, memory leaks, issues related to events, compilation warnings and better support of recent cppzmq versions [13]. It is fully ABI and API compatible with the previous 9.3.x cppTango releases. This version still does not require C++11 support from the compiler, allowing it to be built on older platforms, including Debian 7.

Since the introduction of the TANGO 9 Long Term Support, the Tango C++ Kernel developers are working on improving the code quality by refactoring the source code to make it easier to maintain. This work is being done in the cppTango repository main branch from which cppTango 9.4 will be released at some point. cppTango 9.4 will not be binary compatible with cppTango 9.3.x but

will still be API compatible with cppTango 9.3.x versions. The main development branch requires at least C++14 and will be compatible with C++17 and C++20. This branch is being automatically compiled and tested with GitLab CI on Ubuntu 20.04 LTS, Debian 9, 10, and 11 platforms as well as using the latest releases of GCC and Clang. The migration to GitLab was an opportunity to replace SonarCloud services with CI jobs using Clang Static Analyzer [14] and clang-tidy [15] to detect code quality issues. Also a new CI job that generates a code coverage report was added. Additionally, some steps were taken to improve the memory safety and the overall stability of the C++ core library. As a result a set of sanitizer CI jobs, including address [16], undefined behavior [17] and thread sanitizers [18], was enabled for the main branch.

### *Python Core Library*

Python is still enjoying good popularity in the Tango Controls community. This is largely due to the excellent PyTango binding for Tango to C++. It provides a high level python friendly API which makes developing servers and clients extremely easy.

PyTango 9.3.3 has been released in December 2020 [19]. This marks only the second release since the previous review at ICALEPCS 2019 [20], with the 9.3.4 release is expected this year. Fourteen contributors have been working on the project producing more than 150 commits, in total. PyTango 9.3.3 supports the releases 9.3.x of the Tango C++ library - the minor versions are kept in sync. No major updates were required in this period, so it was largely maintenance.

PyTango fully supports both Python 2 and Python 3 language versions, although Python 2 is nowadays officially obsolete and its usage have been already discouraged for new developments. Having compatibility with both language versions has helped during the transition to Python 3 of legacy python-based projects. The biggest frameworks using PyTango, like Taurus and Sardana, are already running in production using Python 3. Older Python tools and device servers (fandango, pytangochiving, panic) are currently in the process of migration using GitLab CI/CD for validating the migrated code. Unfortunately, the slow pace at which institutes are able to transition all their code to python 3 means that PyTango needs to maintain Python 2 supports for some years still.

The long running port [20] of the C++ extension code from Boost [21] to pybind11 [22] has not progressed significantly. There were few resources to allocate to this work. As there is no major risk of Boost's Python support becoming obsolete, the Tango Steering Committee has decided to pause this effort.

Future work includes making PyTango available as a binary wheel for Linux. This will significantly simplify installation for users.

### *Java Core Library*

Java core library (aka JTango), which is 100% Java, relies on Jacorb [23] and JeroMQ [24], is now built upon Java 8

and Java 11. The latest developments have focused on its quality; by fixing bugs, replacing deprecated Java code with Java 8 code, and adding automatic unit and integration tests. JTango artifacts were deployed automatically to Bintray [25] and manually on Maven Central [26] repositories. Since Bintray has announced its shutdown [27] and we were in the process of migrating to GitLab, the CI/CD pipeline were completely refurbished, to optimise its execution time and to automatically deploy artifacts to Maven Central repository (see details in paper [9] at this conference).

## POGO

Pogo is the Tango code generator for device servers. It allows users to define a Tango class model through its graphical user interface and save it in an .xmi file. Starting from this Tango class model, Pogo is able to generate a device server skeleton in C++, Java or Python and the relevant HTML documentation. The code generation part is based on EMF (Eclipse Model Framework) associated with Xtext and Xtend classes [28]. Pogo source code is available on GitLab [29], and binary distribution is maintained on maven central [30].

In the past years Pogo has continued to be improved. Python support greatly evolved, two flavors of python device servers can be generated. With the introduction of PythonHL, device servers code is now more concise, more readable, easier to maintain, and faster to develop.

Latest developments focus on improving Pogo for automation. Current development workflows rely more and more on CI/CD and Pogo needs to integrate and keep up to date with the latest strategies. This has lead to:

- A ready to use docker image is now available. It will speeds up deployment strategy and can be used for automatic testing.
- Improved cmake integration. Modern cmake is the de facto standard for building C++ projects, it simplifies building and managing dependencies.

## PACKAGING

### RPM

Tango RPM packages used to be built internally by MAX IV and provided to the community via the MAX IV's repository [31]. The Tango SPEC file repository [32] has been moved to the tango-controls group on GitLab. Building is now performed using Copr [33], a build system and infrastructure provided by Fedora. Packages are produced for CentOS 7, CentOS 8, Fedora 32 and 33. The latest version of Tango can be installed on those distributions directly from the Copr repository. RPMs are still available from the MAX IV's repository as well.

### Conda

Conda [34] is an open-source solution for dependency and environment management for any language. It is cross-platform and runs on Windows, macOS and Linux. Some packages (pytango, itango, tango-test) were already

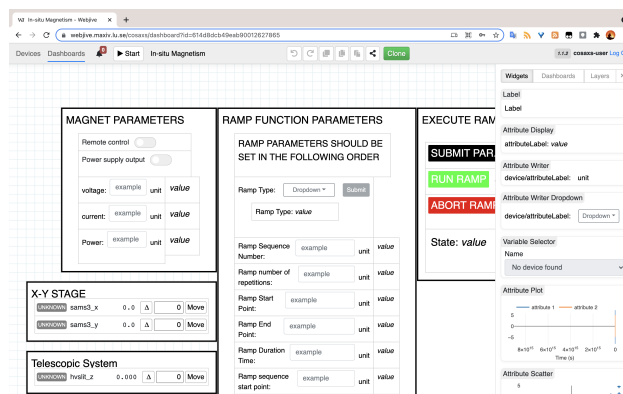

Figure 1: Example of a web interface developed with Taranta - display of status of MAXIV magnets.

available using the tango-controls conda channel [35]. Some effort were made during this year to publish those packages and add new ones to conda-forge [36]. conda-forge is a community-led collection of recipes, build infrastructure and distributions for the conda package manager. It is very active and has become the de facto channel when using conda. Using conda-forge has several advantages:

- existing conda-forge infrastructure makes it easy to build on all supported platforms
- it ensures compatibility with conda-forge packages by using the same build environment and baseline software versions defined in conda-forge-pinning [37]
- makes it easier for people to discover tango packages

The current Tango packages available on conda-forge are: tango-idl, cpptango, tango-database, tango-admin, tango-test, pytango and itango. This move was also beneficial to the wider Tango community allowing software like Sardana, which depends on pytango, to be available on conda-forge. Only Linux is currently supported but work for publishing Windows packages is planned.

## WEB TOOLKIT

During the last 2 years the pandemic situation has demonstrated the importance of using web technology in the Tango Control System. There are currently mainstream 2 solutions maintained by the community members, Taranta [38] and Waltz. Taranta (shown in Fig. 1) is now an official tool of the Tango ecosystem and has moved to the tango-control GitLab repository. Following the example of the Tango REST API which has a formal specification (see [39]), a similar project is planned for the specification of the GraphQL Tango gateway in order to allow different back-end implementations (see [40] for example) to connect to multiple front-end applications using GraphQL.

New initiatives have chosen the ubiquitous web browser for their User Interface (UI) like the Solaris Synchrotron [41] who developed the interlock and machine status UI with the Vue.js [42] framework on top of TangoGQL [43].

In the meantime S2Innovation has developed IC@MS a new web UI for the standard Tango Alarm system (see [44]).

```
use tango_client::*;

let mut dev = DeviceProxy::new("tango://localhost:10000/sys/tg_test/1"?);
let instr = CommandData::from_str("This is a minimal Tango test client.");
let argout = dev.command_inout("DevString", instr)?;
println!("Command exec result: {}", argout.into_string()?);
```

Figure 2: Tango Rust binding example code.

This is an example how the traditional Tango tools are getting a lifting with modern technology.

## BINDINGS

### *Rust Binding*

Rust [45] is a fairly new systems programming language. Because it puts a focus on efficiency while ensuring memory and thread safety at compile time, it has the potential to be used, also in the scientific sector, where code is currently being written both in C/C++ and Python, trying to provide the speed of the former together with the usability of the latter. [46] The Tango Rust binding [47] is a Rust library (“crate”) that provides Rust code with client access to Tango devices, wrapping the C binding. So far, we have implemented a DeviceProxy API up to Tango 8 and rudimentary a Database interface. Figure 2 shows a minimal code example calling a method on a TangoTest server. The library is available on Rust’s central package server crates.io [48] and requires an installation of the C++ libtango to be present on the system to build against, as well as a C compiler to compile the bundled C binding. It is currently only tested on Linux systems.

## TUI

A small text based command line utility have been developed to explore running Tango devices. Devices are presented in a tree structure, from which they can be traversed and selected (see screenshot in Fig. 3). Once a device is selected, their attributes and commands can be seen.

The tool is written in Rust making use of the Rust bindings. The Rust bindings have some limitations that may cause issues when using the tool e.g. enum types are currently not supported. For more details on the tool including its limitations, installation instructions etc. see the project GitHub page [49].

## COMMUNITY WORKSHOPS

The 35th Tango Community Meeting was held on September 14 and 15 2021. Despite the pandemic and the remote nature of this event, +100 people registered and +25 talks has been given. The traditional session dedicated to Projects Status allowed some major Tango-based projects to report on their progress. Among them, were SKAO, the world's largest radio telescope under construction and the ESRF-EBS, the first-of-a-kind fourth-generation

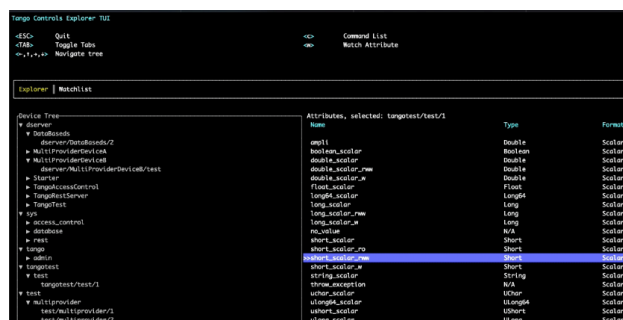

Figure 3: TUI - text based generic client written in Rust.

high-energy synchrotron. The technical sessions related to the Tango ecosystem provided the attendees with latest news of the kernels, the tools and the services around Tango. PyTango - the Python binding based on the C++ kernel - remains the most popular platform for both server and clients development, especially for newcomers. The trend towards the usage of web-based solutions for controls systems GUIs continues, re-enforced by the need for remote controls during the COVID-19 pandemic. The Tango Community Meeting was also an good opportunity to introduce the subcontractors who were selected during the Call for Tender managed by the ESRF.

In addition to regular Tango Kernel Meetings, Tango Kernel Training Sessions and the yearly Tango Community Meeting, the HDB++ Archiving collaboration meetings are now scheduled every two months to boost the collaboration between institutes. These regular follow-ups of the project have enabled the continuous improvement of the main library, the testing and evaluation of the HDB++ core libraries over multiple database engines (PostgreSQL, MySQL, MariaDB, TimeScaleDb, ...) [50] as well as the development of a common AbstractReader class for data extraction.

# TANGO V10

Tango V10 is the code name of the next long term version of Tango which should bring a change in the communication protocol. Since the backward compatibility is one of the main attractions for Tango, the community has decided to collectively understand the consequence of this major change. The first step was to define what is the essence of Tango in the form of RFCs.

The Tango Request For Comment RFC project [51] specifies the data model of Tango, the expected behaviour of the Tango elements and the communication between 2

components, as it is today with version 9. The project of writing these specifications has involved all representatives of the Tango consortium in such a way that the knowledge is built collectively. The draft of the specifications is almost complete before being compared to the existing implementation. At the current state, it covers the essentials of the Tango Model with 12 specifications.

The main communication protocol is the most complex to specify as a large part of it is given by the CORBA implementation. A careful review of the cppTango library allows extracting the main principle, although separate the abstraction from the implementation is a difficult challenge.

The RFCs are published on ReadTheDoc (see [52]). These documents have status *draft*.

The final work in progress concerns RFC-10/The Request-Reply Protocol. The RFC-13/Publisher-Subscriber protocol implementation with ZMQ is waiting for review. Three other RFCs are planned to be written if needed.

The Tango Community plans to organise a workshop for the final edition of the RFCs and plan the next steps.

The Community will follow COSS and use the RFCs as a base for building a prototype of Tango V10. This will verify the specification for completeness and any ambiguity. When a new version of Tango Controls is ready, the documents will be marked as stable [53].

## TRACING VIA LOGS

The SKA project developed a Python library [54] that generates logs with tracing information. A log entry is created upon the entry and exit of the context manager.

The main items in the log messages are:

**transaction ID** Tango device command arguments are generally type string (JSON). The JSON may include a common transaction ID that is passed along as part of the arguments. By searching for this ID in the logs, the execution path can be traced between devices.

**Enter|Exit name** Whether this is the start or end of the context, and an arbitrary name for the log pair.

**marker** A random string used to match “Enter” and “Exit” log entries.

For more details see paper [55]

## CONCLUSION

The Tango Controls Collaboration has again proved to essential in ensuring the continued maintenance and development of the Tango kernel for the coming years and decades thanks to securing high quality sub-contractors on multi-annual contracts. The high quality of the in-kind contributions continue to contribute to the successful development of Tango Controls. Major new projects are based on Tango which puts a strong requirement on sustainability for the coming decades. A new binding is now available for Rust. Rust is a promising language for the future which addresses the problems of memory leaks which

traditional languages like C++, C and Python suffer from. The web developments have been pushed ahead with the wide-spread adoption of the Tango GraphQL protocol. The next step will be to fix the specification of Tango GraphQL to ensure compatibility between multiple implementations. The collaboration is setup for the next 5 years and is open to new members who rely on Tango or plan to use Tango for their facilities and products.

## ACKNOWLEDGEMENTS

The authors acknowledge the support of the Tango Controls Collaboration for funding a number of the developments described here as well as the Tango Controls Community for bug reports, fixes, suggestions for new features and contributions.

# ADAPTATIONS TO COVID-19: HOW WORKING REMOTELY HAS MADE TEAMS WORK EFFICIENTLY TOGETHER

R. Lacuata, B. Blackwell, G. Brunton, M. Fedorov, M. Flegel, D. Koning, P. Koning, S. Townsend, J. Wang, Lawrence Livermore National Laboratory, Livermore, CA, USA

## Abstract

The National Ignition Facility (NIF) is the world's largest 192 laser beam system for Inertial Confinement Fusion (ICF) and High Energy Density Physics (HEDP) experiments. The NIF's Integrated Computer Control System (ICCS) team conducts quarterly software releases, with two to three patches in between. Each of these software releases consists of deployment, regression testing, and a test shot. All of these are done with ICCS software team members inside the NIF control room. In addition, the NIF ICCS database team also performs a dry run and verification before each software release. This is to anticipate any issue that may arise on the day of the release, prepare a solution for it, and make sure that the database part of the upgrade will be completed within the allotted time slot. This paper describes how the NIF ICCS software teams adapted when the LLNL workforce began working remotely due to the COVID-19 pandemic. These adaptations led to a better and more efficient way of conducting the NIF ICCS software upgrades.

## INTRODUCTION

I joined NIF ICCS back in October of 2017. My background was database development and support for an e-commerce company. A few weeks later, I participated in my first NIF ICCS software release. This is when I realized that updating the control systems for the NIF is different than the software releases I did in my previous job.

The NIF ICCS software releases are done quarterly, with two to three patches in between. It requires a lot of effort from operations, hardware, and software teams.

The software release process is pretty standard. It consists of a database dry run and verification, deployment, regression testing, and a test shot. The big difference from my previous job's software release is with the test procedures done to requalify the changes. The qualification testing in NIF ICCS is more involved than just testing the new version of the application with a web browser.

The pre-pandemic version of our software release process involves a lot of group activities. Most of which requires the software team members to go to the control room to execute the task they needed to do.

For example:

Before the release, we perform the database release dry run. This is done in a team member's office. After a successful dry run, we will go to the control room to verify that the database release scripts have been delivered and the console we will use for deployment is working. This is because the production database is accessible only from the control room.

On the day of the release, we will be in the control room again to apply the database updates. After we are done, members of operational staff will activate the new software that was delivered by our configuration management team.

Once the new software is activated, it will become busy in the control room. Members of the software team will start to come in to do regression testing (Fig. 1). Since only members of the operational staff are qualified to operate the laser, they will have to pair up with an operational staff member to run a series of test procedures for them. The operational staff would sit at their consoles and perform the required operations while they stand behind and observe software behaviour.

Elsewhere in the facility, engineers from other teams will be executing their part of the software release to upgrade various computers, servers, and controls hardware.

All of these release activities and qualification testing are coordinated by the release manager who is also inside the control room. He gets constant updates everybody.

Figure 1: Pre-pandemic, ICCS software engineers inside the control room watching the operators' consoles [1].

When the pandemic started, Lawrence Livermore National Laboratory (LLNL) went into Minimum Safe Operations in March 2020. Only essential personnel are allowed onsite. Most of the laboratory's workforce started working remotely, including the ICCS software team.

Because of this, the software release that was scheduled in April 2020 was cancelled.

After some modifications to control room operations to comply with COVID-19 restrictions, NIF shot operations was able to resume. This required the software team to resume software releases to the NIF control systems as well. But the software release process that required most of the software team inside the control room is not possi-

ble. COVID-19 restrictions forced us to rethink our software release process.

NIF ICCS management team met with the software team to figure out how to execute a software release while the entire software team is working remotely. The software release procedure was updated. The changes that were meant to address COVID-19 restrictions also led to a better and more efficient way of conducting software releases.

## LEVERAGING CLOUD COLLABORATION PLATFORMS

We have used most of these tools before the pandemic. For one reason or another, we just have not considered using them for software releases.

### Virtual Desktops

The software team is able to continue development and testing activities remotely because they can connect to the development and testing environments. To support production releases, the NIF provided the database team with virtual desktops. The virtual desktop opened secure connections to computers, databases, and servers in the production environment. This replaced the need for the database team to be in the control room to do database updates and verification. With the database team and the rest of software team working on their own workstations, they have access to their computers and developer tools that would not have been available if they were in the control room. This is invaluable to any software engineer. This has made the software team more effective during the release.

### Smart Phones and Cisco Webex

The NIF issued smartphones to each operational staff member. The software team also leveraged an established video conferencing capability using Cisco Webex to view any operational console inside the control room. The combination of these two provided secure one-to-one audio/video communication between the operational staff and the software team. This replaced the need for the software team to be in the control room during regression testing.

The release manager does not have to be in the control room as well. He too is working from his own workstation. He schedules a single Webex meeting for the entire duration of the software release to coordinate all activities and qualification testing.

When issues come up, remote and onsite teams simply join this online meeting to collaborate and solve problems. Team availability during software releases improved.

### Microsoft Teams

Microsoft Teams provided a platform for the teams to collaborate online. It brings the operations, hardware, and software teams in one place where they can work together, share information, and make decisions to drive the software release into successful completion.

The release manager establishes a Microsoft Teams channel dedicated for each software release where the release activities and qualification testing are organized as channel conversations.

The conversations and status updates from the release channel replaced the face-to-face conversations that used to take place in the control room and status updates via phone calls and e-mails.

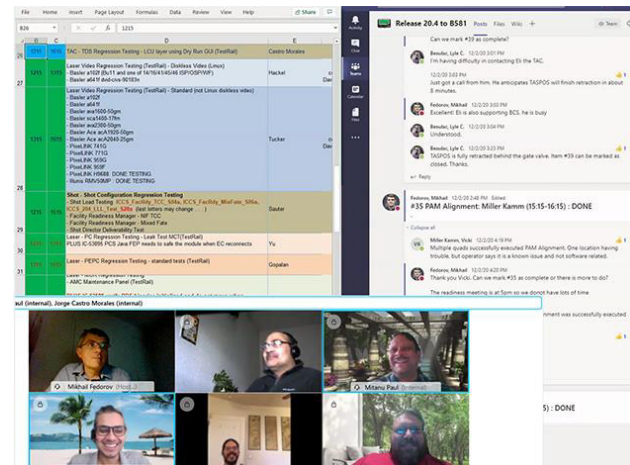

Figure 2: The ICCS software team uses Cisco Webex and Microsoft Teams during one of the software releases [1].

## CONCLUSION

The remote software release met COVID-19 social distancing requirements and more.

For the software team that used to crowd the control room on release days, they can now work comfortably in their own offices, whether onsite or remotely at home (Fig. 2).

For the operational staff working in the control room, the reduced number of people made it more a comfortable working environment for them.

Remote software release facilitated online collaboration. The release manager shares the overall status of the release online. This combined with the status updates from the release channel increased team awareness and communication. If there are issues that needs attention, the team response is much faster. Escalations and resolutions also are recorded in the release channel, makes data available for later analysis.

Remote software release also provided an opportunity to train new members. The new member joins the video conference and watch as the mentor executes the release procedures. Before, this meant bringing the new member in the control room which is not always possible. Now, we have more opportunities to train them.

The software team has completed six remote software releases since the pandemic began. It is such an improvement from the old process that the software team will continue with this new process onwards.

## ACKNOWLEDGEMENTS

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-CONF-827816.

# AGILITY IN MANAGING EXPERIMENT CONTROL SOFTWARE SYSTEMS

K. V. L. Baker, F. A. Akeroyd, T. Löhnert, D. Oram, ISIS Neutron and Muon Source, Didcot, UK

## Abstract

Most software development teams are proponents of Agile methodologies. Control system software teams, working at science facilities, are not always just developers, they undertake operations work, and may also be responsible for infrastructure from computer hardware to networks.

Parts of the workflow this team interacts with may be Agile, but others may not be, and they may enforce deadlines that do not align with the typical agile implementations. There is the need to be more reactive when the facility is operating, which will impact any development work plans. Similarly, friction can occur between an Agile approach and more familiar existing long-standing risk-averse organisational approaches used on hardware projects.

Based on experiences gained during the development of IBEX, the experiment control software used at the ISIS Pulsed Neutron and Muon source, this paper will aim to explore what being Agile means, what challenges a multi-functional team can experience, and some solutions we have employed.

## WHAT DOES AGILE MEAN?

In its' truest form Agile is a way of working [1] rather than the tools to enable this way of working. What is most important to remember is that the manifesto values certain things over others, but the less valued items are still worth considering, just not at the expense of the more valued items. The Agile Manifesto values are as follows:

- Individuals and interactions over processes and tools
- Working software over comprehensive documentation
- Customer collaboration over contract negotiation
- Responding to change over following a plan

It was software developers that started the use of Agile methodologies, as it is often in the fast-paced world of software that the adaptability is most important in the modern age. However, some of the tools used to support Agile methodologies originated separately from software development, and Agile Project Management is slightly different to Agile Software Development.

## What is Agile Project Management?

The Association for Project Management [2] describe Agile Project Management as “an iterative approach to delivering a project throughout its life cycle” [3].

The Agile Manifesto and Principles are generally applied in exactly the same way whether the project in question is software based or not, and instead of working software at each iteration, you aim for working prototypes or solutions.

## Is Agile Always the Right Answer?

It is certainly true that not every project is suited to using an agile methodology. Yet, there are very few project teams

who would deny that continuous collaboration throughout the project from the customer or their representative, and being able to incorporate any requested, or required, changes over the course of a long term project is beneficial to producing a usable item at the end. Some of the tools which are typically seen in Agile, have other roots. A common tool used to map workflows is a board such as a Kanban board (see Fig. 1) [4].

Initially the use of Kanban was by the assembly lines at Toyota [5], but the tool is used by most Agile methodologies to track progress.

Whilst Agile isn't the answer to everything, aspects of it, and the tool sets it uses are still applicable outside of Agile projects, and vice versa. If using any of the standard toolsets used by Agile Project Management, it is worth making sure you use the one that most suits your team and environment, and to continuously evaluate the tools suitability for use as the project and team develops.

## MULTI-FUNCTIONAL TEAMS

Whilst the ideal can be to have teams focussed on just one thing, the practicalities mean that people regularly undertake a variety of tasks.

## Types of Function

For the purposes of this paper a function is defined a family of tasks that an individual can undertake.

**Development (Dev)** The obvious task undertaken by most software developers is development. This mainly covers the introduction of new features to a code base, for example, adding in code to allow a user to change the colour of the interface they are using.

Development covers the full software stack, from the user interface to the lowest levels the team can support, which may even be circuitry. For non-software teams this could be electronic systems, or mechanical ones.

**Systems (Sys)** The focus for systems tasks is usually the hardware and fundamental aspects of the environment the control system is running in, e.g. computers, network switches, and operating systems. It also covers patching and updating the elements mentioned.

**Operations (Ops)** Operations tasks are responses to requests for support on problems that need to be solved in a short time frame to keep systems and software running correctly.

It also covers some of the later parts of the process, such as fixing code. For software teams this is hearing about bugs and dealing with them. It is more likely to be failures and faults for those who are not focussed on software, and is the nature of operations for the Systems function. As such

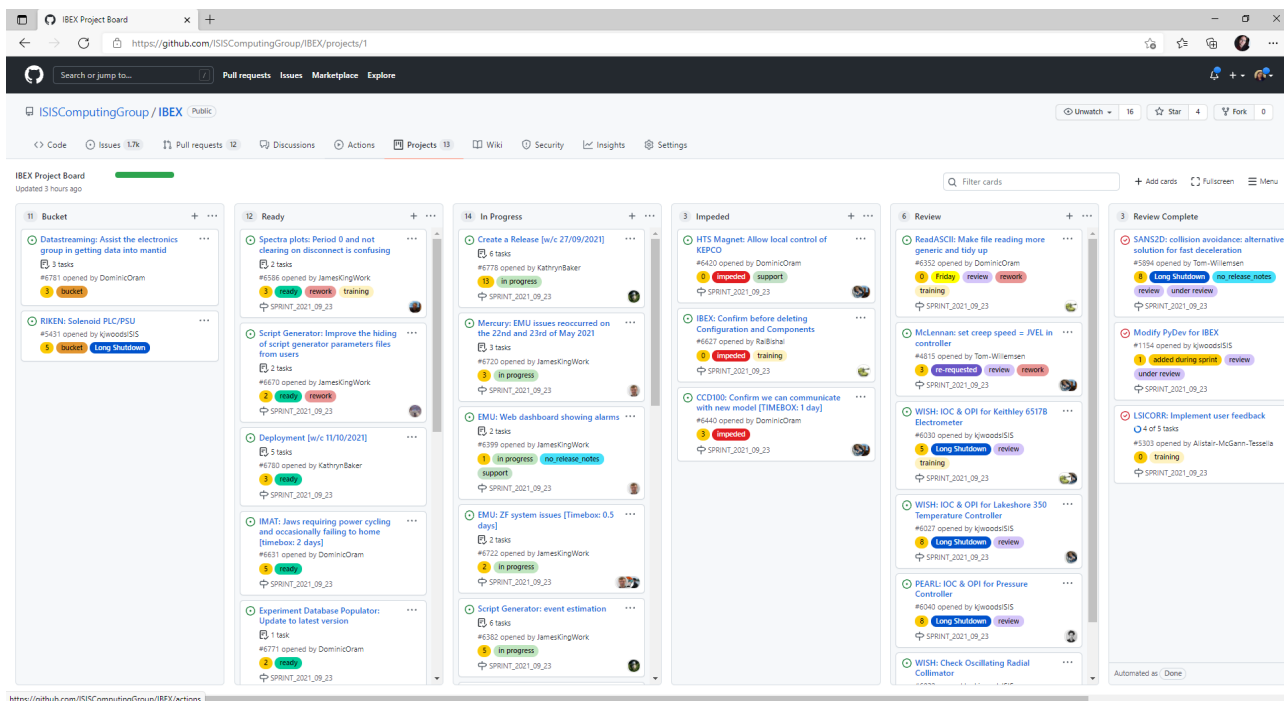

Figure 1: An example of a Kanban board, the one in use on the IBEX project at the start of October 2021.

operations teams can need an understanding of what both the systems and development work entails, although not always to the same depth.

**Project Management, Admin** Whilst it can be the case that project management and admin tasks are undertaken by specialists in those fields. It isn't always the case, and it can fall to the same team that is designing the software to control an experiment to manage the project and to keep the admin tasks related to that system up to date.

This can also be stakeholder management, ensuring that those communication and collaboration channels are kept open for dealing with our scientists.

### What the Basic Challenges are for Multi-Functional Teams

If you are able to split the work between team members with defined functions that do not overlap, then whilst the team might be multi-functional, the only challenges occur when those within a function are not available, and that can be the case for any specialist aspect of the control system.

For a team where each member can be involved in multiple functions, the challenges are often quite different. Not least of which is context switching. If a team member is undertaking some programming work, and is interrupted by a phone call reporting a failed network connection, there is a moment where they have to switch between thinking in a programming language, to how to go about troubleshooting what the issue with the network might be. This kind of switching between tasks has a cost [6], which can have a significant impact on the productivity of a team.

Similar to the context switching, if people are working on multiple projects then interruptions will have an effect

on productivity too [7]. The issue can come on how you differentiate between development work and operational work, and just how many projects the team/individuals are working on.

It is also rare that a team member can be specialist enough in all those areas to be able to provide the same level of support, which can be frustrating for those seeking help of an operations function.

### Where Agile can Help

Due to the central precept of embracing change Agile methodologies allow for systems to change frequently, which will be of benefit to the ever changing needs of a science facility.

If you have individuals with specialist skills then it can be easier to manage their input across multiple projects.

### Where Agile Hinders or is Counterintuitive

The thing we have found causing the greatest friction for us relates to how things are defined as complete. Our iterative approach to development provides a Minimum Viable Product (MVP) and then adds to the product, which often leads to difficulty in defining when a product is in a finished state, effecting team morale.

With a facility such as ISIS, where the customer representatives (the scientists who take care of the instrument) work extended hours during the times that the accelerator is running it can be hard to find their time, or for them to prioritise the collaboration aspects needed for Agile working. Especially when combined with the iteration process.

For a multifunctional team however, Agile methodologies can increase context switching, as the next most important

thing to do might be related to something completely different to what you were just working on, but or the developer can find themselves jumping from one programming language to another.

## HOW OUR TEAM FUNCTIONS, AND HOW WE ARE AGILE

### *What Type of Team is the IBEX Team?*

Within the realm of supporting control software on instruments at a facility such as ISIS [8], we cover all functions within the team. Some members of the team focus more on the Systems side, others on development, and still others will undertake the management tasks.

All members of the team take on an operations role, especially when the ISIS accelerator is running, as that is when the instruments are most active. As the available beam time is limited, we work to support the instruments to ensure that the time can be used to the best possible advantage.

The whole team is also encouraged to take on responsibilities for different parts of the system as their skill sets grow and improve, so that they act as a point of contact to a beamline.

The IBEX team could be described as a SysDevOps Team, and we cover the management tasks as well.

### *How the IBEX Team Employs Agile Methodologies*

At present we use a modified Scrum approach.

Scrum [9] is one of many Agile frameworks. It provides a heuristic way of tracking the work that has been done, and aids in predicting what can be done. It is focused on the team being self-organising. A Scrum team should consist of three main roles:

- A Scrum Master [10] who looks after the Scrum processes and focuses on keeping the work flowing easily by removing impediments to the work
- A Product Owner [11] who ensures that the product being produced is what is actually useful and who makes sure the priorities are suitable understood
- The Developer role [12] as well as actually developing the product being produced are heavily involved in the planning and defining the end point of the work.

Scrum teams work in timebox [13], which for Scrum are referred to as Sprints. A Sprint is a predefined period of time inside which you do as much work as you can and then consider what has been achieved. Knowing what you have achieved in the past allows you to predict what you can achieve next. These predictions help manage expectations as to what will be provided when, with the feedback of what has been achieved before.

Each Sprint starts with a planning meeting, where the work to be produced is agreed. How much and which items are influenced by the availability of the developers, and the items that the product owner has identified as most important to achieve. The requirements for each package of work should also be finalised here.

Each day in the Sprint the team, including the Scrum Master and Product Owner, meet to discuss what is being worked on and what issues may have been found. Identifying those issues, or impediments if a Developer is waiting on information from a third party, in good time allows the others in the team to help as appropriate.

At the end of each Sprint the work produced is demonstrated to as many people as are interested, users and Scrum team members.

The team also puts time aside after the demonstration to discuss in a retrospective the Sprint, what went well, what went badly, what could be done differently. Over time those retrospectives will shape the way the team works potentially to improve the workflows and interactions based on the current team members and the wider work environment of the team.

### *How We have Adapted Scrum to Work for us*

When we implemented our Scrum system we found one big barrier to following the standard framework, it was hard to identify a single Product Owner who could give us the time needed to take on that role. Instead, the developer team took on an element of that, with individual developers talking to groups of users and refining requirements for what those users were interested in developing. Whether that was a specific ISIS Instrument being converted from our older control system to our new one, or functionality like the script generator [14] which runs across many of the instruments. The priorities are often set in a less detailed way by a Project Board which is concerned about the running of the project, and the Science Advisory Group which is concerned with looking for things that impact and improve multiple instruments or scientific disciplines. This disconnect can lead to tension within the planning meetings as there isn't a single voice dictating the priority, and often leads to many of the tasks not being achieved in the best possible order. It also increases the amount of time needed to manage the expectations of our users.

Similarly, it was hard to gather any of our users to demonstrations at the end of each 20 day Sprint, certainly when ISIS was running their time was not available to us. As such, our demonstrations are made just to the development team each Sprint. When we deploy the latest version of IBEX to instruments we talk to the team of scientists who run instruments in appropriate batches to demonstrate what has changed since we last spoke to them, which can be many Sprints worth of work.

Due to the inclusion of operational tasks as well as development ones our stand up migrated from just an update, to a check on services and systems to ensure we got to errors before they occurred as well as the update.

Those operational tasks also mean that we have implemented a pre-planning meeting, to undertake an initial view of the work to be done in the upcoming Sprint, so that we are not spending the whole day in a planning meeting. This also benefits the focus and well-being of the team.

## *Where Scrum hasn't been the Answer for us*

The rigid timeboxes of Scrum, which are usually the same length, have often been unhelpful for the team. Attempting to undertake the change from one Sprint to the next during heavy operational times, some of which can be predicted, added a layer of stress to the process.

Whilst not specific to Scrum, Agile software development tends to employ a code and refactor mentality. You code the bare minimum to achieve what is required, and as you add new functionality you refactor the code to keep it looking tidy. The issue is the larger your code base the harder this can be, and as the development of IBEX has proceeded the harder it can be to implement a change for certain instruments without a large refactoring process which reduces the throughput of the team, and the team starts to lose any of the gains made with the other Agile processes compared to a more traditional project management framework.

Typically, Science focused organisations prefer those more traditional methods, as the code and refactor method is not easy to perceive, especially if you are not involved directly in the team and the work being done.

## *Where Scrum has Worked Well for us*

The use of a single backlog, and individual developers picking up the next ticket in the list has ensured that the skills and knowledge of the system has been shared well across the whole team has been beneficial for the operations side of our work.

The regular consideration of whether our way of working is appropriate has been beneficial as well. This has allowed our processes to grow and adapt to support the ISIS instruments in the best way.

## *What the IBEX Team are Currently Trying*

In keeping with those continuous changes as highlighted from the retrospectives, the team has been looking at other ways of working.

Because of the nature of deploying and dealing with an accelerator that runs in cycles of supplying beam to the instruments we are also experimenting with variable length sprints. Varying the duration of the sprint means that we can avoid the sprint end/start meetings falling when we anticipate that operational requirements will be high.

At present we are trying a different way of filling our list of tasks to undertake in a Sprint. Previously we would look at all the items that have to be worked on, which could mean that important items that didn't have a forceful enough advocate in the planning meeting would be missed. Instead, we are assigning certain members of the team to a "theme" which is more in keeping with eXtreme Programming (XP) [15], which is a different Agile framework.

XP is aimed at solving some of the issues found in large and brittle codebases that have been adjusted to fulfil ever-changing requirements. Adding some of the other XP practices as a team may improve the IBEX codebase, especially

the even greater emphasis on testing and the encouragement to have the programmer consider the actions of the user.

## *What We might Try Next*

Given that the prioritisation is a recognised stalling point, and whilst the team is small the number of products supported are numerous, some of the concepts employed by SAFe [16], which is the Scaled Agile Framework, might benefit the management of the workload. For example, having a "Program Backlog" for a longer term timebox, 3 months or longer, which agrees the work to be undertaken by the team from the business perspective. The team can then plan Sprints with a Scrum flavour, or XP, or more traditional methods, to achieve those agreed items.

## CONCLUSION

Whatever framework is used, Agile or non-Agile, the one tool that does seem to live up to the hype is the Kanban board. As mentioned previously it came from the assembly lines at Toyota, and the ability to track a task or item though an interface that is visible to all can lead to a sense of accomplishment. Whichever aspect of our work is being considered, whether it is an operational task or a new feature, being able to see whether it is waiting to be started, is being worked on, or is complete at a glance is one of the most useful actions we started using.

Different Agile frameworks, such as Scrum, XP, or SAFe, all have benefits and issues. Whilst pure Scrum would not suit the kind of rhythm we have at ISIS in relation to when user cycles start, it can be modified. Other frameworks may offer tools or ways of thinking to overcome the issues we have. However, Agile is a methodology, and the core concepts and where to place value are independent of any framework, and worth bearing in mind when undertaking any work.

# FAIRMAT - A CONSORTIUM OF THE GERMAN RESEARCH-DATA INFRASTRUCTURE (NFDI)

H. Junkes\*, P. Oppermann, R. Schlögl, A. Trunschke, Fritz Haber Institute, Berlin, Germany  
M. Krieger, H. Weber, Universität Erlangen-Nürnberg, Erlangen, Germany

## Abstract

The FAIRmat project, was selected on Friday, July 2, 2021 by the German Joint Science Conference (Gemeinsame Wissenschaftskonferenz – GWK) in a multi-stage competition of the National Research Data Infrastructure (NFDI). The project will receive funding to set up an infrastructure that helps making materials–science data FAIR: Findable, Accessible, Interoperable, and Reusable. This will enable researchers in Germany and beyond to store, share, find, and analyze data over the long term. During the five-year term, a total of 60 project leaders from 34 German institutions will work together in the FAIRmat consortium<sup>1</sup>.

## FAIRMAT CONSORTIUM

When applying for funding for the FAIRmat project, the following Objectives, work program and research environment were described in the letter of intent:

Prosperity and lifestyle of our society are very much governed by achievements of condensed-matter physics, chemistry, and materials science, because new products for the energy, environment, health, mobility, and IT sectors, for example, largely rely on improved or even novel materials. The enormous amounts of research data produced every day in this field, therefore, represent the treasure trove of the 21st century. This treasure trove is, however, of little value, if these data are not comprehensively characterized and made available. How can we refine this feedstock, in other words, turn data into knowledge and value? For this, a FAIR data infrastructure is a must.

Here is where FAIRmat (“FAIR Data Infrastructure for Condensed-Matter Physics and the Chemical Physics of Solids”) comes in. By building a FAIR research-data infrastructure for the noted fields, the consortium will lift the treasure trove of materials data, and therewith contribute to a disruptive change in the way science and R&D are conducted. Within FAIRmat the acronym FAIR is interpreted in a forward-looking way: Research data should be Findable and Artificial-Intelligence Ready. This new perspective will advance scientific culture and practice. This will not replace scientists, but scientists who use such FAIR infrastructure may replace those who don’t.

\* junkes@fhi.mpg.de

<sup>1</sup> FAIRmat press release

## Projekt Plan

FAIRmat will install a FAIR [1] data infrastructure for the wider area of condensed-matter physics and the chemical physics of solids. This represents a very broad range of different communities that can be characterized by either different classes of condensed matter (e.g. semiconductors, metals and alloys, soft and biological matter, etc.), by different techniques (e.g. ranging from crystal-growth and synthesis to experimental and theoretical characterization by a multitude of probes), or by functionality (exemplified here by battery materials, optoelectronics, catalysts, etc.). As a consequence, the data produced by the community are enormously heterogeneous and diverse in terms of the 4V of Big Data

- Volume (amount of data)
- Variety (heterogeneity of form and meaning of data)
- Velocity (rate at which data may change or new data arrive)
- Veracity (uncertainty of data quality).

Also note that many research data produced today may appear irrelevant in the context they have been produced. Being regarded as *waste*, they are not published. However, they may turn out highly valuable for other purposes.

So, the R in FAIR (reusability) also means “store, share, and recycle the waste!” To cope with all the diversity and complexity, a bottom-up approach that satisfies the needs of the different sub-communities is a must to foster acceptance by the community and participation of a large number of individual researchers and laboratories. FAIRmat sets out to tackle this challenge by a user-driven approach to develop easy-to-use tools and an infrastructure towards FAIR data processing, storage, curation, sharing, and future use of materials data. For the latter, a major goal of FAIRmat is making data artificial-intelligence (AI) ready.

Data obtained by a certain experimental technique for a specific sample of a selected material are only worth keeping if the sample is fully characterized and apparatus and measurement conditions as well as the measured quantity are described in detail. Likewise, computed data are only meaningful when method, approximations, code and

code version, as well as all computational parameters are known. In essence, we need an extensive annotation, i.e. a systematic *metadata* catalogue, also covering ontologies. This also includes the description of provenance and data quality (their usefulness for a given context).

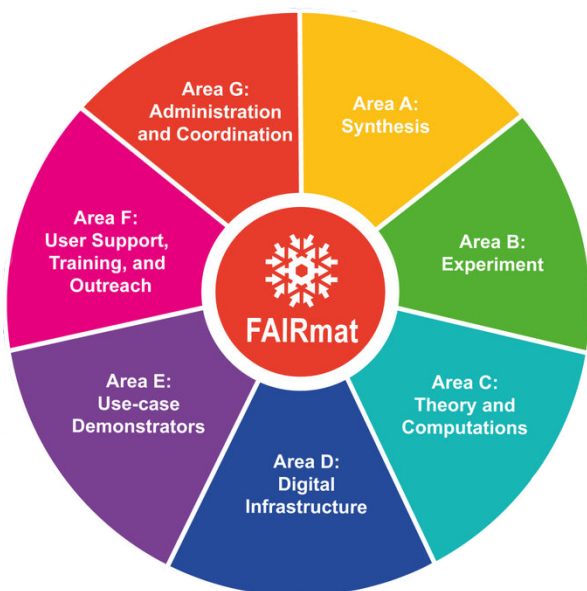

Figure 1: FAIRmat task areas.

To address all these aspects and to support basic science and individual researchers, we have identified several task areas (in short called Areas, see Fig. 1) that are sketched in the following:

- Area A – Synthesis – is dedicated to the full characterization of samples and the corresponding synthesis and growth processes. Without this information, reproducibility of materials and their properties with given quality will be hampered. The specific tasks will consider various synthesis routes, i.e., from the gas, liquid, and solid phases, and by assembly.
- Area B – Experiment – covers the microscopic characterization of materials by a broad variety of measurement techniques. Each of them comes with specific challenges concerning processing, curation, and storage, owing to differences in volume, velocity, data formats, etc. FAIRmat will exemplify its approach in a first phase by a representative selection of experimental probes.
- Area C – Theory and Computation – deals with numerical techniques to compute materials properties. Such techniques differ in the theoretical concepts, approximations, and numerical recipes, depending on the employed software. Our general approach to

tackle this diversity relies on the concepts developed by the NOMAD Laboratory [2]. The tasks of Area C concern extensions towards excitations and strongly correlated materials, as well as towards classical (particle-based) simulations and multi-scale modeling.

- Area D – Digital Infrastructure – will be a common brace to all other areas. Specific tasks will be dedicated to processing and decentral storage, creating a network of data hubs at different locations. The FAIRmat Portal, a web-based graphical user interface, including a Materials Encyclopedia [3], will allow for searching, accessing, and inspecting (meta)data from all over Germany (and worldwide). FAIRmat will develop and provide tools, from processing to post-processing, including analysis by artificial intelligence, and it will provide guidance and advancements of electronic lab-books (ELN), laboratory information management systems (LIMS), etc. Tight collaborations with HPC centers will ensure the embedding into the overall NFDI landscape.
- Area E – Use-Case Demonstrators – will highlight how the tools developed in the above areas will benefit different scientific communities and demonstrate hand-shakes and potential synergies with other consortia. The specific tasks of this area will cover in the first phase use cases on battery materials, heterogeneous catalysis, optoelectronics, spintronics&magnetism, metalorganic frameworks, biological physics applications, and artificial intelligence.
- Area F – User Support, Training&Outreach – will reflect our concept for how to engage with the community, to allow researchers to make use and handle the FAIRmat tools. A variety of workshops and other training opportunities will be offered and support for connecting data hubs to the overall data infrastructure.
- Area G – Administration and Coordination – will deal with all coordination and management issues and the embedding into the Overall NFDI. As such, it will address synergies with other consortia and the interaction with the NFDI Directorate.

FAIRmat represents a broad community of numerous researchers from universities and leading institutions in Germany. It builds on extensive experience with the worldwide biggest data infrastructure in computational materials science, the

Novel Materials Discovery (NOMAD) Laboratory and the association FAIR-DI e.V. FAIRmat aims at covering the full breadth of the Condensed Matter Section of the German Physical Society (DPG) with its 12 divisions, and is further supported by the Chemistry, Physics, and Technology Section of the Max Planck Society, the Bunsen Society for Physical Chemistry, and more. It is fully embedded internationally, e.g., in the Research Data Alliance, the European Open Science Cloud, GO FAIR, etc. and has signed Memoranda of Understanding with leading institutions worldwide, for example NIST (USA), Shanghai University (China), and CSC (Finland). FAIRmat will continue to raise awareness and acceptance of a FAIR research-data infrastructure in Germany, Europe, and beyond. [4, 5]

### Task D5

A universal and easy-to-configure software environment for measurement data acquisition and documentation is to be developed in Task D5 of the FAIRmat consortium.

In the field of Applied Physics, measurement setups with numerous specific measurement devices are often required – in each case adapted to the experimental problem. The diversity requires adaptable and easy-to-configure software for experiment control and data acquisition. But it's not just about the raw data. The experiment description, including all settings of the laboratory equipment used, the *metadata*, is also required. Only in this way, the experiment is documented completely and FAIR, and the valuable measurement data can be re-used by other scientists.

A prototype software developed at the chair of the Department of Physics at the Friedrich-Alexander-Universität (FAU) Department for experiment control with uniform and documented data output has been using for years [6]. In the FAIRmat project this successful concept will be put together with the open-source Experimental Physics and Industrial Control System (EPICS) [7].

## CONFIGURABLE EXPERIMENTAL CONTROL SYSTEM (CECS)

An existing system developed at the Department of Physics (FAU) has been built based on LabVIEW [8].

This system has proven itself at the department in research and teaching (Fig. 2). However, it does not satisfy the FAIR rules. By using LabVIEW, the system is:

- not open source,
- not operating system independent,
- not platform independent,
- is very poorly scalable.

Because of these missing features, the new CECS will be based on EPICS to control the scientific and measurement equipment [9].

Although EPICS is also suitable for small experiments [10], there is a persistent opinion that it can only be used by experts and larger teams of developers. This may also have to do with the fact that the aspect of data acquisition is rarely taught at universities nowadays. One aspect in the development of the new system is the possibility to introduce the users to the data acquisition step by step and transparently.

The system shall provide an easy to use graphical experiment configuration interface like the LAP Measurement before. We decided to implement this configuration interface in python. The packages from Python for Scientific Computing (Fig. 3) are used.

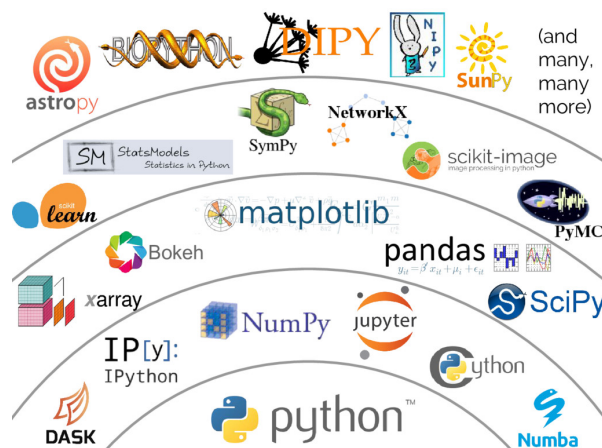

Figure 3: Python for Scientific Computing.

Python has now established itself as a programming language, especially in scientific subjects, and is taught at universities. The premise of CECS is the ability to configure a measurement system graphically without having to have programming knowledge. However, the GUI itself should not yet represent a direct implementation of a measuring program but generate a human (and machine) readable output which then serves as a *recipe* for a measuring program. This gives the possibility to let the configuration system generate a template (python), which one can refine and adapt to special needs. This makes it possible to get deeper and deeper into the system and to adapt it. The experience has shown that the scientist is willing to improve such templates if everything is presented transparently. The configuration system can also be used to specify general structures (e.g. storage location, file format, etc.) and thus achieve a standardized data recording. These *recipes* are excellent for documenting the workflows and can be linked to the documentation system (ELNs, etc). This also makes it possible to save these work steps in a versioning system. This makes it possible to repeat measurements.

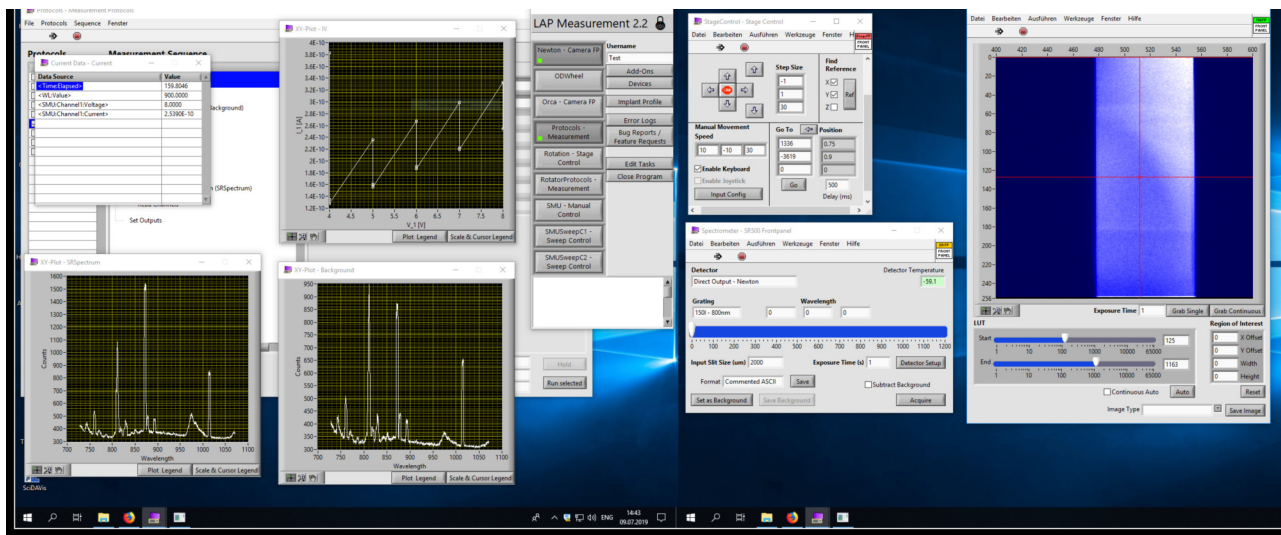

Figure 2: Example of the LAP Measurement User Interface.

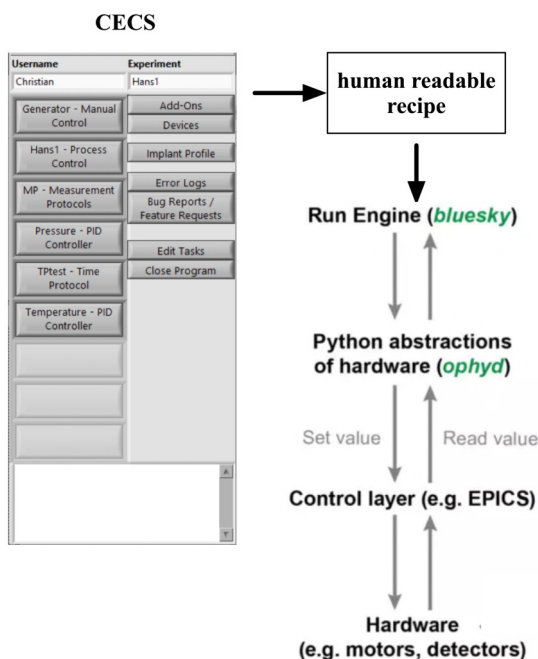

Figure 4: CECS recipe for Bluesky.

With the help of this *recipe*, a plan and virtual devices for Bluesky [11] are created. Bluesky stands on the shoulders of EPICS, and provides additional capabilities such as live visualization and data processing tools, and can export data into nearly any file format in real time. Bluesky was developed using python. That will make Bluesky simple for future scientists to modify, and to implement to new experiments.

## EPICS

**Complex systems** EPICS is a set of software tools and applications which provide a software infrastructure for use in building distributed control systems to operate devices

such as Particle Accelerators, Large Experiments and major Telescopes. Such distributed control systems typically comprise tens or even hundreds of computers, networked together to allow communication between them and to provide control and feedback of the various parts of the device from a central control room, or even remotely over the internet.

**High bandwidth, soft realtime networking applications** EPICS uses Client/Server and Publish/Subscribe techniques to communicate between the various computers. Most servers (called Input/Output Controllers or IOCs) perform real-world I/O and local control tasks, and publish this information to clients using robust, EPICS specific network protocols Channel Access and pvAccess. These protocols are designed for high bandwidth, soft real-time networking applications that EPICS is used for, and is one reason why it can be used to build a control system comprising hundreds of computers.

**Flexible and scalable** E.g. at the Advanced Photon Source national laboratory in the United States, EPICS is used extensively within the control system for the accelerator (see Fig. 5) and many of the experiments. There are about hundreds of IOCs that directly or indirectly control almost every aspect of the machine operation, while 40 workstations and servers in the control room provide higher level control and operator interfaces to the systems, and perform data logging, archiving and analysis.

**Roadmap** EPICS is developed through a collaborative open-source process where anyone is free to contribute to the EPICS family of software. In addition to this, heavy EPICS users – typically large scientific facilities – gather together in an open EPICS council to define a roadmap for the future direction of EPICS.

Figure 5: Beampipe at APS.

**License** EPICS is provided under an open source license called the EPICS Open License, which is similar to the BSD license. The EPICS licensing page [12] gives details and some history.

**Devices supported** The IOC, the Input/Output Controller is the I/O server component of EPICS. Almost any computing platform that can support EPICS basic components like databases and network communication can be used as an IOC. One example is a regular desktop computer, other examples are systems based on real-time operating systems like vxWorks or RTEMS and running on dedicated modular computing platforms like MicroTCA, VME or CompactPCI. EPICS IOC can also run on low-cost hardware like RaspberryPi or similar.

IOCs can support any number of records and record types. Similarly, record support does not contain device-specific knowledge, so each record type can have any number of independent device support modules. If the method for accessing hardware is more complicated than device support, then a device driver can be developed.

Currently, there are already a number of modules available to support instruments that are also commonly used in many experiments, such as temperature controllers (Eurotherm) and mass flow controllers (Bronkhorst) [liste]. These individual instruments can be connected to the IOC via serial or Ethernet interfaces.

## Bluesky

Bluesky [11] is a mini-ecosystem of co-developed but individually useful Python libraries for experiment control and data acquisition, management, and access. The project is developed and maintained by a multi-facility collaboration. The core includes a high-level hardware abstraction above EPICS, an experiment orchestration engine, a formally-defined schema for streaming data and metadata, and data access tools integrated with the open source scientific Python stack (see Fig. 6). It emphasizes the following virtues:

- Live, Streaming Data: Available for inline visualization and processing.

- Rich Metadata: Captured and organized to facilitate reproducibility and searchability.
- Experiment Generality: Seamlessly reuse a procedure on completely different hardware.
- Interruption Recovery: Experiments are *rewindable*, recovering cleanly from interruptions.
- Automated Suspend/Resume: Experiments can be run unattended, automatically suspending and resuming if needed.
- Pluggable I/O: Export data (live) into any desired format or database.
- Customizability: Integrate custom experimental procedures and commands, and get the I/O and interruption features for free.
- Integration with Scientific Python: Interface naturally with numpy and Python scientific stack.

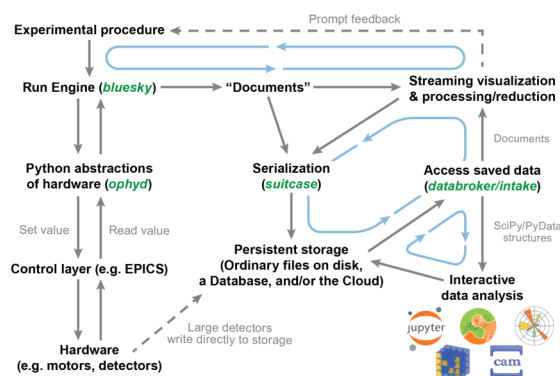

Figure 6: Bluesky project.

## APPLICATION AREAS

Another example of the ideal use of such a low-threshold data acquisition system is in catalysts research.

The challenges of the energy transition can only be solved with the help of innovative catalyst technologies. In catalysis research, a number of empirical concepts exist and predictions of theory are based on first-principles-based models that are subject to a variety of assumptions [13]. For simple reactions, material-function relationships have been predicted very successfully in this way. However, this is much more difficult for complex reactions and catalyst systems that are subject to high dynamics. Energy-relevant reactions, such as the hydrogenation of carbon dioxide, or important catalytic conversions for chemical hydrogen storage, are such complex reactions. Here, catalyst dynamics, i.e. the change in the state of the catalyst depending on the history of the catalyst and the reaction conditions, complicates the application of Big Data analyses and data mining methods because experiments performed according to different workflows can lead to inconsistent data sets. On the other hand,

the complex relationships between catalyst structure and functional properties of the catalyst can probably only be decoded with reasonable effort using artificial intelligence methods. For this purpose, reliable, reproducible data sets with high diversity are required. Handbooks in which the characterisation of catalysts and the determination of kinetic data are precisely prescribed serve to generate such data. These handbooks should specify what minimum data set should be generated for each catalyst and how the measurements should be performed. An example of a workflow in catalysis research is shown in Figure Fig. 7.

Figure 7: Workflow catalyst investigation.

These handbooks can then be converted into readable (human and machine) formats which can then be e.g. read as *recipes* by Bluesky.

For a typical setup in catalyse research see Fig. 8.

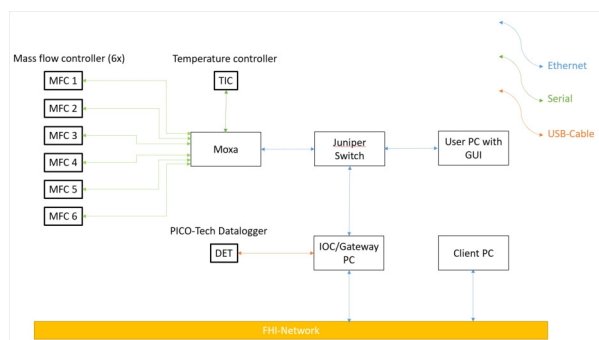

Figure 8: Block diagram of a reactor for testing catalysts.

A gateway computer (see Fig. 9) sets up its own experiment subnet and collects all the data. It is equipped with two Ethernet interfaces and up to 20 serial interfaces. In addition, custom device drivers were written to communicate with analog-to-digital converters, the Modbus protocol is used for this purpose.

## ACKNOWLEDGEMENTS

Alexander Fuchs and Johannes Lehmeyer (FAU) are implementing the new CECS system as part of the FAIRmat

project. Abdulrhman Moshantaf (FHI) implements the control system for the CatLab reactor systems.

# PROTOTYPE OF IMAGE ACQUISITION AND STORAGE SYSTEM FOR SHINE\*

Huihui Lv, Huan Zhao<sup>†</sup>, Danping Bai, Xiaomin Liu  
Shanghai Advanced Research Institute, Chinese Academy of Sciences  
201204 Shanghai, P.R. China

## Abstract

Shanghai High repetition rate XFEL and Extreme light facility (SHINE) is a quasi-continuous wave hard X-ray free electron laser facility, which is currently under construction. The image acquisition and storage system has been designed to handle a large quantity of image data generated by the beam and X-ray diagnostics system, the laser system, etc. A prototype system with Camera Link cameras has been developed to acquire and to reliably transport data at a throughput of 1000MB/sec. The image data are transferred through ZeroMQ protocol to the storage where the image data and the relevant metadata are archived and made available for user analysis. For high-speed frames of image data storage, optimized schema is identified by comparing and testing four schemas. The image data are written to HDF5 files and the metadata pertaining to the image are stored in NoSQL database. It could deliver up to 1.2GB/sec storage speed. The performances are also contrasted between a stand-alone server and the Lustre file system. And the Lustre could provide a better performance. Details of the image acquisition, transfer, and storage schemas will be described in the paper.

## INTRODUCTION

Motivated by the successful operation of X-ray FEL facilities worldwide and the great breakthroughs in atomic, molecular, and optical physics, condensed matter physics, matter in extreme conditions, chemistry and biology, the first hard X-ray FEL light source in China, the so called Shanghai High repetition rate XFEL and Extreme light facility (SHINE), is under construction. SHINE will utilize a photocathode electron gun combined with the superconducting Linac to produce 8 GeV FEL quality electron beams with 1 MHz repetition rate [1].

A myriad of image data will be generated by the beam monitor system, the optical diagnostics system and the laser system, providing the required parameters for the accelerator operation and physics research. In order to measure the laser accurately, CCD cameras in the optical diagnostic system capture images at high speed. In addition, the beam cross section measured by the seed laser system and the drive laser system provides the basis for the commissioning and adjusting the devices' parameters. Thus the accelerator has need of an efficient data acquisition and storage framework to accommodate the high-speed frames of image data, which is of great

value to engineers and physicists to identify errors, component deterioration, poor process optimization, etc. They can also be used for big data analysis to improve control system stability and efficiency, and reduce maintenance cost. We have designed a general image system which is less expensive, using regular commercial hardware. It could acquire, transmit, and store the images at the speed of 1000MB/sec. The relevant tools are also developed to retrieve and display images on real time. Details are described in the following sections.

## ARCHITECTURE

The whole system as shown in Fig. 1 can be divided into five functional modules, namely acquisition, transmission, storage, retrieval and online display.

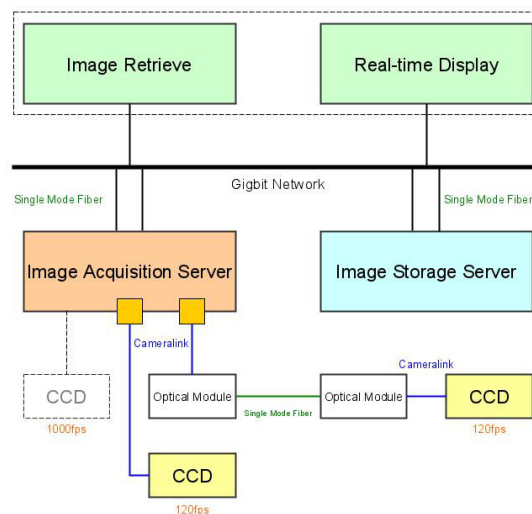

Figure 1: System Architecture.

Two CCD cameras with Camera Link interfaces take images at speed of 120 frames per second. One camera is directly connected to Camera Link Frame Grabber through a cable, while the other is connected to Camera Link Range Extender over a fiber cable, that solves distance limitation of Camera Link. Images are processed and packaged by the acquisition server and then transmitted to the storage server and online-display server through 10 Gigabit Ethernet, using ZeroMQ protocol for communication. After the storage server receives the data stream, it first unpacks it, then saves the image data in files as HDF5 format, and the metadata organized to facilitate searchability in MongoDB database. The web-based retrieval system is based on standard J2EE(Java 2 Platform, Enterprise Edition) Glassfish platform. It is designed to handle remote queries for historical records.

\* Work supported by Shanghai Municipal Science and Technology Major Project(Grant No. 2017SHZDZX02)

<sup>†</sup> zhaohuan@zjlab.org.cn

The online display server can display the images captured from two cameras in real time.

## Acquisition Module

There are three commonly used camera interfaces as shown in Table 1.

Table 1: Camera Interfaces Comparison

Interface	Performance
GigE	slower speeds, 100m cable length
Camera Link	5.4Gbps, short cable length, cost effective
CoaXPress	6.25Gbps, short cable length, expensive

GigE is usually used in systems with less critical speed and timing demands. Camera Link offers higher link speed up to 5.6 Gb/s (Gigabits per second), but cable length is limited and cable cost is a bit high. CoaXPress supports the transfer rate up to 6.25Gb/s, and it is more expensive than Camera Link. Taking cost and performance into consideration, we choose Camera Link and utilize a fiber optic range extender to resolve distance limitation by connecting camera to frame grabber over single fiber cable.

Figure 2: Camera Link Connection.

There are two cameras taking pictures at the same time. One is directly connected to Camera Link Frame Grabber through CL cable that is about 10 meters. The other is connected to CL Range Extender over single fiber cable that solves distance limitation of Camera Link. As shown in Fig. 2, the system is constructed of two converters, one on the camera side and one on the Camera Link frame grabber side. Camera Link Frame Grabber is a PCI Express-based device which allows high bandwidth communication between the device and the motherboard/server. The models of all devices are as shown in Table 2.

We use C language /Matrox Imaging Library(MIL) to develop programs for image capture, processing and annotation. MIL software development kit (SDK) is designed to reduce time and effort required to bring solutions. However, MIL SDK is mainly developed and utilized for Windows OS and has little support for Linux. It even cannot be installed in Linux. In order to install and use it in Linux, we tried multiple Linux versions, e.g.,

CentOS, Debian and Ubuntu. And finally we found Ubuntu 14.04 could match MATROX API.

Table 2: Devices List

Device Name	Performance	Number
CCD Camera	JAI SP-5000M-PMCL	2
Range Extender	Kaya Camralink Range Extender	2
Frame Grabber	Matrox_RAD EV 1G CLSF	2
CL cable		4
SFP module		2

## Transmission Module

We make use of ZeroMQ[2] for image communication. ZeroMQ is a high-performance asynchronous messaging library, aimed at use in concurrent applications. ZeroMQ supports common messaging patterns (e.g., pub/sub, request/reply, client/server) over a variety of transports (e.g., TCP, in-process, inter-process, multicast and more), making inter-process messaging as simple as inter-thread messaging. We use pub/sub and request/reply patterns through TCP channels in the application.

Figure 3: ZeroMQ Communication.

As shown in Fig. 3, request/reply connects the online display server (client) to the acquisition server (service), implementing the handshaking which should be successful before the transfer of data. Request/reply depends on a fixed send -> rcv / rcv ->send sequence. The connection will be interrupted if the sender does not receive the answer. Thus we modified two configuration parameters to realize that even if the sender does not receive a reply, it can continue to ask until the handshake is successful. The other two connections of acquisition server/storage server and display server/storage server are the same. Every two servers must shake hands to ensure the transmission synchronously.

Publish/subscribe connects the acquisition server and display/storage server. The publish-subscribe pattern is used for one-to-many distribution of data from a single publisher to multiple subscribers in a fan out fashion. Unlike request/reply pattern, messages are sent directly to the two servers, without the knowledge of what or if any subscriber of that knowledge exists. We use pub/sub pattern to transmit the stream of image data, allowing two clients to consume the stream.

In order to get high transmitting speed, we modify the parameters of the ten gigabit network switch and servers, making multiple parameters match each other. After the modification, the transmission speed increases from 500MB/sec to 600MB/sec. To further increase the speed, we bind two network interfaces into a single logical 'bonded' interface as shown in Fig. 4. Network bonding increases the network throughput and bandwidth. Whereas network bonding increases CPU consumption and reduces overall performance. So we use two networks logically and in our program, data are transmitted through two networks at the same time. The total transmission speed increases to 1200MB/sec. That could satisfy our need.

Figure 4: Network Bonding.

## Storage Module

The image data represents an image, while the metadata pertaining to the image includes details relevant to the image itself as well as information about its production. What's more, the metadata is organized to facilitate searchability [3].

The image metadata involves:

- Number of the camera capturing the image
- Timestamp to the millisecond
- IP address
- Port number
- The camera resolution
- The depth of every pixels of the camera
- The gain of the camera
- The exposure time

We have designed four schemas for storage.

### Storage Schema 1

The image data itself and the metadata are both stored in MongoDB. The image data is stored as a 2-D array of 8-bit unsigned integers.

### Storage Schema 2

We make use of HDF5 as the permanent storage to store the image data, while using MongoDB as the index to store the metadata. The path where the image is stored is managed by MongoDB and used as the index to retrieve the HDF5 file.

### Storage Schema 3

MongoDB is replaced by Cassandra. The metadata is stored in Cassandra as the index and the image data is stored as HDF5 format.

### Storage Schema 4

Similar to Schema 2, we use DIRECT CHUNK WRITE strategy to write the data to HDF5 files. Others are same.

The storage performance is tested using three different sizes of gray level image, 1024×1024 bytes (1 MB), 1024

× 2048 bytes (2 MB) and 2048 × 2048 bytes (4 MB), respectively. For each image, we record the time consumed to store 100 frames, 200 frames, 300 frames, 400 frames and 500 frames of images. The testing is performed in a rack-mounted server with 512 GB of RAM and 960 GB of SSD hard disk, running Linux/CentOS 7 operating system. There are 2 physical CPUs and each CPU has 6 cores in the server.

The test program is written to perform the same store operation 50 times constantly. Then we calculate the storage speed in MB/sec. The mean value with error bars is displayed in Fig. 5. The number of frames is on the x axis. The y axis corresponds to the storage speed in MB/sec. The image size is given on the bar. For instance, 1 M represents the image of 1024×1024 pixels (width: 1024, height: 1024) and each pixel is represented by a byte (8 bits).

Figure 5: Test Results of Four Storage Schemas.

As we can derive from Fig. 5, to use MongoDB to store the metadata and HDF5 DIRECT CHUNK WRITE to store image data provides the optimal storage performance, about 1200MB/sec. It seems to be difficult to increase the speed from the software design. So as to achieve a higher storage speed, we can consider to extend the hardware. However, the cluster provided by several servers could deliver a combined throughput. If we stream the image data to a cluster, it is likely to further improve the storage speed. Consequently, we use three servers to deploy a Lustre file system. There are a single metadata target (MDT) and two object storage targets (OST). MDT holds metadata information, which is stored separately from file object data. The data content is written to OSTs to persistent storage. Meanwhile, we configure two clients mounting to the Lustre file system using the 10 gigabit network protocol. The image storage performance is tested in the cluster. And we calculate the sum of the storage speed from two storage processes. It is about 1500MB/sec. The result shows that the cluster provides more optimal performance than the stand-alone server. While the Lustre in the test is a small scale distributed file system, which is composed of three servers mounted by two clients. The Lustre system can scale to large scale platforms provided by more servers, and present larger capacity storage space to more clients. Then we can obtain superior combined throughput performance. If there is higher requirement of data storage speed, the Lustre file system could scale easily in the future.

### Retrieval Module

The retrieval system is based on Maven J2EE Glassfish platform with MongoDB and HDF5 utilized as backend data storage. As shown in Fig. 6, the application architecture diagram is composed by three parts: the persistence layer, the business logic layer and the client layer. The persistence layer is a general data storage container for both metadata and image data. The business logic refers to the processing demand to the data carried by the specific client. Data APIs are predefined database queries to facilitate application programming, which provides convenient access to the database. Data APIs use JDBC Connector to connect to MongoDB database to get a specific image's timestamp, cameraNo, index, etc. With index to HDF5 files, it uses Java HDF5 Interface (JHI5)[4] to access the image in HDF5 format. HTTPServlets process demand to the data carried by the web client and return data in JSON format. The client layer utilizes HTML5 Canvas to draw the pixel-level image, Bootstrap to style response websites and jQuery to handle the event handling and Ajax.

Figure 6: Retrieval Module Architecture.

### Online Display Module

The online display module (Fig. 7) makes use of PyDM[5] to build graphic user interface. The image data transmitted through ZeroMQ protocol from the acquisition server are imported to the EPICS database located in the display server by PCASpy[6] interface. The total number of image frames acquired from the acquisition server is also displayed on this interface, compared with the number of images having been stored into the storage server (as shown in Fig. 8). The two are equal and it can indicate that there is no packet lost.

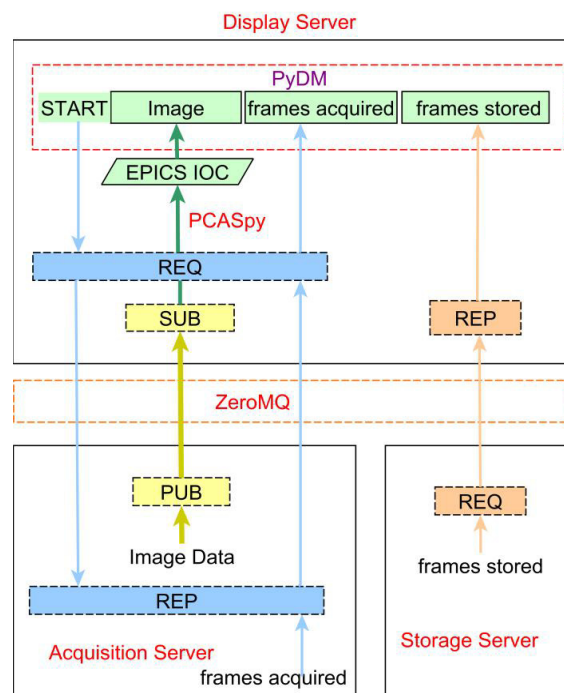

Figure 7: Online Display Module.

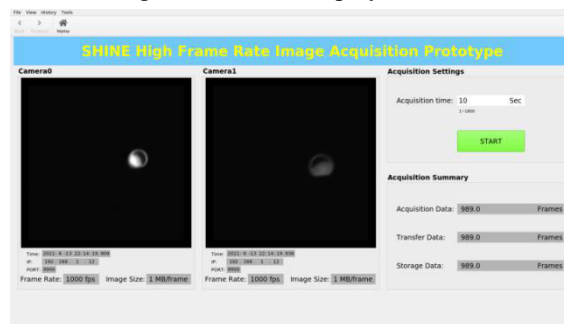

Figure 8: Online Display Interface.

### TESTING

Test is taken by two cameras (120frames/sec, 1024\*1024) illuminated by a diode which is excited by a sine wave signal generator as shown in Fig. 9. According to all images from one camera within two seconds, we find the brightest point of each image, the point with the largest gray value. Then we fit a sine curve using the least-squares method. The curve is shown in Fig. 10. The fitting frequency is equal to the frequency of the signal generator.

Figure 9: Testing.

Figure 10: Fitting Curve.

We also test the performance of a higher speed, 1000 frames/sec with each image size 1MB. We monitor the number of HDF5 files generated every 5 seconds by Linux command 'watch -n 5 "ls |wc -l |tee -a num.log"'. The result is shown in Fig. 11. Then the storage speed could be calculated,  $500\text{MB} \times 10 / 5\text{sec} = 1000 \text{ MB/sec}$ . It shows that our system can get the speed of 1000MB/sec.

Figure 11: Test Results of 1000 Frames/sec.

## CONCLUSION

The system is able to acquire, transmit and store the image data at speed of 1000MB/sec stably without loss. The solution is based on Camera Link interface to capture high-frame rate images, ZeroMQ protocol to transmit stream data, together with HDF5 to store the heavy image data and MongoDB for indexing the heavy data in HDF5. Multi-threading and network binding increases the holistic system performance as well. The hardware architecture and software design is not limited to image data. It could also manipulate the waveform data for SHINE.

# MANAGE THE PHYSICS SETTINGS ON THE MODERN ACCELERATOR\*

T. Zhang<sup>†</sup>, K. Fukushima, T. Maruta, P. Ostroumov, A. Plastun, Q. Zhao  
Facility for Rare Isotope Beams, Michigan State University, East Lansing, USA

## Abstract

The Facility for Rare Isotope Beams (FRIB) at Michigan State University is a unique modern user facility composed of a large-scale superconducting linac capable of accelerating heavy-ion beams from oxygen to uranium. An advanced EPICS-based control system is being used to operate this complex facility. High-level physics applications (HLAs) developed before and during the staged commissioning of the linac are one set of the critical tools that resulted in achieving the commissioning goals quickly, within several shifts. Many of these HLAs are expandable to other EPICS controlled accelerators. Recently developed HLAs deal with the management of extensive data to achieve the repetitive high performance of ion beams in the entire linac measured by non-destructive diagnostics instruments, and open the possibilities to explore the extra values out of the data. This paper presents our recent significant development and utilization of these HLAs.

## INTRODUCTION

The LINAC of the Facility for Rare Isotope Beams project at Michigan State University is a unique modern superconducting accelerator, it is designed to deliver all the stable isotope beams with multiple charge states to the kinetic energy higher than 200 MeV per nucleon, and power of 400 kW on the target [1]. Since the mid of 2017, staged commissioning has achieved a series of remarkable successes [2–4]. Now FRIB project is approaching the next milestone, that is to generate and separate the rare isotope beams at and after the production target system.

To expedite the beam commissioning, various kinds of high-level physics applications (HLAs) have been developed and deployed to FRIB controls network. The Python-based software framework called *phantasy* is designed and developed to drive the entire high-level communication between the accelerator and physicists [5]. Based on *phantasy*, the Python interactive scripting environment is implemented and utilized to prototype the physics tuning algorithms, and also used to control the machine in the advanced expert mode. Graphical user interface (GUI) applications have been developed with well-tested physics algorithms to make machine tuning simple and confident. General tools and GUI widgets based on Qt framework [6], together with physics-related widgets have been developed as another major part of *phantasy* framework to streamline the GUI application development.

To better organize the data generated in the controls network, software applications have been developed to ensure the quality of data, e.g. integrity, reliability, and availability, etc. The next coming sections will present the software development activity of FRIB high-level physics controls, the use cases of the development on the accelerator of FRIB, and the approach of how the physics data is managed.

## THE EVOLUTION OF PHANTASY

Originally, *phantasy* was designed for the object oriented high-level controls for EPICS-based accelerator system. The main goal was to abstract the entire machine to be controllable in the ecosystem of Python, by using the enormous third-party library to fulfill the machine tuning missions [7].

Several critical issues need to be addressed with neat solutions before accomplishing such high-level controls environment:

- Properly present the machine in the view of computing environment.
- Properly handle the value of physics quality in different scenarios, either from the view of device control or physics model.
- Properly interface with the physics model, which is usually separately developed to simulate the accelerator behavior.
- Properly manage the development resources, i.e. source code, support data files, testing, deployment, etc.

With *phantasy*, the physics model-independent machine representation could be generated in the view of object-oriented. The machine is represented as a series of devices, each device is an instance of a general abstracted high-level element class, which is composed of controllable and non-controllable attributes. The non-controllable attributes usually present the static properties of the device and the controllable ones are connected to the process variables which are served through EPICS IOCs. The device control is fulfilled via Python object getter and setter operations, through dotted-syntax. All the device information is maintained separately, such a way the core code of *phantasy* could also be working with other accelerator systems, the same strategy has been applied to the GUI application development.

The interpretation of the values for physics qualities is handled in another separated application called UNICORN [8], which is a web application that features REST API. The Python interface “python-unicorn” [9] is also developed to request either value in physics or engineering unit. The mapping rules between physics and engineering world could be defined based on the needs of the physics model, e.g. for

\* Work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661, the State of Michigan and Michigan State University.

<sup>†</sup> zhangt@frib.msu.edu

the dipole, the current in Ampere could be interpreted to Tesla as the magnetic field strength, or Tesla-Meter as the integral strength, thus two rules could be defined in UNICORN, use `.B` to read the device setting in Tesla, and `.B = <new-value>` to set with new magnetic field in Tesla, it is also possible to read it into Tesla-Meter via `.TM` if it is defined in the device configurations.

Speaking to the model interface, `phantasy` now supports modeling the accelerator with FLAME [10]. The internal virtual accelerator component is also developed with such a linear fast executing model. On top of the abstracted device control layer, any physics tuning algorithms could be prototyped quickly in any Python terminal environment, Jupyter [11] is used as the main one. `phantasy` is also designed with the ability to adapt with other physics models, to do that, the routine of model-dependent machine representation needs to be developed.

All the software development is managed with modern tools. GIT [12] is used to manage the source code, the whole physics application development is managed with the internal Bitbucket service [13]. More than 20 Debian packages are built to deploy the development into FRIB controls network via the automated CI/CD infrastructure [14]. Accumulated code changes will be released as new versions of software and deployed into production through the automated pipeline.

Recently, phantasy has been enhanced a lot on the GUI application development side. New GUI widgets have been developed for PyQt application development. To unify the UI style and make use of existing resources, command-line tools also have been developed and improved. One can initiate the app skeleton by “makeBasePyQtApp“ command. It is the plan to release all the development through PyPI [15] (some of the packages have already been published there) and PPA [16] in the near future, along with the documentation sites, which require a lot of effort.

## MANAGE THE DATA IN THE CONTROLS NETWORK

From the view of the high-level physics controls, there are different kinds of data distributed and generated in the controls network.

The first category is device information, e.g. the name, size, location, controls process variables, etc., all these information is already managed in phantasy framework, with above-mentioned dotted-syntax, all these attributes could be reached naturally in Python environment, as well as IOC application.

The second category is the data from other web services. For instance, the data from directory service ChannelFinder [17], the data from alarm services, the data from Archiver Appliance [18], the data from Olog [19], and the data from UNICORN service, etc.

The third category is the data from various software IOCs. When building the high-level physics controls system, software IOC applications are developed to fulfill the specific

data processing tasks, the results are either integrated into phantasy or exposed as PVs.

The fourth category is the data from physics models, which could be lattice files, simulation results.

Last but not least one is the developed software itself.

On the other side, in the view of machine tuning, all these data should be well-organized to achieve the following goals:

- The developed machine tune should be accurately saved.
- The saved machine tune should be accurately restored.
- There must be some way to verify the restored machine tune.
- There must be some way to easily apply one machine tune to different charge states and ion species.

To address them, systematic software development is undergoing.

### Physics Settings

Here the data of physics settings is defined as a series of device set values along the accelerator beamline. The app named “Settings Manager” has been developed to manage the physics settings. “Settings Manager” is one of the GUI apps that is built upon `phantasy` framework, it can work with different machine/segment, which is defined in “phantasy-machines” (a package that keeps all the configurations of machine/segment for `phantasy`).

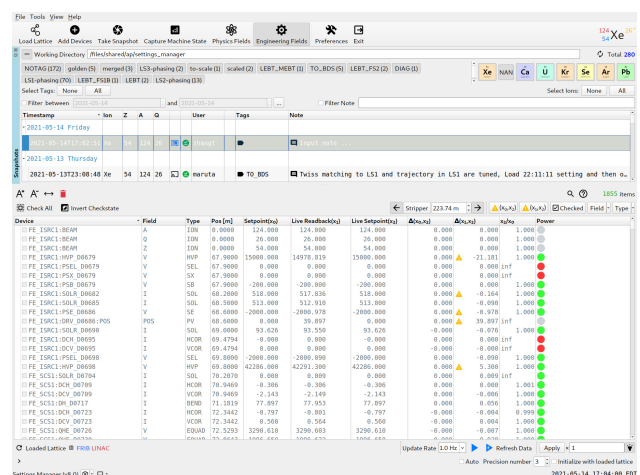

Figure 1: Main user interface of “Settings Manager”.

Figure 1 shows the main user interface of “Settings Manager”. Buttons in the toolbar indicate the features it provides, as well as the current working ion species shown at the right-most. Right below the toolbar is the area for saved physics settings or snapshots. All the snapshots are sorted by the saved time by default, all come with the ion species info, saved user name, tags, and note. “Tags” is a string of words separated by a comma, to label the snapshot data, and “Note” is a string for arbitrary additional info about this snapshot.

The expanded snapshot area is showing in Figure 2, it features tabular view of all the snapshots, supports sorting and filtering, and convenient buttons for filtering by ion names or tags, to quickly locate the snapshot entries.

Figure 2: Snapshot management window of “Settings Manager”.

The snapshots could be loaded and presented in the right bottom area by double-clicking or right-clicking context menu actions. In Figure 1, one can see the listed device settings, each row is for one “Field”, each “Field” is a control knob, the device info could be reached via the context menu on the “Device” column. The saved device settings are shown in column “Setpoint( $x_0$ )”, while current settings are in column “Live Setpoint( $x_2$ )”, column “ $\Delta(x_0, x_2)$ ” indicates how they are matched or not.

The procedure for applying saved settings to machine is, first check the fields that need to be applied (check by clicking, keyboard and context menu actions), then press “Apply” button to do process one by one, the details of device settings could be controlled via the “Preferences” menu. One feature to support multiple charge states settings is applying with a scaling factor, which is right after “Apply” button, the value will be automatically calculated, but also could be modified, default is 1.0. After applying all the settings, recheck column “ $\Delta(x_0, x_2)$ ” to make sure the current settings are updated accurately, for the case of applying with a scaling factor, check column “ $x_2/x_0$ ”, which is expected to be the value of the scaling factor.

The data model of the snapshot supports exporting to different kinds of data files for portability, typical data formats are XLSX and HDF5, from which one can have the metadata and physics settings data, as well as the machine state data.

Machine state data is to address how to verify the machine performance under one specific physics settings. The definition of it is the readings from various diagnostics devices when taking the snapshot. The configuration file for machine state data capturing is a predefined file shown in Figure 3, could work with CLI tool `fetch_mach_state` (which is deployed with `phantasy-apps` package) as well. When taking a snapshot, the machine state data is first captured based on the configuration file, then capture current

```

```

Figure 3: An example of the configuration file for machine state fetching.

physics settings, and save them together into one snapshot, finally shown as one entry in the snapshot window. “Settings Manager” supports managing snapshots in a database or a directory. The machine state data also could be captured at any time via the tool in the toolbar. The obvious benefit of saving physics settings with machine state is that all the data actually been accurately “labeled”, which is very valuable for the future machine learning application.

Figure 4 visualizes the trajectory along the FRIB LINAC from the machine state data, one can also visualize other qualities, e.g. BPM phase, amplitude, to verify the physics settings.

It is also worth mentioning that the physics settings are also pre-generated from physics models before the beam commissioning and imported into “Settings Manager” for use, which significantly speeds the beam tuning efficiency.

## ARCHIVED DATA

Another essential data source for the physics application software is the data archiver. FRIB is using the site-maintained Archiver Appliance application [18] to keep archived PV values. The archiving and data retention policies are defined in each IOC. The time-series data served by Archive Appliance could be visualized in CS-Studio data browser application.

To integrate the archived data into the Python ecosystem, a dedicated Python client package has been developed, called “pyarchappl” [20], which is not only designed for communicating with Archiver Appliance via REST API, but features with data-wrangling capabilities, to work with the archived data with popular data science tools.

One of the useful command-line tools distributed with `pyarchappl` is `pyarchappl-get`, which is a general command for data retrieval from Archiver Appliance. Figure 5 shows the user guide of the command. One can easily get timestamp aligned archived PV data in the form of CSV, XLSX and HDF5.

The retrieved data set could be processed by reading the data file. Figure 6 is the heat map view for the x and y

Figure 4: Typical example of trajectory visualization with BPM data

```

tong ➤ pyarchappl-get -h
usage: pyarchappl-get [-h] [--url URL] [--pv PV_LIST] [--pv-file PV_FILE]
                    [--from FROM_TIME] [--to TO_TIME] [--resample RESAMPLE]
                    [--verbose] [-o OUTPUT] [-f FMT]
                    [--format-args FMT_ARGS]

Retrieve data from Archiver Appliance and export as a file.

optional arguments:
  -h, --help            show this help message and exit
  --url URL              URL of Archiver Appliance, default is FRIB FTC
                        archiver (default: None)
  --pv PV_LIST           List of PVs for retrieval, each define with --pv
                        (default: None)
  --pv-file PV_FILE     A file for PVs, one PV per line (skip line starts with
                        #), append each to pv_list (default: None)
  --from FROM_TIME      A string of begin time in ISO8601 format (default:
                        None)
  --to TO_TIME          A string of end time in ISO8601 format (default: None)
  --resample RESAMPLE   The offset string/object representing target
                        conversion, e.g. '1s' for resample with 1 second
                        (default: None)
  --verbose, -v         Verbosity level of the log output, 0: no output,
                        1(-v): output progress, 2(-vv): output progress with
                        description (default: 0)
  -o OUTPUT, --output OUTPUT
                        File path for output data, print to stdout if not
                        defined (default: None)
  -f FMT, --output-format FMT
                        File format for output data, supported: csv, hdf,
                        excel, html, ... (default: csv)
  --format-args FMT_ARGS
                        Additional arguments passed to data export function in
                        the form of dict, e.g. {"key": "data"} (for hdf
                        format) (default: {})

examples:
# Retrieve raw PV data in the defined time frame
$ pyarchappl-get -o data.csv -v \
  --pv LS1_CA01:BPM.D129:XPDS_RD --pv LS1_CA01:BPM.D129:YPDS_RD \
  --from 2021-04-15T20:10:00.000Z --to 2021-04-15T21:25:00.000Z \

# Align the timestamps, resample at 1 second
$ pyarchappl-get -o data.csv -v \
  --pv LS1_CA01:BPM.D129:XPDS_RD --pv LS1_CA01:BPM.D129:YPDS_RD \
  --from 2021-04-15T20:10:00.000Z --to 2021-04-15T21:25:00.000Z \
  --resample 1s
  
```

Figure 5: Help message of pyarchappl-get.

readings of the 75 BPMs along the accelerator through first LINAC segment (LS1) to the first fold segment (FS1), in the time range from 16:00 to 20:00 EDT on Oct. 13, 2020, total 72000 data entries. The blue boxed areas are the minimal absolute trajectory readings, which is within the range of  $\pm 0.5$  mm after trajectory correction had been performed.

Figure 6: Heat map plot of time-series archived data for central trajectory in x and y.

Tools also have been developed to retrieve the physics settings at the time when the trajectory reached the minimal, then the retrieved data is processed to be a new snapshot for

“Settings Manager”. All these tools will be integrated into “Settings Manager” as new context menu actions.

## CONCLUSION

The high-level physics controls software framework phantasy is continuously moving forward. The enhanced toolkits for PyQt GUI development greatly streamlined the HLA development. The solid software solution has been designed and implemented into the data management of FRIB LINAC commissioning. “Settings Manager” has been developed and used to accurately manage the physics tunes for the entire LINAC, as well as keep the machine state dataset to make the data of physics settings more valuable for other applications. “Settings Manager” expedites the LINAC tuning for multi-charge state operating mode. The Python client package “pyarchappl” for Archiver Appliance has been designed and developed for easy data retrieval and general data analysis with Python third-party packages. The data management solution is continuously consolidating to prepare for the concrete machine learning applications.

## ACKNOWLEDGMENTS

The authors would like to thank A. Cariveau and T. Ashwarya for the useful discussions.

### Abstract

Findability, accessibility, interoperability, and reusability (FAIR) form a set of principles required to ready information for computational exploitation. [1] The Energy Materials In-Situ Laboratory Berlin (EMIL) at BESSY II [2], with its unique analytical instrumentation in direct combination with an industrially-relevant deposition tool, is in the final phase of commissioning. It provides an ideal testbed to ensure workflows are developed around the FAIR principles; enhancing usability for both human and machine agents. FAIR indicators [3] are applied to assess compliance with the principles on an experimental workflow realized using Bluesky. [4] Additional metadata collection by integrating an instrument PID [5], an electronic laboratory book, and a sample tracking system is considered along with staff training. Data are collected in Nexus format and made available in the ICAT repository. This paper reports on experiences, problems overcome, and areas still in need of improvement in future perspectives.

### INTRODUCTION

The FAIR principles – findability, accessibility, interoperability and reusability – are well known and serve as guidelines for data curators and data management stewards along with IT professional; people who manage rather than generate data. Here, we apply high-level data management concepts contained in the FAIR principles on the level of granularity of a complex, beamline-based materials research infrastructure – the EMIL infrastructure at BESSY II, that is in its final phase of commissioning. In doing so we clarify the relationship between data generator, research infrastructure, and data infrastructure; demonstrating how the FAIR principles relate to each actor.

To report the present state of work, the remainder of this paper is organized as follows: First, we sketch the complex scientific infrastructure of EMIL at BESSY II focusing on its end station SISSY I (Solar energy material In-Situ spectroscopy at the Synchrotron). Since the FAIR principles are independent of each other [1] we continue with a discussion of their implementation following the sequence reusability,

interoperability, accessibility, and findability. By balancing user effort and data accuracy we proceed to focus on the sequence of measures taken to find an appropriate workflow. Finally, we apply FAIR indicators and assess the SISSY I end station.

Throughout the paper, the convention of [3] is adopted to distinguish between data and metadata. Here, data refers to the primary output of detectors or other objects of outstanding scientific interest while metadata belongs to information that helps to analyze the primary data such as the sample or the sample's properties. If both types of data are addressed the term (meta)data is used.

### OUTLINE OF EMIL INFRASTRUCTURE

The Energy Material In-Situ Laboratory Berlin (EMIL) [2,6,7] is a newly implemented, complex research infrastructure at BESSY II which combines state-of-the-art synthesis and deposition systems on industry-relevant scale with sophisticated in system/in situ/operando x-ray spectroscopy capabilities, outlined in Fig. 1. By focusing on study of the growth of materials and the formation of functional interfaces EMIL tracks the evolution of material properties through successive processing steps. A fully automated ultra-high vacuum multi-chamber system built by PREVAC [8] transfers samples between various production sites, analysis tools, and the SISSY I end station. As a result samples are changing both their state and location within EMIL and may be placed at in SISSY I end station for characterization.

The SISSY I end station houses an electron analyzer able to detect electrons with kinetic energies between 50 eV and 10 keV. Exploiting the full energy range of EMIL's two-color beamline, photon energies between 80 and 10000 eV – delivered by the two canted undulators (UE48 and U17) – can be used to probe the sample properties by soft and hard x-ray photoelectron emission spectroscopy. [9] Currently, the SISSY I end station is in the final stages of commissioning and so provides an excellent test bed to implement the FAIR principles during the transition to user operation.

The instrument and beamline are controlled with EPICS [10]. Devices are accessed in a Python environment through

\* gerrit.guenther@helmholtz-berlin.de

the abstraction layer Ophyd [11]. The Python library Bluesky [4] uses this abstraction layer to operate the instrument and beamline hardware. Measurement data and metadata are saved together in a mongoDB database [12], which is not publicly accessible. A more detailed outline of the architecture is found in [13].

Figure 1: Schematic presentation of the Sissy@EMIL's setup connecting various processing and analysis chambers, among them the Sissy I endstation.

## REUSABILITY – RICHNESS OF (META)DATA

The Sissy I operation is envisioned to be highly automated. It provides well-defined experimental environments enabling the automatic collection of detailed (meta)data. Unfortunately, not all critical metadata can be collected automatically and crucial information such as sample name, calibration measurements, special setups, or notes during the experiment may be buried in a paper log book and run the potential risk of being permanently lost.

### Sample Information

In most cases sample information cannot be automatically collected but is critical for data reuse. For that reason, we implement the collection of sample information on the instrument level by defining a sample pseudo-axis in the Bluesky control software of Sissy I to enter the sample name, chemical formula, InChi key [14], or another sample identifier. The sample axis is treated in the same way as any motor position which would allow to define the sample by a script running for a lengthy period for example, when a sample holder with several samples is used.

At Sissy I all samples are transferred through the EMIL vacuum transport system, a highly automated environment

in which samples may undergo successive steps of physical treatments and analysis. Each operation is stored in a SQL database and therefore the entire history of a sample is accessible. We implemented a readout routine to update the sample-pseudo axis on demand. If necessary, this can be corrected or enriched by the user during the experiment. It automatically identifies the sample holder currently at Sissy I through the sample database by using the date and time of the measurement. Once the sample holder is identified, the sample information is extracted from the sample database and former entries of the sample are collected in a chronological list of applied processes and measurements. In case the initial state of the sample when entering EMIL corresponds to an industrial standard (such as a silicon wafer) the sample would be fully defined.

For other cases we provide workarounds to add information manually. We implemented a graphical user interface to help describing the sample and enrich (meta)data by additional files such as photos, notes, or documents after the measurement. Further, we implemented a routine to trawl pdf documents from the HZB's proposal system GATE for samples which can be selected from a drop-down menu to add their information. However, direct access to the proposal system would be advantageous and has to be established.

### Electronic Logbook – Another Kind of Metadata

Paper logbooks are still used at most BESSY II beamlines and contain useful or, even essential information for scientific reproducibility. Details of sample preparation, other analytical results, or even the experimental methodology can be found in these log books; additional qualitative information such as the scientists thoughts at the time of measurement, or classification in a wider context can also be found. Such intellectual interpretation of data belongs to another type of metadata that cannot be harvested automatically – but that can be stored electronically. To provide an electronic option of paper notebooks an instance of the ESRF e-logbook [15] was installed as a BESSY II-wide service. The logbook can include comments from the experimental team, as well as comments written automatically by the machine. Information about the current plan being executed is written by Bluesky in a callback.

Since Jupyter notebooks enjoy great popularity in the community to combine code, notes, and visualizations of results within a single file [16], and they are native to the Python Bluesky environment, their integration in a reproducible way is under discussion.

### Persistent Identifiers

The provided information should be unambiguous; using globally unique persistent identifiers ensures clarity when considering important metadata. For example, an ORCID [17] distinguishes multiple individuals clearly even if they share the same name. For this reason, at Sissy I ORCIDs are automatically assigned to members of the experimental team if they are identified through name and facility.

Moreover, globally unique instrument PID [5] identify the instrument SISSY I [18], the soft [19] and hard [20] x-ray EMIL beamlines, and other parts of EMIL [21, 22] to clearly state from where the data originates and where the instrument belongs. In the future, more PIDs will be included to precisely categorize important metadata, not least a semi-automated, globally unique sample identification system.

## INTEROPERABILITY – SPEAKING THE SAME LANGUAGE

SISSY I stores metadata parameters acquired by Bluesky in a Mongo database. The names of these parameters are specific to this facility, beamline, and endstation. So that this metadata is eventually understandable to a wider audience we implemented a routine that converts the database content of a measurement to the NeXus file format [23] which is a well-known standard of the x-ray and neutron community. NeXus uses HDF5 [24] as physical file format and applies the NeXus Definition Language (NXDL) to clearly define the nomenclature and arrangement of information while being versatile enough to meet the demands of a wide range of complex scientific techniques.

The file format is suitable for high-performance data processing [25, 26] and is supported by capable analysis software such as Dawn [27] which provides a Python interface following the spirit of the Bluesky control software.

## ACCESSIBILITY – TWENTY-FOUR/SEVEN

Well-curated data is useful when revisiting work after some time or when continuing another's work, but unleashes its full potential when accessible to co-workers, instrument users, and collaborators from around the world. That is why NeXus files are stored in HZB's central data repository [28] which is an instance of the ICAT software [29, 30] also in use at other Photon and Neutron facilities, including ISIS, Diamond Light Source, and ESRF.

ICAT's authentication system allows the experimental team to access the files associated with its proposal through a web interface using the HTTP standard protocol. According to the HZB data policy [31] raw data and associated metadata become openly accessible after a embargo period of normally five years.

However, the HZB data repository stores data on a tape library which has drawbacks concerning accessibility in general. In order to access the data, a request must be made in the metadata catalogue. The data will then be staged to disk automatically and a download link will be provided once the staging is complete. This might cause accessibility barriers to machine-agents, but there is currently no rigid procedure to deal with the situation.

## FINDABILITY – 'HELLO, WORLD'

SISSY I's local (meta)data storage procedure using Mongo database is more advanced than most current

BESSY II instruments that store data and metadata in various files. The Mongo database is completely searchable and returns measurements and metadata without laborious scans of a (potentially) confusing file structure. The same advantage applies to the ICAT's metadata catalogue which stores selected (meta)data of ingested files in a separate database and is also searchable. The difference is that ICAT is publicly accessible and centrally managed.

To increase visibility we need higher level services than those of HZB to connect (meta)data and the world – we need globally unique persistent identifiers (PID) to give measured raw data an unambiguous identity. While for (processed) data publications a manual procedure for adding PIDs exists, ingested raw data files in ICAT thus far lack this feature. However, the automatic assignment of PID's to single NeXus files containing raw data is a prerequisite to be harvested by higher level catalog services such as B2Find [32] and is currently in the implementation phase. This and the Harmonization of the metadata schema with regard to B2FIND is work in progress and ensure that (meta)data collected at SISSY I will be globally findable once the embargo period has ended. Such high-level search engines are crucial hubs in the world-wide data network and make the instrument's work public to visible to a community beyond that of the repository.

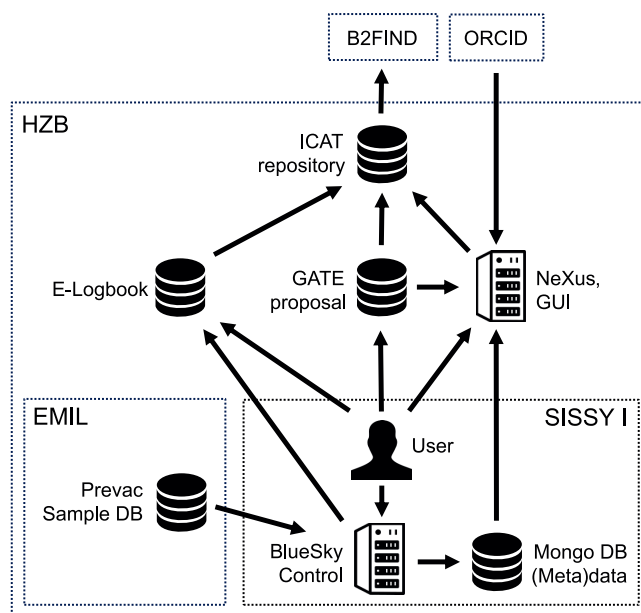

Figure 2: Visualization of the data infrastructure connecting the SISSY I instrument with services inside and outside the HZB.

## WORKFLOW

In the previous sections, we presented tools and services that are implemented or under consideration. We purposefully did not define a unique sequence of executed steps. Since different experiments involve different procedures, we adapt the workflow to the needs of each experiment.

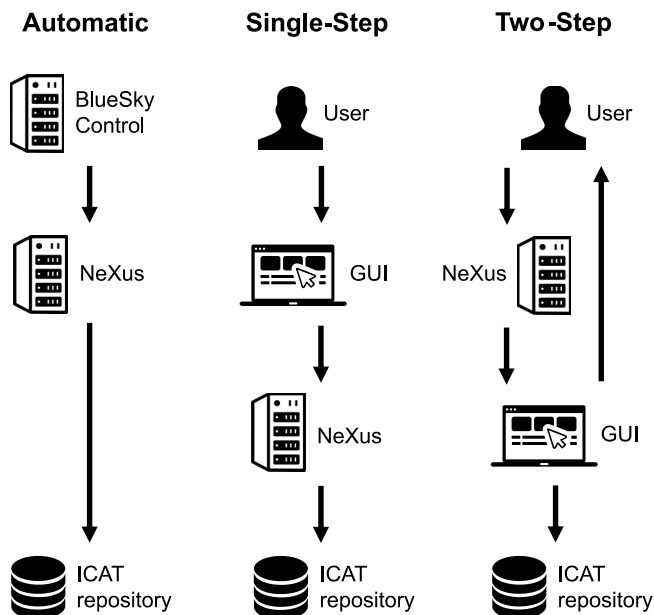

Figure 3: Provided workflows for the Sissy I instrument including automatic and manual processes.

Metadata may become available at different times of the experiment or even after its completion and thus the data management process may become stuck somewhere requiring human input to make data meaningful.

However, general principles guide the implementation of each workflow. Whenever possible procedures are outsourced to a physically separated server to keep the impact of the data management process on the experiment to a minimum. The parallel, mostly independent infrastructure is suitable to update running instruments without interrupting the production of results which is a major problem in fragmented software landscapes such as BESSY II [33].

The central data conversion server runs (i) the readout routine to get (meta)data from Sissy I's Mongo database, (ii) optionally the readout routine to collect sample information from the sample database, (iii) the routine trying to assign ORCIDs to members of the experimental team, and (iv) the NeXus writer routine that creates a NeXus file and feeds the file to the ICAT repository (see Fig. 2). All routines are written in Python, to harmonize with Sissy I's Bluesky process and, also to be transparent to the instrument scientist who is encouraged to maintain the code of the instrument-specific part. A training course is provided to ensure the scientist is supported in this.

Assuming that detailed sample information is available Sissy I's (meta)data are considered to be rich enough to start the data conversion process automatically when a measurement ceases (see Fig. 3). The data conversion server works in the background, only accessing Sissy I's Mongo database once, in the beginning, to get the (meta)data of the run. The subsequent enrichment of (meta)data, the creation of the NeXus file and the ICAT ingest process doesn't affect the Sissy I instrument.

For samples not originating from the EMIL infrastructure there are two manual processes implemented on the data conversion server, shown in Fig. 3, which can be initiated by the instrument scientist of Sissy I. First, the single-step process provides a graphical user interface (GUI) through which essential metadata such as the proposal number, sample information and contacts to the experimental team can be provided. Then the experiment scientist starts the NeXus creation process which proceeds in the same way as the automatic workflow but adds the provided GUI metadata.

Second, for maximum control of ingested data a manual two-step process is offered. Here, the NeXus file is created in the beginning and the GUI displays the selected content that which can be adjusted to the experiment scientist's needs. Changes are written to the NeXus file which can be inspected by the favored software until the content meets the requirements.

In general, instrument scientists and data curators have to balance between automatic (meta)data processing offering low effort but bear the risk of wrong or missing (meta)data and a manual curation accompanied by increased workload but potentially more accurate information. Manual workflows would be the method of choice for example, when the instrument scientist must differentiate between data that can or cannot be made generally accessible, which is a concern when the beamline is shared between scientific users and users from industry whose results are confidential.

Currently, a coherent interface between various parts such as the e-logbook, repository, and the proposal system is missing and represent hurdles to the workflow, as additional user authentications are required. We are building bridges between services but an IT environment avoiding such problems would be desirable.

## RESULTS AND DISCUSSION: FAIR ASSESSMENT

At Sissy I, we built a pure Python environment for beamline control, (meta)data acquisition, metadata enrichment, and conversion. This was made possible by the Python package Bluesky. We improve all fields of FAIR principles to increase data quality for long-term storage. To assess the FAIR status of the Sissy I instrument we apply the FAIR indicators of the FAIR maturity model [34] where results are summarized in table 1 following the presentation in [35]. Most of the time we restrict the discussion to indicators which are classified as 'essential' and therefore focus on the most important indicators to be fulfilled.

Reusability represents mainly the richness of metadata and, thus, we take measures on the instrument level to collect additional information. Since we were able to include sample information, electronic notebook and metadata identifiers such as ORCID or the instrument PID, we consider (meta)data to be sufficiently enriched that it can be reused. Moreover, it is presented in the machine-readable community standard NeXus. Currently, the method of including

FAIR	ID	Indicator	SISSY I
Findability			
F1	RDA-F1-01M	Metadata is identified by a PID	3
F1	RDA-F1-01D	Data is identified by a PID	3

0 – not applicable, 1 – not being considered yet, 2 – under consideration, 3 – in implementation phase, 4 – fully implemented  
Essential FAIR indicators are indicated by gray background.

Table 1: FAIR maturity model indicators for SISSY I in its current state of the commissioning phase.

the reuse license, in this case the HZB data policy, is under discussion.

Interoperability is closely connected to the way the knowledge is presented. Rather than the technical file format here the NeXus Definition Language NXDL is considered. Although no indicator is essential, NXDL is assumed to fulfill most requirements. However, to our understanding the NeXus vocabulary is not fully FAIR-compliant since the terms are not resolvable to let machines understand their

meaning, but this work is up to the NIAC [36] which maintains the NeXus format. According to the assessment summarized in table 1 major deficiencies due to missing connection to other data, e.g., calibration measurements, must be addressed later in the commissioning phase.

By moving (meta)data to HZB's central repository ICAT we address the issue of accessibility. ICAT allows members of the experimental team to access (meta)data through a web interface. Missing the required identifier, (meta)data records

are not yet resolvable and, thus, access through machines is limited.

Like the accessibility, the findability depends mainly on features of the repository. To be globally visible (meta)data must be harvested by higher level services such as B2FIND and the repository itself must be known outside the HZB. A prerequisite to interact with global services is the use of globally unique PIDs that are automatically assigned to (meta)data and which will soon be implemented.

As a result, we expect to realize the essential FAIR indicators at the SISSY I end-station in the near future. However, please note that the assessment seems to be a rather subjective process since some FAIR indicators are ambiguous and need further clarification (e.g., the 'richness' of metadata).

## CONCLUSION

We built a Python environment for automatic data workflow ranging from the sample handling to the instrument control software over the NeXus writing procedure to the repository ingest. Most of the required infrastructure is centralized to have a minimum impact on the instrument's work and share resources as e.g., the major part of writing NeXus files is independent of the scientific technique [15].

Important measures were implemented on the instrument level to increase the reusability significantly such as the automatic collection of sample information, and these have an impact on the workflow at the instrument. The early implementation of FAIR principles during the commissioning phase results in mutually induced workflow changes of instrument control and data management without running risk of increased downtime.

## ACKNOWLEDGMENTS

The authors would like to thank Heike Görz for constructive advice on software developments and Roland Mueller for helpful discussions.

This publication was supported by the Helmholtz Metadata Collaboration (HMC), an incubator-platform of the Helmholtz Association within the framework of the Information and Data Science strategic initiative.

GG, WS, OM conceptualized the project. GG and WS designed the workflow methodology and wrote software. WS and SV integrated Bluesky and metadata collection. GG and MK performed the investigation leading the FAIR assessment. MB and RW provided resources in the form of the EMIL laboratory and SISSY I end station. RK and NG provided software in the form of the e-logbook. RK worked on the instrument PID and provided the ICAT. GG wrote the original draft. All authors contributed to the review and editing process.

# RomLibEmu: NETWORK INTERFACE STRESS TESTS FOR THE CERN RADIATION MONITORING ELECTRONICS (CROME)

K. Ceesay-Seitz<sup>†</sup>, H. Boukabache<sup>\*</sup>, M. Leveneur, D. Perrin, CERN, Geneva, Switzerland

## Abstract

The CERN RadiatiOn Monitoring Electronics (CROME) are a modular safety system for radiation monitoring that is remotely configurable through a supervisory system via a custom protocol on top of a TCP/IP connection. The configuration parameters influence the safety decisions taken by the system. An independent test library has been developed in Python in order to test the system's reaction to misconfigurations. It is used to stress test the application's network interface and the robustness of the software. The library is capable of creating packets with default values, autocompleting packets according to the protocol and it allows the construction of packets from raw data. Malformed packets can be intentionally crafted and the response of the application under test is checked for protocol conformance. New test cases can be added to the test case dictionary. Each time before a new version of the communication library is released, the Python test library is used for regression testing. The current test suite consists of 251 automated test cases. Many application bugs could be found and solved, which improved the reliability and availability of the system.

## INTRODUCTION

The Radiation Protection group within CERN is responsible for measuring levels of ionizing radiation at the CERN sites, experimental areas and in service caverns besides the LHC experiments in order to ensure the radiological safety of the persons on the CERN site as well as the people living in its neighbourhood. The CERN RadiatiOn Monitoring Electronics (CROME) have been developed in-house with the purpose of replacing the older radiation monitoring systems ARCON and RAMSES. In contrast to the old systems, CROME consists of fully independent units, called CROME Measurement and Processing Units (CMPUs), which perform their safety functions autonomously [1]. A CMPU consists of a radiation detector, which is an ionization chamber in most cases, a front-end board for the readout and the processing unit. The latter has at its core a Zynq-7000 System-on-Chip (SoC) with an embedded Linux running on the Processing System (PS) with integrated 32-bit ARM cores and a Programmable Logic (PL) section. Because the PL can operate autonomously and the design architecture is more immune to higher radiation than the PS [2], all the safety critical calculations and decision making are implemented inside the PL.

The CMPU's functionality is entirely configurable at runtime with roughly 150 parameters. This has the advantage that CROME can be deployed for very different usage scenarios – e.g. in service caverns or experimental

areas with higher levels of radiation where it can be configured to trigger visible and audible alarms and with the possibility of being connected to machine interlocking systems, or as environmental monitors where the natural background radiation is monitored over long periods for informational purposes.

Figure 1 presents a system overview. During operation the CMPUs are connected to a SCADA supervisory system called REMUS – Radiation and Environment Monitoring Unified Supervision [3]. The CMPUs on the one communication end and the REMUS servers on the other end use the ROMULUS library [4] for communicating with each other. The library implements a custom protocol on top of TCP/IP that can be used to remotely configure the parameters on the CMPU at runtime, to read out its current and historical status, and to receive real time as well as historical measurement values.

The remote parametrization via REMUS is the only dedicated mechanism for users to configure the behaviour of the CROME system during operation. Radiation protection experts use REMUS to configure the CMPUs corresponding to the expected radiation conditions and safety requirements of a zone. Operators in the control room use REMUS to monitor the status and measurement results sent by the CMPUs.

Figure 1: CROME Overview.

Since it influences the functionality as well as the safety function of the system, the communication mechanism needs to be robust and reliable. The RomLibEmu, the ROMULUS Library Emulation and Test Tool, has been developed to test the functionality and robustness of the ROMULUS library as well as of the CMPU's application.

<sup>†</sup> katharina.ceesay-seitz@cern.ch

<sup>\*</sup> hamza.boukabache@cern.ch

The paper is structured as follows. First a definition for robust systems and robustness testing is provided. Then the RomLibEmu's concepts and functionalities are described in detail. Finally, the results and benefits obtained from using the tool are highlighted. A summary and an outlook conclude the paper.

## BACKGROUND AND RELATED WORK

A system is considered as robust when it shows stability and acceptable behaviour in unforeseen operating conditions. Furthermore, it must not accept invalid input and certainly must not produce faulty output if presented with unexpected inputs. Rather it has to either reject the input or put itself into a safe or degraded state from which it can recover. Robustness is defined by the 610.12-1990 IEEE standard glossary of software engineering as "the degree to which a system or component can function correctly in the presence of invalid inputs or stressful environmental conditions". The latter could be network traffic overload, attacks or a misbehaving connected system [5]. It could also be physical conditions such as extreme temperatures or high radiation levels.

Robustness tests complement functional tests with test cases that particularly focus on sending boundary values or unexpected input values to a system with the goal of determining whether the system enters into an unwanted state such as an abort or a non-responsive state [6]. Common techniques for robustness testing are model-based techniques, fault injection, fuzzing, interception, code changes injection and mutation testing. Communication protocols are often tested with model-based techniques where a model is built from the specification which is then either directly evaluated or used to generate test cases. The most commonly used technique to evaluate the robustness of embedded systems is fault injection [7]. RomLibEmu currently focuses mainly on fault injection. In future it might be extended with model-based or fuzzing approaches.

The CRASH scale has been developed for classifying the severity of failures of operating systems when tested for robustness. CRASH stands for Catastrophic, Restart, Abort, Silent, Hindering [8]. It is widely used to classify robustness test results [7]. It was also adapted to classify failures of controllers in self-adaptive systems. Similar to our results the most common failure of the tested controller fell into the "Silent" category [9].

Besides aiding in the classification of test results it also provides a good guidance for scenarios that have to be tested for. We reinterpreted the scale as Catastrophic, Restart, Abort, Silent/Safety, Hindering/Harmless.

## RomLibEmu: ROMULUS LIBRARY EMULATION AND TEST TOOL

### *Purpose and Motivation*

As mentioned in the introduction, the network interface is the only dedicated mechanism for configuring the CROME Measurement and Processing Units (CMPUs) during operation. The first parametrization can also be

done via the local file system, but this interface is only accessible to the development and maintenance team of CROME. Further utility tools exist that have been developed for testing and diagnosis. A physical test case, called CROME Case, that can read and manipulate external interfaces of the CMPU, has been developed as well. The tools and the test kit use the ROMULUS library for communication via the network. The library is intended to construct well-formed messages conforming to the ROMULUS-REMUS communication protocol. It only allows to send values of the expected datatypes for parameters and it is not capable of intentionally crafting malformed packets. While this feature strengthens the communication mechanism when the same library is used on both communication end points, it prevents the usage of the library itself for testing its own robustness and that of the CMPU application. The RomLibEmu, the ROMULUS Library Emulation and Test Tool, has been developed to overcome this limitation.

There are several scenarios in which it could happen that unexpected messages or malformed packets are sent to a CMPU:

- A fault in the ROMULUS library.
- A fault in the application that uses the ROMULUS library.
- The ROMULUS library versions of the CMPU application and the REMUS server are incompatible.
- Bad network connection or unexpected termination of the remote application causes ROMULUS packets to arrive only partially.
- Network or user-level misconfiguration: Packets that were not intended to be sent to the CMPU reach it because of a network misconfiguration. The application tries to interpret the irrelevant data according to the ROMULUS-REMUS communication protocol.
- Intentional attacks against CROME

Robustness testing of the CMPU's network interface is crucial to increase the availability and reliability of the radiation monitors. The availability would be affected by application crashes or aborts due to unexpected network traffic or heavy loads. The reliability would be affected if the CMPU would accept input values which it cannot process correctly. That could be e.g. input values that cause internal overflows or divisions by zero. The expected functionality of the CMPU would be affected if it would accept parameter values outside of the ranges defined in the requirements. These functional tests could be implemented by using the ROMULUS library itself. The already existing tools were mainly intended for manual tests and diagnosis. The RomLibEmu additionally facilitates the creation and generation of automated functional and robustness test suites. They can be used for automated regression testing as well.

### *Capabilities*

The RomLibEmu has been developed independently from the ROMULUS library based on the protocol specifi-

cation. Figure 2 shows an overview of the test setup. The tool can be used to test any application software that uses the ROMULUS C library or any other library or application that implements the ROMULUS-REMUS communication protocol. The library provides functions for creating, sending and receiving packets via TCP/IP. Packets can be auto-completed to conform to the ROMULUS protocol or they can be intentionally crafted to not or only partially conform to the protocol. Further functions can interpret received packets and check for unexpected responses.

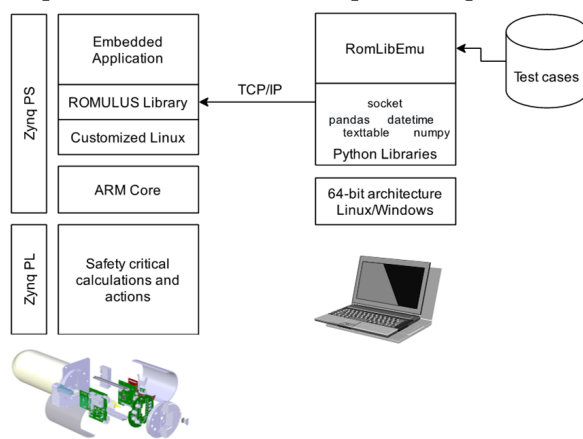

Figure 2: RomLibEmu Overview.

**Metadata** The protocol information is extracted from the protocol definition document in a semi-automated manner. The protocol consists of several different commands with similar structures. Each of them is identified by a unique command code and has a corresponding response code. Depending on the command type either the command or the response contains a list of parameters with or without added ID and of specified data types. Each packet further contains the data length, number of parameters, an ID and a checksum [4]. The command and response codes as well as the acknowledgement code for the messages have to be manually extracted from the documentation into a Python dictionary. The document contains several tables that define the parameter names, IDs and data types for the different messages. These need to be copied into a CSV (comma-separated values) file. The metadata generation scripts of the RomLibEmu reads the information and generates metadata dictionaries which are stored into dedicated files. These dictionaries can be used to access the parameters by name or ID and retrieve the corresponding data type byte size. The generated files are included into the RomLibEmu library. In case different protocol versions shall be tested, it is possible to use different input folders and include different dictionaries into the library.

**Test case generation – conforming packets** The library can be used to create test cases either manually or automatically. A test case can be specified as a dictionary with the ROMULUS packet field names as keys and the field's data as values. All values need to be provided as bytes in the correct byte order as described by the protocol.

Values like the command codes can be retrieved from the generated dictionaries by their names. Several utility functions are available to facilitate the test case construction in a human readable form. The “DATA” field expects as value a dictionary that contains key-value pairs with the name of a parameter as key and its data as value. The parameter ID that will be placed into the protocol message is automatically determined from the metadata. Since the ID depends on the command type (there could be multiple parameters with the same name but different ID for different command types), a command code needs to be specified in the test case. In order to create a conforming packet, the ID, command code, number of parameters and the data need to be specified. The RomLibEmu then calculates the data length and the checksum and places them into the ROMULUS packet.

A test case also contains the expected response by the CPMU under test. The expected acknowledgement code depends on the test scenario and must therefore be added manually. In most cases the expected data values are only known for parameters and not for sensor measurements like the radiation dose or temperatures. In some test cases they can be added to the expected response packet. It is possible to add place holders for data values that cannot be automatically checked. Several fields of the expected response can be automatically determined by the RomLibEmu. The sender ID, the command's response code, the expected number of parameters and the data length can be generated. The checksum of the response packet can be calculated only if the expected data was known.

#### Test case generation – non-conforming packets

Raw data can be inserted by adding a key that starts with the keyword “raw” and any data as value. These fields can be used to craft invalid packets. The default value of each field is an empty string. It is the responsibility of the test case writer to decide whether the lengths of the fields should match the ROMULUS-REMUS communication protocol for conforming packets or whether a non-conforming packet shall be created. In order to construct a packet manually it is possible to add the whole packet as a byte string to one of the fields of the packet and leave all other fields empty. Packets can also be modified after auto completion to facilitate the generation of malformed packets.

**Use case** The main purpose of the RomLibEmu is to facilitate the creation of automated test suits. Test cases can be defined in a test case dictionary. The RomLibEmu provides a function that traverses this dictionary and sends each packet over a TCP/IP socket to the target device. After sending a packet it waits for the response and compares it with the expected one that was defined in the test case. This verifies the ROMULUS packet structure which tests the ROMULUS library implementation as well as the content of the packet which tests the software application that uses the library. Automated test suits can be used fully or partially in regression test runs which are performed whenever a new software version is available.

The functions of the RomLibEmu can also be used to freely create more complex functional test cases that consist of several ROMULUS commands. Scenarios that already lead to failures of the system can be reconstructed for analysis. Once the underlying fault has been removed, the same test case can be used in regression runs. The library can also be used by developers for test-driven development.

## RESULTS

A test plan has been written containing around 80 main test cases which consist of several sub test cases. They are associated to the following categories:

1. Good cases – Packets that conform to the ROMULUS-REMUS communication protocol.
2. Application tests – Packets with correct ROMULUS packet structure, but bad parameter configuration.
3. Bad network connection – Simulating the loss of packets, long delay, etc.
4. ROMULUS library tests – Malformed ROMULUS packets that were generated due to bugs in the ROMULUS library; Network packets that were not targeted to the CMPU but arrive because of misconfiguration and are therefore treated by the application like legitimate traffic.
5. Denial-of-Service – Overload of the network interface by sending too many messages in a short time or in parallel, unexpectedly long packets.
6. Intentional attacks
7. Regression tests – Test cases that have already revealed a bug in some version of the application or the ROMULUS library

The responses of the CMPU's application can be classified according to the CRASH scale [8] as follows:

- Catastrophic – The OS crashes.
- Restart – Application hangs and requires a restart.
- Abort – The application crashes.
- Silent/Safety – An application error is expected but does not get triggered.
- Hindering/Harmless – The application returns a wrong error code.

Each time before a new software or firmware version is released, the test suite implemented with the RomLibEmu is executed. Table 1 lists the failures of the test runs per CRASH category. The robustness and in particular the availability of the CMPU was tested by trying to cause a "Catastrophic", "Restart" or "Abort" scenario. No test scenario fell into the "Catastrophic" category. One test case caused the application to hang and four test cases caused the application to crash, falling into the "Abort" category. "Silent" faults are very critical for safety, therefore we renamed the category into "Silent/Safety". These are scenarios in which the application would accept bad input that it cannot handle and it would not notify the user. In such scenarios one would rely on a faulty safety system in the belief that it is operating as specified, which could be very dangerous. The faults falling into the "Hindering/Harmless" category were not considered as critical. They are wrong

behaviour from a functional perspective, but from a safety perspective in the case of the CMPU it is sufficient if any error code is returned and bad input is rejected. For another system, however, these faults may be critical. We also added a category "Functional" which contains test cases that failed because the response of the system did not fully conform to the protocol, but the error code was the expected one. From safety perspective they are not critical either.

The following test cases lead to "Abort" responses, meaning that the application crashed. (The numbers in brackets following each paragraph are the test case categories):

- A floating point parameter was set to quiet NaN (Not a Number).  
The ROMULUS library is not supposed to accept NaNs, therefore this tested the library implementation as well. Interestingly a test case with a signalling NaN passed. (2, 4, 6)
- An Ethernet frame with maximum data length was sent. The length of the IP header plus the length of the TCP header plus the length of the data equalled the Ethernet MTU of 1500. The TCP data was all 0. A similar test case where the TCP data contained arbitrary data, but the data length specified in the packet matched the maximum legal data length and the ROMULUS packet checksum was correct passed. (4, 6, 7)
- A packet with arbitrary data in the TCP data section with a packet length larger than the maximum ROMULUS packet length was sent. The data length inside the packet was set to 0 and the packet had a wrong checksum. (4, 6, 7)
- Many commands were sent in parallel. (2, 4, 5, 6)

Some examples of "Silent/Safety" failures were:

- Negative/positive infinities as well as quiet and signalling NaNs were sent to floating point parameters. The values were accepted and passed on to the PL that contains the safety critical code. (2, 4, 6)
- Invalid packet structures were accepted. The application therefore treated frame data like the checksum as parameter data and stored it silently. (2, 4, 6)

Table 2 summarizes the test runs. With each run some faults were removed and some more test cases were added. The number of passing test cases increased with each improved software version. In some intermediate test runs, however, previously passing test cases failed due to regressions that were introduced into the software or the firmware of the PL. Thanks to the test suite this could be spotted and fixed before releasing the new software and firmware versions.

## CONCLUSION AND OUTLOOK

The RomLibEmu tool has been developed to test the robustness of the ROMULUS library as well as the CMPU's application that uses the library. It was successfully used

Table 1: Failures per CRASH Category

Test Run	Date of SW	Silent/Safety	Abort	Re-start	Hampering	Functional
1	04/09/19	19	2	1	3	2
2	11/12/19	10	4	0	3	2
3	20/12/19	6	0	0	3	2
4	26/05/20	6	0	0	3	3
5	02/03/21	2	0	0	3	2
6	30/09/21	0	0	0	3	0

Table 2: Test Run Summary

Test Run	Date of SW	Nr. Test Cases	Passed	Failed
1	04/09/19	57	30	27
2	11/12/19	58	39	19
3	20/12/19	64	53	11
4	26/05/20	65	53	12
5	02/03/21	81	74	7
6	30/09/21	83	80	3

Many of the main test cases consist of several sub cases. In total the current test suite contains 251 test cases.

for finding faults triggered by unexpected parameter values or malformed ROMULUS packets. It has been further used to test the input sanitizing module which performs parameter range checks once when receiving parameters over the network or reading them from the file system as well as once before writing derived values to the Programmable Logic section of the SoC. A few test cases have already been written that test functionalities of the full system covering PS and PL sections of the SoC.

This test bench clearly improved the quality, availability and safety of the CROME Measuring and Processing Units. So far the test bench focuses only on a small section of the functionality and on the communication interface. In future version we intend to extend the tool to further facilitate the test case generation for functional and safety tests. More benefits are expected from a more comprehensive test suite. There is also room for more automation. Model-based testing may be done by adding the capability of generating random input values and by adding an interface to a reference

model of the system that predicts the expected outputs. Furthermore the tool may be combined with fuzz testing tools or modules with focus on network security.

# TOWARDS THE OPTIMIZATION OF THE SAFETY LIFE-CYCLE FOR SAFETY INSTRUMENTED SYSTEMS

B. Fernández\*, G. De Assis, R. Speroni, T. Otto, E. Blanco,  
CERN, Geneva, Switzerland

## Abstract

The design and development of Safety Instrumented Systems (SIS) according to the IEC 61511 standard is a long and costly process. Although the standard gives recommendations and guidelines for each phase of the safety life-cycle, implementing them is not a simple task.

Access to reliability data, hardware and systematic safety integrity analysis, software verification, generation of reports, guarantee of traceability between all the phases and management of the project are some of the main challenges. In addition, some of the industrial processes or test benches of large scientific installations are in continuous evolution and changes are very common. This adds extra complexity to the management of these projects.

This paper presents an analysis of the safety life-cycle workflow and discusses the biggest challenges based on our experience at CERN. It also establishes the basis for a selection of the tools for some of the safety life-cycle phases, proposes report templates and management procedures and, finally, describes the roles of the different members in our functional safety projects.

## INTRODUCTION

The design, development and maintenance of Safety Instrumented Systems (SIS) requires a lot of resources and time for a company or organization. It is not enough to develop a reliable SIS based on good engineering practices, it is necessary to prove that the Safety Instrumented Functions (SIF) reduce the existing risk to the tolerable region. The functional safety standards provide the guidelines to design and develop such systems and the methods to prove the compliance with the risk reduction target. For industrial processes, the IEC 61511 [1] is the most appropriate standard. It uses the same principles as the IEC 61508 standard with a more specific language and context.

### The IEC 61511 Safety Life-Cycle

Figure 1 shows the so-called IEC 61511 safety life-cycle, whose requirements are specified in the Clause 6 of the IEC 61511-1:2016. This Clause defines the different phases, organizes the technical activities and ensures that adequate planning exists for the development of the SIS.

In order to claim conformance with the IEC 61511 standard, all requirements from Clause 5 to Clause 19 from the 61511-1:2016 have to be met and the corresponding reports have to be created. All these requirements are clearly specified, but how to implement them is the real challenge.

\* borja.fernandez.adiego@cern.ch

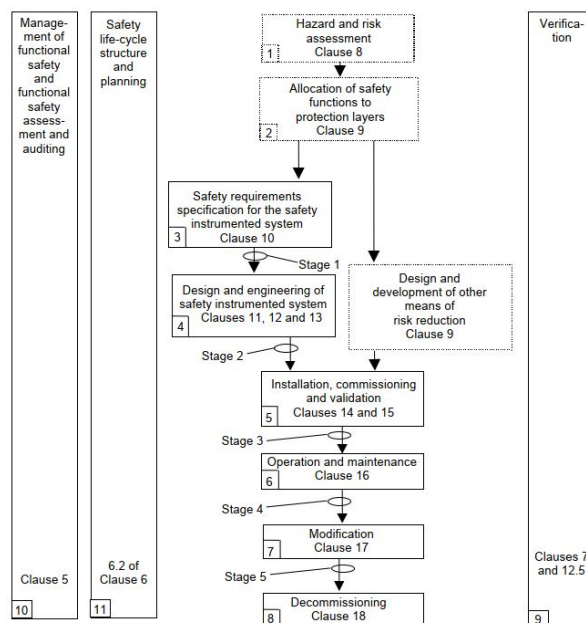

Figure 1: IEC 61511 safety life-cycle.

## Challenges

The main challenges related to the implementation of the safety life-cycle are common to most industries. In our experience, proving the compliance with the standard and guaranteeing the traceability between all phases of the safety life-cycle are two of the most critical ones. Compliance is a very costly and time-consuming process, and lack of traceability most certainly would create discrepancies in the project documents, delays and potential errors.

In addition, at CERN (European Organization for Nuclear Research) and most probably in other large scientific installations, some of the industrial processes or test benches are in continuous evolution and changes that influence the safety of the installation are very common.

## Objectives

Our goal is to overcome the technical and organizational challenges to optimize the allocated resources for the design, development and maintenance of SIS.

More specifically, we aim to:

- Create report templates that are necessary for the documentation and management of such projects.
- Reuse and integrate the existing tools we have at CERN that can be applied to any of the phases of the safety life-cycle.
- Discuss the management procedures and the roles of the different members in our functional safety projects.

## COMMERCIAL TOOLS

There are many commercial tools that offer solutions for one or several phases of the safety life-cycle. Table 1 presents some of the most relevant ones.

Exida's toolkit, exSILentia®, is one of the most popular tools. It covers all the phases of the life-cycle and certainly fulfils the requirements of most engineering teams to design and develop SIS in terms of reporting, management, traceability and reliability. This tool could certainly bring a lot of benefits to our workflow, especially traceability. There are however a few requirements that are not covered by this framework, to the best of our knowledge, regarding code generation and formal verification. At CERN, we have adopted alternative solutions, which are discussed in the following sections.

Another relevant tool is the Reliability Workbench provided by Isograph. It allows the creation of reliability models, such as FTA (Fault Tree Analysis) and RBD (Reliability Block Diagrams), and analyses their compliance with the IEC 61508 standard [2] in terms of random failures and architectural constraints. An example can be found in [3].

The rest of the paper analyses some of the most challenging phases of the safety life-cycle based on our experience and describes the adopted solutions.

## HAZARD AND RISK ASSESSMENT, ALLOCATION OF SAFETY FUNCTIONS TO PROTECTION LAYERS AND SAFETY REQUIREMENTS SPECIFICATION

The hazard and risk assessment, allocation of safety functions to protection layers and Safety Requirements Specification are the first three phases of the safety life-cycle. The IEC 61511-1:2016 Clause 8 defines the requirements to perform

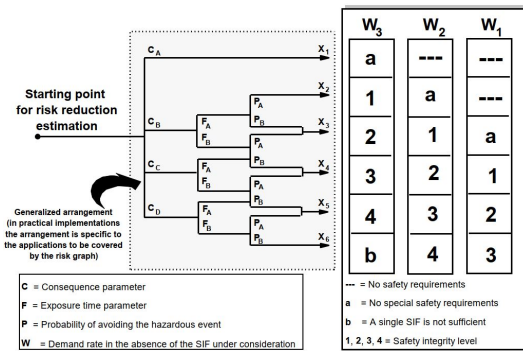

Figure 2: Risk graph: general scheme from IEC 61511-3:2016 Annex D.

the hazard and risk (H&R) analysis from the process and the BPCS (Basic Process Control System). Clause 9 defines the requirements for the allocation of safety functions to protection layers. Clause 10 provides all the requirements to produce the SRS (Safety Requirements Specification) document.

The objectives of these phases are: (1) identify the hazards and risks of the industrial process and the BPCS, and evaluate the necessary risk reduction to the tolerable levels, (2) propose a risk mitigation strategy and (3) provide a detailed and unambiguous specification of the SIS. Annex A from IEC 61511-3:2016 describes the concepts of "tolerable risk target", the layers of protection and how to select the appropriate method to evaluate the risks.

In our case, in order to identify the dangerous hazards that can provoke a risk to operators, environment or asset loss (damage to the installations), we usually apply the FMEA (Failure Mode and Effect Analysis) method. To quantify the necessary risk reduction for each failure mode, we use

Consequence	Occupancy (Frequency of exposition)	Possibility of avoidance	Base prob. of failure	SIL target
CC (1 fatality is possible)	FA (less than 10% of working time)	PB (no other system)	W1 (less than once every 10 years)	SIL1 (risk reduction bet. 10 and 100)

one of the methods proposed by the IEC 61511-3:2016, the calibrated risk graph (Annex D). Figure 2 shows the general scheme of this method.

Tables 2, 3 and 4 show a simplified example of the selected methods (FMEA and calibrated risk graph) applied to an industrial installation at CERN.

In Table 2, a failure mode, its effects and causes are described for a simple example of water-cooled cable subsystem, as part of a superconducting magnet test bench facility.

In Table 3, the calibrated risk graph method is applied to evaluate the necessary risk reduction to protect the operators of the installation for the failure mode example shown in Table 2. The risk reduction factor (RRF) is given by the target SIL (Safety Integrity Level). In this example, a SIL1 implies a RRF between 10 and 100.

In Table 4, the same method is applied for the same failure mode but evaluating the asset loss. In this case, the failure mode could provoke a serious damage on the water-cooled cable subsystem and weeks of delay in the test program.

In our experience, the biggest challenge in these two phases is the risk graph calibration for asset loss. Calibration means assigning numerical values to the risk graph parameters in accordance with the corporate risk criteria. The calibration to define the tolerable risk level for personnel protection is relatively straight forward, following the examples given by the standard (e.g. table D.2 from the IEC 61511-3:2016 Annex D, or table E.1 from the IEC 61508-5:2016 Annex E). A bigger challenge is to calibrate the graph for asset loss. A failure in one of our industrial processes would normally provoke a delay in the physics program of one of our particle accelerators (e.g. the Large Hadron Collider) or in the test program of one of our test benches. We

have calibrated the consequences in "delay time", which is a way for our process and accelerator experts to define the tolerable risk. It is, however, very hard to generalize and provide the same calibration for all the industrial processes we have at CERN. In Table 5, we show an example of the calibration for asset loss in one of our projects.

This calibration has a very big impact in the next phases of the project. It was a very time-consuming process, since it needed the consensus and approval of many members of the functional safety project. However, we have built a sound base for future projects.

Once the risks are identified and the necessary risk reductions (SIL) are calculated, the functional safety expert must propose a mitigation strategy for this risk. If the mitigation method is a SIF, the rest of the safety life-cycle should be completed and a detailed SRS document must be provided to proceed to the next phase. However, SIF is not the only option to mitigate a risk. Other protection layers that should be considered to mitigate a risk (see IEC 61511-1 Clause 9).

This exercise was performed by the functional safety engineer, the process expert, the automation engineer and the Departmental Safety Officer (in charge of evaluating and fixing the acceptable risk levels for the project). Report templates were created for the FMEA-based risk analysis, the risk assessment and the SRS.

## SIS DESIGN AND ENGINEERING

The IEC 61511-1:2016 Clauses 11, 12 and 13 define the requirements of the phase 4 of the safety life-cycle: Design and engineering of the SIS.

The goal is to design an SIS compliant with the requirements defined in the SRS document. This phase is a very

Table 4: Example of Risk Evaluation for Asset Loss Using the Risk Graph Method from IEC 61511-3:2016 - Annex D

Consequence	Occupancy (Frequency of exposition)	Possibility of avoidance	Base prob. of failure	SIL target
CC (several weeks of delay)	FB (max. occupancy)	PB (no other system)	W1 (less than once every 10 years)	SIL2 (risk reduction bet. 100 and 1000)

Table 5: Example of Risk Graph Calibration for Asset Loss

Consequence		Occupancy		Possib. of avoidance		Prob. of failure	
CA	delay < few hours	FB	always	PA	automatic system that detects and alerts the operators	W1	< 1 failure per 10 years
CB	few hours < delay < few days			PB	There is not	W2	< 1 failure per year
CC	few days < delay < few weeks					W3	> 1 failure per year
CD	delay > a month or cancellation of test program						

long and time consuming process. For each SIF specified in the SRS, four main analyses must be conducted: (1) the random hardware failures, (2) the architectural constraints, (3) the systematic failures or selection of the devices and (4) the application program.

### SIF Random Hardware Failures and Architectural Constraints Analysis

In this analysis, the functional safety engineer performs the calculation of the probability of dangerous failure on demand ( $PFD_{avg}$ ), when the SIF operation mode is low demand; or the probability of dangerous failure per hour ( $PFH$ ), when the operation mode is high or continuous demand. For this purpose, the reliability data of the SIF components is needed (e.g. failure rate, mean time to failure, etc.). Once the data for the individual components (sensors, final elements and controller) is collected, a reliability model of the SIF must be created and the global  $PFD_{avg}$  or  $PFH$  is calculated. Table 6 shows the random hardware failure requirements in demand mode for each SIL.

Table 6: Safety Integrity Requirements for Random Hardware Failures from IEC 61511-1:2016 Clause 9.2.3

Demand Mode of Operation		
Safety Integrity Level (SIL)	$PFD_{avg}$	Required risk reduction
4	$\geq 10^{-5}$ to $< 10^{-4}$	$> 10^4$ to $\leq 10^5$
3	$\geq 10^{-4}$ to $< 10^{-3}$	$> 10^3$ to $\leq 10^4$
2	$\geq 10^{-3}$ to $< 10^{-2}$	$> 10^2$ to $\leq 10^3$
1	$\geq 10^{-2}$ to $< 10^{-1}$	$> 10^1$ to $\leq 10^2$

However, this analysis is not enough. It is also needed to evaluate the architecture of the SIF. For sensors and final elements, the IEC 61511-1:2016 Clause 11.4 provides the requirements for the minimum hardware fault tolerance (HFT) of each element of the SIF. Table 7 shows the HFT requirements for each SIL and operation mode.

Although these requirements can be relaxed if the parameter Safe Failure Fraction (SFF) is known for each element. In this case, it is possible to use the Route 1<sub>H</sub> method provided by the IEC 61508-2:2010 Clause 7.4.4. Table 8 shows the HFT requirements for each SIL and the SFF ranges for type A elements (typically, devices without any processor, e.g. simple mechanical sensors or final elements). A similar

table with more strict requirements for type B elements (e.g. controllers) can be found in Clause 7.4.4.

Table 7: Minimum HFT Requirements According to SIL from IEC 61511-1 Clause 11.4

SIL	Minimum HFT
1 (any mode)	0
2 (low demand mode)	0
2 (continuous mode)	1
3 (high demand mode) or continuous mode)	1
4 (any mode)	2

Table 8: Maximum Allowable SIL for a Safety Function Carried Out by a Type A Safety-Related Element or Subsystem from IEC 61508-2:2010 Clause 7.4.4

SFF	HFT		
	0	1	2
$SFF < 60\%$	SIL1	SIL2	SIL3
$60\% \leq SFF < 90\%$	SIL2	SIL3	SIL4
$90\% \leq SFF < 99\%$	SIL3	SIL4	SIL4
$SFF \geq 99\%$	SIL3	SIL4	SIL4

In our case, Isograph is the selected tool for checking the architectural constraints and quantifying the random hardware failures. This tool is widely used at CERN for reliability calculations. It provides access to the reliability component data and supports the IEC 61508 standard ( $PFD_{avg}$  and  $PFH$  formulas are included, as well as the HFT tables from Route 1<sub>H</sub>). The functional safety engineer can create the failure models, which allows to calculate the random hardware failures according to this standard. Figure 3 shows a diagram of a Fault Tree that models one of our SIFs within the Isograph's Reliability Workbench. The SIF components, to mitigate the risk from Table 2, are: a thermoswitch, the Programmable Logic Controller (PLC) and its input/output cards, and the final elements (in this case, the safety "slow abort" and the "main circuit breaker" of a power converter). In this diagram,  $Q$  represents the unavailability, which corresponds to the  $PFD$ . In addition,  $Q_m$  represents the mean unavailability, which corresponds to the  $PFD_{avg}$ .

By using this tool, we have minimized the time of creating the models and performing both analysis. The calculations performed by Isograph can be exported in CSV (comma-separated values) format and integrated in our reports.

When the SFF data is not available, the Route  $2_H$  from the IEC 61508-2:2010 Clause 7.4.4 can be applied. It is based on component reliability data from feedback from end users, increased confidence levels and hardware fault tolerance for specified safety integrity levels.

### SIF Systematic Failures Analysis

Regarding the systematic failures analysis, the selection of the SIF components can be done by complying with the prior use approach from the IEC 61511-1:2016 Clause 11.5.3. In this case, it is necessary to gather sufficient evidence, showing that the dangerous systematic faults have been reduced to a sufficient low level compared to the required safety integrity. Another option is to apply the requirements for systematic safety integrity provided by the IEC 61508-2:2010 Clause 7.4 (Route  $1_S$ ,  $2_S$  or  $3_S$ ).

### SIF Application Program

The application program (AP), which contains the logic of all SIFs, is specified as part of the SRS and usually implemented in a PLC. The AP design and implementation requirements are defined in the IEC 61511-1:2016 Clause 12. In addition, the Annexes A and B from the IEC 61511-2:2016 provide guidelines and recommendations to produce an AP compliant with the standard. Most of our functional safety projects use Siemens Safety PLCs and, depending on the project, we work with Simatic Step7 or TIA Portal<sup>1</sup> programming environments.

<sup>1</sup> <https://new.siemens.com/global/en/products/automation/industry-software/automation-software/tia-portal/softw are.html>

According to the IEC 61511-1:2016, the AP development cycle is divided in three phases: (1) design, (2) implementation and (3) verification.

The first phase consists of specification of the SIS logic and its operation modes in a clear and precise way, free from ambiguity and free from design faults. This functional specification is part of the SRS. The IEC 61511-2:2016 Annexes A, B, D and E show examples of recommended specification methods that can be applied to define the functional logic of a SIF. They also recommend the usage of model-based approaches, for example, in Annex B section B.2, the standard states: "The traditional text based approach of safety AP specification is not efficient enough to handle the advanced, complex safety requirements commonly found in SIF specifications. The most efficient tool to address these challenges is the Model-based design (MBD)...". In the Annex B section B.4.3.4 the standard states: "specification should be implemented in the graphical language of the model checking workbench environment...".

At CERN, depending on the nature of the project, we use one of these two popular model-based specification methods: Logic Diagrams (LD) or Cause and Effect Matrix (CEM). In [4], an example of how the CEM was applied to one of our projects is shown and it also introduces the tool that supports this formalism: SISpec. In addition, another prototype tool has been developed to support LD-based specifications for SIF logic: Grassedit. Both tools have the capabilities of test and verification cases generation for the verification phase.

In the implementation phase, the functional specification is translated into the PLC AP. Siemens safety PLC programs must be written in LADDER or FBD (Functional Block Diagram) with several restrictions in the data types, operations, etc. in order to be compliant with the requirements for LVL (Low Variability Language) defined by the IEC 61511. In addition, PLC brands normally oblige the PLC programmer to manually write the PLC safety program on their own pro-

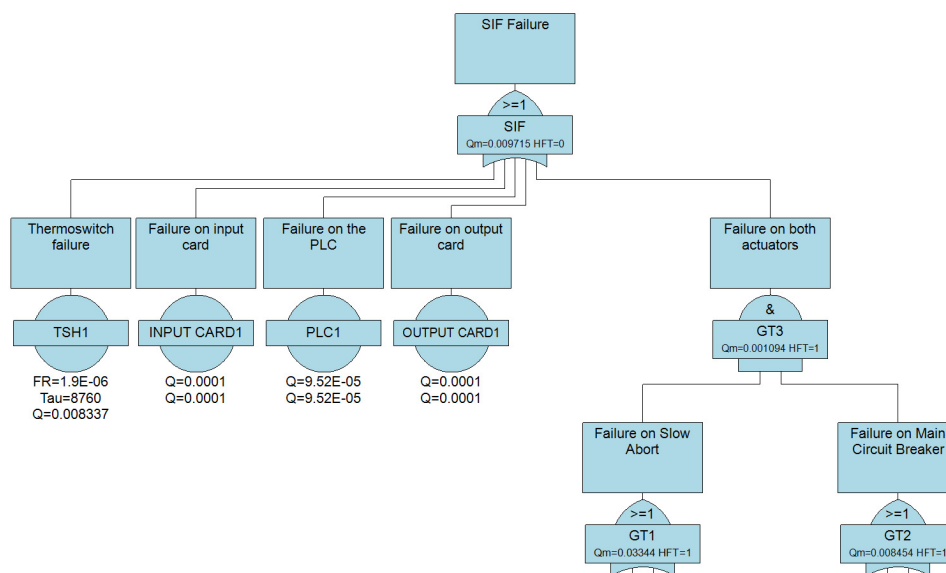

Figure 3: Fault Tree developed with the Isograph's Reliability Workbench.

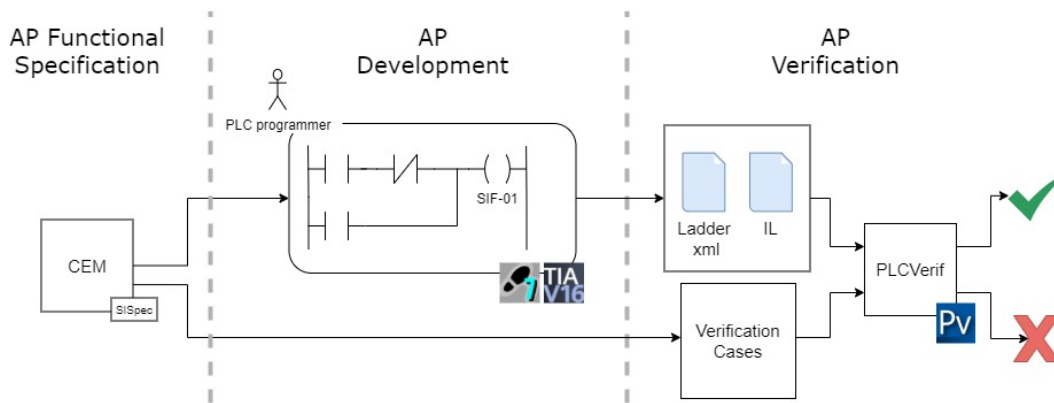

Figure 4: Specification, development and verification of the SIS AP.

programming environment. This is the case for Simatic Step7 from Siemens. However, in their latest programming environment tool, TIA portal, it is possible to generate the AP source code from external tools, import it in TIA portal, compile it and produce a safety AP. This feature opens the door to automatic code generation of the PLC APs.

The verification phase consists of testing and reviewing the AP in order to confirm that the AP implementation corresponds to the AP design, and that there are no unintended states. In our case, in addition to the FAT (Factory Acceptance Test) activities (requirements defined in 61511-1:2016 Clause 13), we apply model checking to our Safety PLC programs, as recommended in Annex B (section B.4.3). By applying model checking, all combinations of the AP are checked to guarantee that the SIF logic from the specification (CEM for example) is respected in the implementation. For that purpose, we use the open-source tool PLCverif<sup>2</sup>, developed at CERN [5]. An example of how PLCverif is applied to a safety PLC program can be found in [6].

Figure 4 illustrates these three phases and associates them with the software tools we use in the development.

SISpec, Grassedit, PLCverif and Isograph can contribute to improve the reliability of the SIS. They are also compliant with the IEC 61508-3:2010 Clause 7.4.4.2 "Software off-line support tools shall be selected as a coherent part of the software development activities". Therefore, it is certainly in the best interest of CERN to use these already available tools.

## MANAGEMENT OF THE FUNCTIONAL SAFETY PROJECT

Management of functional safety projects is probably the most critical activity based on our experience. The requirements are described in IEC 61511-1 Clause 5. At CERN, typically the following roles are defined for each functional safety project:

- A functional safety expert: person with a deep knowledge and experience in applying the functional safety standards. The main activities of this role are the speci-

cation, design and validation of the SIS to be compliant with the risk reduction stated in the risk assessment. This person also participates in the risk analysis phase.

- A process expert: person with an excellent knowledge of the industrial process. The main activities of this role are to provide the operational requirements, contribute to the risk analysis and participate in the commissioning and validation of the SIS.
- The Departmental Safety Officer (DSO): person in charge of defining the tolerable risk levels and provide support to the project members in any safety matter. The main activities of this role are to conduct the risk analysis, define the tolerable risk level, as well as participate in the validation of the SIS.
- Health & Safety and Environmental Protection (HSE) unit representative: person that normally participates in the most safety-critical systems at CERN in coordination with the DSO and provides support in safety matters.
- Instrumentation and control experts: people in charge of selecting the hardware equipment for the SIS (sensors, final elements and controller), according to the SRS document, as well as implementing the AP.

In addition, for the Functional Safety Assessment (FSA), an external person to the project must be included in the FSA team. Moreover, an independent person to the project must conduct the Safety Audit.

## Reporting

Documentation is an important part of the management of these projects. At CERN, report templates were created to cover different phases of the safety life-cycle. One of the most important and problematic aspects of the documentation is to keep the traceability between the documents of the project. For example, when a SIF specification is modified in the SRS, the proof testing document should be updated. We have created templates for the following reports: Hazard and risk assessment, SRS, FSA, proof testing and the safety manual. Traceability is currently maintained manually by the functional safety expert, but this is a topic taken into consideration for future work.

<sup>2</sup> <https://gitlab.com/plcverif-oss/cern.plcverif>

Table 9: Tools, Methods and Report Templates for Our Functional Safety Projects

Safety life-cycle phase	Tools	Methods	Report templates
H&R assessment	-	FMEA and calibrated risk graph	Risk assessment report
SRS	SISpec and Grassedit	CEM and Logic Diagrams	SRS report
Design and engineering	Isograph, PLCverif and UNICOS (future work)	FTA, RBD, model checking and FAT	Design and verification report
Validation	-	-	Proof test
Management	-	-	FSA and safety manual

## CONCLUSIONS

This paper shares our experiences in the design, development and management of functional safety projects that are based on the IEC 61511 standard.

The challenges and the adopted solutions for some of the most critical phases of the safety life-cycle have been discussed. Table 9 summarizes the current solutions adopted for our functional safety projects. In general, we have worked in two main topics:

1. The creation of report templates compliant with the standard. For example, the risk analysis and assessment, the SRS, the proof tests, etc. These templates help us to standardize our projects and speed up the creation of the necessary reports.
2. The integration of external tools that can contribute to improving the reliability of the final SIS and speed up the development, maintenance and verification time. This is the case of the CERN tools, PLCverif, SISpec and Grassedit and the commercial tool, Isograph.

### Future Work

In general, we have faced the optimization challenge individually for each of the phases of the safety life-cycle. As mentioned previously in this paper, an unsolved challenge is to be able to keep traceability in an automatic way. We will explore the possibility of using commercial tools (e.g. exSILentia®) that tackle the problem of traceability and management of changes. We will also evaluate the possibility of developing our own tool that would be able to integrate all our templates, generate automatically an important part of our reports, integrate our existing tools and guarantee the traceability of the project.

In terms of management, we are currently working on the optimization of the workflow of our projects, defining more precisely the different roles and responsibilities of the different groups involved in a functional safety project.

Finally, we want to go a step further in the design and development of the SIS AP. At CERN, we have a large number of control and safety systems and we are always looking for

the standardization of our PLC programs and supervision interfaces. For that purpose, we will aim to create a new component of the UNICOS<sup>3</sup> framework that is able to generate automatically the SIS AP from a formalized specification, respecting the IEC 61511 guidelines.

# THE FAST PROTECTION SYSTEM FOR CSNS ACCELERATOR

Y.L. Zhang<sup>†</sup>, P. Zhu, D.P. Jin

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

## Abstract

The CSNS (China Spallation Neutron Source) consists of an 80 MeV H<sup>-</sup> LINAC, a 1.6 GeV Rapid Cycling Synchrotron, two beam transport lines and one tungsten target and three beam lines. The designed proton beam power is 100 kW in Phase-I [1]. The fast protection system plays an important role to guarantee the safe operation of accelerator. The response time requirement for the CSNS fast protection system is less than 10  $\mu$ s. The design of CSNS FPS was based on FPGA technology, and the VME bus and SFP connector was adopted for the hardware design. Different beam interlock and mitigation logic was designed so as to fulfil the operation requirements.

## INTRODUCTION

CSNS accelerators are designed to accelerate very high intensity proton beam, Fig. 1 shows the schematic layout of the CSNS facility. The uncontrolled beam loss may permanently damage or give a high radiation dose to the accelerator components along the beam line [2, 3]. Therefore, high reliability for machine protection system is the basic requirement. The accelerator protection system must be carefully designed so that we can avoid the unnecessary beam loss. Besides, the availability, scalability, maintainability and the budget were also need to be carefully considered in the design and implementation stage.

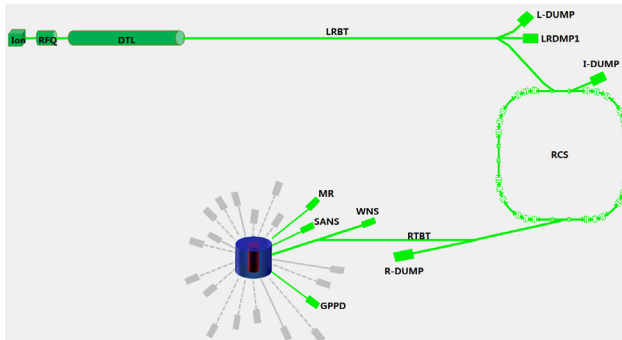

Figure 1: Schematic diagram of CSNS.

CSNS accelerator protection system consists of two protection systems, one is the PLC based slow protection system: NMPS (Normal Machine Protection System), the other is the FPGA based FPS (Fast Protection System). The response time within 20ms and 10 $\mu$ s are required for NMPS and FPS respectively [4]. The overall protection systems for CSNS as shown in Fig. 2. The output signals of PPS (Personnel Protection System) and TPS (Target Protection System) are input into the two NMPS main stations. RMS (Run Management System) can be seen as the beam permit system. Three beam stopping actuators are designed for protection system, which including ion

source timing, post acceleration power supply of ion source and RFQ power source.

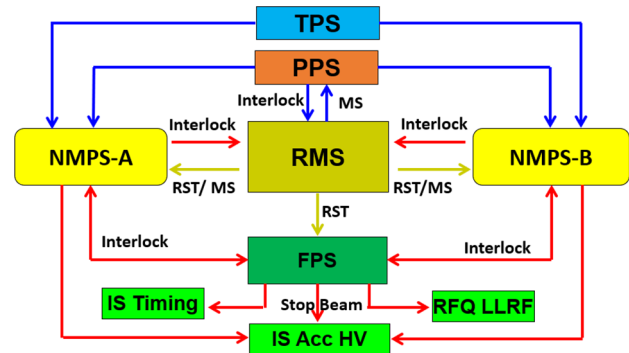

Figure 2: Relations among the protection systems for CSNS facility.

## OVERVIEW OF THE CSNS FPS

The FPS for CSNS accelerator was designed based on the FPGA, the hardware was designed in VME form. In order to unify the hardware type, two kinds of boards were designed, one is the main logic board as shown in Fig. 3, the other is the optical signal input board as shown in Fig.4.

Figure 3: Picture of the FPS main logic board.

Figure 4: Picture of the FPS signal input board.

The high-speed serial communication technology was adopted by the main logic board, and the common plastic

optical connector was utilized by the signal input board. The main logic board can be programmed to perform different function, which can be used for signals convergence or the beam interlock.

The tree topology was adopted by the FPS. In the actual deployment, FPS consists of three layers, the signal input layer, the signal convergence layer and the beam interlock layer. Figure 5 shows the topology diagram of the FPS.

The FPS consists of one beam interlock station, two signal convergence stations and several signal input stations. The beam interlock station is responsible for carrying out the shutdown of beam or mitigation measures. The signal input stations are distributed near the corresponding devices. The total number of input signals is 304, and the signals are from DTL power supplies, beam loss monitors and Linac RF system.

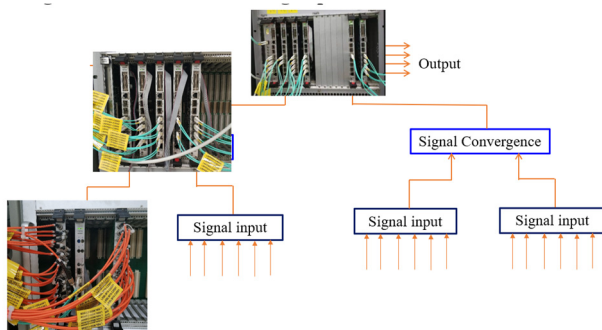

Figure 5: Diagram of the FPS topology.

## BEAM INTERLOCK LOGIC

The input signals of FPS from different devices has different type. For example, the over threshold signal from beam loss monitor is in pulsed type, the fault signal from power supply will be in high level state. So, according to different input signal type, different action will be carried out by FPS. The following will introduce the detail of the interlock logic and actions.

### Logic of Mitigation

For the pulse input signals, the mitigation measures will be carried out by FPS. When FPS receives pulsed signal, it will generate the output to inhibit next 1 second beam. Figure 6 depicts the output logic of inhibiting next 1 second beam. Figure 7 shows the details of mitigation actions, FPS will switch off the timing triggers to ion source and RFQ power source for 1 second, and after 1 second, the timing triggers will back to normal so that the beam will be recovered automatically.

Figure 6: The logic of inhibiting the next 1 second beam.

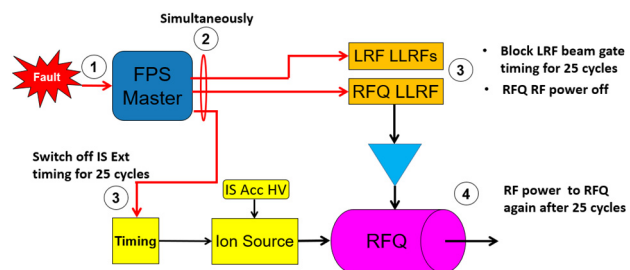

Figure 7: Actions of mitigation measure.

### Logic of Shutdown of the Beam

Figures 8 and 9 show the logic of how the latched output is generated by FPS. When the FPS receives the fault signal, the mitigation measure will be taken place firstly. If the during time of fault signal is more than 5 seconds, or there are two pulsed inputs in 5 seconds, the output of FPS will be latched. The shutdown of the beam actions will be taken place.

Figure 8: The latched output logic for PS input.

Figure 9: The latched output logic for BLM input.

Figure 10 show the detailed actions of shutdown of the beam. If the output of FPS changed to latched state, FPS will send interlock beam signals to MPS and ion source acceleration power supply, then the machine status will be changed to BEAMOFF and the ion source acceleration high voltage will be switched off. In this case, the manual beam recover process should be carried out in order to resume the beam.

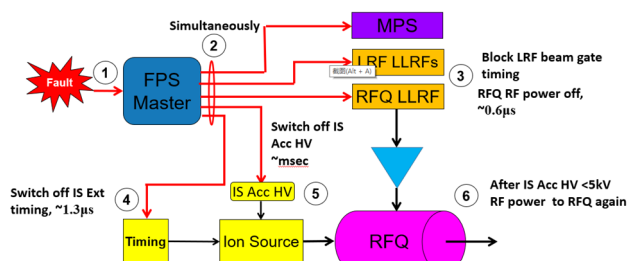

Figure 10: Actions of shutdown of the beam.

## CONCLUSION

The fast protection system for CSNS accelerator has been put into operation for more than three years. Different beam interlock logic was designed to fulfil the operation requirements. The fast protection system runs smoothly and reliable. The hardware will be upgraded in the CSNS-II project.

# SAFEGUARDING LARGE PARTICLE ACCELERATOR RESEARCH FACILITY- A MULTILAYER DISTRIBUTED CONTROL ARCHITECTURE

Feng Tao\*, SLAC National Accelerator Laboratory, Menlo Park, USA

## Abstract

Personnel Protection System (PPS) at SLAC is a global safety system responsible for protecting personnel from radiation hazards. The system's functional design shares similar concepts with machinery safeguarding, though the complexity of PPS is much higher due to its wide geographic distribution, large number of devices, and multiple sources of hazards. In this paper, we will first introduce the multilayer distributed control system architecture of SLAC's PPS, which serves three beam programs, e.g., LCLS, LCLS-II and FACET-II, that co-exist in the same 4km linear accelerator infrastructure. Composed of 50+ sets of redundant safety PLCs and 20+ access control PLCs, SLAC's PPS has five layers: beam program, beam switching and permit, zone access control, zone safety control and sensor/shutoff subsystems. With this architecture, safety functions often involve multiple controllers across several layers, make it a challenge on system analysis, verification, and testing. Therefore, in this paper, we will also discuss functional safety related issues for this type of complex systems.

## OUTLINE OF THE PAPER

In this paper, the machinery safeguarding concepts and the introduction of SLAC's PPS are given first. Then different layers of SLAC and their functions are explained. For the representative E-Stop function, how each layer of PPS control contributes to the safety integrity is analyzed in Section 3. The impacts on system integrity for such a large distributed system are discussed in Section 4, with proposed solutions. At last, some remarks are given in the conclusion section.

## MACHINERY SAFEGUARDING AND SLAC'S PPS

Machinery safety has been a matured and important field for safety-critical control system applications [1]. With the adoption of IEC 61508 [2] and the concept of functional safety, significant progress has been made in various application fields to formalize requirements on typical safety functions and their integrity levels. System designers should follow those standards and use those formalized requirements as a starting point. In machinery sector, there are two functional safety standards, e.g., IEC 62061 [3] and ISO 13849 [4], using different performance metrics Safety Integrity Level (SIL) and performance Level (PL) respectively. In Europe, ISO 13849 has been widely used as a

type B1 standard that many type C specific machine safety standards referred to.

SLAC is a large research facility. It has a 2 miles long linear accelerator (Linac), which is being used to generate either high power electron beam, or extremely bright x-ray laser for scientific experiments. For this reason, the whole facility can be treated as a large "machine" producing electron/x-ray. So those best practice from machinery safety can be applied to SLAC's PPS as well.

There are some similarities and differences between conventional machinery safeguarding with SLAC's PPS.

Common practices include:

- Dual redundant circuitry for system reliability
- Operators' search procedure to secure the area
- Personnel trapped key interlock
- Wide usage of machinery safety certified components, from laser scanner, Emergency stop, trapped keys, circuit breaker, to safety PLCs.

On the other hand, as a large research facility, SLAC's PPS is much more complex than a conventional machinery safety system. The complexity comes from four factors:

- Wide geographical distribution
- Large numbers of field devices to monitor/control
- Multiple sources of hazards to interlock
- Interface to many other complex systems.

Those factors combined altogether pose a design challenge for PPS, which must be a distributed global safety system to meet those challenges.

SLAC's 2-mile long Linac was built in 1960s, and it is the longest linear accelerator in the world. Nowadays, this Linac are serving three different beam programs: LCLS completed in 2009, FACET-II completed in 2020, and the superconducting (SC) LCLS-II, which is under construction and will start operation in early 2021.

Figure 1 shows the locations of three beam programs, each taking up one third of Linac for beam acceleration:

- LCLS-II SC beam: Linac West (Sector 00- Sector 09)
- FACET-II: Linac Middle (Sector 10- Sector 20)
- LCLS-I Cu beam: Linac East (Sector 21- Sector 29)

Figure 1: Layout of SLAC's Beam Lines.

\* The author currently works for Underwriters Laboratories as a Functional Safety Staff Engineer,

† Feng.Tao@ul.com.

The FACET-II beam will not pass Sector 20, but LCLS-I Cu beam and LCLS-II SC beam will enter Beam Switch Yard (BSY), where different routes and destinations of the beam are selected. Downstream to BSY is the Beam Transport Hall (BTH) and undulator complex, where electron beam wiggling through undulators to generate soft x-ray or hard x-ray. The x-ray laser travels across FEE-EBD to reach experiment hutches in Near Experiment Hall (NEH) and Far Experiment Hall (FEH).

To cover such a large facility, PPS needs to be distributed to effectively control/monitor field devices. Legacy systems use long haul trunk cables to connect field devices to control racks and control rooms, which is expensive and lack of flexibility. Just cite one example here: -48VDC was used in legacy systems to compensate voltage drop over a long distance. To modernize the system, we have used fiber-optic to create a dedicated ring topology network for all safety systems. Ethernet cables are been used as the infrastructure to minimize copper cable usage and to connect subsystems.

As each beam program has its own gun and acceleration RF devices, at each location, the PPS should be “aware” of not only the local prompt radiation hazards, but also hazards from all sources. Therefore, information exchange between different beam program is unavoidable.

At SLAC, attributes that distinguish PPS from other safety systems are strict configuration control and annual proof testing (bi-annual for some testing facilities onsite). Those are also the reasons that PPS are being trusted and being requested by many other systems (through interface signals) as a reliable means to bring the system into the safe state.

## DIFFERENT LAYERS OF PPS

As a complex global safety system, PPS needs to meet the needs from different beam programs. It is a loosely connected system that has multiple layers and multiple installations. As a distributed system, it contains five layers:

- Global Beam Programs
- Beam Switching and Permit System (BSP)
- Zone Access Control
- Zone Safety Interlock Control
- Sensor/Shutoff Subsystems

Each layer includes functions that are important to maintain personnel safety, and they are all part of the hazard mitigation scheme. In this section, we will describe functionality of each layer in details.

### Global Beam Program

There are three global PPS systems, corresponding to each beam program, and are conveniently named by their locations: e.g., Linac West Global PPS, Linac Middle Global PPS, and Linac East Global PPS. Each global PPS has separate top level safety controllers, to maintain the separation from other beam programs. This separation is especially important as each program have its own opera-

tion and maintenance schedule. Shutoff of one beam program should have no (or minimal) impacts to the operation of other beam programs.

### Beam Switching and Permit System (BSP)

In the BSY region, there are a group of 5 sets safety controllers that are responsible for beam switching and stopper permit/control. This system determines if both hard x-ray and soft x-ray beamline configurations are correct, and issues permits for stoppers, magnets, kickers and septum in BSY. A detailed BSY beamline layout with stoppers configuration is shown in Figure 2.

Figure 2: BSY Layout and Beam Stoppers.

As majority of stoppers in BSY cannot hold up to the powerful beam indefinitely, this system needs to work with upper layer control, to shut off beam before damages are made.

### Zone Access Control

Each individual PPS zone has an access control system responsible for non-SIL rated protection functions, such as zone search procedure, trapped key release, magnetic door lock, area access control, audio/visual warning etc. Although those functions are not deemed safety critical, they do provide some level of protection, and will be given credit in Layer of Protection Analysis (LOPA) [5]. They are part of the engineering control that reduces risk and lowers the SIL required for safety functions inside safety PLCs.

Other functions contained in access control are state machine for access states, communication with EPICS, sensors checking and maintenance (such as BTM fill/vent routines). For cybersecurity reason, all safety controllers do not directly connect to EPICS, but use access controllers as the bridge by connecting to those controllers using fieldbus modules. This configuration is to provide an air gap for safety controllers to prevent potential cyber-attacks. Access control PLC is also responsible for driving field devices such as E-Stop LEDs and Emergency-Exit buzzers to make safety control portion compact.

### Zone Safety Interlock Control

Zone safety interlock functions are contained in zone safety PLCs. At SLAC, PPS always uses dual redundant architecture, so there are identical Chain A and Chain B safety PLCs for each PPS zone. In *normal* mode, faulted input to Chain A will force both Chain A and Chain B controllers to turn off outputs; while in *test* mode, this cross-interlock between two chains is being turned off to facilitate testing, making it easier to identify faulty components on a single chain.

### Sensor and Shutoff Subsystems

Traditionally those subsystems are customized built chasses with a soldered relay assembly inside. They have

been modernized by using safety PLCs to lower lifecycle cost and to increase reliability. Typical sensors used by PPS are Burn Through Monitor (BTM), Beam Shutoff Ion Chamber (BSOIC) and Residual Dose Monitor (RDM). Shutoff devices usually are relays or contactors to disconnect power supply to radiation generating devices, or solenoid valves to insert beam stoppers into beamline. Those devices are permitted by PPS logic at upper layer, and they also need to provide reliable status to the upper layer for escalated shutoff or setting access to the accelerator.

Historically, outputs of BTM and BSOIC chasses are connected to a 17mA current loop, worked as a logic “AND” gate to sum up all discrete subsystems’ “OK/Fault” status within a given area. This current loop is called “Secure Loop” as it carries the information on whether a given area is secured to turn on hazards. For status of shutoff devices, similar current loops called “Set Entry” loops were built to sum up radiation generation devices’ OFF status in a given area, to indicate if the area is safe to access.

During upgrade, some current loop chasses have been eliminated by directly wiring individual input of the loop to a safety controller, which functions the same but have more diagnostics and is more reliable.

There are no clearly established guidelines on how to define and divide the boundary of PPS subsystems. It involves many project decisions when the project was planned. Global PPS uses Siemens distributed safety PLC family of products, such as S7-315F and the newer S7-1515F. The same fail-safe CPUs are used in access control PLC systems, but I/O modules in those systems are simply not fail-safe. Allen-Bradley ControlLogix is also being used in access control PLC in some PPS zones. Those two layers of PPS use large-size PLCs suitable for distributed applications. On the other hand, zone safety and sensor/shutoff subsystems are usually compact and use Pilz PNOZMulti safety PLCs.

### Functional Block Diagram of Linac West PPS

For better understanding of different layers of PPS, a functional block diagram of the Linac West is given in Figure 3:

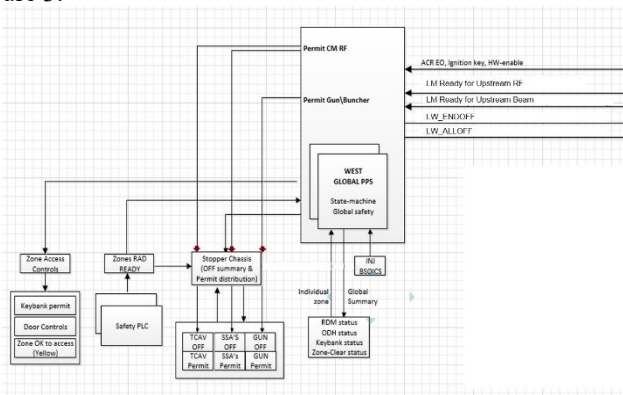

Figure 3: Linac West Functional Block Diagram.

Linac West is under construction for the LCLS-II project. The 10 sectors of Linac have been divided into three PPS zones: Inj-S00 for the injector, S01-S07 is the supercon-

ducting RF section, and S08-S10 will host normal conducting RF, as part of the LCLS-II-HE (High Energy) project scope, to boost electron beam energy from 4GeV to 8GeV. Each PPS zone has one dedicated access control PLC and two zone safety PLCs (Chain A/B), with the exception for S01-S07 zone. To effectively control such a large area over 700 meters, both access control and zone safety control use distributed architecture to make the field wiring manageable. To be specific, the zone access control using S7-1515F controller with 2 remote I/O drops, so that each I/O drop covers no more than 3 sectors. Zone safety control uses “SafeLink” communication modules to connect one “master” Pilz safety PLC with two “slave” PLCs, although the communication protocol itself is “peer-to-peer”.

The West Global PLC is another distributed safety system at the top level to connect other distributed systems at lower levels. It will provide permits to devices that can generate radiation hazards when following conditions are met:

- Zone safety controllers in all 3 PPS zones indicate the entire Linac West is searched and secured
- Interface signal from Linac Middle indicates the downstream area (from Sector 10 down to BTH) is “READY” (searched and secured)
- Beam containment subsystems (BTM, BSOIC, RDM (Residual Dose Monitor)) indicate beam are contained and those subsystems are working properly.
- Interface signals from other safety systems such as ODH (Oxygen Deficiency Hazard), BCS (Beam Containment System) indicate no need for PPS to shut off the accelerator for them.

Linac West Global PPS issues permit signals to stopper control PLCs, which enable operators to turn on circuit breakers that provide power to 280 Solid State Amplifiers (SSAs) and traditional modulators (for LCLS-II-HE). Those SSAs are grouped into 20 facilities Interface Switches (IS) panels, using SIL rated 600A circuit breakers to shut off power supply to a group of SSAs reliably.

### SAFETY INTEGRITY ANALYSIS

In a safety system design, the SIL or PL of a safety function is determined by risk assessment. For a standard machinery safety function, inputs, logic solver and final elements are all local devices. But this is not the case for large accelerator safety functions, making the analysis very tricky. In this section, we will use “Emergency Stop” function at different locations to demonstrate how different layers of PPS control work coordinately and affect the integrity of the overall function. Here the E-Stop function is chosen as the example because it is the most common safety function that required to achieve SIL 2 or PLd integrity performance by many safety standards.

#### Photon Experiment Area

For photon experiment hutches in NEH and FEH, PPS is relatively simple, and its settings are almost identical to those of standard machinery safety. Each experiment hutch is an isolated room with dedicated stopper for that beamline. In this system, safety inputs such as E-Stop, micro-

switches installed on the perimeter boundary, are interlocked to the beam stopper using safety PLCs. The overall system is dual-redundant as well, with diagnostic test pulses applied to PLC's inputs whenever possible.

The E-Stop function in this area is affected by three PPS layers. The bottom layer is the hutch safety controller, which handles safety interlock logic; and the layer above is the access control PLC, which provides additional protection layers related to personnel safety. This helps to reduce the SIL required for those safety functions in the zone safety controllers [5]. For example, the perimeter door magnetic lock function will reduce the probability of challenging door microswitch interlock from outside of the hutch. The audio/visual warning function, which alerts people to leave the area also reduces the need of people left behind pressing E-Stop to initiate emergency shutdown.

In addition to those controllers, there is a diagnostic function implemented by upstream *PPS beam switching and permit system (BSP)*, which will insert the upstream beam stoppers in case the photon beam stopper fails to move in for any reason. This is achieved via a 17mA current loop named "LCLS Secure Loop", which passes through each photon beam stopper chassis in NEH. If any beam stopper has no permit and is not in "IN" position, relay logic inside the chassis will break the current loop. The current loop receiver will repeat the status and feed into BSP controllers to insert upstream stopper(s) in BSY. This function shall be treated as a diagnostic function applied to the output subsystem, photon stopper in this case, to provide a secondary shutoff path in case of the primary path failure. The safety function's reliability block diagram (RBD) is shown in Figure 4. As the overall system is dual-redundant, each block does contain symmetric components on two parallel paths.

Figure 4: RBD for E-Stop Function.

In a previous paper by the author [6], the similar case has been studied, and the PFD value was calculated. Readers can compare the difference between two diagrams. In Figure 4, due to the presence of the additional diagnostic shutoff path, the safety function has a higher safety integrity. It is noticed that add-on diagnostics is a common strategy used in system design to improve system integrity. Such as using a Watch Dog Timer (WDT) as a secondary shutoff path, which can effectively upgrade the implementation from Category 1 to Category 2 for a machinery safety function [4]. But as on the primary shutoff path, dual redundancy should already provide sufficient reliability from electronics perspective; adding a secondary path may only be justified if the stopper has a substantial percentage of non-electrical failures from its failure mode analysis.

## PPS in BTH and FEE-EBD

These sections are upstream to photon experiment area but downstream to BSY. There are no dedicated beam stoppers, so if any input to the zone safety controller faulted, the controller will de-energize its output to directly break the "LCLS Secure Loop". As stated before, this will cause the BSP to remove the BSY beam stopper permit, causing the stopper automatically move in. Therefore, in this case, zone PPS safety controller and BSP safety controller combined to be the logic solver during the safety integrity verification. The reliability block diagram in this case is shown in Figure 5 below:

Figure 5: RBD for E-Stop Function at FEE-EBD and BTH.

In the figure above, the logic solver portion includes two or more safety PLCs (zone safety and BSP safety), LCLS Secure loop transmitter/receiver. Each Pilz safety PLC will add up about 150ms into the function's response time, so if the shutoff action needs to propagate further upstream to the Linac area and involves multiple subsystems, the overall response time should be verified against requirements.

Comparing Figure 4 and Figure 5, for the same E-Stop function, due to the different system configuration, the reliability performance differs, and the E-Stop function in photon area is more reliable.

## PPS in Linac and BSY

The upstream LCLS-II SC beam has a bypass beamline all the way from Sector 10 to Sector 29 and have almost the same destination as LCLS-I beam. Therefore, once it is turned on, its radiation effects will affect downstream all the way to BTH. FACET-II does not have bypass line, but its radiation is dangerous to people in the LCLS-I Linac accelerator tunnel as well.

The impacts of such a layout are two folders:

- The safety functions triggered in a downstream area also include turning off upstream radiation sources.
- To turn on radiation generating devices in the upstream, all downstream areas need to provide enable signals to indicate it is safe to do so.

In both cases, the block diagram of the safety function will become more complex than usual, as more devices are showing up on the shutoff path, makes it even harder to meet the reliability requirements.

Figure 6: Interface Signals between Beam Programs.

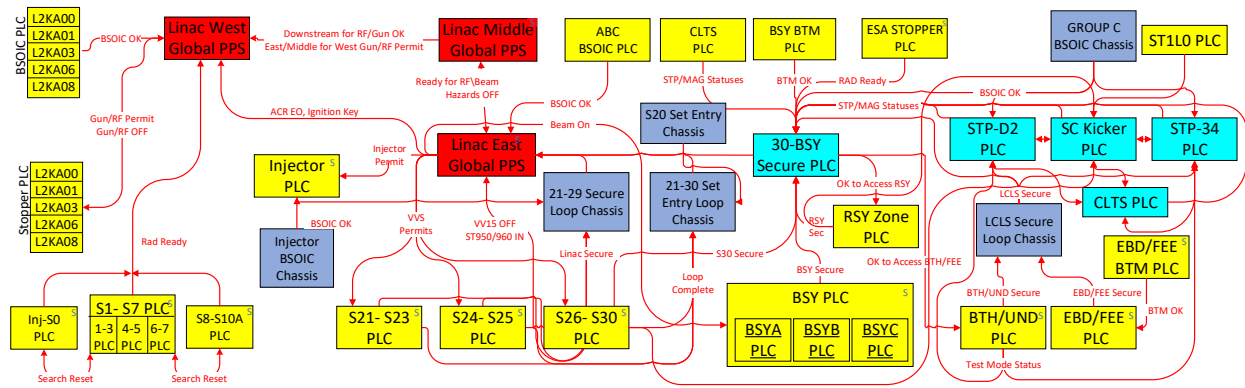

Figure 7: Signal Interfaces among PPS Safety Controllers and Safety Critical Electronics.

Figure 6 shows the interface signals among three global PPS systems. It should be noted that a beam program may have different modes to turn on beam, or RF or both. The hazard level is different for each operation mode.

As there are over 50 sets of safety controllers and safety critical electronic chasses across SLAC. There is a need to identify how those safety-critical signals flow through those subsystems for a better understanding. For SLAC's PPS at electron areas, a completed signal interface diagram is shown in Figure 7, where a letter "S" on the top-right corner of the PLC indicates it has a supervisory (access control) PLC.

This diagram is useful when to determine the safety shutoff action sequence, e.g., how the safety interlock broadcasts from one controller to another.

This diagram is also vital in interface control and test planning. For such a large system, PPS's annual site acceptance tests (SAT) need to be carried out by area and in multiple stages. Every interface signal in the diagram needs to be verified seamlessly on both ends to ensure the overall system functionality is intact.

Reading from Figure 7, we can identify the most challenging scenario for PPS safety interlock, e.g., E-Stop activation in BSY region. In this area, zone safety control also adopts the "master-slave" configuration. So if any E-Stop button wired to a "slave" safety controller is pressed, the shutoff actions will take the following sequence:

1. BSY zone safety "slave" PLC
2. BSY zone safety "master" PLC
3. 30-BSY Secure PLC
4. Linac East Global PPS
5. Linac Middle Global PPS
6. Linac West Global PPS
7. 5 Stopper PLCs (L2KA00/01/03/06/08)

For this scenario, there are 11 safety PLCs shown up in the reliability block diagram. Since all those PLCs are serially connected on the RBD, each PLC's PFH (Probability of Failure per Hour) value will add up to the PFH of the overall function.

If more than one beam program is running, then there are more controllers get involved in the shutoff action. For example, assume that both LCLS-I and LCLS-II beams are running and need to be shut off, then Linac East Global PLC also needs to remove permits sent to four zone safety controllers:

- Injector PLC (at Sector 20)
- S21- S23 PLC
- S24- S25 PLC
- S26- S30 PLC

In this extreme case, there are 15 safety controllers in total must function correctly to shut off all radiation hazards.

The following table from ISO 13849 [4] (Table 11) shows the relationship between number of subsystems, lowest PL and the overall system PL. Though the calculation is based on the average reliability value of each PL, but the message is clear: reliability lowers when more subsystems are connected in a simplex configuration.

Table 1: Calculation of PL for Series Alignment of SRP/CS

$PL_{low}$	$N_{low}$	→	PL
a	$>3$	→	None, not allowed
	$\leq 3$	→	a
b	$>2$	→	a
	$\leq 2$	→	b
c	$>2$	→	b
	$\leq 2$	→	c
d	$>3$	→	c
	$\leq 3$	→	d
e	$>3$	→	d
	$\leq 3$	→	e

Due to the large number of subsystems involved, in our case, it would be a challenge, if not impossible, for the E-Stop function to achieve SIL 2 integrity level!

## Solutions for Meeting Integrity Requirements

There are several possible solutions to improve PPS's integrity:

- Add shielding to the boundary between Sector 9 and Sector 10 to eliminate the need to shut off upstream radiation source, thus simplifying the safety function.
- Re-define the shutoff function, make a clear distinction between interlock to gun and RF. Shutting off gun is more effective than shutting off RF, as RF alone only generates dark current, which is less dangerous than the accelerated beam.
- Simplify system architecture, reduce number of the PLC that re-routes the shutoff command. Safety relays and hardwiring may improve the safety integrity than safety PLCs.
- Add additional shutoff path.

For each option, there are some corresponding concerns as well:

- Adding additional shielding is expensive for the project, though this is the safest approach, and is consistent with the "inherently safe" principle.
- Before re-define the function, detailed study needs to be performed to narrow down the scope of shutoff, reduce the number of safety controllers on the shutoff path.
- Replacing PLCs with relays and cables is a reversal of the trend for more functional integration, modularity, and configurability. This will make the system less flexible and difficult to upgrade later.
- A good candidate for the shutoff path is to use Beam Containment System (BCS), which is another global safety system at SLAC [6]. This system is an independent system using different mechanisms to shut off the beam. Currently it is only being requested by PPS for a fast shutoff when BSY beam stoppers are in motion, so as to avoid the damage caused by beam hitting sides of stoppers. Using BCS as the secondary shutoff path needs additional work to connect two systems, but as there is no common cause factor between primary/secondary shutoff, the PPS's safety integrity can definitely meet the SIL 2 or PLd performance requirement.

Reviewing all options above, the best solution is to use BCS as the secondary shutoff path. The tie-in point from

PPS to BCS should be close to the BSY, to maximize the performance.

## CONCLUSION

SLAC's PPS employs a complex multilayer distributed architecture to protect personnel from prompt radiation hazards. This architecture is far more complex than the standard ones from ISO 13849 and IEC 62061 standards. In this architecture, there are more modular control systems deployed at different levels to meet the operation needs. However, this complexity inevitably lowers the overall system's integrity, which need to be considered and verified during the system implementation. For a successful safety system design, both functional requirements and integrity requirements must be met.

## ACKNOWLEDGEMENTS

I would like to thank my colleagues in the Safety System Department: Enzo Carrone, James Murphy and Keith Belt. I deeply appreciate their supports during my ten years of adventure at SLAC! Accelerator Safety Officer Paul Miller and Michael Stanek, accelerator physicist John Schmerge and Jerry Yocky provided valuable information during discussions and design reviews.

# INTEGRATED SUPERVISION FOR CONVENTIONAL AND MACHINE-PROTECTION CONFIGURATION PARAMETERS AT ITER

D. Karkinsky<sup>†</sup>, W. Van Herck, I. Prieto Diaz, J. Soni, A. Marqueta, ITER Organization, St. Paul lez Durance, France

## Abstract

Configuration parameters for ITER's I&C systems are predominantly high-coupled due to the nature of the process under control. Subsequently, I&C re-configuration requires an integrated supervision approach that addresses coupling through abstraction, automation, scalability, changeability, robustness and re-usability. Moreover, high-coupling might manifest at any tier of the I&C, and certainly spans configuration parameters across both conventional and investment-protection I&C.

Stemming from ITER design guidelines, the handling of investment-protection configuration parameters needs to meet the goals of IEC61508. These goals are mostly in congruence with the main concerns of integrated supervision identified above. However they also extend requirements that bind the supervision process with traceability and audit capabilities from sources to final self-test (run-time) diagnostics.

This presentation describes the provisions for integrated supervision at ITER and elaborates how these provisions can be used to handle machine-protection parameters in compliance with IEC61508.

## INTRODUCTION

The ITER plant configuration system is a component of the Control, Data Access and Communication (CODAC) Supervision and Automation (SUP) system and is tasked to:

- Derive machine parameters from the central planned experiment information contained in the pulse schedule,
- Conduct a multi-stage engineering verification process involving a wide range of codes (e.g. electromagnetic induced forces on mechanical structures, scarce resource budget management, etc.),
- Convert machine parameters to the number and format representation of the various Plant Systems Instrumentation and Control (I&C), and
- Eventually load machine parameters to the Plant Systems Instrumentation and Control (I&C) as part of the experiment preparation.

The ITER plant configuration system interfaces to ITER machine Operation, to a heterogeneous set of data repositories (e.g. pulse schedule queue, machine geometry and condition, operating limits, live measurements, Plant System self-description data, etc.), and the Plant System Instrumentation and Control (I&C) systems that compose the ITER machine.

The ITER plant configuration participates to the ITER defence-in-depth machine protection scheme by ensuring the configuration is as thoroughly verified as deemed necessary before starting lengthy and costly operations.

The baseline design for the Plant System I&C configuration interface is using EPICS records databases and Channel Access (CA). This was challenged during the 2014 CODAC design review. It was then understood that this choice was ill adapted to address the complexity required in the scope of ITER Plant Systems, and in particular in those areas below:

- Large and complex data structures involved.
- Existence of dependencies between parameters.
- Exception handling (e.g. restoration of valid configuration after a failed verification by the Plant System) and reporting.
- Handling of investment protection parameters for the Integrated Control System (ICS).

As a result, the configuration system was designed to support:

- Structured configuration variables,
- Atomicity of loading such, possibly complex, data structures,
- Protection against data corruption.

The protocol for Plant System I&C configuration is defined to follow the sequence outlined in Figure 1. The hash provides protection against data corruption and acts as a digital signature of over a data stream that can encapsulate an arbitrary set of configuration parameters.

In this presentation we report the results from an investigation into how the ITER plant configuration system can integrate with ITERs integrated control system (ICS) for handling investment protection parameters. As per ITER guidelines the ICS needs to meet the goals of IEC61508[1]. We report on the process by which we arrived at an adequate integration point for both systems and the technological solutions that have been put in place in support of this integration.

## SUP SYSTEM DESIGN

ITER defence-in-depth principles, and the overall complexity of the machine, dictate that parameters are verified before being loaded to the plant. Distinct verification processes may be used depending on the nature of the task.

Furthermore, high-level operation will define operation goals, from which Plant System parameters must be derived (e.g. required cryogenic cooling capacity derived from predicted thermal loads).

To accommodate these requirements, the SUP configuration framework contains the following subcomponents:

<sup>†</sup> Damien.Karkinsky@iter.org

- Configuration Verification and Validation Framework (CVVF): this framework encapsulates user-defined transformation and verification codes and exposes these as network services; the framework allows for the integration and invocation of codes that were implemented in different programming languages (e.g. C++ or Python);

- verify that the high-level parameters of the current activity are within operational constraints;
- transform high level parameters from the physics/operational domain to the engineering domain (machine specific);

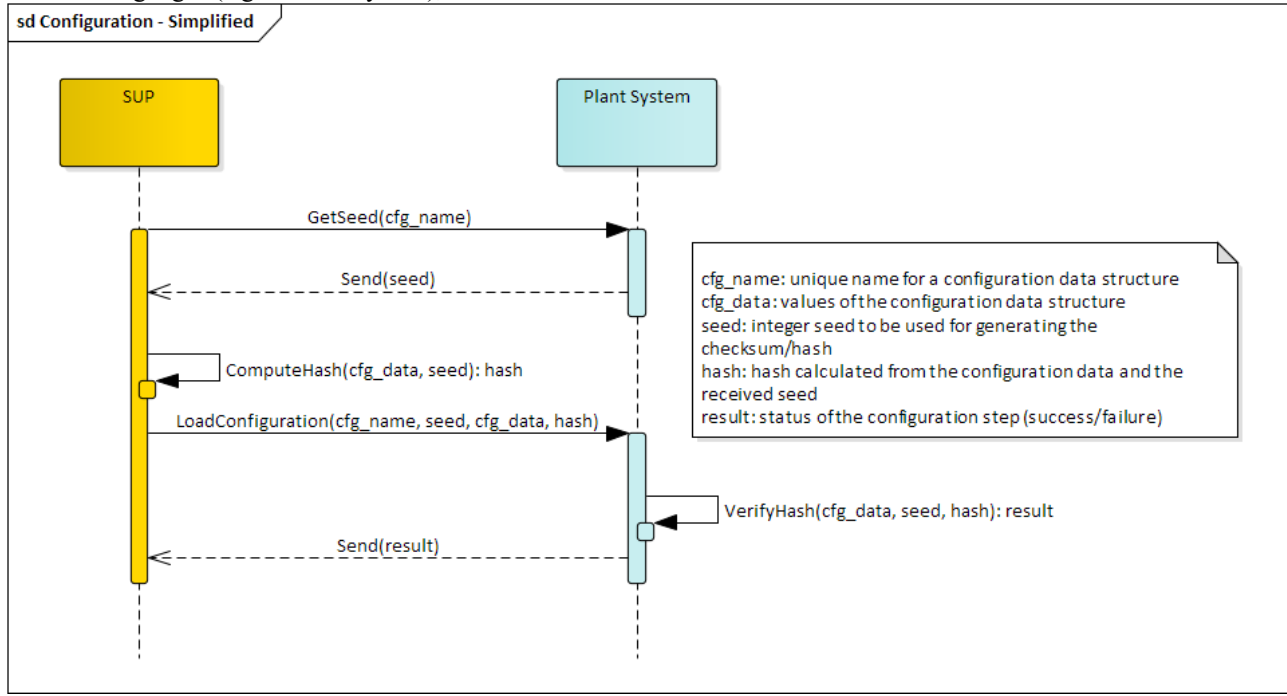

Figure 1: Simplified sequence diagram for Plant System configuration by SUP.

- Chain Data Processing engine (CDP) to define and execute workflows through CVVF applicable to various Plant I&C.

In order to support differentiated workflows for distinct types of users (e.g. operator and expert users), or during distinct life-cycle phases (e.g. testing, commissioning or operation), the configuration process and workflow definition is data driven.

An example of a simple configuration workflow clarifies how different processes in the workflow can depend on one another:

- Retrieve high-level parameters for the current activity;
- Call CVVF service to:
  - verify the authenticity of the received parameters;

- verify that the machine specific configuration parameters do not lead to violations of machine or operational limits and constraints;
- hash the streams of output to each Plant System;
- If all CVVF steps pass without an issue, transmit those parameters to the Plant System I&C in an atomic transaction.

Each of the CVVF processes express the configuration transformation and validation needs, through a set of remote function calls, which are identified using a Uniform Resource Identifier (URI). These function calls are fed with variables from the engine's workspace and result in updating other variables in the workspace.

## INTEGRATED CONTROL SYSTEM AND ITS CONFIGURATION

ITER functions for investment protection are implemented in dedicated Plant System I&C called Plant Interlock Systems (PIS). PIS are coordinated by interlock functions of the Central Interlock System (CIS) where transversal investment protection risks are identified. Together these systems form ITER's Integrated Control System (ICS).

In the baseline design, the configuration of CIS is performed at the CIS desk through a custom High-Integrity Operator Commands (HIOC) [2] application layer protocol based on an OPC-UA interface. This interface is independent from SUP and the configuration of the PIS. Stemming from high-coupling, in almost all situations concerning PIS configuration, SUP configuration is the only realistic solution. This results in a gap of requirements for the ICS on handling critical configuration parameters. For instance, PIS modification without central coordination at the level

of ICS can lead to un-intended side-effects that can affect fault-tolerance claims and the ability of ITER to remain in a given operational state. Additionally, even in the case of some CIS functions it has become clear that certain parameters need to originate from the pulse-schedule, traverse a SUP workflow, and be communicated to the CIS desk with the necessary degree of assurance.

For this reason CIS needs to play a role during PIS modification, if only to ensure that the pre-conditions during PIS-modify actions are met. This justified a need to seek closer integration between HIOC and SUP and to develop a centralised policy for handling configuration parameters.

## IEC61508 COMPLIANCE AND SUP

Investment protection function reliability implemented in ICS is commensurate to integrity targets in the SIL-1 to SIL-3 range according IEC61508. The goal of IEC61508 compliance for investment protection at ITER, is to demonstrate assurance within IO that these functions meet the identified reliability target. In order to drive the requirements for HIOC and SUP integration, we performed an analysis of IEC61508 requirements w.r.t. handling configuration parameters and matched these to SUP requirements.

From the perspective of investment protection, SUP generates outputs which can directly contribute to the executable code of a PIS and therefore, it was considered to be a T3 off-line support tool (see IEC61508-3 7.4.4) for the ICS. There are two main clauses of the standard that we need to respect with regards to such tools:

- a) Treat SUP as a software element of the ICS where the level of reliance that is placed is assessed, failure mechanisms identified and mitigation measures taken (see IEC61508-3 7.4.4.1 and 7.4.4.5),
- b) Define and meet criteria for coherency of this tool in the system development (which includes configuration) activities (see IEC61508-3 7.4.4.2).

In the case of a) only the workflows for storing, verifying and generating the configuration parameters for a PIS are of interest. Moreover, not all software components in a given workflow will need to be of integrity commensurate to the investment protection integrity target. Where parameters pass untrusted software components, adequate trusted measures can be added to close the vulnerabilities introduced from untrusted elements. In the context of PIS configuration, we aim to classify CVVF transformation and verification steps in three tiers:

1. Untrusted, where no guarantees can be placed on the step's correctness or it can introduce errors in the configuration parameters
2. Trusted with low-confidence, where the integrity of the step is not as required by the integrity target or there are intrinsic failure mechanisms in the technique on which the step is based, which cannot be mitigated.
3. Trusted with high-confidence – the integrity of the step is as strict as required by the integrity target and all failure mechanisms have been mitigated.

Confidence is directly related to the systematic capability (see IEC61508-4 3.5.9) with which a step was developed, verified and change managed. For instance; lack of separation of techniques, development teams or the presence of un-mitigated intrinsic vulnerabilities in the implemented method, reduce confidence in the step. However, low-confidence trusted steps can be combined into higher confidence following the constraints placed by systematic capability over elements (see IEC61508-2).

In the case of b) we set the criteria for structured configuration parameters from IEC61508-3 7.3.3.12-13, 7.4.2.14 and (guide) Annex-G. In a broad sense these require:

- a. Verification of the consistency, completeness and compatibility of; data structures, operational parameters and interfaces.
- b. Full transparency over the workflow and in particular identification of all items needed to replay any step in the process of loading configuration parameters.
- c. Detection of unauthorised changes,
- d. Detection of corruption at run-time.

Item a) is partially met from the design requirements of SUP. To meet the requirement fully it is necessary that PIS ROs and ITER Operators take formal steps in determining which configuration parameters pose investment protection risks (e.g. risk assessments) and to drive the specification for the workflows of trusted/untrusted steps within CDP from the identified risks.

In contrast, item b) was identified as a new requirement for SUP. This requirement is not immediately obvious from the perspective of conventional Plant I&C. The requirement requests SUP to ensure that inputs, step configuration, outputs and roles involved in executing each CVVF step at a point in time and in a given workflow, be recorded so that the chain can be audited from the source to destination. The ability to replay CDP workflows gives the ability to identify the source of a fault and drive a policy of continuous improvement.

Items c) is within the domain of ICS, where a central method is necessary to inhibit unauthorised changes, and item d) is in the domain of each PISs which needs to perform run-time verification over static-data as part of its self-check diagnostics.

Given these requirements, the interface point for HIOC and SUP was set at c) and d) and additional measures that will permit a configuration change to be traced to a workflow execution within SUP.

## HIOC AND SUP INTEGRATION

The development of HIOC, followed IEC61508-2 requirements for a “black-channel” interface where measures necessary to ensure the failure performance of the communications process were implemented. IEC61784-3[3], which contains broad risks & measures guidelines for com-

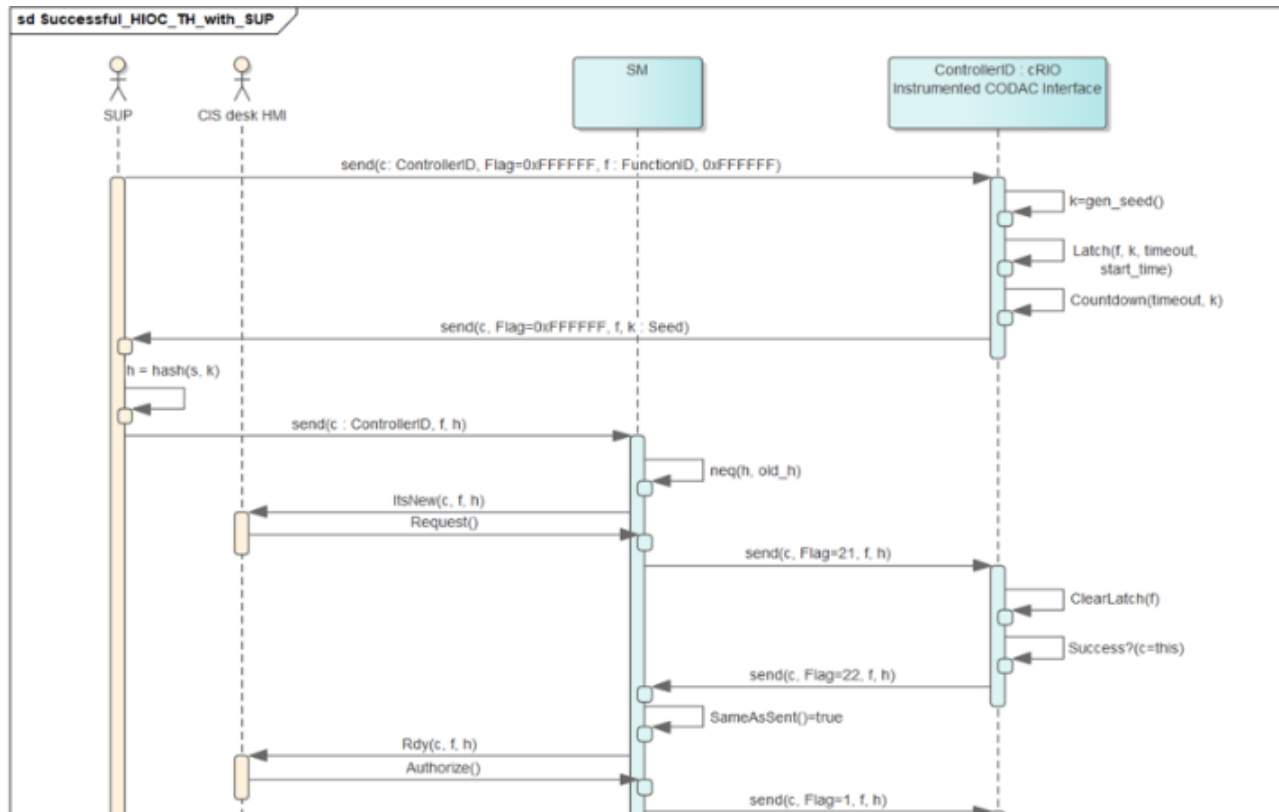

Figure 2: Interaction sequence in HIOC with SUP.

munication channels, was used as the source of requirements. The software elements that have been developed support up-to SIL-3 on PLC and SIL-2 on FPGA types of hardware.

HIOC involves a three-stage configuration process that aims to verify;

1. The controller identity (*ControllerID*) that is being modified is as intended by the operator.
2. The function identity (*FunctionID*) on the controller being modified is as intended by the operator.
3. The configuration parameter value (H) that is being changed is as intended by the operator.

These guarantees are provided at application level, meaning lower level components in the communications hierarchy can be of arbitrary integrity. If one of the three stages fails, HIOC aborts the configuration process which means that the parameter is not loaded into the critical path of the target function's control loop.

The main use-case of HIOC is to modify single value Boolean and Threshold parameters. Such parameters can be used to gate PIS special states e.g. mask the PIS response to a hard or a soft reset or set the maximum plasma current threshold for a given experiment.

In the case of HIOC with SUP integration, the Threshold use-case was re-purposed as an 8-byte SHA-1 hash of a configuration stream. Major assumptions in the use of HIOC is that it shall be utilised within a secure network where all entities are known and are non-malicious. It is

within this assumption that HIOC provides a trusted mechanism to preload this hash and set the PIS's SUP interface in a state where the PIS can accept new parameters.

Each hash is valid for a specified time period and is based on a random seed value generated by the PIS. SUP requests the seed from the PIS on protocol initiation and generates the new hash (Figure 1). It then makes a request to the CIS Supervisor Module (SM in Figure 2). The CIS-SM initiates a HIOC interaction with the PIS to retrieve the seed and authorise the new hash. The first goal is to enter the hash, seed and time into the ICS logs. This permits the HIOC transaction to be traced to the outcome of the CDP workflow execution that produced the hash. The second goal of CIS-SM is to verify that given the current ICS state, the PIS can be modified. This can be done by asking for confirmation from the CIS desk (i.e. manually) or automatically. Rules on when PISs must be fully or partially available result from operator instructions. A fully automatic process is not possible as PIS operating rules vary.

Transmitting the hash through the remaining HIOC steps indicates an authorization to load the particular configuration stream that corresponds to the hash/seed pair.

On obtaining authorization to load new parameters, the PIS enters a wait-state for the parameter stream from SUP. During this state, the PIS might override the relevant investment protection functionalities (e.g. placing the outputs in a known disabled state to avoid a spurious trigger of ICS). If it receives this stream within the allocated timeout it can generate its own hash and compare the result against the hash received via HIOC. If the two hashes

match the PIS can proceed to load them into the critical control loop, which will then re-establish the investment protection outputs to their computed state. The result is reported to the CIS-SM in an abort or a success identifier which is also logged.

Additionally, the PIS can use the hash inside its self-test diagnostics loop to check if the parameters remain unmodified during runtime. Depending on the technology used to store these parameters, they could be susceptible to various forms of memory corruption (e.g. single event upsets).

This approach requires PISs to integrate with HIOC over a separate interface from SUP. The level of separation is dictated by the level of confidence that is required. At the extreme end a different hardware interface can be used. For instance, PIS typically integrate with SUP over the Plant Operations Network (PON). HIOC is normally executed over the Central Interlock Network (CIN), but it can be utilised on PON since the integrity is achieved at the application layer. Additionally EPICS and OPC-UA adaptors have been developed for the common frameworks used in PIS development [4].

## CONCLUSION

In this presentation we reported on a central policy for handling investment protection configuration parameters of arbitrary complexity that arises from interfacing the ITER plant configuration system and the ITER integrated control system.

The requirements from this integration were derived from the IEC61508 standard as required by ITER guidelines. The presentation also outlined the technical design that supports this integration.

A number of open questions remain, such as the need of PIS developers to determine which parameters pose investment protection risks to drive workflow definition requirements and the need to incorporate runtime checks over the consistency of these parameters as part of self-test diagnostic routines.

The use of a central policy for handling configuration parameters and special state gate-keeping will eventually target the realisation of central rules over the level of readiness of components within ICS that govern the effective ITER Operational State or a proposed transition to a new state. In the present baseline, each PIS and CIS are preparing individual concepts of operation, and these plans are an important preliminary step towards identifying central rules for ITER operation.

# TEMPERATURE CONTROL FOR BEAMLINE PRECISION SYSTEMS OF SIRIUS/LNLS

J.L.N. Brito\*, G. S. Baldon, F. R. Lena, M. A. L. Moraes, R. R. Gerales, M. Saveri Silva, L. M. Volpe, Brazilian Synchrotron Light Laboratory (LNLS), CNPEM, Campinas, Brazil

## Abstract

Precision beamline systems, such as monochromators and mirrors, as well as sample stages and sample holders, may require fine thermal management to meet performance targets. Regarding the optical elements, the main aspects of interest include substrate integrity, in case of high power loads and densities; wavefront preservation, due to thermal distortions of the optical surfaces; and beam stability, related to thermal drift. Concerning the sample, nanometer positioning control, for example, may be affected by thermal drifts and the power management of some electrical elements. This work presents the temperature control architecture developed in house for precision elements at the first beamlines of Sirius, the 4th-generation light source at the Brazilian Synchrotron Light Laboratory (LNLS). Taking some optical components as case studies, the predictive thermal-model-based approach, the system identification techniques, the controller design workflow and the implementation in hardware are described, as well as the temperature stability results.

## INTRODUCTION

To address strict performance challenges of the new-generation beamlines at the Sirius 4th-generation light source [1], a series of innovative instruments have been developed in-house by the the Brazilian Synchrotron Light Laboratory (LNLS) over the past few years. Considered critical elements, special attention was given to optical systems – such as the High-Dynamic Double-Crystal Monochromator (HD-DCM) [2], the 4-bounce Crystal Monochromator (4CM) [3], mirror systems [4] and experimental stations [5].

These high-performance systems have been developed according to strong precision engineering and mechatronics principles, in which mechanical, thermal, metrology, control, and software aspects must be jointly addressed since early design stage [6]. Within this scope, sub-system functionalities are decoupled as much as possible from each other to minimized crossed effects, such that, as an example, a cooling system aims to be mechanically decoupled from the element of interest, whereas a positioning system/structure tends to be thermally decoupled from it.

Oftentimes, flexural structures are used as predictive solutions for kinematic mounts and fine positioning capabilities, with complementary thermal isolation possibilities [4, 7, 8]. Indeed, thermal decoupling is an essential aspect in many of these systems because cryogenic solutions were extensively adopted, either for

sample conditioning [8], or for the silicon-based optical elements [2–4], to benefit from the thermal properties of this material at low temperatures in handling heat dissipation and thermal stresses/deformations.

Next, in addition to thermal decoupling, temperature control becomes an indispensable feature in many of these systems, being used for: 1) coarse static compensation in heat-flow for the desired operation temperatures; 2) heat load compensation (with and without beam, for example); 3) reduction of the time constants in the closed-loop systems as compared to passive or open-loop response; and 4) fine temperature control in drift-sensitive systems.

The following sections present the temperature control architecture that has been standardized for some Sirius beamline systems; the hardware, with appropriate actuators and sensors being critical for robust and high-performance control capabilities; predictive and experimentally derived plant models; and illustrative commissioning examples.

## ARCHITECTURE AND HARDWARE

The hardware architecture adopted to control the temperature of the Sirius precision beamline systems is summarized in the Fig. 1, where a NI CompactRIO (cRIO) implements the control by reading the temperature sensors and acting through heaters present in the system, represented by a mirror. The cRIO also interfaces with the equipment protection system (EPS) [9], closing the beam shutter in case of overheating or disabling the cooling system to prevent overcooling, for example.

Figure 1: Temperature control hardware architecture.

The elements of the architecture and its characteristics are presented below.

### Power Driver

The power driver is a multi-channel heater driver [10] in-house developed with 8 channels that delivers up to 1.5 A at 12 V DC per channel, where the voltage output

\* joao.brito@lnls.br

been found in the cryostats, such as sensitivity to the phase transitions (icing, clogging and vibrations) and temperature oscillations in the load due to variations in the Dewar pressure. Indeed, in the pulse tube the flow is controlled by the frequency of the compressor, where are located the moving parts, that can be mechanically decoupled from the cold tip. Limitations in the pulse tube are essentially related to their load capacities, which are not sufficient for many beamline application.

## UHV Heaters

The first cryogenic systems at Sirius beamlines utilized two different thin-film, UHV-compatible Kapton heaters from Taiwan KLC (part number TSC013D003GR36Z01), with nominal resistances of 36  $\Omega$  and 14.4  $\Omega$  for 4 W and 10 W power at 12 V, respectively. Although having an easy integration and proven vacuum compatibility, along with low cost, the flexible nature of the Kapton heaters made the clamping to the components a potential source of failure. Indeed, the components surface characteristics, together with human errors during the assembly process, often led to crushing of the electric track, or to bad contact interface, thus resulting in open or short circuits, overheating and failure. Also, it was found that these heaters might contaminate the vacuum systems in a failure event, due to outgassing. All these aspects reduce the systems robustness, increasing the need of corrective maintenance and posing risks to the sensitive optics.

Therefore, a new heating element is under development for higher reliability. As depicted in Fig. 2, it consists of an SMD (Surface Mount Device) nickel thin film and alumina power resistor from Susumu, soldered over a small aluminium metalcore PCB (Printed Circuit Board) using a lead free (SAC305) solder paste. The board is then encapsulated inside a small aluminium case using the Stycast 2850FT epoxy resin along with CAT11 catalyser. The aluminum PCB and housing serve as efficient heat conductors to the part of interest.

Figure 2: Heater 3D model and internal elements.

Heaters for 4.4 W and 8 W nominal power at 12 V were extensively tested for lifetime and outgassing by cycling them between 60 K and 390 K, as shown in Fig. 3. After 250 cycles, 3 of the 12 heaters tested failed, always within the first 20 cycles, which was observed by the heaters appearing as an open circuits for the power driver. For reference, initial tests with 7 heaters soldered with 63-37% tin-lead alloy did not present failures during all 82 tested cycles between 80 K

to 390 K, indicating that the lead-free solder could be the major culprit.

In fact, the lead-free soldering temperature is higher (220 °C versus 183 °C), making it harder to manually solder by hot air. Then, two possible solutions to the solder problem are: hiring the services of a specialized company for the soldering, allowing for a more consistent process; or ditching the lead-free solder altogether, since the tin-lead solder did not present those problems, which might offer residua risks in terms of vacuum compliance. One last aspect to consider is that, during the whole cycling test, no excessive outgassing was observed (see Fig. 3), which was an important step for validating this heater for UHV systems. Future monochromators, mirror systems and vacuum sample environments will be using the new heaters.

Figure 3: Fatigue and outgassing validation tests for the new heaters: cycling temperatures (top) and pressure (bottom).

### Temperature Sensors

The temperature sensors also had design iteration since the beginning of the commissioning of the first cryogenic beamline instrumentation. Initially, 10k Ohm (0°C nominal) Platinum thin-film RTD sensors from IST (P10K.520.6W.B.010.D) were used for parts in operating temperature below 123 K, whereas ceramic Amphenol DC95F202WN negative temperature coefficient (NTC) sensors were used above 270 K, usually at room temperature components equal to 297 K. The part-through-hole (PTH) sensors were soldered to thin, 30 AWG, varnish insulated copper wires with small amounts of tin-lead (70/30) alloy. The set was then encapsulated with the same Stycast resin into small aluminium cases for thermal conductivity and mounting features.

The strategy with different sensors for different temperature intervals was chosen to better use the full sensing range of the NI 9226 (see Fig. 1), resulting in a temperature resolution better than 0.1 mK for both sensors at their nominal operational temperatures, as shown in Fig. 4. However, it has been recently concluded that, for most applications, it would be advantageous to trade the higher resolution by the possibility of measuring a broader temperature range, namely, the full range from the LN<sub>2</sub> cryogenic condition up to the optics typical baking temperature (> 85 °C).

Furthermore, the thin platinum wire of the 10 kΩ RTDs presented bad solderability and its assembly process was too laborious, resulting in unreliable mechanical bonds and a failure rate beyond acceptable for a robust beamline instrumentation. The alternative was to use 2 kΩ IST RTDs (P2K0.232.3FW.B.007) with custom-made flat gold-plated terminals, resulting in a full range sensor with better solderability and temperature resolution below 0.4 mK over the entire measurable range (see Fig. 4).

Figure 4: Temperature resolution over the measurable range for the three sensors and NI 9226 at high resolution mode.

The final design of the new sensor is depicted in Fig. 5. The encapsulating process is similar, with just slight geometry changes to simplify assembly. For validation, a few units were cycled for fatigue in the same test setup of the heaters (see Fig. 3), ultimately being totally operational. Dozens of these sensors are currently operational at the beamlines with no failure detected. Finally, as a next step towards improved control accuracy, a sensor calibration setup is currently in development and will be presented in a future work.

Figure 5: Temperature sensor assembly.

### CONTROLLER DESIGN

Assuming that a certain knowledge about the plant to be controlled is necessary to specify the control architecture and its parameters, the controller design workflow described below initiates with predictive thermal modeling combined with a system identification method. After that, a model to estimate the plant behavior is defined and a proposed controller is simulated, implemented and validated with the real plant.

## Predictive Thermal Modeling

To develop a predictive thermal model for each precision beamline system, lumped mass thermal models have been implemented together with auxiliary finite elements analyses (FEA) to simulate the system behavior under variable operational conditions, taking into account also non-linear aspects [4, 7, 13].

The predictive models have contributed to validate and improve thermal modeling, not only defining power requirements for control heaters and an initial guess to the controller parameters, but also diagnosing system issues, as the manufacturing limitations. Furthermore, during the design phase the lumped-mass models make the system parts sizing faster than by using only FEA. Recently, with experience and customized modeling tools, the differences found between model predictions and measurements have been below 10 K, as presented in [13].

## System Identification

As mentioned, a relevant aspect about the beamline precision systems is that, although they are composed of different parts operating at different temperatures, these parts are designed to be thermally decoupled [4]. This has been confirmed during the predictive thermal model validation and also during the system identification process, in which the observed thermal coupling is negligible. Because of this, the systems can be seen as a set of isolated single-input single-output (SISO) plants.

Since the controller's goal is to keep the plant temperature stable, the system identification approach was used to find an approximate linear model of each SISO plant for a given operation condition defined by the desired operating temperature.

Taking the HD-DCM from the EMA beamline as a study case, which is a 14-SISO-plant system with 2 plants operating at  $-118^\circ\text{C}$ , 3 at  $-6^\circ\text{C}$  and 9 at  $18^\circ\text{C}$ , system identification based on the step response was performed to estimate continuous-time transfer functions (TFs) for the plants, described in the Laplace domain by

$$\frac{Y(s)}{U(s)} = \frac{k}{(s-p)},$$

where  $s$  is the Laplace variable,  $Y(s)$  is the sensor output in Celsius,  $U(s)$  is the power input in W,  $k$  is the dc gain and  $p$  the pole of the transfer function.

After a set of data acquisitions with the system around the operating temperature for plant identification and TF estimation, another set at slightly different temperatures was selected for validation of the estimated plants. In the latter, the temperatures were taken only a few tens of degrees off, to prevent exceedingly large variations of the non-linear materials thermal properties. Figure 6 shows an example with results of both the identification and the validation sets, obtained for one of the HD-DCM crystals, the most critical element in that system whose desired operating temperature is  $-118^\circ\text{C}$  and maximum estimation error found during the

validation process was less than  $0.7^\circ\text{C}$ . For the other 14 plants, the estimation error remained below  $1^\circ\text{C}$ .

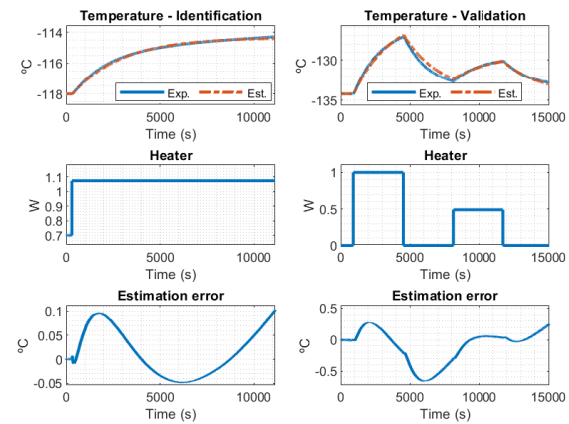

Figure 6: Experimental and identified estimation results of system identification (step response) (left) and validation (right) for the HD-DCM crystal at the EMA beamline.

## Controller

Due to its robustness and ease of tuning and implementation, a proportional integral derivative (PID) controller was selected as the first choice to implement the temperature control for the beamline precision systems. As the controller should be implemented in a digital platform, it was designed in the discrete time domain, in which the ideal PID transfer function is represented by

$$PID(z) = \frac{U(z)}{E(z)} = k_p + \frac{k_i T_s z}{z-1} + \frac{k_d(z-1)}{T_s z},$$

where  $U(z)$  is the controller output,  $E(z)$  is the controller input, defined by the difference between the temperature setpoint and the plant output temperature sensor,  $k_p$  is the proportional gain,  $k_i$  is the integral gain,  $k_d$  is the derivative gain and  $T_s$  is the sampling time.

However, the ideal PID has some undesired effects that need to be avoided. Firstly, about the derivative implementation, an instant variation in the temperature setpoint or even the noise produced by the temperature sensor can cause high derivative response, resulting in unreasonable control output. Thus, to prevent this behavior, the following PID with derivative filtering was implemented

$$PIDF(z) = \frac{U(z)}{E(z)} = k_p + \frac{k_i T_s z}{z-1} + \frac{k_d}{T_f + \frac{T_s z}{z-1}},$$

where  $T_f$  is the derivative filter time constant.

Then, another undesired effect is the integral windup, caused by the continuous integration of the input  $E(z)$  by the integral term even when the power driver output is saturated. Hence, an anti-windup scheme is implemented to turn off the integral term ( $k_i = 0$ ) when the controller output reaches the limits of the power driver.

## Results

Once the plants were identified and the controller model was selected, the controller parameters were calculated to minimize the closed-loops settling time, while keeping the overshoot within less than 10% to a step response. Still considering the HD-DCM crystal from EMA, Fig. 7 shows the experimental and estimated closed-loop step response with a 0.05 °C variation in the setpoint input. In this case, the settling time to within 10% is only 10 min, as compared to the time constant of 1.5 h of the open-loop response, seen in the identification plot in Fig. 6. Similar performances were also achieved in the other controllers.

Figure 7: Simulated and experimental closed-loop step response for the HD-DCM crystal at the EMA beamline.

Then, looking at the long-term temperature stability, a variation of less than 0.004 °C is observed in the 12-hour plot presented in Fig. 8, with the larger dip possibly related to a refilling event in the cryocooler.

Figure 8: Long-term closed-loop thermal stability in the HD-DCM crystal at the EMA beamline.

## CONCLUSION

This work presented the system architecture, the main hardware, and the controller design workflow adopted to the temperature control of Sirius beamline precision systems, where the predictive thermal modeling combined with the system identification approach contributed to define suitable controllers to achieve the design requirements. For reliable and robust beam delivery and experimental conditions, in addition to static compensation at nominal operating temperatures, control levels down to the mK range are, indeed, welcome and desired for ultimate performance in preserving wavefront and/or in positioning optical elements and samples. Over the commissioning time of the first Sirius beamlines models and procedures have been continually improved. The next steps are related to more systematically analyzing the influences of temperature stability on the photon beam position.

## ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology and Innovation, and the contributions of the LNLS team.

# POSITION SCANNING SOLUTIONS AT THE TARUMÃ STATION AT THE CARNAÚBA BEAMLINE AT SIRIUS/LNLS

C. S. N. C. Bueno†, L. G. Capovilla, R. R. Gerales, L. C. Guedes, G. N. Kontogiorgos, L. Martins dos Santos, M. A. L. Moraes, G. B. Z. L. Moreno, A. C. Piccino Neto, J. R. Piton, H. Tolentino, Brazilian Synchrotron Light Laboratory (LNLS), CNPEM, Campinas, Sao Paulo, Brazil.

## Abstract

TARUMÃ is the sub-microprobe station of the CARNAÚBA beamline at Sirius/LNLS. Covering the range from 2.05 to 15keV, the probe consists of a fully-coherent monochromatic beam varying from 550 to 120nm with flux of up to 1e11ph/s/100mA after the achromatic focusing optics. Hence, positioning requirements span from nanometer-level errors for high-resolution experiments to fast continuous trajectories for high throughput, whereas a large flexibility is required for different sample setups and simultaneous multi-technique X-ray analyses, including tomography. To achieve this, the overall architecture of the station relies on a pragmatic sample position-ing solution, with a rotation stage with a range of 220°, coarse stages for sub-micrometer resolution in a range of 20mm in XYZ, and a fine piezo stage for nanometer resolution in a range of 0.3mm in XYZ. Typical scans consist of continuous raster 2D trajectories perpendicularly to the beam, over ranges that vary from tens to hundreds of micrometers, with acquisition times in range of milliseconds. Positioning based on 4th-order trajectories and feedforward, triggering including the multiple detectors and data storage are addressed.

## INTRODUCTION

TARUMÃ [1] is the sub-microprobe station of the CARNAÚBA beamline [2] at Sirius/LNLS [3]. The CARNAÚBA beamline was designed to cover the range from 2.05 to 15keV, and is based on an all-achromatic optical design. The probe consists of a fully-coherent monochromatic beam varying from 550 to 120nm, focused by a set

of KB (Kirkpatrick-Baez) mirrors, and with flux of up to 1e11ph/s/100mA. TARUMÃ was designed to perform simultaneous multi-technique analyses under a variety of conditions, including *in situ*, *in vivo*, and *in operando* experiments. Thus, it complies a number of customized sample environments [1, 4, 5] and a set of detectors of different types, including: two SDD Vortexes (Xspress 3 and Xspress 3X), two area detectors (MobiPix 45D and PiMega 135D), one XEOL detector, and an in-house spectrometer. Figure 1 shows a detailed view of the sample and the detectors (left) and an overview picture of the TARUMÃ station (right).

The sample stage is composed, from bottom up, of: an Aerotech's 300DL XY, a Newport's IDL280 Z20 wedge-type vertical stage, an Aerotech's ABR5 250MP air-bearing rotary stage, and a PI's P-563.3 XYZ stage. The planar and vertical stages are responsible for the rough alignment of the sample with a range of  $\pm 10$ mm in XYZ. The rotary stage, constrained over 220° due to cable management, is used for tomography, diffraction, and Bragg CDI experiments. A cable carrier system allows additional instrumentation, like special gases, heaters, sensors, and vacuum lines, to be used in the sample environment. The XYZ piezo stage is responsible for the sample scans with nanometer resolution over a 300 $\mu$ m range and has a payload capacity of 5 kg.

Resolutions down to the order of 10nm are desired from the experiment's reconstructions, which sets an upper boundary for the relative positioning errors between the sample and the KB mirrors. Thus, to reach these positioning levels, the KB optics and the sample stage are placed

† cassiano.bueno@lnls.br

above a common granite bench [1]. Furthermore, to have a more accurate estimate of the sample position with respect to the focusing optics, a metrology target on the rotor of the rotary stage is measured by 3 capacitive sensors on an external metroframe fixed to the granite bench. Hence, the information of the capacitive metrology can be combined with the data from P-563.3 capacitive sensors to improve the post-processing reconstructions. Finally, the controller of each stage is designed and optimized for the system to achieve the required nanometric resolution.

More information on the overall dynamic design and the other subsystems can be found in [1]. This paper describes the main implementation aspects of the sample positioning system and the related control required for this state-of-the-art X-ray microscopy station. First, the integrated control architecture is reviewed. Next, the high-performance motion control and trajectories are discussed. Finally, commissioning results are presented to demonstrate the current capabilities.

## INTEGRATION ARCHITECTURE

Being TARUMÃ a multi-technique end-station that aims at nanometric resolution and high throughput, it requires, besides the dynamic and motion optimization, a high degree of integration between detectors and motion system, as well as a robust system that can perform hundreds of experiments on a daily basis. Past solutions at the 2nd-generation UVX light source at LNLS generally relied on EPICS (Experimental Physics and Industrial Control System) variables to control sample motion and detectors acquisition. Back then, the default update rates up to 10Hz did introduce overhead time in measurements, but those were acceptable due to the lower fluxes available to the beamlines, with correspondingly longer total experiment

times. At SIRIUS 4th-generation machine, on the other hand, with photon fluxes up to 1000 fold, the experiment times can be drastically shortened and different types of experiments are required, such that previous solutions become incompatible with TARUMÃ's purposes and capabilities. Therefore, a new solution was proposed and implemented, in which all motion systems and detectors are interconnected via TTL signals that enable fast communication and synchronization among systems, allowing experiments to be up to 130 times faster.

Figure 2 summarizes the integration architecture implemented at TARUMÃ, with the control and detection hardware, and the corresponding signal connections. It is based on the Trigger And Timer Unit (TATU) solution, a flexible in-house development for FPGA-based applications created on NI's CompactRIO (cRIO) [6]. Indeed, capable of receiving leading signals and distributing them to the elements in the control network, such as motion controllers and detectors, it also allows for simple logic operations, customized delays and pulse counting of TTL signals, which can be used for synchronizing motion and data acquisition. Any motion controller with a digital output and capable of reading a trajectory file is suitable as the leading system, depending on the scan routine to be executed. This versatility is what makes the solution easily expandable and general enough to be applied to different beamlines.

At TARUMÃ, the core and most demanding task consists in high-resolution 2D mapping with the XYZ piezo stage. Thus, the standard operation is based on a Main cRIO with an in-house FPGA code that: 1) reads a trajectory file at a 10 kHz rate; 2) translates it into proportional voltage signals that are sent to the XYZ motion controller PI E-727; and 3) provides trigger signals to TATU, running in an independent cRIO. Hence, TATU's output signals

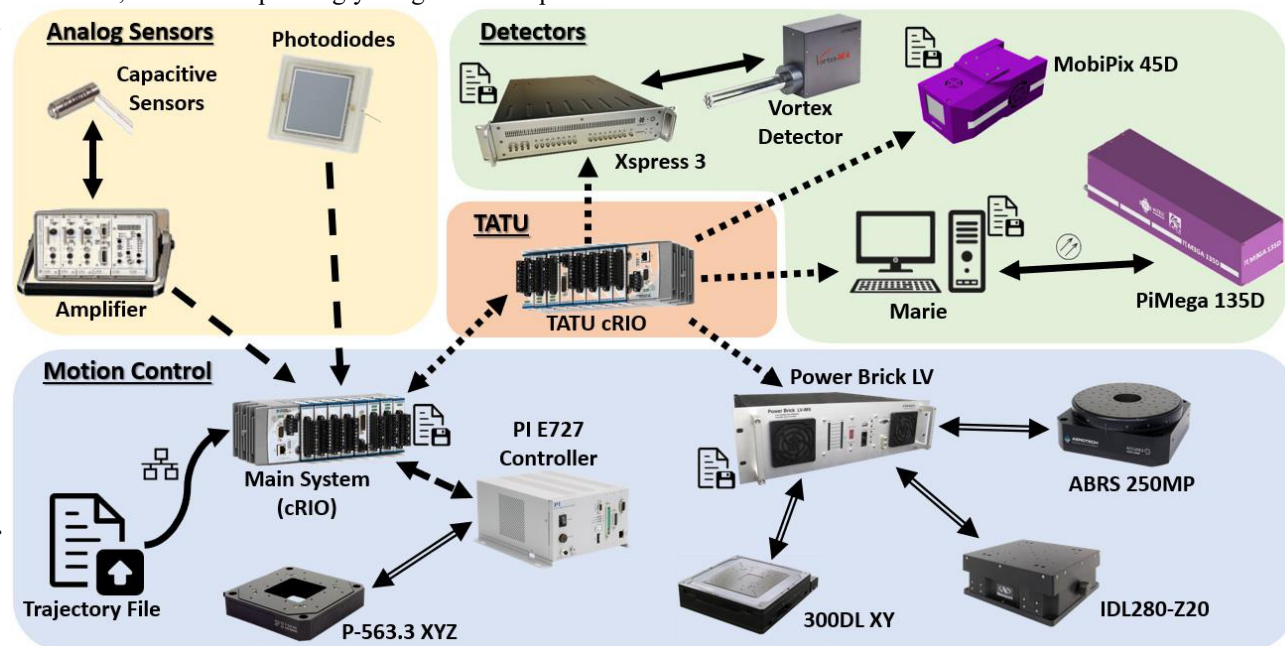

Figure 2: Integration architecture at the TARUMÃ station. The different arrows represent different signal types, namely: solid lines (-) are data transfer signals, dashed lines (--) represent analog signals, dotted lines (.) represent trigger signals and the double thin lines (=) represent closed-loop control signals (feedback and actuators).

can be used to trigger and synchronize acquisition for: 1) the detectors, with images and energy spectra; 2) the analog signals, which include photodiodes, the capacitive sensors on the metrology frame, and the capacitive sensors in PI P-563.3 stage; and 3) the encoder data from the Omron Delta Tau Power Brick LV (PBLV) sample stage controller, which is further used in 2D and 3D reconstructions.

Nowadays, following a common practice regarding software operation at Sirius beamlines, the fly-scans are planned on a Jupyter Notebook [7], hosted in a Jupyter server that runs on the beamline operation computer. The script is written in Python and allows the user to select: the detectors, the energy regions of interest (ROI) for fluorescence, and the desired trajectory to performed. Currently, 25 predefined trajectories are directly available, as detailed in the following section, whereas unforeseen trajectories may accepted but must be previously calculated and deployed to the cRIO memory. In the near future, the Jupyter Notebook functionality is expected to be expanded with a friendly graphical interface, according to already existing Sirius standards and software tools, in which new trajectories will be dynamically calculated from user input parameters. The Jupyter Notebook is also programmed to configure all detectors and EPICS IOCs desired parameters, such as the number of points and the filenames to be saved.

A fly-scan data-flow example is summarized in Fig. 3. After setting all parameters, the selected trajectory starts with the Main cRIO moving the XYZ piezo stage and sending the trigger signal to TATU, which is properly broadcast to the detectors and complementary controllers. By the end of the task, the files created in each sub-system are merged into one final experiment file and saved in a central storage. Due to the large amount of data generated by the detectors, the files are merged in a powerful Power 8 desktop computer, known by its nickname “Marie”, and then sent to the data storage.

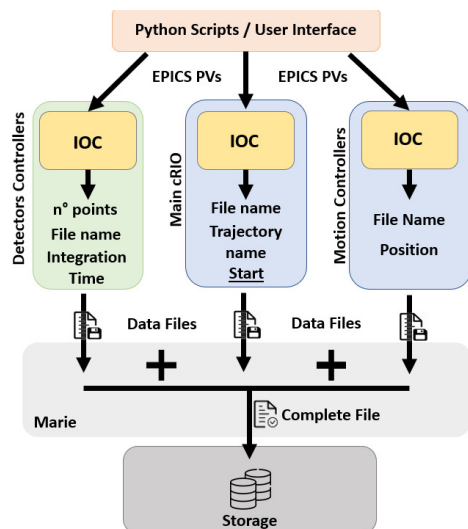

Figure 3: Data-flow schematic in TARUMÁ fly-scans, from the user interface to the data storage.

Still, the flexibility and the easiness in programming the Jupyter Notebook routines in the implemented solution

make it possible to include these fly-scans in broader tasks with other beamline components, such as: the sample rotary stage, for tomography; the four-crystal monochromator, for spectroscopy; and the coarse XZ and Y sample stages to perform long-range high-resolution images via stitching. All these different processes have already been successfully commissioned at TARUMÁ, but are also continuously updated and expanded.

## MOTION CONTROL

### Models and Guidelines

To reach the nanometric positioning capacity, mechanical and control and aspects of the entire station must be taken in count. To help the studies regarding trajectories simple lumped-mass models, as exemplified in figure 4, were implemented to simulate vertical and lateral performances of sample stage and guide motion strategies. The mechanical stiffness between stages and inside the stages (rotor-to-stator) were measured or estimated. In addition, to more accurately derive the models, the individual closed-loop responses were either measured, for the Aero-tech DL300 XY and PI 563.3 stages, or estimated, for the IDL280 Y stage, and individually matched in the separate models, before finally integrated.

Figure 4: Lumped mass model of the sample stack, used to evaluate vertical and lateral positioning performances.

Firstly, to instruct towards the most suitable trajectory orientation, Fig. 5 depicts the simulated closed-loop Bode plot, both for the vertical and horizontal axes, from the commanded position reference in the P-563.3 to the absolute position of the sample in an arbitrary sample holder weighing 300 g. It can be seen that the vertical axis has a higher bandwidth, around 60Hz, as compared to the horizontal axis, around 20Hz. Thus, the vertical axis exhibits a higher virtual stiffness against disturbances, and can also follow more aggressive trajectory setpoints (velocities and accelerations).

Next, the models were used to investigate the impact of the trajectories on the sample stack, due to, for example, the reaction forces induced in the stages below, with corresponding control errors. Two types of *S-curve* trajectories were considered, namely: 3<sup>rd</sup> [8] and 4<sup>th</sup> [9] orders. Third order trajectories are simpler and more commonly employed in commercial motion controllers, but since fourth order trajectories are smoother, due to the higher order continuous derivatives, this application was taken as a case study to compare both solutions.

Figure 6 displays the simulated disturbances induced by trajectories of  $14.5\mu\text{m}$ , with  $20\mu\text{m/s}$  cruise velocity, maximum acceleration of  $100\mu\text{m/s}^2$  and maximum jerk of  $1000\mu\text{m/s}^3$ . The difference lies in the 4<sup>th</sup> order limiting also the jerk derivate (snap) in  $2400\mu\text{m/s}^4$ . The simulations are for the more compliant horizontal axis for the sake of demonstration, reaching errors in the order of a few nm, but equivalent results in the sub-nm range (scaled roughly by a factor 10) would be found for the vertical axis. Naturally, the magnitude of these errors vary for different accelerations and payloads, but it is possible to notice that the total disturbances induced in the planar stage can be significantly lower and smoother with a 4th-order trajectory, as expected.

Figure 5: Closed-loop Bode plot for the sample stack in the vertical and horizontal axes, from the P-563 stage reference to the absolute sample position.

Figure 6: Simulated induced disturbances in the planar 300DL for 3rd and 4th-order trajectories with the P-563.

## Trajectories

Based on the previous observations, 4th-order trajectories with the most aggressive setpoints in the vertical axis were chosen for the beamline operation. Then, to cover 2D maps, the fly-scan profile that has been used so far at TARUMÄ is shown in Fig. 7, being composed of long vertical and short horizontal 4th-order trajectories that are concatenated to form a snake-raster pattern. The scans are defined by the following user inputs: vertical velocity, the vertical and horizontal stroke, the trigger length per acquisition point, and the horizontal pitch.

Figure 7: 2D fly-scan pattern at TARUMÄ, highlighting the horizontal and vertical 4th-order trajectories, and the trigger vector as a function of time

To simplify the post-processing of data, the vertical trajectory is calculated so that the constant velocity segment has the exact length of the desired scanning ROI selected by the user. The horizontal trajectory starts when the vertical trajectory is decelerating, and it is optimized so that the horizontal motion ends just before the start of the next constant velocity segment in the vertical axis. This ensures that the accelerations and, consequently, the forces that are applied due to the horizontal motion in the stages below are minimized during acquisition.

The scan vectors are described in 10kHz, which is five to ten times faster than the maximum acquisition rates of 1 to 2kHz that are planned for the beamline. They are saved in the file to be consumed during the experiments. Moreover, besides the vertical and horizontal trajectories, a trigger vector is included in the same file, consisting of a pulse train in which the high level designates acquisition to detectors, such that the acquisition time for each point (integration time) is defined by the pulse width.

## Performance refinement

The first offline tests with the piezo XYZ stage indicated following error peaks of up to 500nm for the desired 4th-order vertical trajectories, which might critically compromise data post-processing or at least burden it by requiring more iterations before the final image reconstruction. In that way, the position feedforward gain ( $k_{ff}$ ) available in the E-727 controller was studied to optimize the following errors. Figure 8 shows the P-563 stage control error for different scenarios, emphasizing the importance of including an optimal feedforward gain, with improvements by up to a factor 5.

Figure 8: Following errors measured with the P-563 stage for a 4th-order vertical trajectory with different position feedforward gains in E-727 controller.

Another concern regarding the system controller is the diversity of sample holders that will be used at TARUMÃ, with different weights, and various boundary conditions like gases, vacuum, and temperature. Indeed, keeping control errors and trajectory following performances in the desired levels becomes a practical challenge. The current solution is to previously characterize and optimize the control parameters, including the feedforward gain, for each different setup and provide a selectable controller to the beamline user. For future experiments, a new routine will be developed to automatically optimize (as much as possible) the control parameters for each sample in each sample holder. Such solutions are only possible thanks to the integration of the E-727 controller in EPICS, that allows to easily update the control parameters.

## RESULTS

Using the discussed implementation, the first commissioning tests at the beamline, still without beam, were performed during the storage ring 2020/2021 holidays shutdown, whereas the first tests with beam took place in early March 2021. The implementation of the fly-scan routine made it possible to significantly increase the number of experiments performed daily at the CARNAÚBA beamline. For comparison, a  $10 \times 10 \mu\text{m}^2$  mapping, with 10.000 points (100nm resolution) using the previous EPICS-based architecture would take a total of about 2.8 hours, i.e. almost 1s per point. Using the new fly-scan architecture, on the other hand, the same experiment required just 250s before some control optimization and only 75s after that, resulting in a gain of 130 fold for the same quality. Figure 9 shows a fluorescence image (left) and the ptychography reconstruction (right) of an USAF pattern that is used for beam characterization, validating the motion control and the synchronization between different detectors (for more details, see [2]). The image was acquired in 130s, with a  $5 \times 5 \mu\text{m}^2$  scan and 6.25ms integration time per point.

Figure 9: USAF pattern in fluorescence (left) and ptychography (right), with resolution of 300 nm (out of focus) and 70 nm, respectively, validating the synchronism between detectors and motions system.

In addition to throughput, the improvement in experiment time helps minimizing the effects of experimental disturbances, such as vacuum and temperature interlocks, that in the past have been responsible for acquisition losses with the previous architecture. This gain also accelerated several steps in the beamline commissioning, as refinement in mirrors alignment, correction of the KB astigmatism, and commissioning of detectors. Moreover, the minor time

per experiment and the modular characteristic of the implementation made it possible to step forward to more advanced experimental routines like energy scans (spectroscopy), tomography, and large 2D mapping (up to 2mm) with sub-micron resolution.

Due to ongoing commissioning and studies regarding the area detectors, the integration time in ptychography and fluorescence is currently limited to a minimum of 5ms per point, with velocities around  $50 \mu\text{m/s}$  to avoid data loss. During alignment, in turn, especial trajectories with  $500 \mu\text{s}$  of integration time can be used with transmission data in photodiodes, since the cRIO that acquires the analog signals is capable of measurements up to 100kHz. Yet, to reach sub-ms integration time, velocity must be increased up to  $800 \mu\text{m/s}$ , leading to large following errors in addition to making it necessary to rearrange and interpolate the detectors data with respect to the encoders data to compose the final images. Nevertheless, even with interpolation, the quality loss is sufficient for alignment purposes.

As an example, Fig. 10 shows  $80 \times 80 \mu\text{m}^2$  absorption images of a sample with  $800 \text{nm}$  pixel size, with mapping both in fast scanning with  $500 \mu\text{s}$  of integration time (total time of 30s including overhead) in the left, and in standard scanning with integration time of 10ms (total time of 140s including overhead).

Figure 10: Sample absorption images for interpolated fast mapping at  $800 \mu\text{m/s}$  (left) and standard  $40 \mu\text{m/s}$  (right).

## CONCLUSION

The successful deployment of the first version of fly-scan mapping at TARUMÃ is questions and challenges to a next level. The 100-fold faster scan solution allows the scientists and beamline staff to have immediate answers for samples and the commissioning equipment. Moreover, the general and flexible control architecture enables other motion systems, like the sample coarse stages, or the monochromator, to be integrated to the detectors and perform fast scans as well. The next challenges include the creation of a friendly user interface, and the design of an automatic routine to optimize control parameters for different samples and sample environments. Concerning of more complex experiments, tomography alignment and execution routines and Power Brick fly-scans are under development.

## ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology and Innovation, and the contribution and diligent work of the LNLS teams.

## Abstract

The High-Dynamic Double-Crystal Monochromator (HD-DCM) has been developed since 2015 at Sirius/LNLS with an innovative high-bandwidth mechatronic architecture to reach the unprecedented target of 10 nrad RMS (1 Hz - 2.5 kHz) in crystals parallelism also during energy flyscans. Now, for beamlines requiring a smaller energy range (3.1 keV to 43 keV, as compared to 2.3 keV to 72 keV), there is the opportunity to adapt the existing design towards the so-called HD-DCM-Lite. The control architecture of the HD-DCM is kept, reaching a 20 kHz control rate in NI's CompactRIO (cRIO). Yet, the smaller gap stroke between crystals allows for removing the long-stroke mechanism and reducing the main inertia by a factor 6, not only simplifying the dynamics of the system, but also enabling faster energy scans. With sinusoidal scans of hundreds of eV up to 20 Hz, this creates an unparallel bridge between slow step-scan DCMs, and channel-cut quick-EXAFS monochromators. This work presents the dynamic error budgeting and scanning perspectives for the HD-DCM-Lite, including discussions on the feedback control via loop shaping, feedforward considerations, and leader-follower control strategies.

## INTRODUCTION

After successfully designing, installing and commissioning the High-Dynamic Double-Crystal Monochromator (HD-DCM) [1] at the MANACÁ (crystallography) and the EMA (extreme conditions) beamlines, QUATI (quick absorption spectroscopy) and SAPUCAIA (small-angle-scattering) are two forthcoming Sirius beamlines demanding an HD-DCM at the Brazilian Synchrotron Light Laboratory (LNLS). Since these new beamlines require a smaller energy range (3.1 to 43 keV), the total gap stroke of the instrument can be significantly reduced from 9 mm to about 2.75 mm, such that an opportunity is created to adapt the existing design towards the so-called HD-DCM-Lite.

Removing the long-stroke module (see [1]) for the large gap adjustments allows not only for cost reduction and simplification in the assembly, but also for significant improvement in dynamics. By reducing the main inertia by a factor of 6, the HD-DCM-Lite is expected to deliver energy flyscans of hundreds of eV up to at least 4 to 40 times per second, while keeping fixed exit and the inter-crystal parallelism in the range of a few tens of nrad RMS (root mean square) for the 1 Hz - 2.5 kHz range. Thus, QUATI (superbend-based) may

take full advantage of this capability in time-resolved analysis, whereas new science opportunities may be explored for SAPUCAIA. The new design focuses on extending the scanning capabilities while preserving positional accuracy, creating a solution between the current HD-DCM (limited in speed but with fixed-offset and already extremely stable) and fast channel-cut monochromators [2], which suffer from beam walk due to offset variation.

An overview of the mechanical design of the HD-DCM-Lite, with the CAD drawing of its in-vacuum mechanics and a simplified lumped-mass model, is given in Fig. 1. Two crystal sets, with Si(111) and Si(311) orientations for options in energy filtering bandwidth and range, are mounted side by side, being alternatively selected during operation. At the lower side, the so-called 1<sup>st</sup> Crystals (CR1) (6) are mounted to a common Metrology Frame (MF1) (5), which, in turn, is fixed to an Auxiliary Frame (AF1) (4), that is, finally, fixed to the Goniometer Frame (GOF) (3), which is driven by two rotary stages (ROT) (2) for controlling the angle of incidence of the incoming X-ray beam on the crystals for energy selection according to Bragg's law of diffraction.

At the upper side, the so-called 2<sup>nd</sup> Crystals (CR2) (7) are used to redirect the beam in the fixed-exit configuration that defines the operational principles of an X-ray DCM. They are mounted to a common metrology frame as well, which, in this case, is a Short-Stroke stage (SHS) (8) that is actively controlled with nanometer level with respect to the MF1 in 3 degrees of freedom (DOF). Indeed, the distance (gap) and parallelism between crystals — or, more precisely, between their metrology frames — can be adjusted via closed-loop control based on 3 voice-coil actuators and 3 laser interferometers. The reaction forces of these actuators act on a Balance-mass (BMS) (10) for dynamic filtering purposes, and both the SHS and the BMS are mounted via flexural folded leaf-springs to the Auxiliary frame 2 (AF2) (9), which is also fixed to the GOF.

The supports of the ROT are stiffly fixed to a vacuum flange, as part of the complete vacuum vessel (VES) (not shown), which, in turn, is stiffly fixed to a granite bench (GRA) (1) for alignment purposes and crystal set selection at the beamline, building the dynamic architecture of the system all the way up from experimental floor (GND).

With the previous experience from the HD-DCM as a high-end mechatronic system, here again a systematic approach based on precision engineering principles and predictive modeling has been adopted to maximize the efficiency in development time and costs, according to a "first-time-right"

philosophy. Using the Dynamic Error Budgeting (DEB) methodology [3, 4], the effects of system disturbances can be investigated as the mechatronic design of the machine is iteratively refined until compliance with specs.

Introductory aspects of the HD-DCM-Lite, such as the control effort, maximum displacement amplitude, speed budget, and thermal management, and the resulting time-resolved capabilities analysis were briefly introduced in [5]. Regarding its control architecture, it is expected to very closely follow the FPGA-based solution with NI's CompactRIO (cRIO) that has been developed for the HD-DCM, such that control rates up to 20 kHz should be possible for conformity with closed-loop bandwidths up to 250 Hz, or higher. The latest status in this topic, including integration aspects at Sirius beamlines can be found in [6].

Here, using a DEB toolbox that has been developed at LNLS during the HD-DCM project, the following sections discuss the mechatronic and disturbance models for the system, and present the high-performance predictions both in stand-still and scanning operation modes.

## MECHATRONIC MODEL

As described below, the mechatronic model consists in a state-space representation composed of the electro-mechanical plant, including the mechanical dynamics, actuators and sensors, and the controllers.

### Plant

The mechanical plant is developed according to the lumped-mass model shown in Fig. 1, with the mechanical system being derived in 6DOF via Dynamic Substructuring (DS) methods [7]. Firstly, inertia and geometrical parameters for each body are extracted from the CAD drawing in Autodesk® Inventor and exported to MATLAB®, where the whole customized toolbox has been implemented. Then, the links between lumps are defined as stiffness values, obtained either from simulated Structural Analysis with Ansys® Mechanical or from experimental data (see [3]). Next, the mechanical system is coupled via well-known DS transformations, written in state-space representation and

put in modal basis, such that modal damping factors, based on experience or experimental results, can be individually applied to each mode shape. Finally, transformation matrices are computed to account for the geometry of the metrology points of sensors, and the action points of actuators and points subject mechanical disturbances.

### Controllers

As the HD-DCM, the HD-DCM-Lite was designed in such way that the DOF of interest can be statically decoupled to transform the original multiple-input-multiple-output (MIMO) system in independent single-input-single-output (SISO) systems, which greatly simplifies the design of the controllers and robustness analyses [8]. Thus, four individual control loops can be considered, namely: BRG, for the Bragg angle; and GAP, PTC and RLL, for the inter-crystals gap, and the pitch and roll angles, in the so-called crystal cage (CCG), respectively.

**Feedback** The first step consists in designing robust feedback controllers, which is done via the loop-shaping technique [9]. Indeed, thanks to the damped mass-spring approximation (second-order system) with low-frequency decoupling that characterizes the plants of the four loops (see [8]), simple and generic proportional-integral-derivative (PID) controllers can be implemented with practical “rules of thumb” [10].

First, the bandwidth frequencies, defined as those in which the open-loop transfer functions cross 0 dB, are chosen as  $f_{bw} = 20$  Hz for the BRG and  $f_{bw} = 250$  Hz for the CCG loops. Then, for phase margin, a lead filter is added with a zero at  $f_{bw}/3$  and a pole at  $3f_{bw}$ . Next, to avoid high-frequency amplification of dynamics and reduce sensor noise, a low-pass filter is added at  $5f_{bw}$ . After that, an integral action is added with a zero at  $f_{bw}/5$  for zero-frequency (DC) error. Finally, analyzing the open-loop system for gain and phase margins, a couple of notch filters may be added as necessary. Here, 2 notches are used for the RLL loop and 1 for the remaining ones. The modeled feedback closed-loop

Figure 2: BRG and PTC transfer functions for the feedback closed-loop and for a feedback plus feedforward equivalent. The feedback bandwidths are also indicated in dashed lines.

transfer functions from reference (r) to output (m) for BRG and PTC can be seen in Fig. 2.

**Feedforward** To reduce the transient errors and expand the demanding scanning possibilities beyond the feedback bandwidth limits, particularly for the BRG loop, simple feedforward filters are also included in the model. Thus, assuming well-designed trajectory setpoints, with limited energy content in the high-frequency range, and once again benefiting from the reasonable second-order approximation for the plants in the low and mid-frequency ranges, high-order inversion-based filters can be prevented, and the feedforward blocks can be simply based on stiffness, damping and inertia constants.

In the model, the parameters can be directly extracted and perfectly compensated for. In practice, experimental tuning shall be realized. In this sense, this simplified feedforward structure will also ease the experimental tuning, thanks to the small number of parameters, in addition to saving implementation resources in the control hardware.

As an indication of the intended concept, the simulated transfer functions from reference (r) to output (m) with feedback plus feedforward for BRG and PTC are also depicted in Fig. 2. It can be seen that setpoints over a broader frequency range should be possible thanks to the feedforward action, but also that the energy content of these setpoints (visible in Fourier analyses, for instance) should be carefully designed below 200 Hz to prevent issues, such as amplification effects and saturation, especially in the BRG loop.

## DISTURBANCE MODELS

Once the mechatronic model has been built, the disturbances that will eventually determine the system per-

formance must be addressed. Conceptually, they may be grouped as mechanical disturbances, as forces acting on the system, and electronic disturbances, which are related to the control hardware.

The main mechanical disturbances are the floor vibrations (GND) and Flow-Induced Vibrations (FIV) induced by the cryogenic cooling architecture of the silicon crystals via liquid nitrogen (see [11]). For the GND, the floor spectra is directly available from measurements with accelerometers and seismometers. Modeling FIV disturbances, on the other hand, is far more challenging due to the complexity of the flow effects and the cryogenic conditions required for real measurements. Thus, FIV was modeled according to best guesstimates. These disturbances are described in details for the HD-DCM in [3] and reused here.

The electronic disturbances, in turn, can be subdivided into actuators and sensors. All actuators will be controlled via the NI-9269 digital-to-analog converter (DAC), with a certain contribution in electronic noise, such as quantization. Then, the Aerotech APR260-S-240-83 rotary stages will use the Varedan LA-415-SA-T linear amplifier, whereas the Akribis AVM40-HF-6.5 voice-coils will rely on Trust Automation TA105. Each amplifier has its own noise level and spectral signature, affecting the closed-loop control error. Regarding the sensors, the rotary stages will be based on Renishaw TONIC encoders, whereas the sensors in the CCG will be SmarAct PicoScale Michelson interferometers. This electronic noise also enters the closed-loop system as disturbances. All these elements were already experimentally characterized for HD-DCM, as detailed in [3] as well.

## SDE

While, as demonstrated in [3], the previous disturbance sources are sufficient to predict and describe the HD-DCM and the HD-DCM-Lite performances in stand-still condition, another type of sensor disturbance is introduced during motion, which becomes critical for the fast scanning purposes of the HD-DCM-Lite. Indeed, Sub-divisional Errors (SDE) are periodical patterns that are commonly found in optical sensors, such as encoders and interferometers, resulting from the measurement physical principles, together with alignment characteristics, and each particular electronic processing [12].

Based on empirical data, the SDE of the interferometers were found to be in the order of  $\pm 2$  nm with a periodicity of 775 nm (i.e. half of its infrared wavelength), which has a negligible impact on the control error of the system. The SDE for rotary encoder, on the other hand, reaches 300 nrad of amplitude with a periodicity of  $10 \mu\text{m}$  (i.e. half of the scale pitch), which translates to about  $100 \mu\text{rad}$  given the scale size. Since the typical stand-still control errors in the rotary stages are in the range of few tens of nrad RMS (see Table 1 in the Performance Predictions section), the harmful potential of the encoder SDE becomes clear.

Being artifacts, these patterns are deviations from the ideal measurements, and intrinsic accuracy limitations in the sensors, which can not be differentiated by the control

Figure 3: Boundary scanning possibilities for different energy scan amplitudes with either crystal set and ten representative points for performance analysis.

loop *a priori* from what would be the ideal signal. Thus, during motion, unless more advanced calibration and filtering strategies can be implemented via control, these errors appear at frequencies related to the traveling speed, being introduced in the closed control loop through its complementary sensitivity function.

Hence, at low frequencies the errors are followed by the system, around the bandwidth frequency they are amplified, and then they are gradually filtered out for increasingly higher frequencies. In the following and amplification regions these errors are converted to actuation effort (torque), which may excite internal mechanical resonances or at least increase the disturbances to the CCG control loops. This is why this effect must be carefully investigated.

Still, as the encoder SDE contribution depends completely on the trajectory being executed, some assumptions must be made for modeling purposes. Considering that as many repetitive energy scans per second as possible are desired for spectroscopy experiments with the HD-DCM-Lite, torque and motion disturbances can be expected to be minimized for sinusoidal trajectories in the rotary stage.

Taking into account all practical boundary limitations, and the non-linear relations among the desired energy and the Bragg angle for both crystal sets and gap between crystals, Fig. 3 provides an abacus with maximum expected scanning frequency for the Bragg amplitudes related to different energy scan amplitudes (see [5]). Finally, given the sinusoidal trajectories, the SDE can be modeled via *sine sweeps*, in which the maximum frequency is proportional to the maximum sinusoidal angular speed. Ten case studies selected for performance analysis in the following section are also highlighted in Fig. 3.

## PERFORMANCE PREDICTIONS

Having the mechatronic and disturbance models, the performance predictions can be finally derived in the DEB toolbox. Thanks to the superposition nature of the linear time-invariant (LTI) formalism, the role of the different error sources can be independently investigated, which, in particular, allows for straightforward comparisons between static

and scanning performances. Since the low frequency content of the reference trajectories should be mostly handled by feedforward, the SDE becomes the main additional noise source during scans.

A graphical example of one such performance prediction is illustrated in the cumulative power spectrum (CPS) plots in Fig 4, with the disturbances grouped according to what was presented in the Disturbances section. It shows the leftmost case of Fig. 3, i.e. sinusoidal scans with the largest Bragg amplitude (around 60 mrad, or 3.4 deg) and lowest sinusoidal scanning frequency (around 0.3 Hz). It can be seen that the SDE has a brutal effect in the BRG loop, being more than 10 times larger than the second highest effect, which is the GND. The total error approaches 0.5  $\mu$ rad, which exceeds the original spec of 0.15  $\mu$ rad by more than a factor 3, requiring some attention, as discussed below.

Similarly, for the PTC, which is the most sensitive control loop for beam position variation, the SDE dominates the error budget, with the 10 nrad spec being marginally exceeded. Without it, representing the stand-still condition, the errors are limited to about 5 nrad only. For the GAP and RLL loops, in turn, most of the contribution is due to the floor vibrations, with negligible contributions from the remaining elements. Still the values are well within the specs of 300 nm and 90 nrad, respectively.

The complete prediction results, with the RMS (1 Hz-2.5 kHz) control error for all simulated sinusoidal scan trajectories, are summarized in Table 1. The stand-still subset and original specification are also indicated in the last rows for completeness. It should be noted that the frequency and angular amplitude are identifying the scans according to Fig. 3, but these two parameters alone are not sufficient to fully describe a scan, since the mean energy also plays a role. Nonetheless, it is possible to notice that the SDE influence grows with the scanning frequency, as it might be expected.

It can be seen the the BRG loop is the one that is most critically affected by the SDE, with the errors exceeding the original spec by more than a factor 10. Still, the PTC also shows increasing errors with higher scanning frequencies, reaching nearly 40 nrad. Thus, a future topic of research is looking for a practical solution for filtering the sweeping SDE contribution via control or calibration. In the meantime, if truly sensitive to these error levels, the experiments may need to be limited to sufficiently lower scanning frequencies.

Furthermore, it is worth mentioning that, while the CCG loops are practically implemented as followers of the BRG loop, due to the geometrical relation of the gap and to fine calibrations with respect to the Bragg angle (see [13]), the appropriate leading signal must come from the BRG reference, not its sensor (see also [6]). All the performance results presented here follow this approach. Indeed, the control errors in the BRG are small as far as the gap and the calibration parameters are concerned, such that the reference signal provides a sufficiently accurate reference for the remaining loops. Otherwise, if following the measurement signal, the whole dynamics of the BRG loop, including its

Figure 4: Cumulative power spectrum (CPS) according to the DEB simulations considering all the disturbance sources for a sinusoidal scan with  $f = 0.3$  Hz and  $\theta_A = 60$  mrad.

Table 1: Position stability (RMS) results for disturbances on control loops for different scan amplitudes  $\theta_A$  and frequencies  $f$  between 1 kHz to 2.5 kHz

$\theta_A$ [mrad]	$f$ [Hz]	BRG_e [nrad]	GAP_e [nm]	PTC_e [nrad]	RLL_e [nrad]
60	0.3	470	12	11	21
40	0.4	450	12	11	21
40	0.9	430	12	9.6	21
20	0.9	460	12	11	21
20	3.0	780	12	13	21
7.0	2.4	1000	12	22	21
8.0	7.7	1600	12	24	22
2.0	15	1800	13	36	22
0.5	30	1300	13	30	22
0.2	54	1600	13	38	22
No SDE:		55	12	4.8	21
Spec:		150	300	10	90

SDE errors would couple to the CCG loops, more significantly degrading their performances.

The scanning results discussed here find their most direct potential at bending magnet beamlines, such as QUATI, due to their broad-band emission spectra. With undulators, opportunities will depend on motion limitations, including the potential influences on the storage ring, and detuned operation possibilities. Hence, in the short term, integration and synchronization efforts are expected to be focused mainly between the monochromator and the detectors (which may reach acquisition rates of a few MHz). In that sense, promising initial results have been recently demonstrated with the HD-DCM (see [14] and [15]).

Finally, one potential disturbance source that may turn out to have a significantly negative impact in scans is the mechanical bearings in the rotary stage. The reason why it has been left out of the analyses, was the difficulty in modeling it, given the strong non-linear dependencies on mechanical tolerances, payload, speed and lubrication/friction. Consequently, although conservative in the modeled disturbances, the numbers presented here cannot be considered fully con-

servative performance predictions for the HD-DCM-Lite design. The commissioning results with the first prototype, due to the next few months, will provide further insights and occasionally suggest that smoother bearings, such as contactless air bearings or magnetically levitating bearings, may be required for ultimate performance.

## CONCLUSION

Dynamic error budgeting (DEB) is a powerful methodology to be used in the predictive design of high-performance mechatronic systems. The toolbox developed in-house over the course of the High-Dynamic Double-Crystal Monochromator (HD-DCM) project is now applied in the development of the HD-DCM-Lite for extended scanning capabilities at Sirius light source. The model predictions, which provided very good agreement with experimental data in the HD-DCM, here point to an unprecedented inter-crystal parallelism level in the range of 5 nrad RMS (1 Hz – 2.5 kHz) in stand-still conditions. Yet, the results also suggest that the detrimental effects of sub-divisional errors (SDE) in the sensors to the most demanding scanning trajectories might increase the control errors by more than a factor 10. The actual impact of the occasional performance reduction may need to be confronted with particular experimental sensitivity at the beamlines, but effective filtering strategies should be investigated as soon as possible. Finally, possibly limiting disturbances arising from the mechanical bearings during scans will require deeper experimental investigations during commissioning, which is expected by early 2022.

## ACKNOWLEDGEMENT

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology and Innovation and the contributions of the LNLS team. They also recognize the essential role of MI-Partners in the development of the original HD-DCM and in the workflow adopted here, and the discussions that allowed for the development of many of the tools used in this work as part of a PhD project carried out with the CST group at TUE, with Marteen Steinbuch and Hans Vermeulen as promoters, and Gert Witvoet as co-promoter.

# EXPERIMENT AUTOMATION USING EPICS

D. Cosic<sup>†1</sup>, M. Vićentijević, Ruđer Bošković Institute, Zagreb, Croatia

<sup>1</sup>Faculty of Electrical Engineering, Mechanical Engineering and Navel Architecture,  
University of Split, Split, Croatia

## Abstract

Beam time at accelerator facilities around the world is very expensive and scarce, prompting the need for experiments to be performed as efficiently as possible. Efficiency of an accelerator facility is measured as a ratio of experiment time to beam optimization time. At RBI we have four ion sources, two accelerators, ten experimental end stations. We can obtain around 50 different ion species, each requiring a different set of parameters for optimal operation.

Automating repetitive procedures can increase efficiency of an experiment and beam setup time. Currently, operators manually fine tune the parameters to optimize the beam current. This process can be very long and requires many iterations. Automatic optimization of parameters can save valuable accelerator time. Based on a successful implementation of EPICS [1], the system was expanded to automate reoccurring procedures. To achieve this, a PLC was integrated into EPICS and our acquisition system was modified to communicate with devices through EPICS. This allowed us to use tools available in EPICS to do beam optimization much faster than a human operator can, and therefore significantly increased the efficiency of our facility.

## INTRODUCTION

Some experiments performed have a standardized procedure which must be repeated on many samples sequentially. In the Laboratory for Ion Beam Interaction at the Ruđer Bošković Institute these experiments are for material analysis purposes and are performed on a dedicated beam line specifically designed for such studies. Materials are studied by applying Rutherford Backscattering (RBS) and Particle Induced X-Ray Emission (PIXE) ion beam analysis techniques. Using these quantitative analysis methods, a precise elemental composition ( $N_Z$ ) of the target samples can be calculated. Typically, the elemental concentrations of an unknown sample are determined by measuring a standard with a known concentration of an element and comparing it to the sample of interest, using the following formula [2].

$$N_Z = N_A \frac{I_Z m_Z \sigma_A^x \text{eff}_A Q_A}{I_A m_A \sigma_Z^x \text{eff}_Z Q_Z} \quad (1)$$

where  $N_Z$  is the concentration ( $\text{g/cm}^2$ ) of the element in the sample,  $N_A$  is the concentration in the standard,  $I_Z$  and  $I_A$  refer to the integral of the peak in the accumulated spectrum,  $m$  is the mass,  $\sigma$  is the cross-section,  $\text{eff}$  is the

efficiency of the detectors, and  $Q$  is the integrated projectile charge. The experimental chamber on this beam line consists of two particle detectors and two x-ray detectors that are connected to a custom data acquisition system [3]. The integral of the peak ( $I$ ) is calculated by constructing a histogram from the data acquired from the detectors. The total charge ( $Q$ ) is collected by measuring the current from the target if it is a thick sample, or a Faraday cup located behind the sample, if it is thin. This current is measured by an Electrometer and integrated over the time of the experiment to get the total projectile charge on the target.

The measurement procedure consists of the following steps:

1. Setting the target in the beam position.
2. Setting the acquisition system to start recording.
3. Resetting the charge counter.
4. Opening the chamber valve so the ion beam can enter the chamber and hit the target.
5. Waiting for enough statistics to be collected for a well-defined histogram, which typically requires about  $1 \mu\text{C}$  of charge.
6. Closing the valve to the chamber.
7. Stopping the acquisition system.
8. Reading the total charge from the electrometer.
9. Logging the results.

These 9 steps must be repeated for each sample being measured which in one day could be as many as 30 times. Due to this highly repetitive process, errors can occur where the electrometer is not reset, the positioning of the sample is not correct or simply the steps are performed out of order. Such mistakes result in having to repeat measurements, decreasing beam time utilization efficiency.

Many of these steps can be automated if the various hardware and software components could be controlled remotely. EPICS was used to interconnect all the elements because it creates a common communication framework through which repetitive processes can be automated.

## IMPLEMENTATION

As we are still in the preliminary phase of upgrading our accelerator control system to an industrial standard such as EPICS, it was crucial that all implementation for this work were made to work in parallel with our existing system and could easily be disconnected. The existing system utilized

<sup>†</sup> email address: dcovic@irb.hr

to this existing Ethernet control network and two soft Input Output Controllers (IOCs) were programmed to scan parameters from instruments on the network without writing to them, leaving the current LabView based control system to run without interference.

Instead of using a EPICS sequencer [4], communication with the abstracted EPICS commands was implemented into the acquisition control system used on the beam line. The data acquisition software SPECTOR is written in C/C++ and handles all communication with the data acquisition hardware and instrumentation on the beam line. This software starts the experimental measurement and handles data visualization and storage. EPICS commands provided by the EPICS server were integrated into the acquisition flow of SPECTOR in the following sequence:

1. Researcher presses the “Start” button
2. Initialize electrometer
3. Start charge measurement
4. Start data acquisition from detectors
5. Open chamber valve
6. Current and charge values are read with detector data and displayed to the user
7. Chamber valve is automatically closed when a user preset charge value is reached
8. Final data from detectors and electrometer is read into the program

## 9. Data with the total charge is saved with the histogram spectrum

Figure 2 depicts how the SPECTOR user interface was modified to display the information from the electrometer. The whole implementation does not change the acquisition process for the researcher and can be enabled or disabled by selecting a menu option.

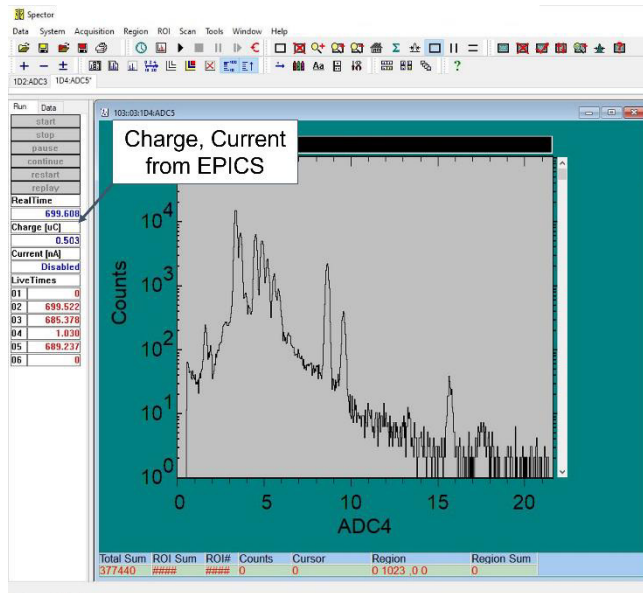

Figure 2: SPECTOR Integration.

## RESULTS AND DISCUSSION

The implementation was very quickly accepted by researchers due to minimal changes introduced to the measurement procedure. It increased the number of samples that could be analyzed per beam time and proved to be more reliable when compared to the manual setup. An added benefit was that it stimulated researchers to suggest further automation on other beam lines which will further streamline the operating procedure in the laboratory. However, complications and challenges are also experienced during the implementation of the system. Communication delays and indeterministic response times from the IOCs running on the EPICS server created problem during the integration into SPECTOR as data was not always available when requested. This delay along with the mechanical delay of the pneumatic valve required modifications and redundancies to be added into the program flow of SPECTOR. SPECTOR was developed in cooperation with the IAEA [5] in 2002 and it mostly written in C with basic WIN32 libraries make it very difficult to modify due to unstructured code.

Further automation can be achieved by integrating the sample positioner located in the experimental chamber into EPICS. This would allow the system to automatically measure all the loaded samples with minimal supervision resulting in a further increase in laboratory efficiency. However, this would require precise sample position information in a feedback loop to confirm that the sample is located in the beam spot as not all samples are of standard shape and size. The integration of the acquisition system into EPICS would decrease the development time required to introduce further automation into the laboratory.

## CONCLUSION

Expanding on the feasibility study/preliminary implementation of EPICS [1] at the Ruđer Bošković Institute Laboratory for Ion Beam Interactions, the advantages of such a control system were successfully demonstrated by adding automation to beam line measurements, and with it increased beam time utilization. The implementation of this simple system demonstrated the benefits of EPICS to the research staff and opened the doors to future automation.

This work implements only a small portion of the EPICS framework and future work is planned to incorporate other EPICS modules to expand the system. At the moment, the backward compatibility with the existing control system is limiting the implementation. Switching to an EPICS only control system will allow for further automation to both the accelerator and experimental systems.

# AUTOMATED OPERATION OF ITER USING BEHAVIOR TREE SEMANTICS

W. Van Herck<sup>†</sup>, B. Bauvir, G. Ferro, ITER Organization, St. Paul lez Durance, France

## Abstract

The inherent complexity of the ITER machine and the diversity of the ways it will be operated in different phases, like commissioning or engineering operation, poses a great challenge for striking the right balance between operability, integration and automation.

To facilitate the creation and execution of operational procedures in a robust and repeatable way, a software framework was designed and developed: the Sequencer. As a supporting framework for tasks that are mostly goal-oriented, the Sequencer's semantics are based on a behavior tree model that also supports concurrent flows of execution [1].

In view of its intended use in very diverse situations, from small scale tests to full integrated operation, the architecture was designed to be composable and extensible from the start. User interactions with the Sequencer are fully decoupled and can be linked through dependency injection.

The Sequencer library is currently feature-complete and comes with a command line interface for the encapsulation of procedures as system daemons or simple interactive use. It is highly maintainable due to its small and low complexity code base and dependencies to third party libraries are properly encapsulated.

Forecasted activities for this year include its use for the commissioning of plant systems, its incorporation as a foundation for ITER CODAC central monitoring and automation functions and the development of a graphical user interface.

## INTRODUCTION

During the different phases of the ITER machine, many operational procedures will need to be defined, verified and executed in a traceable and maintainable way.

During regular operation, these procedures are mainly associated with Operational Tasks, e.g. venting, baking, etc. These procedures will very likely need to evolve in the lifetime of ITER, either by:

- changing the content and order of the different steps,
- changing parameters that influence the execution of the steps, or by
- increasing the automation of the execution by removing unnecessary user interactions as the procedure becomes more mature and trusted.

During the testing, calibration and commissioning of plant systems, local procedures will be defined to carry out tasks in a repeatable and traceable way. These procedures will likely be even more often adapted.

The Sequencer is a software tool meant to facilitate the creation, adaptation, approval and execution of those procedures. It also defines the format of these procedures, allowing version control and easy traceability. It provides a means to replace procedural documents with instructions and integrate automatic verification.

It will rely on the configuration, monitoring and control functions of the Supervision and Automation System (SUP) to carry out certain actions defined in the procedure. The Sequencer will thus need to adhere to the protocols defined by SUP.

This tool also has to provide the flexibility to be deployed and used in different environments:

- SUP interfacing with the Sequencer to execute a procedure,
- local activities using a standalone GUI,
- creation and editing can be done in an offline environment.

This paper describes the design and implementation choices and provides an outlook to future enhancements or extensions of the framework.

## DESIGN

The language of operational procedures, whether for engineering operations or commissioning tasks, formulates certain goals that need to be achieved at each step. The Sequencer framework was based on behavior tree semantics since, as a formal language, it is generally better adapted to express such goal-oriented procedures than for example finite state machines. Goals can be described by a variety of rules that apply to sub-goals, such as: a Sequence succeeds if all its sub-goals succeed. Another advantage of behavior tree semantics is that it can express parallelism in a natural way. This is often required in operational procedures, where certain goals need to be achieved while maintaining conditions on the machine.

A procedure in the Sequencer library consists of tree structures of instruction objects and a workspace, providing access to variables that need to be shared or communicated between instructions. A procedure is executed by sending 'Execute' commands to a root instruction in the tree until it indicates failure or success. The root instruction is responsible for propagating this 'Execute' command further down the tree.

Figure 1 shows a simplified example of how the goal of starting up a plant system consists of either successfully activating the system (left branch) or, if that fails, executing steps to recover the system to a known and safe state (right branch). Each of those goals can in turn be expressed as a number of actions that need to be carried out sequentially.

<sup>†</sup> Walter.Vanherck@iter.org

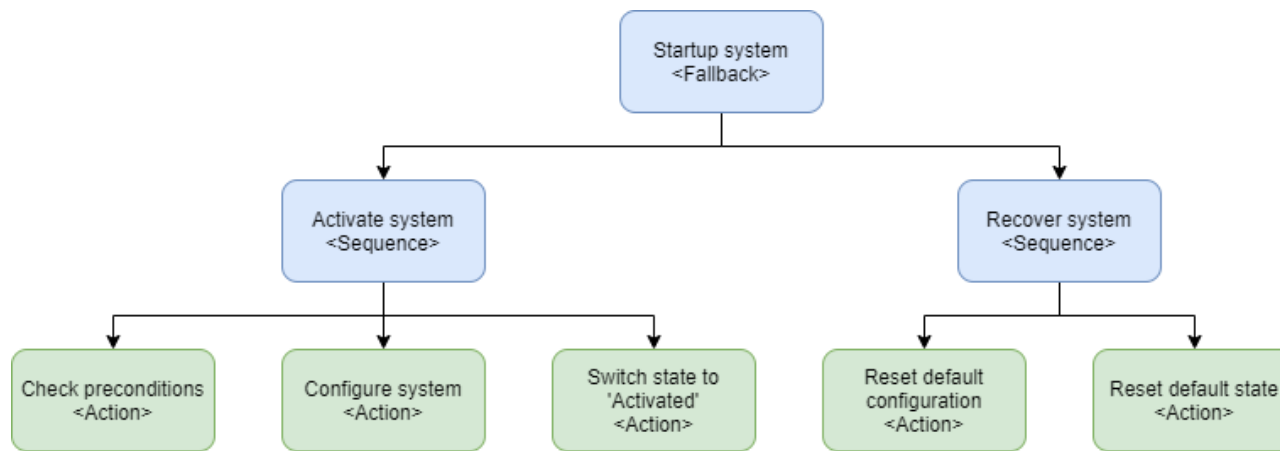

Figure 1: Example procedure for starting up a plant system.

The 'Action' instructions typically contain the domain specific commands or goals, while the compound instructions, such as 'Sequence' or 'Fallback', are domain agnostic.

The core library of the Sequencer framework contains generic instructions and variable types. Domain specific behavior or general extensions can be provided by a plugin mechanism, where extra instruction or variable types can be defined. By loading different plugins, the Sequencer framework can be used in different environments.

The framework also supports serialization of procedures in a human readable format (currently only XML is supported) to allow for version control and traceability.

## IMPLEMENTATION AND QUALITY ASSURANCE

To support usage of the Sequencer framework for varied operational tasks and in different environments, composability and extensibility are key. Composability is provided by the basic building blocks of behavior trees: actions/goals are aggregated into compound goals. The Sequencer framework also allows to include a whole instruction tree from either the same or another procedure file. This allows designers of operational procedures to build complex procedures from ever simpler building blocks.

Extensibility is provided by a plugin mechanism and a generic API for instructions and variables. Behavior can then be customized by implementing instructions and variables that comply with this API and then exposing them as a plugin library.

The framework is implemented in C++11 and is highly maintainable due to its small codebase (currently ca. 5k lines of code) and the amount of decoupling between different components. The source code passes the current criteria for CODAC Software Integrity Level 1 (>95% unit test coverage, no major/critical/blocker issues).

User interaction with procedure execution, e.g. to allow for step-by-step execution or get visual feedback on the progress, is provided by a pure interface and concrete implementations of this user interface are injected into the framework (see Fig. 2). The core framework currently provides two such implementations:

- sequencer-cli: a command line interface to run procedure files with configurable amount of verbosity,
- sequencer-daemon: a non-interactive executable targeted to be run as a daemon process.

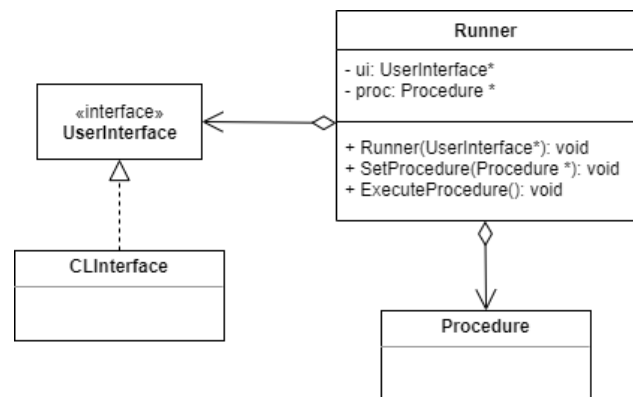

Figure 2: Constructor injection of UserInterface into the execution engine (Runner). Here, a command line interface (CLIInterface) is shown as an example.

## FORWARD LOOK

It is expected that the framework, but also its possible use cases, will continue to evolve due to changing and extending requirements. For reasons of compatibility and stability, such changes need to minimize the impact on the core library and should therefore be implemented in plugins whenever possible.

For the coming year, a number of use cases and further development activities have been identified:

- The framework will be used during the commissioning of plant systems: procedures will be developed to commission and automate routine tasks, such as starting up or shutting down the plant system. Concretely, it will be used for the commissioning of the Reactive Power Compensation and Harmonic Filter system and for the Site Acceptance Test and commissioning of the Magnetics Diagnostics.
- The Sequencer will also be evaluated for use in monitoring the ITER plant and automating central control

system activities. As part of these activities, a plugin is being developed for SUP specific instructions (e.g. for plant system configuration and verification).

- Lastly, a graphical user interface (GUI) is being developed that will enable users to easily create and edit Sequencer procedures. This GUI will also allow to interactively execute such procedures in multiple ways: step-by-step execution, breakpoints at given instructions, etc.

# MACHINE LEARNING PROJECTS AT THE 1.5-GEV SYNCHROTRON LIGHT SOURCE DELTA

D. Schirmer\*, A. Althaus, S. Hüser, S. Khan, T. Schüngel

Center for Synchrotron Radiation (DELTA), TU Dortmund University, Germany

## Abstract

In recent years, several machine learning (ML) based projects have been developed to support automated monitoring and operation of the DELTA electron storage ring facility. This includes self-regulating global and local orbit correction of the stored electron beam, betatron tune feedback as well as electron transfer rate (injection) optimization. Furthermore, the implementation for a ML-based chromaticity control is currently prepared. Some of these processes were initially simulated and then successfully transferred to real machine operation. This report provides an overview of the current status of these projects.

## INTRODUCTION

DELTA is a 1.5-GeV electron storage ring facility operated by the TU Dortmund University as a synchrotron light source [1] and as a facility for ultrashort pulses in the VUV and THz regime [2, 3]. Due to thermal orbit movements and magnetic field changes caused by different insertion device setups, the beam orbit and the betatron tunes may vary during storage ring operation. Therefore, autonomous local and global beam position corrections as well as self-adjusting tunes controls are important tasks, as otherwise sudden beam losses can occur. For this purpose, conventional, fully connected, shallow feed-forward neural networks (NNs) were investigated and have been successfully implemented. Both machine learning (ML) based controls were first simulated and tested on a detailed storage ring model within the Accelerator Toolbox (AT, [4, 5]) framework and were then successfully applied during real accelerator operation.

So far, the storage ring chromaticity values have been adjusted empirically based on experience. Setting of new values can only be done by time-consuming trial and error. For this reason, a ML-based algorithm for automated chromaticity adjustment is currently being prepared, very similar to the already implemented ML-based betatron tunes control. Classical, non-deep NNs are also used in this case.

At present, the electron transfer efficiency from the booster synchrotron to the storage ring is being optimized with the help of ML techniques, too. Here, NNs as well as Gaussian process regression (GPR) methods are explored.

## ORBIT CORRECTION

Extensive studies for a ML-based orbit correction (OC) at the storage ring DELTA started already in 2017. Therefore, initially only the horizontal beam positions were disturbed by horizontally deflection corrector magnets (steerer) and the

corresponding data pairs (orbit/steerer changes) were used as training data for supervised learning of fully connected neural NNs. First simulations have shown that already three-layered neural networks were able to learn correlations between beam position deviations and steerer strength changes. The application of such trained networks on the real storage ring results in similarly good beam position correction quality compared to conventional OC methods like SVD-based (singular value decomposition [6]) programs, however, with significantly fewer correction steps [7]. Subsequently, the ML algorithm was extended to both accelerator planes ( $x/y$ -coupled orbit), including weighted beam position monitor (BPM) signals. Thus, exposed positions in the DELTA storage ring (e.g., injection region, synchrotron radiation source points) can now be adequately considered in the ML-based OC.

In comparison with a more advanced numerical OC approach (qp-cone [8, 9]), the ML-based version results also in similar correction performance, which is scored by the weighted rms orbit error summed for both planes. On average the ML method still required fewer OC steps in this benchmark.

Exemplarily, some benchmark results are depicted in Fig. 1 (ML-based) and Fig. 2 (conventional). Even beam position deviations provoked by perturbations which were not applied during the training (e-j) could also be compensated equally. In all cases, after each provoked orbit disturbance, the residual weighted orbit error, as a measure for the OC

Figure 1: Individual correction steps for different scenarios of orbit deviations (a-j) performed with the ML-based OC program. In comparison to Fig. 2, similar final residual orbit qualities, scored by the weighted rms orbit error, are achieved in significantly fewer iterations.

performance, converged to less than 3 mm. Further details of the ML-based orbit correction procedure are documented in [7, 10].

## BETATRON TUNE CONTROL

To obtain appropriate data for NN training, the set values of seven independent quadrupole families located in the storage ring arcs were randomly changed and subsequently the associated tune shifts were recorded. Three-layered NNs were trained with experimental machine data as well as with simulated data based on a detailed lattice model of the stor-

Figure 3: Validation of NNs trained with experimental data and applied to real machine operation. Two experiments demonstrate tune matching from start to goal tunes without beam losses. In the first experiment, 10 steps were performed (superconducting wiggler magnet switched on, rectangular markers) and in the second test 50 steps were executed (superconducting wiggler magnet switched off, diamond markers) [12].

age ring [11]. Thereby, for supervised learning a variety of different gradient backpropagation methods were tested [12].

With both data sources, comparable tune correction accuracies were achieved, both, in real machine operation and for the simulated storage ring model. In addition, it was also possible to perform tunes control 'crosswise', i.e., control of the real storage ring with NNs only trained by simulated model data; and vice versa, NNs only trained with real machine data and then applied to the simulation model. In all cases, the desired tune matching was successful.

In contrast to conventional PID control methods [13], trained NNs are able to approach the desired target tunes in fewer steps, which could enable a more controlled scanning in the tune diagram. Since the DELTA quadrupole power supplies lack the feature to drive synchronously in real-time, an iterative procedure for the NN-based tune control loop must necessarily be applied. Figure 3 depicts typical ML-based tune matching examples. Further examples and a more detailed description can be found in [12].

## CHROMATICITY CONTROL

Similar to the ML-based tune control, the procedure can likewise be transferred to an automatic ML-based chromaticity control. At the DELTA storage ring, the chromaticity values are manually adjusted using 15 independent sextupole power supply circuits. However, to account for the symmetry of the optics, these circuits are grouped into 7 sextupole families during standard machine operation.

To acquire suitable ML training data, first, the sextupole strengths are scanned systematically for single and then randomly varied for all families. For each strength change, the associated chromaticity shifts are measured. Figure 4 visualizes corresponding simulation results for a DELTA storage ring model. With these data pairs (strength varia-

Figure 4: Distribution of 3000 chromaticity shifts invoked by uniformly randomized strength variations of seven independent sextupole families. The data are obtained by AT optics calculations based on a Delta storage ring model and are used for supervised training of NNs.

Figure 5: Example for verification of NNs trained by simulated data (see Fig. 4) and applied to the DELTA storage ring model. The desired target values for compensated chromaticity (goal:  $\xi_x = \xi_y = 0$ ) were reached in iterative steps starting at the setting for natural chromaticity ( $\xi_x = -21$ ,  $\xi_y = -8$ , sextupoles switched off).

Figure 6: FFT beam spectrum from turn-by-turn orbit data recorded at a dedicated 'fast' BPM (blue) and after (red) a cavity radiofrequency (RF) variation of 5 kHz. The horizontal and vertical chromaticities are calculated by determining the betatron tune peak shifts induced by the cavity RF variation.

tions and chromaticity shifts), 'chromaticity-models' will be trained, which later could serve to adjust and control the chromaticity values automatically during real machine operation. Figure 5 illustrates an example for simulated chromaticity matching performed with a 3-layered NN which has been trained by conjugate gradient backpropagation using the data depicted in Fig. 4. The natural chromaticity ( $\xi_x = -21$ ,  $\xi_y = -8$ ) which occurs with all sextupole switched off (start) can be adjusted to full chromaticity compensated values ( $\xi_x = \xi_y = 0$ ) by the ML-based control loop. The step size (number of iterations) is adjustable and depends mainly on the granularity of the trainings data.

For chromaticity determination in real ring operation, the cavity radiofrequency (RF) must be shifted and then the tune shifts  $\Delta Q$  is determined via an FFT spectrum from turn-by-turn orbit data at a dedicated 'fast' BPM (see Fig. 6 as an example). With  $\Delta Q = \xi \cdot \Delta p/p$  follows for the chromaticity

$\xi = \Delta Q \cdot p / \Delta p = -\alpha_c h \Delta f_\beta / \Delta f_{RF}$ .  $\Delta f_{RF}$  corresponds to changes of the cavity radiofrequency,  $\Delta f_\beta$  is the measured betatron frequency shift,  $h$  is the harmonic number and the momentum compaction factor  $\alpha_c = (\Delta L/L)/(\Delta p/p)$  relates the relative orbit path length change  $\Delta L/L$  to the relative momentum change  $\Delta p/p$ . Work on this project has just started in the framework of a master's thesis.

## INJECTION OPTIMIZATION

Already in 2005, first attempts were made to optimize the electron transfer rate (injection efficiency) from the booster synchrotron to the storage ring by a combination of genetic algorithms and neural networks [14, 15]. Currently, this idea is being resumed but now with an expanded number of parameters and with a significantly enlarged database for ML-based training. In addition to the strength settings of the transfer line magnets, the injection elements of the storage ring (e.g., kicker magnets, magnets of a static injection bump) as well as the trigger timings of all pulsed transfer line and injection magnets are now taken into account, too.

In total, currently up to 30 different parameters can be varied systematically or randomly. For each individual injection parameter variation, the corresponding change of the injection efficiency is measured simultaneously. In this way, several thousand pairs of experimental data sets were generated which served as inputs for various machine learning techniques. So far, classical feed-forward neural networks (NNs) and Gaussian process regression (GPR) methods were used for modeling [16, 17]. First training results are shown in Fig. 7 (GPR-based) and Fig. 8 (NN-based). They show the trained model predictions of the injection efficiencies as a function of approx. 750 measured transfer efficiencies.

Figure 7: Injection efficiencies predicted by a Gaussian process regression (GPR) model versus measured efficiencies. The machine learning was performed with approx. 750 measured data sets. The GPR applied the nonisotropic exponential kernel function for model adaption [16]. The fit results in a correlation coefficient of  $R^2 = 0.89$  and a root mean squared value (RMSE) of 4.3.

Figure 8: Injection efficiencies predicted by a model based on a narrow neural network (NN) versus measured efficiencies. The machine learning was performed with the same 750 data sets as used for GPR-based modelling. The NN is composed of three fully connected ReLU-layers (28/10/1) [16]. The fit results in a correlation coefficient of  $R^2 = 0.67$  and a root mean squared value (RMSE) of 7.5.

The plots were obtained applying the  $k$ -fold cross validation method. Therefore, the training data sets were randomly shuffled and then divided into  $k$  partitions. For each training-validation iteration a different partition for validation was used. The remaining data was applied for testing. Thus, each data partition was used once for validation and  $k - 1$  times for training.

Both ML methods find clear correlations, whereby the GPR-trained model results in a significantly larger correlation coefficient  $R$  and thus seemed to be more suitable for transfer rate modeling. The next step is to apply these models to keep the injection efficiency at a high level in an automated way using an optimization algorithm (e.g. BFGS [18] or Bayesian optimization [19]) without the need for operator interventions [20]. These studies are currently being continued.

## SUMMARY

ML-based techniques are increasingly replacing conventional optimization methods in the fields of particle accelerator controls. At the electron storage ring facility DELTA, it was demonstrated that specially designed and trained neural networks are suitable for a variety of control tasks. Supervised training of the NNs was performed with data recorded during real machine operation and with simulation data based on accelerator models. Compared to classical numerical methods, it was shown that the different ML-based applications could achieve comparable correction accuracies. In contrast to conventional numerical methods, neural networks are in principle able to converge to the desired target values in fewer iterations, resulting in a faster correction convergence behaviour. Inspired by a variety of ML-supported

applications in other scientific fields, additional use cases in the domain of accelerator controls are being evaluated. First ideas for a neuro-fuzzy feedback loop, e.g., for the water cooling system of the new EU-type RF cavity installed at the DELTA storage ring, have already been discussed [7]. It is planned to migrate all ML-based programs to a dedicated GPU-based ML server which provides a powerful hardware platform and a more user friendly ML framework (ML workflow) for future, more sophisticated ML applications.

## ACKNOWLEDGEMENT

We thank all colleagues of the DELTA team for many inspiring advises and suggestions as well as for providing sufficient data acquisition time during accelerator shifts.

# ONLINE AUTOMATIC PERFORMANCE OPTIMIZATION FOR THE ELETTRA SYNCHROTRON

G. Gaio†, S. Krecic, F. Tripaldi, Elettra-Sincrotrone Trieste S.C.p.A., Trieste, Italy

## Abstract

Online automatic performance optimization is a common practice in particle accelerators. Beside the attempts based on Machine Learning, which is effective especially on non-linear systems and images but are very complex to tune and manage, one of the most simple and robust algorithms, the simplex Nelder Mead, is extensively used at Elettra to automatically optimize the synchrotron parameters. It is currently applied to optimize the efficiency of the booster injector by tuning the pre-injector energy, the trajectory and optics of the transfer lines, and the injection system of the storage ring. It has also been applied to maximize the intensity of the photon beam on a beamline by changing the electron beam position and angle inside the undulator. The optimization algorithm has been embedded in a Tango device that also implements generic and configurable multi-input multi-output feedback systems. This optimization tool is usually included in a high-level automation framework based on Behavior Trees [1] in charge of the whole process of machine preparation for the experiments.

## INTRODUCTION

Similarly to most of the modern light sources, the Elettra 2-2.4GeV synchrotron relies on feedback systems to keep the beams stable and, more recently, on automatic optimization systems to help operators in maximizing the performance.

Feedback and optimization systems look in some aspects very similar. They have both sensors, actuators and have in common the objective of minimizing the distance between sensors and a reference. In feedback systems the reference is a setpoint of a machine parameter that have to kept fixed no matter the noise or external perturbations affecting the accelerator. In optimization problems the reference is still present but usually set to an arbitrarily very high /very low value if the intention is to maximize / minimize the sensor value.

By the way, excluding the algorithmic part, the software internal components (acquisition, command and control) are the same.

In light sources programmable feedback and/or optimization tools are quite common. Some of them are implemented as high-level applications [2,3] others are server applications [4].

At Elettra a programmable C++ Tango server, called MIMOFB (Multi Input Multi Output Feedback), has been developed to replace legacy applications implementing slow feedback systems and to implement automatic optimization procedures.

† email: giulio.gaio@elettra.eu

## MIMOFB

When configured as a feedback, the MIMOFB implements a correction scheme based on a linear model that link sensors and actuators. This relationship is an approximation that is empirically calculated by measuring the perturbation generated on the sensors by one actuator at a time. The result of this process is a matrix, formally a Response Matrix (RM). The product between the inverse of the response matrix, usually inverted using the Singular Value Decomposition (SVD) algorithm, and the error vector returns the values to subtract from actuators to minimize the distance between the sensors and the reference.

Regarding optimization, the MIMOFB implements only model-less optimization schemes. In this case the objective function  $F(1)$  is the sum of the normalized distances between  $N$  sensor values and corresponding references multiplied by the sensor weights.

$$F = \sum_{i=0}^N w_i * \frac{abs(x_i - x_i^{ref})}{x_i^{max\_thres} - x_i^{min\_thres}} \quad (1)$$

The configuration of a MIMOFB device is stored in several device properties.

For each sensor the developer has to configure:

- the sensors Tango attributes
- the number of sensor readings per cycle
- descriptive label
- weight
- minimum threshold value
- maximum threshold value
- dead-band
- sensor update rate in ms
- type of filtering (none, mean, median) when the number of readings per cycle is higher than one
- Tango device allowed states
- list of actuators affecting the sensors

For each actuator it is required to specify:

- the actuator Tango attribute
- descriptive label
- minimum threshold value
- maximum threshold value
- scan range
- RM kick; this value is used in response matrix calculation and as the initial step in optimization algorithms
- maximum backlash (useful when working with motors)
- dead-band
- maximum difference between last read and set value
- RM kick settling time (msec.); this value changes proportionally to RM kick amplitude

- constant settling time in msec.
- tango device allowed states.

Thus, the repetition frequency of the algorithm depends only by the refresh rate and the settling time of the I/O. Acquiring sensors and setting actuators could be performed in series or parallel. When configured in series one iteration lasts the sum of all refresh and settling times. When configured in parallel, the repetition period is equal to the sum of the slowest sensor and actuator response. The repetition frequency can be tuned further by acting on a time factor that compress or expand all settling times.

### Feedback Algorithm

The response matrix calculation is performed by the MIMOFB. At the end of the procedure the user can choose to load the new response matrix or just save it. In the response matrix inversion, the SVD singular values can be weighted and weights can be saved.

When the feedback is running, users can activate an adaptive procedure that improve the matching between the response matrix and the real machine. Basically, after a given feedback iteration, one actuator at a time performs a kick. The corresponding perturbation is acquired by the sensors to update the corresponding part of the response matrix that will be afterwards inverted for the next feedback step.

A procedure assists the user to estimate what is the optimal kick amplitude used for the response matrix calculation and at the start of the optimization procedures. The optimal kick amplitude is a tradeoff between a step that increases the *rms* of the sensor readings by at least 50% and the minimum step that drive at least one of the sensors out of range.

The closed loop algorithm is a proportional-integral-derivative controller (PID). The user can switch between the PID default configuration and a predefined one that

the closed loop gain and guarantee a better feedback stability. Users can enable the anti-windup, the dead-band control and the slew-rate control on the actuators.

### Optimization Algorithms

At the moment there are four model-less optimization algorithms available:

- 1D scan, one parameter
- 2D scan, two parameters
- Simultaneous Perturbation Stochastic Approximation (SPSA) [5], multi-parameter
- Nelder Mead [6], multi-parameter.

In the near future many model free algorithms provided by the NLOpt library [7] will be integrated in the server.

The optimization algorithm could run one shot or, by means of a programmable optimization scheduler (see Fig. 1), cycle between different combinations of optimization algorithms and actuators. For NM and SPSA the user can limit the maximum number of iterations or seconds per optimization. During execution, if no improvement occurs within one third of the remaining time, the optimization stops.

### Monitoring and Recovery

The MIMOFB stops in fault state when sensor/actuator values and their statuses are out of allowed values for a number of consecutive cycles. Afterwards, the feedback/optimization can automatically restart once sensor and actuators are back in range.

When enabled, the processing automatically disables the sensors whose value remain constant for more than two samples or equal to zero.

If the sensor value is an average of more then one sample (mean/median), a threshold fixes the maximum number of outliers before marking the sensor invalid.

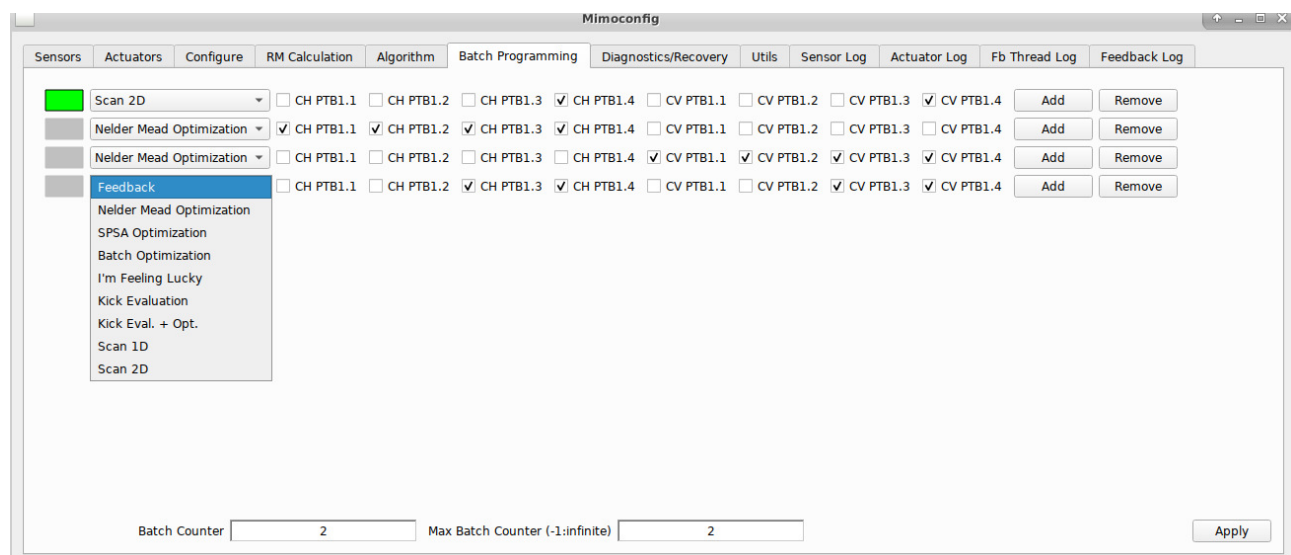

Figure 1: Configuration panel of the MIMOFB. The “Batch Programming” tab configures the optimization scheduler (example). CHV\_PTBX.X are corrector magnets of a transfer-line. The optimization target is the booster accumulated current. The “I’m Feeling lucky” optimization mode couples randomly actuators and optimization algorithms.

Sensor and actuator data and error messages are stored into dedicated buffers (see Fig. 2). Similarly, the optimization / feedback engine has a dedicated logging buffer for saving error and debugging messages.

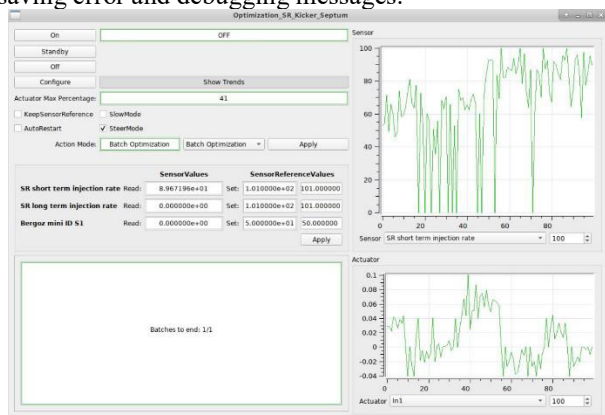

Figure 2: MIMOFB main control panel with logging buffers.

### Sequencers Integration

The MIMOFB can be configured to execute a sequence of instructions, based on sequencers [1], at the start and at the end of the correction / optimization process.

Each sensor reading can be preceded and followed by the execution of a sequencer. Similarly, a sequencer can be executed before and after the setting of an actuator. In all cases the correction/optimization process waits sequencers to complete their task before going on. If the sequencer will end its task in fault state then the MIMOFB itself will fail.

The sequencers greatly expand the capabilities of the MIMOFB. A significant example is the alignment procedure, based on MIMOFB, of an electron/laser beam based on intercepting fluorescent screens. In this case the acquisition of the position of the beam on the screen has to be preceded by the insertion of the screen and followed by its extraction (to let the beam go to the next screen). This mechanical process is demanded to pre and post sensor sequencers that can be easily integrated without touching any internal logic of the MIMOFB. In another example a pre-sensor sequencer selects the most reliable sensor between two by acting on the weights of the sensors.

## OPTIMIZATIONS

At Elettra the MIMOFB has slowly replaced all legacy high-level applications used for machine tuning and beam stabilization. MIMOFB implements slow local and global orbit correction in the storage ring, tune feedback, RF path length feedback and booster-to-storage ring transfer-line orbit feedback. However, the most interesting applications of the MIMOFB concern the optimization that, until recently, was performed manually by operators.

In Elettra the machine optimizations are one of the most critical steps in the automatic process that recovers the machine from a faulty state and gives back light to the users.

The optimization process has to be:

- maintainable by the operators
- aware of the machine state

- resilient to external perturbations
- able to restore the machine in case of any failure.

Basically, in all optimization schemes the Nelder-Mead (NM) algorithm together with the programmable optimization scheduler gets the best results. At Elettra the optimizer is used routinely for tuning ([description];[actuators];[algorithm];[target function]):

- pre-injector energy (see Fig. 3, num. 1); one actuator, pre-injector HV power supply; algorithm scan-1D; booster accumulated current
- pre-injector to booster RF phase matching (see Fig. 3, num. 2); one actuator, rf phase shifter; algorithm scan-1D; booster accumulated current
- booster to storage ring transfer line orbit (see Fig. 3, num. 5); four actuators, corrector magnet power supplies; algorithm Nelder-Mead; injection efficiency (see Fig. 3)
- storage ring injection system (Fig. 3, num. 6); four actuators, HV power supplies; algorithm Nelder-Mead; injection efficiency.

The optimizer is also used for tuning during machine preparation or machine physics shifts:

- pre-injector to booster transfer-line orbit (see Fig. 3, num. 3); four actuators, corrector magnet power supplies; algorithm Nelder-Mead; booster accumulated current
- pre-injector to booster transfer-line optics (see Fig. 3, num. 4); two actuators, quadrupole magnet power supplies; algorithm Nelder-Mead; booster accumulated current
- beamline photon flux (see Fig.3, num. 7); four actuators, position/angle at source point (eight correctors); algorithm Nelder-Mead; beamline photodiode (see Fig. 4)

Figure 3: Elettra automatic optimized systems

## CONCLUSION

The MIMOFB Tango server has become a key component in the Elettra operations. Thanks to the fact that it is a server, it can be embedded in the high level software framework based on sequencers, which carries out most of the

Figure 4: Optimization of the Elettra injection efficiency by changing the last correctors of the booster to storage-ring transfer line

Figure 5: Optimization of the photon beam flux on a beam-line by changing position and angle of the electron beam inside the undulator. Eight correctors are involved in the local orbit optimization procedure [8]. The batch programming engine runs the optimization for two cycles. In the second cycle the initial step amplitude was half the one of the first cycle.

tasks that operators should perform manually to prepare the machine and the electron beam for the beamline experiments.

Since the optimization procedures have to run without any human supervision, we have preferred robust and model-less algorithms with a minimum number of hyperparameters to tune. For the same reason we chose to limit to four the number of parameters involved contemporary in any unsupervised optimization process.

Programming batches can execute several combinations of optimization algorithms and different actuators to expand the limits of using just one setup. The Nelder-Mead restart technique [9] that can be easily implemented with batch programming speed up the process of finding the best working point. The necessity for any online algorithm to have a minimum signal for starting, can be mitigated with the possibility to performing 1D-2D wide range scans for signal recovering before running more sophisticated algorithms.

## Abstract

We have developed a machine-learning-based operation tuning scheme for the KEK e-/e+ injector linac (Linac), to improve the injection efficiency.

The tuning scheme is based on the various accelerator operation data (control parameters, monitoring data and environmental data) of Linac.

For the studies, we use the accumulated Linac operation data from 2018 to 2021. In this paper, we show the results on our R&Ds of, 1. visualization of the accelerator parameters (~1000) based on the dimensionality reduction, and, 2. accelerator tuning using the deep neural network (DNN). In the latter R&D, estimation of the accelerator parameters using DNN, and the accelerator simulator based on the Generative Adversarial Network (GAN) have been studied.

## INTRODUCTION

We have developed an operation tuning scheme for the KEK e-/e+ injector linac (Linac) [1]. The Linac accelerator is a 600m long injector linac to distribute electrons and positrons to four ring accelerators: the Photon Factory (PF), the PF Advanced Ring (PF-AR), the SuperKEKB Electron Ring (HER) and the Positron Ring (LER). The Linac accelerator is capable of operating at up to 50 Hz in two bunches (96 ns apart), which is equipped with 100 beam position monitors (BPM), 30 steering magnets and 60 RF monitors.

Though the precise beam tuning and high injection efficiency are required, there exist several problems on the accelerator tuning as: 1. A lot of parameters (~1000) should be tuned, and these parameters are intricately correlated with each other; and 2. Continuous environmental change, due to temperature change, ground motion, tidal force, etc., affects to the operation tuning.

To solve the above problems, we have developed, 1. visualization of the accelerator parameters (~1000) trend/correlation distribution based on the dimensionality reduction to two parameters, and 2. accelerator tuning using the deep

neural network, which is continuously updated with the accelerator data to adapt for continuous environmental change. to adapt the environment changes.

In this paper, we show the results on our R&D. For the studies, we use the electron beam data for Super KEKB injection accumulated in 2018 Nov. - 2021 Jun. This beam data includes the following parameters.

- 500 operating parameters (Steering magnet)
- 732 environmental parameters

In addition, we use the ratio of the upstream (SP\_A1\_M) and downstream (SP\_58\_0) charges of the accelerator as a quantitative measure of the injection efficiency of the accelerator.

## VISUALIZATION OF THE ACCELERATOR PARAMETERS

In this study, we use dimensionality reduction with a Variational AutoEncoder (VAE) [2] as a visualization method of accelerator parameters. VAE is a neural network consisting of two networks: the encoder, which converts the input data into "latent variables" of arbitrary dimensions, and the decoder, which reconstructs the input data from the latent variables. Here, VAE assumes that "latent variables" are normally distributed, so that latent variables for similar trend input data are closely distributed when they are plotted on a space. Using this property, we can visualize the accelerator parameters by dimensionally reducing them to two-dimensional "latent variables" and plotting them in a two-dimensional space.

To check the visualisation performance by VAE, we created an accelerator parameters dataset containing 1232 parameters (operating params + env params). Figure 1 shows the results of the visualisation of the accelerator parameters accumulated between 2018 Nov. and 2021 Jun. using VAE trained by 2018 Nov to 2021 May data. The output results are coloured according to the injection efficiency of the input accelerator data.

As a result of Figure. 1, the accelerator parameter dataset containing 1232 parameters is visualized by VAE with di-

<sup>†</sup> m20sa029@uv.osaka-cu.ac.jp

<sup>#</sup> masako@osaka-cu.ac.jp

mensionality reduction to two dimensions. And, the visualisation results show that in the short term(~1month) the accelerator trend does not drastically change, but in the long term(>3month) accelerator trend vary over a wide range.

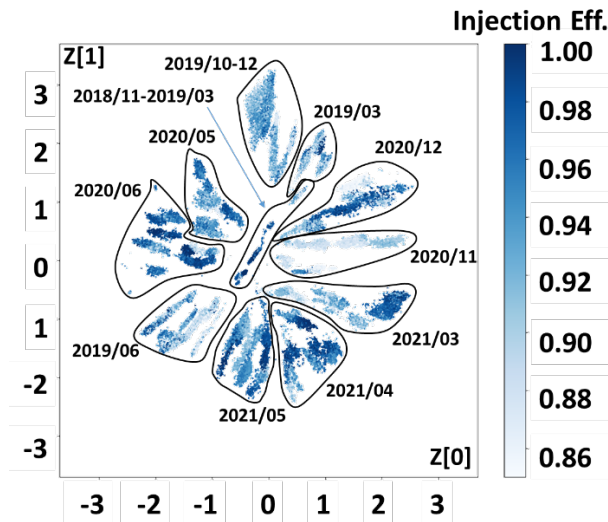

Figure 1: VAE output (two-dimensional Latent variables) from the 2018 Nov to 2021 June accelerator data. VAE is trained using 2018 Nov to 2021 May data. The output results are coloured according to the injection efficiency of the input accelerator data.

## ACCELERATOR TUNING USING THE DEEP NEURAL NETWORK

The operating environment of the accelerator is continuously changing. In addition, the correlations between the parameters are complex. In this situation, to continuously adapt to the environmental changes to get the high injection efficiency, the environment driven DNN (Reinforcement ML) is a good candidate. However, to apply the Reinforcement ML to the operation tuning, we need 1. Estimation of the acc. parames using DNN, 2. realistic accelerator simulator. In the following, we introduce these R&D.

### Estimation of the Acc. Parames using DNN

For the reinforcement learning, it is important to start from the optimized (the best) accelerator parameter value, so that ML doesn't need to search in wide parameter range. In addition, we need to obtain the relationship between efficiency and accelerator parameters, for the effective parameter optimization.

Therefore, we have developed a method to estimate an injection efficiency using DNN with accelerator parameters inputs, to assure to get the relationship between them.

In this study, we designed a Regression-DNN that takes 1232 accelerator parameters (operating params and env params) as input and outputs the injection efficiency. The implementation of the DNN is based on Tensorflow [3].

**Evaluate the performance of DNN** To evaluate the performance of DNN, we extract 150,000 events data from Linac data accumulated in 2018 Nov. - 2021 Jun. Note that

the injection efficiency of the dataset is extracted to be uniformly distributed over 0.85. Out of 150,000 events, we use 135,000 events for training and 15,000 events for validation.

We trained and validated Regression-DNN on dataset described above. As a result, the mean squared error (MSE) between the predicted injection efficiency and the real injection efficiency is 0.00030 for the whole data interval. Figure. 2 shows injection efficiencies of predicted by DNN (orange) and real (blue), for 2020/11/30-2020/12/07 evaluation data. Vertical and horizontal axis indicate injection efficiency and date, respectively.

Figure 2: Injection efficiencies of predicted by DNN (orange) and real (blue), for 2020/11/30-2020/12/07 evaluation data. Vertical and horizontal axis indicate injection efficiency and date, respectively.

These results show that Regression-DNN can predict injection efficiency. In other words, Regression-DNN can describe the relationship accelerator parameters and injection efficiency.

**Training DNN with past data** Figure 1 shows that 2D latent value for 2021 Jun. is close to 2021 May. This indicates that the 2021 May accelerator data are similar to the 2021 Jun. accelerator data. So, using DNN trained with 2021 May data, we may be able to predict the injection efficiency in 2021 Jun. To test our hypotheses, we create three datasets with different inclusion periods. Figure 3 shows an overview of the three datasets.

Figure 2: Overview of the datasets (1)-(3).

Each dataset contains 135,000 events for training and 15,000 events for validation. We trained and validated DNN on each dataset. As a result, the mean squared error of injection efficiency output by DNN trained on datasets (1)-(3) as validation data is 0.00038 (Dataset (1)), 0.00038 (Dataset (2)), 0.00300 (Dataset (3)). Figure 3 shows the comparison between the injection efficiency predicted by DNN (Dataset (1) orange, (2) red, (3) green) and the real

incident efficiency (blue). Vertical and horizontal axis indicate injection efficiency and date, respectively.

The results show that the DNN trained with 2021 May data; dataset (1,2), can predict 2021 Jun. injection eff. In other words, in order to predict the injection efficiency with DNN trained on past data, it is necessary that the training data of DNN contains similar data to the trend of the period we want to predict.

Figure 3: Predicted injection efficiencies for the 2021 June evaluation data, based on the DNN predictions with Dataset (1) to (3) (orange, red, and green), and the real operation injection eff.(blue). Vertical and horizontal axis indicate the injection eff. and date, respectively.

### Accelerator Simulator Based on GAN

For the reinforcement learning, it is dangerous to do the parameter optimization based on the actual operation with the real accelerator. Therefore, realistic simulator is necessary for the pre-training of the actual reinforcement learning.

In this study, we develop a method using GAN (Generative Adversarial Network) [4]. Generative Adversarial Network (GAN) is a class of machine learning frameworks. Given a training set (real data), this technique learns to generate new data with the same statistics as the training set.

GAN consists of two networks (Generator and Discriminator) that compete with each other. The Generator is a network with noise data as input and new data with the same statistics as the training set as output. The Discriminator is a network with training set data(real) and output of Generator(fake) as input and discriminate between real and fake as output. By alternately training two competing networks, we can increase the similarity between the Generator output (fake data) and the training set (real data).

Using this property, by training GAN on the accelerator parameters data, it is expected to be possible to reproduce the data with keeping the correlation between the parameters. So, we verify whether the GAN trained by real data of

the accelerator can generate data reproducing the correlation between parameters.

For GAN training, we create the following two datasets with different parameter configurations.

- Dataset(a) 2params  
Injection eff. + specific steering magnet param
- Dataset(b) 1233params  
Injection eff. + operating params+ env params

Please note that, Injection efficiencies in the datasets are uniformly extracted. And, each dataset contains 540,000 events for training and 60,000 events for validation.

**Training by Dataset(a)** We trained the GAN on the dataset (a), which consists of two parameters, the injection efficiency, extracted with a uniform distribution and specific steering magnet parameter (PY\_32\_4). Figure 4, shows a histogram of the magnet parameter (PY\_32\_4) reproduced by this trained GAN, and the real data used for training

Figure 4: Histogram of the specific magnet (PY\_32\_4) param. reproduced by GAN trained Dataset(b) (orange) and the real data (blue).

In this case, from the results in Figure 4, we can see that GAN reproduces the characteristics (peaks, distribution) of real data by training. However, it is necessary to reproduce the correlation between the parameters as well as the characteristics of the individual parameters. Therefore, we examined the correlation between the injection efficiency and the steering magnet parameters in the dataset by making two-dimensional histograms. The created two-dimensional histogram is shown in Figure. 5.

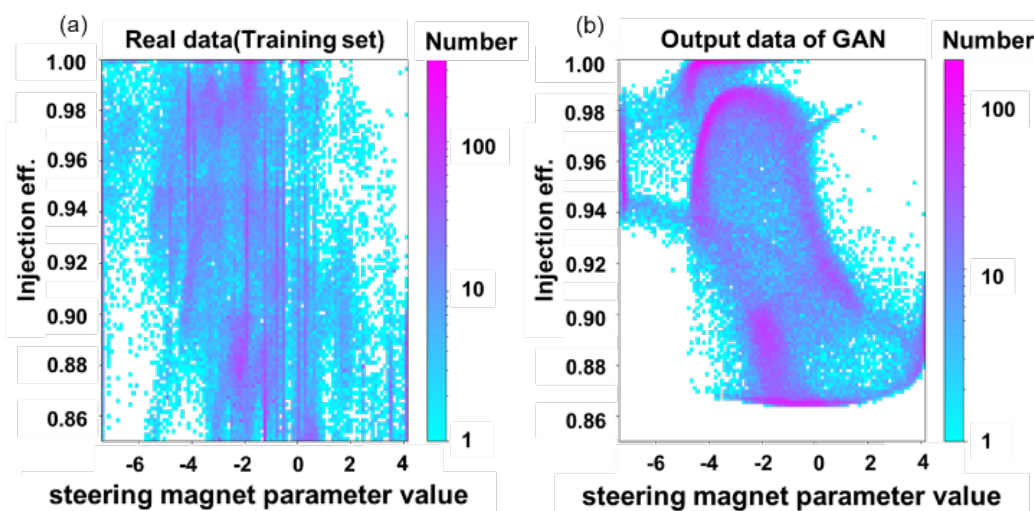

Figure 5: Two-dimensional histogram of real data(a) and reproduced data(b). Vertical and horizontal axis indicate Injection eff. and steering magnet parameter value.

From the results in Figure 5, we can see that GAN reproduces the two-parameter correlation trend. However, the GAN output data has peaks that did not match the real data and does not cover the full range of the real data.

**Training by Dataset(b)** We trained the GAN on the dataset (b), which consists of 1233 parameters, the injection efficiency extracted with a uniform distribution, steering magnet parameters and environmental parameters. Figure 6, shows a histogram of the magnet parameter (PY\_32\_4) reproduced by this trained GAN, and the real data used for training.

Figure 6: Histogram of the specific magnet (PY\_32\_4) param. reproduced by GAN trained Dataset(b) (orange) and the real data (blue).

From the results in Figure 6, we can see that GAN reproduces the characteristics (peaks, distribution) of real data by training. But we need to verify that the trained GAN is able to reproduce the correlations of the 1233 parameters, not just the individual parameters characteristics.

Here, it is difficult to compare the real data with the reproduced data for the 1233 parameters. Therefore, we use the visualisation method with dimensionality reduction by VAE described above. Figure 7 shows two-dimensional histogram of the visualisation of the real data and reproduced data by GAN, using VAE trained by 2018 Nov to 2021 Jun data.

From the results in Figure 7, we can see that GAN output data dose not reproduce the whole period of the real data. Such a result, where the GAN can only reproduce part of the data used for training, is a possible event in the training of GAN, called "mode collapse".

## SUMMARY

We have developed a machine-learning-based operation tuning scheme for the KEK e-/e+ injector linac (Linac), to improve the injection efficiency.

In this paper, we show the results on our R&Ds of, 1. visualization of the accelerator parameters (~1000) trend/correlation distribution based on the dimensionality reduction using VAE, 2. predicting injection efficiency using Regression-DNN, and 3. reproduction of accelerator parameters using GAN.

Using the electron beam data for Super KEKB injection accumulated in 2018 Nov. - 2021 Jun, we show that 1. It is possible to visualize the 1232 parameters by dimensionality reduction to two dimensions using VAE; 2. It is possible to predict the injection efficiency of accelerators using Regression-DNN. The prediction with the past data which has the similar parameter features, is effective to improve the prediction accuracy; 3. Accelerator simulator based on GAN reproduces the overall parameters correlation trend. On the other hand, GAN's output data dose not reproduce the whole period of the real data due to the "mode collapse", and further improvement is necessary to use for the pretraining of the reinforcement learning for the accelerator tuning system.

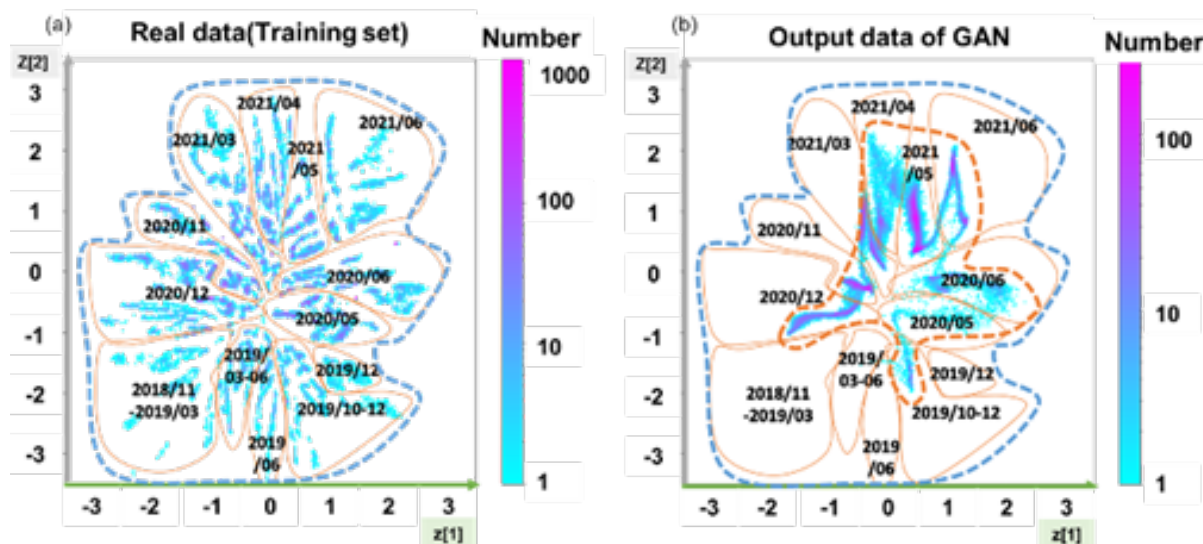

Figure 7: Two-dimensional histogram of real data(a) and reproduced data(b). Vertical and horizontal axis indicate VAE 2D latent value  $z[2]$  and  $z[1]$ .

# RESEARCH ON CORRECTION OF BEAM BETA FUNCTION OF HLS-II STORAGE RING BASED ON DEEP LEARNING

Yong-Bo Yu\*, Ke Xuan, Gong-Fa Liu, Wei Xu, Chuan Li, Wei-Min Li

National Synchrotron Radiation Laboratory, University of Science and Technology of China, Hefei Anhui, China

## Abstract

In recent years, artificial intelligence (AI) has experienced a renaissance in many fields. AI-based concepts are nature-inspired and can also be used in the area of accelerator controls. At HLS-II, there are not many studies on these procedures. We focused on HLS-II beam stability in order to get better performance. We have created a deep learning-based approach for correcting beta function. Simulation studies reveal that the method presented in this work performs well in terms of correction outcomes and efficiency, resulting in a new way to adjust the accelerator beam function.

## INTRODUCTION

Since the 1980s, artificial intelligence (AI) approaches in accelerator control have been studied [1]. In the light of recent theoretical and practical advances in machine learning and the use of deep neural network-based modeling and controlling techniques, new approaches for the control and monitoring of particle accelerators are emerging. Furthermore, the availability of powerful deep learning programmings frameworks like TensorFlow [2], PyTorch [3], Keras [4], and Matlab allow rapid and optimized implementations of complex algorithms and network architectures. Therefore, we propose a method based on a deep neural network to correct the beta function.

## FEEDBACK THEORY

### Corrective Theory for the Beta Function

The beta function is the lateral dynamic function of the particle, and it is one of the most important optical parameters of a beam. The focus intensity  $K$  of the quadrupole and the change  $\Delta Q_{x,y}$  of the storage ring tune at this time are recorded so as to calculate the beta function of the quadrupole. When changing  $\Delta K$ , the theoretical formula for maintaining the measured value of the ring beta function is

$$\beta_{x,y} = \pm \frac{2}{\Delta K l} \left( \cot(2\pi Q_{x,y}) [1 - \cos(2\pi \Delta Q_{x,y})] + \sin(2\pi Q_{x,y}) \right) \quad (1)$$

The theoretical formula for the measured value of the function can be simplified as follows when the tune is far from the integer or half-integer resonance line, and the change value is small.

$$\beta_{x,y} \approx \pm 4\pi \frac{\Delta Q_{x,y}}{\Delta K l} \quad (2)$$

\* yybnsrl@mail.ustc.edu.cn

According to the formula, the beta function at the location a quadrupole magnet is calculated using the variation of the quadrupole strength and the measured tune shift.

### Using a Deep Learning Model to Conduct Beta Function Correction

The beta function of the storage ring receives feedback correction based on the generated storage ring beam function model. The feedback correction diagram of the HLS beam beta function is shown in Fig. 1. The steps involved in beta function feedback correction are followed: The focus intensity change of the storage ring quadrupole is obtained by feeding the beta function error value into the storage ring beam model. The focus intensity change is sent back to the storage ring to obtain the amended beta function value. This goes back and forth until the beta function is wholly corrected.

Figure 1: Schematic of the beta function correction system using a Neural network method.

## MACHINE LEARNING DESIGN STEPS

Five significant steps are involved in developing an ML-based beat function application (see Fig. 2). Data acquisition and cleaning are the first steps. The topology of the neuron network is then defined and optimized. Finally, the beat function correction application must be tested after multiple training sessions and continuous performance tests. In the following sections, we will go over the most critical development steps.

### Data Generation

In order to perform supervised neural network learning, A large number of data pairs must be provided. As a result, we took the Lattice as an object and created the HLS-II virtual storage ring model. The final data is finished with MATLAB's AT toolbox and a python program created with pyAT. After that, 10,000 data pairs were created. Each data pair has 96 data points, with  $\Delta\text{betax}$  (32),  $\Delta\text{betay}$  (32), and  $\Delta k$  (32).

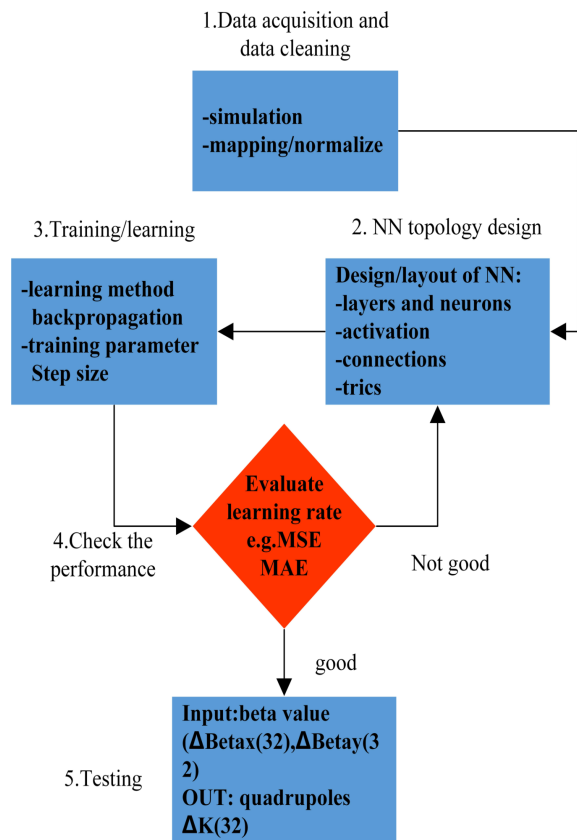

Figure 2: Development stages for an ML-based beta function correction.

### Definition of Neural Network Structure

The topology diagram of the neural network after screening is illustrated in Fig. 3, which includes four hidden layers, batchnorm layers, and dropout layers. It has six layers of neurons, with 64 input neurons (related to the number of beta functions) and 32 output layer neurons (for the number of quadrupole values). The neurons in the buried layer are chosen based on previous experience [5]. Deep neural networks can approximate continuous functions of any complexity with arbitrary precision, according to research. For simulation, we use a deep feedforward neural network. The TensorFlow2.0 framework is used to create the deep neural network model.

### Some Processing

Normalization is applied to both the input and output, and they are on a single uniform standard. Full connection is used in the neural network connection, and Dropout is used in this application. Dropout is a type of learning strategy that's used to improve neural networks. Dropout randomly disables a small number of neurons throughout each training phase, drastically reducing the complexity of the connection. It can also help to reduce overfitting caused by data while also improving the generalization of neural networks.

Figure 3: Feed Forward Neural Network (FFNN) topology used for ML-based beta function correction.

### Model Train

The data comes from the previous virtual storage ring. A total of 1,000 groups are generated. These training data sets are divided into two parts in proportion.

1. data just for pure training, adjusting weights and bias values to minimize the MSE (80%)
2. Testing data is used to measure how accurately the network was trained (20%)

Adjusting the hyperparameters involves the first change, which is changing the learning rate. Let us use Adam, a gradient-based optimization approach rather than stochastic gradient descent. Because of his excellent computational efficiency and minimal memory footprint, Adam enjoys the advantages. It is pretty simple to use the hyperparameters, and just a few parameter tweaks result in the desired outcome. The iteration count is also critical. This is the number of times the entire training set is input to the neural network. Iterations can be considered adequate when the difference between test and training is minimal. It is over-fitting if the loss value initially decreases and then increases. The training times must be lowered. After testing, it was found that the number of epochs is 100 iterations, resulting in superior outcomes. The losses on the training set are known as "train loss" and on the test set as "value loss." MSE is a quantitative representation of model performance. So after around 80 iterations, the training set and test set stabilized. The MSE is less than 10-e5. Currently, it is confirmed that the neural network fitting algorithm's accuracy is acceptable, and the measured results are also rather dependable.

### SIMULATION ANALYSIS

Therefore, we have corrected the beta function using a fairly complete neural network model so far. Through simulation, we generate beta function that have errors at random.

The results are depicted in Fig. 4 using this Storage ring beam model. We see that after many corrections, the beta function close in on their theoretical values quickly. The method has been proven to be feasible. The beta functions of the storage ring was measured before and after the lattice correction for comparison [6]. A before-and-after comparison shows that the average beatx beating was 22.82% and 3.3%, respectively. However, due to the tiny fluctuation in vertical, the correction has not changed significantly.

Figure 4: Beta parameters after iterations through the model.

## CONCLUSION

The neural network approach is introduced to address the current beta function correction problem. Through the neu-

ral network model, the beta function is effectively corrected and has a good effect, providing fresh ideas and enhancing beam stability. Make a drawing. Other beam current properties on the storage ring can be studied using the neural network approach. It can be used to solve various optimization issues, including multi-parameter, multi-objective, so on and so forth.

# BEAM FAST RECOVERY STUDY AND APPLICATION FOR CAFE

Jiaosai Li<sup>†</sup>, Youxin Chen, Jing Wang, Feng Yang, Hai Zheng, Institute of Modern Physics, Chinese Academy of Sciences (IMP/CAS), Lanzhou, China

## Abstract

Based on the MASAR (MACHine Snapshot, Archiving, and Retrieve) system [1], a beam fast recovery system was designed and tested in CAFE (Chinese ADS Front-end Demo Superconducting Linac) at IMP/CAS for high current CW (Continuous Wave) beam. The proton beam was accelerated to about 20 MeV with 23 SC (Superconducting) cavities, and the maximum current reaches about 10 mA. The fast-recovery system plays a major role in the 100-hours-100-kW long-term test, during which the average time of the beam recovery is 7 seconds, achieving the availability higher than 90%. The system verifies the possibility for high current beam fast recovery in CiADS (China initiative Accelerator Driven sub-critical System).

## INTRODUCTION

The ADS superconducting proton linac prototype (CAFe) led by the Institute of Modern Physics, Chinese Academy of Sciences has continuously improved technology and achieved remarkable innovation in commissioning and operation in recent years: 15~16 MeV@2mA CW proton beam stable operation up to 100 hours in the early of 2019 [2], 100 kW proton beam stable operation at 10 mA in CW mode at the beginning of 2021 [3]. The control system provides an important safeguard for CAFE linac during

the stable operation. This paper introduces MASAR and its application in CAFE linac, mainly concerning beam fast re-tuning.

## MASAR

MASAR is an epics V4 service, which is developed based on C++ and python. It was originally proposed and developed by Brookhaven National Laboratory in the United States, and then applied to the second generation synchrotron radiation light source (NSLS-II). The function is just like its name, including the archiving, comparison and restoration of machine snapshots, data archiving and data retrieval [1].

The MASAR consists of client and server: the client has a client Python API library, which can be used by both Python scripting and the GUI. A default PyQt4 GUI is developed for data viewing, snapshot taking, comparing a snapshot with a live machine, and restoring the machine to a particular status using a snapshot. The server has 4 layers: Service communication control; Service: parses a command from the client, implements the desired action, and returns the result to the client; Channel Access Client; DSL (data source layer) and Data layer [3][4]. Figure 1 shows the MASAR Architecture.

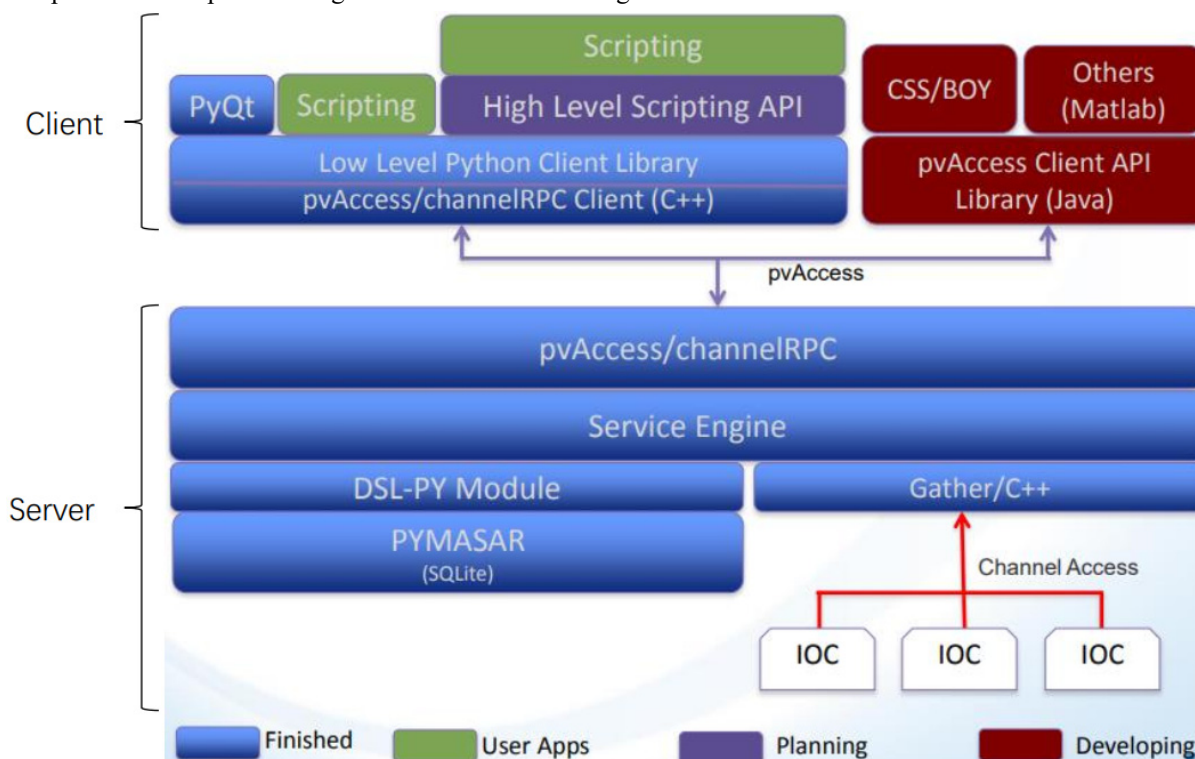

Figure 1: MASAR Architecture.

## BEAM FAST RECOVERY EXPERIMENT BASED ON MASAR

The purpose of beam fast recovery is, when faults occur to the machine, the beam is recovered in a short time. The machine faults should be judged before the recovery action by MPS: if the faults are serious, like severe LLRF (Low-Level Radio Frequency) failure, then the beam should be stopped before the RFQ (Radio Frequency Quadrupole); otherwise, the beam fast recovery system takes action. The beam fast recovery system helps improve the availability of the machine and ensures the stable operation of the beam for a long time.

Considering various recoverable faults, a series of orderly automatic recovery measures are taken. When BPMs (Beam Position Monitor) detect abnormal beam status, the beam will be stopped quickly; when all system returns to normal, the beam will be quickly restored.

The beam fast recovery system includes the operation, monitoring and judgment of MPS (Machine Protection System), BPS (Bypass Control System), timing and LLRF systems. The optimization of existing hardware improves the reliability and recovery speed, and main manual operation including pulling out the FC (Faraday Cup) before RFQ is replaced by the control system, without losing machine safety at the same time.

During beam recovery, it is necessary to judge the beam status (it is probe beam or continuous wave beam) and BPM status (the phase and position of the beam at all BPMs). Therefore, before the recovery, the machine

snapshot should be taken when the machine operates normally and stably (beam operation leader confirms that the beam reaches normal status), and the 81 BPMs snapshots (27 BPMs in total, each consists of Phase, X position and Y position) are saved, which is treated as the standard for BPM comparison and judgment. To ensure that the phase and position information of the beam at BPMs are saved at the same time, MASAR needs to be used for one-click operation.

When BPM judgment starts, the PV should be judged whether it is disconnecting. If so, set disconnect\_Flag to true, otherwise false. The trigger number (trig\_No.) is initialized to 0.

If  $\text{trig\_No.} < 3$ , Count (the number of PVs' value satisfied the conditions) is initialized to 0. If BPM's PV is bypassed, Count plus 1; otherwise, the PVs' value is judged whether within the standard threshold. If within, Count plus 1 and Flag is set to true; if not within, F\_Count (F\_Count indicates the number of PVs' value not satisfied conditions) plus 1 and Flag is set to False. Then, judge  $\text{F\_Count} > 6$ , if not, judge next PV is bypassed. If so, break off PV judgment.

Then judge whether  $\text{count} \geq 76$ : if so, return 1, indicating that the judgment passed; otherwise, Trig\_No. plus 1.

If  $\text{Trig\_No.} \geq 3$ , check disconnect\_Flag is true or not. If true, return -1, the reason for not passing the judgment is that PV disconnect. If not, return 0, the reason for not passing the judgment is the number of PV's value satisfied conditions is less than required. Figure 2 shows the BPM judgment process.

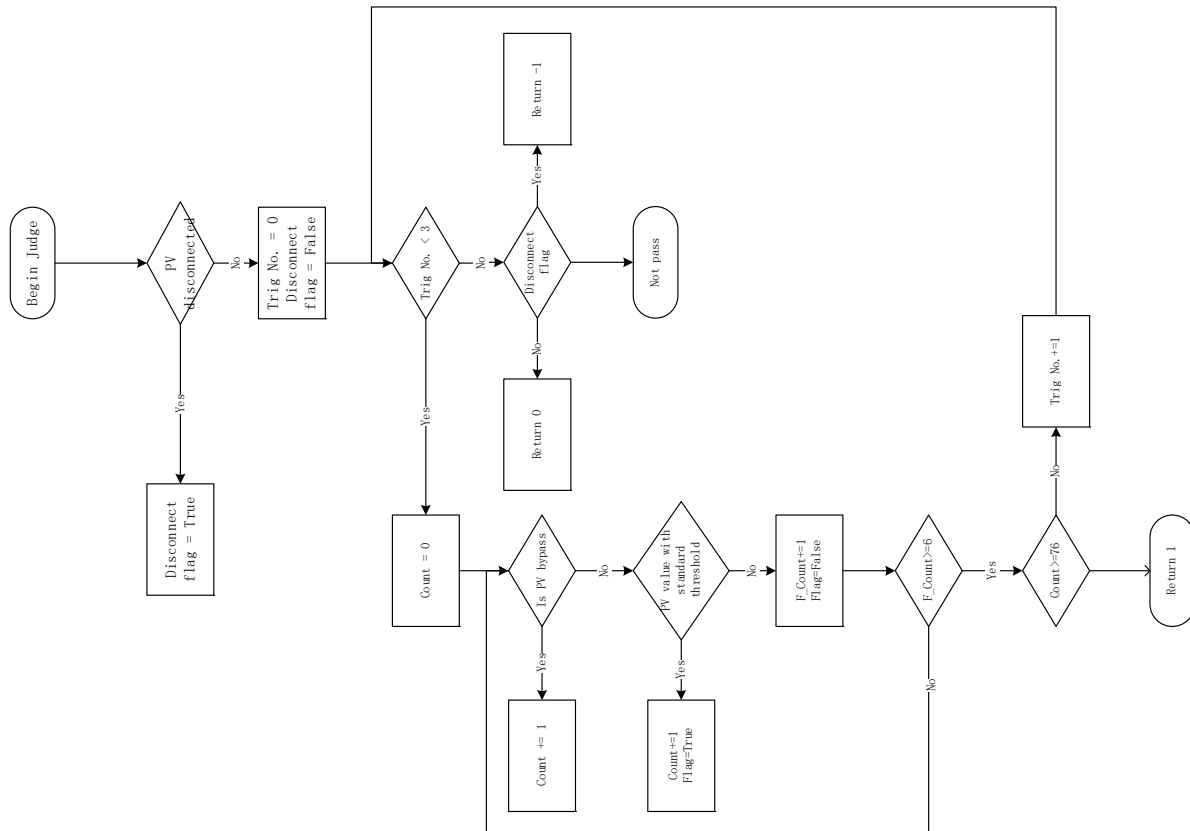

Figure 2: BPM judgment process.

We use MASAR to save the relevant information of BPM beam: Firstly, save the PV list of 81 beam phase and position information of BPM in masarService/example/pvs/beam\_auto\_Re.txt text file; Secondly, configure the PV group of MASAR and establish a connection with

the PV related to publishing BPM, so that the PV value can be obtained through CA protocol when it is necessary. Edit the masarService/Python/pymasarsqlite/db/settings.py file and add the following content:

```
# pv group name: [pv list file, description]
pvgroups= {
    'BEAM_AUTO_RE': ['pvs/beam_auto_re.txt', 'beam auto recovery use snap give bpm']
}
# config name: [config desc, system]
configs= {
    'BEAM_AUTO_RE': ['beam auto recovery use snap give bpm', 'BM']
}
# config name: [pvgroup,]
pvg2config= {
    'BEAM_AUTO_RE': ['BEAM_AUTO_RE']
}
```

Finally, create the SQLite3 database: Python masarService/python/pymasarsqlite/db/configmasardb.py. So far, the

BPM snapshot of MASAR has been configured. Restart the MASAR server:

```
$ cd masarService/cpp
$ ./bin/linux-x86_64/masarServiceRun
```

The interface is shown in Figure 3.

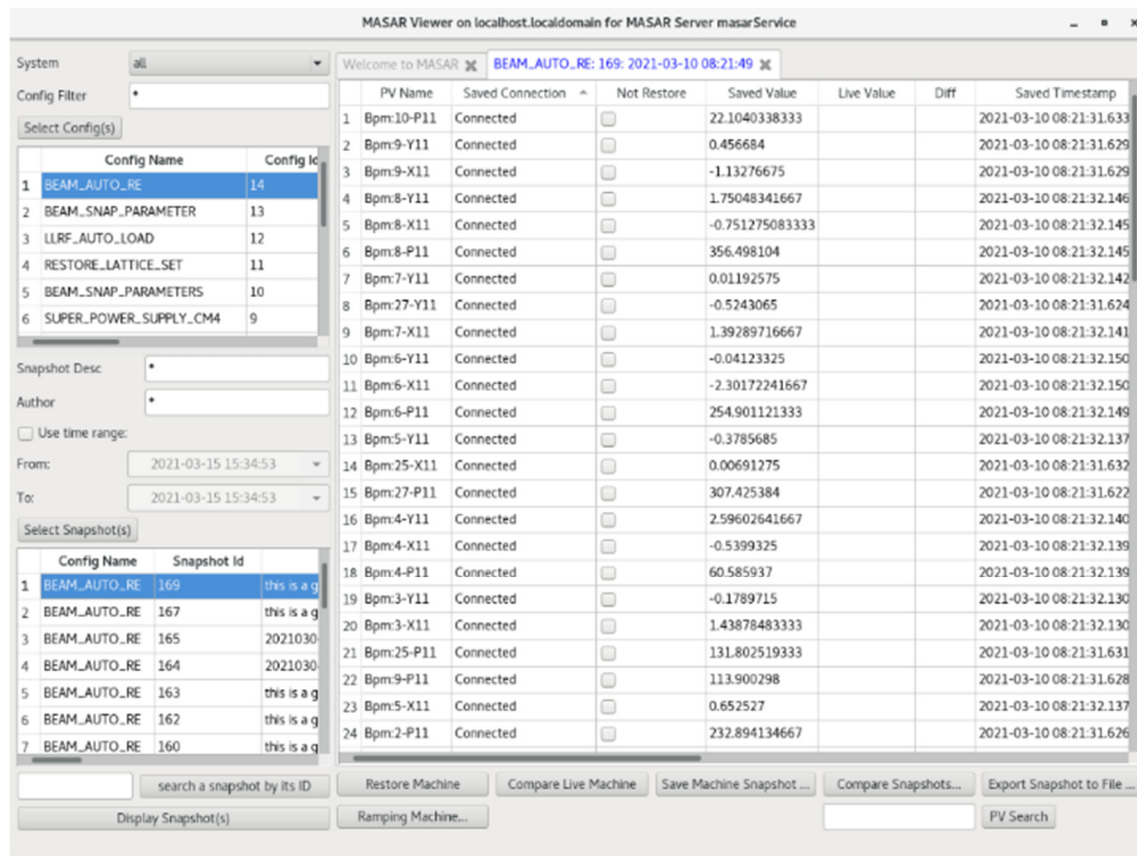

Figure 3: MASAR view

According to the operation status of the machine, the beam operation leader judges when the beam reaches a normal state, and the MASAR snapshot is saved with the beam phase and position information at all BPM. Call the saveSnapshot() function of MASAR, and use it as the judgment standard of BPM beam phase and position information during beam fast recovery. Before the subsequent machine operation, retrieve the beam phase and position information from the previously saved BPM data, then call the retrieveSnapshot() function, and assign the saved PV values of the BPM phase and position to the standard PV values of the corresponding BPM phase and position one by one, for the comparison in the beam fast recovery experiment.

CONCLUSION AND PROSPECT

In the experiment, as a tool of EPICS, MASAR realized fast saving snapshot, retrieving snapshot data and assisting snapshot data value recovery in 1 s, which leaves enough time for the adjustment of the hardware system, shortened the beam recovery time and improved the availability of the machine. The results of the 100-hours-100-kW beam stability test are shown in Table 1, and the availability of the machine is up to 93.5% with beam fast recovery. The beam recovery time distribution is shown in Figure 4, and recovery issues within 6 s take higher than 80%. The frequency statistics for automatic recovery are shown in Figure 5, of which 90% have the condition for automatic recovery and 78% are successful. The system verifies the possibility for high current beam fast recovery in CiADS.

Table 1: Test Results

Parameters	Value	Unit
Beam energy	17.272±0.034	MeV
Average current intensity	7.2966±0.0244	mA
Beam power	126.0	kW
Total test time	108	h
RF superconducting system availability	98	%
Machine availability	93.5	%

Figure 4: The time required for beam recovery.

Figure 5: The automatic recovery times.

There are many advantages in beam fast recovery system: compared with manual recovery, the time is very short; automatically judge the beam status, which is more reliable; automatic execution, greatly reducing labor intensity and improving reaction speed; most trip situations could be judged and handled.

There are still some issues that need to be optimized in the beam fast recovery system. PV disconnection occasionally occurs during the experiment, and with the number of disconnection times increases, the time required for reconnection becomes longer, which is related to the reconnection mechanism of PV. In addition, the beam fast recovery system is not stable enough, and the stability of the program needs to be improved.

## ACKNOWLEDGEMENTS

The authors would like to thank the linac center in IMP/CAS, especially the control group for their help.

# DESIGN OF MAGNET MEASUREMENT SYSTEM BASED ON MULTI-HALL SENSOR

B. J. Wang\*, Y. H. Guo, N. Xie, R. Wang  
Institute of Modern Physics, Lanzhou, China, 730000

## Abstract

High-precision magnetic field measurement and control technique significantly guarantees the accurate realization of the magnetic confinement of accelerators. Using real-time magnetic field intensity as the feedback to adjust the magnetic field current input can be a promising strategy. However, the measurement accuracy of the Hall-sensor is hard to meet feedback requirements because of multiple affection from external factors. Meanwhile, the NMR(Nuclear Magnetic Resonance sensor), which can provide high-precision magnetic field measurement, can hardly meet the requirements against the real-time control due to its strict requirements on the uniformity of the measured magnetic field, as well as its low data acquisition speed. Therefore, a magnetic field measurement system based on multi-Hall sensors is designed to solve this problem. Four Hall-sensors are used to measure the target magnetic field in this system. An Adaptive fusion algorithm is used to fused collected values to obtain the best estimate of the magnetic field intensity. This system effectively improves the accuracy of magnetic field measurement and ensures the instantaneity of the measurement.

## INTRODUCTION

Magnetic confinement plays a decisive role when stabilizing the accelerator beam. At present, the control of magnetic confinement is mostly based on the feedback of the power supply current to implement of the current input of magnet [1], which indirectly ensures the stability of the magnetic field. However, this method is difficult to ensures the effect of the control of the magnetic field, due to magnet's own factors such as magnet eddy current and iron core aging. Therefore, directly using magnetic field strength, as a feedback signal becomes a more promising solution. Nevertheless, it is limited by the sampling rate and accuracy of magnetic field measurement, which makes the progress of this solution relatively slow.

Present main methods of magnetic field measurement and their accuracy are shown in Fig. 1 [2]. The feedback signal of magnetic field control requires high precision and wide range of measurement. So, NMR, hall, and fluxmeter meets the requirement. However, the NMR sampling frequency is than expected, and it needs a certain period of time to lock the value of non-uniform magnetic field. For instance, the sampling frequency of Metrolab PT2026 is only 33 Hz, and the search time is approx [3]. Thus, NMR is difficult to meet the magnetic field control requirements. Fluxmeter is commonly used for dynamic measurement. But its size is large,

which makes it difficult to be broadly deployed on site. Hall sensor advantages of high sampling rate, excellent dynamic characteristics, small volume and easy deployment. So, it is the most suitable magnetic field measurement scheme for feedback control.

Figure 1: Magnetic field measurement range and accuracy.

## SYSTEM DESIGN

### Signal Preprocessing

The main noise of the measurement system includes the offset voltage and thermal error of Hall element [4], as well as the gain error, offset voltage and accidental high-frequency noise of the measurement module [5]. To eliminate these noises, the single-channel measurement signal is preprocessed. The high-frequency noise and offset voltage are mainly filtered by pre-filter and differential algorithm within the measurement module. The pre-filter distinguishes signals according to the frequency of the signal and blocks the high-frequency noise. On this basis, differential operation is performed on the input signal. The offset voltage of each ADC in the measurement module is approximately same. Equations (1) and (2) represents signal  $V_m$ .

$$V_{m+} = V_{id} + V_{of} \quad (1)$$

$$V_{m-} = -V_{id} + V_{of} \quad (2)$$

Where  $V_{of}$  is the offset voltage,  $V_{id}$  is the ideal signal.  $V_{m+}$  and  $V_{m-}$  represents a pair of measurements with opposite phases.

As shown in Eq. (3), an ideal input signal without offset voltage can be obtained by subtracting the input with opposite phase.

$$V_{m+} - V_{m-} = 2V_{id} \quad (3)$$

For Hall thermal error and measurement module gain error, the corresponding calibration parameters need to be obtained and compensated by software. Calibrating gain

\* wangbaojia@impcas.ac.cn

error of measurement module with high precision calibration source. By comparing the calibration source with the measured voltage, the compensation coefficient  $\alpha$  can be obtained. For the compensation of the Hall thermal error, it needs to be divided into two situations to calibrate the correction coefficient of Hall which are constant temperature with plus different magnetic field and constant field with plus different temperature. The correction value corresponding to different gradient magnetic fields at 25 °C is shown in Fig. 2.

Figure 2: the correction value corresponding to different gradient magnetic fields at 25 °C.

### Adaptive Weighted Fusion Algorithm

The offset voltage of Hall element is a kind of random noise which is it difficult to remove through common frequency-domain filter. Therefore, the offset voltage needs to be filtered by time-domain method. For a single sensor, the variance of the sensor cannot be changed, and the posterior error can be only reduced by increasing the measurement data. But this method increases the amount of computation and reduces the convergence rate. The method of multi-sensor adaptive fusion will not only improve the accuracy of measurement value, but also reduce the amount of measurement and accelerate the convergence rate.

For the adaptive weighted fusion algorithm, the fused value and adaptive weighting factor shall meet Eq. (4).

$$X = \sum_{n=1}^4 W_n X_n, \sum_{n=1}^4 W_n = 1 \quad (4)$$

Where  $X$ ,  $X_n$  and  $W_n$  are respectively fused value, measured value of hall sensors and adaptive weighting factor.

The measured value of any sensor has the structure shown in Eq. (5).

$$X_n = ide_n + nis_n \quad (5)$$

Where the  $ide_n$  is measured value without noise.  $nis_n$  is offset noise, its variance is  $\sigma_n^2$ .

Then the weighting factor should satisfy Eq. (6). After weighting, the observation noise should be 0 or *constant*. So that the signal exclude noise can be obtained directly through linear correction. .

$$\sum_{n=1}^4 W_n nis_n = 0 \text{ or } constant \quad (6)$$

From the analysis above, the optimal weighting factor is determined by the variance of each sensor. However, the variance of sensors is often uncertain and will be affected by many factors. Therefore, directly calculating the sensor variance through the measured value and adaptively changing the weighting factor can reduce the noise to the greatest extent. When there are multiple sensors, the measured data can be used to obtain [6]. Take Hall sensors 1 and 2 as an example, where  $k$  is the sampling period, and the solution formula is represented as Eq. (7).

$$\sigma_1^2 = R_{1,1} - R_{1,2} \quad (7)$$

The  $R_{1,1}$ ,  $R_{1,2}$  solution algorithm is shown in Eqs. (8) and (9).

$$R_{1,1}(k) = \frac{k-1}{k} R_{1,1}(k-1) + \frac{1}{k} X_1(k) X_1(k) \quad (8)$$

$$R_{1,2}(k) = \frac{k-1}{k} R_{1,2}(k-1) + \frac{1}{k} X_1(k) X_2(k) \quad (9)$$

And through  $\delta^2$  can be solved the optimal weighting factor, where  $p$  is one of the four sensors, and its algorithm is shown in Eq. (10).

$$W_p = 1 / (\delta_p^2 \sum_{n=1}^4 \frac{1}{\delta_n^2}) \quad (10)$$

Thus, an adaptive fusion filter for four-way hall sensors is implemented. After the filtered signal is calibrated by NMR, the magnetic field intensity with few noise can be obtained.

### Testing Platform Construction

The overall structure of the system is shown in Fig. 3. A standard dipole magnet is used as the detection object and NMR is used as the measurement datum. At the center of the pole of the bipolar magnet, four Hall sensors are deployed on both sides of the NMR probe. NI CompactRIO (CRIO) is used for data acquisition and processing of four-way Hall sensors. The host is responsible for collecting NMR and processed Hall data. And it also has the function of adjusting the power supply output to control the magnetic field.

Figure 3: Overall structure of multi-hall magnetic field measurement experimental platform.

The host connects with CRIO and power supply through TCP/IP and carries out commands such as data reading and

current output. The CRIO runs the EPICS program to publishes PVs. PVs includes four HALL readings and the magnetic field values after algorithm processing. Magnetic field measurements of NMR are directly transferred to the host through USB.

## SIMULATION TESTING

Four independent groups of zero mean noise were used to simulate the observation error of hall sensor. The variance of white noise in each group were 0.001, 0.002, 0.0025, 0.0015, and the true value was 0.35 T. True value and white noise were added together to simulate four groups of sensor measurement data.

Figure 4 shows measured value of hall sensor with minimum variance and adaptive fused value. The measurement value of a single Hall sensor fluctuates around 0.35 T. The estimated value of adaptive fusion will have a short-term drift at the beginning due to insufficient data. As the number of data increases, the magnetic field data will become stable and converge to the true value.

Figure 4: Comparison of minimum variance Hall magnetic field data with the estimated value after adaptive fusion.

The result of comparing errors between measured value of Hall sensor and fused value shows that the adaptive fusion algorithm can greatly reduce the measurement errors. As shown in Fig. 5, after using the adaptive filtering algorithm, the error quickly converges to the minimum with the step size. After 20 steps of data fusion, the error converges to 0. Accurate measurement of magnetic field is achieved.

Figure 5: The estimation error of adaptive fusion and the error of Hall measurement with minimum variance.

In Fig. 6, the mean filter was a method that directly averaging the measurements of the four sensors. The effect

Figure 6: Comparison of adaptive fusion filter and mean filter.

of mean filter is obviously worse than that of the adaptive fusion algorithm because it simply sets the weighting factor of all Hall sensor measurements to 0.25.

## CONCLUSION

In this paper, a measurement system is designed with multiple Hall sensor. A filtering scheme is designed for the noise of hall and measurement module. It includes pre-processing the HALL measurement value, which are weakening the high-frequency noise and offset voltage through filter and differential algorithm. The correction of thermal error of hall sensor and gain error of measurement module is also implemented. Eventually, the offset voltage of Hall sensor is eliminated by the adaptive fusion algorithm of multi-hall sensor. The final simulation results show that the measurement error of the magnet measurement system can be significantly reduced by using the adaptive fusion algorithm of multi-hall sensors.

# DEVELOPMENT OF THE RF PHASE SCAN APPLICATION FOR THE BEAM ENERGY MEASUREMENT AT KOMAC\*

SungYun Cho<sup>†</sup>, Jeong-Jeung Dang, Jae-Ha Kim, Young-Gi Song

Korea Multi-purpose Accelerator Complex, Korea Atomic Energy Research Institute, Gyeongju, Korea

## Abstract

The Korea Multi-purpose Accelerator Complex (KOMAC) has been operating the 100MeV proton linear accelerator. The output beam energy from each drift tube linac (DTL) can be changed by the operation RF phase. The KOMAC linac is consisted of 11 tanks that need to proper setting of RF phase. The phase scan application was developed on the Java eclipse. On the other hand, the analysis program was developed on the Matlab. Since the data analysis processes as soon as finished the scan processing, the application integration need. This paper describes the implementation of the integrated application based on python and Experimental Physics and Industrial Control System (EPICS).

## INTRODUCTION

The KOMAC control system has been operating based on the EPICS framework [1]. The distributed system that is an input output controller (IOC) controls the subsystem for each local system. The process variables (PVs) are operation parameters for control and monitoring from the IOC. Several programs can be access to EPICS IOC's parameters by channel access (CA). The RF phase scan application has been developed based on python and can be access to IOC using pyepics library [2]. The scan I/O variables were designed using that. The data processing step has been developed based on python numba library [3]. A scan step and data processing are described separately in order. The below figure is the schema regarding the KOMAC control system.

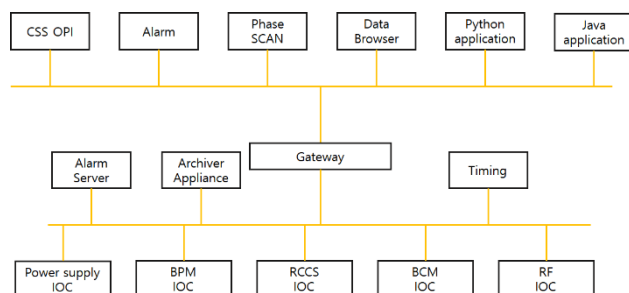

Figure 1: KOMAC distributed control system.

## THE STRUCTURE OF THE PHASE SCAN APPLICATION

The basic structure of the application is based on Python Display Manager (PyDM) [4]. The PyDM is a building user interfaces tool based on PyQt5 with plugged in pyepics. The PyDM uses Signal & Slot for calling events. The

I/O variables are connected with Slot functions. Some calculation function are developed based on numba. Figure 2 shows the working structure of the phase scan application.

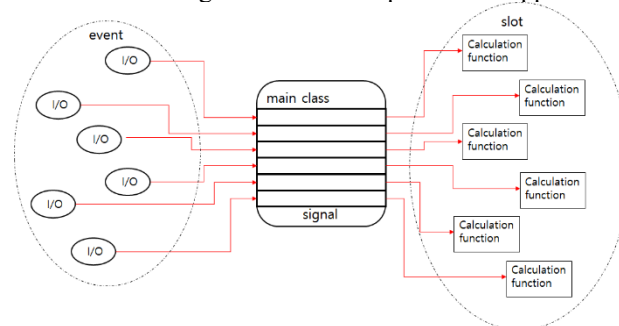

Figure 2: The mechanism of the application.

## SCAN CODE DEVELOPMENT

The moving parameter is a phase set value that is different for each tank. After the parameters regarding scan settings are determined, the phase measure experiment will start. The measured phases are from the prior tank and current tank. So the moving parameter is just one and the monitoring parameters are two. Figure 3 shows the concept of process.

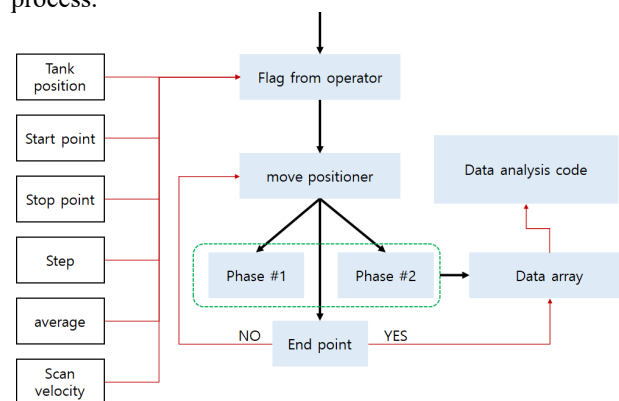

Figure 3: The schematic of scan algorithm.

The original program was developed by the Java language. Since the scan mechanism has to be transplanted to the new program, the EPICS sscan record that's similar to the original algorithm was selected [5]. The sscan record has a function to move positioners and record detector data at each of the positions. The positioner is the moving parameter for the phase setting. When the EXSC field that's a flag signal is executed, sscan record start the process. Many fields work organically during the process. The output signal is sent to positioner PV. If the changing value is finished, the sscan waits the delay time by PDLY field and the detector PV records the target value. The moving step

is determined by the NPTS field. The step can be changed by the custom function using calcout record, since the NPTS is the number of points in a range of between the P1SP and P1EP fields. The monitoring data is saved on the ai record. I/O signals control and monitor the PVs via pyepics library. Figure 4 shows the I/O signals with the IOC.

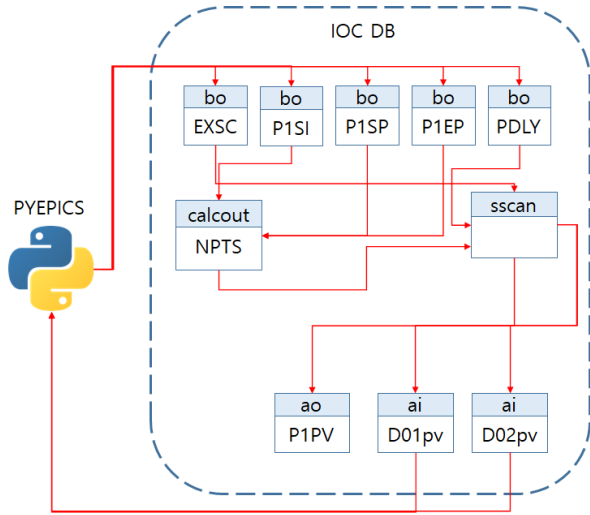

Figure 4: I/O signals from the python application.

The sscan record access to ao record via Channel Access because the set variable works other IOC. When the scan is finished, the monitoring data group is saved to the array and it is output to the python application.

## THE DATA ANALYSIS

Figure 5 is overall schematic regarding the system mechanism.

Figure 5: The schematic of the application integration.

The original analysis code was developed by the Matlab. The goal of development is high implementation and speed similar to the original. Because Matlab can provide a rapid calculation process more than python language, the calculation process needs to be rapid platform. The numba library is selected because of it. The numba is a just-in-time compiler for python, it is suited to use with the numpy arrays and functions, and loops.

If the data inputs to the application, the data processing is started. Accumulated data is the phase values that are each target tank and prior tank. The first data processing is that phase values convert to energy data. The velocity of the beam can be calculated from the phase difference. The

energy of the beam can be calculated according to einstein's equation. Figure 6 describes the phase scan method [6].

Figure 6: The phase scan signature matching.

The diagnostic device is a beam position monitor (BPM) that has offset value because it isn't synchronous with timing system. So each measurement point has to be calculated considering the offset value between -180 and 180 degree. It is implemented with 360 loops for each step based on numba environment.

After the energy list is accumulated, it can be called measured results. The measured results need to compare with the calculated results in order to determine the proper RF operating point. The calculated results can get from PARMILA calculation. Because the calculated results have to match the number of data for comparison, the data is selected the same RF operation phase with measured results. The optimized RF operation phase can be determined from the minimum chi-square value. Chi-squared test is the method that is determining whether the difference between the observed data with expected data.

$$\chi^2 = \sum \frac{(\text{observed value} - \text{expected value})^2}{\text{expected value}}$$

The calculated results have several data group depending on RF amplitude. The result of chi-square is for each amplitude of parmila data. The results can be fitted to a quadratic equation using scipy library that provides the curve-fit function. Figure 7 shows the result of fitting.

Figure 7: The results of the fitting.

However, if the scipy library is used, the calculation speed is slow remarkably. Since the scipy library can't be used in the environment of numba, the custom fitting function needs to be built. The fitting function can be similar to the shape of a general equation. The quadratic gradient can determine whether it is concave or convex. The RF operation phase is selected when the result of fitting is a concave. The key of time reduction is just to do discrimination action in the loop except set up an equation. This method is approximately 200 times rapidly more than scipy function on the numba environment. But the overall result is a little broadly than the original result. Figure 8 shows the result of comparing.

Figure 8: The overall result of the chi-square compared with original result.

Because the purpose of the fitting is determination the minimum chi square, the determining of the optimized point isn't problem on the new calculation code whether the data fitting function was accurate.

## THE GRAPHICAL INTERFACE

The graphical interface was implemented using qt-designer. The interface was created using a grid layout for the responsive interface when the size of the display is changed. The scan variables are created using pydm widgets in order to direct use epics access. Figure 9 shows the graphical interface.

Figure 9: The graphical interface based on pydm.

## CONCLUSION

The integrated application is implemented based on python language. The python is selected because of rapid development speed and high scalability. Rapid calculation process is replaced from the matlab function to python numba function and the scan algorithm is replaced from the java scan code to EPICS sscan record. Because the scan and the data analysis was integrated on the one application, the development or the maintenance is more flexibility and the interface is more user-friendly.

Furthermore, the future object of development is implement that's the auto scan function. If this function is implemented, the scan time will be significantly reduced.

# THE AUTOMATIC LHC COLLIMATOR BEAM-BASED ALIGNMENT SOFTWARE PACKAGE

G. Azzopardi\*, G. Valentino<sup>2</sup>, B. Salvachua<sup>1</sup>

<sup>1</sup> CERN, Geneva, Switzerland,

<sup>2</sup> University of Malta, Malta

## Abstract

The Large Hadron Collider (LHC) at CERN makes use of a complex collimation system to protect its sensitive equipment from unavoidable beam losses. The collimators are positioned around the beam respecting a strict transverse hierarchy. The position of each collimator is determined following a beam-based alignment technique which determines the required jaw settings for optimum performance. During the LHC Run 2 (2015-2018), a new automatic alignment software package was developed and used for collimator alignments throughout 2018. This paper discusses the usability and flexibility of this new package describing the implementation in detail, as well as the latest improvements and features in preparation for Run 3 starting in 2022. The automation has already successfully decreased the alignment time by 70% in 2018 and this paper explores how to further exploit this software package. Its implementation provides a solid foundation to automatically align any new collimation configurations in the future, as well as allows for further analysis and upgrades of its individual modules.

## INTRODUCTION

The CERN Large Hadron Collider (LHC) is the world's largest particle accelerator, built to accelerate and collide two counter-rotating beams towards an unprecedented center-of-mass energy of 14 TeV [1, 2]. The LHC is susceptible to beam losses from normal and abnormal conditions, which can perturb the state of superconductivity of its magnets and potentially damage equipment. A robust collimation system handles beam losses of halo particles by safely disposing the losses in the collimation regions, with a 99.998% cleaning efficiency [3].

The collimation system consists of more than 100 collimators [4], each made up of two parallel absorbing blocks, referred to as jaws, inside a vacuum tank. The collimators are installed with a fixed rotational angle, depending on their location and functionality, which allows to clean in either the horizontal (H), vertical (V) or skew (S) plane. The jaws must be positioned symmetrically around the beam to ensure safe machine operation. Each jaw can be moved individually using two stepper motors at the jaw corners, allowing collimators to be positioned at different gaps and angles.

## BEAM-BASED COLLIMATOR ALIGNMENT

Two types of beam instrumentation are available to align collimators; the Beam Position Monitoring (BPM) and the Beam Loss Monitoring (BLM) systems. BPM pick-up buttons are installed in 30% of the collimators, embedded in their jaws to provide a direct measurement of the beam orbit at the collimator location [5]. BPMs allow for a safe and fast alignment by analysing the electrode signals without needing to touch the beam. The remaining 70% of the collimators can only rely on dedicated BLMs positioned outside the beam vacuum, immediately downstream from the collimator [6]. BLMs are used to detect beam losses generated when halo particles impact the collimator jaws, such that characteristic spikes recorded in the losses indicate that the reference halo has been touched. The procedure of aligning collimators, with BLMs or BPMs, is referred to as beam-based alignment (BBA).

The beam-based alignment with BLM devices is performed via a four-step procedure established in [6]. This involves aligning a reference collimator in addition to the collimator in question (*i*). The reference collimator is taken to be the primary collimator (*TCP*) in the same plane (*p*) as collimator *i*. This creates a *reference halo* that extends into the aperture of collimator *i*. The procedure is to align the reference collimator before and after collimator *i*, as depicted in Fig. 1.

Figure 1: State machine of the beam-based alignment with reference collimator (TCP), from [7].

Once the beam has a well-defined halo amplitude shaped with the primary collimator, the alignment of a collimator can begin. A collimator is aligned by first aligning both jaws simultaneously towards the beam, followed by independently aligning the collimator jaws sequentially. The procedure, as depicted in Fig. 2, involves selecting a BLM threshold to stop the jaw movement when the recorded beam losses

\* gabriella.azzopardi@cern.ch

surpass this threshold. Once the movement is stopped, the final step is to determine whether the jaw is aligned. A jaw is classified as aligned when an alignment spike pattern is detected in the losses, on two separate alignment instances. An alignment spike indicates that the collimator jaw has reached a transverse position closer to the beam than the reference collimator.

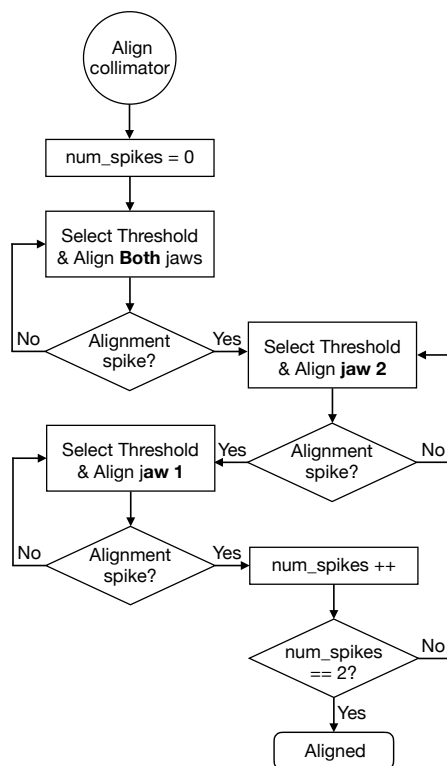

Figure 2: Flowchart of the beam-based alignment of an individual collimator, from [7].

The BBA procedure involves moving the collimator jaws towards the beam in steps of 5-20  $\mu\text{m}$  whilst monitoring the beam loss signal recorded in the collimator's respective BLM. The alignment of any collimator relies on being able to identify an alignment spike when a jaw touches the reference halo: in this condition, the jaw reached the same aperture defined by the primary collimator with an accuracy of the step size. From this measurement, one can infer the local orbit position and the relative opening with respect to the primary collimator, which is used to establish the collimation hierarchy [8]. The BBA depends on being able to efficiently recognize alignment spikes and distinguish them from spurious signals that are often encountered, such that a collimator must continuously move towards the beam ignoring any spurious spikes, until a clear alignment spike is observed.

At the start of each year, and in case of major machine configuration changes during a run, the LHC goes through a commissioning phase to ensure that everything is correctly set up and ready for nominal operation. During the commissioning phase various alignment campaigns take place

in order to set up the correct collimation hierarchy. Such campaigns make use of the BBA to align all collimators during their respective machine stages (injection, top energy, collisions, etc.).

To speed-up the procedure during such large alignment campaigns, the first step is to move all collimators in the same plane in parallel towards the beam, until the losses exceed the predefined thresholds. Once all collimators stop moving, each collimator is then aligned individually. The primary collimator of the plane is also aligned before and after moving the plane collimators in parallel to create the reference halo. The entire procedure is displayed in Fig. 3.

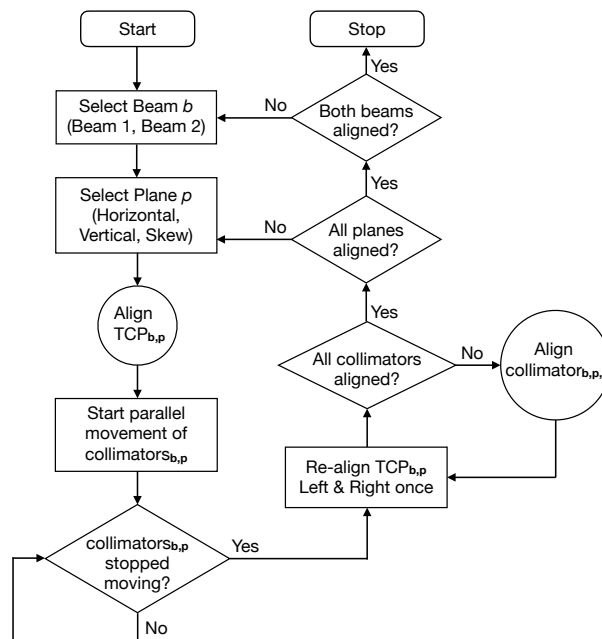

Figure 3: Flowchart of a collimator alignment campaign using the BBA in Fig. 2, from [7].

In addition to this, collimators from the two beams can be aligned in parallel to further speed-up the procedure. In such cases, one must consider the cross-talk across collimators, whereby losses generated by a collimator are not only detected by its corresponding BLM, but also by other BLM detectors around the LHC [9].

## LHC COLLIMATION SOFTWARE ARCHITECTURE

Collimator alignments are performed from the CERN Control Center using a top-level application, allowing users to control collimators and monitor their BLM signal. The software architecture designed for the collimation system is implemented via a 3-tier structure as shown in Fig. 4.

The hardware consists of actuators, sensors and measurement devices. These allow for adjusting a number of parameters, including the collimators' jaw positions.

This hardware is abstracted and controlled in real-time through FESA (Front-End Software Architecture) [11], the

Figure 4: Software architecture diagram showing an example of FESA acting as the middleware between the Java application and hardware devices, from [10].

C/C++ framework used to develop LHC ring front-end equipment software which sends motor step commands [12]. FESA is a complete environment to design, develop, test and deploy real-time control software for front-end computers (FECs), standardizing front-end software development.

The high-level control system communicates with the FEC through devices. A device is the elementary control unit that exposes a public interface made up of properties. Most devices are software abstractions of the hardware (e.g. a collimator). FESA devices are grouped into a *FESA class* which defines the: property interface, private data and real-time behavior, for all devices belonging to that class.

Finally, the top level consists of Java Swing GUI applications. These interact with the FESA middleware framework through the Java API for Parameter Control (JAPC) [13], to control accelerator devices.

## AUTOMATIC BBA IMPLEMENTATION

The fully-automatic alignment software introduced at the end of Run 2, was used throughout 2018 for all collimator alignments [14, 15]. When provided with a list of collimators, this new tool is able to automatically align them following the procedure defined in Fig. 3.

The automation acts as a supervisor of the beam-based alignment, as it determines the order of tasks to be executed, controls the flow of collimator alignments, and reacts to the different states reached during an alignment campaign. The entire fully-automatic alignment is implemented on top of the beam-based alignment, within a dedicated FESA class - *CollAlignSupervisor* [10].

This software relies on the automation of three main components:

- **Collimator Selection** - The parallel alignment of collimators is automatically determined to minimize any cross-talk across the two beams. This makes use of off-line analysis performed on 2018 commissioning data to determine the pairs of collimators that can be aligned in parallel without affecting each other [7]. The results of this analysis are available in an external file which can be updated in real-time for the FESA class to use directly.

- **Threshold Selection** - The collimator movement towards the beam is stopped when the BLM losses exceed this predefined threshold. The threshold is automatically selected and updated based on the real-time BLM losses detected at the collimator. Data from 2016 alignment campaigns was analysed to determine a suitable algorithm, which is implemented directly within the FESA class [16].

- **Spike Classification** - A “spike” is a signal triggered when the BLM losses reach the selected threshold. Supervised machine learning (ML) is used to automatically classify the BLM loss spikes into two classes; alignment spike or spurious spike. Features are extracted from the BLM loss signal and are used as inputs to the pre-trained ML models for classification [17]. The pre-trained models are available in external files which can be updated in real-time for the FESA class to use through Python. The FESA class handles the Python call for classification in a dedicated thread, which then communicates the final result to the original thread executing the fully-automatic alignment [10].

These three components are developed as individual modules within the automatic alignment software package, independently available for any improvements/upgrades, as demonstrated in [18].

## Multi-threading

At any point in time only two collimators can be aligned in parallel, one from each beam, due to the same reference halo used by collimators in the same plane, and cross-talk restrictions across planes. In order to provide this functionality, two devices are defined for the *CollAlignSupervisor* FESA class, allowing two instances of the fully-automatic alignment software to run in parallel, i.e. two threads.

Each thread constantly communicates the following:

- The current beam and plane being aligned.
- The status of the primary collimator in the plane, i.e. moving and waiting statuses.
- The collimator ongoing alignment, for cross-talk purposes.
- The global wait status, i.e. if any thread is waiting for an action from the other thread.

## GUI Application Communication

The *CollAlignSupervisor* FESA class provides a number of properties available to the GUI application for collimator control and monitoring. To begin a new alignment the user selects the list of collimators to be aligned, which are automatically sorted into the two beams and aligned sequentially. To align the two beams in parallel the user must open two instances of the GUI application, as this is common practice in the Control Centre. In this case, the user must select two separate lists of collimators to be aligned, one per beam.

Table 1: *CollAlignSupervisor* Properties Available for User Monitoring

Property	State	Definition
Auto status	ERROR_AUTO(-1)	Alignment halted with error.
	HALT_AUTO(0)	User paused/stopped alignment.
	PLAY_AUTO(1)	Alignment ongoing.
Align status	PARALLEL_ALIGN(-3)	Plane collimators moving in parallel.
	PARALLEL_DONE(-2)	Parallel plane movement ready.
	IGNORE(-1)	Property not in use.
	START_ALIGN(0)	Collimator alignment starting.
	DONE_ALIGN(1)	Collimator aligned.
	SAVE_SETTINGS(2)	Collimator aligned and settings saved.
Parallel status	DEADLOCK(-1)	Both beams waiting for each other.
	OK(0)	Property not in use.
	WAIT_CROSSTALK(1)	Wait due to crosstalk with alignment in other beam.
	WAIT_PARALLEL(2)	Wait parallel plane movement in other beam.
	WAIT_PAUSE(3)	Wait for other beam to pause alignment.
	WAIT_TCP(4)	Wait for TCP alignment in other beam.
Parallel message	WAIT_CHANGE(5)	Wait for collimator to change in other beam.
	-	Any message to display in GUI.
TCP status	TCP_NOT_DONE(-4)	TCP not yet aligned before collimator.
	TCP_DONE(-3)	TCP aligned before collimator.
	PARALLEL(-2)	TCP aligned before parallel plane movement.
	NOT_MOVING(-1)	Property not in use.
	BEFORE_COLL(0)	Ongoing TCP alignment before collimator.
	AFTER_COLL(1)	Ongoing TCP alignment after collimator.
Collimator status	-	Name of collimator ongoing alignment.
Jaw status	NO_JAW(-1)	Property not in use.
	FIRST(0)	First jaw alignment ongoing.
	SECOND(1)	Second jaw alignment ongoing.
	BOTH(2)	Both jaws alignment ongoing
Spike class	NO_CLASS(-2)	Property not in use.
	ERROR(-1)	Error on classification.
	NO_SPIKE(0)	BLM signal classified as non-alignment spike.
	SPIKE(1)	BLM signal classified as alignment spike.

Two FESA properties are used by the Java application to start new alignments:

- Multithreading status - FESA exposes which thread(s) are currently in use, to begin new alignments on available threads.
- Beam status - The beam(s) being aligned by each thread to ensure the user does not attempt to align collimators from the same beam in parallel. In cases of beam overlap the user is requested to wait until the ongoing alignment in the respective beam is completed or paused/stopped by the user.

Once an alignment campaign begins, the user is allowed to pause/resume or stop the alignment. The Java application keeps track of the subset of collimators which are still to be aligned, such that only these are sent to FESA. The user

can monitor the status of the automatic alignment, as the FESA class constantly communicates the status through the properties listed in Table 1.

### Automatic Alignment Features

The automatic alignment was designed to be autonomous. It must independently “make decisions” in real-time based on the alignment status, until the alignment of all selected collimators is complete. In addition to this, a number of “smart” features have been introduced to the automatic alignment when aligning the two beams in parallel. The aim of these features is to imitate, as much as possible, the decisions a user would take when aligning collimators. This software must align the collimators as efficiently as possible, whilst ensuring the correct alignment and must avoid classifying a

collimator “aligned”, if it has not reached the reference halo. The incorporated “smart” features include:

- Alternating between collimators from the two beams that must be aligned sequentially due to cross-talk.
- Automatically wait when the collimators in the other beam are performing the parallel plane movement.
- Before starting the parallel plane movement, wait for the collimator in the other beam to finish its alignment (with TCP) and save settings.
- If both beams are close to start the parallel plane movement, wait to move both planes together.
- On pause then resume, the collimators in the current plane are assumed to have already moved in parallel.
- On pause/stop, the other thread will automatically resume (if waiting), as expected.
- Any deadlocks are handled by resuming the alignment on thread 1.

## GUI APPLICATION USABILITY

The users have various options newly available at the start of Run 3, including:

- After selecting the list of collimators to align, subsets of the list can be further selected for grouping alignments.
- Collimators can be manually removed from the list during the alignment and re-added at a later stage, in cases of issues with particular collimator or if different settings are to be used for different collimators.
- Preset selections for aligning subsets of collimators, e.g. aligning only collimators with/without BPMs.
- Aligning the TCP before/after collimators (recall Fig. 1) is now optional for the user to select. A combination of having a subset of collimators aligned with TCP and others without TCP is also available.
- Moving the collimators in the current plane in parallel is now optional. (By default, this is not selected at flat top due to a beam dump that occurred in the past [7].)

Overall the user always has full control of the automatic alignment with the play/pause/stop buttons. To select subsets of collimators or to change any settings, the user must first pause or stop the alignment. Finally, closing the application is an automatic stop if any alignment is ongoing.

## ALIGNMENT OUTLOOK

Introducing the automatic alignment software has made various alignment configurations accessible and feasible to execute on a regular basis:

- Aligning collimators at an angle potentially allows for tighter collimator settings [19]. However, this procedure is longer, as the BBA is applied at different jaw angles to find the most optimal one. The automatic software makes such angular alignments more accessible.
- Any combinations of collimators, with or without TCP, are now available for the users to perform more efficiently with minimal effort.
- Specific collimator alignments can be performed more frequently during LHC operation, rather than having to wait for dedicated beam time for alignment campaigns.
- Collimator configurations, e.g. for ion beams, can now become more independent. In this case, the automatic alignment allows for evaluating dedicated configurations for ion beams, rather than being bound to keeping the identical setup used for proton beams.

## CONCLUSION

The LHC is equipped with more than 100 collimators to protect its sensitive equipment. In order to ensure safe beam operation, dedicated collimator alignment campaigns are performed at the start of each year and whenever the LHC configuration is changed, to determine the collimator settings for nominal operation. This is a critical phase to ensure safe operations and various improvements were carried out year after year, in order to reduce the required time while ensuring the accurate alignment necessary.

The majority of collimator alignments are applied using the BBA procedure relying on dedicated beam loss monitors. This procedure has been fully-automated by means of a new software package introduced in 2018, providing a solid foundation to align collimators automatically, yielding a 70% speed-up in collimator alignments [14, 15].

The automatic alignment software package relies on three components that have been developed as independent modules; collimator selection, threshold selection and spike classification. This implementation design provides the flexibility to independently extract each of these modules for further analysis and possibly replace with software upgrades.

This software package is readily available with various new features, to be used as the primary tool for collimator alignments during Run 3. This will enable the configuration of new collimator settings for different machine setups, that were not feasible to be determined in the past due to time restrictions. Moreover, this will make collimator alignments accessible during LHC operation to possibly align subsets of collimators more frequently, rather than waiting for large alignment campaigns to be scheduled.

## ACKNOWLEDGEMENTS

The authors would like to thank the collimation team (BE-ABP-NDC) for their feedback as front-end users and the LHC operational crew (BE-OP) for support during software tests with beam.

# THE LINAC4 SOURCE AUTOPILOT

M. Hrabia, M. Peryt, R. Scrivens, CERN, Geneva, Switzerland  
D. Noll, European Spallation Source, Lund, Sweden

## Abstract

The Linac4 source is a 2MHz, RF driven, H<sup>-</sup> ion source, using caesium injection to enhance H<sup>-</sup> production and lower the electron to H<sup>-</sup> ratio. The source operates with 800μs long pulses at 1.2 second intervals. The stability of the beam intensity from the source requires adjustment of parameters like RF power used for plasma heating.

The Linac4 Source Autopilot improves the stability and uptime of the source, by using high-level automation to monitor and control Device parameters of the source, in a time range of minutes to days.

This paper describes the Autopilot Framework, which incorporates standard CERN accelerator Controls infrastructure, and enables users to add domain specific code for their needs. User code typically runs continuously, adapting Device settings based on acquisitions. Typical use cases are slow feedback systems and procedure automation (e.g. resetting equipment).

The novelty of the Autopilot is the successful integration of the Controls software based predominantly on Java technologies, with domain specific user code written in Python. This allows users to leverage a robust Controls infrastructure, with minimal effort, using the agility of the Python ecosystem.

## INTRODUCTION

The CERN Linac4 ion source is a 2MHz RF driven H<sup>-</sup> ion source, using caesium injection to enhance H<sup>-</sup> production and lower the electron to H<sup>-</sup> ratio. The source operates for Linac4 with 800μs long pulses at 1.2 second intervals.

The stability of the H<sup>-</sup> beam intensity from the source over the period of minutes to days requires adjustment of parameters like the RF power used for plasma heating. Controlling the source on this timescale is the objective of the Autopilot. It is not conceived to work from pulse to pulse, or within a pulse, which would require dedicated systems at the front-end computer level.

The Autopilot Framework was developed in 2019 and used successfully to automatically tune the source during the test runs for Linac4. It is currently operating 24/7 helping the operations team to run the linear accelerator. Another instance has been successfully deployed in the CERN ion linac, Linac3. It replaces a highly specific version developed in 2017 [1], which lacked flexibility.

## FRAMEWORK

The Autopilot Framework, henceforth referred to as the framework, is a set of services and tools (see Fig. 1.) that allow the users to deploy and execute the algorithmic tasks in a self-service manner, where the framework provides the necessary tooling and infrastructure. Typical use cases are

slow feedback systems and automated procedures (like re-setting and restarting equipment that has stopped due to a fault state).

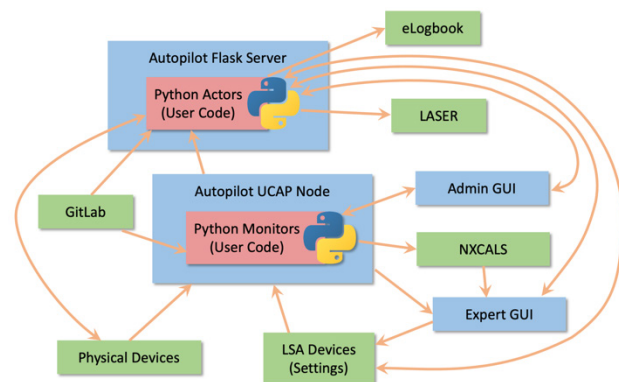

Figure1: Schematic diagram of the Autopilot Framework. Blue boxes signify the Autopilot framework components.

The framework allows the users to subscribe to the Control parameters of their choice, process the received values, and publish the output as properties of Virtual Devices, i.e. Control Devices that are implemented exclusively in software, with no hardware component. Those Virtual Devices can in turn be used like any other Control Device, in particular they can provide inputs to the user-supplied regulation algorithms (subsequently referred to as actors) that interact with the Linac4 H<sup>-</sup> ion source.

A particularity of the framework is that although it is based on the accelerator Controls software stack, that is predominantly developed in Java, it allows the user code to be written in Python. Another characteristic of the framework is that it leverages the well-established services and components that form the accelerator Controls, in particular the Controls Configuration Service (CCS) [2], Controls Middleware (CMW) [3], Role-Based Access System (RBAC) [4], the Unified Controls Acquisition and Processing (UCAP) framework [5], LSA (Accelerator Settings Management) [6], LASER (Accelerator Alarms Service) [7], and NXCALLS (Accelerator Logging Service) [8], thus reducing the need for developing custom components.

At the core of the framework lies a UCAP node that subscribes to physical and virtual Devices according to the recipes provided by the users. The recipes also contain the triggering conditions. When those conditions occur, the events containing the accumulated data are constructed and forwarded to the user-provided transformation routines, known as “Monitors”. The Monitors calculate the output values and give them back to UCAP, for publishing as virtual Device Properties through controls middleware.

Along with the UCAP recipes, and the Monitors, the Flask server also manages the user-provided control tasks called “Actors”. These are basically Python scripts whose job is to act upon the updates received from the Monitors

and perform the necessary actions to keep the parameters of the Linac4 source within the requested limits. The benefit of the Actors using Monitors, is that the UCAP system takes care of synchronizing multiple data inputs, allowing the Actor to receive all required data in a single subscription.

## Server

The server is a REST service powered by the Flask micro-framework combined with Gunicorn as HTTP Server. The REST communication is hidden behind a simple web interface, which serves as a bridge between the user and the framework itself. The service was built with the use of Acc-Py, a CERN Accelerator Controls Python distribution.

The web interface consists of three subpages, each dedicated to a separate part of the Autopilot Tasks: Monitors, Actors and UCAP configuration. Each of them provides a status view of uploaded user scripts, as well as interactive tools to manage the content of the service, such as adding and removing script files or starting and stopping Task execution.

To make sure that the communication is secure, an HTTPS connection to the server has been set up, with the help of tools provided by the CERN Certification Authority, giving an encrypted communication channel between the service and the user.

To restrict access to authorised users, Role Based Access (RBAC) is used for user authentication. On top of that, to distinguish between the different types of users and restrict access even further, three different internal roles (Guest, Operator, SuperUser) have been defined allowing for the fine-tuned levels of control over the framework.

The web interface also provides a set of features to help the users service their Tasks in case they do not behave as expected, such as:

- Checking python script correctness at start-up time – when the user tries to start a new python script, the check for basic code errors, like wrong indentation level, is performed. Since obvious mistakes like this would prevent the script from running correctly, an error message specifying the reason of the failure is shown to the user, and the new process is never started.
- Logging mechanisms – the user is provided with a pre-defined logger, which can be used inside user's script to log any useful information during code execution. User logs are stored on the server and are easily accessible through the web-interface.
- Automatically catching runtime exceptions – execution errors which may happen at runtime and are not handled by user code are captured by the framework and put into the user logs for post-mortem analysis.
- Subscription status preview – for each Monitor Task, the list of all its Data Sources and their connection statuses is provided. This allows the user to see in real time if the data from each Data Source is available. For quick debugging of broken subscriptions, a remote 'test get' feature is provided to query the input devices.
- File peeking – the user can visualise the task code directly in the web interface.

- Test data generation – before the Monitor script will be uploaded to the server it has to be written offline. Python at its core is a language where it is easy to make coding errors, so we give the possibility to record a specified amount of input data from UCAP in the form of JSON files, that can be downloaded by the users and fed to their algorithms offline, making it easier to find some obvious problems upfront, before the final version will be uploaded to the server.

## Source Code Management – GitLab

To manage the state and content of user script files, the server is connected to a dedicated git repository hosted on CERN's GitLab service. The repository contains a configuration file listing explicitly all Actors, Monitors and UCAP configuration files. This allows the server to easily recognize the expected role of a given file and handle it accordingly.

By using GitLab, the history of changes is available for all files, providing a clear trace of how content was changed, by whom and when. It also gives a simple way to roll back to a previous version of the file in case the new version is not behaving as expected.

The server uses the GitLab REST API to compare files from the repository with those currently hosted on the server as well as download them if necessary.

From the server perspective, updating any script file is as simple as two clicks on the web panel. First click to 'check' for any changes, where the server compares commit IDs of the files, and the second click to 'synchronize' the file, meaning downloading the latest version of the file from the GitLab repository if it is newer than the version currently on the server.

For safety reasons the script files can only be synchronized if the corresponding Autopilot Task is not in a 'running' state. However, the version check can be done at any time, as it does not impact the content of the server.

When any script file has been recognized as outdated – a notification label is shown next to the file name on the web panel, making it easily noticeable. As an added value, the label itself is a hyperlink to the GitLab webpage commit details, which highlights changes in the script file content between versions, thus allowing for a quick verification before deciding to synchronize script files to the server.

The server is also capable of being notified by a GitLab web hook automatically, after any file has been changed, sparing the user the necessity of invoking the 'check' operation manually.

No automation is foreseen for the non-interactive synchronization of script files. Since those files are actually running on the server, it is critical for stable operations, to only update runtime content when there is a safe operational window for doing that. This update can only be performed by super-users, as defined in the preceding section.

## UCAP

The Unified Controls Acquisition and Processing (UCAP) project aims to provide “a generic, self-service, controls data processing platform”.

In simpler terms, UCAP is a platform that allows the creation of a standard Virtual Device, which receives data from a predefined list of signals, gives that data to the user-written or configured code (known as a Transformation), which can in turn perform any kind of calculations and processing, and publishes the result back to the Controls system using a standard middleware protocol. State is retained between calls to the user transformation, so that it is possible to apply transformations over multiple beam cycles (for example averaging a value over some time window).

At the core of the Linac4 Source Autopilot, Monitors are in fact UCAP Virtual Devices, publishing transformed data that is in-turn used by the Actors to interact with the Source. Corresponding data is stored in the logging database (NXCALs) and can be used later for purposes such as diagnostics.

## Monitors

As explained above, Monitors are Virtual Devices running on a UCAP node. The Autopilot server simply acts as a man-in-the-middle between the user and the UCAP framework, meaning the user uploads UCAP configuration and transformation code files using the aforementioned web panel, and the Autopilot servers takes care of turning that into a request understandable by the UCAP framework.

It is the responsibility of the UCAP framework to create a new process to receive, transform and publish data. The Autopilot server does nothing more than ask UCAP to add/remove or start/stop the Virtual Device in question.

The data transformation code is written in Python using the provided `ucap-python` package, which contains all interfaces representing the data model of UCAP. The usage of this package is mandatory for every Autopilot Monitor script.

By design, Monitors only read and transform the data published by other Devices and do not interact themselves with the Control system.

Monitors can also receive configuration parameters for their execution by including LSA virtual settings values in their data input. For example, a minimum and maximum needed to perform a value validation can be created as a LSA virtual setting, and input to an Autopilot Monitor along with the real Device acquisition for comparison. In this way the LSA parameters allow many different ways to incorporate settings into Autopilot applications, at the same time keeping a history of changes to these settings inside the LSA settings history repository.

## Actors

Actors are Tasks that continuously receive data produced by Monitors, and possibly some other sources such as LSA settings (both from real Devices, and Virtual Devices). Based on these inputs they can decide to invoke a particular

action if necessary. Each Actor Task runs as a separate process.

Actor Tasks can use a special API to notify the Autopilot server about certain events by invoking specific actions, which are typically reflected on the web panels (and through other services like the electronic Logbook (eLogbook) and LASER alarms system). They give useful real-time feedback of a running Actor's behaviour. Invokable actions include:

- `heartbeat` – an Actor script can call this method to announce that it is alive. It is usually invoked by the user whenever new data is received by the Actor.
- `set_last_acted` – an Actor script can notify that it is performing an action it considers as an ‘act’ method (like applying a new hardware setting) and provide a short message describing it.
- `set_last_error` / `clear_last_error` – an Actor script can notify the server that it recognized a situation considered as an error, for example that it received corrupted data.
- `abort_task` – an Actor script can ask the server to cleanly abort the Task execution, for example where a set of conditions have no path defined, and the situation is considered unsafe for the Actor.
- `write_to_elogbook` – an Actor script can write a short message to the eLogbook service.
- `set_alarm` / `clear_alarm` – an Actor script can create a new alarm that will be shown on the LASER console expanding further possibilities of notifying operators that something on the Autopilot requires attention.

Unlike Monitors whose lifecycle is managed within UCAP, the lifecycle of Actor Tasks, is managed directly by the Autopilot server. This means the Autopilot server is responsible for creating a new process and shutting it down later when the user requests the Task to be started or stopped, respectively.

## Graphical User Interface

The Autopilot can be monitored and, to a certain extent, controlled through an interactive expert application (GUI) that can be started from the Common Console Manager (CCM). The main screen of the GUI is the Beam Current Transformer (BCT) Stabilize panel. This panel provides a graphical overview of the current and historic state of the source current stabilization Task, discussed in some detail further in this document. It also allows one to start and stop the regulation Tasks, and to control the current set points.

Along with the BCT Stabilize panel, the GUI provides a number of additional panels with a similar functionality, namely the electron to H<sup>+</sup> (eH) Ratio panel, the Caesium Flow panel, and the High Voltage (HV) Reset panel.

## Integration with Accelerator Controls Services

The configuration of the input and output devices of the Autopilot is handled by the Controls Configuration Service.

To allow the Autopilot server to communicate its important actions to the outside world when necessary, Actor

Tasks have the possibility to write messages to the eLogbook. Behind the scenes the server uses the REST API of the eLogbook to write messages from the Actor Task to the appropriate section of the logbook.

This functionality is limited solely to Actor Tasks, as they are the only processes whose actions can have implications for the operation of the accelerator, and thus should be announced to operators when necessary.

The Autopilot server is also integrated with the LASER (Alarms) service, giving Actor Tasks the possibility to create a new alarm that will be visible by operators on the LASER console. The functionality is limited to Actor Tasks for the same reason as explained above for the eLogbook integration.

LSA (Settings Management Service) is used by the Autopilot to manage Actor settings. This allows the standard Accelerator controls graphical applications to visualise data published by the Autopilot, and to influence the behaviour of the Autopilot.

NXCALS (Logging Service) is used by the Autopilot to log the values published by the Monitors. Data is also extracted from NXCALS when starting the Autopilot GUI, to prefill charts with a certain amount of historical data.

### Deployment

The two core parts of the framework are the Autopilot Flask Server, and the Autopilot UCAP Node (see Fig. 2.). The Autopilot Flask Server, as an Acc-Py-based service, uses Acc-Py tools for the releases of new versions. However, for the deployment on its dedicated server, a custom deployment script had to be developed, as currently Acc-Py lacks tools for services deployment. The UCAP Node, being a Java application at its core, uses CBNG [9] for both releasing and deployment.

Both services run on the same server running CentOS 7.

## USER TASKS FOR THE SOURCE AUTOPILOT

In this section we describe the user tasks available and their status as of this writing.

### BCT Stabilize

This task is the main workhorse of the Autopilot and its effect is illustrated in Fig. 3. Its objective is to keep the H<sup>-</sup> beam current constant by adjusting the forward power of the 2MHz RF used for plasma production and heating based on readings from a Beam Current Transformer (BCT) in the Low Energy Beam Transport line (LEBT).

### Phase Stabilize

As well as the RF power to the ion source, the phase of the RF is also measured. This phase can be used to assess the efficiency of the coupling of the RFQ power to the source plasma. The Phase Stabilize Task monitors the measured phase over defined windows and compares them to the set point. If outside a dead band, the frequency is adjusted along the pulse to return to the phase set point.

### HV Reset

Ion sources typically suffer from sparking events in the order of a few per day. The source power converters go into a fault state when an over-current is detected, and do not deliver the voltage until reset.

The HV Reset Monitor delivers the present status of the HV converters, as well as counting the number of times that they have gone from ON to FAULT status in the last 24 hours.

The Actor reads the repeated HV converter statuses from the Monitor, and when it moves from ON to FAULT status, it initiates a procedure to restart them.

### eH Ratio

The eH ratio is a Monitor that uses the currents measured on the source high voltage power converters, and the BCT

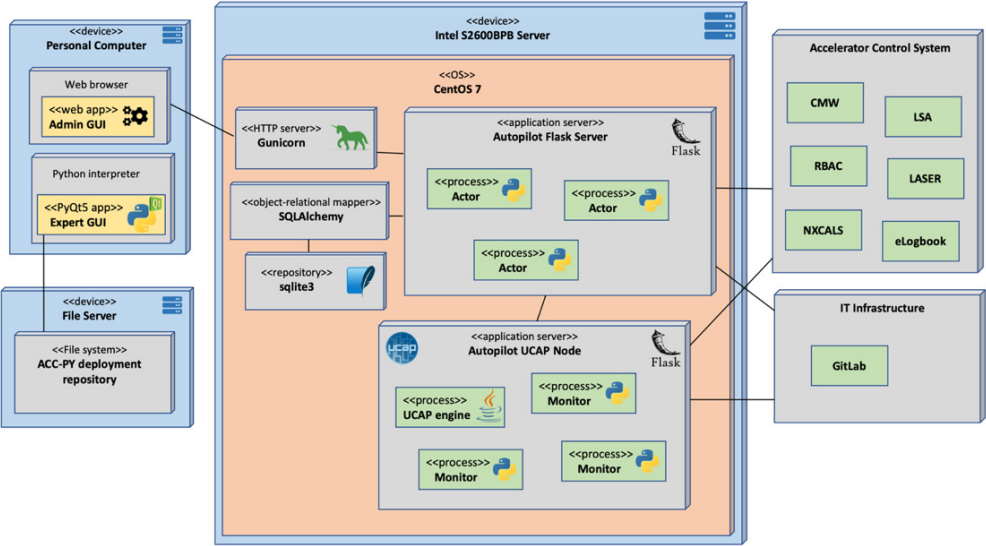

Figure 2: Autopilot deployment overview.

Figure 3: Beam intensity and RF set power from 2 December 2019 to 5 December 2019. Black vertical line shows the time after which the autopilot was started to maintain the MEBT beam intensity constant. Cyan= MEBT measured intensity. Blue=LEBT measured intensity, Orange=LEBT requested intensity, Purple=RF requested power.

current in the LEBT, in order to calculate the electron to H<sup>+</sup> ratio from the source.

### Cs Flow

The Linac4 ion source uses caesium to reduce the work function of the plasma electrode, which enhances negative ion production. Caesium is evaporated into the source, under vacuum, from a heated oven.

The amount of caesium that exits the oven can be estimated by scaling of the vapour pressure in the oven to a calibration point. Integrating the flow over time gives a total mass. This monitor produces this calculation in real-time, and allows the instantaneous flow and total mass data to be logged over time using the NXCALS system.

## SUMMARY

Within the Linac4 Source Autopilot project, a framework has been developed to allow users to develop code in Python that runs on a stable server, and interfaces to several accelerator controls components to allow monitoring, settings, diagnostics, and testing. The framework is in use at CERN helping to control the Linac3 and Linac4 sources. The framework described in this paper can be deployed in various operational scenarios involving the integration of user code with general controls services. Although the accelerator Controls services leveraged by the framework are CERN specific, we are confident that fundamental building blocks of the framework can be reused outside the Organization.

Within this framework, tasks have been developed to continuously adjust the source RF power and perform automatic resets of the High Voltage converters. Thanks to this the stability of the source has improved remarkably over this period.

## ACKNOWLEDGEMENTS

The authors would like to thank the Linac4 ion source team in BE-ABP for providing the motivation for this project and testing time, as well as to the software teams within BE-CCS for their work to make this project possible, in particular the UCAP, Acc-Py, and LASER teams.

# RENOVATION OF THE BEAM-BASED FEEDBACK CONTROLLER IN THE LHC

L. Grech\*, G. Valentino, University of Malta, MSD 2080 Msida, Malta

D. Alves, A. Calia, M. Hostettler, J. Wenninger, S. Jackson, CERN, 1211 Geneva 23, Switzerland

## Abstract

This work presents an extensive overview of the design choices and implementation of the Beam-Based Feedback System (BBFS) used in operation until the LHC Run 2. The main limitations of the BBFS are listed and a new design called BFCLHC, which uses the CERN Front-End Software Architecture (FESA), framework is proposed. The main implementation details and new features which improve upon the usability of the new design are then emphasised. Finally, a hardware agnostic testing framework developed by the LHC operations section is introduced.

## INTRODUCTION

The Large Hadron Collider (LHC) was designed to handle particle momenta between one and two orders of magnitude higher than previous accelerators [1]. The highly energetic beams inside the vacuum chambers are stripped off of halo particles by a beam cleaning and machine protection system, also known as the collimation system. The collimation system required the machine tolerances to be tightened to work effectively. As a result, the LHC was the first proton accelerator to require automatic feedback control systems on various beam and machine parameters [2].

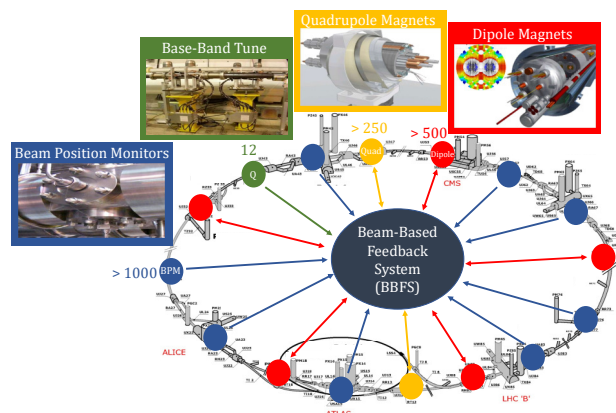

Figure 1: Schematic view of the BBFS in the LHC complex.

In this work, Beam-Based Feedback System (BBFS) denotes the program which was originally responsible for implementing the feedback control of the Radio Frequency (RF) systems, orbit and tune [3]. Figure 1 shows the BBFS within the LHC complex. The systematic beam energy offset from the ideal trajectory can be inferred from the orbit and in turn, the orbit is obtained from the measurements of

1088 Beam Position Monitors (BPMs) placed at different locations in the LHC [2, 4]. The Base-Band Tune (BBQ) systems are responsible for estimating the horizontal and vertical tunes of both beams in the LHC [5]. It is well known that the tune estimates from the BBQ were unstable due to 50 Hz noise harmonics present in the BBQ spectra [6, 7]. This instability also caused the Tune Feedback (QFB) to frequently switch off. As a consequence, the QFB was used intermittently and only when necessary, e.g. at the start of the ramp.

In its original design, the BBFS was foreseen to automatically control the coupling and chromaticity as well. Both these quantities are derived estimates from the BBQ system measurements. Considering that the tune estimates were often unstable, the control of coupling and chromaticity was deemed impractical to be used in operation, despite being implemented in the code.

The BBFS was made up of two components, which were historically named the Orbit Feedback Controller (OFC) and the Orbit Feedback Service Unit (OFSU). The OFC comprised the main program written in C++ and was primarily responsible for communicating with real-time Front-End Computers (FECs) to obtain beam measurements and applying magnetic corrections. The OFSU was implemented using the Front-End Software Architecture (FESA) framework used at CERN [8].

This work will provide a summary of the design and the limitations of the BBFS which was used in operation until the end of Run 2 in 2018. The BBFS underwent renovation during the LHC Long Shutdown 2 (LS2) and the upgraded version is called the Beam Feedback Controller LHC (BFCLHC). The BFCLHC is a FESA-based application which incorporates all the useful functionality of the BBFS, along with new features requested by the LHC operators. During LS2, our colleagues from the LHC operations section also developed a testing framework for the BFCLHC which for the first time allows closed loop tests to be performed on the feedbacks offline.

## DESIGN UNTIL LHC RUN 2

Figure 2 illustrates a more detailed view of the BBFS architecture which is comprised of the OFSU and the OFC. The OFSU is connected to the OFC via a private Ethernet connection where Transmission Control Protocol (TCP) is used for lossless communication of the OFC settings and User Datagram Protocol (UDP) is used to stream real-time acquisition BPM, BBQ and magnet data from the OFC to the OFSU. Measurement data coming from the BPM and the BBQ systems is received by the OFC in the form of User

\* leander.grech.14@um.edu.mt

Datagram Protocol (UDP) packets. The BPM packets arrive from 67 FECs, which can interface up to 18 BPMs each. In addition, longitudinally consecutive BPMs are interleaved amongst at least two, geographically nearby FECs, so that if a FEC fails, a contiguous section worth of measurements is not entirely lost. Similarly, the calculated current corrections for the magnets are sent to the Power Converter (PC) gateways via UDP packets. These gateways are connected to the Function Generator/Controllers (FGCs) which control the current flowing in the magnets [9].

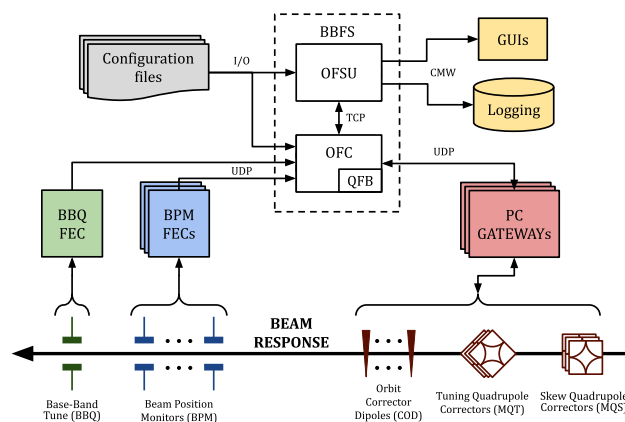

Figure 2: Schematic view of the data paths and a more detailed view of the BBFS architecture.

The principle design objective of the BBFS was to obtain a deterministic behaviour of the feedbacks on the hardware available at the time. The modular nature of the BBFS allowed the OFC to collect information about the tune and orbit in real-time, and calculate the required magnet corrections at a rate of 25 Hz. By keeping the program structure of the OFC simple, the designers could ensure a deterministic execution [2].

The OFC was written in object-oriented C++ and relied heavily on ROOT libraries. ROOT is written and maintained by CERN and was originally developed for efficient calculations on very large data accumulated by high-energy physics experiments [10]. The programming paradigm of ROOT is object-oriented where all objects derive from what is called a TObject. All TObjects can use the various functionalities implemented in ROOT, such as I/O handling, memory management and error handling. The OFC consists of several TObject-derived classes, which implement all the required functionality. The core of the OFC was a loop-based program, where every iteration was one simultaneous pass through the control loops of the OFC and the QFB. The latest version of the OFC used ROOT Release 5.34/20 [11].

Figure 2 also shows that the OFSU served as an interface for the OFC and was used by the LHC operators to monitor and control the OFC [3]. The OFSU was also responsible for loading some of the configuration files, which contained the settings and beam optics required by the OFC. This information was communicated to the OFC upon initialisation as well as by request of the operators. The OFSU also served

as a hub for the data collected by the OFC and as a result a myriad of Graphical User Interfaces (GUIs) used by the LHC operators depended on the data relayed by the OFSU. One example is the relay of BPM orbit data, which: (a) underwent serialisation through ROOT TInterlink objects; (b) sent via UDP to the OFSU; (c) and finally set to the appropriate OFSU FESA property for orbit data. The OFSU was responsible for logging the data collected by the OFC along with the settings of the BBFS itself. The OFSU was developed using the FESA real-time framework and the sheer number of tasks described above made the OFSU the largest FESA-based application at CERN until LHC Run 2 [8, 12].

In its initial implementation the BBFS comprised a series of nested feedback loops, each controlling a specific LHC parameter. First and foremost was the orbit feedback loop, which calculated the change in Closed Orbit Dipole (COD) deflections necessary to steer the beam towards the reference orbit. Second was the RF frequency feedback loop, which calculated the change in frequency required in the RF cavities to counteract any systematic momentum offset introduced by the CODs during orbit correction. The other three nested feedback loops controlled the tune, coupling and chromaticity simultaneously. It is important to note that in the latest implementation of the OFC, only the QFB remained. Due to the instabilities observed in the tune estimates, subsequently derived measurements, namely coupling and chromaticity, were not reliable enough to allow for feedback loops of their own. When adjustments on the coupling and chromaticity were required, operator-calculated corrections had to be sent manually to the skew quadrupoles and sextupoles [13].

The impact of a change of currents in the CODs on the beam orbit is estimated using a Response Matrix (RM). The main principle behind the orbit correction performed by the OFC is to: (a) measure the average beam positions using the BPMs; (b) calculate its difference with respect to the reference orbit; (c) use a Proportional-Integral (PI) controller as a feedback loop; (d) calculate the change in current needed in each COD to correct the beam position; (e) scale down all the currents by the same factor to accommodate the slowest acting magnet and finally; (f) send the current corrections to the CODs. A similar procedure is used by the QFB to correct the tunes in both planes for both beams using quadrupole correctors.

Figure 3 shows the flowchart of the OFC main program. GLOBAL\_RUN was the variable which controlled the control loop. The INIT block is expanded in Fig. 4 where it can be seen that several initialisation files were required to set up the OFC. The configuration file set up the thread parameters such as their priority and affinity and also contained two important parameters related to testing the OFC; SIM\_MODE and BASE\_PORT. SIM\_MODE were used extensively throughout all the OFC code to change its behaviour during testing. Functionalities such as sending the UDP packets to the Power Converters (PCs) and RF cavities were suppressed when SIM\_MODE was set in order to confine the output of the OFC to the testing framework. BASE\_PORT served as an offset port number for all the network sockets used by the

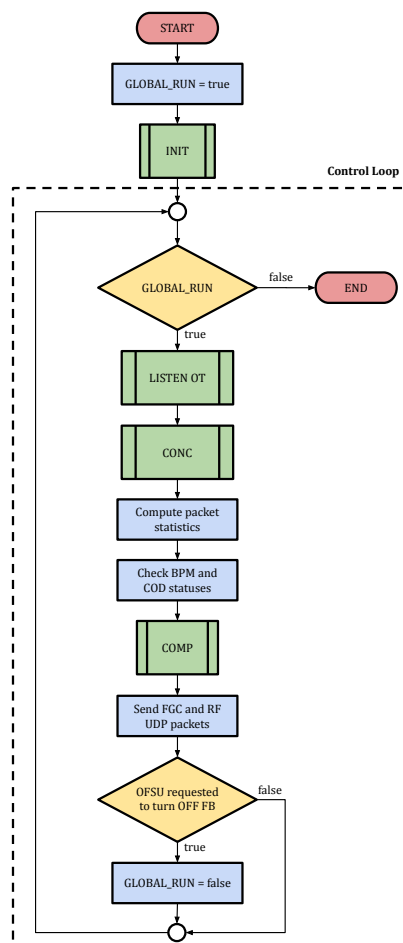

Figure 3: Flowchart of the main program of the OFC.

OFC. It was only changed during testing, when data was supplied by the testing framework. The configuration file contained other parameters, however, their use had become deprecated throughout the OFC lifetime.

The OFC also required a ROOT file upon initialisation which contained default optics stored in a ROOT object. This file existed since the first version of the OFC and due to its age it proved difficult to verify its contents. Its removal was also deemed dangerous due to its ubiquitous use throughout the initialisation code and therefore it was left up to the next major renovation to be removed. Several other text files were also required upon initialisation which provided: a) the hostnames of all the FECs that the OFC communicated with; b) the parameters of the magnets, e.g. maximum current rate; c) network routing information for all the BPMs, CODs, and quadrupoles required to create the network packets.

The OFSU was the interface that the operators used during real operation in order to monitor the status of the OFC, and changing parameters needed for operation. Two of the main problems with the OFSU were that it was bloated with unused functionality as well as complicated and less intuitive procedures which were required to change certain settings, e.g. fetching optics. The early design of the BBFS allowed access to more dedicated settings in the OFC, however, op-

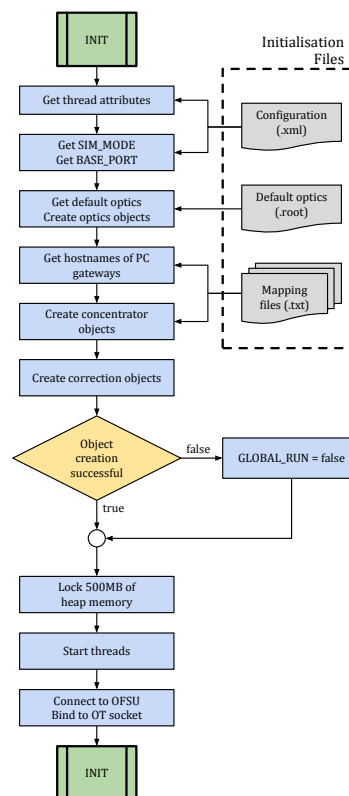

Figure 4: Flowchart of the INIT block in Fig. 3.

erator experience throughout the years has dictated which functionality to keep and improve, and which is not relevant for operations. On a final note, to avoid changing the major release of the BBFS during Run 2, any code renovations were delayed until LS2.

## CODE RENOVATION

During LS2 it was decided to condense all the code in the BBFS, into one FESA-based application called BFCLHC. The hardware requirements were no longer an issue following a hardware upgrade of the OFC and OFSU machines. The hardware upgrade was from a 24-core, 32 GB RAM, 15 MB cache machine to a 64-core, 200 GB RAM and 22MB cache machine [14]. This upgrade meant that the conservative measures taken in the initial design of the OFC could be relaxed. During LHC operation, the OFC never crashed due to insufficient hardware requirements, therefore the hardware upgrade meant that it was safe to implement more advanced code and retain a deterministic execution.

At the same time, the FESA framework was undergoing development. With the introduction of new features, most of the basic operations done by the BBFS until Run 2 could be replaced by simple FESA commands. Some of the code used in the OFC and QFB was left intact: a) concentration of the COD, BPM and BBQ data; b) computation of the corrections required on the CODs and the tuning quadrupoles; c) Sending of the corrections to the respective gateways. The main program shown in Fig. 3 and the OFSU FESA class,

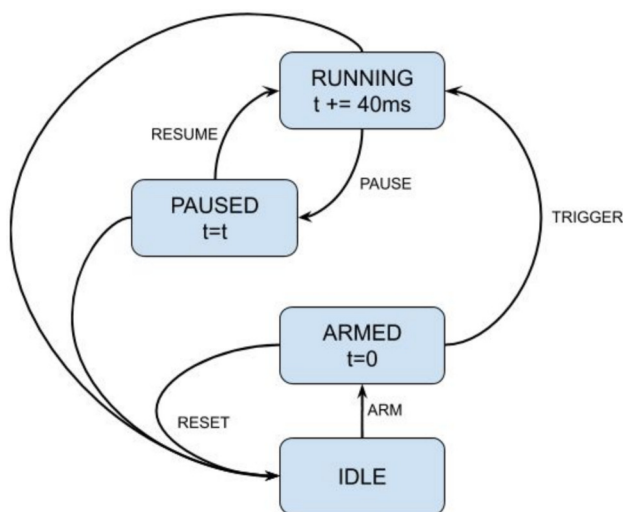

Figure 5: State machine of the FP as implemented in the BFCLHC.

contained the majority of the code which was replaced. The FESA framework was used to re-implement the logic of the main program.

To improve maintainability, the BFCLHC was designed to have a minimal amount of user code by relying more on the FESA framework features to implement the basic logic of the BFCLHC. For example, the data concentration is performed in a Real-Time Action (RTA), which updates the shared memory of the device with the latest BPM orbit data. A standard FESA interface property is then set up for providing the most recent BPM orbit measurements directly from shared memory. Following this design approach, trivial tasks (e.g. relaying data from real-time devices to users) were easier to implement and to debug. Considering that back-compatibility is ensured by FESA, future versions of BFCLHC will be easier to maintain [15]. It is important to note that the design of the BFCLHC Application Programming Interface (API) was based on the API of the OFSU, however, it was adapted significantly to better fit the needs of the operators.

Function Players (FPs) was a new feature that was added to the BFCLHC, at the request of the LHC operators. Using FPs for automated settings control was introduced in [16]. In the BFCLHC, the FPs are used to automate the change of: a) reference values, e.g. reference orbit; b) control loop gains; and c) optics models. Presently, the BFCLHC can accept a list of reference values along with a list of time offsets when the references should be applied. Linear interpolation of reference values was also implemented, e.g. varying the reference orbit linearly. Each FP is used depending on its current state. Figure 5 shows the general state machine of the FPs as implemented in the BFCLHC. The state is stored in the FESA shared memory, and can be changed by a FESA command. To change the state of the FP, the operators must either manually send events, or synchronise them with LHC timing. Some events are only available in specific states and

a FESA exception is thrown when the user violates the state machine rules shown in Fig. 5; e.g. when the FP is in the ARMED state, only a TRIGGER or RESET event can change its state. A function can only be set when the respective FP is in IDLE state.

The optics calculation procedures are now delegated to the BFCLHC class. The approach to initialising and loading new optics to the feedbacks has therefore been changed. Any optics model must now be added to the BFCLHC memory via a FESA set command. Subsequently, a FP must be used to instruct the feedbacks when to change to new optics. The operators rely on their own sub-routines which can obtain a set of optic models from LHC Software Architecture (LSA) settings database [17], and forward it to the BFCLHC.

Following the Hardware Acceleration (HA) feasibility study in [18], we concluded that the use of GPUs did not improve computation times when calculating the Pseudo-Inverse (PInv) of the RMs when compared to a multi-core approach. In the new design, after an optics model is added, a new thread is spawned which calculates the Response Matrix (RM) as well as the corresponding PInv. In the event of a sensor or magnet malfunction, a thread per optic model can be spawned to re-calculate the adjusted models without blocking the control loop. The time to perform an optics recalculation took in the order of minutes to complete on the BBFS. The BFCLHC reduces this time to the order of seconds, which makes it possible to attempt in real-time in the LHC Run 3.

## TESTING FRAMEWORK

The first formal testing of the OFC occurred at the start of the LHC Run 2 in 2014/15, during a code renovation that saw to the porting of the OFC and OFSU code from a 32-bit to a 64-bit architecture [19]. Considering the maintenance and correct porting of more than 90,000 lines of code, our colleagues from the operations group have built a separate testing framework during LS2 which mimics the input signals of the BBFS, by sending UDP packets disguised as coming from the BPM FECs.

The original design of the OFC made this operation complex due to its global control loop architecture. A series of code changes had to be made to the OFC and OFSU themselves simply to be able to test them. In particular, a global variable controlled key mechanisms within the OFC which determined whether the code was being used operationally or within a simulation. In addition, the output network ports were also tweaked in order to allow for a different base port to be used during testing. This was done as a protective measure against UDP packets being sent to the magnets during testing.

One of the main goals of the first testing framework was to verify that the renovated code respected all operational boundaries of the OFC. An identical hardware setup which was set up as a back-up to the operational hardware, had to be used to run the tests. The tests were written in a Java-embedded Domain Specific Language (eDSL) and the JUnit

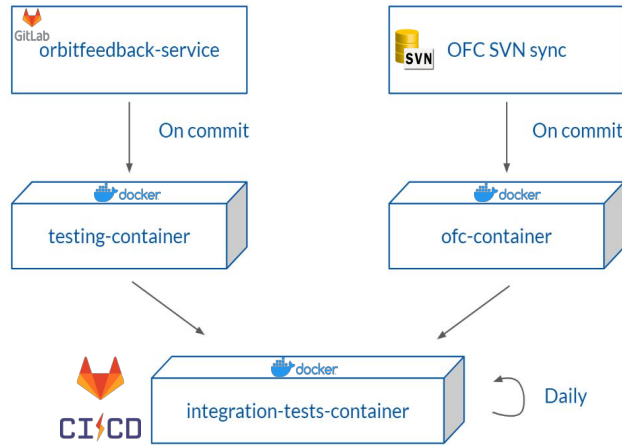

Figure 6: Testing framework schematic, showing the use of Docker containers in the GitLab Continuous Integration (CI) framework.

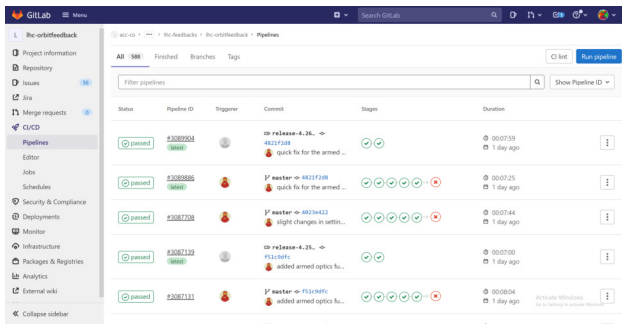

Figure 7: Screenshot of the BFCLHC testing framework test results using CI on GitLab.

framework was used to create the tests and generate reports. Due to the inherent complexity of this testing framework it was quickly realised that it was difficult to maintain and to use efficiently. Despite these limitations, this testing framework was successful in detecting bugs which aided the code renovation prior to the LHC Run 2.

The new BFCLHC testing framework is still undergoing development, and will continue at least until the start of Run 3. Figure 6 shows the basic structure of the latest design. It was decided to make the testing framework hardware agnostic with the use of Docker containers [20]. This new design allowed tests to be performed on the BFCLHC during active development through the use of Continuous Integration (CI) tools in GitLab [21]. As an example, algorithm 1 shows the pseudo-code for a test that checks the limit on the number of optics that can be loaded to the BFCLHC. Figure 7 is a screenshot from GitLab CI which shows the results of the tests that were performed automatically after successful compilation and Docker image creation.

## CONCLUSION

The BBFS implemented the automatic feedbacks on the RF frequency, beam orbit and the tunes until LHC Run 2

**Algorithm 1** Test which asserts that only 30 optics can be loaded to BFCLHC.

```

optics_set           ▷ Contains set of 30 optics
bfc                 ▷ Running instance of BFCLHC
extra_optics       ▷ 1 extra optics
res                 ▷ Test result

for optics in optics_set do
  bfc.loadOptics(optics)
  if Allowable time expired then
    res ← Fail
    Exit
  else if not bfc.opticsLoadedSuccessfully() then
    res ← Fail
    Exit
  end if
end for
bfc.loadOptics(extra_optics)
if bfc.opticsLoadedSuccessfully() then
  res ← Fail
else
  res ← Success
end if

```

in 2018. The renovation of the BBFS during LS2 saw the upgrade of the hardware, software and operational sides of the feedbacks. The experience gained when operating the feedbacks in the past, was taken into consideration during the renovation of the BBFS. Ultimately, the renovated BBFS is a FESA-based application called the BFCLHC, which includes all the required functionality of the BBFS, along with the addition of new features. The three main upgrades are: a) Introduction of FPs for the automatic changing of settings during LHC operation; b) More efficient optics computations and; c) a simpler and more user-friendly interface. A hardware agnostic testing framework was also developed by the LHC operations section to help with the development of the BFCLHC.

# LEARNING TO LASE: MACHINE LEARNING PREDICTION OF FEL BEAM PROPERTIES

A.E. Pollard\*, D.J. Dunning, M. Maheshwari  
ASTeC, Cockcroft Institute, STFC Daresbury Laboratory, UK

## Abstract

Accurate prediction of longitudinal phase space and other properties of the electron beam are computationally expensive. In addition, some diagnostics are destructive in nature and/or cannot be readily accessed. Machine learning based virtual diagnostics can allow for the real-time generation of longitudinal phase space and other graphs, allowing for rapid parameter searches, and enabling operators to predict otherwise unavailable beam properties. We present a machine learning model for predicting a range of diagnostic screens along the accelerator beamline of a free-electron laser facility, conditional on linac and other parameters. Our model is a combination of a conditional variational autoencoder and a generative adversarial network, which generates high fidelity images that accurately match simulation data. Work to date is based on start-to-end simulation data, as a prototype for experimental applications.

## INTRODUCTION

Free-electron lasers (FELs) are sources of ultra-short and ultra-bright pulses of light, which are used to reveal the dynamics of important processes across various scientific disciplines [1]. For effective and efficient facility operation, it is necessary to rapidly reconfigure and optimise different setups to meet user needs. Machine diagnostics are essential for this task, and while some measurements can be taken non-invasively and on every shot, others are destructive to the beam, relatively slow, or otherwise constrained. For example, the longitudinal phase space (LPS) of the beam is critically important for FEL performance but this is an invasive measurement that can only be made at locations with dedicated hardware. Simulations are commonly used to supplement the experimental data; however, they can be computationally expensive and often require significant iteration to improve their match to experimental conditions. Machine learning offers the potential to leverage the large volumes of accessible diagnostic and simulation data to build surrogate models that enable accurate modelling with real-time execution, thereby delivering virtual diagnostics and rapid optimisation of beam conditions on demand.

Artificial Neural Networks have shown great utility in the generation of complex data. From synthesised speech to faces of non-existent people, several architectures have been developed to effectively generate artificial data that is indistinguishable from the training data. Autoencoders, autoregressive models, and generative adversarial networks comprise the three main classes of these generative networks and the focus of modern research.

\* amelia.pollard@stfc.ac.uk

Autoencoders are an excellent choice for generating complex and variable data in an unsupervised manner. Their ability to condense inputs into a significantly lower dimensional representation before reconstructing the input from this representation provides a powerful method of learning the key components of target images, such as input parameters. Variational autoencoders [2] build on this to codify the latent space representation as a series of probability distributions which can be further extended by making those distributions conditional on input parameters. This Conditional Variational Autoencoder (CVAE) model enables effective learning of the parameterised generation of images.

Generative Adversarial Networks [3] (GAN) represent the current state-of-the-art approach to image generation and function on a principle of adversarial learning. Adversarial learning functions by one network attempting to generate realistic data, while another network attempts to discern real data from generated data. This technique enables image generation with fidelity orders of magnitude higher than that of generative networks alone, but it is prone to stability issues and is highly sensitive to hyperparameter choices.

Our work combines a CVAE and a GAN into the CVAE-GAN architecture [4] and uses a combination of these powerful techniques to produce high-fidelity longitudinal phase space graphs for arbitrary parameter configurations as a virtual diagnostic for end users. We also demonstrate an ability to search the space of LPS graphs for particular graphs as drawn by an end user, allowing for highly customisable longitudinal beam profiles.

## RELATED WORK

The first steps to incorporating image recognition into particle accelerator control using convolutional neural networks were taken in Edelen et al. [5] and developed further in Scheinker et al. [6]. Conversely, machine learning *prediction* of longitudinal phase space from machine parameters has been explored, with good results, as in Emma et al. (2018 and 2019) [7, 8]. While these simple networks seem to lead to artifacts and sub-optimal reconstruction of fine structure details, more complex networks featuring convolutional and upsampling layers do appear to provide some improvement [9]. The use of additional information besides machine settings, in the form of non-invasive shot-to-shot spectral measurements, has also been shown to improve the accuracy of LPS predictions [10]. Additionally, recent work based solely on experimental data has demonstrated LPS prediction at significantly higher resolution to previous studies [11].

## METHODOLOGY

We used a dataset of longitudinal phase space images and associated parameters, as described in [12] and briefly outlined here. This was generated from the results of previous work, using a Multi-Objective Genetic Algorithm [13] to find optimal beam characteristics on the XARA lattice [14]. The XARA lattice is a possible upgrade to the existing CLARA facility [15], using high-gradient X-band RF technology. A diagram of the XARA lattice can be found in Fig. 1. 10,000 start-to-end simulations of the accelerator were generated using the simulation code ASTRA [16] (up to the linac 1 exit) and Elegant [17] for the remainder. Using the 6D bunch distributions produced, LPS images were created by calculating the maximum and minimum values of the z-positions and beam energies for each individual distribution and binning the particles in a 2D histogram defined by this region of interest (ROI) to create 100×100 pixel images. Though not used in this study, another set of images was generated for which the maxima and minima were taken over all distributions, for a fixed ‘screen size’ (referred to as non-ROI or fixed extent images).

Each example in the dataset consists of an 100×100 pixel LPS image at a location immediately upstream of the undulator line, 4 real values describing the bounds of the ROI in the fixed extent, and 17 accelerator parameters describing the phase and amplitude of the linacs, the laser heater factor, the dechirper factor, and the bunch compression. In this work, all fixed extent images shown were generated by placing the ROI image in accordance with the bounds generated by the network.

Figure 1: Schematic layout of CLARA with the potential XARA upgrade overlaid. The total length is approximately 90 m. The LPS images used in this study were generated at a location following the X-band linacs and before the modulator undulators.

Following the approach taken in previous studies [7], we began by developing a fully connected parameter to image generative model as part of Maheshwari et al. [12]. A parameter to CNN generative model was also tried, which performed poorly, generating approximations which were of the correct scale but lacking a well-defined structure. This work led directly to the development of this more complex architecture.

We then developed a conditional variational autoencoder model and experimented with CNN and DNN based generators to produce high quality images. However, as seen in previous works, the generator showed a tendency to produce a great many artifacts and fine details were lost. We therefore created a deep neural network which utilised a

convolutional conditional variational autoencoder, with the addition of a discriminator, resulting in a model known as a CVAE-GAN (as shown in Fig. 2) [4]. A discriminator endeavours to identify real and generated images. When this is affixed to the generative model (the CVAE), the weights of the discriminator are frozen and the generated images are intentionally mislabelled as being real images. The resulting error is then backpropagated through the generative network to train the generator to produce images which would ‘fool’ the discriminator. This error is combined with an absolute difference error metric between the input and output images, as well as the Kullback-Liebler divergence constraint on the latent space of the CVAE.

Hyperparameters were found by Bayesian optimisation to minimise absolute difference over a validation set composed of 10% of the total dataset. The network was trained utilising 90% of the dataset, with 10% held back for testing. The Adam optimiser was used with a learning rate of  $1.0 \times 10^{-3}$ , with the error function defined in Eq. (1). Note that  $D_{kl}$  represents the Kullback-Liebler divergence [18].

$$E(x) = D_{kl}(N(0, 1) || P(x|\mu, \sigma, y)) + abs(x - \bar{x}) - (x_d \log(\hat{x}_d) + (1 - x_d) \log(1 - \hat{x}_d)) \quad (1)$$

Figure 2: The model of the CVAE-GAN, with the encoder highlighted in blue, the latent space layer highlighted in orange, the decoder highlighted in green, and the discriminator highlighted in purple. Note the additional 1×4 output layer which generates the position of the region of interest in the fixed extent image.

## RESULTS

We found that the CVAE-GAN model allowed for the real-time generation of longitudinal phase space graphs with high verisimilitude to simulation. This therefore achieves the stated goal of providing a virtual diagnostic of longitudinal phase space that would allow operators to carefully choose parameters to achieve specific bunch energy profiles.

Most notably, our technique delivers high quality representation of fine-grain details as can be seen in Fig. 3. This is a consequence of the application of the discriminator, which constrains the generator to produce more realistic images where more traditional error functions, such as absolute difference, generally result in blurring of fine details.

Given that the forward pass of neural networks can be run in linear time, this allows for the rapid sampling of LPS graphs from the space. In combination with Bayesian

Figure 3: A pair of examples from the LPS GUI showing both the fixed extent and region of interest. Note the fine-grain details of the region of interest image, which are generally lost in simpler models.

Figure 4: Fixed extent images and ground truth from Elegant simulations with the same parameters. Variations in the position of ROI are due to scale differences in the output. Significantly, the finer detail structure of the LPS graph is strongly matched to the output of Elegant.

Optimisation, we can therefore perform a guided search for image similarity with an LPS graph drawn by an operator, as shown in the example in Fig. 5, to yield the required machine settings. This feature is one part of a graphical user interface (GUI) for the model, shown in Fig. 6.

Figure 5: An example of the drawing interface with target drawn by operator (right) and the resulting LPS graph (left) which most closely matched the operator's drawing. On a mid-range laptop, this search took approximately 20 seconds.

## CONCLUSION

Utilising the CVAE-GAN architecture allows for high fidelity linear time virtual diagnostics of the longitudinal phase space for arbitrary accelerator parameters. However, expanding of the dataset to encompass a wider range of parameters significantly increases the quantity of data required to provide an accurate surrogate model. In continuing this research to expand this work to multiple screen locations along the beamline and to a wider parameter space, we have found that this increase in the generative range of the model has led to common Generative Adversarial Network pitfalls such as mode collapse and instability. We therefore conclude that this technique, while extremely powerful, is also quite difficult to implement reliably and care should be taken to avoid such issues.

Future work will include the simultaneous generation of LPS graphs for multiple points along the beamline, as well as comparisons to real-world data using a transverse deflecting cavity and potentially applying transfer learning using a small quantity of TDC data to augment a larger quantity of simulation data.

# MACHINE LEARNING FOR RF BREAKDOWN DETECTION AT CLARA

A. E. Pollard\*, A. J. Gilfellow<sup>1</sup>, D. J. Dunning

ASTeC, Cockcroft Institute, STFC Daresbury Laboratory, Warrington, UK

<sup>1</sup>also at The University of Manchester, Manchester, UK

## Abstract

Maximising the accelerating gradient of RF structures is fundamental to improving accelerator facility performance and cost-effectiveness. Structures must be subjected to a conditioning process before operational use, in which the gradient is gradually increased up to the operating value. A limiting effect during this process is breakdown or vacuum arcing, which can cause damage that limits the ultimate operating gradient. Techniques to efficiently condition the cavities while minimising the number of breakdowns are therefore important. In this paper, machine learning techniques are applied to detect breakdown events in RF pulse traces by approaching the problem as anomaly detection, using a variational autoencoder. This process detects deviations from normal operation and classifies them with near perfect accuracy. Offline data from various sources has been used to develop the techniques, which we aim to test at the CLARA facility at Daresbury Laboratory. These techniques could then be applied generally.

## INTRODUCTION

There are two main aims with this project. Firstly, we aim to assemble a machine learning (ML) based system that could be used to replace the current mask method of radio frequency (RF) breakdown (BD) detection which is standard in the automated code used in the RF conditioning of accelerating cavities. Secondly, we aim to ensure that the mid-process features of the same mechanism could be used as inputs for an ML algorithm designed to predict whether or not the next RF pulse would lead to a BD.

To this end, we constructed a  $\beta$  convolutional variational autoencoder ( $\beta$ CVAE)[1] with RF conditioning data as inputs. After being trained as an anomaly detector this acted as a live BD detector, in conjunction with a dense neural network (NN), which would act with the capacity to replace the current non-ML based BD detection system. In addition to this, the  $\beta$ CVAE's latent space could act as a viable input for a long short-term memory (LSTM) recurrent neural network (RNN) that could be used to predict BDs, based on the methodology set out by Kates-Harbeck et al.[2] who had success in predicting disruptive instabilities in controlled fusion plasmas.

For this investigation, we used data from the CLARA accelerator (Compact Linear Accelerator for Research and Applications) based at Daresbury Laboratory. CLARA is a dedicated accelerator test facility with the capacity to deliver high quality electron beams for industry and research. In addition to the CLARA data, a larger dataset was provided

by the CLIC team at CERN covering a cavity test which took place in CERN's XBOX-2 test stand. The structure tested in this dataset was a T24 high-gradient prototype X-band cavity produced at the Paul Scherrer Institute; further details of this design have been reported previously [3, 4]. The CLARA data was collected as part of the routine RF breakdown detection system.

## RELATED WORK

Solopova et al.'s [5] application of a decision tree model to assign both a fault type and cavity-specific location to a collected breakdown signal at CEBAF represents the first foray into using machine learning to classify RF cavity faults. This work was then continued in Tennant et al.[6] where the authors applied a random forest model to the classification of faults and cavity identity for a larger dataset of breakdown events.

Obermair et al. [7] took the first step towards machine learning based detection and prediction of breakdowns. The authors separately applied deep learning on two available data types (event and trend data) to predict breakdowns. In so doing, they were able to predict breakdowns 20ms in advance with good accuracy. In addition, they utilised explainable AI on these models to elucidate the physics of a breakdown. This pointed them towards an increased pressure in the vacuum system before a breakdown, which they indicated as an option for an improved interlocking system. Their analysis of event data alone also reveals the possibility to predict breakdowns with good accuracy, if there has already been a breakdown in the previous minute, i.e. prediction of follow-up breakdowns.

Previous work within our organisation also informed the present studies. Another dataset from XBOX cavity testing was analysed for missed breakdowns using principal component analysis and neural networks [8]. Very high classification accuracy was reported, but there was suspected duplication of traces in the dataset.

## METHODOLOGY

### CLARA

Here we use data gathered during the RF conditioning of CLARA's 10 Hz photoinjector (Gun-10), which includes both the RF pulse traces themselves and other non-RF, such as the temperature and pressure inside Gun-10. The RF trace data was gathered before ML was taken into consideration and was therefore not ideal for our purposes, but it was deemed to be sufficient for progress to be made. The trace data was only recorded when the RF breakdown detector was activated and a BD identified, then the conditioning script

\* amelia.pollard@stfc.ac.uk

Figure 1: A plot of the results of applying the t-SNE/DBSCAN method to label the CLARA Gun-10 data set. Each cluster is given an index with its population displayed below, i.e. the cluster in the top right corner of the plot has an index of 6 and a population of 159. As examples of the principal trace types, the large central cluster indexed as 1 represents noise traces, cluster 4 contains only healthy traces, 8 breakdown traces, and 7 is composite (healthy/BD).

would record the pulse associated with the BD, as well as the two previous and two subsequent pulses. Altogether, there were 40 traces recorded per breakdown event (8 traces for each of the 5 pulses). Specifically the traces were: klystron (forward, reverse power, and phase), and cavity, (forward, reverse power, and phase).

In order to provide the ground truth and label each recorded trace as either, noise, healthy, BD or anomaly, the traces were first grouped together by using sklearn's t-SNE[9] (t-distributed Stochastic Neighbour Embedding) and DBSCAN (Density-Based Spatial Clustering of Applications with Noise) functions. The traces from each delivered cluster were then over-plotted and inspected by eye with any pure groups receiving the appropriate label and composite clusters undergoing further t-SNE/DBSCAN analysis until only pure groups remained. Figure 1 shows an example of the clustering that was returned by the t-SNE/DBSCAN method for this data set.

The next step was to construct the  $\beta$ CVAE at the core of the BD detector and at the beginning of the planned BD predictor. After much experimentation with spectrograms, phase traces, and temperature and pressure data, it was found that the most effective input for the  $\beta$ CVAE was a 2D array comprised of the four normalised power traces, with dimensions of  $4 \times 1017$ . The most optimal structure of the found for  $\beta$ CVAE is displayed and described in Fig. 2.

The  $\beta$ CVAE was trained on 4659 healthy traces in order to create the anomaly detector, which was then validated using another 1164 healthy traces. For both training and validation the Adam optimiser and categorical cross entropy loss function were used. Testing the  $\beta$ CVAE involved exposing the algorithm to 706 healthy and 706 BD traces (1412 traces in total) and subtracting the reconstructed traces from

the original traces to produce 1D reconstruction error traces. These were then used as an input for a simple dense neural network classifier with one ReLU activated hidden layer with the same dimensions as the input layer and a binary (healthy or BD) softmax activated output layer. Again the Adam optimiser and categorical cross entropy loss function were used.

A confusion matrix was then constructed by comparing the class assigned by the model to the ground truth in order to check for the accuracy and recall of the BD row for the system, as in Table 2. For this dataset, the key statistic was the recall of the BD row, since the accelerator not reacting to a false negative could be damaging to the accelerating structure, whereas reacting to a false positive merely results in a slight reduction in the time efficiency of the accelerator. An accuracy of 96.9% and a BD row recall of 98.0% was achieved using the methods outlined above. We also noted that approximately half of the false negative traces were in fact healthy or anomalous after manual inspection. This is not surprising since the labelling process relied on unsupervised ML processes and, had time allowed, all traces would have been labelled individually by an RF expert.

Future work will include the integration of the ML BD detector into the next version upgrade of the RF conditioning code and the construction of the LSTM RNN for the predictive system. However, before this can be effective, more appropriate data may need to be gathered from CLARA, particularly more traces before a BD event and at a higher RF repetition rate than 10 Hz. Since CLARA RF power is pulsed if we were to follow the methodology set out in Kates-Harbeck et al.[2] we can think of the noise between pulses as missing data. In order to quantify the proportion of data that is effectively missing, or pseudo-missing, we can use the following relation,

$$R_{\text{DATA}} = 1 - D, \quad (1)$$

where  $R_{\text{DATA}}$  is the proportion of the data that is pseudo-missing and  $D$ , the compliment of  $R_{\text{DATA}}$ , is the dimensionless duty cycle of the RF system, defined as,

$$D = \text{PRR} \times \tau_{\text{pulse}}, \quad (2)$$

where PRR is the pulse repetition rate in Hz and  $\tau_{\text{pulse}}$  is the RF pulse length in seconds. For CLARA's Gun-10 we have a PRR of 10 Hz and an operational pulse length of  $2.5 \mu\text{s}$ , which gives a duty cycle of  $2.5 \times 10^{-5}$ , or 0.0025% and consequently a proportion of pseudo-missing data of 0.999975, or 99.997%. It seems reasonable to assume that for any given system there may exist a "duty cycle threshold" below which BD prediction using ML with RF trace data is not practically possible and which may only be determined experimentally.

## CERN

The CERN XBOX data consisted of two primary data types: event and trend. The trend data contained environmental data concerning the test cavity (i.e. temperature,

Figure 2: The final structure of the  $\beta$ CVAE for the CLARA dataset study. The encoding half of the  $\beta$ CVAE was constructed by using 2D arrays consisting of the four power traces ( $4 \times 1017$ ) as inputs to the first 2D ReLU activated convolutional layer with subsequent 2D max pooling layer, the arrays were then flattened and inputted into a  $1 \times 4$  ReLU activated dense layer before being passed into the  $1 \times 2$  latent space. The decoder consisted of two dense ReLU activated layers of dimensions  $1 \times 8$  and  $1 \times 32$ , before a sigmoid activated output layer of  $1 \times 4068 (= 4 \times 1017)$ . The outputted 1D array was then reshaped into a  $4 \times 1017$  2D array in order to produce the reconstructed traces with the original input layer dimensions.

vacuum pressure) while the event data contained the signal traces from a number of components of the RF system.

To keep consistency with the CLARA breakdown detector, the trend data was discarded and only the RF traces were used. These traces consisted of 16 channels, of which we excluded 7, as follows. Two of the channels ('DC UP' and 'DC DOWN') corresponded to the Faraday cups upstream and downstream of the RF cavity, and these were used for automated labelling of the samples. A reading of less than  $-0.05$  from either cup would mark that trace as a breakdown. The remaining 5 excluded channels were removed as they were either repeated signals (i.e. the 'PSR log' channel repeated 'PSR Amplitude' channel, but with log scaling) or essentially noise (such as the Beam Loss Monitor signal, which was indistinguishable from noise).

Further filtering was applied to ensure the quality of the data, and traces were removed wherein the mean and variance of the amplitude traces indicated that the RF cavity was not active ( $\bar{x} \times \sigma^2(x) < 1e-4$ ), and the signals were therefore considered noise. This filtering and classification resulted in 254,656 samples, of which 5,930 samples contained a breakdown.

We then developed a beta variational autoencoder model, as shown in Fig. 3, to reconstruct only healthy signals. The network was trained using 90% of the healthy signals. The Adam optimiser was used with a learning rate of  $1e-3$ , with the error function defined in equation (3). The network was trained to convergence, which took 27 epochs. For  $\beta$  a value of 5 was chosen by grid search.

$$E(x) = \beta D_{kl}(N(0, 1) || P(x | \mu, \sigma)) + abs(x - \bar{x}) \quad (3)$$

Note that  $D_{kl}$  represents the Kullback-Liebler divergence[10].

Once sufficiently trained to reconstruct healthy signals, we utilised this *overfitting* to detect breakdown events as anomalies. That is to say, when the network fails to reconstruct the signal well, we can be reasonably assured that this represents a deviation from normal operation and thus a breakdown event.

In order to classify the breakdown events, we began by passing all breakdown events and an equal number of non-breakdown events through the autoencoder, taking the reconstruction error for each channel and compiling those values into a vector. Applying a K-nearest neighbour algorithm to the per-channel reconstruction error vector resulted in mediocre performance, as shown in Table 1. As such, we elected to implement a simple multi-layer neural network to perform the classification, while also concatenating the latent space representation of the example to the per-channel reconstruction errors to form the input vector. This new neural network was then trained to convergence in 20 epochs using the Adam optimiser, with a learning rate of  $1e-2$  and a binary cross-entropy loss function. Results from this network are shown in Table 3.

Table 1: kNN Results on CERN XBOX Data

	Positive	Negative
True	89.6%	98.8%
False	10.4%	1.2%

Early work into prediction of breakdowns was undertaken by replacing the classification network with an LSTM which was trained on a label of time-until-breakdown. Unfortunately, this achieved little success with our most effective attempt achieving 73% accuracy at predicting breakdowns within 30 second windows. We hypothesise this is due to the sparse nature of the sampling of shots, and future work

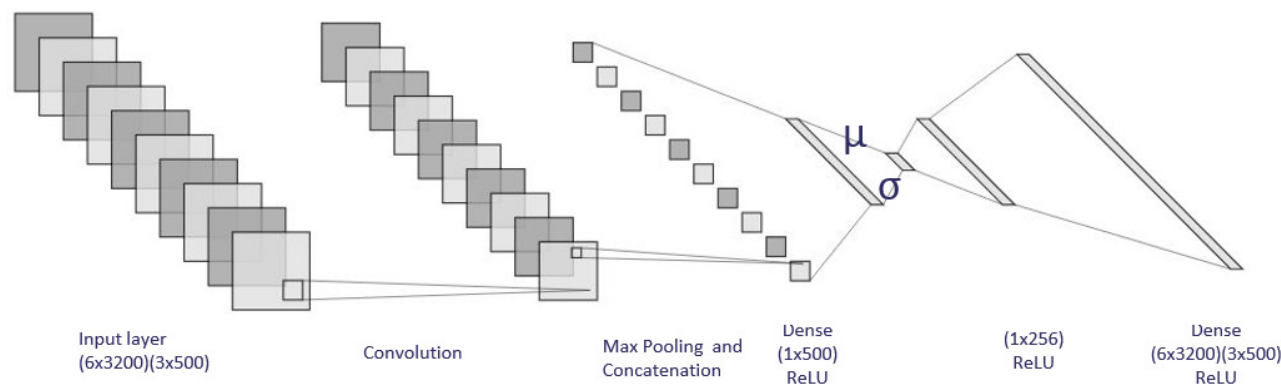

Figure 3: For the CERN XBOX data, three of the input channels were of a lower dimension, and each channel was processed by a CNN with filters of size  $1 \times 5$ , with the resulting feature vectors flattened and concatenated before being passed to a dense ReLU layer and encoded into the latent space. The decoder is constructed of a single dense ReLU layer with each channel consisting of a linear dense layer.

will involve collecting a higher frequency sampling of shots such that this prediction might be enabled.

## RESULTS

As can clearly be seen, both networks produced strong results very high recall and accuracy. In particular, the high recall value is significant for such an unbalanced dataset. If of a system of this type were to be deployed to an edge ML system on an accelerator, a low false positive rate would be extremely important for operator trust of the system.

Table 2: Results on CLARA Data

	Positive	Negative
True	95.8%	98.0%
False	4.2%	2.0%

Table 3: Results on CERN XBOX Data

	Positive	Negative
True	97.9%	99.6%
False	2.1%	0.4%

It is of note that approximately half of the false positives in the CERN XBOX data are in fact true positives that were mislabelled by the automated labelling, as verified by manual inspection.

## CONCLUSION

We find that the application of a variational autoencoder as an anomaly detector is extremely effective as a breakdown detector for RF cavities. A significant benefit of this approach is that it requires only healthy signals to train a strong detector, in contrast to supervised approaches which require careful balancing of positive and negative signals. Obermair et al.[7] showed that environmental trend data was sufficient to predict breakdowns with good accuracy up to 20ms in advance. They also found that shot traces

are sufficient to predict breakdowns with good accuracy, if and only if there has already been a breakdown in the last minute. In agreement with their results, we find that the shot traces from the cavity alone are not sufficient at this sampling frequency to predict breakdowns ex nihilo. We plan to collect additional data from CLARA with complete shot capture. With this data, we hope to demonstrate breakdown prediction using only per-shot phase and amplitude traces and the anomaly detection method presented herein.

## ACKNOWLEDGEMENTS

The authors would like to thank the CLIC team and the Paul Scherrer Institute for the provision of their high-gradient structure test data, in addition to Christoph Obermair and Lee Millar from CERN for their advice on interpreting it. We would also like to thank Hannah Kockelbergh (The University of Liverpool) for the studies that led on to this work, as well as STFC's Scientific Machine Learning (SciML) Group, particularly Keith Butler, for supervising A. J. Gilfellon's work on this project.

# SAMPLE ALIGNMENT IN NEUTRON SCATTERING EXPERIMENTS USING DEEP NEURAL NETWORK

A. Diaw \*, K. Bruhwiler, J. P. Edelen, C. C. Hall, RadiaSoft LLC, Boulder, CO

## Abstract

Neutron scattering facilities, such as Oak Ridge National Laboratory (ORNL) and the NIST Center for Neutron Research, provide a source of neutrons to investigate a wide variety of scientific and technologically relevant areas, including material science, chemistry, biology, physics, and engineering. In these experiments, the quality of the data collected is sensitive to sample and beam alignment. This alignment changes both between different samples and during measurements. The sample alignment optimization process requires human intervention to tune the beam and sample positions. While this procedure works, it is inefficient, time-consuming, and often not optimized to high precision alignment. This paper uses different neural network architectures on neutron camera images from the HB-2A powder diffractometer beamline at the High flux Isotope Reactor (HFIR) and optical camera images from the TOPAZ single crystal diffractometer at the Spallation Neutron Source (SNS), both at ORNL. The results show that the trained network on a few images accurately predicts the sample position on holdout test images. The resulting surrogate model can then be used via feedback-driven adaptive controls to tune the experimental parameters to get the desired beam and sample position.

## INTRODUCTION

Neutron scattering experiments probe the structure and dynamics of materials to provide unique insights into physical, chemical, nanostructured, biological and engineering materials science. At present the US Government operates two premier neutron scattering user centers [1]; one at Oak Ridge National Laboratory and one at the NIST Center for Neutron Research. These large scale facilities offer flagship research capabilities to academia and industry that serve a broad and growing user community which necessitates their improved operational efficiency and capacity. The experiments involve collecting data on samples in a neutron beam on highly optimized neutron instruments. The position of the sample in the beam is often critical to the subsequent data analysis and measurements success, however the need to perform sample alignment and realignment during experiments reduces the amount of time spent collecting data. While there have been efforts to improve sample alignment [2] and to automate switching between samples [3, 4], manual intervention from facility beamline scientists or expert users is still necessary. At present optimization of the experimental environment requires a facility beamline scientist or expert user to interpret image data of the sample either through an

optical camera or a neutron camera. A correction is then applied manually based on the data from these images until the sample is aligned in the beam. The automation of this process will result in more efficient and accurate use of neutron facilities and therefore increase the overall quality and reliability of their scientific output. During our studies we have focused on developments for two experimental stations, the HB-2A neutron powder diffractometer and the TOPAZ neutron single crystal diffractometer.

The HB-2A neutron powder diffractometer (as shown in Fig. 1) is located at the High Flux Isotope Reactor at ORNL and is primarily utilized for magnetic structure determination while focusing on experiments at ultra-low temperatures with the options of high external fields or applied pressures. The constant energy neutron beam in a low noise environment and a simple incident beam profile makes HB-2A well suited to a variety of interchangeable environments with minimal calibration required. There are a variety of sample changer options that can allow multiple samples to be loaded at a time. With a focus on weak magnetic signals the sample alignment and beam optimization with adjustable slits and sample stage motors is crucial to reducing unwanted background scattering and to maximise the sample signal. With further optimization of the beamline to include a new detector count rates would increase by over an order of magnitude, resulting in a significant increase in the number of samples being run, further motivating the advancement of automated sample alignment. For more details about the HB-2A instrument and scientific applications see [5].

Figure 1: The HB2A powder neutron diffraction instrument. The sample and detector area is shown on the left, with the neutron camera behind the sample. Middle shows a standard sample holder that the powder sample is loaded into, with the scale shown in millimeters. An example of a neutron image is shown on the right, with the powder appearing as a shadow-like image in the white beam.

\* diaw@radiasoft.net

Figure 2: TOPAZ neutron single crystal diffraction instrument. (a) The sample and detector area is shown as viewed from above the instrument. (b) Top image shows the sample goniometer arm. Samples are loaded on pins and attached to the end of the arm. The middle and bottom images show images of the samples attached to sample mounts.

The TOPAZ neutron single crystal diffractometer (as shown in Fig. 2) is located at the Spallation Neutron Source at ORNL and offers high resolution measurements of crystal structures in small sample volumes. The smallest crystals studied to date in this instrument are  $0.065 \text{ mm}^3$  in size. TOPAZ has recently been upgraded to include the installation of a focusing high-flux neutron guide end-section. This enables routine measurements of sub-millimeter crystal samples. TOPAZ is also capable of continuous 3DQ-space mapping for a specific region of reciprocal space volume given a stationary single-crystal sample. This is particularly useful when studying phase transitions as a function of temperature or other external stimuli. TOPAZ possess state of the art data acquisition and reduction tools making it one of the more advanced neutron scattering end stations available for users. These capabilities, however, are under utilized in part due to limited temperature range and manual alignment of the sample in the environment. Improved tools for automatic sample alignment and stabilization promise to increase the throughput of the detector and therefore increase its net scientific output. For more specifics about the TOPAZ diffractometer and other diffractometers at ORNL see [6].

The two neutron beamlines HB-2A and TOPAZ use different methods to image the sample and optimize the alignment. HB-2A uses a neutron camera that is placed in the neutron beam after the powder sample. The sample and any ancillary equipment that are in the neutron beam appear as a shadow in the beam, with the contrast varying depending on the neutron absorbing characteristics of the material. The beam size has a maximum of  $20 \text{ mm} \times 60 \text{ mm}$  (Horizontal  $\times$  Vertical) and the samples are typically enclosed within a cylindrical can  $\sim 60 \text{ mm}$  tall with diameters in the range 4–15 mm. The target sample alignment is to center the sam-

ple in the beam horizontally and vertically, translate to the center of the detector arc to ensure reliable data quality and to mask out any unwanted beam not hitting the sample that would add unwanted background scattering. For the TOPAZ diffractometer, centering of samples in the neutron beam is accomplished via an optical camera. The sample sizes are in the mm to sub mm size, with a beamsize of 2.0–4.0 mm in diameter. The sample shape and dimension are often irregular and can vary significantly between samples. To view the sample a video camera is installed below the sample and individual images or series of images with respect to a marked beam center position are recorded. The sample is aligned remotely using a software algorithm. All associated metadata and beamline configuration data are recorded and associated with the image. This alignment procedure is done both at the start of the experiment when a sample is initially installed and after the sample temperature has changed which results in a non-trivial alteration of the sample position due to thermal expansion/contraction of the sample environment. Temperature changes can occur multiple times per experiment.

Machine learning has recently been of interest for a range of automation tasks in particle accelerators [7, 8] and experimental end stations [9, 10]. Convolutional neural networks are of particular interest due to their ability to efficiently process image data [11, 12]. Here we will detail the prototyping and testing of new machine learning methods for sample alignment and stabilization of samples at neutron scattering beamlines. Our approach employed the use of convolutional neural networks to either relate diagnostic images to a series of machine settings in operational experiments or reconstruct a binary image outlining the sample. These algorithms can then be used during neutron experiments in conjunction with a feedback algorithm to stabilize samples in the beam. This paper provides an overview of our recent efforts to build convolutional neural networks to assist with the automation of sample alignment in neutron beamlines.

## METHOD AND RESULTS

We focus on designing an efficient approach to dealing with images of different samples obtained during the neutron-scattering experiment.

First, we consider the HB2A dataset. Figure 1 shows an example of the neutron camera image with the powder appearing as a shadow-like image in the white beam. Our dataset

Figure 3: Left: Training an validation loss function at each epoch. Right: the coefficient of determination  $R^2$  for each of the 9 motor parameters.

Figure 4: Test of the CNN surrogate performance in the test dataset. Each plot title corresponds to a different instrument motor that can control sample position and beam size. On the x-axis we have the data from the experiment, y-axis represents the model prediction.

consisted of a collection of 530 images sized  $480 \times 640 \times 4$  and 9 relevant motor parameters such as *smpl\_stk* to selecting the motor position for a sample, *stu* to translate the sample horizontally in the beam or *slit\_pre\_tp* to control the beam size with motorized slits. Our focus was to find a surrogate model that can take a neutron image and predict the motor parameters. This was accomplished using vanilla convolutional neural networks implemented in keras [14]. These structures are well suited for extracting scalar quantities from image data. The CNN consists of a series of  $4 \times 4$  convolution layers. Each layer comprises three types of operations: convolution, rectified linear units, and batch normalization. A dropout of 0.25 is applied between layers and there is a dense layer (256) after the last convolution. A network was trained to learn the behavior of a dataset; this means fine-tuning each layer's parameters (weights and biases) to produce a valid model. We employ a conventional formulation based on the minimization of a loss function  $L$  with the mean-squared error:

$$L = \frac{1}{n_{\text{batch}}} \sum_{s,t} (\hat{X}_s^t - X_s^t)^2. \quad (1)$$

Here  $s$  loops over the training examples, and  $t$  runs over training targets.  $\hat{X}_s^t$  is the  $t$ -th image for example  $s$ , and  $X_s^t$  is the output of the  $t$ -th neuron in the last layer of the network, and where  $n_{\text{batch}}$  is the batch number. We minimize this output by accelerated gradient descent with Adam optimizer with a learning rate set to  $lr = 10^{-4}$  in a series of *epochs*.

Figures 3 and 4 illustrates the network performance. For each motor position, the coefficient of determination  $R^2 > 0.9$ , indicating that the training approach yields robust surrogate models.

Although we successfully trained a network on the dataset, the inverse problem of predicting a sample position from the CNN model using the machine setting parameters did not yield good results. Much of this is related to the degenerate

Figure 5: The proposed U-net architecture uses a contraction and an expansion paths. The blue boxes represent multi-channel feature map while the white boxes are their copies. The gray arrows correspond to the operations from left to right. This figure was taken from Ref. [13].

nature of the system. This limits our ability to provide a feed-forward adjustment to the motors based on a neural network model. An alternative approach is to identify the sample position from the image and use feedback on the motors to position the sample. This sample identification approach was applied to the Topaz dataset using a slightly different architecture.

For the Topaz data, our problem is as follows: Given an image, localize sample position in the image and return the center of the mass of the sample. To do so, we trained a convolution neural network based on the segmentation algorithm 2D-U-net [13]. The U-net architecture shown in Fig. 5 consists of contracting and expansive paths and overall has 23 convolutional layers. For the contracting layer, a vector input  $y$  is passed to two  $3 \times 3$  convolutions, each followed by an activation unit, and produces a vector of activations,  $y'$ , via

$$y' = f(Wy + b), \quad (2)$$

Figure 6: Learning curve. Training and validation loss at each *epoch*.

Figure 7: Examples images obtained from the experiment. The lower plots show binary image masks created around the sample. For images with no sample the mask is empty.

Figure 8: Test model performance for some random images in the test dataset. Top row are the test image (ground truth), middle row: the test image label, and bottom row are the predicted test binary by the U-net algorithm. The predicted test image is visually identical to the ground truth.

where  $W$  is a weight matrix,  $b$  is a bias vector, and  $f$  is an activation function. We choose the rectified linear unit (ReLU) function  $f(s) = \max(0, s)$ . Then, we introduce a downsampling layer consisting of  $2 \times 2$  max pooling operation with stride 2. The downsampling factor was set 2 at each step while the number of feature channels doubles. For the expansive path, we have an upsampling operator of the feature map. A  $2 \times 2$  convolution is employed to reduce the number of feature channels and two  $3 \times 3$  convolutions. After the last convolution layer, we applied a  $1 \times 1$  convolution to map each 64-component feature vector to produce the desired clean image.

Our training dataset is composed of images and the corresponding masks (binary), where each image of size  $964 \times 1292$  has either a sample or no sample, as shown in Fig. 7. Because these images are extremely large, we resized them to  $128 \times 128$  before applying them to the network. Although this procedure may introduce artifacts in the sample images, it did not seem to impact the result of the training. The dataset consists of 611 images, and it was obtained by randomly varying the parameter settings of the optical camera images from the TOPAZ single crystal diffractometer. All model evaluation was carried out using a hold-out 20% validation set, which contains no overlap with the training set. We used a formulation based on the cross-entropy loss function. This latter is minimized by accelerated gradient descent with the Adam optimizer in a series of epochs, that is, passes over the entire training dataset, using a learning rate of  $10^{-3}$  and batches of size  $n_{\text{batch}} = 32$ . A patience-based learning scheduler is used to stop the training and revert to the last best network if the validation loss does not

improve over  $n_{\text{patience}} = 10$  epochs, with a global termination of  $n_{\text{epochs}} = 500$  at maximum. Figure 6 illustrates the training and validation loss error. The network terminates within few epochs ( $\sim 50$ ).

Finally, Fig. 8 shows random samples from the ground truth data, their labels, and corresponding predictions obtained using our surrogate model, demonstrating that the u-net approach captures details very accurately across the sample types.

## CONCLUSION

Machine learning tools are promising for the increased automation of neutron beamlines. We have shown the ability for convolutional neural networks to predict motor positions from images in the HB-2A beamline and to contour the sample for optical images collected from the TOPAZ beamline. Using the output of the U-net architecture we can compute the center of mass of the sample and hand that off to the motor controllers in order to maintain sample alignment during the experiment.

# DEVELOPMENT OF A SMART ALARM SYSTEM FOR THE CEBAF INJECTOR\*

Dan Tyler Abell, Jonathan Edelen, RadiaSoft LLC, Boulder, Colorado, USA  
 Daniel Grady Moser, Brian Freeman, Reza Kazimi, Chris Tennant  
 Thomas Jefferson National Accelerator Facility, Newport News, Virginia, USA

## Abstract

RadiaSoft and Jefferson Laboratory are working together to develop a machine-learning-based smart alarm system for the CEBAF injector. Because of the injector's large number of parameters and possible fault scenarios, it is highly desirable to have an autonomous alarm system that can quickly identify and diagnose unusual machine states. We present our work on artificial neural networks designed to identify such undesirable machine states. Our initial efforts have been focused on model prototyping and data curation. In this paper we present an overview of our initial findings and our efforts to generate a robust dataset for the alarm system. We conclude with a discussion of plans for future work.

## INTRODUCTION

A significant aspect of accelerator operations involves identifying the root causes of faulty machine states. For example, the machine trips on a beam loss monitor. But why? What underlying cause trips the machine? Sometimes the reason is obvious, while other times not. Existing alarm systems commonly indicate when specific machine parameters drift outside their normal tolerances. However, operators must still interpret these alarms in the context of many interacting systems and subsystems before they can take the the most appropriate corrective action.

The project described in this paper has at its primary objective the development of a machine-learning-based model with the ability to rapidly identify potential root causes of machine faults (hence the term Smart Alarm). More specifically, given machine readings (defined more precisely later), the system continuously compares the model's predictions of the expected machine settings (also defined later) against actual machine settings. When a discrepancy arises that exceeds some user-defined threshold, the system raises an alarm that directs operators (or subject matter experts) to the "bad" setting (*e.g.*, corrector, solenoid, rf gradient, *etc.*). If this effort succeeds, a more ambitious goal will be to extend the work to monitor the machine for parameter drifts and identify when the machine needs "tweaking" before a fault event occurs.

During our initial efforts at training and validating machine learning (ML) models, we obtained puzzling and disappointing results. The problems at issue we traced back to various difficulties with our data, including some outlier (read nonsensical) vacuum readings. In the process of that investigation, we examined our data more carefully and found

\* Work supported, in part, by the US Department of Energy, Office of Science, Office of Nuclear Physics, including grant No. DE-SC0019682.

Figure 1: Inverse model trained on operations data from the JLab injector.

other aspects of data collection and selection that required careful consideration. The lesson to learn here is that *understanding one's data*—though time-consuming—*constitutes a critical part of any ML effort*.

In the following sections, we describe briefly some of our early ML efforts and how they led us to make a thorough investigation of our data and the data collection process. We then describe our data, the collection process, and our evolving understanding of how best to curate data that will prove useful for the training and validation of future ML models. We conclude with our plans for future work.

## INITIAL ML EFFORTS

Among our first efforts was training an inverse model on data taken from the JLab injector, with the goal of using measurements (readings) to predict machine settings. Figure 1 shows the loss functions and the somewhat disappointing  $R^2$  fit results for one training run with this data. Modifications to the network architecture, number of epochs, choice of optimizer, *etc.*, made relatively little improvement on the overall results.

This circumstance led us to undertake a critical examination of our data, which at the time comprised that taken during (i) regular *operations* of the injector and (ii) a dedicated *study* of the machine. The various parameters (called

Figure 2: Summary of all Set (upper) and Read (lower) PV data. For each index, the red and blue vertical bars show the range of values spanned respectively by injector operations data and by injector study data. The vertical scales have been compressed by taking a cube-root. The medians of the operations data have been subtracted out.

Process Variables, or PVs) are divided into *Settings* and *Readings*. Figure 2 shows the ranges spanned by the data taken for each of the PVs, and in particular the overlap of the ranges between operations and study data. The hope was to use, say, operations data (of which we had much more) for training and validation, and the study data for testing. For that to work well, however, one would need to see that, say, the range of each *Study* PV lies within the range of its corresponding *Operations* PV—or vice versa. But, as shown by the graphics in Fig. 2, neither case consistently holds.

Another aspect of the data, not illustrated here, is that many of the Set PVs take on just a very few discrete values. This minimal variation suggests that it will, as we have found so far, prove difficult for ML networks trained on this data to achieve a useful characterization of the JLab injector. The solution, of course, is more data and, more importantly, better data.

A newer dataset from the JLab injector comprises some 409 500 instances averaged over one-second intervals for some seven weeks last summer. (See the next section for more details.) This data has no natural divide along which one might assign the different records into separate train and validation datasets; hence we attempted such a split randomly. In this case, too, we found some PVs for which the training range covers the validation range, and other PVs for which the reverse holds. This presents a challenge for training because there are ranges where the model would be trying to extrapolate to a new domain. This, a fundamental challenge for machine learning, and one of the challenges of model-

based anomaly detection, means that a full understanding of the data is critical to success.

## CURATING THE DATA

Five datasets were collected using several different methods. The variety of approaches reflects how our understanding of capturing machine data has evolved (and how it continues to do so). The results of this work will likely inform the modification of current—or the development of new—tools to capture and/or mine data more efficiently.

### Collected Datasets

The datasets collected exist in tabular form, with each column representing an EPICS process variable (PV), and each row a particular snapshot in time. For example, collecting data for the three PVs *Date*, *R047GSET*, and *R047PSET* every hour, on the hour, for two days of operation would yield a dataset of size of  $48 \times 3$  [= (2 days  $\times$  24 readings/day)  $\times$  (3 PVs)] (as shown in Fig. 3). We also give the range of dates (to the nearest day) covered by each dataset below (listed in the order collected).

- **Dataset A** Data collected from dedicated beam studies in which select injector beamline components were systematically varied and downstream responses recorded. Date: 2020-09-08 (swing shift) and 2020-09-14 (swing shift). Size:  $654 \times 223$ .
- **Dataset B** First attempt at mining the operational archiver for “good beam”. Date: 2020-08-30 to 2020-09-18. Size:  $24 \times 302$ .

Figure 3: Ranges of the Scaled setting (upper) and Reading (lower) PVs, color coded by data split.

- **Dataset C** Mining the operational archiver for “good beam” (using less stringent constraints). Date: 2020-08-01 to 2020-09-21. Size:  $5467 \times 303$ .
- **Dataset D** Mining the operational archiver without imposing “good beam” constraints. Data was collected and averaged over each second of the Fall 2020 operational run. Date: 2020-08-01 to 2020-09-20. Size:  $409\,549 \times 318$ . (This represents an initial filtering for beam-on conditions.)
- **Dataset E** Mining the historical archiver without imposing “good beam” constraints. Data was collected hourly for the last two years. Whereas the operational archiver stores machine data from the last several months, the historical archiver contains data from the previous few years. Date: 2019-02-01 to 2021-01-30. Size:  $17\,520 \times 262$ . (The period from 2020-09-20 to 2021-01-30 represents a scheduled accelerator down period and contains no useful data.)

Several observations can be made. First, many of the datasets contain overlapping dates. Second, each dataset records a different number of PVs. Finally, there is a clear evolution in data collection strategy: It started with conventional beam studies efforts where knobs were varied and

responses recorded (Dataset A). While this provided several hundred examples, both the complexity of the problem we are trying to solve and the means with which to solve it (deep learning) necessitates *much* more data. We then transitioned to mining the archiver for PV values. Initial efforts placed the burden on carefully designing constraints so as to ensure that we collected only PVs corresponding to “good beam”. This resulted in several thousand examples (Dataset C). We then transitioned to a mode of a collecting data from the archiver at regular intervals (either hourly or every second) with no filtering. This shifted the burden of extracting the appropriate data for training models from the data collection effort to the data pre-processing step.

### Cleaning the Data

Because the dates of Dataset D overlap those the three previous datasets (A, B, and C), we now focus only on Datasets D and E. Some initial “cleaning” of the data involved clerical matters—reformatting, renaming columns, combining and the like. The more significant matters included various filters applied to the data:

- Refine filtering from “beam on” to “beam being on” and transported to the end of the injector.

- Remove those (few) columns that contain a large number of NaNs.
- If a column contains a missing value (e.g., NaN), remove the associated row (across all columns).
- Some PVs take only integer values (e.g., 0 or 1). Because of the averaging the entries occasionally have non-integer values, indicating a change of state. Remove those rows.

After combining the resulting versions of Datasets D and E, removing duplicate rows, and retaining only the common set of PVs (there are 235), we arrive at a dataset of size  $406\,397 \times 235$ .

### Partitioning the Data

Regardless of neural network architecture, one needs a well-defined set of inputs that the model learns to map to a well-defined set of outputs. Our next step here involves partitioning the 234 PVs (we exclude the Date column) into appropriate Setting and Reading datasets. At first, we define a *Setting* as any PV that an operator can adjust during routine beam tuning. These include phase and gradient set-points of radio-frequency (rf) cavities, solenoid strengths, corrector strengths, and the like. A *Reading*, on the other hand, we characterize as read-backs of various diagnostic systems. These include readings from beam loss monitors (BLMs), beam position monitors (BPMs), vacuum signals, beam current monitors (BCMs), and statistical descriptions of the beam as extracted from a synchrotron light monitor (SLM) image. In the end, we identify 108 Setting and 126 Reading PVs.

Executing a partition, however, proves less obvious than it sounds. Consider the beam current monitors: Should they count as Readings, as seems obvious, or as Settings? The BPM wire-sum signals, clearly Readings, act as a proxy for the beam current, which would seem to be a Setting. Depending on the details of a given ML architecture, we might want the model to learn the BCM current readings from BPM wire sums, or learn the wire sums from the BCM readings. In either of these cases, we shall have to reclassify some PVs from Readings to Settings. Or perhaps we ought to add laser power PVs as Settings, so as to capture an alternate proxy for the beam current treated as a Setting.

In the course of this review of PVs, we identified other issues: Several PVs do not appear in the data, including settings for one of the rf cavities and readings from several vacuum PVs. In addition, solenoids and correctors appear in the data, but quadrupoles do not. With regard to excluding the quadrupole PVs, the initial thinking was that quadrupoles

do not often change value, and static (or nearly static) training data contains very little not serve to teach a given ML model. Whether to include then in the future requires further consideration.

For future data collection efforts, each injector PV need to be examined and a decision made as to whether or not to include it in the dataset for addressing the problem at hand. Moreover, those PVs should be explicitly defined at the outset, so as to ensure that all subsequent data collection efforts include a common, consistent set of PVs.

## FUTURE WORK

Two primary challenges underlie the construction of a Smart Alarm system. The first is feature selection/down-selection, and the second is choosing an appropriate model. We will explore the use of different feature selection tools to develop reduced representations of given datasets. In addition to auto-encoders, we plan to develop both linear and nonlinear classifiers, including the possible use of neural networks and decision trees as nonlinear classifiers. We will compare the performance of different classifiers trained using supervised learning and establish some general heuristics for fault detection on this type of injector. We will begin by identifying a few simple fault scenarios, and then build on this to include a range of different faults, including those caused by coupled errors within the machine. We will also explore the use of unsupervised learning to train classifiers. Algorithms such as DBSCAN, gaussian mixture modeling, and agglomerative clustering are well suited for clustering a variety of distinct types of data. Once trained, those models can track the vicinity of a given machine state to the locations of distinct clusters determined from training.

## CONCLUSION

Data provides the fuel for machine learning. In the context of the CEBAF injector, we are still learning how best to collect and curate the appropriate data for training our models. The archiver provides a rich—though largely under-utilized—source of data. Using the toolkit of data science, we believe there is potential for a deeper understanding of machine performance from data that has already been collected.

## Abstract

We present recent developments on control of x-ray beamlines for synchrotron light sources. Effective models of the x-ray transport are updated based on diagnostics data, and take the form of simplified physics models as well as learned models from scanning over mirror and slit configurations. We are developing this approach to beamline control in collaboration with several beamlines at the NSLS-II. By connecting our online models to the Blue-Sky framework, we enable a convenient interface between the operating machine and the model that may be applied to beamlines at multiple facilities involved in this collaborative software development.

## INTRODUCTION

Electron storage ring based light sources and x-ray FELs provide radiation for a vast array of scientific research. The radiation is created in either undulator or bending magnet sources and then passes down an optical beamline, transporting the radiation to the sample for use in a scientific study.

Although modeling of beamline components and x-ray transport plays an important role in the design and commissioning of x-ray beamlines, these methods are largely unused during day to day operations. In comparison to the electron beam storage ring, in which reduced models combined with diagnostics play a crucial role in electron beam control, little has been done on the x-ray beamline side regarding such methods.

Modeling codes for x-ray beamlines can generally be broken into two classes, either wavefront propagation or ray tracing. The two most widely used codes of these types are Synchrotron Radiation Workshop (SRW) and Shadow. Whereas in principle, either of these codes could be suitable for an online model, there are some deficiencies which we look to improve. In particular, ray tracing methods, though fast and accurate, do not take into account diffraction effects or the effects of partial coherence. Wavefront propagation, on the other hand, while including diffraction effects, is substantially more computationally intensive, particularly when partially coherent computations are required.

We propose two types of simplified models that provide additional tools with which to build fast online models for

x-ray beamlines. The first is a physics based model based on what we call a *Matrix-Aperture Beamline*[1]. And the second type of model is a surrogate model using the methods of machine learning on either simulated or measured training data. We describe our progress on the development of each of these types of models and their application to x-ray beamlines at NSLS-II at Brookhaven National Laboratory.

Next, in order to create an accurate online model that ties the beamline and photon beam status to a software model, we must make measurements at beamline diagnostics and take into account beamline component positions using the existing beamline control software. For this purpose, we use the BlueSky software, developed at NSLS-II, but with a goal for wider adoption across the world of synchrotron light sources in the US and beyond.

We document here our continuing efforts to improve this situation by creation of online models in synchrotron light sources that may be used for automated beamline control. We are working with the TES bending magnet beamline at NSLS-II [2], and thus draw our simulations and control examples from this beamline.

## REDUCED PHYSICS MODELS

Our reduced physics models are based on the concept of a *Matrix-Aperture-Beamline*. We call the code we are building to implement this concept MABTrack, and a diagram for the case of two apertures is shown in Fig. 1. The MABTrack code is being developed on GitHub in the *rslight* repository<sup>1</sup> and will be available as an open source package.

The MABTrack code starts with a model in SHADOW to compute reference orbit  $\vec{z}_0(s)$ , ABCD matrices  $M_j(s)$  and physical apertures  $t_j(\vec{x})$ . Three levels of sophistication in modeling are being developed within MABTrack. At the simplest level, one computes the propagation of the radiation second moment matrix  $\Sigma(s)$ , defined as  $\Sigma_{jk}(s) = \langle \vec{z}_j \vec{z}_k \rangle$  with  $\vec{z}(s) = \vec{z}(s) - \vec{z}_0(s)$ , i.e. subtracting off the reference orbit. The second moments propagate as

$$\Sigma(s) = M(s)\Sigma_0 M^T(s) \quad (1)$$

with  $\Sigma_0$  as the initial values of the second moments.

As a second level of sophistication, we will use *linear canonical transforms* (LCTs) to transport wavefronts [3]. LCTs have an intimate connection to the so-called *ABCD*

\* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, including grant No. DE-SC0020593

<sup>1</sup> <https://github.com/radiasoft/rslight>

Figure 1: Structure for MABTrack, Matrix Aperture Beamline Tracking code for the case with 2 physical apertures  $t_1(\vec{x})$  and  $t_2(\vec{x})$ . Transfer matrices ( $M_0$ ,  $M_1$ , and  $M_2$ ) are assumed to be known, either analytically, or via a ray tracing code such as Shadow. Either electric fields  $E_0(\vec{x})$  or Wigner functions  $W_0(\vec{z})$  may be propagated through the beamline.

matrices of ray optics, and constitute a generalization of the various integral transforms—including Fresnel transforms, Fourier transforms, fractional Fourier transforms, scaling, and chirp multiplication (multiplication by a Gaussian)—used for computations in wave optics. In one degree of freedom, one may write the LCT of a function  $g$  in the form [3]

$$\tilde{g}^M(u) = e^{-i\pi/4} \sqrt{\beta} \times \int_{-\infty}^{\infty} \exp[i\pi(au^2 - 2\beta uu' + \gamma u'^2)] g(u') du'. \quad (2)$$

As an alternative to the parameters  $\alpha$ ,  $\beta$ ,  $\gamma$ , one may instead parameterize 1D LCTs in terms of the entries of a  $2 \times 2$  symplectic matrix  $M$ —an  $ABCD$  matrix, the superscript seen on the left-hand side of (2)—according to the rule

$$M = \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} \gamma/\beta & 1/\beta \\ -\beta + \alpha\gamma/\beta & \alpha/\beta \end{pmatrix}. \quad (3)$$

When computed naïvely, the integral transform (2) represents a computationally expensive task. To address this difficulty, one may take advantage of the *group property* of the LCT, which states that

$$\tilde{g}^{M_2 M_1} = \tilde{g}^{M_2} \circ \tilde{g}^{M_1}. \quad (4)$$

This property tells us that if one can factor the matrix  $M$  into a product of (simpler) matrices  $M_1$  and  $M_2$ , and if one can easily compute the LCTs corresponding to those simpler matrices, then one may easily compute the full LCT by composition. This remains true even if when we factor  $M$  into a product of more than two matrices.

In special cases, the LCT becomes quite tractable. In the case  $\alpha = \gamma = 0$  and  $\beta = 1$ , for example, the LCT becomes, apart from a normalization, a Fourier transform. Other choices of the parameters lead to the other well-known transforms mentioned above, for which fast algorithms are known. Moreover, it is always possible to factor  $M$  into a product of matrices corresponding to such transformations. Indeed, there exists a substantial literature on this topic. See, for example, [4–10]. It is worth mentioning that, as described in some of the references, that the general procedure described above works also for 2D LCTs. In addition, we mention that, despite the large literature, it appears that

no (publicly available) LCT library currently exists. Hence the need to write one of our own.

To implement the LCT, we have begun with the case of one degree of freedom, and have implemented (i) some needed utility functions, (ii) the component LCT functions, and (iii) functions to decompose the given LCT into simpler parts and to compose the resulting component LCTs. Because this code is being written in Python, we make—in writing all these functions—extensive use of `numpy`<sup>2</sup>, a high-performance numerical library for Python.

The mentioned utilities enable us to convert between parameters  $a$ ,  $b$ ,  $c$ ,  $d$  and  $\alpha$ ,  $\beta$ ,  $\gamma$  (`convert_params_3to4` and `convert_params_4to3`); construct the abscissae for a given signal (`abscissae`); and resample a given signal (`resample_data`), which is needed because chirp multiplication increases the effective time-bandwidth product [5, 9]. All these utilities have been implemented and tested.

For the component LCTs, we need scaling (`scale_data`), the Fourier transform (`fourier`), and chirp multiplication (`chirp_multiply`). All three of these have been written, and we are in the process of testing.

The remaining functions we need are one for decomposing a given LCT into simpler parts (`lct_decompose`), and a second for composing the component LCTs (`apply_lct`). These functions have also been written, and they have passed some (rather trivial) tests. Final testing will happen after we complete testing of the component LCTs. When the LCT algorithms have been tested, they will be integrated into MABTrack. This effort will then be generalized to 2D LCTs.

The final level of sophistication in MABTrack involves direct propagation of Wigner functions which allows for inclusion of partial coherence. See [11] for details of this approach. Alternate approaches to partial coherence include propagation of the cross spectral density (Fourier transform of Wigner function), macroparticle (MP) sampling of the electron beam distribution and coherent propagation, and Coherent Mode Decomposition (CMD), leading to a smaller number of coherent modes than the MP method. We will explore all these methods, comparing efficiency to decide on our partially coherent model. As a fast CMD method has recently been implemented in SRW, we will be applying this to bending magnet and undulator beamlines and then performing the coherent propagation via LCT using the computed ABCD matrices from Shadow.

## MACHINE LEARNING MODELS

Preliminary efforts to apply ML algorithms to learn a surrogate beamline model were reported in [1] in which a sample KB beamline was used to train a neural network with SRW simulations to reconstruct mirror errors. We have since generalized the tools for the SRW simulations, integrating them into our Sirepo GUI interface to SRW<sup>3</sup>. The data generated by the resulting simulations can then be used to train ML algorithms. We have included more elements in the

<sup>2</sup> <https://numpy.org/>

<sup>3</sup> <https://www.sirepo.com/srw#>

Figure 2: Horizontal (blue) and vertical (orange) beam-size propagation in the beam statistics report for the TES beamline.

interface for the data generating scripts initially developed as part of Phase I. In particular, we have implemented the following new elements and their corresponding parameters:

- aperture (position, and horizontal and vertical size);
- circular cylinder (position, rotation, and radius);
- toroidal mirror (position, rotation, and tangential and sagittal radii).

Figure 3 shows a screenshot of the interface for these new elements.

Continuing to develop our ML beamline capabilities, a subset of the NSLS-II development team worked on the Deep Beamline Simulation software.<sup>4</sup> That effort aims to train neural networks on solved problems, with the goal of lowering the computational cost of x-ray beamline simulations by using machine learning to simulate beamlines with a fidelity similar to SRW. We want to determine whether or not a neural network trained on data generated by previously created simulation tools (Sirepo-Bluesky, SRW, Shadow) can effectively identify relevant patterns and then solve newly-posed problems of similar type. In Fig. 4 we show some preliminary results from that effort. Tensorboard has been used to plot the loss function as the network learns the distribution resulting from varying a physical aperture in the beamline.

## INTERFACE WITH BLUESKY BEAMLINE CONTROL SOFTWARE

The BlueSky software<sup>5</sup>[12] allows beamline scientists to control their beamline while performing x-ray experiments. BlueSky plans are created which lead to motion of beamline components such as mirrors, monochromators, slits, etc. In order to connect the physical beamline to a simulated beamline, the Sirepo-Bluesky library.<sup>6</sup>[13] has been created. Sirepo allows access to beamline simulation codes such as

SRW and SHADOW, and will also include the MABTrack code when completed.

We have addressed a number of topics to improve the Sirepo-Bluesky library. When first developed, the library focused on supporting the SRW simulation code within Sirepo. After their recent refactoring of the library, the team added support for the Shadow simulation code within Sirepo. This effort has resulted in a more modular code: Support for SRW and Shadow are now implemented in separate Python modules, which provides for a cleaner separation between corresponding classes. This work included the creation of corresponding tests for the newly added features, as well as updates to the previous tests to ensure that new additions do not cause any regression or performance issues. As part of updating the testing framework, we changed the Continuous Integration (CI) service provider from TravisCI to GitHub Actions. This change allows us to run the tests free of charge, and also provides a more reliable and future-proof infrastructure.

Now that Shadow has been integrated into Sirepo-Bluesky, one may perform the same Bluesky scans as were formerly possible, but now with *either* SRW or Shadow as the underlying engine. Scans of interest include counts read from Sirepo's virtual "detector", step scans of a single parameter scanned over a range of values, and grid scans of multiple parameters over multiple ranges of values. In addition, the new integration of Shadow into Sirepo-Bluesky provides access to the Beam Statistics Report implemented in Sirepo-Shadow.

Because RadiaSoft personnel lack direct access to the BNL environment, but want to perform testing in as similar an environment as possible, we examined the possibility of using `sirepo.lib` (part of Sirepo) for working with Sirepo simulations in the absence of a server. Enhancements to the local development environment that better support Jupyterhub now allow developers to run Sirepo-Jupyter on their local machine for faster testing of new features in Sirepo-Bluesky.

Figure 3: New beamline elements and their parameters for data generation. When the user provides a range of parameters, a script is produced that allows SRW to be run using `rsopt`, and will compute intensity data over the entire parameter range given.

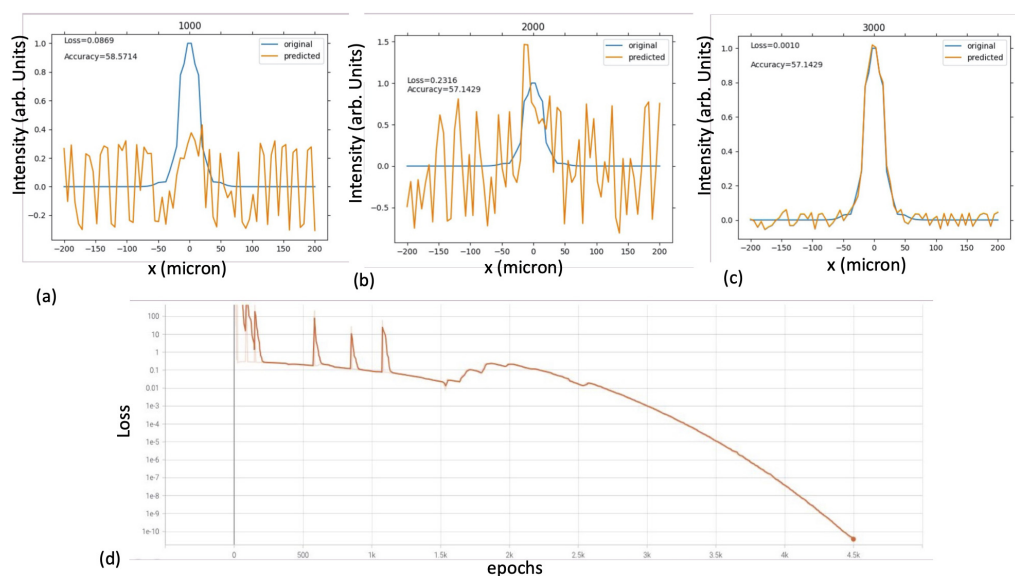

Figure 4: Tensorboard plots of loss function with varying epoch of (a)1000, (b)2000, and (c)3000. Gaussian radiation is produced in SRW, and a simple beamline with an aperture at 25 meters is varying, with the intensity observed at a watchpoint of 27 meters. (d) shows the accuracy as a function of all epochs during the learning process.

## TES BEAMLINE MEASUREMENTS

Preliminary beam size measurements were carried out by Yonghua Du on the TES beamline, allowing us to begin comparison with the different types of propagation models. The TES beamline as set up in Sirepo SRW is shown in figure citefig:TES.Sirepo.SRW. The layout for where the measurements were taken are shown in Figure 6. See [2] for more details about the layout and instrumentation of the TES beamline.

The beam size was measured at three positions: the fluorescent screen (FS) at  $\sim 50.242$  m, the secondary slit aperture (SSA), and at the K-B mirror in the end station. The FS is mounted on the micrometer, which allows a measurement of the full horizontal beam size of  $\sim 1.5$  mm. The beam size at the SSA was measured on the basis of SSA slit position and ion chamber (IC0) current. The full horizontal beam

size is  $\sim 0.6$  mm and vertical beam size is  $> 0.44$  mm where  $\sim 50\%$  flux passed. The beam size at the K-B mirror was measured using the K-B step motor and the YAG crystal at the sample stage. The full horizontal beam size is  $\sim 1.1$  mm and full vertical beam size is  $\sim 0.45$  mm. During the measurement, we found that the vertical focusing point of the beam from toroidal mirror is between the KBV and sample position, not at the SSA. Comparison of these measurements to TES SRW simulations and moment propagation is ongoing, and improvements to the TES diagnostics are foreseen.

## CONCLUSION

We have summarized our recent efforts to create reduced models suitable for an online model of x-ray beamlines and to allow access to these models integrated within the beamline control software, Bluesky. Working with the TES beam-

Figure 5: TES beamline in Sirepo SRW.

## TES Beam size measurement

line, we are attempting a proof of principle demonstration of the creation of such an online model that will facilitate automated beamline control and reconfiguration.

## Abstract

The Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Laboratory is a CW recirculating linear accelerator (linac) that utilizes over 400 superconducting radio-frequency (SRF) cavities to accelerate electrons up to 12 GeV through 5-passes. Recent work has shown that given RF signals from a cavity during a fault as input, machine learning approaches can accurately classify the fault type. In this paper, we report initial results of predicting a fault onset using only data prior to the failure event. A dataset was constructed using time-series data immediately before a fault (“unstable”) and 1.5 seconds prior to a fault (“stable”) gathered from over 5,000 saved fault events. The data was used to train a binary classifier. The results gave key insights into the behaviour of several fault types and provided motivation to investigate whether data prior to a failure event could also predict the type of fault. We discuss our method using a sliding window approach. Based on encouraging initial results, we outline a path forward to leverage deep learning on streaming data for fault type prediction.

## INTRODUCTION

The Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Lab is a high power, continuous wave recirculating linac servicing four different experimental nuclear physics end stations [1]. CEBAF completed an energy upgrade in 2017 with a goal of effectively doubling its energy reach from 6 GeV to 12 GeV. The upgrade required the installation of 11 additional cryomodules, named C100s denoting their capability for providing 100 MV of energy gain. A schematic of CEBAF with locations of the new C100 cryomodules is provided in Figure 1. Each cryomodule is composed of 8 superconducting radio-frequency (SRF) cavities. In addition, a digital low-level radio frequency system (LLRF) is implemented to regulate the new cryomodules.

CEBAF experiences frequent short machine downtime trips caused by SRF system faults, particularly when the cavity gradients are pushed to their upper limits. A significant portion of the SRF system faults occur within the C100 cryomodules. Consequently, a data acquisition system is implemented to record data from these cryomodules to investigate the nature and the origin of the SRF faults. The system is configured to record time-series

Figure 1: CEBAF schematic with locations of C100 cryomodules.

waveform data when any of the C100 cavities fault. These recorded waveform data are analyzed by a subject matter expert (SME) to determine the cavity that caused the trip, and the type of fault. In previous studies we have investigated the possibility of using artificial intelligence (AI) techniques to automate this highly tedious waveform analysis process [2, 3]. It is quite helpful to expedite the beam recovery process with fast automated cavity fault identification after an event. However, it may be further beneficial to investigate the possibility of using AI to predict RF failures beforehand in order to reduce certain faults from occurring. While the data acquisition system is being upgraded for compatibility with such predictive models, we conduct a feasibility study for RF fault prediction using currently available data.

## CAVITY FAULT CLASSIFICATION

The cavity fault classification is posed as a supervised machine learning (ML) problem, with ground truth fault labels for recorded data provided by SMEs. The data used for the classification task is the full time-series waveforms pertaining to each fault event recorded by the data acquisition system. The entire time-series waveform represents approximately 1638.4 ms (from  $t = -1536$  ms to

\* This work is supported by the U.S. Department of Energy, Office of Science, Office of Nuclear Physics under Contract No. DE-AC05-06OR23177.

<sup>†</sup> lasithav@jlab.org

Figure 2: Waveform captured by the data acquisition system. The total duration of the waveform is 1.64 seconds.

$t = +102.4$  ms) comprised of both pre-fault and post-fault signals as shown in Figure 2. Waveforms are sampled at a constant rate of 5 kHz. We record 17 different RF signals from each C100 cavity, and a selection of these are used for analysis. In effect, the classification task uses both pre-fault and post-fault waveforms to identify the cavity that failed and the type of fault in a given cryomodule. Detailed discussions on the classical ML and deep learning (DL) models developed for cavity fault classification and associated performance characteristic can be found in [3, 4]. Table 1 summarizes the performance of ML and DL models for cavity fault classification with testing data. The best performing ML models are deployed within CEBAF.

Table 1: Cavity and Fault Type Classification Accuracy

	Cavity Identification	Fault Classification
ML Model (%)	88.0	86.9
DL Model (%)	87.8	81.3

Note that the classification task exploits both pre-fault and post-fault data to achieve the model accuracy shown in Table 1. However, a fault prediction model can only utilize data prior to a fault event to make predictions on an impending fault. Moreover, fault prediction must be performed at the cavity level as prediction of a fault would inherently identify the associated cavity. We therefore conduct the feasibility study for fault prediction as a two-step process as follows: 1) we define a binary classification task to identify waveforms describing impending faults, and 2) a moving window based multi-class classification task to predict the type of failure before onset.

## BINARY CLASSIFICATION TASK

Binary classification task is designed to investigate the possibility of distinguishing waveforms representing imminent faults from waveforms representing stable running conditions.

## Dataset

The dataset utilized for this study consists of a total of 5,047 fault events. Table 2 summarizes the dataset composition with respect to fault types.

Table 2: Fault Prediction Dataset

Fault Type	Number of Events
Single Cavity Turn Off	885
Microphonics	710
100 ms Quench	608
Controls Fault	847
Electronic Quench	673
3 ms Quench	542
Heat Riser Choke	720
Unknown	62

The current data acquisition system is set up to collect data only in the event of a RF cavity trip (see Figure 2). Note that approximately 94% of the captured waveform ( $t < 0$ ) represents pre-fault activity, with  $t = 0$  the fault onset, and  $t > 0$  the post-fault data. Therefore, we utilize 100 ms segments extracted from the waveforms to represent stable running and impending fault classes as follows: for stable running, extract a 100 ms segment from the earliest possible window of the captured waveform (annotated as “Stable running” in Figure 2, with a window of  $[-1536$  ms,  $-1436$  ms]). Segments of this region are verified by SMEs as sufficient representations of stable running conditions. For the impending fault, we extract a 100 ms window as close as possible to the fault onset (annotated as “Impending fault” in Figure 2). Accordingly, we extract impending fault segments with a window of  $[-105$  ms,  $-5$  ms], with a 5 ms buffer to ensure that fault onset activity is not inadvertently captured. As a result, for the binary classification task we obtain 5,047 examples. Additionally, we retain labels of the underlying fault type in the

waveforms representing the impending fault phase to perform a follow-up analysis on the feasibility of predicting fault types.

Prediction Model and Training

We develop a deep recurrent neural network (DRL) architecture to process the time-series for the binary classification task. The detailed architecture is shown in Figure 3.

Figure 3: DRL architecture for binary classification of pre-fault data.

The 100 ms segments extracted for this study represents time-series data with each 500 time steps long. The Long Short Term Memory (LSTM) [5] layers in the above model processes the time-series input, and the corresponding features are classified at the last layer (softmax activation). The architecture and the training scheme is developed using the PyTorch deep learning library [6]. The data is divided with fault based stratification to obtain 60% for training, 20% for validation, and the remaining 20% for testing.

Binary Classification Results

The confusion matrix obtained from the testing data is

Figure 4: Confusion matrix for classification of stable running versus impending fault.

shown in Figure 4. The overall testing data classification accuracy is 74.74%. Detailed testing results are summarized in Table 3. However, the confusion matrix shows a distinct issue in the models ability to recognize many impending fault events correctly, highlighted by the large false negative percentage (23.48%). This is also

observed in Table 3 where the recall rate for impending fault, and the precision for stable running classes are both low.

Table 3: Binary Classification Performance

Class	Precision	Recall	F1-score
Stable running	67.8%	96.5%	79.6%
Impending fault	93.4%	51.8%	66.7%

This behavior indicates that certain impending fault segments may closely resemble stable running conditions prior to fault onset, to a degree that the model is unable to distinguish between the two classes. We speculate that certain fault types identified by SMEs may not present sufficient precursors within the waveforms we use for the analysis. In order to further investigate this issue, we take a closer look at the fault types that represent the false negatives. Figure 5 shows the distribution of false negative events in terms of the ground truth fault type.

Figure 5: Percentage of events with false negative classification according to fault type.

It is evident from Figure 5 that the false negatives are dominated by events from ‘Single Cav Turn Off’, ‘E\_Quench’, and ‘Controls Fault’ fault types. Upon discussion with domain experts, it was confirmed that these fault types oftentimes require ancillary data for correct identification due to the lack of precursors present in the waveforms used for the study. Therefore we conducted a secondary experiment where we discard events from the three aforementioned fault types and obtain a secondary dataset of 2,642 fault events. We use the same model architecture, and follow the same training procedure. The model achieves a classification accuracy 92.1% for this dataset.

FAULT TYPE PREDICTION TASK

Given encouraging results from the binary classification task, we investigate the possibility of predicting the fault type before the onset of beam trip. In order to quantify the ability to predict the fault type with respect to the onset, we define a window-based analysis on the waveform data that we have collected. Specifically, a window of a specific

Figure 6: Window based fault prediction analysis scheme.

length  $l$  is positioned over the waveform data, centered on a time stamp  $t$  before the onset of the fault, as illustrated in Figure 6. The data that falls within the window is extracted to perform analysis on fault prediction. This is repeated over window locations that incrementally move from  $t = -600$  ms to 0 ms in 50 ms intervals. The value of  $-600$  ms is chosen as the furthest time stamp prior to the fault event based on suggestions of domain experts, and 0 ms denotes the fault event onset.

## Dataset

We utilize the same dataset described in Table 2 as our base dataset. The window-based analysis in Figure 6 results in multiple experiments conducted over each window location. In essence, for a given window location  $t$ , data that falls within the window is extracted from all examples to create training, validation, and testing sets specific to location  $t$ . Analysis using this data yields fault prediction performance for  $t$  ms prior to fault onset. In addition to multiple window locations, we also experiment with the effect of window size on prediction performance using lengths of  $l = 100$  ms, 200 ms, 300 ms.

## Prediction Model and Training

We utilize the same general deep LSTM architecture shown in Figure 3 for this analysis. However, fault type prediction is essentially a multiclass classification task. Therefore, we augment the classification layer of the network to accommodate 8 fault classes. The same training and testing procedures used in the binary classification task are leveraged for each window dataset. Model development, training, and testing is performed using the PyTorch library [6].

## Fault Type Prediction Results

Although the prediction network is trained and tested for each window experiment in a multiclass manner, we inspect the prediction performance for each class separately. This allows for observing the prediction efficacy for each fault more efficiently, considering the insights obtained through the binary classification task. Figure 7 shows performance of the prediction model plotted as a function of time prior to onset of “Microphonics”, and “E\_Quench” fault types. The horizontal axis of the plots shows the center of the window used to extract data for the prediction task. For instance,

Figure 7: F1-score plots for the window based fault type prediction of microphonics and electronic quench fault types.

the F1-score at -600 ms for a given fault type indicates the model's ability to predict the fault type 600 ms prior to the fault onset. We also observe that the predictive power of the model is highly dependent of the type of fault. For instance, the model is able to predict microphonics faults

Figure 8: Fault specific model prediction performance for the case of 300 ms data window centered at -200 ms.

with over 0.5 F1-score from -600 ms with significant improvements with window locations closer to onset. Conversely, the model is unable to predict E\_Quench events with acceptable accuracy until the window overlaps the fault onset. Figure 8 shows a snapshot of the fault dependent prediction performance for the case of 300 ms data window centered at -200 ms (200 ms before the fault onset).

This analysis further demonstrates that certain faults such as microphonics show precursors prior to onset, which can be used to predict the faults prior to a trip. The analysis also provides insights into several fault types that may not show precursors due to their nature, or may not be sufficiently captured in the waveforms used in this study.

## FUTURE WORK

We have discussed our initial studies into the possibility of automated prediction of RF faults in C100 cavities using

Figure 9: Preliminary framework for using machine learning models with continuously streaming data.

ML models. The investigations have yielded promising results, with insights into the possible prediction time ranges for multiple fault types. However, this study leverages static RF fault data. An effective fault prediction framework would require a data acquisition system that is able to stream the data signals in real-time during CEBAF operation. The C100 modules, and the associated LLRF systems, are currently undergoing a firmware upgrade to

allow the collection of streaming data. This will provide valuable information regarding variations encountered in stable running conditions, and possible non-RF related fault events in CEBAF.

Streaming data provides an opportunity to further improve and adapt the machine learning models to predict faults before they occur. To that end, we envision a data processing framework as shown in Figure 9. According to the preliminary framework, the prediction model gets direct access to the continuous data to make predictions on stable running versus impending fault, with probable fault type in real-time. The framework also allows storing select subset of the data for the purposes of routine model performance evaluation, developing new models, re-training and fine-tuning of the deployed models. We also envision the C100 firmware upgrades and the proposed streaming data processing framework will generate significant amounts of information-rich data that may be useful to diagnose other CEBAF machine events beyond SRF cavity faults.

## HARDWARE DESIGN

### Power Driver Topology

The power driver is based on a simple buck DC-DC voltage regulator [8], which has its output voltage controlled by an input voltage ( $V_C$ ) applied to a series resistor ( $R_C$ ) at the feedback node, as shown in Fig. 2:

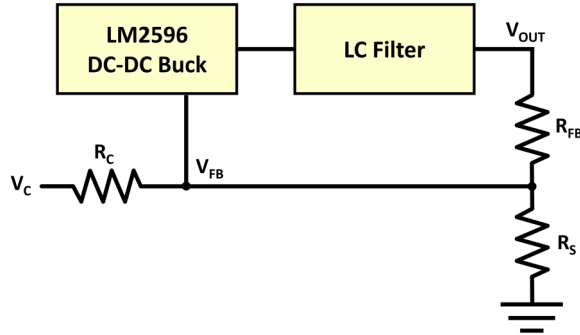

Figure 2: LM2596 Control Principle.

Assuming a DC-DC stable control loop, the feedback node voltage ( $V_{FB}$ ) is fixed at 1.3V [8]. Considering the current drawn by the regulator feedback node ( $I_{FB}$  10nA typical [8]) can be neglected, the output voltage is a linear function of control voltage ( $V_C$ ) described by Eq. (1):

$$\frac{V_{OUT}-V_{FB}}{R_{FB}} = \frac{V_{FB}}{R_S} + \frac{V_{FB}-V_C}{R_C} \quad (1)$$

The maximum output voltage can be obtained by Eq. (2), assuming  $V_C$  at 0V and LM2596 input voltage higher than  $V_{OUT\_MAX}$ :

$$V_{OUT\_MAX} = V_{FB} \left( 1 + \frac{R_{FB}(R_S+R_C)}{R_S R_C} \right) \quad (2)$$

Similarly, assuming 0V the desired minimum output voltage, solving Eq. (1) at this condition, the maximum control voltage can be obtained, as shown in Eq. 3:

$$V_{C\_MAX} = V_{FB} \left( 1 + \frac{R_C(R_S+R_{FB})}{R_S R_{FB}} \right) \quad (3)$$

These equations were used to determine resistors values to 12V maximum output voltage at 15V power supply. The control voltage is generated by a PWM signal applied to a Sallen-Key second-order low-pass active filter [9] ( $C_1=C_2=100\text{nF}$  and  $R_1=R_2=100\text{k}\Omega$ ) designed to limit bandwidth at 16Hz, transfer function shown by Eq. (4):

$$H(s) = \frac{1}{1+2RCs+(RCs)^2} = \frac{1}{1+0.02s+10^{-4}s^2} \quad (4)$$

The control bandwidth is expected to be limited by this filter, once the internal control loop response of the bulk regulator is considerably faster than 16Hz.

A current limiter is designed based on an analog comparator switching a PNP transistor that injects current directly at LM2596 feedback node. Since the load current overcomes the configured DAC threshold, the transistor turns on, dropping the LM2596 output voltage.

The power driver has been designed to provide 12V output voltage, however the hardware can be easily adapted to provide 24V output. This modification allows each channel to deliver up to 36W (1.5A at 24V) for higher power heaters, as used in Tarumã cryogenic experimental station [5].

### Signal Acquisition

Multiple channel 12-bit ADCs (AMC7812B) acquire 24 analog voltages. Conditioning circuits with rail-to-rail single supply operational amplifiers were designed for ADC protection and signal conditioning. Therefore, the device perform 3 measurements per channel:

- The voltage across a shunt resistor, measuring the output current indirectly.
- The output voltage.
- The control voltage (Fig. 2  $V_C$ ), inversely proportional to the PWM input duty cycle.

Passive anti-aliasing filters are included at ADC inputs.

### Additional Features

Optocoupled normally open enable inputs were designed to prevent power deliver in critical failure situations. These inputs are tied directly to LM2596 enable pins, that is, they are not firmware dependents.

Based on voltage and current diagnostics is possible to deduce open-load and short-circuit failures, triggering 5V TTL compatible optocoupled outputs at the rear panel.

## FIRMWARE ARCHITECTURE

The microcontroller LPC1768 is programmed using Mbed framework [10], running Mbed Os 2 as real-time operating system, arranging tasks in 4 separate threads:

- **Main thread:** running at normal priority, responsible for Ethernet reconnection in case of failure, device startup configuration and save persistent data into internal Flash.
- **Sampling thread:** running at real-time priority, this thread samples ADCs at 100 samples per second and applies a digital filter.
- **Webserver socket thread:** running at normal priority, a TCP socket server is available at port 80, in which a HTTP server is implemented for quick diagnostics.
- **TCP socket thread:** running at normal priority, this thread implements a TCP socket server at port 6767 with a question/answer protocol command list to configure the device and read diagnostics data. The IOC (Input/Output Controller) makes use of this connection to integrate the device with EPICS control system.

The sampling thread performs an exponential moving average IIR (Infinite Impulse Response) filter, as shown in Eq. (5).

$$y[n] = (1 - \alpha)y[n - 1] + \alpha x[n] \quad (5)$$

Considering 100 samples per second and  $\alpha$  equals to 0.17, the cutoff frequency is 3Hz, as shown by Eq. (6):

$$f_{3dB} = \frac{F_s}{2\pi} \cos^{-1} \left( 1 - \frac{\alpha^2}{2(1-\alpha)} \right) \cong 3Hz \quad (6)$$

## MECHANICAL DESIGN

The driver is enclosed in a 1U 19" rack mount metallic case, as shown in Fig. 3. Two power supplies provide board voltages:

- 15V up to 13.4A (200W) to power drivers.
- 5V up to 5A (25W) to logic and I/O's (Inputs and Outputs).

Figure 3: Mechanical Assembly.

The front panel, shown in Fig. 4, displays channels status, provides a main switch, ethernet input and USB input for firmware updates.

Figure 4: Front Panel.

At the rear panel, shown in Fig. 5, the AC line input and 2A fuse are connected to power supplies and 5 25-pin Dsub connectors provide output power to heaters and I/O's to controller: Control Input, Failure Output, Interlock/Enable Input, Power Output (2x).

Figure 5: Rear Panel.

## RESULTS

### Electronics characterization

Due to hardware limitations, the output response is linear from 10% to 85% PWM duty cycle, as shown in Fig. 6, obtained delivering power to 20Ω loads. PWM frequency has been adjusted to 1kHz.

Figure 6: Output Linearity.

As mentioned in Hardware Design section, the driver bandwidth is limited by the Sallen-Key filter, designed to cut-off over 16Hz. Figure 7 shows driver frequency response, that has been obtained using a sinusoidal modulated 1kHz PWM signal delivering power to 20Ω loads. The sinusoidal signal modulates from 20% to 80% duty cycle with 100mHz to 100Hz variation. The normalized output refers to peak-to-peak AC load voltage at a given frequency.

Figure 7: Single-channel Frequency Response.

The null-input output noise presents 100kHz 60mVpp spikes, shown in Fig. 8. At this condition, 31.75mV DC voltage is applied to 20Ω loads.

Figure 8: Output Voltage (Shorted-input and 20Ω load, AC coupling).

The output noise worst case occurs at 50% duty cycle input, 200mVpp spikes at 1kHz PWM frequency are shown in Fig. 9. In this condition, the driver delivers 5.89V to a 20Ω load.

Figure 9: Output Voltage (1kHz 50% PWM Input delivering 5.89V to 20Ω load, AC coupling).

Temperature variations involved in thermal systems are usually long-term changes, thus tens of mV spikes at kHz frequencies does not affect overall performance.

The enable input is necessary to avoid unexpected over-temperatures in case of controller's failure. The output rise and fall times have been obtained by adjusting 100% duty cycle PWM inputs and applying a 5Hz square wave to enable inputs. Results are shown in Table 1.

Table 1: Enable Input Timing Performance

Enable	95% Settling Time
Rise edge	44ms
Fall edge	51ms

### Field Application Results

The heaters driver is employed in several optical devices at Sirius beamlines. The simplified block diagram of the Double Crystal Monochromator (HD-DCM) [3] thermal management control system is presented in Fig. 10, using a NI CompactRIO [11] as main controller:

Figure 10: Sirius HD-DCM heaters driver application simplified block diagram.

A closed loop 24-hour long-term thermal stability is shown in Fig. 11, spotting DCM crystals temperature sensors during a regular user shift at EMA (Extreme condition Methods of Analysis) beamline [12]:

Figure 11: 24-hour HD-DCM crystal temperature measurements.

There is a strong correlation between variations and gamma shutter events, nevertheless crystals temperatures remain below 0.05°C deviation over 24 hours.

The HD-DCM thermal system characterization and control loop tuning are not intended to be presented at this paper, however related works [4, 13] discuss this subject in-depth.

## CONCLUSION

This work presented the hardware design concepts and results about a multi-channel heaters driver, intended to be used at beamlines optical devices, such as mirrors and monochromators. The driver is capable to deliver up to 18W per channel at 12V (36W per channel at 24V) simultaneously to eight ohmic heaters. The output power is controlled by 5V PWM signals that can be easily integrated to any digital controller.

In addition, 5V TTL failure outputs signalize malfunction heaters and enable inputs turn off power outputs 51ms afterwards a falling edge. An embedded webserver is

implemented to allow fast diagnostics and a TCP socket is available for EPICS infrastructure integration.

Power outputs noise levels have not significant influence for thermal systems, typically characterized with long-term variations.

The first 20 units production set currently being used in first 6 Sirius` beamlines were manufactured in 2018. In 2021, 12 additional units have been produced for upcoming beamlines. Driver hardware failures have not been reported in the past years, supporting driver high reliability, usually an essential requirement for thermal management systems.

## ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the Brazilian Ministry of Science and Technology as funding agency and all the engineering and science teams members working for the Sirius project.

# EXPANDABLE AND MODULAR MONITORING AND ACTUATION SYSTEM FOR ENGINEERING CABINETS AT SIRIUS LIGHT SOURCE

P. H. Nallin<sup>†</sup>, J. G. R. S. Franco, G. F. Freitas, R. W. Polli

Brazilian Center for Research in Energy and Materials, Campinas, Brazil

## Abstract

Having multipurpose hardware architectures for controls and monitoring systems has become a need nowadays. When it comes to modular and easily expandable devices, it brings together a system which is easy to maintain and can reach many applications. Concerning Sirius accelerators, which is a 4<sup>th</sup> generation light source, monitoring environment variables becomes crucial when it comes to accelerator stability and reliability. Several cabinets make up engineering infrastructure, therefore, monitoring, and acting over their environment such as internal temperature, pressure, and fan status, increases overall system reliability. This paper presents an inexpensive hardware topology to deal with multiple sensors and actuators mainly designed to monitor cabinets and prevent beam quality losses due to equipment faults.

## INTRODUCTION

Sirius accelerator, the new 4<sup>th</sup> generation Brazilian synchrotron light source, has been under commissioning since 2019. Some improvements and maintenance have been accomplished for increasing machine performance and reliability in various subsystems.

Although the machine has not reached its project parameters yet, internal, and external scientists can run their experiments in available beamlines infrastructure, along with commissioning and maintenance shifts.

Both commissioning and user shifts require subsystems to work properly. For this purpose, it is necessary to have more information about the environment where equipment is located. The more scalable and easier to expand the solution is, the more useful it will be regarding future needs. The concept of a multipurpose monitoring and actuating system, which will be initially installed in the Engineering Area, leads to acquiring a large variety of signals, making it easy to prevent, detect or even predict malfunction of a specific device.

## OVERVIEW AND MOTIVATIONS

In order to have a bright and stable photon beam, it is also necessary to keep the accelerators' installation area stable and reliable, which leads to the monitoring of some environment variables, such as the temperature of many different locations, the humidity where each equipment is located, the ambient pressure and several other data.

Sirius' monitoring network, an in-house project called SIMAR (Cabinet Monitoring and Actuation System), has been under development and its main purpose is to obtain data information from the cabinets, which store a large

variety of equipment used in Sirius subsystems, such as vacuum, diagnostics and power supply equipment.

## SYSTEM ARCHITECTURE

SIMAR is a multipurpose project, based on a Beagle Board single board computer, widely used in Sirius Control System [1]. It aims to handle multiple modular hardware, each one designed to run independently, making it possible to use various sensors and actuators in the same system and, also, flexible enough to operate in different conditions. The figure 1 shows the structure of the SIMAR project.

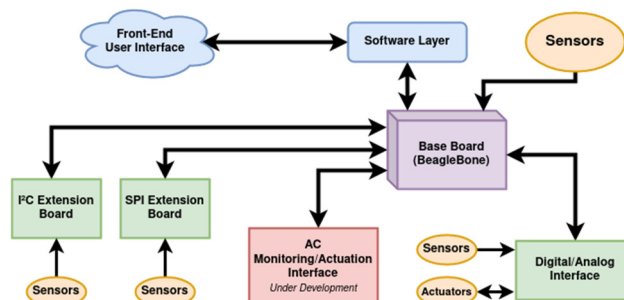

Figure 1: SIMAR conceptual design. It can integrate multiple devices, extend digital communication and easily scalable.

According to the environment to be monitored, additional stacked boards may be added as well as addressable splitters for multidrop digital communication channels. Every board must be hardware-configured prior to any new installation, in order to have a unique address identification.

Considering BeagleBone software integration, it is quite satisfactory to have one single disk image for all nodes in Controls Network, based on Debian. For that purpose, SIMAR has also been integrated into the BeagleBone-functionality-discovery service, which runs at initialization and gets information about hardware and equipment connected to a node. Then, all necessary applications are run.

## HARDWARE DEVELOPMENTS

### Base Board

The base board is the SIMAR main stack hardware project. It is responsible for functioning as a master on the communication buses and input/output pins. It also integrates the Programmable Real-time Units (PRUs) [2] into SIMAR interface for real-time data processing.

<sup>†</sup>patricia.nallin@cnpem.br

Four serial protocol signals (SPI, I<sup>2</sup>C, UART and 1-wire) are available on the base stack and they can be used for communication with several devices and sensors.

### *Digital and Analog Interface Stack*

The first auxiliary board for SIMAR project is a general-purpose input/output digital and input analog data interface. This board makes it possible to write and read an 8-bit digital word and read up to six analog signal channels. This interface stack is controlled by the base board, as shown in figure 2, through SPI communication. Among the transmitted data, one byte is used to select the interface board, according to its unique address and to select the functionality inside of the interface board (for example, read or write digital data). If necessary, one byte for updating the digital outputs.

To write or read digital data, SPI registers (serial-in/parallel-out and parallel-in/serial-out) are available on the board.

For reading analog signals, the BeagleBone's internal 12-bit ADCs are used. Since the original input range is from 0V up to 1.8 V, signal conditioning and protecting circuits are included in order to increase voltage range and, also, prevent over voltage on BeagleBone pins.

In addition to communicating with external signals, this stack has an integrated SPI EEPROM memory, making it possible to store the latest output values to be recovered after a power outage, general board information and further necessities. The interface board is compatible with many SPI EEPROM models.

Figure 2: SIMAR base board and interface stack prototypes assembled, together, minimal unit installed in Sirius cabinets.

### *SPI and I<sup>2</sup>C Extender Modules*

Another auxiliary device for SIMAR is a SPI extension, which aims to split and enable communication with up to six other devices. Device selection is performed by decoding four bits, which address the chip-select signal to the correspondent device. These bits get into the SPI expander as a configuration word.

Similarly, an I<sup>2</sup>C extender has been designed.

## **DATA ACQUISITION AND MONITORING**

### *Acquiring Sensor Data*

In order to increase system performance and allow it to work with multiple sensors, all coding is in C/C++ and Python modules may be created from these libraries.

With the base board only, SIMAR communicates through up to 4 different I<sup>2</sup>C channels, making it possible to monitor multiple cabinets with a single unit, greatly reducing costs. Switching is done through memory mapped input/output, diminishing switching times and increasing maximum polling frequencies. This strategy is also applied to other interfaces, such as SPI and digital inputs/outputs.

Currently, SIMAR supports the BMx280 family of sensors, automatically detecting and naming up to 8 different sensors (2 sensors per channel). Communication speed and sampling rates are limited by I<sup>2</sup>C channel switching delay and minimum reading/standby times for the sensors, which result in a maximum sample rate of approximately 800 Hz per sensor when all channels are active. If only one sensor per channel is active, it is possible to reach a theoretical limit of 1200 Hz for sample rates, given that only basic system and SIMAR processes are running on the main core.

For other sensors and auxiliary boards that require a faster communication solution, the BeagleBone's PRU may also be used as some of its pins are mapped on SIMAR bus, allowing higher polling rates and predictability [3]. For example, it could count multi-purpose pulses, up to 10 MHz, in 4 channels, while simultaneously performing other functions in the main core. Functions could be communicating with 8 different sensors, an external ADC, processing remote commands. One of the expected features concerning PRUs and SIMAR is to measure duty cycles of a digital waveform in the order of tens of MHz.

Even though a containerized Redis database [4] is running in Controls cluster, latest values for any variable are stored on a local database running on each BeagleBone. Data transfer is fast, reliable and dumps to disk are easily configurable. Output signals are recovered from this database after either a cold or warm system boot. Yet, if needed, a copy of all logged sensor data is also written to any USB storage device connected to SIMAR automatically.

### *Deduction Algorithms for Door Status*

Through the BMx280's family high accuracy and sensitivity to pressure changes (with its IIR filter disabled), it is possible to eliminate the need for a door status sensor such as a switch. By monitoring pressure moving averages, sustained and significant (> 0.3 hPa) pressure changes are counted as door status changes.

Thanks to the use of a Redis database, power outages and unplanned shutdowns do not affect the pressure moving average comparisons. When any of these situations happen, the moving average is automatically adjusted based on external pressure changes which accompany the expected pressure changes inside the cabinet since the last time it was connected. The system has shown itself to be resilient against false positives.

### *Wireless Connection*

A very special SIMAR use-case, under software development and integration tests, is using a wireless connection.

tion to share data values between sensors and a remote Redis database. In this case, SIMAR connects to the cluster and retrieves data from the containerized database, so that static BeagleBone IPs are not mandatory to access acquired data.

It also allows the possibility to have portable SIMAR units, which are powered and start data acquisition on startup and data streaming automatically once a compatible wireless network is available.

## EPICS INTEGRATION

Sirius' Control System is EPICS based, which leads to the need to translate SIMAR Redis variables into EPICS Process Variables (PVs). The EPICS IOC for this application runs atop a custom auto-failover Asyn driver [5], developed in collaboration with Dirk Zimoch, from Paul Scherrer Institute (PSI). With this driver, it automatically switches to alternative servers in case of any disconnections, which is especially useful when coupled with high availability solutions, as a cluster or systems with hardware redundancy.

The IOCs are containerized and run on the Controls System cluster, querying Redis databases for data updates, utilizing a custom auto generated Redis IOC [6]. This approach reduces overheads resulting from hosting an additional communication channel for each SIMAR unit, since Redis is already present on the default Sirius BeagleBone image.

Performance-wise, the IOC solutions applied to SIMAR make for high-frequency polling that accompanies the performance of the main program running on all SIMAR units, reducing data losses. Utilizing Redis also allows holding the data for as long as possible while the IOC catches up, in case that ever occurs. The conceptual design of the software stack is shown in figure 3.

Figure 3: SIMAR's software stack.

## USER INTERFACE

The user interface for SIMAR (figure 4) is web-based and responsive, allowing access from mobile devices and desktops alike. Based on the Vue framework, it features real-time data updates, graphical configuration menus,

granular permissions, and safe authentication, based on Microsoft Azure's technology [7], which is the default authentication for CNPEM collaborators.

Fetching information is also trivial, since the designed GUI makes use of "Epics2Web" [8] API, utilizing web sockets to communicate in an efficient and quick manner with the EPICS server. In addition, the GUI supplies dynamic links to the EPICS Web Archiver Viewer, allowing users to quickly view historic data for each device.

Communication also occurs through a custom version of Webdis [9], an HTTP interface for Redis database. Added functionalities regarding default applications are server-side logging and authentication for additional security. In order to increase performance, Redis' script cache functionality is used, bundling together batch requests.

Authentication was added to restrict interaction with outlet actuation and custom alert limit functionalities. No user credentials are stored, and all communication is compliant with OAuth2 and HTTPS standards, with only a token being received by the Webdis server, which is used to confirm the user's identity.

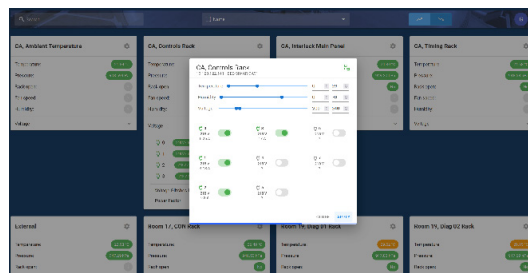

Figure 4: SIMAR's web-based graphical user interface.

In addition, in-house tools are available which allow users to be notified whenever a limit is exceeded, transmitting notifications through email and Telegram instant messages, for example.

## INITIAL INSTALLATION

Currently, SIMAR prototypes have been applied to monitor some critical environments, such as 12 default cabinets from various subsystems in a high-density area subjected to higher ambient temperatures. A base board acquires data from sensors located inside each cabinet, positioned on the most critical region.

Figure 5: Sensor unit placed inside a cabinet.

A wireless unit, initially connected to the corporate network due to connectivity availability, has been in operation for some months in order to acquire environmental data (ambient pressure, humidity, and temperature) outside the building for metrology refinements.

Dedicated cabinets (timing system, controls servers and interlock system) have recently started being monitored by SIMAR, acting as a replacement for a system that required physically dismantling the sensor to retrieve data and recharge batteries, figure 5 demonstrates a sensor installation in a cabinet. The graphs shown in figure 6, figure 7 and figure 8, exemplify how the environment data is being presented to the user.

Figure 6: Temperature measurement of special cabinets and environment temperature at Connectivity Area.

Figure 7: Temperature, pressure and humidity measurement for a pulsed-magnet cabinet.

Figure 8: External (out of building) measurements, helping with subsystem stabilities.

The data provided by SIMAR allows new or existing HVAC installations to be tailored to the needs of each individual room, subsystem, or cabinet. They also help with narrowing down possible issues with airflow and humidity-sensitive equipment, as well as making it easier for operators to monitor engineering cabinets health and status. It is also important for detecting unusual temperature variations (both internal/external cabinets and outside

the building), thanks to its high precision, data acquisition rate, ease of installation and high mobility.

## FUTURE APPLICATIONS AND IMPROVEMENTS

Many improvements are planned, and some are already in progress. The next application under development considers power outlets switching and monitoring (voltage, current, frequency and power factor), which will greatly increase system added value and expand actuating possibilities.

Other features are also planned, such as sound signature analysis in order to predict and prevent failures more reliably, local alarms and support for more sensors. Powering through PoE would reduce the number of cables and a dedicated IoT wireless network would eliminate communication weak points.

## CONCLUSION

As part of Sirius' engineering team effort to continuously improve and reach new standards of reliability, efficiency, and stability, SIMAR has demonstrated that it is quite essential for on analyzing environmental and operational data and act over it whenever it is necessary.

Such data can be used to predict failures, schedule preventive maintenance, and help members to planout upgrades in advance, while remote actuation provides a channel of interaction for otherwise inaccessible devices and systems. If environment data is acquired and all the necessary interfaces to actuate over it are available, analyzing that data along with specific subsystem variables might lead to a better environment that increases overall stability and reliability.

Although SIMAR is still in its commissioning phase, it is currently expected to be installed in all Sirius Engineering cabinets, along with other locations and systems as requested, since it is highly versatile, easy to set up and a low-cost solution compared to commercial ones.

These developments are part of the many steps to guarantee that Sirius' commissioning and operation are efficient, stable, and reliable, achieving the expected research output.

# CompactRIO CUSTOM MODULE DESIGN FOR THE BEAMLINE'S CONTROL SYSTEM AT SIRIUS

L. S. Perissinotto<sup>†</sup>, F. H. Cardoso, M. M. Donatti  
Brazilian Synchrotron Light Laboratory (LNLS), Campinas, Brazil

## Abstract

The CompactRIO (cRIO) platform is the standard hardware choice for data acquisition, controls and synchronization tasks at Sirius beamlines. The cRIO controllers are equipped with a processor running a Real-Time Linux and an embedded FPGA, that could be programmed using Labview. The platform supports industrial I/O modules for a wide variety of signals, sensors, and interfaces. Even with many available commercial modules, complex synchrotron radiation experiments demand customized signal acquisition hardware to achieve proper measurements and control systems integration. This work aims to describe hardware and software aspects of the first custom 8-channel differential digital I/O module (compatible with RS485/RS422) developed for the Sirius beamlines. The module is compliant with cRIO specifications and can perform differential communication with a maximum 20 MHz update rate. The features, architecture and its benchmark tests will be presented. This project is part of an effort to expand the use of the cRIO platform in scientific experiments at Sirius and brings the opportunity to increase the expertise to develop custom hardware solutions to cover future applications.

## INTRODUCTION

In a typical synchrotron beamline, a wide variety of electronic devices are employed for controlling and monitoring complex scientific experiments. In a general aspect, these equipment acts to control the beamline components such as shutters, mirrors, monochromators, diagnostic elements, motors, vacuum pumps, etc. These devices have different types of communication interfaces or electrical I/Os in different voltage levels or standards that must be properly integrated to the EPICS control system [1]. The CompactRIO (cRIO) [2] platform is the standard hardware controller used for data acquisition, control and synchronization tasks. The platform supports industrial I/O modules for manipulating a wide variety of signals and interfaces and despite the broad portfolio of commercially available I/O modules, custom hardware designs are often needed. To supply the demand for differential signaling communication, the first in-house C-series module was designed and comprises a 20 MHz max. update rate digital I/O compatible with RS485/RS422 [3] standard.

The hardware and software development were guided by the National Instruments cRIO-9951 [4] development kit, which provides guidelines for design implementation. The developed module will be used for long distance differential communication, triggering and synchronization. The knowledge applied in this development will be useful to develop custom hardware for future applications.

## HARDWARE

The module has 8 differential channels with configurable direction, compatible with RS485/RS422, and can achieve up to 20 MHz update rate. An external power supply may be required in some conditions, which depends on the channels' directions and data rate. Differential signals and external power supply are available to the user in the front panel through a 37-pin DSUB connector and it has two led indicators that shows the internal powering status and external powering needs. The module is connected to CompactRIO using a high density 15-pin D-SUB connector on the back of the board.

To safeguard the controller from ESD damage, insulation topology [5] was adopted using digital isolators between all internal and external signals to cRIO bus. The circuit is physically separated into the non-insulated side, where compactRIO is attached, and the insulated side where the application signals are available.

The module circuit is divided into three main blocks: power supply, transceivers, and control logic. The power supply block is responsible for insulating, protecting, and managing all power supply sources, internal and external. The transceivers block converts the internal bus single-ended signals into insulated external differential signals, or vice versa, depending on the configured direction. The control logic block identifies compactRIO control signals and implements all internal mode's support logic. The blocks organization in the PCB can be seen in Fig. 1.

Figure 1: Device blocks on PCB.

<sup>†</sup> lucas.perissinotto@lnls.br

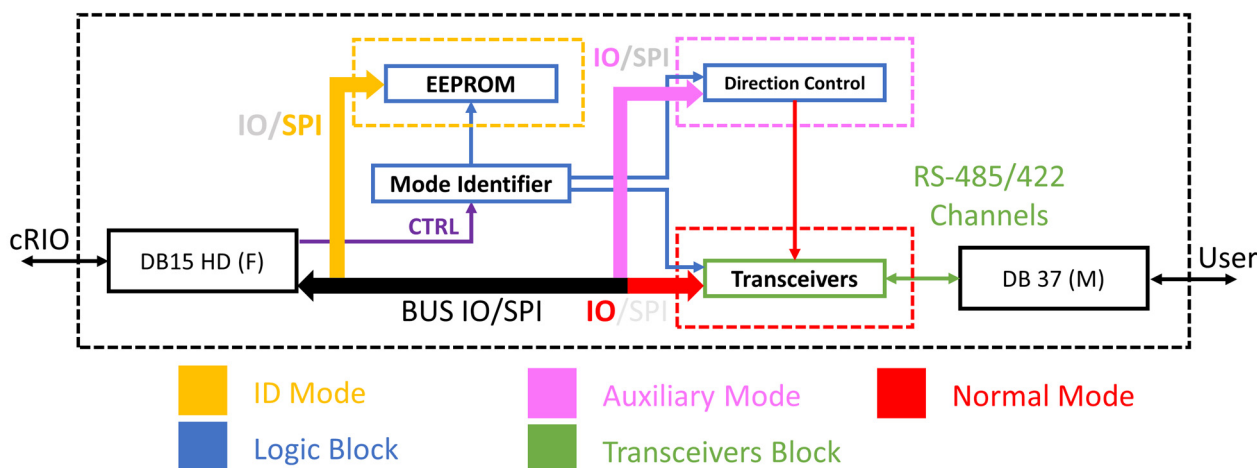

Figure 2: Device block diagram.

The module supports the four internal compactRIO operating modes [6]: Idle, Id, Auxiliary and Normal. In each mode, the bus is used to control a different interface except for the Idle mode, where all module interfaces are disabled. In Id mode, the bus is used to access the embedded EEPROM, allowing the module's identification procedure. The Auxiliary mode allow the user to configure differential channel direction. In Normal mode, the bus is used to access transceivers input or output data channels, depending on the direction set in Auxiliary mode. The operation modes diagram is shown in Fig. 2.

### Transceivers

To obtain the required performance and protection, eight insulated half-duplex transceivers IC [7] is used. The transceiver converts single-ended (TTL) signals to differential (RS485) standard with a maximum 20 MHz update rate. Each transceiver's channel is connected directly to the compactRIO bus.

The transceivers have two pins for data signals, one for input (R) and another for output (D). Since the transceivers are half-duplex, both data signals tied together to reduce the number of demanded digital I/O from the controller. This arrangement can be seen in Fig. 6.

In Normal mode, the transceivers have their inputs and outputs set as pre-defined in Auxiliary mode. When other modes are selected, all data pins from the transceivers switch to high impedance state, granting the bus the ability to be used in module identification procedure or channels direction configuration. The differential side are also switched to high impedance to prevent any damage during module initialization.

Regarding the physical aspects of the transceivers block, the differential signals were routed as a pair and designed to have 120 ohms characteristic impedance. The differential traces have termination resistors, that can be enabled by manual jumpers, to provide matched load for tests and specific applications.

### Control Logic

The logic block is responsible for identifying each compactRIO internal operation mode and controlling all interfaces that access the bus. The interfaces include the EEPROM, direction control and transceivers. All logic was implemented using logic gates from the 74 IC family. The logic implementation for internal modes identification is shown in Fig. 3.

Figure 3: Internal operation mode logic identifier circuit.

The signals ~ID, SPI\_FUNC and SPI\_CLK comes directly from compactRIO bus in which the first two are intrinsically planned for this purpose. There is no signal intended to determine Normal mode, thus SPI\_CLK was selected to be used as a digital I/O since SPI isn't used in this mode.

The EEPROM logic was implemented using the Id mode signal and the chip select SPI signal, as can be seen in Fig. 4. EEPROM SPI signals share the bus with I/O's used in Normal and Auxiliary mode. For this reason, the EEPROM SPI interface is activated only by control signal ~CS during Id mode.

Figure 4: EEPROM ~CS logic control.

An 8-bit shift register [8] with output implemented by flip-flops is used to set and store the data channels logic state directions in Auxiliary mode. Auxiliary mode signal provides access to the shift register for three digital I/O's from the bus. Figure 5 shows the logical scheme implemented to store channels direction that are used in Normal mode.

Figure 5: Shift Register and control logic.

The transceiver, on the non-insulated side, has different input and output data pins. Each data pin has its configuration pin, which configures channels direction and high impedance state. Both data pins have been tied together to reduce the need of extra digital I/Os from the bus. The implemented control logic for configuration pins allows it to be used in both directions during normal mode and keeps the outputs at high impedance in other modes. The logic implemented to control each transceiver can be seen in Fig. 6.

Figure 6: Transceiver control logic.

### Power Supply

The power supply block was carefully designed to attend the voltage and current specification and provide protection for the external and internal circuitry. When internal power is used (from cRIO controller), isolators and current limiters are used to guarantee that compactRIO is protected from damaged caused by short-circuit, overcurrent or electrostatic discharge.

The current limiter was placed on the isolated side, thus an overcurrent or short-circuit would not disable the logic block on the non-insulated side. National Instruments documentation restricts the bus current draw to 200 mA.

The current consumption of the non-insulated side was estimated at 45 mA, consequently, the non-insulated side could draw a limit of 155 mA. Considering the transformer conversion factor (1:1.1) and the conversion efficiency (90%), the limiter was configured to limit current draw to 120 mA, in order to limit the input module current in 190 mA. The power supply block diagram can be seen in Fig. 7.

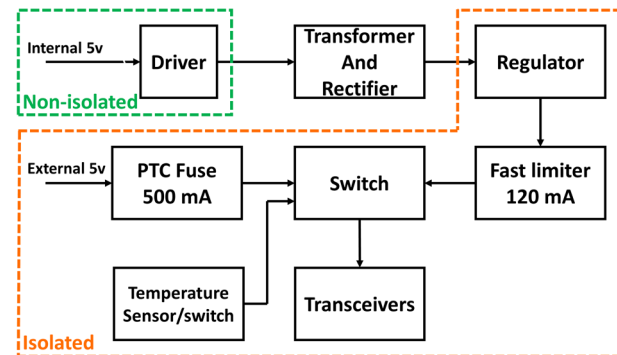

Figure 7: Module's Power Supply.

The internal power supply is adequate for some use conditions, but often an external power supply will be necessary. An electronic power switch is used to manage the use of external/internal power supply. A 500 mA PTC fuse protects the input from short circuits. Two led indicators (LED's) are present in the front panel: a red light indicates the limiter is activated, so external power supply is needed; a green light indicates the module is internally powered.

The external power supply is needed when current consumption exceeds the 200mA bus limit, but the internal module total power dissipation could be monitored to avoid temperature rising. The design rules limit the internal power dissipation in 1.5 W and for all transceivers used at same time (at the highest update rate) the board dissipates nominally 2.4 W. A temperature sensor and switch were used to monitoring the internal temperature in the maximum dissipation power condition and turn off the external power supply in case temperature rise above 60 °C. The temperature monitor is configurable and can be used in any desired protection logic defined by the user.

### SOFTWARE

The module software supports comprises the development of configuration files (XML) and Labview codes (VI). The elaboration of such items involves a series of steps and development modes, and all must be done using Labview environment and is detailed described in the development kit software documentation.

CompactRIO users interact with modules in FPGA environment [9] through Nodes (specific labview block) [10], which types can be I/O's, Methods or Properties. Each module Node usually has codes scripted behind them or can be mapped directly to digital I/O available in compactRIO (D-Sub-15-HD).

The strategy adopted to achieve an update rate close to FPGA clock speed was to map the digital I/O's behind I/O Node. As described in the transceiver's subsection, the controller digital I/O's are connected to the module's

internal bus just when the module is in Normal Mode. The differential signal works as an extended digital I/O's mapped in the I/O Node. This arrangement can be seen in Fig. 8.

Figure 8: I/O's Node mapped direct in module bus.

In module support block, there is the module core code that works as a “main” function in a textual programming language. The core code executed in this module is responsible for module initialization and channel direction change procedure. This code runs in a loop, waiting for a direction change to be indicated by a Method Node. When a Method Node is used, a byte is passed as an argument, and each bit has, respectively, a differential channel associated, as shown in Figure 9.

Figure 9: Change direction Method Node.

The core code switches the module to Auxiliary mode at the beginning of each channel direction change procedure. It transfers a byte (bit-by-bit) the to the shift register over DIO3 during the rising edge of DIO1. In the end, the shift register output is updated by a rising edge on DIO0, and the module returns to Normal Mode. The block diagram of direction change is shown at Fig. 10.

Figure 10: Change direction core code diagram.

## TESTS

The module was initially tested using an in-house developed test jig based on LPC1768 [11] microcontroller. All compactRIO modes, functions and I/O's were emulated and tested before board connection at cRIO data bus. With a mature software version ready, performance, consumption and temperature tests were performed.

Performance tests were conducted and the module was able to reach the maximum specified 20 MHz output data rate, as shown in Fig. 11. Communication tests were performed using three strategies: a loopback connection, a commercial NI-9753 [12] module and another developed prototype. In these communication tests, long cables (20 meters) and termination resistors (120 ohms) were used with all simultaneous channels transmitting or receiving data in both directions.

Figure 11: Module maximum update rate output waveform.

The current consumption was measured with the channels configured as input and output. In the input direction test, the module was supplied through the compactRIO connector. Differential signals were applied in the external connector by another module, while the current and limiter indication were verified for different update rates. The results are shown in Table 1.

Table 1: Module Internal Current Consumption

Update Rate Input (MHz)	Internal Cur- rent (mA)	Limiter indicator
20	215	1
10	190	0
5	179	0
2.5	173	0
1.25	170	0
0.1	167	0

For the transmitting data (output direction), the module was powered by both sides (internal and external power supply), and the current consumption was measured in the external connector for different data rates. The results are summarized in Table 2.

Table 2: Module External Current Consumption

Update Rate Input (MHz)	External Current (mA)
20	403
10	372
5	342
2.5	311
1.25	280
0.1	169

The maximum measured consumed power, in the transmission test (output direction) was 2W. During this test, the internal current was not monitored but is estimated to be less than half of the values presented in Table 1. In this case, the total dissipated power reaches approximately 2.5W, above the stipulated limit at design rules. The effects of excess power dissipations were verified by keeping three adjacent modules under such conditions, while the temperature was being monitored until stabilization. The observed module temperature was 47.5°C, working at the room temperature about 23±1°C and stabilization took two hours.

## CONCLUSIONS

The first custom 8-channel differential digital I/O module (compatible with RS485/RS422) in a C-series form factor for the Sirius beamlines was designed. Using high-performance isolated half-duplex differential line transceivers, the module can perform differential communication with a maximum 20 MHz data rate. The module is pin-compatible with the commercial NI-9753 module [12], and it has eight channels independently configurable as input or output. A selectable 120 Ohms resistor is placed to guarantee proper termination in receiver mode.

The designed module is compliant with NI cRIO specification in certain conditions and it has some operational limitations related to the current draw, which can be overcome by the use of external power supplies.

In terms of power dissipation, the module could exceed the defined 1.5 Watts limit in some situations. When the cRIO crate is fully populated, the module temperature must be monitored, and the use of temperature interlock must be evaluated.

Due to the use of low-cost transceivers, the module was able to be manufactured for less than one-tenth the price of the commercial benchmark, which makes it a cost-effective alternative for a wide variety of applications, in special for long-distance digital signal transmission.

## FUTURE PLANS

This project is part of an extensive effort to expand the use of the cRIO platform at Sirius beamlines. The developed prototype fulfilled its objective, allowing the developers to obtain the necessary knowledge in hardware and software implementation. The experience acquired by the development team will contribute for the design of more

complex modules. Future developments aim to provide solutions for high-resolution digitizers, low latency/low jitter triggering modules, and other scientific experiment-oriented demand.

## ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the Brazilian Ministry of Science and Technology as funding agency and all the engineering and science teams members working for the Sirius project.

# STATUS OF THE uTCA DIGITAL LLRF DESIGN FOR SARAF PHASE II

J. S. Fernandez, P. Gil, G. Ramirez, Seven Solutions, Granada, Spain  
G. Ferrand, F. Gohier, G. Desmarchelier, N. Pichoff, CEA, Saclay, France

## Abstract

One of the crucial control systems of any particle accelerator is the Low-Level Radio Frequency (LLRF). The purpose of a LLRF is to control the amplitude and phase of the field inside the accelerating cavity. The LLRF is a subsystem of the CEA (Commissariat à l'Energie Atomique) control domain for the SARAF-LINAC (Soreq Applied Research Accelerator Facility – Linear Accelerator) instrumentation and Seven Solutions has designed, developed, manufactured, and tested the system based on CEA technical specifications. The final version of this digital LLRF will be installed in the SARAF accelerator in Israel at the end of 2021. The architecture, design, and development as well as the performance of the LLRF system will be presented in this paper. The benefits of the proposed architecture and the first results will be shown.

## INTRODUCTION

The SARAF-LINAC project intends to accelerate proton and deuteron beam currents from 0.4mA to 5mA up to 40MeV for deuterons and 35 MeV for protons. To achieve this, the field in the cavities needs to be controlled and regulated. The LLRF is the device in charge of maintaining the cavity gradient and phase stability in presence of beam. Seven Solutions has designed and implemented the LLRF system including all the hardware, gateway (FPGA code) and software needed to fulfil the specifications derived from [1]. The LLRF channels required for the SARAF-LINAC phase II [2] will drive both normal conducting cavities and superconducting cavities.

The factory acceptance tests (FAT) results will be detailed in this paper.

## SPECIFICATIONS

The LLRF must be able to regulate the cavity field both in pulsed mode and in continuous wave (CW). From the simulations and studies performed in [1], the main LLRF system requirements were derived. They are listed in Table 1. The frequency of the full accelerator is 176MHz. This is the reference frequency for the LLRF system.

Table 1: LLRF Requirements

Requirement	Value
Operation frequency range	176MHz +/-100KHz
LLRF delay	< 1us
Input amplitude RMS error	< 0.03%
Input phase RMS error	< 0.03°
Output amplitude stability	< 5%
Output phase stability	< 5°

## HARDWARE

The LLRF HW is based on the uTCA.4 technology. The system is composed by two boards (Fig. 1):

The LFE (LLRF Front End) is in charge of conditioning the RF inputs signals to interface them to the ADCs. In addition, the RF drive outputs are amplified and filtered in this board.

The AMC (Advanced Mezzanine Card) digitizer controller board includes all the components (ADCs, DACs, PLL, FPGA, DDR memory...) needed to perform the acquisition and generation of the RF signals as well as all the digital signals processing to implement the different algorithms and features included in a LLRF system. The design based on a FPGA provides the system with a great flexibility making it capable of being adapted to the requirements of different accelerator facilities and to be placed on a rack or in a single standalone mode.

Figure 1: LLRF HW composed of LFE and AMC boards.

The HW is designed to have two LLRF channels making possible to control two cavities with one set of board. Each channel generates one RF drive signal (Uamp) and monitors three RF signals (Fig. 2):

- U<sub>cav</sub>: Cavity voltage.
- U<sub>ci</sub>: Incident voltage.
- U<sub>cr</sub>: Reflected voltage.

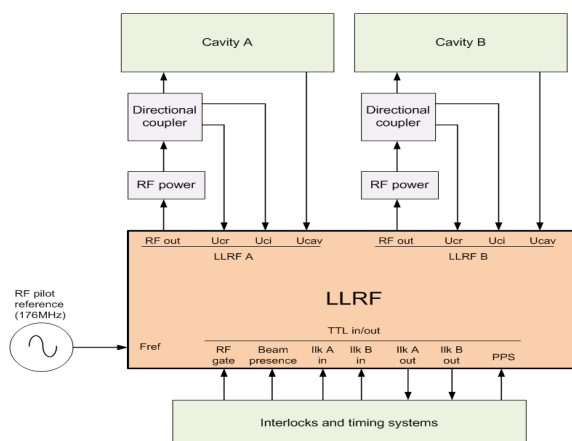

Figure 2: LLRF block diagram.

## GATEWARE

The LLRF system is based on SoC technology. A Zynq UltraScale FPGA from Xilinx has been used in the design. This family of FPGAs combines a great amount of programmable logic and two dual core ARM processors in the same chip, offering enough resources and flexibility to implement all the functionalities that characterize a LLRF system.

A block diagram with the main gateway elements is shown in Fig. 3.

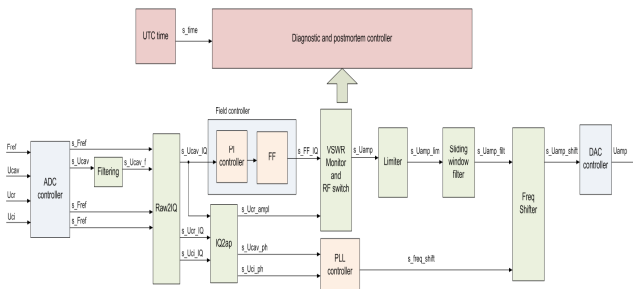

Figure 3: Gateway architecture block diagram.

The LLRF system can operate both in pulsed mode and in continuous wave. Moreover, it can operate in opened loop for conditioning and in closed loop for cavity regulation.

The main functionalities implemented in the FPGA are:

- ADC controller: In charge of configuring the ADC chips and acquiring the RF samples from them.
- Demodulation: To get the IQ component of the RF signal from the ADCs.
- Calibration: Used to compensate gain and phase offsets in the acquired RF signals.
- Field controller: Composed by a PI (Proportional-Integral) controller, to maintain stable the amplitude and phase of the cavity field, and a feedforward controller to compensate the beam loading effects.
- VSWR monitor: To monitor the reflected voltage and shut off the RF generation in case this voltage exceeds a configurable limit.
- Limiter: To prevent from generating undesired high RF output levels.
- Sliding window filter: To perform pulse shaping over the RF output pulses.
- Freq shifter: Used to cause a frequency displacement over the RF output signal.
- PLL controller: Allows to track the cavity resonant frequency automatically when the LLRF is operating in opened loop.
- DAC controller: Responsible for configuring the DAC chips and sending the data to be converted to analog domain.
- Diagnostic and post-mortem: The systems store the value of the RF signal as well as other internal signals of interest and the status of the system in the DDR memory. These data are used for displaying in real time some information. In addition, postmortem files

are generated, in case of alarm, which allow the operator to investigate the causes of the alarm and to know the status of the LLRF at that time.

## EMBEDDED SOFTWARE

Figure 4 illustrates the main architecture developed on the Zynq UltraScale to provide the functionality and communications required for the control system installed on the LLRF system.

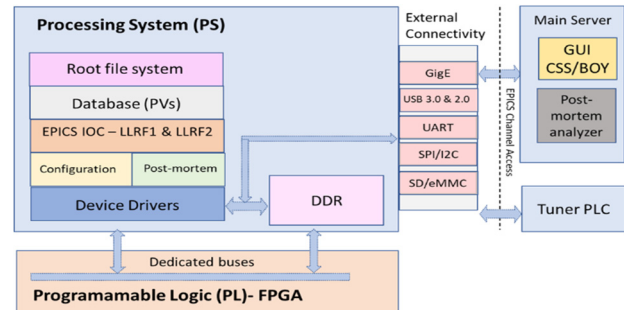

Figure 4: Software architecture.

The presented architecture consists of:

- Operating system: generated using the open-source tool Buildroot. Generates a single image to be loaded on the board contain the Linux kernel image, root file system, BOOT.bin (FPGA image), device tree and uboot.
- Low level drivers: allows the communication between the control system layer and low level devices. Communication between FPGA, DDR memory and I2C/SPI devices, such as EEPROM, are part of the drivers included in the embedded software.
- Control system layer: allows the communication between the low level drivers and the EPICS Channel Access. EPICS based is used in this development, and more specifically, AsynPortDriver is used as interface to the EPICS Channel Access (CA). Records and PVs are defined to access to the different elements defined to monitor and control the LLRF.

## OPERATOR INTERFACE

The operator interface is implemented in CSS (Control System Studio) and Python. It enables the user to easily control the system making use of the interface provided by EPICS with the process variables (PV). Figure 5 is an example of how to control tasks such as monitoring, settings and display of PVs on a very easy way.

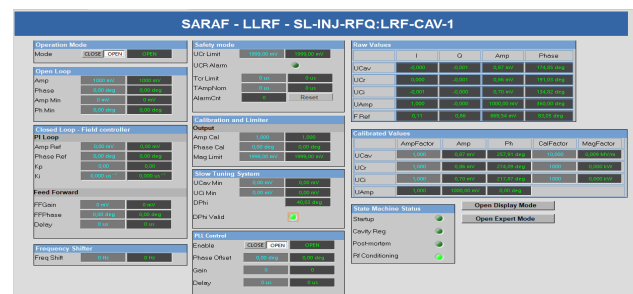

Figure 5: Graphical user interface.

## Functional Tests

Several functionality tests have been carried out to check the different features that the LLRF systems implements.

A 176MHz bandpass filter with high Q factor (13000) has been used to test some features in conditions like those when the LLRF is connected to a cavity. In Fig. 9 it can be seen the LLRF regulating the voltage when the RF output ( $U_{amp}$ ) is connected to the bandpass filter and the filter output is connected to  $U_{cav}$ . The LLRF is operating in closed loop and pulsed mode (RF gate in pink in the figure). In yellow we can see  $U_{amp}$  and in blue  $U_{cav}$  (the output of the bandpass filter).

The feedforward capability has been also tested during the FAT. In Fig. 10 it is shown RF gate signal in blue and the beam presence gate signal in yellow. As the LLRF is no connected to a cavity and there is no beam, it is observed how the  $U_{cav}$  signal increase its level, with the rising edge of the beam presence gate signal, but immediately the PI loop compensate this increase. In the same way, when the feedforward stops having effect,  $U_{cav}$  suffers a level drop that is quickly compensated by the PI controller.

Figure 9: LLRF  $U_{cav}$  regulation test.

Figure 10: Feedforward capability test.

One of the most interesting functionalities of the LLRF system is its PLL functionality. Thanks to this functionality, the LLRF can track, when operating in opened loop, the resonant frequency of the cavity.

Two measurements of the filter phase characteristic were done separately. The first test, blue curve in Fig. 11, is the following: the incident voltage ( $U_{ci}$ ) and the output frequency of the LLRF are fixed. The transmitted voltage ( $U_{cav}$ ) is measured (in mV), as well as the phase shift between  $U_{ci}$  and  $U_{cav}$ . It gives a first graph of the phase as a function of the transmitted voltage for different frequencies. Then, instead of fixing the frequency, we did a second test by fixing the phase between  $U_{ci}$  and  $U_{cav}$ . The PLL should lock to the frequency that provides the phase. This is the red curve in Fig. 11. In principle, if the PLL locks to the phase as expected, red and blue curves should be identical. This is precisely what was measured, validating the PLL function.

Figure 11: PLL functionality test.

## CONCLUSIONS

This paper presents the LLRF system for SARAF project phase II designing and manufactured by Seven Solutions according to the specifications given by CEA. The FAT tests have been satisfactory, and the next step will be the integration of the LLRF systems (18 resulting in a total of 36 channels) in the SARAF facilities in Israel.

# ARCHITECTURE OF A MULTI-CHANNEL DATA STREAMING DEVICE WITH AN FPGA AS A COPROCESSOR\*

J. M. Nogiec†, P. Thompson, FNAL, Batavia, IL 60510, USA

## Abstract

The design of a data acquisition system often involves the integration of a Field Programmable Gate Array (FPGA) with analog front-end components to achieve precise timing and control. Reuse of these hardware systems can be difficult since they need to be tightly coupled to the communications interface and timing requirements of the specific ADC used. A hybrid design exploring the use of an FPGA as a coprocessor to a traditional CPU in a dataflow architecture is presented. Reduction in the volume of data and gradual transitioning of data processing away from a hard real-time environment are both discussed. Chief design concerns, including data throughput and precise synchronization with external stimuli, are addressed. The discussion is illustrated by the implementation of a multi-channel digital integrator, a device based entirely on commercial off-the-shelf (COTS) equipment.

## INTRODUCTION

One of the typical dilemmas designers face when building a system is whether to buy or build its components. This also applies to test and measurement systems used in High Energy Physics. Readily available, so-called commercial off-the-shelf (COTS) components are ubiquitous and can reduce development cost and offer product support by manufacturers. Unfortunately, the offered instruments or modules may not be precisely what is needed. A solution can be to build an instrument in-house, but from available COTS subcomponents, as is the case for the digital integrator device discussed in this article.

Construction of a multi-channel streaming integrator from COTS subcomponents is presented in the context of using an FPGA as a coprocessor in order to provide predictable and guaranteed data processing performance. The discussed integrator is functionally extensible, thus it has been named the Extensible Digital Integrator (EDI).

Digital integrators have been very successful in testing accelerator magnets, and they are crucial parts of rotating coil systems and single stretched wire systems, the cornerstones of the measurement toolset used in this domain.

## FPGA AS COPROCESSOR

A Field Programmable Gate Array (FPGA) allows engineers to design and program data acquisition and control hardware to cater to the specific needs of their applications. Typically, systems employ FPGAs as

controllers of hardware and signal preprocessors or conditioners. In these architectures, the FPGA is positioned between the I/O and the higher layers of data processing or control (see Fig. 1a).

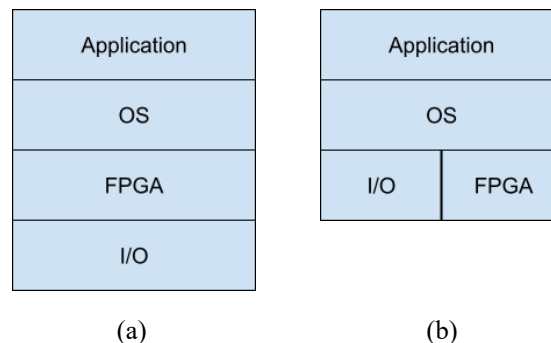

Figure 1: Layers in the system using an FPGA: a) for signal acquisition, b) as a coprocessor.

Another typical application of FPGAs is as a coprocessor offloading computationally intensive functions from a main processor. This solution offers deterministic performance in demanding data processing situations, especially in real-time applications (see Fig. 1b).

The EDI combines both of these hardware organizations into a single architecture. Here, the FPGA serves as both a coprocessor integrating signals and a real-time signal processor acquiring external triggering signals.

The performance of the analog-to-digital converters in dedicated PXI coprocessor modules is inadequate for our needs, and there is no access to the selected DSA ADC boards directly from the FPGA. These factors contributed to some design specifics of the EDI solution.

## INTEGRATORS

Digital integrators have proven to be useful in building test systems to measure magnetic fields in accelerator magnets. In fact, they are often a crucial instrument in systems based on the rotating coil and single stretched wire techniques.

These instruments integrate input signals (voltages) over time intervals provided by internal or external triggers, such as a train of pulses or the output of an angular encoder. Historically, these systems evolved from voltage-to-frequency converters connected to up-down counters and trigger boxes [1, 2] to systems using analog-to-digital converters coupled with DSP coprocessors performing integration [3-8]. More recently, FPGAs have offered a very attractive alternative to other integrator hardware

\* Work supported by the U.S. Department of Energy under contract no. DE-AC02-07CH11359

† nogiec@fnal.gov

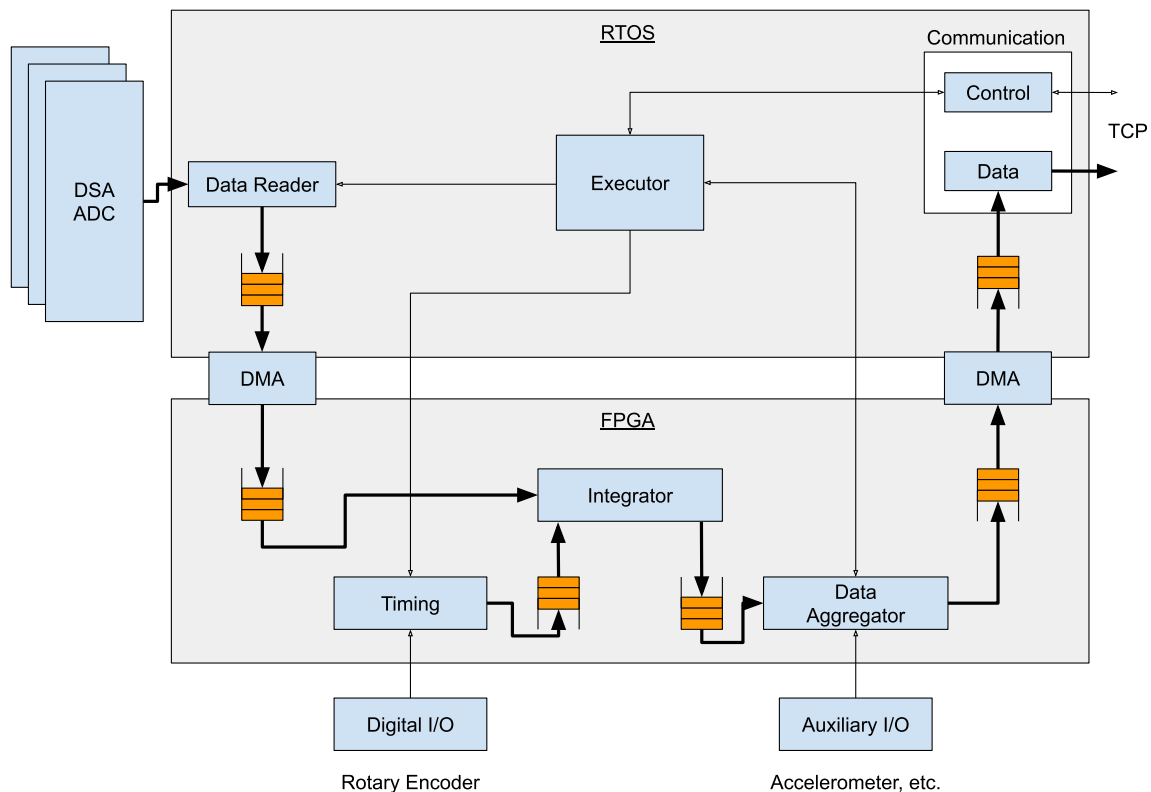

Figure 2: Organization of the EDI.

solutions, allowing for both acquisition of signals and signal processing [9, 10].

## EDI HARDWARE

The EDI uses an FPGA for acquisition of external timing signals and a PXI bus for acquiring data from a set of analog-to-digital converters. Both the ADCs and the FPGA come as COTS PXIe modules produced by National Instruments Corporation.

### FPGA

The PXIe-7856 reconfigurable I/O module featuring a Xilinx Kintex-7 FPGA provides ample logic area for creating integration and data processing algorithms. Memory space for queues is supplied in part by its 11,700 kbits of block RAM [11]. When used with a compatible PXIe chassis, these FPGA cards as well as the ADC cards will automatically synchronize with the 100 MHz chassis backplane clock with less than 250 ps of skew between modules [12]. Therefore, the ADC sampling clock and the 40 MHz FPGA clock used for keeping time between encoder triggers are derived from the same time base, which effectively eliminates clock drift between the modules.

Additionally, some ancillary functions (e.g., accelerometer readings for probe orientation monitoring) are provided by some built-in 16-bit successive approximation register (SAR) ADCs [13].

### ADC

The PXIe-4464 ADC cards are members of the Dynamic Signal Acquisition (DSA) family of modules from National Instruments. With programmable gains and good frequency domain performance, these cards are well suited for harmonics measurement applications. The sampling rate is also adjustable, with a maximum of 204.8 kS/s. A CMRR of up to 105 dBc (depending on selected gain) provides adequate noise rejection on long probe cable runs. Samples are provided by a delta-sigma ADC with a resolution of 24 bits [14].

However, one potential drawback of this card is that it is not compatible with peer-to-peer streaming, necessitating the routing of sample data through the RT controller (adding some overhead) before it can be sent to the FPGA.

## EDI ORGANIZATION

The programmatic implementation of the EDI includes software in the real-time operating system (RTOS) layer and firmware in the FPGA layer (see Fig. 2). Both the software and firmware are built as a set of collaborating modules communicating via queues.

Commands directing the operation of the EDI come via a TCP connection and are encoded by the control and communication module and are then sent to the executor module. The executor module keeps the state of the integrator and orchestrates the operation of other software and firmware modules.

The input data reader module starts data acquisition in the ADC channels and reads the incoming data, which subsequently are sent via a DMA channel to the FPGA where they are appended to the raw data queue.

At the same time, the timing module starts to read the triggering signals and for each trigger appends an element to the timing queue. The element contains the time elapsed from the previous trigger (integration time).

The integrator module reads an element from the head of the timing queue, calculates the number of ADC samples to integrate, performs integration, and appends the results of integration and integration time to the integrator output queue.

Depending on the configuration, a given number of elements in the integrator output queue are combined in the data aggregator module and sent via a DMA channel to the RTOS layer.

The integrated and aggregated data are received by the RTOS and are passed to the data communication module, which send them via a channel in the TCP-based connection to the consumer of the data.

Figure 3: Integration interval and ADC sampling time.

## INTEGRATION

The process of integrating signals over a given period of time is conducted in the FPGA. In this process, the samples from a given time interval are added up. The signals/pulses that trigger the starting and stopping of each integration interval come asynchronously to samples produced by the analog-to-digital converters. This necessitates the inclusion in the integration calculations the fractions of the first and last sample in the integration window (see Fig. 3). The beginning and end of each integration window is calculated using the sampling frequency and the integration time. The integrator module maintains a timeline for the sequence of samples that allows it to determine the number of samples (with the precision of a fraction of a sample) to be removed from the input queue and summed up.

The triggering information and the integration timeline are common to all data channels and the same operations are performed on each signal channel for each integration window. The original raw data stream is significantly reduced in size due to this integration process.

The implementation of integration has been conducted while paying close attention to the precision of calculations.

Figure 4: Sample angular encoder signals. Note noise example on A signal.

## TRIGGERING

There are two main types of integrator triggering: internal and external.

Internal triggering relies on the FPGA clock to specify integration windows. The clock ticks are counted and after a required number is reached a new element is added to the timing queue.

External triggering is based on monitoring digital inputs for changes in their levels. A simple version will use a single digital input, providing a train of pulses controlling integration intervals. A more complex method, normally used in rotating coil measurement systems, is to trigger using angular encoder signals (see Fig. 4). Here, three signals are monitored to detect changes of their levels: index, A, and B. The A and B signals have their phases shifted, therefore allowing for detection of rotation direction. A, B, or a combination of both are used for generating timing triggers. The index pulse allows for starting the integration process at a known angular position (index position).

In practice, the external triggering signals may be distorted, which may lead to improper operation of the integrator. One problem is associated with vibrations of the mechanical parts attached to encoders, which may result in detecting multiple closely coupled triggers (see Fig.4). To eliminate such problems, the timing module ignores any trigger occurring too close to the previous trigger. The timing module also counts the number of triggers in each full revolution, index-to-index, and compares with the expected number.

A second problem has to do with spikes produced by noise in angular encoder signals that can be detected as “false” triggers. Multiple probing is used to eliminate these disturbances. In essence, whenever a rising edge is detected on a trigger line, the inter-trigger time is saved to a temporary register (in units of 40 MHz clock ticks) and a small debouncing delay is started. If the trigger line still reads as logic high by the end of this delay, then the inter-trigger time is validated and is placed on the queue. Counting then restarts using this debouncing delay period length as a starting point instead of zero, since this delay

period has elapsed after what would have been the reset-to-zero condition for the time counter. Otherwise, if the trigger line returns to a logic low state, then the contents of the temporary register are discarded and time-counting continues to increment.

With this method, false triggers can be ignored without introducing any phase drift to the inter-trigger times. This debouncing delay is user-settable and is determined through empirical observation since noise conditions at different test stands can be unique.

## EDI INTERFACE

The EDI is controlled via an Ethernet interface. Commands and data are sent through the same multichannel socket connection with separate channels devoted to streaming data and exchanging control messages. This basic functionality can be extended by adding additional channels devoted to transmission of auxiliary data and their control information.

On the client side, applications use the provided set of commands to communicate with the EDI. A subset of commands that captures the core functionality of the EDI includes:

- **CONFIG:** a command that sends a cluster of settings of various EDI properties and parameters,
- **RUN:** a request to start streaming of integrated data from all configured ADC channels,
- **ABORT:** a command used to stop the streaming of data (typically, the EDI is configured to send only a discrete number of integrated samples),
- **TEMPERATURE:** a command that reads the temperatures of all ADC modules, which can be used to correct results or check operating conditions,
- **ACCELEROMETER:** as an example of specialized commands added to tailor EDI functionality to a specific application, this is a request to read auxiliary analog inputs connected to an accelerometer

Depending on the configuration selected, the EDI may either perform integration using a discrete number of triggers, or it may run in a continuous mode. In this continuous mode, the EDI will not stop streaming integrated data until an abort command is received. In either mode, data is never saved to disk on the EDI but is instead always sent over the network, allowing for potential further processing of the data by other consumers on the network.

## PERFORMANCE

There are some performance limitations inherent to the organization of the EDI. The integration time is provided with a resolution limited by the FPGA clock. Also, over a longer period of time, the timeline calculations will introduce additional errors due to their limited computational precision. Therefore, over a very long continuous integration measurement run (measured in hours), operations need to be periodically restarted to

eliminate accumulation of errors and avoid a substantial phase shift.

Having two separate clocks in the system, with one used by the ADCs and another in the FPGA for inter-trigger timing, could also adversely impact the performance of the EDI. To address this very problem, both clocks have been synchronized.

The performance of the EDI is also strongly dependent on the performance of the ADCs, their time and temperature stability, offset, noise level, and dynamic range, among other factors.

## EXTENSIBILITY

The EDI device has a configurable number of ADC integration channels with a minimum of 4 channels and has been tested with 8, 12 and 16-channel configurations. Access to additional digital and analog I/O modules allows for the instrument to also serve some auxiliary functions.

One example is the extension to read accelerometers developed for the rotating coil system for the HL-LHC AUP project [15]. The available auxiliary analog input channels are read via the FPGA and data are sent to the consumer via a separate communication channel.

Another extension developed for the same measurement system allows for receiving a stream of real-time readouts of magnet current obtained from a DCCT and distributed in the measurement hall via a fiber optic connection. This implementation uses the auxiliary digital inputs to create a receiver of encoded data packets in the FPGA.

As a future extension, the authors plan to include drift compensation and discrete Fourier transform calculations in the FPGA, therefore allowing for the conversion of integrated signals to a frequency spectrum.

## SUMMARY

Building instruments from COTS parts is an attractive alternative to buying devices that don't necessarily fulfill all the requirements or building complex instruments in-house. It offers shorter development cycles, lowers development costs, and produces a device fully suited to the task.

The Extensible Digital Integrator (EDI) is an example of successfully combining several COTS hardware component and, by adding software and firmware, creating a powerful and specialized test instrument.

The EDI employs an FPGA mainly as a coprocessor, but also for synchronizing acquired analog data with external timing signals. It can be further extended to acquire and process other signals via the auxiliary I/O on the FPGA.

The use of an FPGA not only as a signal preprocessor, but as a coprocessor, can also be applied in other situations in real-time systems where data needs to be processed with hard real-time constraints.

The described digital integrator is fully functional and the conducted performance tests and comparisons with other available integrators show its satisfactory performance. In a multichannel configuration of 16 ADC channels it is capable of continuously processing 4096 triggers per second.

## Abstract

The beamlines and front ends at Sirius, the Brazilian 4th generation synchrotron light source, require monitoring and protection systems for personal and equipment safety in general, due to the high beam power dissipated along the beamline, vacuum safety, secure radiation levels, use of robots, special gases, cryogenic systems, and other highly sensitive and costly equipment throughout the facility. Two distinct programable logic controllers (PLC) were then deployed to create the Equipment Protection System (EPS) and the Personal Protection System (PPS). This work presents an overview of the EPS/PPS - requirements, architecture, design and deployment details, and commissioning results for the first set of beamlines.

## INTRODUCTION

The personal protection system (PPS) and equipment protection systems (EPS) are individual per beamline and are implemented in general by two programmable logic controllers (PLCs). The PPS central process unit (CPU) is the Siemens's safety model 1516F-3 and the EPS CPU is Siemens's standard model 1516-3. Both systems use distributed I/Os with Profinet communication with the CPU. The main Graphical User Interface (GUI) is implemented by a Human Machine Interface (HMI) common to other PLC based subsystems and the Input/Output Controller (IOC) [1] is used to allow communication via OPC Unified Architecture (OPC UA) [2, 3] between the PLCs and the Experimental and Industrial Control System (EPICS) [1].

This article is divided into three parts: The first part is about the EPS, the second part is about the PPS and the third is about common subjects related to EPS and PPS.

## EPS

### Basic Principles

The principles of EPS are low response time, use of positive logic, distributed I/O modules, and simplified detection of the protection logic triggers. The protection logics are very similar among the beamlines, the main protection logics are related to vacuum, temperature, position, and power loss. The program is modularized by hatches, the interface data and functions with the sensors and components form an object's library. The interface with other systems happens through galvanic isolated

signals, then the EPS logic and the other system logic actuate together.

There are three checklists for commissioning the EPS: I/Os signals validation, HMI validation, and protection logic validation.

### Protection Logics

The protection logic related to vacuum, temperature, position, and blackout fail are following. These protection logics are triggered by an EPS reading or an interface signal with other systems.

**Vacuum protection.** The vacuum protection system is divided into fast vacuum protection, slow vacuum protection, and low vacuum protection.

Fast vacuum protection is treated individually by the following VAT's devices: Controller VF-2, cold cathode gauge and shutter valve [4]. The shutter valve is installed in the front-end (FE) and the gauge is installed in the vacuum path between FE and the first optical hatch. These devices aim to protect the storage ring (SR) from a high-speed shock wave that could come from the beamline. A detailed description of tests and validation of this matter can be consulted in the article [5].

Slow vacuum protection is used in ultra-high vacuum (UHV) regions, it consists in isolate vacuum paths and interlocks the valve opening in case of high pressure detected. Ionic pump and cold cathode gauge controllers diagnose high pressure through digital signals. Intended to keep the beam on SR, the FE's protection system is triggered if the ionic pump and the cold cathode gauge detect high pressure. Disconnecting the cold cathode gauge connector, it reads a very low pressure, which could indicate a safe condition to FE's protection system even if the ionic pump is turned off. To avoid this unsafe condition, the gate valves opening is allowed only if all ionic pumps before FE's shutter are detecting pressure below the limit, and all cables are connected.

Low vacuum regions are usually situated in experimental stations, with pressures between 1000 mBar and  $1 \times 10^{-7}$  mBar. The protection logics are specific for each region.

From FE's shutter, if a high pressure is detected on a vacuum path by any sensor, the protection logic is triggered closing and interlock the opening of all the gate valves in UHV downstream to the shutter where the trigger occurred. The valves opening logic between shutters are sequential, from downstream shutter to upstream shutter.

Some vacuum paths are specified as critical paths. On these critical paths, due to a fast actuating needed by the

\* Work supported by the Brazilian Ministry of Science, Technology and Innovation

<sup>†</sup> lucas.arruda@lnls.br

valves, valve's close commands and shutters' close commands are sent simultaneously. The critical paths are usually presented in vacuum paths close to experimental stations' windows.

**High temperature protection.** The protection against high temperature is made through temperature measurement right on device structure and water flow measurement. The most used temperature sensors are PT100, PT1000, and thermocouple type K. For PT100 and PT1000, it's preferentially connected using the four wires connection. The water flow sensors are manufactured by SMC [6], model series PF3W, and uses the Kármán vortex measurement method. If the temperature read by EPS is higher than the limit or water flow is lower than the limit, the upstream shutter is closed and interlocked.

**Position protection.** This protection system is present usually on beam visualization devices, monochromators, and devices next to robots' workstations. The position protection ensures that the beam does not focus on parts not prepared for beam. On other devices, it also guarantees that collisions do not happen. The most used sensors are inductive or optical barrier types. In case some sensor detects an unsafe position, the upstream shutter is closed and interlocked, or the unsafe device has its motion interrupted and interlocked.

**Power outage protection.** This protection logic is triggered in case of fail on EPS' power supply 24 VDC. The power supply consists of the use beamline's UPS circuit, two voltage sources 24 VDC, a redundancy module, a buffer, fuses, and selectivity modules. The following Fig. 1 exposes a connection diagram of these devices.

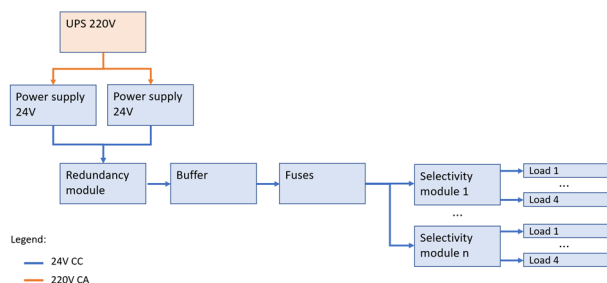

Figure 1: EPS and PPS's 24 VDC connection diagram.

The power supply failure occurs due to a beamline UPS device fail, 24 VDC power supply distribution device fail or by pressing the electricity emergency button. In case of pressed electricity emergency button, because of safe conditions defined together with Sirius' safety group, all the components of the beamline are shutdown, including ionic pumps, turbopumps, and mechanical pumps. This protection logic's priority is to keep beamline vacuum paths in a safe condition before EPS shutdown, this safe condition is guaranteed closing all the valves.

A power outage failure diagnostic is made through state signals available by the voltage sources, redundancy modules, buffers, and selectivity modules. The buffer generates a delay on the shutdown between 200 ms and 10 s, which is enough time to execute the protection logic.

## Software Structure

EPS' program was separated into: Protection logic, devices' objects, other systems interface, and communication. Figure 2 represents the software structure scheme.

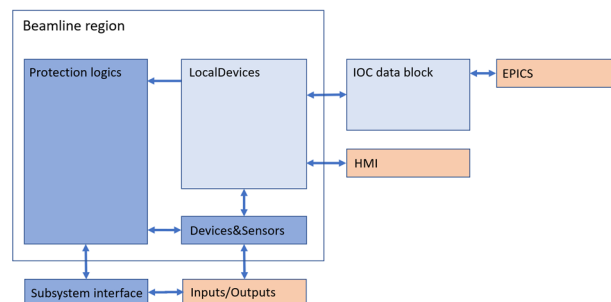

Figure 2: Scheme containing function blocks (dark blue), data blocks (light blue) and external interfaces (orange).

**Objects.** The objects in EPS are a set of variables and functions that allow actuating on devices, generate alarms, set settings, and collect information. As the connected signals are like each other in all beamlines, the set of object types, like gate valves, digital sensors, analog sensors, and among others, creates a library. In EPS, the objects' variables are contained in a data block called LocalDevices, and the functions of each device are contained in a function block called Devices&Sensors.

The creation of objects and the use of the library favors standardization and decreases developing time because it provides a simpler programming interface, the diagnostics variables that are used in protection logics, alarms, and devices' data accessed through HMI and EPICS communication.

By using this patterned structure of the devices, was developed a script that generates the files of IOC's settings, and the code in SCL programming language that moves LocalDevices' data blocks to EPICS' interface communication data block.

**Interlock.** In the functions' interface inside Devices&Sensors, there are inputs dedicated to interlock. These inputs work with positive logic and the interlock function is executed independently the others inputs' state.

**Vacuum protection logic.** The slow vacuum protection logic owns a patterned structure. The first part of the code generates diagnostic flags that indicates if the regions before or after the shutter are with a good vacuum. For that, each vacuum path has a logic AND or OR among the vacuum gauges depending on the path's location. Posteriorly, the generated flags of the regions before or after the shutter are used below in each valve's logic, which could trigger the device's interlocks inputs.

## Commissioning

To execute the beamlines EPS' commissioning three tests was developed: signals checklist, protection logics tests, and HMI tests. The signals checklist verifies if the signal's tag on the PLC matches physically to the device and if the signal behaves as specified in the tag's

description. The protection logic tests consist in emulating in PLC all fail conditions in the beamline that triggers one of the protection logics and watch the resulting signals and components' states. In HMI all the visual indicators and commands are verified.

After these three tests validation, the hutch can operate from the equipment protection system point of view. The software division mentioned in Software structure by hutchers allowed a faster availability of hutchers to commissioning with the beam.

## PPS

### Basic Principles

The PPS consists of an automation system designed to allow facilities to operate at the appropriate security levels, determined by personal risk analysis. The solutions applied are based on engineering good practices, Brazilian and international technical standards, acquired experiences over the years in the first Brazilian synchrotron light source and from the other countries synchrotron light sources, and using certificated security components commercially available.

### Protection Logics

From risk analysis in the beamlines and previous experience, four main protection logics are highlighted.

**Search.** The search procedure is monitored by PPS, performed by one person, and consists in a visual inspection of the hutch or a beamline's region and pressing the search buttons, to guarantee that there is nobody inside the risk region.

The search procedure must be executed by a trained and enabled person. Beyond these administrative requirements, is in development an enabling system of the search that uses an RFID card. This system will be responsible for generating a data logging containing data about the performer of the search: The date, time, and local that the search has been done. Besides, the system can set an expiration time to each RFID card.

As an improvement, light curtains were installed on the region of the hutch's door and are used to verify if more than one person goes into the hutch during the procedure. In case of interruption on the curtain's beam before all the buttons being pressed, the search process is interrupted and must be restarted. After the procedure's finalization, the light curtain inside the hutch keeps monitoring and is used as an additional emergency signal, in this case, the shutter is closed, the beamline goes to fail state and the doors are unlocked.

**Security locks.** On the hutchers' doors were installed security locks from different manufactures to offer diversity and redundancy. One of the locks counts with an electromagnetic lock and the other with a mechanical lock, so that exists a position monitoring and a lock that generates a force maintaining the door in a safe position.

**Enabling keys.** Each beamline count with a set of keys monitored by PPS. Being one for each hutch, a general enabling key used by the radiological protection group, and

a key for reset. The chicanes own monitored keys by PPS and use the trapped key system.

**Emergency buttons.** The types of emergency buttons were reduced to only two buttons, being the personal protection emergency button and the electrical emergency button. The personal protection buttons are distributed over the beamline and monitored by PPS to react in case of pressing, immediately closing the shutters and disabling other systems that could exist in the beamlines, like robots.

### Software Structure

The PPS's program is separated into some logical parts: safety protection logic, non-safety protection logic, data blocks to create an interface between safety and non-safety logic, and data blocks used for communication. Figure 3 represents the software structure scheme.

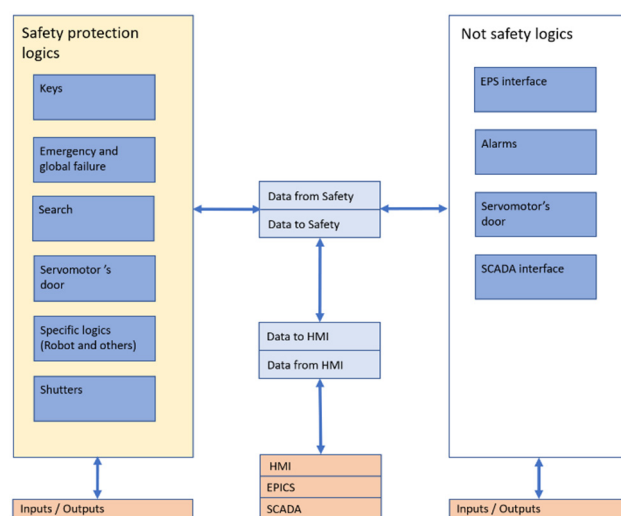

Figure 3: Scheme containing the main function blocks (dark blue), data blocks (light blue) and external interfaces (orange) to the PPS.

The search and shutter function blocks are equal functions for all the regions that need these functionalities.

The HMI, EPICS, and SCADA communication data blocks were separated from the safety data for security.

### Initial Tests of the Protection Logics

To validate the PPS's logic before using the program in the beamline were developed a simulation software by tables using a virtual controller through an API from S7-PLCSIM Advanced and an application based on SimTableApplication, made available by Siemens [7].

The program inputs consist of tables with initial beamline conditions, inputs with changed values in an interval of time, and the expected states to the outputs. By executing the program, the generated outputs by the virtual controller are compared with the expected states and are generated a report indicating the comparison result.

### Commissioning

To execute the beamlines PPS's commissioning, initial tests of hardware operation are made (indicator lights, buttons, safety locks, and others), following is a checklist

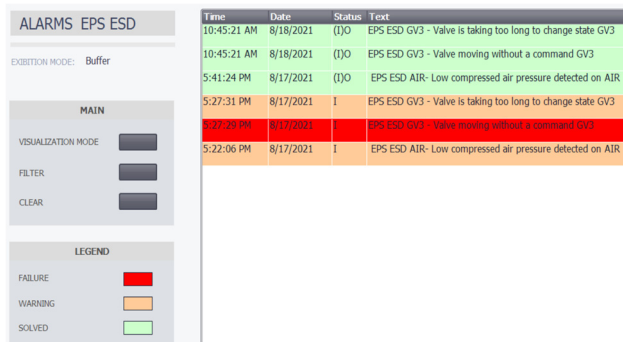

Figure 6: Sequence of alarms registered when there was a lack of compressed air on D hutch from beamline Carnaubá.

For example, analyzing the alarms in Fig. 6 is possible to conclude that probably the lack of air made the valves move to a position different from that EPS was commanding, it caused a failure on the beamline, and that the insufficient pressure did not close the valve completely. It's also observed when the pressure was back to normal and when the valve moved to a close position. Only using Archiver [8], this analysis of causes and effects could consume a time considerably higher.

### Sirius Improvements and UVX

In UVX, EPS and PPS worked differently than was projected to Sirius. The principal characteristics in UVX were: There was only one CPU per beamline from manufacturer Pepperl Fuchs [10] for both systems EPS and PPS, personal safety logics were executed using safety relays, distributed I/Os with ASI communication, and the interface with the user was made through panels with pushbuttons and a graphic interface developed by LNLS called Superinter to generation and verification of alarms communicated by RS232. In this system, no analog sensors were reading, only digitals because of the used hardware characteristics.

The main improvements in Sirius are related to infrastructure, software structure, communication, user interfaces, EPICS communication, and alarms diagnostics.

## ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology, and Innovation and the contribution of the LNLS team involved in the development, installation, and commissioning in the EPS and PPS subsystems.

# THE LMJ TARGET CHAMBER DIAGNOSTIC MODULE

R. Clot, CEA, Le Barp, France

## Abstract

The Laser MegaJoule (LMJ), the French 176-beam laser facility, is located at the CEA CESTA Laboratory near Bordeaux (France). It is designed to deliver about 1.4 MJ of energy on targets, for high energy density physics experiments, including fusion experiments. The first bundle of 8-beams was commissioned in October 2014. By the end of 2021, ten bundles of 8-beams are expected to be fully operational.

Due to the energy levels achieved, the optical components located at the end of the bundles are highly subject to damage stresses. This is particularly the case with vacuum windows whose integrity is critical.

To measure these damages, identify the growth laws, and prevent their degradation (through blockers), the Target Chamber Diagnostic Module (called by its french acronym MDCC) was integrated into the LMJ installation in 2019. This diagnostic, which also measures the windows transmission rate, as well as the spatial energy distribution at the end of the bundles, has been designed to operate automatically at night, between two experiments.

This presentation describes this three years feedback of MDCC. It also presents the areas for improvement which have been identified to optimize its efficiency and reduce its timeline.

## INTRODUCTION

The laser Megajoule (LMJ) facility, developed by the “Commissariat à l’Energie Atomique et aux Energies Alternatives” (CEA), is designed to provide the experimental capabilities to study High Energy Density Physics (HEDP). The LMJ is a keystone of the Simulation Program, which combines improvement of physics models, high performance numerical simulation, and experimental validation, in order to guarantee the safety and the reliability of French deterrent weapons. Once fully operationnal, the LMJ will deliver a total energy of 1.4 MJ of  $0.35 \mu\text{m}$  ( $3\omega$ ) light and a maximum power of 400 TW.

The LMJ is sized to accommodate 176 beams grouped into 22 bundles of 8 beams. These will be located in the four laser bays arranged on both sides of the central target bay of 60-meter diameter and 40-meter height. The target chamber and the associated equipment are located in the center of the target bay.

Due to the energy levels achieved, the optical components located at the end of the bundles are highly subject to damage stresses. This is particularly the case with vacuum windows whose integrity is critical as it is a safety component which constitutes the vacuum limit of the chamber where the experiments take place. It’s also an expensive component that we need to take care of.

To measure the damages they suffer, identify the growth laws, and prevent their degradation, the Target Chamber Diagnostic Module (called by its French acronym MDCC)

was integrated into the LMJ facility at the end of 2019. This diagnostic inqtrument, which also measures the windows transmission rate, as well as the spatial energy distribution at the end of the bundles, has been designed to operate automatically by night, between two experiments.

This paper reminds the LMJ facility principle before presenting the MDCC and its functionalities with a focus on the measurement of optical component damaging. It also presents the feedback of the measurement sequence timeline and the work achieved to reduce it and make it fit in the facility timeline.

## LMJ OPERATING REMINDER

The LMJ 176 beams ( $37 \times 35.6 \text{ cm}^2$  each) are grouped into 22 bundles of 8 beams. In the switchyards, each individual bundle is divided into two quads of 4 beams, the basic independent unit for experiments, which are directed to the upper and lower hemispheres of the target chamber.

Basically, an LMJ laser beam line is composed of three parts: the front-end, the amplifying section, the switchyard and the final optics assembly.

The front end delivers the initial laser pulse (up to 500mJ). It provides the desired temporal pulse shape and spatial energy profile.

The initial pulse leaving the front end is amplified four times through two amplifiers, in order to obtain the energy required for the experiments (up to 15 kJ at  $1\omega$  per beam). Positioned between the two amplifiers, focusing lenses, associated to a diaphragm (spatial filter pinhole), take out the parasitic (noise) beams that may arise. Beyond the two amplifiers is a reflecting mirror (M1), making the four passes possible through angular multiplexing, as shown on Fig. 1. The surface of this mirror is deformable (being controlled by electro-mechanical actuators), allowing beam wave-front distortions to be controlled.

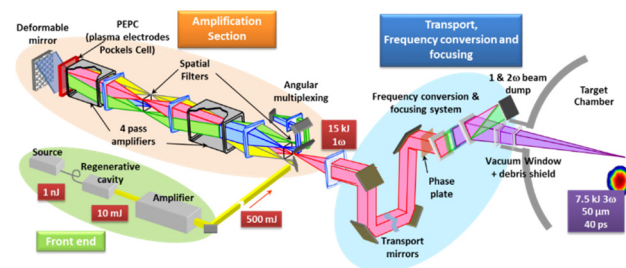

Figure 1: Laser beamline schematic diagram.

The 8 beams coming from the amplification section are divided into two quads. Each quad is transported over more than 40 meters into the target bay and is directed to the upper or the lower hemisphere of the target chamber using six transport mirrors per beam. Each quad arrives into a frequency conversion and focusing system (SCF). Inside the SCF, the beams frequency is changed from infrared ( $1,053$

nm) to ultraviolet (351 nm). The frequency conversion is realized by two KDP crystals, with a global efficiency of about 60%. The beams are focused on target using a  $3\omega$  focusing grating. This specific component allows spectral separation (to ensure only 351 nm wavelength reaches the target).

## MDCC MEASUREMENTS

The MDCC achieves three different measurements on LMJ facility.

The first one is the damaging of the end of bundle optical components: the vacuum windows and the  $3\omega$  gratings. The vacuum windows being the most important optical component, they make the damaging measurement critical for LMJ facility security.

The second measurement is the vacuum windows transmission rate. It consists in an intensity comparison of a monitored ultraviolet LED signal send through the vacuum window, and the returned signal (reflected) measured by the MDCC.

The third measurement is the energy distribution at the end of the bundles, which is measured by the MDCC on the vacuum window on a 1J shot to the target chamber.

## MDCC PRESENTATION

The MDCC is made up of two subsystems: an Optical Block and a Motion Block (Fig. 2).

Figure 2: MDCC presentation.

The Optical Block is assigned to the acquisition part of measurement. It's especially made up of a large lens and a CCD camera which receive and acquire the signals. Transmission between them is handled by two redirection mirrors which enable the camera focus thanks to a motor. Three other motors are used on the Optical Block to correct the camera camber, to move a wheel to filter wavelengths, and to insert a mirror dedicated to a UV LED redirection for the transmission rate measurement.

The Motion Block is assigned to the diagnostic positioning. It carries the Optical Block and enables to address the various optical components of the installation thanks to two motors and two rotation angles.

## DAMAGING MEASUREMENT PROCESS

The acquisition of damages on vacuum windows is realized shot to shot at night with the MDCC while teams are resting (Fig. 3).

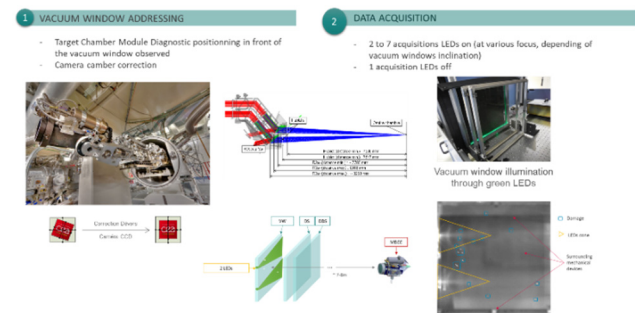

Figure 3: Damaging measurement process.

In the first part of the measurement, the MDCC positions itself in front of the vacuum window observed, 7 to 8 meters away. The camera camber, dependent of the component tracked, is corrected at the same time to center the window on the camera.

Two green LEDs on the side of the vacuum window are used to light the surface and optimize the damage tracking. Each damage becomes a bright spot visible on acquisitions. The illustration down center shows the LEDs cone in yellow and the damages surrounded by blue squares.

Several acquisitions are made at various camera focus to take in account the different vacuum window inclination and the camera depth of field.

A final acquisition, with LEDs off, is made to subtract a noise image to the useful ones and also enhance acquisition analysis.

## DAMAGING MEASUREMENT STAKES

The vacuum window damaging measurement is the most critical and has 3 determining stakes for LMJ facility (Fig. 4).

### 3 determining stakes

- Ensure installation security
  - 2 safety criteria for vacuum windows
- Enhance optical component durability
  - To limit costs and because of production and maintenance capability
  - Damage growth stop thanks to spot blockers
  - Recycle loop possible if damage size < 750  $\mu\text{m}$  (reminder : MDCC resolution = 100  $\mu\text{m}$ )
- Damage prediction
  - Damage laws knowledge for laser performances
  - Short term (maintenance) and long term (planification) prediction

Figure 4: Damaging measurements stakes.

Thanks to MDCC, we're able to detect damages of a 50 micrometers size. This size corresponds to the triggering of damages and the beginning of their growth. To characterize them we track 2 safety criteria thanks to a software analysis with one being the most restrictive. By keeping C2 criteria under 60% for any  $2 \times 2 \text{ cm}^2$  sub-aperture, we ensure the LMJ installation security.

A second stake of the damage measurement is to enhance our optical components durability. Our goal is to stop the growth of damages from 400  $\mu\text{m}$  as we are unable to repair damages bigger than 750  $\mu\text{m}$ .

The challenge is therefore to be able to monitor damage growth in noisy images before damage size reaches 5 pixels.

We also have to set efficient algorithms to detect and track damages.

To prevent the growth of the damages and keep them under the limit which allows their repair, we developed a new functionality on the LMJ installation. It enables to set spot blockers on the energy spatial distribution at the start of the laser bundles, and also prevents spreading energy on the most damaged surfaces of the vacuum windows. The pictures down right show a spot blockers grid at the start and at the end of a bundle.

The third stake of the damage measurement is the prediction capability. We need to identify the damage laws to improve laser performances, optical components maintenance at short term, and installation planification at longer term.

Our strategy is also to protect our end of bundle optical components is based on a complete scheme including acquisition, damage detection, damages growth brake and recycling loop of the components.

The first steps are already in use, whereas the first recycled components will be back on the installation around 2025.

SEQUENCE TIMELINE

MDCC has been designed to operate automatically by night, without needing any operator intervention. This is very important for the LMJ installation as experiments are prepared from the early morning for the shot to happen in the evening. The damage measurement at night is also critical to give the green light to the experiment of the next day.

After MDCC integration at the end of 2018, the sequence duration put in the front that by extrapolation it was well too long and totally incompatible with installation timeline.

So we launched a research for solutions to shorten the sequence and make it fit the 4 hour time slot allocated in the targeted installation timeline.

TIMELINE IMPROVEMENTS

Thanks to an efficient team work, 12 improvements have been identified to reduce the damaging measurement sequence timeline. They have been classified in 4 themes whether they relate to the camera, the MDCC mechanics, the measurement principles or the command control.

Two of them have been dropped as they were either too complex to implement or too restrictive on performances.

The other ten have been considered in view of their gain on the timeline and our ability to implement them quickly or in the long-term (Fig. 5).

THEME	IMPROVEMENT	IMPLEMENTATION COMPLEXITY	TIME GAIN FROM INITIAL SEQUENCE CONFIGURATION	PERFORMANCES IMPACT
CAMERA	Upgrade of acquisition card electronics	Average	4h30	-
	Camera model change (CCD to CMOS)	High	6h	-
MECHANICALS	Compensation of vacuum window tilt through MDCC	Very high	8h	Very good
	Compensation of vacuum window tilt through MDCC	High	8h	Very good
	Addressing motor speed enhancement	Very low	35min	Minor or none
MEASUREMENT	Optimisation of useful acquisition number	Low	6min	Very good
	Reduction of noise acquisitions number	Low	4h10	Minor
	Decrease of acquisitions resolution	Very low	6h	Very bad
COMMAND CONTROL	Deletion of sequence configuration bypassing	Very low	10 min	-
	Deletion of double results production	Very low	3h20	-
	Enhancement of results production	Low	1h45	-
	Parallelization of configuration and results production	Average	3h20	-

<sup>1</sup> Cost/Time compromise  
<sup>2</sup> Improvements combination reduce timesaver compared to sum of individual improvement timesavers

Figure 5: Sequence timeline improvements.

IMPROVEMENTS IMPLEMENTATION PLAN

To reduce the sequence timeline according to the LMJ installation needs, we built an implementation plan of the selected improvements. We planned each other into one of 3 phases forecasted between 2020 and 2024 (Fig. 6).

THEME	IMPROVEMENT	IMPLEMENTATION STATE
COMMAND CONTROL	Deletion of sequence configuration bypassing	Achieved in 2020
	Deletion of double results production	Achieved in 2020

THEME	IMPROVEMENT	IMPLEMENTATION STATE
CAMERA	Upgrade of acquisition card electronics	Achieved in 2021
MEASUREMENT	Optimisation of useful acquisition number	Achieved in 2021
MEASUREMENT	Reduction of noise acquisitions number	Achieved in 2021
COMMAND CONTROL	Enhancement of results production	Achieved in 2021

THEME	IMPROVEMENT	IMPLEMENTATION PLANNING
CAMERA	Camera model change (CCD to CMOS)	2024-2025
MECHANICALS	Addressing motor speed enhancement	2022
	Compensation of vacuum window tilt through MDCC	2024
COMMAND CONTROL	Parallelization of configuration and results production	2024

Figure 6: Improvements implementation plan.

The first one has been achieved in 2020 and the second mid-2021. The results confirm the expectations we made as we already reduced the sequence timeline by more than 50% as foreseen.

Without surprise, the mechanicals improvements and the camera change will be the latest to be implemented, as they lead to an important work of preparation and maintenance.

EVOLUTION OF SEQUENCE TIMELINE

The following diagram (Fig. 7) presents the damaging sequence timeline evolution thanks to the implementation plan previously described.

Figure 7: Sequence timeline evolution.

It shows the way the sequence timeline shortens through the 3 phases displayed in the previous slide.

Each colored line matches a configuration of LMJ, that is to say the number of laser bundles used for the main milestones of the installation.

Thanks to Phase 1, we're now already able to run the damaging measurement sequence in less than 4 hours for 11 laser bundles, which is our next milestone in 2022.

Phase 2 will be a prerequisite for the next ones when we will use 15 and 22 laser bundles, with an expectation of hardly 2 hours and 20 minutes for LMJ nominal configuration.

It will mean MDCC came a long way if we consider where is started in term of sequence timeline.

## SUMMARY

To sum up, there are six things to remember:

1. MDCC is a recent and autonomous laser diagnostic which achieves three measurements.
2. The vacuum windows damaging one is the most critical for LMJ installation as it's the greenlight for the next experiment.
3. MDCC also enables to ensure installation security and enhance optical components durability.
4. The first sequences led to a warning on the duration of the damaging measurement sequence.
5. To reduce it we identified various improvements that we started to implement, with the main ones to come.
6. The evolution of sequence timeline is promising to fulfil the installation needs and our expectations.

# DEVELOPMENT OF A VOLTAGE INTERLOCK SYSTEM FOR NORMAL-CONDUCTING MAGNETS IN THE NEUTRINO EXPERIMENTAL FACILITY AT J-PARC

K. Nakayoshi\*, K. Sakashita, Y. Fujii

High Energy Accelerator Research Organization (KEK), Tsukuba, Japan

## Abstract

We are upgrading the neutrino experimental facility beamline at J-PARC to realize its 1.3 MW operation. One of the upgrade items is to strengthen the machine protection interlocks at the beamline. So far, we have developed an interlock system that monitors the output current of the power supplies for the normal-conducting magnets in the primary beamline. On the other hand, a coil-short in one of the bending magnets at a beam transport line (3-50BT) at J-PARC happened in 2019, and it caused a drift of the beam orbit over time. Our present interlock system cannot detect a similar coil-short in the magnet, while such a change of the beam orbit may cause serious damages. One possible way to detect such a coil-short is to monitor the voltage of the magnet coil. Actually, a significant voltage drop between layers of the coil was observed for the 3-50BT magnet coil-short. Focusing on that fact, we are developing a system that continuously monitors the voltage value of the magnets at the primary beamline and issues an interlock when there is a fluctuation exceeding a threshold value. We report on the progress of the development of this system.

## BACKGROUND

At the neutrino experimental facility at J-PARC, a large amount of neutrinos are generated using a high-intensity proton beam extracted from the Main Ring Synchrotron (MR) and sent towards the Super-Kamiokande detector, 295 km away, for a long baseline neutrino oscillation experiment (the T2K experiment) [1]. The MR stopped operation in July 2021 and upgrades, such as replacing the power supplies are ongoing. The beam to the T2K experiment is scheduled to resume in the fall of 2022. Also, the neutrino beamline equipment is being upgraded to support a beam intensity enhancement [2]. Figure 1 shows the primary proton beamline of the neutrino experimental facility. The proton beam extracted from the MR is transported to the graphite target 240 m away by 14 doublet super-conducting magnets (hatched in yellow) and 21 normal-conducting (NC) magnets (hatched in blue). If an abnormality occurs in the transport system of the primary proton beamline during beam operation, the high-intensity proton beam may deviate from the normal orbit and hit the beamline equipment. In that case, the thermal shock of the high-intensity proton beam could cause serious damages to the beamline equipment, which would take a long time to recover. In order to avoid such a situation, we have strengthened the interlock so far. For NC

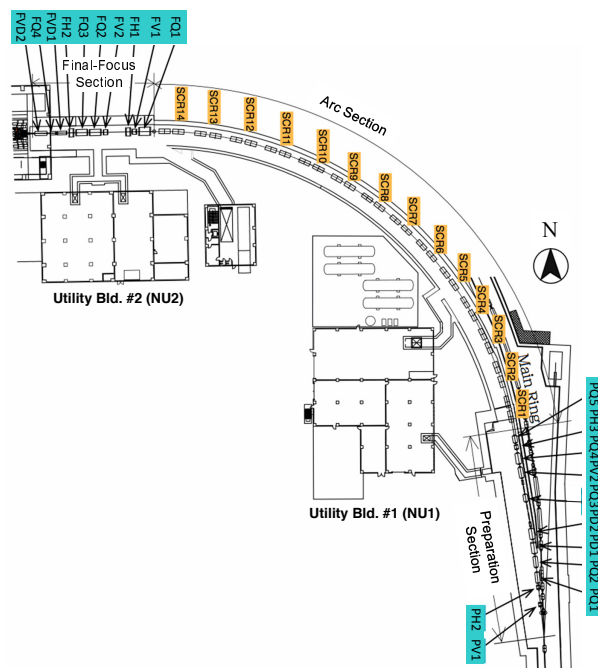

Figure 1: The primary proton beamline of the neutrino experimental facility at J-PARC.

magnets, we have developed an interlock system for detecting current fluctuations in the NC power supplies and have been operating this system from 2012 to the present [3, 4]. When an interlayer short circuit occurred in a dipole magnet coil of J-PARC's beam transport line in 2019, there was no change in the current Value of the power supply, but fluctuations in the voltage of the corresponding magnet coil were observed [5]. This means that our current fluctuation interlock cannot detect an interlayer short circuit of the NC magnets. In order to further strengthen the interlock of the NC magnet system, we are developing a system that detects a voltage fluctuation of the NC magnets and issues an interlock. The target value of the voltage fluctuation detection system was set to 1%.

## PRELIMINARY STUDY

### How Can We Measure the Magnet Coil Voltage?

Before developing the voltage interlock system, we made a preliminary measurement of the magnet coil voltage. During the accelerator operation, the voltage of the magnet coil

\* kazuo.nakayoshi@kek.jp

was measured to check its noise level, and whether an interlock that detects voltage fluctuations and issues an interlock is feasible. The measurement was performed for 5 hours using a digital multimeter Keithley 2701. Figure 2 shows a histogram of the results of the measurement. The average value of the histogram in Fig. 2 is 49.5 V and the full width is 0.120 V (*full width/average* = 0.24%). It was found that the voltage of the magnet coil could be measured at the power supply on the ground floor with the required accuracy even when the accelerator was in operation.

Figure 2: The result of a preliminary measurement of the magnet coil voltage.

### What Kind of System We Will Adopt?

Figure 3 shows the equivalent circuit of our voltage fluctuation detection circuit. In order to minimize the magnet current deviation, we considered a voltage divider circuit. The NC magnet impedance is 39.3 mΩ. Taking the power consumption of the voltage fluctuation detection circuit into account, we decided to set the impedance  $R_s$  of the voltage divider circuit + ADC to  $10 \text{ k}\Omega \leq R_s \leq 10 \text{ M}\Omega$ .

Figure 3: Equivalent circuit when the voltage divider circuit and ADC are connected to the magnet and power supply.

In order to realize a small latency and an intelligence function, we are evaluating a system using an Arduino UNO [6] left side of Fig. 4 and external ADC. For this study, we evaluated a Pmod-type ADC board [7] equipped with AD7685 (16 bit, 250 kSPS), right side of Fig. 4. The input impedance

of this board is as small as 0.4 kΩ, and since it does not meet the impedance required by this system, the resistance of the board was changed to 10 kΩ. An external resistor of 190 kΩ was attached in front of the ADC to divide the voltage at 20:1.

We will use EPICS as a control framework for the voltage interlock system like other interlocks in the neutrino facility. Also, a Raspberry Pi 3 [8] is used as an interface between the EPICS IOC and Arduino.

Figure 4: Arduino UNO (left) and Pmod type ADC (right).

## VALIDATION OF THE USE OF ARDUINO AND ADC

### Check Feasibility of ADC Readout by Arduino With SPI

Since the Pmod ADC board supports SPI (Serial Peripheral Interface, an interface bus commonly used to send data between microcontrollers and peripherals), we implemented SPI transfer with the Arduino. Figure 5 shows the wiring of the Arduino and Pmod ADC for SPI transfer. It was confirmed that the data can be read by SPI communication using a 3-wire mode with no busy indicator.

Figure 5: Wiring for SPI between the Arduino and Pmod ADC.

To check if the Arduino could read the ADC sampling data correctly, we read a sine wave output from a function generator using the Arduino. Figure 6 shows a graph of a 3 Hz, 1 V<sub>pp</sub> input signal obtained by the Arduino.

We also measured the linearity of the Pmod ADC. The input to the Pmod ADC is the output of the DC power supply. Figure 7 shows the results.

### Check the Functions Required for the Interlock System

We checked the Arduino for the following features needed for the interlock function.

- Checking the ability to compare read data with thresholds
- Implementation of threshold setting using interrupts
- Confirmation that the signal can be output as an interlock

Figure 6: Sine waveform acquired by the Arduino and Pmod ADC.

Figure 7: Results of linearity check for Pmod ADC.

The prototype provided the three operating modes shown in Fig. 8. In the normal mode, the Arduino reads the ADC

Figure 8: Operation modes for the Arduino.

value at 1 kHz, compares it with the threshold value, and transfers the ADC and threshold value to the Raspberry Pi at 1 Hz. When the ADC value exceeds the threshold value, the mode transitions to the interlock mode. The Arduino sets the digital output pin to HIGH and issues an interlock. In the threshold setting mode, the threshold value can be changed by sending a new threshold value from the Raspberry Pi to the Arduino. Changing the operation mode between the normal mode and the threshold setting mode is done utilizing the interrupt function of the Arduino.

### Threshold Setting Using Interrupts

Arduino interrupts were used to set the threshold for detecting voltage fluctuations. By turning on the interrupt signal for the Arduino from the GPIO pin of Raspberry Pi, an

interrupt for the Arduino is generated. The function called at the time of interrupt reads the threshold value written before the interrupt from the buffer and updates the threshold.

## PROTOTYPE DEVELOPMENT

### Prototype Configuration

Figure 9 shows the configuration of the prototype. The Pmod ADC board and Arduino are connected via a conversion board. The Arduino is connected to a relay board to output the interlock signal. The Arduino and the Raspberry Pi are connected with a USB cable and serial transfer is possible. Also, a cable is connected between the Raspberry Pi and Arduino for an interrupt signal. The Raspberry Pi communicates with the EPICS IOC via a media converter.

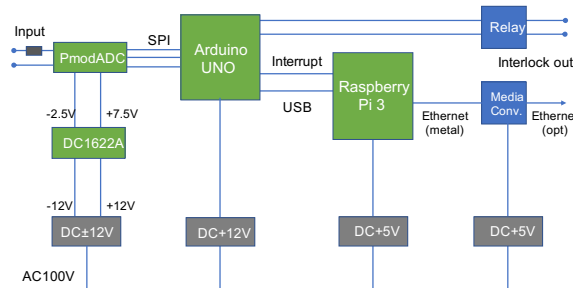

Figure 9: Diagram of the prototype.

### The Prototype in a Box

The prototype has been made into a single box for future performance evaluation tests (Fig. 10). The relay module and media converter for Ethernet keep this box electrically isolated from downstream systems. The size of the box is 430 mm × 330 mm × 115 mm.

Figure 10: The prototype in a box.

## PERFORMANCE EVALUATION

### Long-Term Stability Test

To evaluate the performance of the prototype, a stability test was conducted for 8 hours. As an input signal, a constant DC voltage of 10 V was injected using a DC power

supply. The results are shown in Fig. 11. We found some noise spikes, but they were smaller than our target of <1% variation (red dashed line in the figure). We are now trying to determine the cause of these noise spikes and how to reduce them.

Figure 11: The result of the long-term stability test.

Figure 12: The result of the interlock latency measurement.

### Interlock Latency Measurement

To measure the latency of the interlock, we used a DC power supply with an output of 10 V. The threshold value was set to  $\pm 1\%$  of the average value, and the output voltage was changed to trigger the interlock by hand. The latency time was measured by an oscilloscope (Fig. 12). In Fig. 12, CH2 (blue line) is an input to the ADC from the DC power

supply, and CH1 (yellow line) is an output of the Arduino to the relay.  $t_0$  is the time when the voltage starts to decrease.  $t_1$  is the time when the voltage has decreased by 1%.  $t_2$  is the time the interlock was activated. We fit the CH2 data with two linear functions and set their intersection point as  $t_0$ . The latency time was calculated as  $t_2 - t_1$ . Ten measurements were taken, and the average latency time was 2.1 ms.

## SUMMARY AND FUTURE PLANS

In order to strengthen the interlock of the primary proton beamline NC magnets of the J-PARC neutrino experimental facility, we are developing a system that continuously monitors the voltage of the magnet coils and issues an interlock when the threshold is exceeded. We developed a prototype of the system. For the next step, the prototype will be attached to the NC power supply for testing and improvement. After that, the actual system will be fabricated, and when the experiment resumes in the fall of 2022, the beamline will be operated with this interlock installed.

# PERFORMANCE VERIFICATION OF NEW MACHINE PROTECTION SYSTEM PROTOTYPE FOR RIKEN RI BEAM FACTORY

M. Komiyama<sup>†</sup>, A. Uchiyama, M. Fujimaki, K. Kumagai, N. Fukunishi, RIKEN Nishina Center, Wako, Saitama, Japan

T. Nakamura, M. Hamanaka, SHI Accelerator Service, Ltd., Shinagawa, Tokyo, Japan

## Abstract

We herein report on the performance verification of a new machine protection system prototype for the RIKEN Radioactive Isotope Beam Factory (RIBF) and on the study to improve its performance. This prototype has been developed to update the existing beam interlock system (BIS) that has been in operation since 2006. The new system, as was the BIS, was configured using programmable logic controllers (PLC).

We applied the prototype to a small part of RIBF and started its operation in September 2020. It consists of two separate PLC stations, has 28 digital and 23 analog inputs as interlock signals, and has five digital outputs used to stop a beam. The observed response time averaged 2 ms and 5.4 ms, within one station and with both stations, respectively. When deploying the prototype at the same scale as the BIS, which consists of five PLC stations with roughly 400 signals, the resulting performance would barely meet our requirements. Further, there is a risk that the system cannot protect the hardware when the beam intensity of the RIBF becomes higher. Therefore, we are re-designing a system by adding field-programmable gate arrays to significantly shorten the response time, rather than repeating minor improvements to save a few milliseconds.

## INTRODUCTION

The RIKEN Radioactive Isotope Beam Factory (RIBF) consists of two heavy-ion linear accelerators and five heavy-ion cyclotrons. One of the linear accelerators is mainly used for experiments to search for super heavy elements, whereas the other is used as an injector to the cascades of the cyclotrons used for nuclear physics, material science, and life science applications. The cyclotron cascades can provide the world's most intense RI beams over the entire atomic mass range by using fragmentation or fission of high-energy heavy ions [1].

The components of the RIBF accelerator complex (such as the magnet power supplies, beam diagnostic devices, and vacuum systems) are controlled by the Experimental Physics and Industrial Control System (EPICS) [2] with a few exceptions, such as the control system dedicated to RIBF's radio frequency system [3]. However, all the essential operation datasets of the EPICS and other control systems were integrated into an EPICS-based control system [4]. Additionally, two types of independent interlock systems are operated in the RIBF facility: a radiation safety

interlock system for human protection [5] and a beam interlock system (BIS) that protects hardware from high-power heavy-ion beams [6].

## BIS OVERVIEW AND DEVELOPMENT OF NEW MACHINE PROTECTION SYSTEM

The BIS began operation in 2006, along with the beam commissioning of the RIBF. Figure 1 shows the hardware configuration and process flow of the BIS, which was developed based on Melsec-Q series programmable logic controllers (PLCs) [7]. It was designed to stop beams within 10 ms after receiving an alarm signal from the accelerator and beam line components. Upon receiving an alarm signal, the BIS outputs a signal to one of the beam choppers, which immediately deflects the beam just below the ion source. It also inserts one of the beam stoppers (Faraday cup) installed upstream of the problematic component. The BIS ignores the problems that occur downstream of the beam stopper insertion point. After inserting the relevant beam stopper, the beam chopper can be switched off, and the beam delivery can resume up to the inserted beam stopper. This feature is particularly important because if the problematic component cannot be recovered within a short time, the problem recovery time can be effectively used to readjust the beam to the inserted beam stopper. The inserted beam stopper can then be extracted from the beam line after the problem is fixed.

Figure 1: Example of the hardware configuration and process flow in the BIS. The green line signifies communication via Ethernet.

The BIS is still under stable operation; however, its maintenance has become gradually difficult because some

<sup>†</sup> misaki@riken.jp

of the modules used in the system are discontinued and cannot be replaced. Additionally, the performance of the system has been declining owing to the increasing interlock signals input to the system during the 15-year developments of RIBF. The measurements performed in summer 2020 show that the average response time of the BIS, the time from when the system receives the interlock signal to when the beam is stopped is approximately 18 ms, which is greater than 10 ms, the system response time that was originally required. A response time of 10 ms or less is required to operate higher-power beams more safely in the future. Therefore, we have been developing a successor system to the BIS for a few years and attempted to apply the prototype to a small part of the facility: the AVF cyclotron and its low-energy experimental facility (AVF-BIS) in summer 2020.

The hardware constitution and process flow of the prototype and modules used in the prototype are summarized in Fig. 2 and Table 1, respectively.

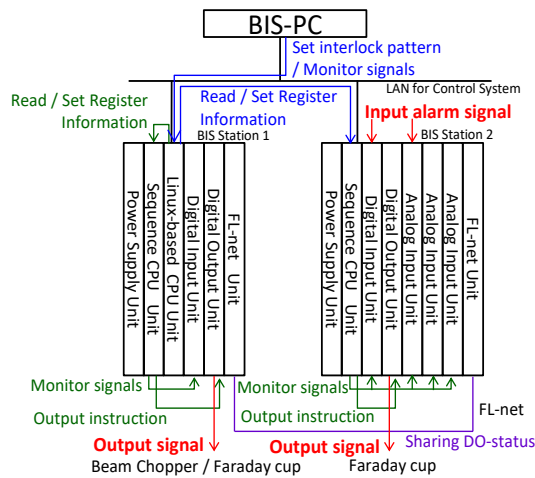

Figure 2: Hardware constitution and process flow in the prototype. Blue lines represent communication via Ethernet, green lines represent communication via PLC bus, and purple lines represent communication via FL-net.

Table 1: FA-M3 Modules Used in the Prototype

Type	Product	Note
CPU1	F3SP71-4S	Sequence CPU
CPU2	F3RP61-2L	Linux-based CPU
DI Module	F3XD32-3F	
DO Module	F3YD14-5A	Transistor contact
AI Module	F3AD08-1V	
FL-net Module	F3LX02-1N	Transmission speed: 10 Mbps

To develop the prototype, instead of adopting the Melsec-Q series PLC following the BIS, we adopted the

FA-M3 series PLC, a product of Yokogawa Electric Corporation, which is widely used in RIBF control systems [8]. Details of the prototype were reported previously [9].

A new advantage of the prototype is that it utilizes two different types of central processing units (CPUs): the sequence CPU and Linux-based CPU. The former is dedicated to high-speed signal processing such as beam stop after receiving an alarm signal, whereas the latter mainly handles tasks that do not require high-speed response, such as the parameter setting of the interlock system. The introduction of the latter reduces tasks for the former, and a reduction in the response time is expected. We set up a prototype comprising two PLC stations: one with a Linux-based CPU and a sequence CPU installed in a location close to the ion sources, and the other with a sequence CPU installed in the location where wiring of various input signals was gathered. The communication between the two stations is performed through FL-net (an open network protocol used for interconnection between controllers) using dedicated wiring [10], and the signal setting and monitoring are performed by the terminal in the control room via Ethernet. In the AVF-BIS, 28 digital inputs and 23 analog inputs were used as interlock signals, and five digital outputs were used to stop the beam.

As a result of the oscilloscope-measured signal response speed in the AVF-BIS, the observed response time averaged 2 ms and 5.4 ms, respectively, within one station and with both stations. Figures 3 and 4 depict examples of the measurements, in which the yellow and green lines show the input and output signals, respectively. In Fig. 3, the signal is input to BIS station 1 in Fig. 2 and the output from BIS station 1. In Fig. 4, the signal is input to BIS station 2 and the output from BIS station 1. For both measurements, the oscilloscope was connected to BIS station 1. Therefore, in the measurement shown in Fig. 4, a cable is temporarily laid from BIS station 2 to the oscilloscope placed beside BIS station 1, and the signal is input to BIS station 2 and at the same time input to the oscilloscope via the cable.

Figure 3: Signal output timing at AVF-BIS (within the same station, 1.85 ms).

Figure 4: Signal output timing at AVF-BIS (between separate stations, 5.28 ms).

The average response time was obtained as 1.4 ms and 3.8 ms for the operation within one station and using two stations, respectively, in the test involving two stations side by side before installing the prototype as AVF-BIS [11]. The results of the two aforementioned measurements show that the signal response time increases after the prototype is installed as the AVF-BIS. There are mainly two differences before and after installing the prototype as AVF-BIS: one is that the distance between two stations increases from side by side to approximately 70 m, and the other is that the length of the program executed on the sequence CPU increases by approximately 1.2 times in the AVF-BIS as compared to the measurement in the prototype. However, these reasons are not sufficient to explain the difference in the response time, and details of the cause are currently under investigation.

The measurement result of the response time was sufficient for the performance of the AVF-BIS. However, scaling up the prototype to a system consisting of five PLC stations with approximately 400 signals, similar to the existing BIS, it is estimated that the response time of the system will be long because the transmission time varies depending on the number of stations. According to the data released by Yokogawa Electric Corporation, when the number of stations in the system increases from two to five, the signal transmission time is almost doubled under the condition that the size of the transmitted data is the scale of the AVF-BIS. Because the ratio of the transmission time to the response time between two stations is under investigation and is not currently clear, it is not possible to accurately estimate the response time of the system when the AVF-BIS is expanded to five stations. However, we reckoned that it was necessary to consider the possibility that the performance required for the system could not be achieved with a sufficient margin in the expansion of the current system using the sequence CPU and FL-net. Therefore, we began to redesign the system.

To reduce the signal transmission time in the stations, we opted to use a twisted cable. Additionally, to further shorten the response time, we plan to introduce a field-programmable gate array (FPGA) to process interlock signals as fast as possible in the new system. Because the signal propagation speeds of the twisted cables range from 4.5 to 5.5 ns/m,

the response speed of the new system is expected to be an order of magnitude faster than the existing BIS.

## DEVELOPMENT OF FPGA-BASED MACHINE PROTECTION SYSTEM

In the development of a BIS system using FPGAs (hereinafter, FPGA-BIS), the method of stopping a beam to protect the machine is basically the same as that of the BIS and AVF-BIS. In the AVF-BIS, which has been improved based on the operational experiences of the BIS, the system response time was successfully reduced using two types of CPUs according to the required processing speed. Therefore, we also properly use FPGAs and CPUs according to the signal processing time required in FPGA-BIS, which will be used to evaluate various interlock conditions imposed on each input signal as fast as possible. For example, we require a certain duration time for some interlock signals to avoid false alarm signals originating from the malfunction and/or noises of the system. Furthermore, the BIS should stop the beam only when an alarm signal is output from the device upstream of the beam stopper inserted in the beam line. By executing these condition judgements on the FPGA, we expect that the high-speed processing of signals in the system is realized. However, CPUs constantly execute processing such as setting signal parameters and monitoring signals indicating the state of the beam stopper. As in the case of the AVF-BIS, the EPICS will be executed on the CPU.

Each station that composes the FPGA-BIS will be installed at or near the existing BIS station to maximize the reuse of the existing signal wiring of the BIS. Therefore, the stations are widely distributed in the facility as well as in the BIS.

To achieve the performance required in FPGA-BIS, we are now studying two systems as candidates: FA-M3 series PLC by adding input/output (I/O) modules with an FPGA (FPIO module) [12], and CompactRIO, a product by National Instruments [13]. The FPIO module (F3DF01-0N) was equipped with an FPGA and had 24 input contacts and 24 output contacts. The advantages and disadvantages of each system are as follows.

- The advantage of the FA-M3 PLC system is that it is familiar with its operation because it is widely used in the RIBF control system. Additionally, because each FPIO module has an FPGA, the processing of the input signal can be closed in the module, thus, the system can be expanded simply by adding the FPIO module (there is no need to coordinate with other FPIO modules).
- The disadvantage of the FA-M3 PLC system is that the total cost increases. The FPIO module is more expensive than a normal I/O module; however, many FPIO modules are required because all alarm and output signals that require high-speed processing need to be connected to the FPIO module. Another concern is the duration of maintaining the present FPIO module that uses Spartan 6 FPGA, the release of which was more than 10 years ago.

- The advantage of the CompactRIO system is that the total cost can be reduced (estimated to be approximately half that of the FPIO system). In the CompactRIO system, an FPGA is mounted on the chassis instead of individual modules, thus, normal I/O modules can be used to connect the signals even if they require high-speed processing. Additionally, LabVIEW can be used to develop FPGA logic [14], and even if the FPGA is updated to a new one, it is not necessary to recreate the logic once it is developed on LabVIEW because it is expected to absorb the difference between different FPGA versions. LabVIEW is widely used in various systems at the RIBF, so it is familiar to us as well as the FA-M3 PLC system. Furthermore, the machine protection system using CompactRIO has been in operation for more than 10 years at one of the core experimental facilities of the RIBF and can be used as a reference, although the system scale is different [15].
- The disadvantage of the CompactRIO system is that it is necessary to recompile the FPGA logic whenever the number of signals handled by the system increases and new modules are added.

We are currently preparing to build prototypes for both the systems. After testing both prototypes, we selected the FPGA-BIS. We aim to replace the BIS with the FPGA-BIS within 2 years.

# NOVEL PERSONNEL SAFETY SYSTEM FOR HLS-II\*

Z. Huang, K. Xuan, C. Li, J. Wang, X. Sun, S. Xu, G. Liu<sup>†</sup>, NSRL, USTC, Hefei, Anhui 230029, China

## Abstract

The Hefei Light Source-II (HLS-II) is a vacuum ultraviolet synchrotron light source. The Personnel Safety System (PSS) is the crucial part to protect staff and users from radiation damages. In order to share access control information and improve the reliability for HLS-II, the novel PSS is designed based on Siemens redundant PLC under EPICS environment which is composed by the safety interlock system, access control system and the radiation monitoring system. This paper will demonstrate the architecture and the specific design of this novel PSS and shows the operation performance after it has been implemented for 2 years.

## INTRODUCTION

The Hefei Light Source-II (HLS-II) is a dedicated synchrotron radiation facility which can provide radiation from infrared to vacuum ultraviolet with both Top-Off and Decay operation modes [1]. The Personnel Safety System (PSS) is the crucial part of the HLS-II to keep radiation damage away from the staffs and users. The previous PSS in HLS-II was developed by Siemens SiPass system which lacked of personnel management function and it's hard to share information. For solving these disadvantages, the novel PSS has been designed for HLS-II.

The Programmable Logic Controller (PLC) and redundant technology are widely used in the PSS design of big scientific facilities to meet the requirements of the high reliability and stability, such as the European Spallation Source (ESS) [2] and the High Intensity D-T fusion neutron generator (HINEG) [3]. The novel HLS-II PSS is designed based on the Siemens redundant PLC S7-412-5H under the Experimental Physics and Industrial Control System (EPICS). EPICS is a set of open-source software tools, libraries, and applications that are widely used in big scientific facilities [4, 5]. The novel HLS-II PSS contains 3 parts: the safety interlock system, the access control system and the radiation monitoring system. The safety interlock system is used to define the interlock logic to be implemented, the access control system is designed to restrict the access of the staffs and users at HLS-II and provide the personnel management function, and the radiation monitoring system is used to monitor the dose rate in the light source and the surrounding areas.

In this paper, section II introduces the system architecture of the novel HLS-II PSS, section III gives the details about the design of the safety interlock system and the personnel management function in the access control system, and section V shows the operator interfaces (OPIs) design and the operation situation of the novel HLS-II PSS.

<sup>†</sup> Corresponding author, gffiu@ustc.edu.cn

## SYSTEM ARCHITECTURE

The novel HLS-II PSS ensures the personal safety by monitoring the radiation dose rate, controlling interlock signals and executing interlock actions. We integrate the safety interlock system, the access control system and the radiation monitoring system into EPICS environments for information sharing. Meanwhile, we can use the existing data archiver and alarm toolkits provided by the EPICS community to archive the historical data and publish the alarm information [6]. The system architecture of the novel HLS-II PSS consists of 3 layers: the EPICS layer, the controller layer and the devices layer as Fig. 1 shown.

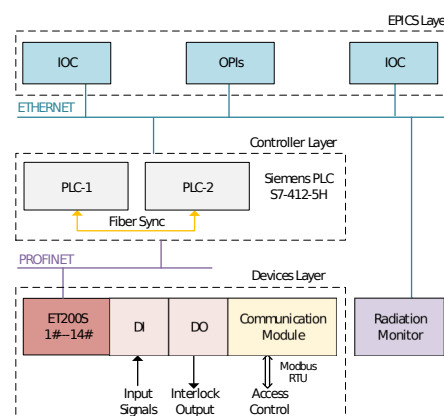

Figure 1: Architecture of the Novel HLS-II PSS.

In the controller layer, there is only one pair of Siemens redundant PLC S7-412-5H. PLC can gather IO signals and access data from 14 IO stations by fiber optic cables, and receive the radiation monitoring signal and commands from other EPICS IOC. The redundant PLC pair has two high performance PLCs that are backed up with each other, one of them takes the role of MASTER PLC and the other one takes the role of SLAVE PLC. During the operation, those two PLCs synchronise programs and real-time data over a high-speed fiber, and the roles between two PLCs can switch over when the MASTER PLC fails.

In the devices layer, 14 Siemens ET200S IO stations are distributed nearby the 14 security doors. The input signals of search buttons, emergency buttons and security doors are collected into the IO stations through the DI modules. The signals of the audible and visual alarm devices, button lamps and the interlock actions are outputted through the DO modules. In addition, the data of card reader is transmitted into the IO station via Modbus-RTU protocol.

According to the design, there are 134 input signals monitored, including 41 search buttons signals, 25 emergency stop buttons signals, 42 security doors signals, and 26 radiation monitoring signals. All the signals are from IO stations, except the radiation monitoring signals. The communication

between PLC and IO stations adopts PROFICIENT Real-Time protocol, the communication cycle time is 2 ms. The communication between IOC and PLC uses Ethernet with a communication cycle time of 100 ms. Radiation monitoring signal is used to monitor the average of the radiation dose in 5 seconds, so the real-time performance for this signal is not high. It is transmitted between IOCs over EPICS Channel Access protocol.

## DESIGN OF THE SAFETY INTERLOCK SYSTEM AND ACCESS CONTROL SYSTEM

The radiation monitoring system has been developed based on EPICS and deployed at HLS-II in 2017 [7]. Therefore this section focuses on the design details of the safety interlock system and the access control system.

### Safety Interlock System

The safety interlock system is the crucial system to process the interlock logic. Figure 2 shows the workflow chart of the safety interlock system and Table 1 shows the definition and actions of all states. During the operation of the safety interlock system, there are 3 operation states: the released state, the searching state and the interlocked state.

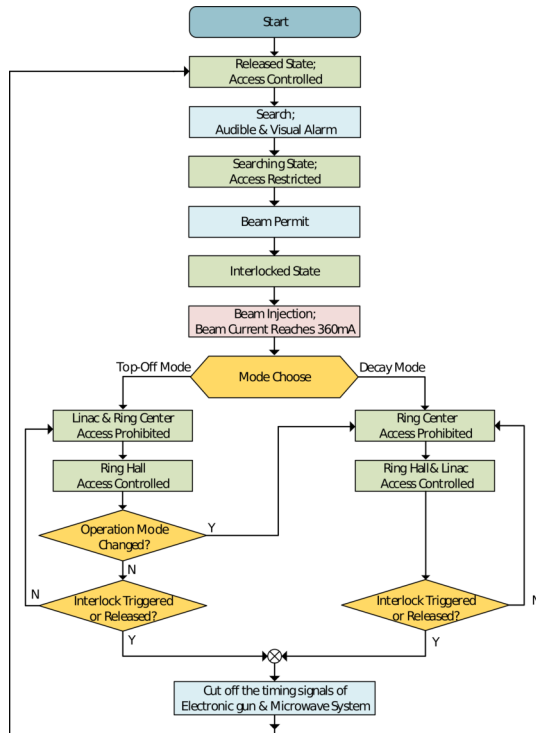

Figure 2: Workflow of the Safety Interlock System.

When the facility is turned on, the safety interlock system enters into the released state. At HLS-II, there are 3 safety interlock areas: the linac, the ring center and the ring hall. In the released state, the interlock system of the 3 areas should be released. All the interlock signals are reset and the search lamps are turned off.

States	Definition	Actions
Released State	Release the interlock	Reset interlock logic Turn off search lamps
Searching State	To establish the interlock	Audible and visual alarm Search the interlock areas Turn on search lamps Lock the security doors
Interlocked State	Interlock is established	Beam Injection Operation mode choose

The searching state is aimed to establish the interlock. When the searching state starts, the operator should inform all person to leave the interlock areas by audible and visual alarm, then the operator searches the interlock areas in the order of the linac, ring center and ring hall. If all the search buttons are pressed and the security doors is locked, the operator can give the beam permit command to transit the operation state into the interlocked state.

For the HLS-II, after the beam is injected and the beam current of storage ring reaches 360 mA, there are 2 types of operation modes to choose: Top-Off mode and Decay mode. Top-Off mode is a high performance operation mode, and the beam is injected in every few minutes [8]. Thus the linac and the ring center should be kept in the interlocked state in Top-Off mode. For Decay mode, the beam is injected in every few hours, the interlock of the linac and the ring hall can be released while the ring center must be kept in the interlocked state.

During the interlocked state, if the interlock system is released by the operator or triggered by the interlock signals, such as the emergency buttons is pressed or the radiation monitoring system detects excessive radiation dose, the safety interlock system will cut off the timing signals of the electronic gun and the microwave system, and transit into the released state.

### Access Control System

The design of the access control system at HLS-II is based on the principle of classified protection. The interlock areas can be classified into 3 kinds according to the radiation dose rates: the high radiation area, the radiation area and the safety area. The radiation dose rate of the high radiation area is more than 10  $\mu\text{Sv/h}$ , of the radiation area is between 1  $\mu\text{Sv/h}$  and 10  $\mu\text{Sv/h}$ , and of the safety area is less than 1  $\mu\text{Sv/h}$ . Table 2 shows the safety classification of the interlock areas at the different PSS state. For the high radiation area, the access of security doors is prohibited, and no personnel is allowed to open the doors under any conditions; for the radiation area, only the staffs have the restricted access authority; and for the safety area, staffs, users and all other personnel can open the security doors with the access card.

At HLS-II, the security doors must be opened by access card. When access card is swiped, the card information

Operation States		Linac	Ring Center	Ring Hall
Released State		Radiation Area	Radiation Area	Safety Area
Searching State		Radiation Area	Radiation Area	Radiation Area
Interlocked State	Beam Enable	High Radiation Area	High Radiation Area	High Radiation Area
	Top-Off Mode	High Radiation Area	High Radiation Area	Safety Area
	Decay Mode	High Radiation Area	Radiation Area	Safety Area

will be sent to the PLC. Then the PLC judges the access permission according to the access authorities for each card and the safety classification of the interlock areas. The card number and authentication information are sent to IOC and archived in EPICS database as an event for recording and tracking. Meanwhile, the OPIs can display the access state synchronously.

In the access control system, the personnel count function is realized in the EPICS IOC by state notation language (SNL). SNL is a domain specific programming language which can provide a simple yet powerful tool for sequential operations in a real-time control system. According to the card number and authentication information, the SNL program counts the personnel number for each interlock areas, and writes the count results into the EPICS records.

# OPI DESIGN

The OPIs of the novel HLS-II PSS is composed of the OPI of the linac area and the OPI of the storage ring area, as shown in Figs. 3 and 4. The linac area includes the linac tunnel and transport line tunnel. The storage ring area includes the ring center and the ring hall.

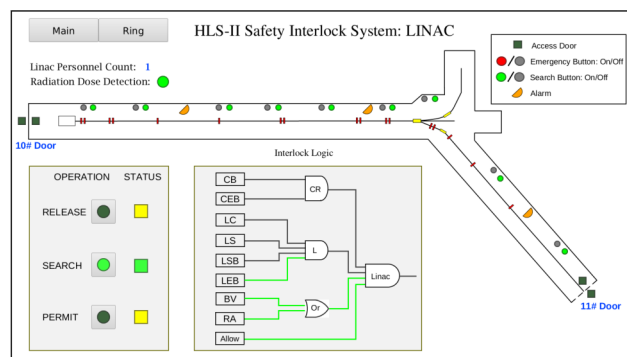

Figure 3: The OPI of Linac.

The OPI can be divided into four parts: 1) the distribution and state of the security doors, the emergency buttons, the search buttons and the alarm devices; 2) the personnel count and the radiation dose monitoring state for the interlock areas; 3) the interlock logic diagram; 4) the operation commands and the related states. The line color in the interlock logic diagram is variable depending on the logic value, it is gray when the logic value is 0, and green when the logic value is 1.

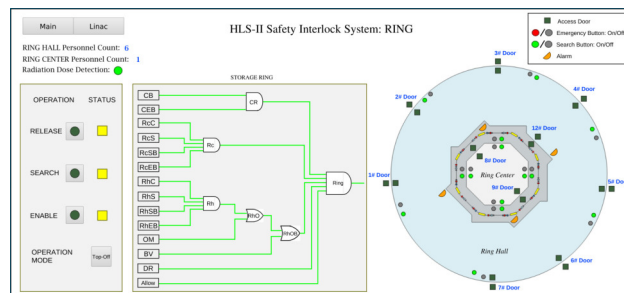

Figure 4: The OPI of Storage Ring.

## OPERATION STATUS

The development of the novel HLS-II PSS is completed. To ensure that this system could work as designed, we set up the offline platform and continuously tested for one month. The test results demonstrate that all the devices can run well and stably, the interlock actions can be executed effectively, and the Top-Off mode and Decay mode can be supported successfully. Meanwhile, the offline platform can work properly during the redundant PLCs switch over.

The development of the novel HLS-II PSS is completed and it's deployed during 2019 summer. Figure 5 is the photo of the Door Display OPI which is located beside the No.7 security door. Distinct from the OPIs in Linac area and storage ring area, this OPI will shown the operation modes and access state as well. When the access card is swiped, it can alarm the access result via audio and text at the meantime.

During the 2 years operation, the novel HLS-II PSS keeps running stably behind the control of redundant PLCs. The safety interlock system can executed interlock actions precisely and all 3 interlock states can be switched timely . It also performs well on supporting both of Top-off mode and Decay mode. The new access control system improves the effectivity of personnal management, and the radiation system can be integrated into this novel PSS smoothly. All the data in novel PSS can be shared and processed real-timely under EPICS environment.

## CONCLUSION

In the novel design of HLS-II PSS, the safety interlock system, the access control system and the radiation monitoring system are integrated into EPICS environments, it is easy to share information and use the existing toolkits provided by the EPICS community. In the access control

Figure 5: Photo of the novel HLS-II PSS Door Display OPI.

system, the personnel management function is designed for monitoring the entry and exit of staffs and users to meet the HLS-II management requirements. After 2 years successful operation from 2019, the novel HLS-II PSS has proofed its highly reliability and stability which can fullfull the design requirements.

# DESIGN OF MACHINE PROTECTION SYSTEM FOR SXFEL-UF

Chunlei YU, Jianguo DING, Huan Zhao

Shanghai Advanced Research Institute, Chinese Academy of Sciences, Shanghai, P.R China

## Abstract

Shanghai Soft X-ray Free-Electron Laser (SXFEL) facility is divided into two phases: the SXFEL test facility (SXFEL-TF) and the SXFEL user facility (SXFEL-UF). SXFEL-TF has met all the design specifications and has been available in beam operating state. SXFEL-UF is currently under commissioning and is planned to generate 3 nm FEL radiation using a 1.5 GeV electron LINAC. To protect the critical equipment rapidly and effectively from unexpected damage, a reliable safety interlocking system needs to be designed. Machine Protection System (MPS) is designed by Programmable Logic Controller (PLC) and Experimental Physics and Industrial Control System (EPICS) which is based on a master-slave architecture. In order to meet different commissioning and operation requirements, the management and switching functions of eight operation modes are introduced in the MPS system. There are two FEL lines in user facility named SXFEL beamline project (BSP) and undulator (UD), and the corresponding design of MPS is completed. This paper focuses on the progress and challenges associated with the SXFEL-UF MPS.

## INTRODUCTION

Shanghai Soft X-ray Free-Electron Laser test facility(SXFEL-TF) has been successfully completed in 2020, and the beam energy of the test facility is 840 MeV. The SXFEL user facility (SXFEL-TF) is a critical development step toward the construction of a soft X-ray FEL user facility in China and has been currently undergoing commissioning at the Shanghai Synchrotron Radiation Facility (SSRF) campus[1]. The LINAC accelerator of SXFEL-UF is designed to increase the beam energy to 1.5GeV[2]. Not only the original undulator beam line has been upgrade in SXFEL-UF, but also a new undulator beam line adopts high-throughput working modes such as SASE has been new built.

The requested response time of Machine Protection System (MPS) is less than 20ms, so PLC is employed to execute the underlying logic. Experimental Physics and Industrial Control System (EPICS) is a set of software tools for building distributed control system to operate devices such as particle accelerators and large experiments[3]. The EPICS framework is adopted in the control system in SXFEL-UF and MPS. Due to the hardware structure and function division for test facility, modification and extension has been implemented for new demands of SXFEL-UF.

## MPS COMPONENT

### System Structure

The structure of SXFEL machine protection system is shown in Figure 1. The operator interface (OPI) is connected to the input and output controller (IOC) through the local area network, and takes a approach of the EPICS CA protocol. IOC runs on Linux system, and MOXA DA-662 embedded computer is used as IOC server, equipped with 16 serial ports and 4 network ports. Embedded software and hardware technology is applied to complete the development of embedded EPICS IOC.

Figure 1: The scheme of SXFEL-UF MPS.

### Signal Statistics

Almost all the systems should be assigned the interfaces with MPS, such as radio frequency system, vacuum system, power supply system, water cooling system, timing system and personal safety protection system (PPS) and so on. At present, the number of interlocking input/output signals is about 1000, the main equipment interlocking signals are listed in Table 1.

Table 1: Summary of Main Interlock Signals

No.	device/signal	number
1	timing control	17
2	vacuum warn and alarm	234
3	pump power supply	302
4	vacuum valve status and control	135
5	modulator status and control	51
6	PPS signal	12
7	cooling water status	78
8	RF switch signal	8
9	Leakage/pressure monitor signal	24

### Function Realization

Omron CS1G-H series PLC are applied in MPS, and the CPU model is CPU43. There were 7 PLC stations used for master-slave architecture in SXFEL-TF, including one station for injector (IN), 3 stations for Linac (LA), 2 stations for undulator (UD) section, and one master station for comprehensive treatment. In SXFEL-UF MPS, 9 stations have been arranged for total interlock processing together, which the master station, injector station and 3 linac stations are reserved, but more signals and logic processing are increased. Transmission line (TL) are new added before undulator lines in user facility, so one station for TL and 3 UD stations used for both undulator lines have been restudied and implemented in our new design.

Master station is provided with the function to management and switching the operation mode, and more important function is can synthesize the selected mode and interlock input signals to make corresponding logical judgments and responses. One of the features is to logically integrate the global interlock signal and the output signal from each slave station and fan out to other slave stations. Another feature is to permit the global output signals, the exciting permit signals such as:

- Beam permit.
- Timing system permit signals.
- Driving laser shutter.
- PPS and shutter permit.
- Undulator line selection.
- Operation mode switching.

The local sub stations are connected with device signals such as vacuum, valves, water cooling, air pressure, and water leakage of the accelerator section where they are located. Every sub-station operates at different interlocking logic in accordance with different interlocking requirements to ensure the normal operation of the equipment in its own section. And sub-stations also send the beam permit signal and timing control output signal to master station through synthesis all the logic signals.

In addition, SXFEL has been arranged by a total of 17 modulators. According to the interlock signals of the section where the modulator is located and the command from the Master station, some of the sub-stations need to complete the judgment of the modulator interlock status and control the operation of the modulator

Another significant function of the local sub-station is to realize the local vacuum protection. When there is a vacuum leakage, the vacuum isolation is realized through valve control to avoid leakage and spreading. The vacuum alarm signal needs to be transmitted between the sub-stations, and the upstream station transmits the end vacuum status signal to the downstream sub-station as the vacuum protection input signal. The main signal interaction between each stations shown in figure 2.

### OPERATION MODE DESIGN

In the early stage of beam debugging, RF conditioning and section commissioning of accelerator are required. In order to facilitate the operation and reduce the occurrence of misoperation, mode control and switching have been realized in MPS according to different accelerator operating conditions. The adjustment personnel can select a specific mode according to the specific conditions of debugging, and MPS can automatically match different interlock logic in different modes.

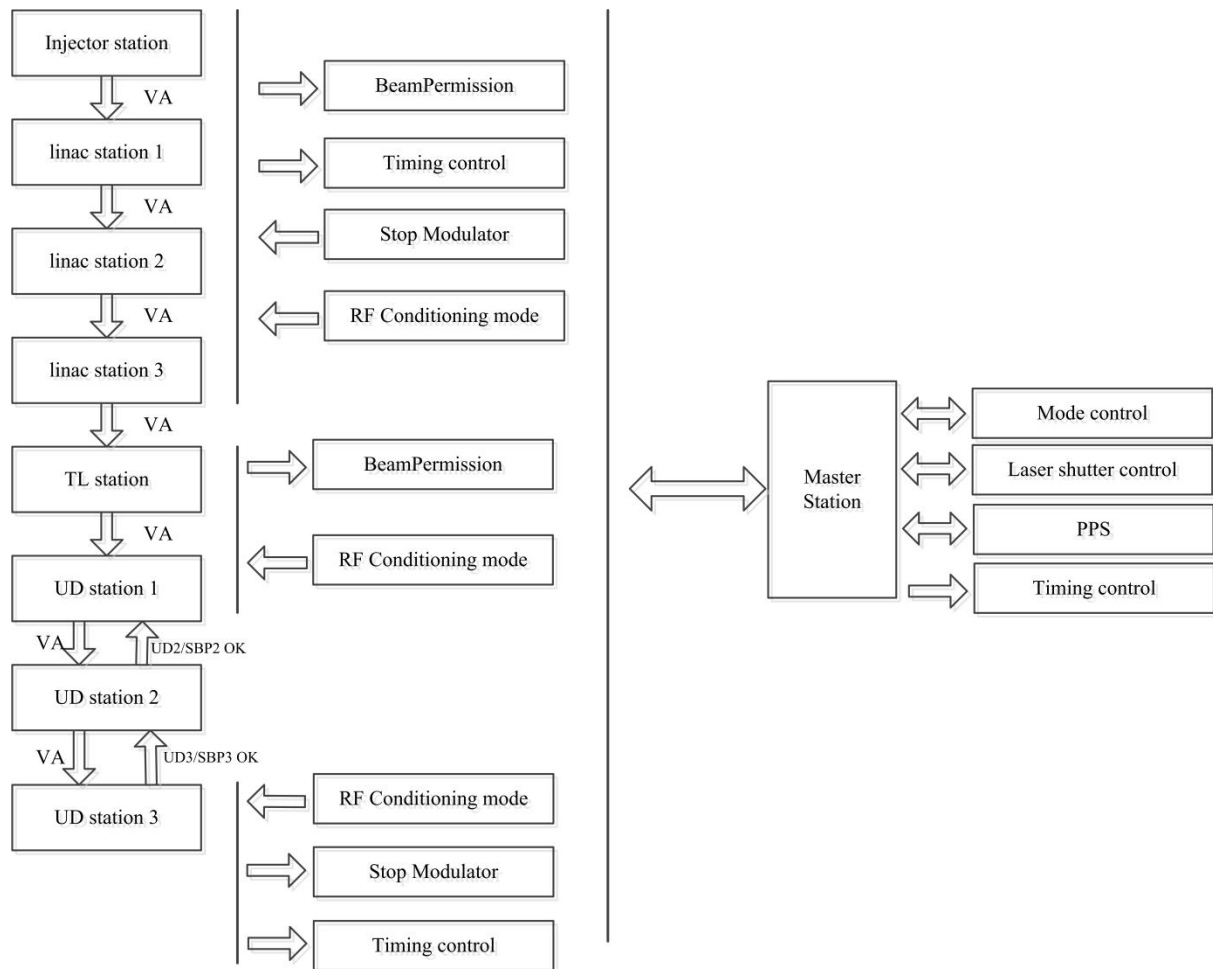

Figure 2: The structure of stations and signal interaction.

7 operation modes are realized in SXFEL-UF MPS, which continuing the original design in test facility. Two beamlines can be chosen flexibly, and the beamline selection is achieved individually.

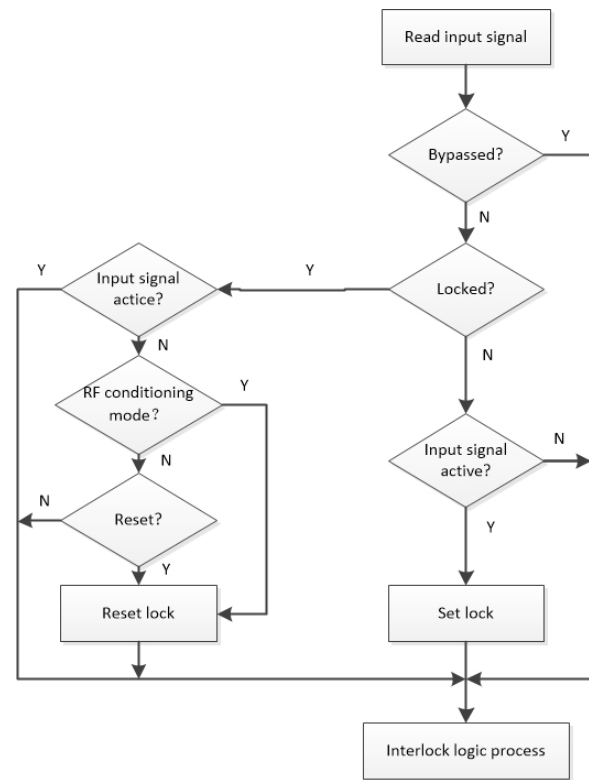

- STOP mode. The driving laser shutter should be shut down, all timing trigger signals should be stop and all vacuum valves are closed.
- RF Conditioning mode. it is necessary to stop the timing control for the driving laser and close the laser shutter, and the timing trigger to all power sources should be maintain in the normal interlock state.
- Injector debug mode. In this mode, only debugging of the injector section is performed. So the interlock for injector section is normal, but signals from other sections such as linac or undulators are bypassed.
- Linac debug mode. It is necessary to establish a normal interlock from the injector section to the end of the main accelerator, and bypass the interlock input signals from the undulator section.

- Undulator debug mode. Establish normal interlock from the injector section to the end of the main accelerator, but the signal of the B iron at the end of UD should be bypassed.
- Running mode. MPS should operate normally in accordance with the predetermined interlock logic.
- Laser debug mode. All timing triggers should be stop except the trigger for laser system.

The operation mode control is realized by hardware, and the control of the mode panel and the specific logic switching are all achieved by the master station. The design of the mode control panel is shown in Figure 3. The operator needs the key to activate the mode selection function, and the key can be switched between "mode lock" and "mode selection". After entering the "mode selection", 7 modes can be cyclic selected by clicking the "selection button". After the selection is completed, the key should be turned to "mode lock" to complete the switching. The master station also sends effective information to each sub-station and device after the mode is locked, and then the entire system can perform the interlock logic under the new mode.

interlocking input signal corresponds to a latch signal and a reset signal. The processing flow of the SXFEL-UF MPS input signals is shown in Figure 4.

## OPERATION GUI

SXFEL control system base on EPICS, and MPS remote control system uses MOXA DA-662 embedded sever built-in Monta Vista Linux system as EPICS IOC. The netDev IOC device driver developed by Japan KEK is used, which can realize the communication with OMRON CS1 series PLC through Ethernet module[4].

The operator interface (OPI) is developed by EDM, which is composed of the main interface of MPS and various sub-interfaces. 6 new sub interfaces for both undulator lines have been added, and the two lines selection and enable judgment have been finished and modified at main interface for SXFEL-UF. The global interface of SXFEL-UF MPS shown in Figure 5, and the interface of MPS for SXFEL injector is shown in Figure 6.

The current operating mode of the accelerator, the interlock status of each station, and overview information of MPS signals such as vacuum and water cooling are all displayed in main interface. At the interface of each accelerator section and undulator section, the specific information of the interlock input signals can be obtained at the sub-interface divided by accelerator section. Also the corresponding control operations for reset, bypass and equipment control can also be performed.

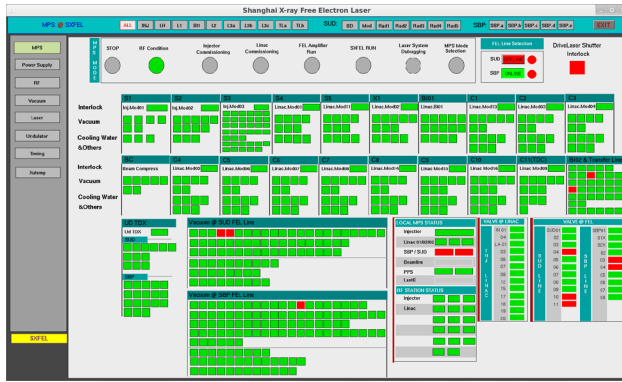

Figure 5: The global interface of SXFEL-UF MPS.

Figure 6: The interface of interlock system for SXFEL injector.

## CONCLUSION

PLC is used to achieve the collection, calculation and interlocking protection of all interlocking signals at SXFEL-UF MPS. Based on the architecture of Master main station and local sub-station design, interlocking protection with operation mode switching and management functions is realized. The interlocking protection requirements of various systems such as vacuum, water cooling, high frequency, timing and personal safety have been available in our system. And distributed control system based on the standard model and EPICS have been build and realized for SXFEL-UF MPS system.

Through online testing, the response time of the system is less than 15 ms, which totally meets the physical requirements of 100 ms response time at the device repetition frequency of 10 Hz. The performance may also satisfy the demand of 20 ms response time .

After a long-term operation measurement, the SXFEL-UF MPS is stable and reliable, and the interlocking function is running normally, which effectively meets the requirements of debugging and operation at various stages.

# IMPLEMENTATION OF A VHDL APPLICATION FOR INTERFACING ANYBUS CompactCom

S.Gabourin\*, S. Pavinato, A. Nordt, European Spallation Source, Lund, Sweden

## Abstract

The European Spallation Source (ESS ERIC), based in Lund (Sweden), will be in a few years the most powerful neutron source in Europe with an average beam power of 5 MW. It will accelerate proton beam pulses to a Tungsten wheel to generate neutrons by the spallation effect. For such beam, the Machine Protection System (MPS) at ESS must be fast and reliable, and for this reason a Fast Beam Interlock System (FBIS) based on FPGAs is required. Some protection functions monitoring slow values (like temperature, mechanical movements, magnetic fields) need however less strict reaction times and are managed by PLCs.

The communications protocol established between PLCs and FBIS is PROFINET fieldbus based. The Anybus CompactCom allows an host to have connectivity to industrial networks as PROFINET. In this context, FBIS represents the host and the application code to interface the AnyBus CompactCom has been fully developed in VHDL.

This paper describes an open source implementation to interface a CompactCom M40 with an FPGA.

## INTRODUCTION

The European Spallation Source (ESS), an accelerator driven research facility located outside of Lund, Sweden, is currently in its construction and early operation phase, and aims to be the most powerful and bright neutron source in the world by 2025. ESS is a long-pulse neutron source, and consists of a 600 m long proton LINAC, a rotating helium-cooled tungsten target, creating neutrons through the spallation process and 22 different neutron beam ports, equipped with neutron scattering research instruments. The unique time structure of long neutron pulses (2.86 ms) at low frequency (14 Hz) will significantly expand the possibilities for neutron science to probe material structures and dynamics [1]. The proton beam power of 125 MW per pulse (5 MW average) will be unprecedented and its uncontrolled release can cause serious damage of equipment within a few microseconds only. To maximize operational efficiency of ESS, allowing for very high beam availability with high reliability towards the end-users, accidents shall be avoided and interruptions of beam operation have to be minimized and be limited to a short time. Finding an optimum balance between appropriate protection of equipment from damage and high beam availability is the key principle on which the ESS Machine Protection Strategy is being based on [2]. Implementing and realizing the measures needed to provide the correct level of protection in case of a complex facility like ESS, requires a systematic approach, enabling seamless integration of the several 100 protection functions that span over

multiple systems. The entity performing the final logic on whether beam operation is allowed or needs to be interrupted, is called Beam Interlock System (BIS), and consists of four PLC based interlock systems and the FPGA based Fast Beam Interlock System (FBIS). The FBIS takes the ultimate decision on safe beam operation and is the only system that can trigger a beam stop. It is designed to stop beam production within 3  $\mu$ s for the fastest failures at a safety integrity level of SIL2 according to the IEC61508 standard. These requirements result from a hazard and risk analysis being performed for all systems at ESS. The complexity of the ESS machine (multiple beam destinations, beam modes, etc) requires not only transferring binary data from the PLC based interlock systems to the FPGA based Fast Beam Interlock System (Beam Permit OK/NOK), but also to transfer information on e.g. machine configuration, device location, etc.. For that purpose, a so-called datalink has been implemented. It transmits data from the PLCs via PROFINET towards the FPGAs, using an intermediate commercial module, a CompactCom, which communicates via SPI with an ESS in-house developed firmware driver. This paper describes the implementation of this link that was particularly challenging, as the CompactCom is designed to communicate with software entities like microprocessors, but not with FPGA firmware written in VHDL.

## ANYBUS CompactCom OVERVIEW

The Anybus CompactCom module is a flexible and cheap way to connect to a PROFINET network. It is already well known and used also in the domain of Machine Protection in laboratories like CERN. In order to understand more in details the following section a brief overview of Anybus CompactCom M40 is done.

As written in the datasheet [3], the Anybus CompactCom M40 for PROFINET is a complete communication module which enables your products to communicate on a PROFINET-RT or IRT network. The module supports fast communication speeds, making it suitable also for high-end industrial devices.

Anybus CompactCom provides different application interfaces to the host: parallel, SPI, with a baudrate up to 20 MHz, shift register interface and UART. At ESS the SPI interface has been chosen as it is faster than UART and shift register interfaces. Also, even if it is slower than the parallel interface, it is less IO consuming. Then the communication is master/slave mode based, where the master, the host, is the FPGA and the slave is the Anybus CompactCom.

Figure 1, shows the interfaces available between an host and the CompactCom with details on its internal structure. In order to interface the PROFINET Network the signals

\* stephane.gabourin@ess.eu

sent by the host have to pass through Anybus CPU, the Communication Controller and finally the Physical Interface. The data flow goes also in the opposite direction.

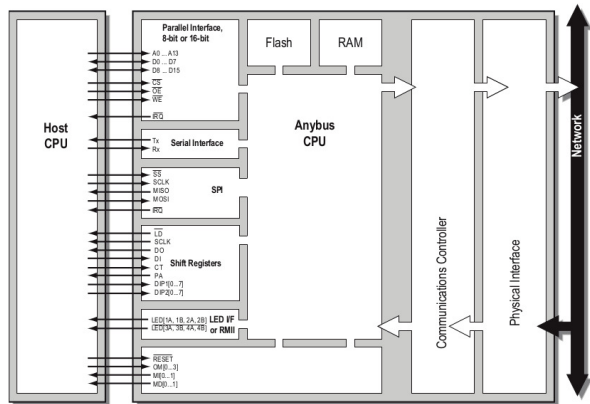

Figure 1: Host - CompactCom interface [4].

For the host the Anybus CompactCom is a grey box, where its behavior can be represented by the Anybus State machine, Fig. 2. This state machine, a Moore FSM, is a fundamental part of the Anybus CompactCom 40 that reflects the status of the module and the network. The host application is not required to keep track of all state transitions, however it is expected to perform certain tasks in each state.

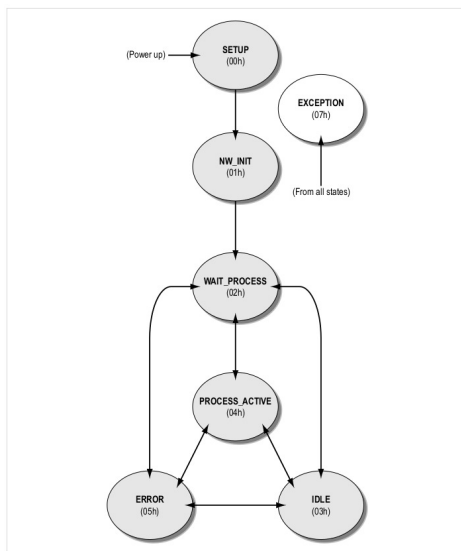

Figure 2: Anybus State Machine [4].

Lastly the host application has to be aware of the addressing scheme of the Anybus module. The software interface is object structured. According to the software documentation [4], related information and services are grouped into entities called 'Objects'. Each object can hold subentities called 'Instances', which in turn may contain a number of fields called 'Attributes'. Attributes typically represent information or settings associated with the Object. There are nine different types of objects and two are mandatory to be

implemented in the host application: the Application Data Object and the Application Object.

Object messaging, between host application and Anybus module, involves two types of messages; commands and responses. On the message level, there is no master-slave relationship between the host application and the Anybus CompactCom module; both parts may issue commands, and are required to respond. Commands and responses are always associated with an instance within the Anybus object model [4].

## VHDL IMPLEMENTATION

This section describes the host application code. For machine protection criticality reason, the code is written purely in VHDL and so far has been tested in two different hosts: a Xilinx Kintex UltraScale Development Kit (as shown in Fig. 3), mounting a Xilinx XCKU040 FPGA, and a custom board SCS\_1600 designed by IOxOS mounting an Zynq® UltraScale+™ MPSoC XCZU7EG-FFVF1517 (as shown in Fig. 4).

Figure 3: Anybus mounted on the Xilinx XCKU040 Development Kit via the FMC connector.

Figure 4: Highlighted the Anybus mounted on the MC. On the left and right of the crate the two cards where the Zynq® UltraScale+™ MPSoC XCZU7EG-FFVF1517 are mounted.

As written in the previous section the application has been design to support the SPI interface. The SPI frames can have two different sizes depending on if the Anybus is or not in Setup or Network Init state. To manage this, two impure functions to build MOSI frame have been written. So far only the mandatory host objects and some of their instances

and attributes are handled in the application. They have been defined as constants used to fill the SPI frames when requested.

Then two main state machines have been designed:

- the first state machine handles detection, initialization and starting of the Anybus CompactCom module
- the second state machine (named SPI FSM) is the one tracing the anybus state machine illustrated in Fig. 2, keeping communicating with the Anybus CompactCom through command and response messages.

As mentioned above the FSM in Fig. 2 is mimicked. In each of its state a subset of the SPI FSM handles communication until the Anybus reaches the Process Active state in which the system becomes fully operational. The Fig. 5 shows a simplified view of the SPI FSM subset used in Process Active. This cyclic communication was needed to:

- keep the Write Process Data updated since this data is buffered by the Anybus CompactCom, and may be sent to the network after a state shift, as recommended in [4].
- catch the responses received by the Anybus CompactCom and according to the object, instance and attribute read, build the proper following command. In the case the firmware cannot catch the response an object error is sent back.
- send the commands. Depending on the type of commands one or more SPI frames have to be delivered to the Anybus CompactCom.

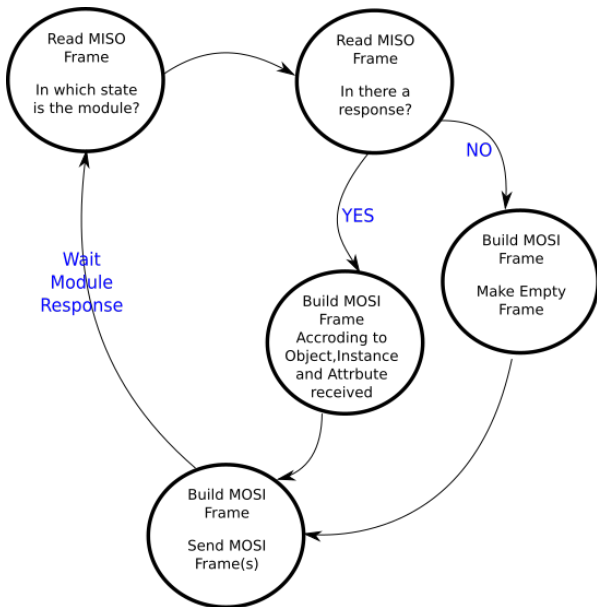

Figure 5: Detail of a status implementation in the FSM written.

With the SPI working at 20MHz and with a Process Data field of 46 bytes, the SPI frames are around 20us long, but

in the process of the state machine, the data refresh rate is 1.3 ms.

FBIS is a redundant system with two channels reading data from the Anybus CompactCom. According to the SPI protocol, the Anybus CompactCom is the slave that has to be accessed by two masters SCS\_1600. Currently one of the two masters engages the Anybus CompactCom, and informs the second master that stays in idle state. The second master gets then the decoded frame of the Anybus CompactCom from the first master. The link between the two masters is done via backplane and is based on a UART protocol. If the first master can't engage the module, the second master takes over, re-initializing the module and trying to reach the process active state. In case the second master fails also, the first master tries again and so on.

## CURRENT STATE

The firmware has been generated using Xilinx Vivado 2018.3. As mentioned in the previous section so far it has been hardware validated in two different Xilinx device families. The maximum clock frequency tested was 250 MHz. In Table 1 a device utilization metrics for a Xilinx XCKU040 FPGA is reported.

Table 1: Xilinx XCKU040 Utilization Metrics

LUT	LUTRAM	BRAM	DSP48	Max. Freq.
2170	21	0	0	250 MHz

Currently at ESS is in the first phase commissioning of part of the normal conducting linac. FBIS interfaces three PLC systems with a PROFINET. A more detailed description of one of this system is here [5], based on PROFINET real-time fieldbus communications protocol and Anybus CompactCom M40 module.

As mentioned above, data decoded from one Anybus CompactCom has to be read by two different masters. Actually just one master engages the module instead of the second master reads decoded data from the first master.

In Fig. 6, two OPIs providing details on the status of the FSMs implemented in the two redundant masters. The OPI on the left provides details about the master that has engaged the Anybus CompactCom. The master has properly detected and identified the Anybus CompactCom module (green leds) and the module is in "Process Active" state (blue led). The master also provides module data to the UART link on the backplane. Instead of in the OPI on the right, the master doesn't read information about the module, and its logic managing the SPI communication is in idle state (blue sys\_reset led). It reads information of the first master from the UART (UART alive led).

## FURTHER IMPROVEMENTS

So far only a limited number of objects are caught in the code. The ones implemented were chosen empirically,

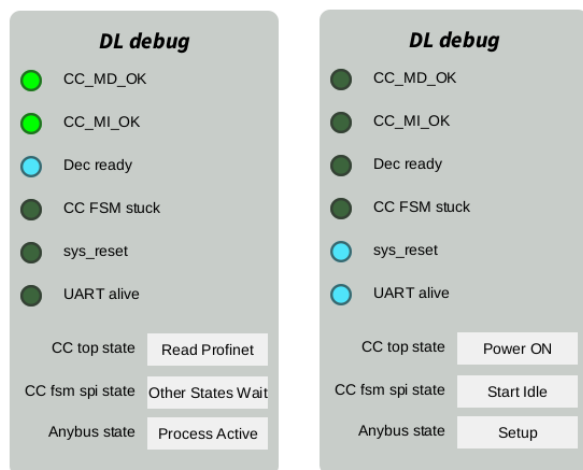

Figure 6: OPIs about the status in the two different masters. On the left the master that has engaged the Anybus CompactCom. On the right the master reading decoded data via UART.

looking at the SPI commands issued by the Anybus CompactCom. In case the module sends a command requesting an answer that is not foreseen in the host, this can lead to the Anybus state machine getting trapped in the Network Init or Wait Process state.

Now in order to overcome this, the module is reset and re-initialized. Future development will handle all possible commands and provide proper responses.

Both masters communicate through UART to arbitrate which one interfaces the module. Now it's under investigation the opportunity to exploit the backplane ethernet communication in order to replace the UART link.

The communication with the Anybus CompactCom could be managed by both master in parallel. As there is only 1 slave, the CS is whatever always in use (tied to 0) and the arbitration just has to be managed between the masters, out of the SPI protocol. However the module requests some specificity in the SPI frames that makes the dual master implementation delicate:

- a bit has to be toggled between 2 messages (command/response) except in some circumstances like errors. If it is not properly toggled, the module will not interpret messages properly.

- responses are not requested to come in the same order than commands were sent, each master has to interpret responses to check it is the one of its own command.
- some commands or responses take more than 1 SPI frame in case the Process Data field is not large enough. This adds complexity in managing the communication, especially in VHDL

## CONCLUSION

An host application, written in VHDL, to interface the Anybus CompactCom has been presented.

It is integrated in the whole FBIS logic. FBIS is currently working during the first phase of the normal conducting linac for which the beam commissioning is about to start.

For the next commissioning phases we are planning to make some improvements in the code in order to facilitate the module starting, the reading during operation by our redundant system, but also to get more diagnostics from the module itself or PROFINET, and potentially send data back to PLCs.

# APPLYING MODEL CHECKING TO HIGHLY-CONFIGURABLE SAFETY CRITICAL SOFTWARE: THE SPS-PPS PLC PROGRAM

B. Fernández\*, I. D. Lopez-Miguel, J-C. Tournier, E. Blanco,  
T. Ladzinski, F. Havart, CERN, Geneva, Switzerland

## Abstract

An important aspect of many particle accelerators is the constant evolution and frequent configuration changes that are needed to perform the experiments they are designed for.

This often leads to the design of configurable software that can absorb these changes and perform the required control and protection actions. This design strategy minimizes the engineering and maintenance costs, but it makes the software verification activities more challenging since safety properties must be guaranteed for any of the possible configurations.

Software model checking is a popular automated verification technique in many industries. This verification method explores all possible combinations of the system model to guarantee its compliance with certain properties or specification. This is a very appropriate technique for highly configurable software, since there is usually an enormous amount of combinations to be checked.

This paper presents how PLCverif, a CERN model checking platform, has been applied to a highly configurable Programmable Logic Controller (PLC) program, the SPS Personnel Protection System (PPS). The benefits and challenges of this verification approach are also discussed.

## INTRODUCTION

Model checking is a popular verification technique that has been applied in many industries to guarantee that a critical system meets the specifications. Model checking algorithms explore all possible combinations of a system model, trying to find a violation of the formalized specification in the model. This technique is very appropriate for highly configurable projects, since it is necessary to guarantee the safety of the system for all possible configurations.

When model checking shows a discrepancy between the PLC program and the specification, it means that either the PLC program has a bug or the specification is incomplete or incorrect.

In the domain of critical PLC programs, several researchers and engineers published their experiences in the field. To name but a few, in [1] the authors translate the PLC program of an interlocking railway system, written in the FBD (Function Block Diagrams) language, into the input format language of NuSMV to verify their specification written as CTL (Computation Tree Logic) properties. In [2], the PLC program that controls the doors' opening and closing in the trains from the Metro in Brasília, Brazil, was formally verified. In this case, a B model [3] is created automatically

from the PLC code. This model is formally verified using the model checker ProB [4].

When applying model checking to PLC programs, three main challenges are faced: (1) building the mathematical model of the program, (2) formalizing the requirements to be checked and (3) the state-space explosion, i.e. the number of possible input combinations and execution traces is too big to be exhaustively explored. In our case, we use the open-source tool PLCverif[5], developed at CERN. It creates automatically the models out of the PLC program and integrates three state-of-the-art model checkers: nuXmv [6], Theta [7] and CBMC [8]. It also implements some reduction and abstraction mechanisms to reduce the number of states to be explored and to speed up the verification. Therefore, challenges 1 and 3 are transparent for the user. There are certainly still limitations and large state-space PLC program models cannot be verified. Regarding challenge 2, PLCverif also provides mechanisms to help the users to formalize their requirements and provide a precise specification. However, this is normally a difficult task, specially for configurable programs. In this paper, we will show examples of functional requirements formalization with PLCverif. More details about PLCverif can be found in [5, 9].

This paper aims to show the benefits of applying model checking to verify highly configurable PLC programs. In such systems, it is usually unfeasible to check all possible combinations by traditional testing methods and model checking is a good complement to these methods, especially for module verification.

In particular, this paper shows how PLCverif was applied to the PLC programs of the SPS Personnel Protection System (PPS) [10] and how it helped to improve their original specification and correct PLC bugs before the commissioning of the system.

## SPS PERSONNEL PROTECTION SYSTEM

The SPS-PPS is a large distributed control system in charge of the access control and the personnel protection of the SPS accelerator.

The SPS has 16 access zones divided in different sectors and each access zone has an access point. Several access zones are always interlocked with the same elements inhibiting operation with beam when a hazardous event is detected. This is the concept of a safety chain. Each safety chain contains the "important safety elements" to stop the beam (EISb) when a hazardous event is detected or to avoid access (EISa) when the accelerator is in Beam mode.

All details of the system can be found in [10].

\* borja.fernandez.adiego@cern.ch

Figure 1: Simplified SPS-PPS PLC interlock architecture.

The SPS evolves with time as new access zones are added or existing ones modified. For that reason, a configurable system was designed.

### Hardware Architecture

The SPS-PPS safety-interlock part is based on Siemens S7-1500F series of PLC controllers. It is formed by the following 3 layers as shown in Fig. 1:

- The central layer is composed by the Global Interlock (GI) PLC. This PLC receives the information of all the Site PLCs and computes, for example, the conditions to allow Beam or Access modes to each safety chain and the conditions to apply veto to all the EISa and EISb associated to the safety chain.
- The site layer is composed by 16 Site PLCs (1 PLC per access zone). These PLCs monitor the EISa devices (doors, emergency handles, etc.), receive the status from the AP PLCs, perform some automatic control procedures (e.g. patrol management) and apply the safety interlock actions (e.g. stop the beam) with the commands received from the GI PLC for each access zone.
- The equipment layer is composed by 16 Access Point (AP) PLCs (1 PLC per access point). They monitor and control the PAD (Personnel Access Device) and the MAD (Material Access Device) of the access point.

### Software Architecture

All Site PLCs run the same generic PLC program, a common logic for all of them with a specific configuration for each access zone. The logic is composed by a set of Functions (FC) and Function Blocks (FBs) executed sequentially from a cyclic interrupt every 300 ms. Each access zone has a different configuration, indicating for example how many EISa and EISb are installed in each of them, in which sector they are located and to which safety chain they belong.

A similar approach is in place for the AP PLCs.

The GI PLC contains less configurable parameters since it communicates with all Site PLCs, having a global view of the system.

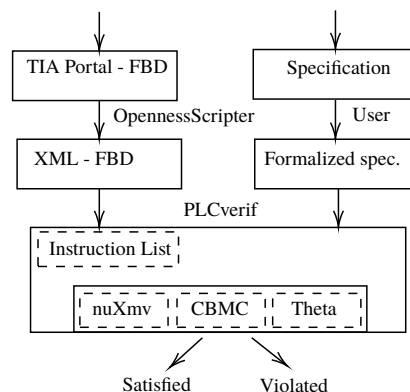

Figure 2: PLCverif workflow to verify TIA portal Safety programs.

### Software Modules Specification

The different program modules (FC and FBs) are specified in a detailed design document. It contains 106 formulas that describe the requirements for the 29 FC and FBs.

The chosen formalism for the specification is a simple *if-else* conditional statement that contains Boolean formulas, as shown in the example Specification 1. The goal was to have a simple pseudo-formal specification providing precise and unambiguous requirements for each module of the system.

**Specification 1** Template for specifying protection actions of the Safety program.

```

if (Boolean expression condition) then
    result ← 0
else if (Boolean expression condition 2) then
    result ← 1
else
    result ← result
end if

```

## MODULES VERIFICATION WITH PLCVERIF

PLCverif was the tool to apply model checking to the SPS-PPS modules (FC and FBs). All the necessary model transformations to create the formal model of the PLC program are done automatically. The user only needs to provide the exported PLC program from the programming environment tool, Siemens TIA Portal<sup>1</sup>, import it into PLCverif and finally formalize the requirements to be verified.

Figure 2 shows the workflow to verify a FC or FB from a TIA Portal safety PLC project with PLCverif:

1. The project is hosted in TIA Portal and the PLC program is written in the FBD (Function Block Diagram) programming language. An example of how this language looks like is shown in Fig. 3. Here an AND gate and an OR gate are displayed.

<sup>1</sup> <https://new.siemens.com/global/en/products/automation/industry-software/automation-software/tia-portal/software.html>

Figure 3: FBD program example.

2. Taking advantage of the Siemens OpennessScripter tool<sup>2</sup>, the program is exported to XML (*F\_FBD* XML format). An example of how an AND gate is represented in this language is shown in Listing 1.
3. PLCverif can then import that XML code, translating it into STL code, which can be understood by PLCverif. Subsequently, it creates the formal models.
4. From the specification created by the process engineers, the user needs to formalize the requirements, such as the assertion shown in Listing 2. This can be direct input to PLCverif.
5. Finally, PLCverif executes one of the model checking backends and generates a report, stating whether the property is satisfied or violated. In case it is violated, it shows the trace leading to that property failure (the counterexample).

## VERIFICATION RESULTS AND ANALYSIS

Although various safety functions were verified during this project, due to space limitations for this paper, only two of them will be shown here: the *SIF-X1* Function from the Site PLCs and the *SIF-2* Function from the GI PLC. Each of these PLC Functions implements several requirements of a similar nature and each of these requirements was verified with PLCverif by including an assertion which represents the mathematical Boolean formula given for that requirement. After executing a verification case with PLCverif, the following outcomes can occur:

- Satisfied property. It will be shown in Example 1 from SIF-X1.
- Violated property. The reasons why this happens need to be further investigated, leading to the following two possibilities:
  - Incomplete specification. Example 2 from SIF-2.
  - Bug in the program. Example 3 from SIF-2.

### *SIF-X1* Function

This function is in charge of monitoring all the EISa of the access zone and computing the status (safe or unsafe) for each safety chain.

**Example 1 - Satisfied property.** The selected requirement for this use case is the following: For each Safety Chain, this Function monitors all the EISa that are installed in the access zone and belong to the Safety Chain. It also receives the status from its access point (PAD, MAD and token distributor status). If all these elements are in a safe state, it returns a Boolean variable indicating that the Safety Chain is safe.

The formalized requirement is shown in Specification 2, where

$i$  is the EISa index,

$j$  is the safety chain index,

$N_j$  is the number of EISa assigned to the safety chain  $j$  (the maximum number of EISa per access zone is 32),

$I\_EISa\_Pos[i]\_Stat$  represents the status of the EISa  $i$ : true if  $i$  is closed,

$I\_EISa\_PU[i]\_Stat$  represents the status of the emergency handle of the EISa  $i$ : true if the emergency handle is armed,  $I\_EISa\_Pos[i]$  is a configuration variable: true if the EISa  $i$  is installed in the access zone,

*I\_EISa\_PU*[*i*] is configuration variable: true if the EISa *i* has an emergency handle,

$SC - Sj[i]$  is configuration variable: true if the EISA  $i$  belongs to the Safety Chain  $j$ ,

$S0\_AP\_Pos[j]$ ,  $S0\_AP\_PU[j]$  and  $S0\_AP\_Key\_Distrib[j]$  represent the status of the access point: true if the access point is closed, the emergency handle is armed and the token distributor is safe respectively,

$N\_EISa\_Safe[j]$  is the output variable of the Function and represents the status of the safety chain  $j$ : true if  $j$  is safe.

**Specification 2** Partial, simplified requirement of SIF-X1.

```

if (
   $\bigwedge_{i=1}^{N_j} ((I\_EISa\_Pos\_Stat[i] \vee I\_EISa\_Bypass[i])$ 
     $\bigwedge_{\forall i \in [1, N_j]: (I\_EISa\_Pos[i]=1 \wedge SC-S[j][i]=1}$ 
     $\bigwedge_{i=1}^{N_j} ((I\_EISa\_PU\_Stat[i] \vee I\_EISa\_Bypass[i])$ 
     $\bigwedge_{\forall i \in [1, N_j]: (I\_EISa\_PU[i]=1 \wedge SC-S[j][i]=1}$ 
     $\bigwedge$ 
     $S0\_AP\_Pos[j] \wedge S0\_AP\_PU[j] \wedge S0\_AP\_Key\_Distrib[j]$ 
  ) then
     $N\_EISa\_Safe[j] \leftarrow 1$ 
  else
     $N\_EISa\_Safe[j] \leftarrow 0$ 
  end if

```

The behaviour of this relatively complex specification is shown in Table 1 with an example. Here, 2 doors ( $EISa$ ) are installed in this access zone (indexes 1 and 4 of  $EISa\_Pos[i]$ ), only one of them has an emergency handle (index 1 of  $EISa\_PU[i]$ ). One of the  $EISa$  belongs to the Safety Chain 0 (index 1 of  $SC - S\_0[i]$ ) and the other one to the Safety Chain 1 (index 4 of  $SC - S\_1[i]$ ). For each safety chain  $j$ , the resultant  $N\_EISa\_Safe[j]$  is true if the installed doors and emergency handles are in the safe state ( $EISa\_Pos\_Stat[i]$  and  $EISa\_PU\_Stat[i]$ ).

Table 1: SIF-X1 Expected Behaviour

Source	Variable	Value
Input	$EISa\_Pos\_Stat$	0000 0000 0000 1001
Input	$EISa\_PU\_Stat$	0000 0000 0000 0001
...	...	...
Input (AP PLC)	$SO\_AP\_Pos$	0000 0000 0000 1001
...	...	...
Configuration	$EISa\_Pos$	0000 0000 0000 1001
Configuration	$EISa\_PU$	0000 0000 0000 0001
...	...	...
Configuration	$SC - S_0$	0000 0000 0000 0001
Configuration	$SC - S_1$	0000 0000 0000 1000
...	...	...
Output	$N\_EISa\_Safe$	0000 0000 0000 1001

The specification was translated into 16 verification cases (one per safety chain), in order to guarantee that this property is respected in all safety chains for all possible combinations of the input and configuration variables. The example for the safety chain 0 can be seen in Listing 3 (simplified assertion).

The corresponding PLC program has 94 WORD (16-bit variable) and 4 BOOL configuration variables, and 21

WORD and 2 BOOL input variables to implement all the requirements. This implies approximately  $2^{16 \cdot (94+21)+6} = 2^{1846} \approx 5.0 \cdot 10^{555}$  combinations to be checked. The equivalent STL code of the original F-FBD version is around 700 lines of code.

PLCverif was able to validate the 16 verification cases in 41 seconds. The result of all properties (assertions) was satisfied. This means that no counterexamples were found and, hence, the properties always hold true.

Listing 3: SIF-X1 formalized requirement for PLCverif.

```

//#ASSERT
(((I_EISa_Pos_Stat OR I_EISa_Bypass) AND
(SC-S_0 AND I_EISa_Pos))
= (SC-S_0 OR I_EISa_Pos)) AND
(((I_EISa_PU_Stat OR I_EISa_Bypass) AND
(SC-S_0 AND I_EISa_PU))
= (SC-S_0 OR I_EISa_PU)) AND
(SO_AP_Key_Distrib.%X0 AND
SO_AP_PU.%X0 AND SO_AP_Pos.%X0)
= N EISa Safe.%X0

```

### SIF-2 Function

The following two examples belong to the verification of the SIF-2 Function. In this function, PLCverif was able to find several discrepancies between the PLC program and the specification and two of them are presented here.

This function contains the transitions rules between the Beam and Access modes for each safety chain  $j$ . In order to allow the transition between modes, the function checks the status of the safety chain (computed variable calculated by another GI PLC function) and the requests from the operator, via the OKP (Operator Key Panel). When all safety conditions are met, this function authorizes the change of mode. The function also contains the conditions to lock or release the keys from the OKP.

The implementation of the SIF-2 Function Block has 19 WORD and 1 BOOL input variables to implement all the requirements. This implies approximately  $2^{19 \cdot 16 + 1} = 2^{305} \approx 6.5 \cdot 10^{91}$  combinations to be checked.

The equivalent STL code of the original F-FBD version is around 1200 lines of code.

**Example 2 - Incomplete specification.** This specification was related to the conditions to switch to Beam mode. The property was formalized with the assertion shown in Listing 4:

Listing 4: SIF-2 Beam mode activation formalized requirement for PLCverif.

```

//ASSERT
((NOT((N_EXT_ACCE_OK AND N_NO-SAFETY_ERR) AND
((I_PB_TEST_ON AND I_Key_TEST) OR
(I_PB_Acce_ON AND I_Key_Acce))))
OR (NOT N MODE BEAM)) = 16#FFFF)

```

This assertion was verified with PLCverif in 93 seconds and a counterexample was found, meaning that the property was violated. The reason for this violation was a missing variable in the formula from the documentation.

**Example 3 - Bug in the PLC program.** In this case, the conditions to release an access key from the OKP for one of the safety chains were used as specification. The formalized assertion was the one shown in Listing 5:

Listing 5: SIF-2 extractors access key release formalized requirement for PLCverif.

```
//#ASSERT
((N_SECU_NO-REQ_Down.%X15 AND N_EXT_BEAM_OK.%X15)
= (SIF-2_TAGS.0_RLS_ACCESS.%X15))
```

PLCverif was able to verify this assertion in 147 seconds. The result was not satisfied and a counterexample was provided. After analysing the counterexample and discussing with the SPS-PPS experts, it was concluded that there was a problem in the PLC program. The program was modified accordingly to include the missing variables before the commissioning of the system.

### Analysis

PLCverif hides most of the complexity of applying model checking to PLC programs. Nevertheless, a few manual steps were still needed in this project. In particular to import the program in PLCverif and to create the formal properties from the pseudo-formalized specification.

We also encounter the state-space explosion problem in other functions, where the number of configurations and input variables was much bigger.

Overall, PLCverif helped to validate a few critical functions from the SPS-PPS PLC program and it was a good complement to the testing activities performed in the lab by the access control experts at CERN (e.g. the SIF-X1 function).

PLCverif was able to find discrepancies between some of the specifications and the PLC program before the commissioning of the system, sometimes due to an incomplete or erroneous specification, other times due to a bug in the program (e.g. the SIF-2 function). Due to the complexity of some of the specifications, it was sometimes very hard for experts to validate the desired behaviour. By using model checking, the experts were able to find undesirable corner cases, helping them to understand the behaviour of the system and modifying the specification when necessary.

## CONCLUSIONS

This paper presented a highly configurable PLC program and the benefits and challenges of applying model checking to verify it. In general, we can conclude that model checking contributed to this project to (1) detect bugs in the PLC program before the commissioning, (2) identify deficiencies in the specification, and (3) help experts to better understand the behaviour of the program for all possible configurations.

There are still several challenges to overcome for model checking to become a common practice in the industrial automation domain. Probably the more important ones are:

(1) the integration of model checking in PLC programming environments (e.g. TIA portal) to minimize the number of manual steps and (2) the improvement of verification performance with better algorithms and abstraction techniques.

In the context of the PLCverif project, the future work will focus on the following directions: (1) improve PLCverif to reduce the verification time, (2) support more PLC manufacturers – we are currently working on supporting Schneider ST and IL programs. More information about the current and future work of PLCverif can be found in [9].

# BEAM PROFILE MEASUREMENTS AS PART OF THE SAFE AND EFFICIENT OPERATION OF THE NEW SPS BEAM DUMP SYSTEM

A. Topaloudis\*, E. Bravin, S. Burger, S. Jackson, F. Maria Velotti, E. Veyrunes,  
CERN, Geneva, Switzerland

## Abstract

In the framework of the LHC Injectors Upgrade (LIU) project, the Super Proton Synchrotron (SPS) accelerator at CERN is undergoing a profound upgrade including a new high-energy beam dump. The new Target Internal Dump Vertical Graphite (TIDVG#5) is designed to withstand an average dumped beam power as high as 235 kW to cope with the increased intensity and brightness of the LIU beams whose energies in the SPS range from 14 to 450 GeV. Considering such highly demanding specifications, the constant monitoring of the device's status and the characteristics of the beams that are dumped to it is of utmost importance to guarantee an efficient operation with little or no limitations. While the former is ensured with several internal temperature sensors, a Beam Observation system based on a scintillating screen and a digital camera is installed to extract the profile of the beam dumped in TIDVG#5 for post mortem analysis. This paper describes the overall system that uses the BTV images to contribute to the safe and efficient operation of the SPS Beam Dump System (SBDS) and hence the accelerator.

## INTRODUCTION

While the accelerators of the proton injector chain at CERN deliver beams to the Large Hadron Collider (LHC) within specification, the requirements for the upgraded High-Luminosity LHC (HL-LHC) exceed their current capabilities. The LHC Injectors Upgrade (LIU) project aims to address this by upgrading the proton injectors to deliver the high brightness beams needed by the HL-LHC [1].

In the framework of the LIU project, the SPS underwent several important upgrades including a new high-energy beam dump [2]. Such a system is meant to dispose of the circulating beam in the accelerator whenever necessary, i.e. in case of emergency, during machine developments (MD), LHC beam setup or LHC filling and after the slow-extraction process to eliminate the remnants of the beam for fixed targets (FT). In order to minimise the associated thermo-mechanical stresses in the dump, the energy density deposited in it is reduced by diluting the beam with the kicker magnets, producing a sinusoidal pattern on the front of the first absorbing dump block [3]. The principle is depicted in Fig. 1 along with a simulation of the expected dilution of a Fixed Target beam.

Until now, the SBDS consisted of two internal dumps, i.e. Target Internal Dump Horizontal (TIDH) and Target Internal Dump Vertical Graphite (TIDVG#4) which used to absorb beams with energy from 14 to 28.9 GeV and between 102.2 and 450 GeV accordingly. During CERN's Long Shutdown

\* athanasios.topaloudis@cern.ch

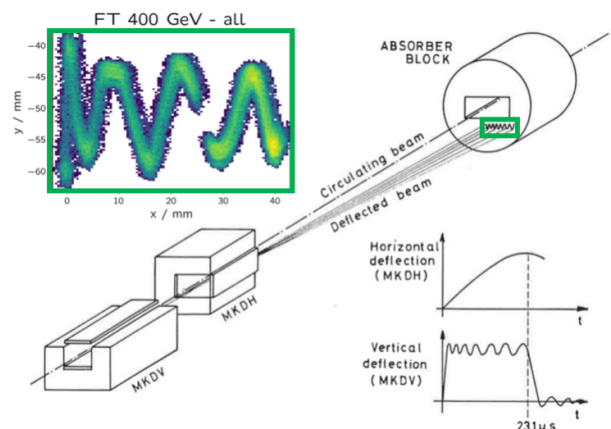

Figure 1: Principle of beam dumping in the SPS and simulation of a Fixed Target diluted beam.

2 (LS2) (2019-2020), the new TIDVG#5 replaced both the aforementioned dumps in order to cope with the increased intensity and brightness of the LIU beams which are expected to produce an average dumped beam power as high as 235 kW instead of 60kW. Consequently, the new system is required to withstand all beam energies in the SPS, i.e. from 14 to 450 GeV, including the previously so-called “forbidden” range, 28.9–102.2 GeV; hence, removing this limitation for the beam operation [4].

## MOTIVATION

In order to reduce the local energy deposition while maintaining the total required beam absorption, several innovations have been implemented in the design of the TIDVG#5, e.g. core materials, cooling and shielding. The design was done base on the most demanding beam dump scenarios taking into account possible failures of the extraction kickers responsible to dilute the particles [4].

However, to ensure the safe operation of the system and its components, the design specifications should be guaranteed. This can be achieved by constantly monitoring the characteristics of the dumped beams, i.e. the exact position of the dumped beam with respect to the dump as well as its shape and inhibit further beam injections in case of operational problems. For this, a Beam Observation system was installed to capture an image of the particles before impacting the dump block [5] to be included in the Post-Mortem analysis that verifies the quality of each dump.

## BEAM OBSERVATION SYSTEM

A Beam Observation System, known at CERN as Beam TV (BTV), is widely used to acquire the image of the beam in all accelerator complexes. This is achieved by intercepting the trajectory of the beam inside the vacuum chamber with a screen. When the beam particles hit the screen, visible light is emitted proportionally to its local intensity. The resulting beam footprint can subsequently be observed by a detector e.g. a camera, through a dedicated view port and optical line [6].

### SBDS Installation

In the case of the SBDS, a scintillation screen made of Alumina doped with Chromium (CHROMOX) is installed about 1.6m upstream of the dump shielding blocks [7]. The light produced on the screen is picked-up by a GigE digital camera from Basler [8] with a Complementary Metal–Oxide–Semiconductor (CMOS) sensor.

In order to protect the detector from the high levels of radiation produced on the dump block and to minimize the number of electronics Single-Event-Upset (SEU), the camera is installed in a low radiation area below the dump platform. In addition, it is contained in a dedicated shielding enclosure with a movable door to facilitate any maintenance access [7].

The detector's location was chosen following a set of FLUKA simulations [9] which also allowed the definition of the 17m optical line between the camera and the screen consisting of 5 high quality mirrors. The entire optical line volume is enclosed to avoid parasitic light and any damage on the mirrors and can be depicted in Fig. 2 [10].

Figure 2: Optical line of the imaging system around the new SPS dump.

### Acquisition System

The acquisition system at the SBDS installation is based on the relatively low decay time ( $> \text{few } 100 \text{ ms}$ ) of the light yield of the CHROMOX screen used. Taking advantage of the beam footprint staying on the screen for several milliseconds, the system continuously monitors the screen and selects the first image that is not saturated.

**Hardware** A CPU installed at a front-end computer hosts two network mezzanines, one dedicated to the communication with the camera and one for connecting the system to the control system. The camera is connected to the CPU over Ethernet through a switch and is managed by the software running in the same CPU. At the same front-end computer, a timing receiver is installed to integrate the central SPS timing to the system and custom electronics to enable the remote power management of the switch.

Figure 3: Image acquisition software model.

**Software** The real-time C++ server that orchestrates the acquisition process is designed with the Front-End Software Architecture (FESA) framework [11] and is split into two main parts:

- the *real-time* that manages the communication with the camera and its synchronization.
- the *server* that manages the communication with the clients.

The low-level access to the camera is achieved via the pylon Software Development Kit (SDK) [12] provided by Basler.

The image acquisition is organised in blocks that can be seen in Fig. 3. In order to improve the server's performance and avoid its blockage and consequently a potential image loss, each of the blocks run on a separate thread.

**Readout** During normal operation, the camera acquires images at its maximum internal frame rate, 35 Hz. The images are consecutively fed to the server by notifying the latter in the form of interrupts generated at the CPU. The server continuously grabs the new images as they arrive and copies them to intermediate storage to release the camera's buffer as soon as possible so that the camera is always ready for the next image acquisition.

**Processing** The copied images are subsequently provided to the analysis block for identifying if they are saturated or not. This is achieved by scanning their individual

pixels to find the maximum value. In a saturated image, this value will be the same as the maximum value the camera's Analogue to Digital Converter (ADC) can produce, i.e. 4095 is the maximum value that can be represented by 12 bits.

**Internal Storage** The images are then sent to the internal storage block to be copied to one of the software's rolling buffers. The total number of rolling buffers is configurable and by default is 8 to keep the last 7 dump events in the memory. At any given time, there is an active rolling buffer that is used only for storing the images and is not available to the user. The number of images each rolling buffer can hold is configurable up to 100, split into two categories, pre and post trigger ones.

**Image Selection** In order to select and publish the appropriate image, the server listens to an external trigger, i.e. that the beam was dumped, via the timing receiver. This trigger enables the selection process that counts the number of images received until the rolling buffer's size is reached, before freezing it and switching to the next available one. The first image in the rolling buffer (post-trigger) that is not saturated is selected for publication and storage in the logging and Post-Mortem data base. An example of this process is depicted in Fig. 4 with the first (saturated) image in the rolling buffer on top and the sixth (the first non saturated) in the same buffer at the bottom.

Figure 4: Example of the automatic image selection with a Fixed Target dumped beam.

**Image Cleaning** In order to improve the signal-to-noise ratio of the published image, an empty image, i.e. pre-trigger and without beam in the rolling buffer, is subtracted from any selected images. This process is particularly important to minimise the noise background in the published image, as light can still be present on the screen from a previous event, when two consecutive beam dumps occur relatively closely.

**Image Availability** Regardless of the selected image that is published, all the images of the rolling buffers, except the active one, can be retrieved before they are overwritten. This is important for verifying the aforementioned selection and cleaning mechanisms as well as the validation of the internal storage and its categorisation into pre and post trigger images.

Additionally it is also crucial during the commissioning phase of the system to set up the camera (i.e. gain, exposure time) such that it covers all SPS beam types and a non saturated image is always present in the buffers.

**Internal Watchdog** In order to verify the quality of each dump, the system should be 100% available so that there is always an image of the dumped beam stored for Post-Mortem analysis. The availability of the system is ensured by an internal watchdog mechanism that periodically checks and publishes the status of the acquisition and camera along with the actual image reception rate. Both statuses are subsequently monitored by the SPS Software Interlocks System [13] that inhibits further beam injections in case of anomalies.

The acquisition status is based on the image reception flagging; if they are arriving normally to the server from the camera; if there are no images arriving; or if there is an issue with their publication to the Post-Mortem database.

Moreover, the camera settings are periodically read out and checked for consistency with those expected in software. Thus the watchdog can flag if the camera status is OK, in error (i.e. having different settings) or not reachable at all.

To compliment the status publication, the mechanism includes a remote power reset of the camera via custom electronics to recover from any unexpected instability.

## Operational Integration

During the SPS beam commissioning period after LS2, the Beam Observation system was validated with dumped beams varying from low intensity single bunch to trains of high intensity bunches. All features of the acquisition system were commissioned and enabled the quick setting up of the camera to cover all SPS beam types even from day 1 as they were progressively been dumped.

The system was then extensively used to commission the whole SBDS system measuring the transfer function of the kicker magnets, verifying their polarity, and assessing the effects of their potential failure.

Since the start of the SPS beam commissioning period, the system has been integrated into the operational fixed display, monitoring the SBDS status as seen in Fig. 5. The display observes various statuses of the SBDS that can be seen at the left panel. Additionally, it displays the selected non-saturated image with the dumped beam from our Beam Observation system at its center and both of the aforementioned acquisition and camera statuses on top of it. Finally, it also depicts the beam filling pattern before being dumped, at the red plot below the image.

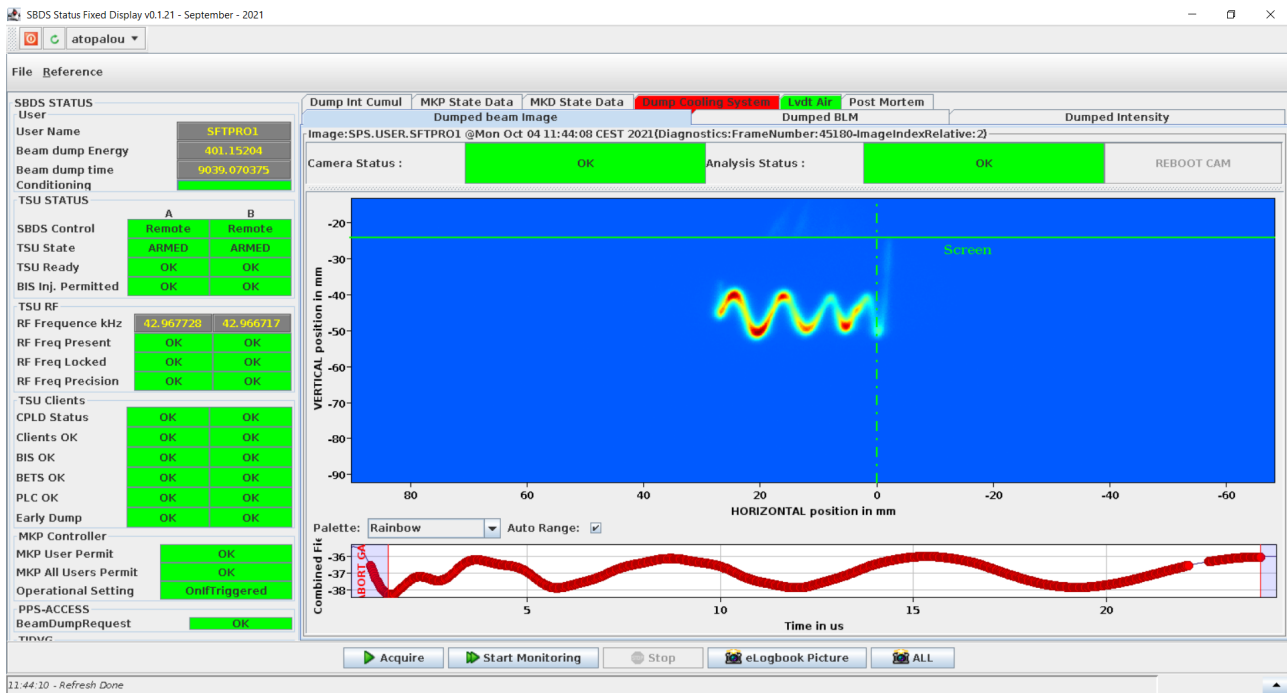

Figure 5: SBDS status Fixed Display depicting a Fix Target dump event.

## CONCLUSION

In order to ensure the safe and optimal operation of the new SBDS, a Beam Observation system based on a scintillating screen and a digital camera was installed to capture and publish the image of the dumped beam.

The system acquisition is based on a free running mode, with images being acquired by the camera continuously at its maximum rate. The system integrates an *automatic detection* of the best image for publication and Post-Mortem analysis that removes the need of setting up the camera according to each beam type the SPS can produce. Additionally, it includes an *image cleaning* algorithm to improve the signal-to-noise ratio and an *internal watchdog* mechanism to monitor the statuses of the acquisition and the camera that are integrated into the SPS SIS.

During the SPS beam commissioning, the system was validated with various types of beams and was crucial in the commissioning of the new SBDS. It remains an essential part of the operational SBDS status Fix Display.

# SUPPORTING FLEXIBLE RUNTIME CONTROL AND STORAGE RING OPERATION WITH THE FAIR SETTINGS MANAGEMENT SYSTEM

R. Mueller, J. Fitzek, H. Hüther, H. Liebermann, D. Ondreka, A. Schaller, A. Walter  
GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany

## Abstract

The FAIR Settings Management System has now been used productively for the GSI accelerator facility operating synchrotrons, storage rings, and transfer lines. The system's core is being developed in a collaboration with CERN [1], and is based on CERN's LHC Software Architecture (LSA) framework [2].

At GSI, 2018 was dedicated to integrating the Beam Scheduling System (BSS). Major implementations for storage rings were performed in 2019, while 2020 the main focus was on optimizing the performance of the overall Control System.

Integrating BSS allows us to configure the beam execution directly from the Settings Management System. Defining signals and conditions enables us to control the runtime behavior of the machine.

The Storage Ring Mode supports flexible operation with features allowing to pause the machine and execute in-cycle modifications, using concepts like breakpoints, repetitions, skipping, and manipulation.

After providing these major new features and their successful productive use, the focus was shifted on optimizing their performance. The performance was analyzed and improved based on real-world scenarios defined by operations and machine experts.

## PREFACE

Patterns and Beam Production Chains (Chains) are the central technical concepts within the new LSA-based Settings Management System at GSI [3,4]. Chains are foreseen to provide a beam-oriented view on the facility from source to target, for now this is not utilized and they still represent an accelerator-oriented view. To be able to coordinate multiple beams traversing the facility in parallel, Chains are grouped into Patterns. See Fig. 1.

Figure 1: Patterns and Beam Production Chains as concepts for scheduling beams.

The term LSA will be used throughout this paper when the FAIR Settings Management System business logic is referenced.

## RUNTIME CONTROL THROUGH BSS

Conceptually, LSA is an offline system which has no information about real-time scheduling, issued beam requests or machine status. BSS is an online system that, at runtime, processes scheduled event sequences and their dependencies on beam requests, accelerator status and beam modes.

Figure 2 shows an overview of the data that is exchanged between the systems.

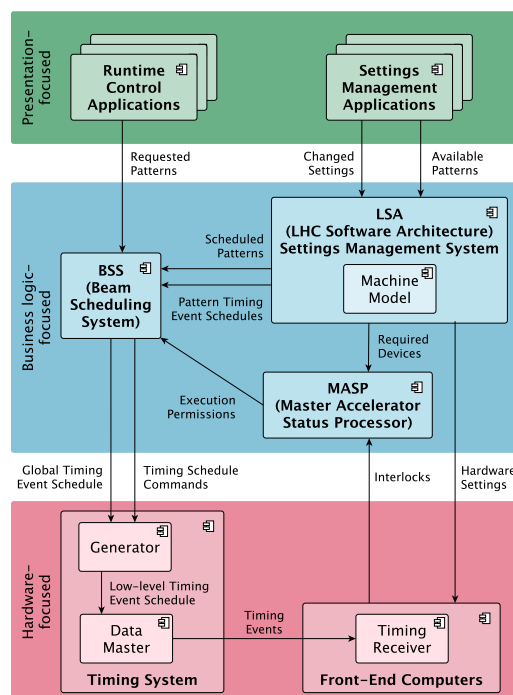

Figure 2: Control system interaction diagram.

The BSS's beam scheduling description is using LSA's own concepts like Patterns, Chains and additionally generated scheduling information like

- description of alternative timing event sequences
- definition of synchronization points
- causal description of branching depending on beam requests, accelerator status and beam-mode
- signal definitions that are used to switch between the aforementioned points

For a detailed description of BSS see [5].

A major effort was to implement the foundation that all the information needed by BSS can be generated in LSA.

Originally at CERN, LSA only has the concept of resident contexts. A resident context represents a corresponding set of set-values, that are loaded into the devices and the Timing System could potentially send events to execute them.

At first the machine model at GSI, like the one at CERN, only contained set-values for devices. In discussion with the machine experts it was decided to introduce an additional hierarchy into the model that also calculates tables of timing events that are needed to execute the settings.

Figure 3 shows a part of the timing hierarchy that is used to calculate the timing event sequences.

LSA at GSI now has full control over the series of timing events which can be adapted depending on factors like element, isotope, energy, ramp speed/length, number of injections, etc.

The calculations lead to a series of timing events (see Table 1) that are converted into a DOT graph [6] description and sent to BSS (see Fig. 4).

Table 1: Simplified Event Sequence as Generated by the LSA Model

Timing Group	Chain	Chain Start	Event Id	Event Time $\mu$ s	Comment
300	1	1	256	0	Start of sub-sequence
300	1	0	512	0	Prepare Function Generators (FG)
300	1	0	352	0	Request beam transfer
300	1	0	256	16000	Start of sub-sequence
300	1	0	351	16000	End beam transfer
300	1	0	513	16000	Start FGs and Ramp

Patterns were extended by the possibility to add execution conditions and a repetition count. Both are used by LSA to generate branching conditions. First LSA determines which branches exist and generates BSS Signals to enable switching between branches. These Signals are then used at runtime to determine the branch that should be taken for this Pattern execution.

Figure 3: Simplified timing hierarchy to calculate the timing event sequence.

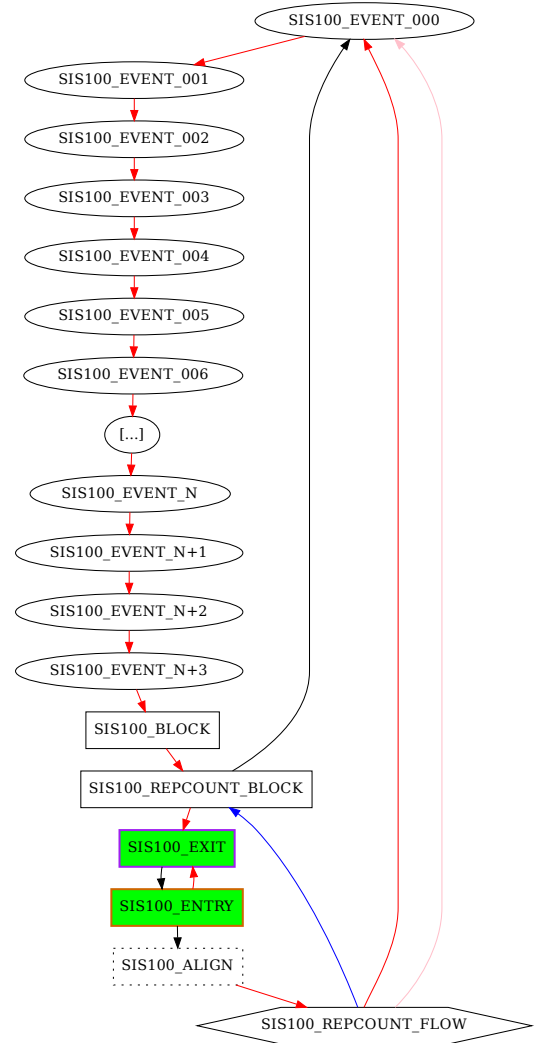

Figure 4: Schematic timing graph that is sent to BSS as DOT.

As an example Fig. 5 shows a simplified graph that allows to repeat or skip a Pattern.

Since setting manipulation happens per Pattern, the schedule graph information sent is also strictly per Pattern. Only BSS has an overview of the whole schedule.

On top of the resident concept from CERN, the concept of "Pattern Groups" has been introduced into LSA at GSI.

Figure 5: Simplified Pattern repetition and skip graph.

They tell BSS which Patterns can run alternately and which can be executed concurrently.

To describe that a beam is transferred between Patterns from different Pattern Groups, a concept that is called "coupling" is used. If *Pattern B* is coupled with *Pattern A*, *Pattern B* halts at injection level, requesting that *Pattern A* is executed. Once *Pattern A* is ready to transfer the beam, it signals for *Pattern B* to continue its execution. The extraction from *Pattern A* and the injection in *Pattern B* is now executed synchronously. The whole process, its timing schedule and conditions, are pre-planned offline using LSA and sent to BSS. At runtime, everything is handled at the lower-level Timing System. Figure 6 shows a simplified coupling graph.

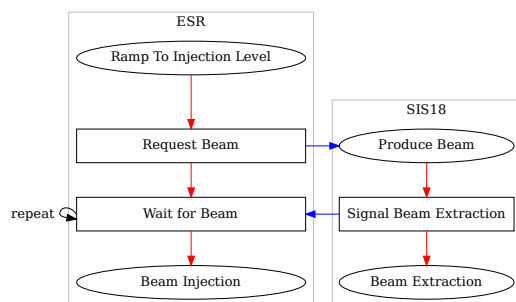

Figure 6: Schematic SIS18<->ESR coupling graph.

Realizing these features enables runtime control through BSS's signals and the timing event graph without the need of further interaction with LSA. It can be prepared beforehand what is possible at runtime.

The integration of BSS was also a precondition for Storage Ring Mode features that require manual user input at runtime to control the beam execution interactively.

## STORAGE RING MODE

Ever since the commissioning of the heavy ion storage ring ESR in 1990, storage ring operation has been a regular,

routine mode of operation at GSI. A second, smaller heavy ion storage ring called CRYRING [7], which had previously been installed at Stockholm University, became a part of the GSI facility in 2016.

LSA already supported fully pre-planned, usually short contexts used for synchrotron operation. As some of the storage rings can store a beam for several days, a more flexible, interactive approach that allowed certain in-cycle modifications was required.

Based on the experience of the ESR and CRYRING experts and the requirements for future storage rings at FAIR, a suitable concept for the new GSI Accelerator Control System was subsequently developed and implemented in 2019. It introduces smaller building blocks within the Chain that represents the full storage ring cycle. The desired functionality is provided by four key features for flexible operation that affect the building blocks: breakpoints, skipping, repetitions, and manipulations (see Fig. 7). Apart from manipulation, the other features can be combined with each other in a single building block.

All features can be configured and triggered by operators using a specialized Storage Ring Mode application (see Fig. 8).

1. Breakpoint: break and continue on user action

2. Skipping: used for optional parts, e.g. measurements

3. Repetition: repeat for a predefined number of executions

4. Manipulation: pause execution and modify settings

Figure 7: The four key features of the Storage Ring Mode.

## Breakpoint

Breakpoints are pre-defined points at the end of a block in a storage ring Chain at which the execution can be interactively paused while the beam is still circulating in the ring. Using the specialized application, the operator can activate a breakpoint. The next time the Chain execution reaches this point, it will halt there until the operator deactivates the breakpoint and execution resumes.

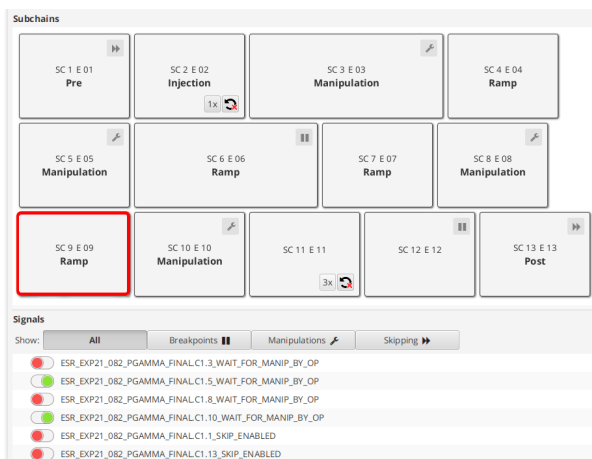

Figure 8: Partial screenshot of Storage Ring Mode application.

This feature can be used for example to pause for an indeterminate time while performing measurements, until sufficient data has been collected.

### Skipping

For blocks of the storage ring Chain that are skippable, the operator can configure whether these blocks are executed or skipped.

Skipping can be used e.g. to quickly reach the end of a Chain execution and start from the beginning, for example in case of unexpected beam loss. This feature is currently also utilized to execute optional parts at the very beginning and end of a Chain. These parts bring the ring devices from their initial state up to an operational level and down again, and only need to be performed when the storage ring operation is started and stopped, but not between shots. This saves time, reduces energy consumption, and reduces the load on the devices.

### Repetition

Blocks of the storage ring Chain can be repeated for a well-defined amount of repetitions. The operator can define that amount, and can decide to abort currently executed repetitions.

Repetitions are used to perform certain parts of the storage ring Chain multiple times, e.g. to take a certain number of measurements. They can also be useful to have a pre-planned way of "stalling" the execution for a pre-determined amount of time while beam is circulating – in contrast to breakpoints, which are used interactively and for an indeterminate time.

### Manipulation

The most complex Storage Ring Mode feature is the manipulation. Similar to breakpoints, they offer the possibility to not only pause at certain points in the storage ring Chain, but also to modify certain settings in this state, until the operator decides to leave the paused state.

The manipulation feature is used to influence the beam while it is stored in the machine, e.g. by slightly changing its orbit. This provides the operators with a lot of flexibility to interactively find good settings by performing multiple small trims on stored beams.

### Storage Ring Mode in Production

The Storage Ring Mode comprised of the features described above was successfully used in production during the beamtimes in 2020 and 2021 at ESR and CRYRING. Using this new flexibility allowed for multiple machine and science experiments.

Once Storage Ring Mode operation had been established, the performance of the Control System became the new center of attention.

## PERFORMANCE OPTIMIZATION

During beamtime 2019/2020, operating identified massive performance problems with the Control System, some of which were intensified by the new features. With the system's increasing functional range and complexity, especially due to in-cycle modifications, the importance of performance as a Control System feature became apparent.

To improve the overall performance, a full stack scenario-based approach was defined [8].

Real-world scenarios that fit common use cases and are used frequently were defined, as well as very complex use cases that are not used often. A baseline measurement was performed after the beamtime for each scenario to compare the efforts that were made during shutdown 2020, see Fig. 9.

Figure 9: SIS18 scenario measurements – Total before and after optimization.

Each scenario has then been performed with applied diagnostic logging to find the parts in the stack that took a long time (see baseline in Fig. 10).

The identified long running parts were then revised by the domain experts and developers across departments working together. In addition to internal optimizations within the individual components, interfaces and APIs were redesigned to make the whole process more efficient. This full stack approach allowed precise identification of affected parts, e.g. database, BSS or LSA. In LSA, the main performance issues

Figure 10: SIS18 scenario measurement – Critical data points before and after optimization.

were located in looking up data from and writing data to the database, and calculating new set-values. The database parts led to new and more efficient queries that were partially merged back to CERN's code base. During the trim, values were kept with higher precision than needed, leading to more complex calculations. Also more data points were kept for further calculations than needed. By reducing them to a minimum, the calculation was sped up as well as the database performance since less points have to be persisted. Also the interaction with BSS was optimized so that Patterns can be supplied more efficiently after calculating new set-values. After all optimizations had been applied through the entire Control System stack, a final measurement was made and compared to the baseline, see Fig. 10.

The overall speedup is between 7.91 for the 'Small trim' scenario down to 3.1 for the 'Energy Trim' scenario. During beamtime 2020/2021, the optimizations have been used productively and operation reported a noticeable speedup [9].

## OUTLOOK

Focus is now more on features for FAIR, further discussing the general concept of "Patterns" and also reviewing the existing concepts. Other topics are requirements for upgrading the UNILAC and integrating it into the new Control System.

### Current Development

**Booster Mode Support** Booster Mode in SIS18 is needed for FAIR. It is used for beam accumulation by stacking four SIS18 cycles into SIS100 using bunch-to-bucket transfer. At the moment, UNILAC is operated in a different way than the rest of the facility and needs to be synchronized with SIS18.

For this purpose, it was decided to introduce the possibility to start a set of timing events asynchronously in the Timing System. This way, UNILAC's deviation can be taken into account.

First tests with a first implementation that does not cover all corner cases and requires specific setup are expected during machine experiments in 2022.

**Injector Controls Upgrade Project** UNILAC is operated at 50 Hz, which means a cycle is only 20 ms and we

can switch between cycles on this timescale. The current UNILAC Supercycle needs to be integrated into the LSA concepts, we have to make it possible to derive a current UNILAC schedule taking into account the beam requests that are expected from SIS18. Possibly the current concept of having Chains, Patterns and Pattern Groups has to be reworked.

**Rework of Pattern Concept** The current operating is done by executing different Patterns that each contains only one Chain while one Chain describes the beam from a source to a target. A source in this case may be an ion source or another linac or ring and a target also may be another ring or an experiment.

For the future FAIR Facility this concept needs to be developed to be more flexible. The focus will switch from machine-oriented point of view like it is now to a beam-oriented view. This means that a Pattern should contain all Chains from ion source via all participating rings and transfer lines to an experiment.

With the background of the "Injector Controls Upgrade Project" the current idea is, that there are only loosely coupled Chains within a Pattern while one Chain now describes the beam from an ion source to an experiment.

There may be multiple Patterns, but in this case, they all do different things, e.g. providing beam for an experiment on request or executing a Storage Ring Mode Chain in parallel. Ultimately, the Pattern Groups will then no longer be needed, and the Pattern itself will no longer be a context in the sense of LSA's context grouping set-values.

This allows to fulfill the special needs for the UNILAC as well as a beam-oriented view on the facility. Discussion on these concepts is ongoing.

# AN ARCHIVER APPLIANCE PERFORMANCE AND RESOURCES CONSUMPTION STUDY

R. Fernandes<sup>†</sup>, H. Kocevar, S. Armanet, S. Regnell, European Spallation Source, Lund, Sweden

## Abstract

At the European Spallation Source (ESS), 1.6 million signals are expected to be generated by a (distributed) control layer composed of around 1 500 EPICS IOCs. A substantial amount of these signals – i.e. PVs – will be stored by the Archiving Service, a service that is currently under development at the Integrated Control System (ICS) Division. From a technical point of view, the Archiving Service is implemented using a software application called the Archiver Appliance. This application, originally developed at SLAC, records PVs as a function of time and stores these in its persistence layer. A study based on multiple simulation scenarios that model ESS (future) *modus operandi* has been conducted by ICS to understand how the Archiver Appliance performs and consumes resources (e.g. RAM memory) under disparate workloads.

## INTRODUCTION

The ICS Division at ESS is mandated to deliver a system to control both its accelerator and end-station instruments. To create the system, the open-source framework EPICS [1] was chosen. With worldwide usage, EPICS allows the creation of Input/Output Controllers (IOCs) which software applications (e.g. Archiver Appliance, CS-Studio) may consume (i.e. connect to) to tackle domain specific businesses (e.g. signals archiving, signals displaying).

Typically, an IOC is an executable (i.e. software process) that utilizes resources from EPICS modules to interface (logical or physical) devices and exposes their input and output signals as Process Variables (PVs). Eventually, an IOC may also implement logic to control these devices.

A PV is a named piece of data, usually associated with devices to represent input and output signals (e.g. status, setpoint). A PV can be read, written or monitored by applications and tools using the Channel Access (CA) library.

Given that a significant number of PVs will be archived by the Archiver Appliance [2] at ESS, the present paper introduces a study to understand how this application performs when storing (i.e. writing) and retrieving (i.e. reading) PV data into and from its persistence layer thanks to a panoply of simulation scenarios designed to stress test it. In addition, the paper explores how the Archiver Appliance consumes resources (e.g. RAM memory) when handling these scenarios.

## SIMULATION SCENARIOS

Thanks to discussions with domain experts to understand the type of data and volume important to test the Archiver Appliance with, four dimensions were identified along with relevant ranges of values. This helped specify simulation scenarios close to what ICS will likely face in terms of

PV archiving needs and requirements from end-users, thus testing the application in a (more) meaningful way. The dimensions and ranges of values are:

- Number of PV waveforms: 1, 100, 1 000, 10 000
- Data points (per waveform): 1 000, 10 000, 100 000
- Data type: integer (4 bytes), double (8 bytes)
- Update frequency: 1 Hz, 14 Hz

Based on these, 48 simulation scenarios were specified (see Table 1).

Table 1: Simulation Scenarios

## TOOLS

A tool named Prometheus was used to collect metrics to help evaluate the performance of the Archiver Appliance when storing and retrieving the aforementioned simulation scenarios into and from its persistence layer, as well as the stress – in terms of resources consumption – these produce on the physical machines involved in the study (i.e. MicroTCA running the IOC, Supermicro running the Archiver Appliance, and another Supermicro running a Python tool to retrieve data).

Metrics collected by Prometheus were then aggregated/displayed by another tool named Grafana. This tool can synthesize vast amounts of collected metrics very quickly in a graphical fashion through personalized dashboards – thus providing highly insightful information.

## STORAGE STUDY

### Environment

To enable a proper study of the Archiver Appliance in terms of PV data storage performance and resources consumption, three components were configured and used: a producer, a consumer, and a network connecting the two.

**Producer** The producer of PV data is an EPICS IOC running in a dedicated MicroTCA machine. The IOC was built with EPICS base version 7.0.3.1 as a 64 bit executable and uses the following EPICS modules:

- asyn (version 4.7)
- sncseq (version 2.2.8)
- procserv (version 2.8.0)
- aatest (version 1.0)
- aatestsioc (version 1.0)

In detail, the IOC is based on the EPICS asyn module and it extends the asynPortDriver C++ class. Several asyn parameters were implemented to provide control and monitoring of the PV waveforms. The IOC startup specifies how many waveforms are generated along with the number of data points for each waveform. Two types of waveforms are provided: integer (4 bytes) and double (8 bytes). On each waveform update only the first data point is modified – this is sufficient to trigger the PV update, consequently forcing the Archiver Appliance to archive the new data. It is also possible to control the delay between two consecutive waveform updates allowing the simulation of different update frequencies (e.g. 14 Hz). Multiple CPU cores may be utilized by running several IOCs at the same time, each

generating/serving a fraction of the PV waveforms – crucial for running the “heaviest” simulation scenarios, which would not have been possible otherwise.

The MicroTCA machine runs CentOS 7 64 bit and has the following main characteristics:

- Manufacturer: Schroff
- Model: 3U
- CPU: Intel Xeon E3-1505M 2.80 GHz (4 cores)
- RAM: 16 GB
- Chassis: MTCA NAT-MCH

**Consumer** The consumer of PV data is an instance of the Archiver Appliance running in a dedicated physical storage server. The Archiver Appliance is a Java-based application that automatically records PV data in function of time in its persistence layer using Protocol Buffers [3], an extensible mechanism for serializing structured data. The instance refers to version 0.0.1 (Fall 2018 Release) of the Archiver Appliance and uses Java version 1.8.0\_191 with a heap size of 16 GB. The storage server runs CentOS 7 64 bit and has the following main characteristics:

- Manufacturer: Supermicro
- Model: SSG-6029P-E1CR12L
- CPU: 2 x Intel 6126 2.60 GHz (12 cores per CPU)
- RAM: 128 GB
- Storage: ZFS 0.7.12 composed of 12 x 6 TB HDD (NL-SAS) and 2 x NVMe Intel P4600 4 TB

**Network** The network is based on a Gigabit fiber optic cable configured to transmit standard Ethernet frames (with a payload equal to 1 500 bytes) at a maximum throughput of 1 Gb/s between the producer and consumer.

### Metrics

The following resources were monitored and metrics about their usages collected every five seconds while running a certain simulation scenario: CPU (load in percentage (%)), RAM (usage in gigabyte (GB)) and Network (traffic in megabit per second (Mb/s)). In addition, at the end of running the scenario, the following metrics were calculated: Disk (usage in gigabyte (GB)) and Dropped (amount of PV frames dropped in percentage (%)).

### Methodology

The main method followed during the storage performance and resources consumption study of the Archiver Appliance was to have each of the 48 simulation scenarios configured to generate either 3 600 frames or 50 400 frames in a run, depending on whether the update frequency is 1 Hz or 14 Hz, respectively. This meant that each scenario would theoretically run for exactly 60 minutes.

Even though no special cache was (explicitly) implemented/configured in the MicroTCA and Supermicro machines, or in the Archiver Appliance, each simulation scenario ran with interval spaces of at least 30 minutes. This pause not only increased the confidence that the activities of a previous scenario (e.g. CPU usage) would not impact the next scenario (thus potentially distorting the collected

metrics) but also eased the delimitation of time range queries when subsequently displaying and analysing metrics in Grafana. Moreover, to make sure that collected metrics would not be disturbed by an unknown/undesired state of the control layer, the IOC was systematically restarted before running a new scenario.

For simulation scenarios involving 1, 100 and 1 000 waveforms, only one IOC was successful in generating these. For scenarios involving 10 000 waveforms, 8 IOCs were launched simultaneously, each generating 1 250 waveforms. The main reason for this segmentation was to spread the computation cost across multiple CPU cores (of the MicroTCA) as only one IOC trying to manage this very large number of waveforms revealed impracticable (i.e. only one IOC would saturate the CPU core where it ran and, consequently, stop responding).

To help determine the rate of data effectively stored by the Archiver Appliance, a tool was developed at ICS. This tool, implemented in Python, retrieves data stored in the Archiver Appliance and calculates the dropping factor (i.e. frames that have not been archived but should have been) of a certain PV for a given time range. Specifically, it subtracts from the number 1 the result of the division of the

number of frames stored in the Archiver Appliance by the number of frames that are theoretically supposed to be stored in this application. Since the retrieval of archived data for all the PVs involved in a particular scenario revealed unfeasible (prohibitively time consuming), the solution found was to retrieve only a subset of these PVs in an evenly distributed fashion (as it was assumed that frames were being archived or not (i.e. dropped) in a normal distribution fashion – thus the dropping factor of PVs would be similar to each other).

In addition, the tool consumes a CSV-based text file containing information about each simulation scenario to know how to process it. One of the main advantages of this approach is that, in case of need, the text file can easily be extended with additional scenarios without the burden to have to modify the tool to cope with these.

## Results

Table 2 contains the results of the performance and resources consumption of the Archiver Appliance from a storage point of view, while [4] provides additional details.

Table 2: Results of the Storage Study (Based on Collected Metrics)

## RETRIEVAL STUDY

### Environment

To enable a proper study of the Archiver Appliance in terms of PV data retrieval performance and resources consumption, three components were configured and used: a producer, a consumer, and a network connecting the two.

**Producer** The producer of PV data is an instance of the Archiver Appliance running in a dedicated physical storage server. The instance refers to version 0.0.1 (Fall 2018 Release) of the Archiver Appliance. The storage server is a Supermicro machine and runs CentOS 7 64 bit. See subsection Environment (in section Storage Study) for additional details about the Archiver Appliance and storage server.

**Consumer** The consumer of PV data is a Python tool that retrieves data from the Archiver Appliance and runs in a dedicated physical machine. Thanks to its multi-threading architecture, the tool may simulate multiple clients (e.g. CS-Studio) retrieving data from the Archiver Appliance simultaneously (i.e. in parallel). The machine used for the Python tool runs CentOS 7 64 bit and has the following main characteristics:

- Manufacturer: Supermicro
- Model: SYS-1018R-WC0R
- CPU: 2 x Intel E5-2637 3.50 GHz (4 cores per CPU)
- RAM: 64 GB

**Network** The network is based on a Gigabit fiber optic cable configured to transmit standard Ethernet frames (with a payload equal to 1 500 bytes) at a maximum throughput of 1 Gb/s between the producer and consumer.

### Metrics

The following resources were monitored and metrics about their usages collected every five seconds while run-

ning a certain simulation scenario: CPU (load in percentage (%)), RAM (usage in gigabyte (GB)) and Network (traffic in megabit per second (Mb/s)). In addition, at the end of running the scenario, the following metrics were calculated: Data Retrieved (in gigabyte (GB)) and Retrieval Time (in second (s)).

### Methodology

The main method followed during the retrieval performance and resources consumption study was to retrieve PV data stored in the Archiver Appliance using a Python tool created for this purpose. It retrieved data using a RESTful interface provided by the Archiver Appliance. Although the tool was prepared to retrieve data in different formats – namely: TXT, CSV, JSON and RAW – it was decided that the retrieval study should be based on CSV since this format is the one that users will likely use when retrieving data, as well as being very suitable as a baseline/reference when compared with other formats (due to its simplicity).

Through a configuration parameter, the Python tool was able to launch multiple threads at the same time, each retrieving PV data independently from remaining threads. The idea was to simulate multiple clients (i.e. people and/or applications) retrieving data simultaneously. In this retrieval study, metrics were collected while running the tool with 1 thread, 10 threads and 100 threads.

Since the simulation scenarios based on 100, 1 000 and 10 000 PV waveforms are essentially the same as the scenarios based on 1 waveform (in terms of data points, data type and update frequency – the only difference being the number of waveforms), it was decided to only retrieve the latter scenarios from the Archiver Appliance when conducting the retrieval study.

### Results

Table 3 contains the results of the performance and resources consumption of the Archiver Appliance from a retrieval point of view, while [4] provides additional details.

Table 3: Results of the Retrieval Study (Based on Collected Metrics)

## RESOURCES SATURATION STUDY

The results based on the metrics collected during the storage study (see Table 1) and retrieval study (see Table 2) make it evident that the network is the resource that reduced the success to store data and increased the time it took to retrieve data due to saturation. In this section, an attempt is therefore made to understand 1) the maximum number of PVs that can safely be archived (i.e. no data is dropped) by the Archiver Appliance and 2) the maximum number of threads (i.e. people and/or applications) that can concurrently retrieve data from this application if the network is never saturated (i.e. is not a bottleneck) and in function of the remaining two other resources, namely: CPU and RAM. Consequently, the attempt – which is based on extrapolations using regression lines – focuses on understanding the saturation of these two resources of the storage server. See subsection Environment (in section Storage Study) for additional details about this server. This understanding may help better manage/implement the underlying infrastructure if, for example, a system owner needs to archive a set of PVs in a proper way – by, e.g., procuring a storage server with particular characteristics –

or if already deployed resources are sufficient (performance and storage wise) to cope with these PVs.

### Storage

Based on the metrics collected during the PV data storage study, regression lines were calculated to model both the CPU load and the RAM usage of the storage server in function of the number of PV waveforms stored (i.e. archived) concurrently. For the calculations of these regression lines, a (single) PV waveform was assumed to have the following characteristics:

- Data points: 37 000 ( (1 000 + 10 000 + 100 000) / 3 )
- Data point size: 6 bytes ( (4 + 8) / 2 )
- Update frequency: 7.5 Hz ( (1 + 14) / 2 )

**CPU** The regression line that models the CPU load of the storage server in function of the number of PV waveforms that it may store concurrently is the following:

$$cpu\_load = 0.00001 * number\_waveforms + 0.02463$$

This means it takes around 100 000 waveforms being stored concurrently by the Archiver Appliance to saturate the CPU of the storage server. Above this number, the CPU becomes a bottleneck forcing the application to start dropping (i.e. not archiving) PV data.

**RAM** The regression line that models the RAM usage of the storage server in function of the number of PV waveforms that it may store concurrently is the following:

$$ram\_usage = 0.00003 * number\_waveforms + 0.40192$$

This means it takes around 33 333 waveforms being stored concurrently by the Archiver Appliance to saturate the RAM memory of the storage server. Above this number, the RAM memory becomes a bottleneck forcing the application to start dropping (i.e. not archiving) PV data.

### Retrieval

Based on the metrics collected during the PV data retrieval study, regression lines were calculated that model both the CPU load and the RAM usage of the storage server in function of the number of threads (i.e. people and/or applications) that it may serve concurrently.

**CPU** The regression line that models the CPU load of the storage server in function of the number of threads that it may serve concurrently is the following:

$$cpu\_load = 0.00118 * number\_threads + 0.02739$$

This means it takes around 847 threads to retrieve data concurrently from the Archiver Appliance to saturate the CPU of the storage server. Above this number, the CPU becomes a bottleneck forcing the application to increase the time it takes to satisfy requests.

**RAM** The regression line that models the RAM usage of the storage server in function of the number of threads that it may serve concurrently is the following:

$$ram\_usage = 0.0001 * number\_threads + 0.55964$$

This means it takes around 9 999 threads to retrieve data concurrently from the Archiver Appliance to saturate the RAM memory of the storage server. Above this number, the RAM memory becomes a bottleneck forcing the application to increase the time it takes to satisfy requests.

## CONCLUSION

The results of this study imply that the Archiver Appliance appears reliable to cope with the storage (i.e. writing) of a high number of PV waveforms. This will be crucial at ESS since several thousands of devices (interfaced in EPICS) will have their control signals exposed through PV waveforms, including some of long sizes.

Thanks to the collected metrics, it can also be concluded that the Archiver Appliance consumes CPU and RAM memory in function of the number of PVs to be archived (as expected). In no simulation scenario that ran, did the CPU or the RAM of the machine running this application represent bottlenecks. Moreover, scenarios AAPS-0710 and AAPS-0720 were not executed due to the Archiver Appliance being unable to handle all the PVs (with an erratic behavior observed). Despite restarting the IOC and re-installing the Archiver Appliance, this behavior still persisted. The reason for this is unclear but we hypothesize that the sheer number of PVs and long sizes were the likely cause.

Due to the study, it is now possible to better predict/calculate if existing deployed resources (e.g. network, storage space, archiver appliance instances) are able to successfully cope with a request to, e.g., archive a new system or if additional resources are needed and provided in a preemptive fashion (thus without having to wait for PV data to be dropped to only then add more resources).

Finally, a detailed report about the performance of the Archiver Appliance and how it consumes resources to handle the simulation scenarios can be accessed in [4].

## ACKNOWLEDGEMENT

The authors would like to thank everyone who helped enable the Archiver Appliance performance and resources consumption study at ESS, in particular Benjamin Bertrand, Johan Christensson, Alessio Curri, Fábio dos Santos Alves and Faye Chicken for their effective support.

# CONTROLS DATA ARCHIVING AT THE ISIS NEUTRON AND MUON SOURCE FOR IN-DEPTH ANALYSIS AND ML APPLICATIONS

I. D. Finch\*, G. D. Howells, A. Saoulis, ISIS Neutron and Muon Source,  
Rutherford Appleton Laboratory, Didcot, United Kingdom

## Abstract

The ISIS Neutron and Muon Source accelerators are currently operated using Vsystem control software. Archiving of controls data is necessary for immediate fault finding, to facilitate analysis of long-term trends, and to provide training datasets for machine learning applications. While Vsystem has built-in logging and data archiving tools, in recent years we have greatly expanded the range and quantity of data archived using an open-source software stack including MQTT as a messaging system, Telegraf as a metrics collection agent, and the InfluxDB time-series database as a storage backend.

Now that ISIS has begun the transition from Vsystem to EPICS this software stack will need to be replaced or adapted. To explore the practicality of adaptation, a new Telegraf plugin allowing direct collection of EPICS data has been developed. We describe the current Vsystem-based controls data archiving solution in use at ISIS, future plans for EPICS, and our plans for the transition while maintaining continuity of data.

## INTRODUCTION

The ISIS Neutron and Muon Source accelerators [1, 2] are currently controlled using the Vista Control System's software product Vsystem [3] (often colloquially called Vista), while the majority of beamlines and associated instruments [4, 5] are controlled using the Experimental Physics and Industrial Control System (EPICS) [6].

Vsystem and EPICS both originated in work done in the 1980s to create a control system for the Ground Test Accelerator Control System at Los Alamos National Laboratory [7]. While EPICS became an open-source project developed as a collaboration between multiple accelerator organisations, Vista is a closed-source commercial product with paid support. Both are distributed control systems with common features such as databases, and channels (Vsystem) or process variables (EPICS).

At ISIS Vsystem is deployed on four Itanium servers running the OpenVMS operating system. (Vsystem can be deployed on MS Windows, Linux, and OpenVMS, and operated in a hybrid configuration using any combination of these operating systems.) With the announced discontinuation of the Itanium processor architecture [8] a transition to a different processor architecture is required.

A decision has been made to transition the ISIS accelerators control system from Vsystem on OpenVMS / Itanium to EPICS on Linux / x86. This is planned as a gradual transition while ISIS is operating instead of an all-at-once con-

version [9]. There will thus be a period in which both Vsystem and EPICS must operate in concert, and an early transition period in which EPICS operates only a small proportion of hardware.

This paper describes the logging functionality included with Vsystem, the software stack developed and deployed at ISIS to improve on this system, and the way in which it has been applied to machine learning and other applications at the facility. Software tools designed to allow EPICS to be used as a data source for this logging framework during the control system transition are then described.

## VSYS-TEM LOGGING AT ISIS

### Vsystem Built-in Logging

Vsystem has an integrated logging subsystem called Vlogger [10] which consists of a Vlogger service that archives data from Vsystem databases to file, Vtrend for visualizing archived data, and utilities to manage and extract data from the generated archive files (including an SQL-like query language allowing CSV export).

At ISIS Vlogger is used to maintain short-term archives of data sampled every 30 seconds for 7 days, and longer-term data sampled every 30 minutes for 7 weeks. Both short- and longer-term archives are circular buffers. Permanent copies of the longer-term data are made at the end of each user cycle. The ISIS archive of this longer-term lower time resolution data begins in 2003, covered key channels by 2005, and subsequently steadily increased in scope.

The main limitations of this Vlogger system at ISIS are that:

- It must be run on a licensed Vsystem installation, with users therefore requiring access to and familiarity with our operations-critical OpenVMS server infrastructure.
- Channels to be logged must be specified in advance.
- It lacks a modern web-based query and visualisation interface.

For these and other reasons a parallel logging system for Vsystem was developed at ISIS.

### InfluxDB Logging of Vsystem

Vsystem has an extensive and well-documented API [11] which can be used to access the Vsystem databases and their channels. Specifically, an event based callback API can be used to monitor for changes to live databases or channels.

Python code called vista\_mqtt was developed to use the event based callback API to forward the changes in value and alarm states of all channels to an MQTT broker. MQTT is a publish/subscribe messaging standard and was chosen

\* ivan.finch@stfc.ac.uk

for its simplicity and for its availability on OpenVMS. At the time the code was written the latest standard was 3.1.1 [12]; due to limitations in the client software there are no plans to move to MQTT 5. The MQTT broker selected was Eclipse Mosquitto [13], again chosen for its simplicity and ease of deployment. One important result of this architecture is that Mosquitto and all systems downstream (e.g. Telegraf, InfluxDB) of it may be run on the transition end-point Linux operating system.

Vsystem as implemented at ISIS is primarily a pull-based architecture for reading, i.e. any interfaces to external systems and hardware are polled periodically. (Any writes to external systems or hardware are performed immediately.) Most polling is conducted at a 2 second cadence, though a small number of systems are polled faster or slower. The fastest cadence is 0.5 seconds for diagnostic profile and beam line monitors, some interlocks, etc. Monitored changes to values or alarm states are forwarded by `vista_mqtt` via MQTT immediately. In the case of reads from hardware this is at most at the polling frequency.

Telegraf [14, 15], currently run on the same Linux virtual machine as Mosquitto, subscribes to all MQTT topics published by `vista_mqtt` and writes the data to a single InfluxDB version 1.x time-series database [16, 17]. An upgrade to Influxdb version 2 is planned. The earliest retained data in this system dates to 2018 and the system was expanded to log changes in the value and alarm states of all single value Vsystem channels in 2019. This data is recorded at the full-time resolution. Data is interactively queried and visualised using the web-based Chronograf [18] or Grafana [19] tools.

The ISIS deployment of Vsystem currently manages more than 33,000 channels, of which approximately 1,500 may trigger alarm states. Together with the described update cadence this establishes a maximum data rate that the MQTT systems must support. In practice the data rate is significantly lower, as most values do not change at every polling interval. The current archiving rate is approximately 20 GB per user cycle (~70 days), and data rates are much lower during shutdowns.

The deployed Python-based monitoring code has proven reliable but has been found to be resource intensive on Itanium-servers which cannot be easily upgraded or expanded. Under high load this has caused system responsiveness issues and slowed down sampling of channel data which has affected the throughput of the logging system. For this reason an alternate C-based system is being developed to replicate the existing Python-based functionality, and to add monitoring of changes to other channel fields to facilitate the ongoing EPICS transition [20].

### *Other uses of vista\_mqtt, Mosquitto, and InfluxDB*

Vsystem's alarm viewer is called Valarm [21] and while reliable it is inflexible. It is a Motif-based X Window application which precludes being easily run on modern mobile devices, and as a closed source product it is difficult to integrate with locally developed software such as ISIS's FLD [22] fault diagnostics tool. `Vista_mqtt` publishes all

changes to the alarm states of Vsystem channels and this has been used to develop a web-based alarm viewer called Rona which will address identified shortcomings.

The ability to set the value of Vsystem channel values and other fields via MQTT has been added to `mqtt_vista`, making it a general remote access interface to Vsystem. Although not originally designed for the purpose, this has allowed it to be leveraged to form an important component of the planned EPICS transition [9, 20].

Since the Mosquitto broker and InfluxDB time-series databases are now supported as part of normal ISIS operations, other internal groups have made use of these services. Some low-power RF functions in the synchrotron magnets are transferred via MQTT and integrated beam loss monitor and intensity data is stored in InfluxDB, though neither pass through Vsystem.

### *Support for Machine Learning*

The relatively high time resolution logging of all inputs to the ISIS accelerators control system has been used to enable machine learning studies. One example is the real-time detection of temperature anomalies in the ISIS Target 1 methane moderator [23].

## **ISIS ACCELERATORS CONTROL SYSTEM TRANSITION TO EPICS**

The planned transition from Vsystem to EPICS at the ISIS accelerators will be a gradual process, and initially EPICS will be a small subset of the accelerators control system. For this reason it is attractive to initially integrate EPICS into the existing logging infrastructure rather than to implement a "native" EPICS solution such as the EPICS Archiver Appliance [24]. Moving too soon to an EPICS based system would split data across two systems, making access and analysis more difficult.

In the medium-term an evaluation of EPICS logging systems will be conducted and, if necessary, a strategy will be developed to migrate our existing data holdings.

## **TELEGRAF AND EPICS**

Telegraf is already used to aggregate and write the stream of Vsystem value changes from MQTT to InfluxDB. To support integrating EPICS into the existing logging system at ISIS, plugins have been developed for reading EPICS process variables (PVs) using Telegraf.

Telegraf is one of many metrics collection agents (others include Logstash, Metricbeat, statsd) used to collect metrics and telemetry from local and remote systems, process and aggregate that data, and then dispatch to other systems for storage or other purposes such as alert notification. Telegraf was originally selected in 2018 as it forms part of the TICK (Telegraf, InfluxDB, Chronograf, Kapacitor) stack [25] and InfluxDB had been chosen as our time-series data storage backend. In 2020 a more in-depth analysis of alternate metrics and telemetry frameworks was conducted, including a deployment of the full ELK (Elasticsearch, Logstash, Kibana) stack [26]. Our conclusion was that for our requirements there was little to

distinguish between the metric collection agents, and consequently little reason to switch from Telegraf given our existing expertise with the software.

Telegraf has a large number of input plugins (218 at the time of writing) used to collect data from a variety of sources and formats. EPICS is not currently among the supported data sources. There are two ways of adding the capability to handle a new source or format to Telegraf. The first is to develop a new plugin [27] for Telegraf in the Go language [28] in which Telegraf is written. The second, added in Telegraf 1.14 [29], is the use of the execd input plugin [30, 31] to collect data from an externally run program.

EPICS has two protocols used to transfer data. The Channel Access (CA) protocol [32] is the most widely deployed protocol, being supported in EPICS with revisions since at least v3.11 [33]. In EPICS v4 a new protocol called PVaccess (PVA) [34] was developed and since EPICS v7.0.1 both CA and PVA protocols have been supported by the main release series.

For the ISIS accelerator control system the intention is to use PVA where possible, and CA where necessary or convenient. This establishes a requirement to support both protocols with the existing logging software stack.

### EPICS Telegraf Plugins

The CA Plugin for Telegraf developed at ISIS was based on the goca package [35]. The goca package uses Go's cgo system [36] (a binding to C libraries) to interface with the standard EPICS CA libraries. A minor modification to the package's handleEvent Go code was required to enable it to handle values of types other than double.

The CA Plugin for Telegraf is a simple development of the example Telegraf plugin and is only ~100 lines long. The channels to be monitored are simply defined in the Telegraf configuration file.

The cgo system used for the CA Plugin for Telegraf described above does not have a direct interface to C++ (or Java). There are therefore two methods available to develop a PVA plugin for Telegraf, either develop a supported interface in Go (e.g., via a shim to C) or develop a native Go implementation of the PVA protocol. Both would require significant development effort.

Instead the Telegraf execd input plugin [30] was used. This plugin allows an external program to be run as a long-running daemon and monitors the daemon's output on stdout. The execd input plugin will accept metrics in any of Telegraf's compatible input data formats [37], which Telegraf then aggregates and forwards to downstream applications.

A program called pvxs-archiver was developed in C++ using the pvxs module [38] for use with the Telegraf execd input plugin. It monitors a list of PVs listed in a configuration file and writes all changes to stdout in InfluxDB line protocol.

The CA Plugin and pvxs-archiver each handle a single EPICS protocol. Both are used to store the PVs they monitor in InfluxDB alongside any Vsystem data.

### Docker and Telegraf Plugin Development

At ISIS Docker [39] containers are extensively used for development and testing [40]. Both EPICS Telegraf plugins were developed in similar Docker environments, utilising Docker Compose to instantiate containers with Telegraf running the plugin under development and InfluxDB acting as storage. Either a test IOC within a container environment or external test IOCs provided test input. This allowed a self-contained testing environment from IOC to storage backend, independent of any live systems.

### Limitations

Telegraf is a metrics collection agent designed to accept timestamped metric values and timestamped log messages. It expects metrics values to be single-valued and has no direct support for more complex data structures such as 2D images. The current ISIS accelerators control system only needs to support single and 1-D array values. The latter is supported via conversion to strings which are stored in that format in InfluxDB.

## CONCLUSIONS

Since 2018 the ISIS Neutron and Muon accelerators control system has greatly increased its capacity for logging Vsystem data, with a new software stack developed and deployed for this purpose. Amongst other uses the additional data collected has been used for machine learning, including detection of anomalies. As part of the transition to EPICS new plugins for Telegraf have been developed to allow designated EPICS PVs to be logged using this software stack.

# MACHINE LEARNING TOOLS IMPROVE BESSY II OPERATION

L. Vera Ramírez\*, T. Birke, G. Hartmann, R. Müller, M. Ries, A. Schällicke, P. Schnizer  
Helmholtz-Zentrum Berlin, Germany

## Abstract

At the Helmholtz-Zentrum Berlin (HZB), user facility BESSY II Machine Learning (ML) technologies aim at advanced analysis, automation, explainability and performance improvements for accelerator and beamline operation. The development of these tools is intertwined with improvements of the prediction part of the digital twin instances at BESSY II [1] and the integration into the Bluesky Suite [2, 3]. On the accelerator side, several use cases have recently been identified, pipelines designed and models tested. Previous studies applied Deep Reinforcement Learning (RL) to booster current and injection efficiency. RL now tackles a more demanding scenario: the mitigation of harmonic orbit perturbations induced by external civil noise sources. This paper presents methodology, design and simulation phases as well as challenges and first results. Further ML use cases under study are, among others, anomaly detection prototypes with anomaly scores for individual features.

## MOTIVATION

The complexity of a large-scale facility such as the light source BESSY II in Berlin-Adlershof represents a perfect benchmark for the development, implementation and testing of Machine Learning (ML) tools due to the enormous set of use cases that can be identified - some of which were already presented in [4]. An important factor in order to prioritise these applications is the added value that might be gained through ML, which is enormous in the two cases presented in this paper.

We will first focus on a very challenging application: the mitigation of harmonic orbit perturbations. In this case ML tools aim to improve existing correction systems in the frequency domain (beyond the possibilities of current analytical methods), seeking an increase of the electron beam stability - a critical factor in order to achieve light radiation with high quality brilliance and brightness over time. Besides we will also further introduce original developments towards an anomaly detection system with feature anomaly assignment. This automatic system might extend existing preprogrammed alert system in BESSY's control room and provide additional support to human operators.

## MITIGATION OF HARMONIC ORBIT PERTURBATIONS

At the light source BESSY II, the stability of the orbit in the storage ring (within the transverse beam dimensions  $100 \times 20 \mu\text{m}$ ) is currently pursued with a system called Fast Orbit Feedback (FOFB, [5]) running at 150 Hz. FOFB correction is based on the linear approximation  $\Delta \mathbf{x} \approx S \Delta \mathbf{c}$  with

$\mathbf{x}$  relative beam position,  $\mathbf{c}$  corrector magnets strength and  $S$  the so-called *response matrix* (calculated or measured at the accelerator). Hence, for  $\mathbf{x}_{t+1} = \mathbf{0}$  we can apply recursively  $\mathbf{c}_{t+1} := \mathbf{c}_t - \alpha S^{-1} \mathbf{x}_t$  with  $S^{-1}$  Moore-Penrose pseudoinverse of  $S$  and  $\alpha$  positive constant (at BESSY  $\alpha = 0.8$ ).

FOFB manages to correct orbit perturbations due e.g. to imprecisions of the magnet positioning in a very efficient way. But beyond that, there are several external elements such as civil noise, main power at 50 Hz and some imperfectly isolated magnetic sources (e.g. booster power supply at 10 Hz) that also produce additional inherent perturbations (see Fig. 1). The correction induced by the FOFB system (Fig. 2) is able to mitigate perturbations at lower frequencies (less than ca. 15 Hz) but beyond that point the FOFB system is not that effective and even induces further perturbations (especially in the region 20-40 Hz).

Figure 1: Horizontal beam motion spectra between injections without FOFB (cumulated along 22/04/20, BESSY Archiver data).

Figure 2: Horizontal beam motion spectra between injections with FOFB (cumulated along 13/05/20, BESSY Archiver data).

A first approach to face this problem was proposed, implemented and tested with simulations in [6]: an explicit correction of the 10 Hz perturbation with a *inverse wave* and an improvement of the PID correction coefficients (proportional-integral-derivative response) in the FOFB algorithm. In this work, we explore the application of ML techniques (in particular Reinforcement Learning, RL) in order to extend the analytical approach with an agent that learns the dynamics

\* luis.vera\_ramirez@helmholtz-berlin.de

of the system through observation and interaction directly at the machine.

### Chronology

- **Early 2020:** first RL tests with simulations (code from [6] and OCELOT [7]). These feasibility tests showed that a RL agent acting in time domain with a proper configuration should be able to also reduce perturbations in frequency domain.
- **July 2020:** infrastructure set-up during machine commissioning and first plausibility tests of the Bluesky-based framework ([2]) up to 20 Hz ([3]).
- **September 2020:** direct zmq-communication with the mBox (fast orbit correction infrastructure), communication up to 100 Hz. First learning results.
- **Since February 2021:** zmq-communication improved, stable RL-interaction loop at 75 Hz, further attempts at 150 Hz.

### Baselines

In all the experiments presented in this section, we will compare the performance of our models with three different baseline correction systems:

- *Static steerers:* steerers set back to the initial strength, precalculated with the slow correction system ([8]). The performance of this baseline varies due to machine drifting.
- *FOFB:* standard FOFB system for orbit correction at BESSY II ([5]). For comparison we took a 5-minute period at the end of the corresponding learning tests.
- *FOFB (zmq):* reimplementation of the response-matrix correction (conditioning 0.04) synchronized with the zmq loop.

### Model-Free Approach

The first approach that was tested in BESSY's control room was a direct translation of the simulations carried out during 2020: the orbit correction is completely undertaken by a RL agent learning and interacting in time domain in a model-free way - i.e. no explicit modelling of the environment is learnt, only the *optimisation dynamics*. According to the simulations, this agent should also be able to stabilise the orbit in frequency domain.

Following our positive experiences in [4] the chosen algorithm was Deep Deterministic Policy Gradient (DDPG, [9]). DDPG is a well-known deep-RL algorithm for continuous environments based on the update of the so-called action-value function  $Q : S \times A \rightarrow \mathbb{R}$  with deterministic target policy  $\mu : S \rightarrow A$ , where  $S$  denotes the state space and  $A$  the action space. In the DDPG agent proposed in [9], both  $Q$ -function and policy are approximated with neural networks - a so-called *deep actor-critic* architecture. The detailed hyperparameter configuration used in our tests can be found in the Appendix.

Regarding the environment settings, we defined the **state** as the last observation of 6 beam position monitors (BPMs) along the ring measured in mm ( $\Delta$ 's w.r.t. the reference

orbit). On the other side, we define the **action** as the strength of 6 horizontal steerers along the ring modified up to  $\pm 20$  mA ( $\Delta$ 's w.r.t. the initial strength). The picked BPMs and steerers are those presenting higher absolute values in the response matrix - i.e. those presenting higher linear correlation. Finally, among the many different definitions tested for the **reward** function, we are presenting the most minimalistic and the most ambitious cases so far.

**Reward defined for a single BPM:** In our first tests, conceived as a proof-of-concept, the reward was defined through a exponential transformation of the deviation of the next reading from BPMZ5D7R:

$$2e^{-\beta |x_{t+1}|} - 1$$

with  $\beta$  positive constant (for this experiment  $\beta = 20$ ). This BPM was picked because it is used as reference for the beam motion supervision at BESSY II. During this experiment the machine was set in decay mode starting at ca. 20 mA and the zmq-communication was carried out at 75 Hz.

Figure 3 shows the evolution of the beam deviation (in this case measured at a single BPM) during the whole experiment. It alternates exploration periods with baselines and exploitation periods, and the convergence can be easily perceived. Figure 4 carries out the comparison of the last baseline and exploitation period of the experiment with a subsequent FOFB running in comparable machine conditions. One can see that the agent achieves better results in time domain (for this single BPM) than any baseline.

Figure 3: Beam deviation (RMSE) during the whole learning process (test with BPMZ5D7R, 1/3/21, Archiver data).

Figure 4: Comparison of the beam deviation (RMSE) after learning (test with BPMZ5D7R, 1/3/21, Archiver data).

If we switch to frequency domain with the reference beam motion measurement at BESSY II (Figs. 5 and 6), we can see that the RL agent carries out the correction of the beam position in a *smooth* way: beyond 20 Hz it improves the stability of standard FOFB and, although it does not manage to correct the inherent harmonic perturbations, it does not add any

extra perturbations either, as both FOFB implementations do.

Figure 5: Mean horizontal beam motion spectra comparison (test with BPMZ5D7R, 1/3/21, Archiver data).

Figure 6: Integrated mean horizontal beam motion spectra comparison (test with BPMZ5D7R, 1/3/21, Archiver data).

Nevertheless, if we carry out an additional frequency analysis through the spectra of the beam motion RMSE with data gathered during the experiment (Figs. 7 and 8), we can observe a reduction of the harmonic perturbations (in norm). In this case, *FOFB* baseline can not be plotted since the data was obtained through the zmq-loop in real time and no comparable data for *FOFB* can be hence obtained.

Figure 7: RMSE spectra compasion (test with BPMZ5D7R, 1/3/21, on-the-fly data).

Figure 8: Integrated RMSE spectra compasion (test with BPMZ5D7R, 1/3/21, on-the-fly data).

**Reward defined for all BPMs:** Now we redefine the reward as an exponential transformation of the RMSE of the next BPM observation for all active BPMs ( $m = 102$ ):

$$2e^{-\beta \text{RMSE}[\mathbf{x}_{t+1}]} - 1 = 2e^{-\beta \sqrt{\frac{\sum_{i=1}^m (x_{t+1}^i)^2}{m}}} - 1$$

with  $\beta$  positive constant (here also  $\beta = 20$ ). This is indeed a much more challenging case for the RL agent (recall that it is only observing 6 BPMs and acting on 6 steerers). In this case the machine was also set in decay mode at ca. 20 mA but the zmq-loop was carried out at 150 Hz, bringing more correction power but also some instabilities in the communication.

Figure 9 shows the evolution of the beam deviation (RMSE for all BPMs) during the whole experiment. In this period the machine suffered from drifting, which made the learning process even more difficult, affecting the baselines as well; Nevertheless, convergence can be also perceived. In the comparison showed in Fig. 10 we can see that this time the agent improves the beam deviation but does not manage to beat the FOFBs in time domain - probably the 6 steerers might not be enough for the global correction.

Figure 9: Beam deviation (RMSE) during the whole learning process (test with all BPMs, 1/3/21, BESSY Archiver data).

Figure 10: Comparison of the beam deviation (RMSE) after learning (test with all BPMs, 1/3/21, BESSY Archiver data).

On the other side, this experiment's outcome is more positive in frequency domain (Figs. 11 and 12): in the region between ca. 18 Hz and 50 Hz it improves the stability of all baselines, including the *static steerers* - meaning that the inherent perturbations get also slightly mitigated.

The additional frequency analysis through the spectra of the beam motion RMSE (Figs. 13 and 14) shows an even stronger reduction of the harmonic perturbations (in norm).

A natural question might be if the reason for stability in frequency domain is a *low* activity of the steerers when they are controlled by the RL agent. Figure 15 shows that it does not seem to be the case - the 6 steerers manipulated by the

Figure 11: Mean horizontal beam motion spectra comparison (test with all BPMs, 1/3/21, BESSY Archiver data).

Figure 12: Integrated mean horizontal beam motion spectra comparison (test with all BPMs, 1/3/21, BESSY Archiver data).

Figure 13: RMSE spectra compasion (test with all BPMs, 1/3/21, on-the-fly data).

Figure 14: Integrated RMSE spectra compasion (test with all BPMs, 1/3/21, on-the-fly data).

agent present active motion patterns, which remind of the beam motion perturbations they are supposed to counteract.

### Towards a Model-Based Approach

Previous experiments with a model-free RL agent were able to carry out sensible orbit corrections in frequency domain. Nevertheless, in time domain traditional algorithms still have a major advantage when the target involves the correction of all BPMs: the need to include more horizontal

Figure 15: Steerers motion spectra with RL agent (test with all BPMs, 1/3/21, on-the-fly data).

steerers implies an increase of the action space dimensionality and complicates the convergence of the RL agent.

In this sense, an optimal set up might be a *combination* between global response-matrix-based correction "smoothed" with RL for the frequency domain. Our first attempts in this direction (RL agent action added to or introduced into the global response-matrix correction) were not successful - probably because the dynamics of the environment got more complicated to learn with the standard model-free RL loop.

As a consequence, we have started exploring some model-based approaches. The idea is to *encapsulate* the dynamic system induced by the harmonic perturbation patterns within a surrogate model that can be used for combination with the response-matrix-based correction but also for policy training in a model-based RL context. We seek hence a surrogate model in the form

$$F : \mathbb{R}^{n \times m} \times \mathbb{R}^l \rightarrow \mathbb{R}^m$$

$$(\mathbf{x}_{t-n}, \dots, \mathbf{x}_t, \mathbf{c}_{t+1}) \mapsto \mathbf{x}_{t+1}$$

where  $n$  is the window size,  $m$  the number of BPMs and  $l$  the number of steerers.

In our first tests of this approach at the machine, the role of surrogate model was undertaken by a neural network whose architecture is sketched in Fig. 16. This network was directly fed with real data obtained via zmzq in real-time interaction with the machine: random steerer strengths were set sporadically and the BPM response to these modifications was tracked. But since the steerer modifications were carried out slowly (see Appendix), the (windowed) BPM data also included the inherent harmonic perturbations.

Figure 16: Surrogate model architecture schema.

Table 1 shows that system dynamics were accurately learnt by the model. In this table, model prediction error on unseen test data is compared with several baselines: average of the test data, previous observations in the test data ( $\mathbf{x}_t, \mathbf{x}_{t-1}, \mathbf{x}_{t-2}, \mathbf{x}_{t-3}$  and  $\mathbf{x}_{t-4}$ ) and prediction obtained by the application of the response matrix:  $\mathbf{x}_{t+1} \approx \mathbf{x}_t + S(\mathbf{c}_{t+1} - \mathbf{c}_t)$ .

Table 1: Surrogate Model and Baseline Prediction Errors

Error	Test Set Avg.	Previous BPM Data					Resp. Matrix: $\mathbf{x}_t + S(\mathbf{c}_{t+1} - \mathbf{c}_t)$	Model: $F(\mathbf{x}_{t-9}, \dots, \mathbf{x}_t, \mathbf{c}_{t+1})$
		$\mathbf{x}_t$	$\mathbf{x}_{t-1}$	$\mathbf{x}_{t-2}$	$\mathbf{x}_{t-3}$	$\mathbf{x}_{t-4}$		
RMSE	0.0154	0.0274	0.0178	0.0236	0.0204	0.0229	0.0098	0.0036
$R^2$	0	-2.172	-0.3455	-1.3492	-0.769	-1.2223	0.5896	0.9441

The impressive performance of the surrogate model encouraged us to embed it into an algorithm (sketched as Algorithm 1) where its prediction accuracy is used in order to recursively improve the correction given by the response matrix pseudo-inverse. In each iteration, the implicit linear prediction calculated with the response matrix is replaced by the model prediction, which takes into account the inherent orbit perturbations that are not captured by the measured response matrix.

**Data:**  $S$  response matrix,  $S^{-1}$  response matrix pseudoinverse,  $\mathbf{x}_t$  current BPMs,  $\mathbf{c}_t$  current steerer strengths (corrections),  $F$  surrogate model

$$\mathbf{c}_{t+1}^0 := \mathbf{c}_t - \alpha S^{-1} \mathbf{x}_t$$

**repeat**

$$\begin{aligned} \mathbf{x}_{t+1}^k &:= \mathbf{x}_t + S(\mathbf{c}_{t+1}^k - \mathbf{c}_t) \\ \tilde{\mathbf{x}}_{t+1}^k &:= F(\mathbf{x}_{t-n}, \dots, \mathbf{x}_t, \mathbf{c}_{t+1}^k) \\ \mathbf{c}_{t+1}^{k+1} &:= \mathbf{c}_t + \alpha S^{-1} [ -(\tilde{\mathbf{x}}_{t+1}^k - \mathbf{x}_{t+1}^k) - \mathbf{x}_t ] \end{aligned}$$

**until** convergence or  $k$  too large

Algorithm 1: Combination of surrogate model and response-matrix-based correction.

A test run at the machine of Algorithm 1 (300 mA in decay mode, 150 Hz,  $k = 1$ ) can be visualised in Figs. 17, 18 and 19. Notice that the algorithm is directly constructed over the baseline *FOFB* (*zmq*), and the results are coherent with its theoretical construction: the performance in time domain is quite similar to *FOFB* (*zmq*)'s, whereas it is much more stable in frequency domain.

Figure 17: Comparison of the beam deviation (RMSE) after learning (test with surrogate model, 21/6/21, BESSY Archiver data).

**Interpretability:** A major advantage of the model-based approach we are seeking is the possibility of a more direct interpretability analysis. As an example, we want to briefly analyse the behaviour of the surrogate model  $F$

Figure 18: Mean horizontal beam motion spectra comparison (test with surrogate model, 21/6/21, BESSY Archiver data).

Figure 19: Integrated mean horizontal beam motion spectra comparison (test with surrogate model, 21/6/21, BESSY Archiver data).

trained in the previous section. Recall that  $F$  is a neural network with ReLU and linear activation functions; it means that  $F$  is differentiable almost everywhere and with the help of Tensorflow's automatic differentiation we can approximate its *jacobian* w.r.t. the steerer strengths:

$$J^c := \begin{pmatrix} \frac{\partial F^1}{\partial c_{t+1}^1} & \dots & \frac{\partial F^m}{\partial c_{t+1}^1} \\ \vdots & \ddots & \vdots \\ \frac{\partial F^1}{\partial c_{t+1}^l} & \dots & \frac{\partial F^m}{\partial c_{t+1}^l} \end{pmatrix}$$

An averaged evaluation of matrices  $J^c$  with test data (approximating  $\mathbb{E}_{(\mathbf{x}_{t-n}, \dots, \mathbf{x}_t, \mathbf{c}_{t+1})} [J^c |_{(\mathbf{x}_{t-n}, \dots, \mathbf{x}_t, \mathbf{c}_{t+1})}]$ ) can be visualised in Fig. 20. Notice that, as expected, the matrix structure is almost identical to the measured response matrix (Fig. 21).

Furthermore, a visualisation of the standard deviation of the evaluated matrices  $J^c$  (Fig. 22) gives us additional insights about which steerer-BPM interactions are captured by the surrogate model  $F$  in a more *non-linear* way: those entries presenting higher variance in the set of evaluated  $J^c$ 's.

Figure 20: Average of matrices  $J^c$  evaluated at 4000 test points.

Figure 21: Horizontal response matrix measured at BESSY II (February 2021).

Figure 22: Standard deviation of matrices  $J^c$  evaluated at 4000 test points.

## ANOMALY DETECTION WITH FEATURE ASSIGNATION

The use of anomaly detection algorithms for accelerator parameters is another field in current development at BESSY II. In particular we have started experimenting with Isolation Forests [10], whose simple and elegant foundations (outliers as points with *short path lengths*) have allowed us to develop additional anomaly scores that can be individually assigned to the input features. Our feature anomaly scores are conceived online and complement the information given by the global anomaly score: They should evaluate *how anomalous* the features of the current observation are. The idea is based on the philosophy of feature importance for fully randomized trees in [11] and similar to LFI in [12]. The results are comparable to SHAP [13] but with much better time performance for large data sets.

Given a point  $x$ , its node path in  $i$ -th tree  $T_i$  will be denoted as  $\mathcal{P}_i(x) = \{N_0, N_1, \dots, N_l\}$ . Notice that  $N_0$  will be the root node and  $N_l$  a leaf. For each node  $N$  in  $T_i$  let  $s(N)$  denote the number of samples assigned to this node after training.

We can hence define a *splitting path* of a given point  $x$  in  $T_i$  that tracks the reduction of training samples along the path

$$\mathcal{P}_i(x) := \left\{ \left( 1 - \frac{s(N_{j+1})}{s(N_j)} \right)^p \right\}_{N_j, N_{j+1} \in \mathcal{P}_i(x), j=1, \dots, l}$$

with  $p > 0$  *sparsity* coefficient. If we denote as  $F(N_j)$  the feature used for splitting at node  $N_j$  with  $j = 0, \dots, l-1$ , we can assign to it the  $j$ -th quantity within  $\mathcal{P}_i(x)$ . Therefore, given a point  $x$  and a feature  $F$ , we can define their *anomaly score* at tree  $T_i$  as

$$a_i(F, x) := \sum_j \{s_j \in \mathcal{P}_i(x) \mid F(N_j) = F\}$$

and extend it naturally to all trees in the forest:

$$a(F, x) := \frac{1}{k} \sum_{i=1}^k a_i(F, x)$$

Figure 23 shows an anomaly detection application prototype including these feature anomaly scores and conceived as a first proof-of-concept. It corresponds to an isolation forest trained with ca. 125k data points along three weeks from 22 BESSY's top-up variables. Once the model has been trained, the application starts evaluating data points read in real-time and detects a decay of the global anomaly score, mainly assigned to a single variable (booster current per bunch). This value was indeed anomalous according to BESSY's predefined alert intervals; The algorithm had been able to recognize it without any previous information about these intervals.

Figure 23: Screenshot of the live application for anomaly detection at BESSY II: An anomaly score decay (lower right plot) is assigned in real time to the booster current per bunch (first bar in the upper plot).

## CONCLUSION

The central use case presented in this paper (mitigation of harmonic orbit perturbations) was firstly faced with a model-free deep RL agent working with 6 BPMs and horizontal steerers that, as expected, improved stability in frequency domain but does not overcome traditional global methods in time domain. First steps towards model-based global optimisation with all 100 BPMs and 48 horizontal steerers keeping

the time domain correction quality and improving also stability in frequency domain were introduced as well. These first model-based approaches are based on very accurate surrogate models encapsulating the inherent perturbations of the orbit. Finally, we have introduced further original ideas and a proof-of-concept for anomaly detection with feature assignation, whose first prototypes are ready for integration at the machine.

## APPENDIX

- **Frameworks:** [14–16]
- **DDPG - Hyperparameters:**
  - **Actor:** feedforward network with three hidden layers (50-20-10 neurons), ReLU as activation function (output with  $\tanh$ )
  - **Critic:** feedforward network with four hidden layers (50-(50+action)-20-10) neurons, ReLU as activation function, Adam as optimizer
  - **Learning:**  $\gamma = 0.99$ , target model update rate = 0.01, batch size = 32
  - **Exploration:** Ornstein-Uhlenbeck process ( $\sigma = 0.05$ ,  $\theta = 0.1$ , no annealing), memory buffer with 20000 steps, short episodes (50 steps) followed by steerers random restart.
- **Surrogate model correction - Hyperparameters:**
  - **Model:** architecture plotted in Fig. 16, ReLU as activation function, linear output, Adam as optimizer
  - **Learning:** 16000 points for training, 4000 for test (gathered at 150 Hz), validation split 0.05, batch size = 32, 50 epochs.
  - **Steerer randomisation:** steerer intensities sampled from  $\mathcal{N}(0, 5)$  (in mA) and actually set with probability  $p = 0.005$ .

# BAYESIAN TECHNIQUES FOR ACCELERATOR CHARACTERIZATION AND CONTROL

R. Roussel\*, A. Edelen, C. Mayes, SLAC National Accelerator Laboratory, 94025 Menlo Park, USA  
J. P. Gonzalez-Aguilera, Y.K. Kim, University of Chicago, 60637 Chicago, USA

## Abstract

Accelerators and other large experimental facilities are complex, noisy systems that are difficult to characterize and control efficiently. Bayesian statistical modeling techniques are well suited to this task, as they minimize the number of experimental measurements needed to create robust models, by incorporating prior, but not necessarily exact, information about the target system. Furthermore, these models inherently take into account noisy and/or uncertain measurements and can react to time-varying systems. Here we will describe several advanced methods for using these models in accelerator characterization and optimization. First, we describe a method for rapid, turn-key exploration of input parameter spaces using little-to-no prior information about the target system. Second, we highlight the use of Multi-Objective Bayesian optimization towards efficiently characterizing the experimental Pareto front of a system. Throughout, we describe how unknown constraints and parameter modification costs are incorporated into these algorithms.

## INTRODUCTION

Tuning accelerators to meet operational goals of a given facility is a time-consuming task that limits valuable beam time resources for experimental users. This process represents a difficult to solve optimization problem, where there are many free parameters and limited, expensive to conduct measurements available to diagnose target objectives. Accelerator optimization problems also exist in tightly constrained parameter spaces where large regions of parameter space prevent even simple measurements of the beam. Finally, due to the complexity of accelerator systems, measurements are often noisy and/or have large uncertainties.

Model based optimization methods have been shown to speed up convergence of optimizing black box problems, where derivative information about the target function is not accessible, making routine operations faster and previously impossible to solve problems solvable in realistic settings. Of particular interest is the use of Bayesian optimization (BO) techniques for solving optimization problems [1, 2] including experimental optimization of accelerators [3, 4]. Bayesian statistical models aim to represent measurements as probability distributions, instead of scalar values. This naturally lends itself to characterizing experimental accelerator measurements, which have inherent noise and uncertainty. Bayesian optimization explicitly takes these uncertainties into account when performing optimization, resulting in an algorithm that is robust to noise (an issue faced by many other types of algorithms) [5]. This method is especially

proficient at *efficient* global optimization, since the Bayesian surrogate model encodes high level information about the target function behavior (such as function smoothness), allowing it to make accurate predictions about the function with limited data sets, thus significantly improving optimization performance over other methods.

Bayesian optimization consists of two elements, a statistical surrogate model that makes predictions about a given target function and an acquisition function which uses those predictions to choose future points in input space to measure. The surrogate model is usually chosen to be a Gaussian process (GP) [6]. This model treats the value of the target function at each point in input space  $\mathbf{x}$  as a random variable taken from a normal distribution  $f \sim \mathcal{N}(\mu(\mathbf{x}), \sigma(\mathbf{x})^2)$  where  $\mu(\mathbf{x})$  is the mean and  $\sigma(\mathbf{x})$  is the standard deviation. Gaussian processes treat the joint probability distribution of the function values at each point in input space as a Multivariate normal distribution, specified by a mean function  $\mu$  and a covariance matrix  $\Sigma$ . We encode the expected behavior of the target function by specifying  $\Sigma$  via a kernel function  $K(\mathbf{x}, \mathbf{x}')$  that describes how strongly function values at locations  $\mathbf{x}, \mathbf{x}'$  are correlated with one another. A common class of kernel functions, known as “stationary kernels”, are based solely on the distance between the two points,  $\|\mathbf{x} - \mathbf{x}'\|$ . We can then specify the expected smoothness of our function with a length-scale hyperparameter in specific kernels, such as the radial basis function (RBF) or Matern kernels [6]. Once experimental data is incorporated into the model, it can then be used to predict the function mean and corresponding uncertainty everywhere in the input domain.

Once a model is generated, we can then specify an acquisition function  $\alpha(\mathbf{x})$  characterizes how valuable future observations are as a function of input parameters. For example, if we have high confidence in our model, we can choose to make measurements where the predicted function mean is at an extremum, thus heavily weighting “exploitation”. On the other hand, if we wish to improve our understanding of the target function, we can place a high value on making observations in regions of high uncertainty, thus reducing the overall uncertainty of the model by heavily weighting “exploration”. The most popular acquisition functions for single objective global optimization balances these two aspects, either implicitly using expected improvement over the best previously observed function value [7], or explicitly using an optimization hyperparameter [8].

In this work, we describe two acquisition functions that are specifically tailored to solve accelerator control problems. The first example describes “Bayesian exploration”, an algorithm that enables automatic, efficient characterization of target functions, replacing the need for grid-like parameter

\* rroussel@slac.stanford.edu

scans. The second is Multi-Objective Bayesian optimization (MOBO) which can be used to determine the entire Pareto front of a multi-objective optimization problem, as is often the case for control systems of large experimental facilities, using serialized measurements. We describe experimental demonstrations of each of these algorithms at two experimental facilities, the Linac Coherent Light Source (LCLS) and the Argonne Wakefield Accelerator (AWA). While our demonstrations are focused on the use of these algorithms in accelerator control systems, they can be easily used in a variety of other large experimental physics control systems.

## BAYESIAN EXPLORATION

Due to the complex and time-consuming nature of accelerator diagnostics, characterization of beam response to input parameters is often limited to simple, uniformly spaced, grid-like parameter scans in one or two dimensions. This limitation results from the poor scaling of grid-like scans to higher dimensional spaces, where the number of samples needed grows exponentially with the number of input parameters. Furthermore, when attempting to characterize unknown systems it is often difficult to determine the ideal parameters of a grid scan that would result in an efficient and valid parameter scan.

The existence of tight constraints on which measurements are viable further complicates this process. For example, transverse beam size measurements on diagnostic screens are limited by the screen size, which in turn, imposes limits on the strength of upstream focusing magnet parameters. Simulation studies or extra measurements are needed beforehand to determine these limits. While these limits can be easily determined for a single parameter experimentally, it becomes infeasible to efficiently determine limits in higher dimensional input spaces, as they are often correlated with multiple parameters. Limitations such as these are shared among many types of control and optimization problems [9].

Finally, it is desirable to prevent rapid changes in accelerator input parameters during characterization. In some cases, it is temporally expensive to make changes in parameters, such as when mechanical actuators are used to change the phase of accelerating cavities. In other cases, fast feedback algorithms used in accelerator subsystems rely on adiabatic changes in external parameters to maintain system stability. Large jumps in parameter space can delay convergence of these feedback systems to stability or worse, cause them to fail entirely [10]. Practical experimental considerations such as these must be considered when automated sampling algorithms are used, which should strike a balance between costs associated with changing input parameters and the information gained.

To solve this problem, we developed an acquisition function to enable automated characterization of a target function in an efficient manner [11]. The acquisition function is given

by

$$\alpha(\mathbf{x}, \mathbf{x}_0) = \sigma(\mathbf{x}) \Psi(\mathbf{x}, \mathbf{x}_0) \prod_{i=1}^N P_i[g_i(\mathbf{x}) \geq h_i] \quad (1)$$

$$\Psi(\mathbf{x}, \mathbf{x}_0) = \exp\left(-\frac{1}{2}(\mathbf{x} - \mathbf{x}_0)^T \Sigma^{-1}(\mathbf{x} - \mathbf{x}_0)\right) \quad (2)$$

where  $\sigma(\mathbf{x})$  is the standard deviation of the GP model,  $\mathbf{x}_0$  is the most recently observed point,  $\Sigma$  is a diagonal, positive semi-definite matrix chosen by the experimenter and  $P_i[g_i(\mathbf{x}) \geq h_i]$  represents the probability that the  $i$ 'th operational constraint  $g_i(\mathbf{x}) \geq h_i$  is satisfied. The terms of this acquisition function are as follows.

The first term  $\sigma(\mathbf{x})$  is used to highly value points where model uncertainty is largest and has been shown to maximize information gain about the model [8]. When used with a GP kernel that has separate length scales for each free parameter in a process known as automatic relevance determination [6], this term will cause the optimizer to increase sampling frequency along the dimension with the shortest length scale, as seen in Fig. 1.

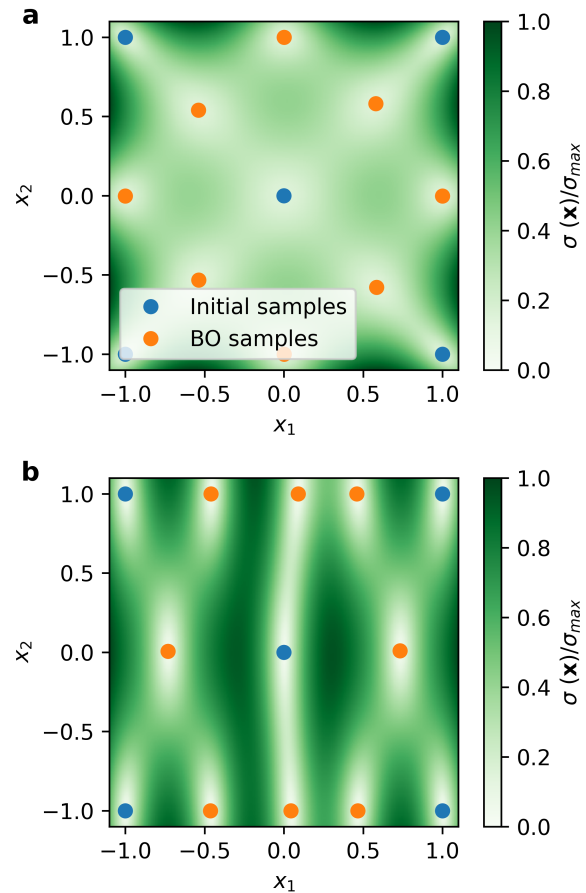

Figure 1: Plots showing Bayesian optimization sampling patterns depending on the kernel length scale using  $\alpha(\mathbf{x}) = \sigma(\mathbf{x})$ . Blue points are initial samples and orange points are determined via Bayesian optimization. (a) Length scales for both  $[x_1, x_2]$  are set to 1. (b) Length scales for variables  $[x_1, x_2]$  are set to  $[0.25, 1]$ . Reproduced from [11].

Figure 2: Parameter values (in arbitrary units) as a function of sample index during Bayesian exploration along with sample density histograms.

The second term  $\Psi(\mathbf{x}, \mathbf{x}_0)$  is a proximal weighting term, which biases the optimizer towards taking small steps in parameter steps. Another viable way to achieve this effect would be to place a hard limit on the maximum step size that the optimizer can take by setting the acquisition function to zero outside a given radius away from the last observed point. However, this negatively impacts the “exploration” advantages afforded by Bayesian optimization. By specifying a weighting that never reaches zero, we allow the optimizer to travel large distances in input space if it predicts a high potential value for the measurement.

Finally, the last term represents weighting due to constraining functions. For each constraint, we create a separate GP model that is used to calculate the probability that a given constraining function  $g_i(\mathbf{x})$  satisfies  $g_i(\mathbf{x}) \geq h_i$  where  $h_i$  is a constant. By weighting the acquisition function by these probabilities, it is less likely to propose points that violate any of the constraining functions, without prior knowledge of what those functions look like.

We conducted an experiment at the Argonne Wakefield Accelerator [12] to characterize the horizontal beam size at a diagnostic screen as a function of drive beam line parameters. These parameters included a solenoid around the photoinjector (FS), a solenoid just downstream of the photoinjector (MS) and three quadrupoles near the diagnostic screen (DQ4, DQ5, DQ6). The measurement was constrained by an upper bound on transverse beam size in both directions on the diagnostic screen and an upper bound on beam centroid distance from the screen center. We started the optimizer at a point in input space that satisfied the constraints and allowed it to explore for 100 iterations, taking 5 samples at each step and averaging the beam properties. At a repetition rate of 1 Hz, 100 iterations of the algorithm took less than 20 minutes, averaging less than 12 s per sample.

A trace of the sampled points in input space during exploration is seen in Fig. 2. Many of the parameters (FS,

DQ4-6) did not have a strong effect on the bunch size over the given domain, which is inferred from the length scales of the fitted GP model for each parameter. As a result, most of the samples are on the domain boundaries and midpoints of each parameters’ domain. Also note that these results imply that the next exploration run should happen over a larger domain if technologically feasible. On the other hand, we determined from its short length scale that the beam size was strongly correlated with the strength of the second solenoid (MS) relative to its input domain. Furthermore, we observe that only a narrow set of values for this solenoid satisfy the imposed constraints on the measurement. If we had attempted to characterize this input domain with a grid-like parameter scan, it is likely that a substantial number of measurements would have violated the constraints. Instead, our measurements using Bayesian exploration were valid about 80 percent of the time and sampling density was much higher for parameters that had strong correlations with our target measurement.

## MULTI-OBJECTIVE BAYESIAN OPTIMIZATION

Many problems in accelerator physics optimization are multi-objective, where we must determine points in input space that optimally balance the trade-off between multiple, competing objectives, also known as the Pareto front. A popular set of techniques used to accomplish this are known as evolutionary algorithms. These algorithms, such as Non-dominated Sorting Genetic Algorithm II (NSGA-II) [13] or Multi-Objective Particle Swarm Optimization [14–16], are based on the generation of a diverse collection of candidate solutions, which are then observed via simulation or experiment, usually in a parallelized manner. The results from each observation are then sorted into non-dominated and dominated subsets. The non-dominated subset of can-

didate solutions is used to produce the next “generation” of candidate solutions using a stochastic heuristic, which are then re-evaluated. The process is repeated over several generations until the non-dominated set of observations converges to a stationary Pareto front or the hypervolume has converged to a maximum value. It has been shown that these methods are well suited for solving accelerator design optimization problems [17, 18].

However, these algorithms are poorly suited for online accelerator optimization. Evolutionary type algorithms often rely on parallelized evaluation of the objective functions. However, they become practically inefficient when restricted to serialized evaluations, as is the case for online accelerator optimization. This inefficiency rises from evolutionary algorithms use of the binary classification metric of Pareto dominance to generate the next generation of potential observation candidates. As a result, this metric does not guarantee optimal expansion of the Pareto front, as it does not consider the relative hypervolume improvement of individuals in the non-dominated subset of candidates.

The Multi-Objective Bayesian Optimization (MOBO) algorithm [19] on the other hand, maximizes optimization efficiency by using an explicit calculation of the hypervolume improvement as an acquisition function to select the best candidates to expand the Pareto frontier. The hypervolume improvement  $\mathcal{H}_I$  is defined as the increase in Pareto front hypervolume by adding a new observation  $\mathbf{y}$  (see Fig. 3). Each objective is modeled using a GP surrogate model which can be used to predict the hypervolume improvement as a func-

Figure 3: Cartoon of multi-objective optimization where each objective is to be minimized. Multi-objective optimization attempts to find a set of points known as the Pareto front  $\mathcal{P}$  that dominate over a reference point  $\mathbf{r}$  and any other observed points in objective space. The Pareto front hypervolume  $\mathcal{H}$  (shown in blue) is the axis-aligned volume enclosed by the Pareto front and a reference point  $\mathbf{r}$ . Making a new observation  $\mathbf{y}$ , that dominates over points in the current Pareto front, leads to an increase in hypervolume (shown in green), referred to as the hypervolume improvement  $\mathcal{H}_I$ . Reproduced from [20].

tion of input parameters. By maximizing the hypervolume improvement acquisition function, MOBO can determine a single point that maximally increases the Pareto front hypervolume at every step when evaluated in a serialized manner, making it ideal for online accelerator optimization.

The most common multi-objective acquisition function, expected hypervolume improvement (EHVI), is analogous to the popular single-objective expected improvement acquisition function [21]. This acquisition function calculates the average increase in hypervolume using the probability distribution of each objective function from the surrogate model. The EHVI acquisition function is formally defined as

$$\alpha_{EHVI}(\mu, \sigma, \mathcal{P}, \mathbf{r}) := \int_{\mathbb{R}^P} \mathcal{H}_I(\mathcal{P}, \mathbf{y}, \mathbf{r}) \cdot \xi_{\mu, \sigma}(\mathbf{y}) d\mathbf{y} \quad (3)$$

where  $\mathcal{P}$  is the current set of Pareto optimal points,  $\mathbf{r}$  is the reference point,  $\mathcal{H}_I(\mathcal{P}, \mathbf{y}, \mathbf{r})$  is the hypervolume improvement from an observed point  $\mathbf{y}$  in objective space, and  $\xi_{\mu, \sigma}$  is the multivariate Gaussian probability distribution function with the GP predicted mean  $\mu$  and standard deviation  $\sigma$  for each objective. A downside of this acquisition function is the calculation cost of determining the expected hypervolume improvement in high-dimensional objective spaces. A similar acquisition function, upper confidence bound hypervolume improvement (UCB-HVI) can be used as a cheaper to evaluate substitute with similar performance to EHVI [22].

We demonstrated the use of MOBO on optimizing the LCLS photoinjector [23]. Our goal was to determine the ideal trade-off between minimizing both the longitudinal bunch size  $\sigma_z$  and the vertical transverse beam size  $\sigma_y$  with respect to three tunable parameters, the gun solenoid, a focusing quadrupole magnet and a skew quadrupole magnet. The bounds of each free parameter were determined prior to experimentation from operator experience. The longitudinal bunch length was measured by a transverse deflecting cavity in the horizontal direction. Beam size measurements were conducted using optical transition radiation and statistics for each measurement were calculated from 5 samples each.

We began by randomly sampling 20 points in input space, producing the blue measurements in Fig. 4. We then used MOBO, with the UCB-HVI acquisition function to perform optimization for 20 iterations, initialized with data from the random search, shown in red in Fig. 4. Within these iterations MOBO was able to determine an approximate Pareto front (shown in the inset) that drastically improves over points found over random sampling. While this demonstration was a simple one, previous simulation results of optimizing the Argonne Wakefield Accelerator photoinjector with 7 objectives and 6 free input parameters show significant improvement over evolutionary algorithms commonly used by the accelerator community [20]. Furthermore, we also demonstrated that the same treatment of constraints and proximal biasing as was used in Bayesian exploration could also be incorporated into the MOBO acquisition function.

Figure 4: Results from running random search and then multi-objective Bayesian optimization to optimize the trade-off between electron bunch length  $\sigma_z$  and transverse beam size  $\sigma_y$  for the LCLS photoinjector. Free parameters included the gun solenoid, a focusing quadrupole and a skew quadrupole. Error bars denote  $1\sigma$  error for each measurement due to jitter. Inset: Approximate Pareto front (PF) after 20 MOBO iterations.

## Xopt: EASILY ACCESSIBLE IMPLEMENTATION OF ADVANCED ALGORITHMS

Using these algorithms on novel problems can take a significant amount of set-up and training to be successful. To reduce the upfront costs of using these and other complex algorithms for experimenters we have developed a flexible framework *Xopt* [24] for connecting advanced optimization algorithms to experimental control systems or simulations. Users need only to specify an algorithm by name and a python function that handles evaluation of target functions. Customization of optimization algorithms is also easily done, although their default configurations have been set to handle most problems off the shelf. *Xopt* has been used to both control the AWA accelerator and dispatch parallelized simulations on the Cori high performance computing cluster at NERSC [25]. The code is freely available at <https://github.com/ChristopherMayes/Xopt>.

## CONCLUSION

In this work we have shown that Bayesian techniques can be used to efficiently characterize and optimize accelerators. They can navigate tightly constrained systems without prior knowledge regarding those systems. Furthermore, they can be modified by proximal biasing factors which promote adiabatic changes in controllable parameters, a requirement

for efficient and stable optimization of large experimental systems.

## ACKNOWLEDGEMENTS

We would like to thank the operations staff at both LCLS and AWA for their contributions to this work. This work was supported by the U.S. Department of Energy, under DOE Contracts No. DE-AC02-76SF00515, DE-AC02-06CH11357, the Office of Science, Office of Basic Energy Sciences as well as the Office of High Energy Physics, and U.S. National Science Foundation under Award No. PHY-1549132, the Center for Bright Beams.

# MACHINE LEARNING BASED MIDDLE-LAYER FOR AUTONOMOUS ACCELERATOR OPERATION AND CONTROL

S. Pioli\*, B. Buonomo, F. Cardelli, P. Ciuffetti, L. G. Foggetta, C. Di Giulio,  
D. Di Giovenale, G. Piermarini, INFN-LNF, Frascati, Italy  
V. Martinelli, INFN-LNL, Legnaro, Italy

## Abstract

The Singularity project, led by National Laboratories of Frascati of the National Institute for Nuclear Physics (INFN-LNF), aim to develop automated machine-independent middle-layer to control accelerator operation through machine learning (ML) algorithms like Reinforcement Learning (RL) and Clustering, integrated with accelerator sub-systems. In this work we will present the actual LINAC control system and the necessary effort to implement the architecture and the middle-layer necessary to develop autonomous operation control with RL algorithms together with the fault detection capability improved by Clustering approach as for waveguides or accelerator sections breakdown. Results of the first tentative operation of Singularity on the LINAC system will be reported.

## INTRODUCTION

In this paper we will present our effort to integrate a Machine Learning (ML) based middle-layer integrated in the DAΦNE LINAC in order to demonstrate the feasibility of autonomous operation driven by RL algorithm together with Clustering fault detection methods to identify breakdown activities.

The main obstacle to implement the Singularity project [1] in the DAΦNE LINAC is related to the time available for the development and test the system in an operating accelerator for 4500 hours per year. The COVID periods with the reduced activities permits to implement the necessary step to provides at Singularity the data to implements the algorithms.

In the first part of this work introduction of the LINAC elements will be provided and an overview on the the actual control system is shown to introduce the architecture of the system and the middle layer implemented to provides the data to Singularity.

In the second part of the work description of RL algorithms and Singularity middle layer will presented and related integration and performances obtain on off-line operation will be presented and discussed.

## THE DAΦNE LINAC

The DAΦNE injector is composed by a ~60 m long Linac that produces and accelerates up to the collider operation energy (510 MeV) both the positron and electron beams. It has been designed and built by the USA firm TITAN BETA and commissioned by the INFN-LNF staff [2]. In Fig. 1 shows

Figure 1: The LINAC layout.

the LINAC RF layout. The injector subsystem includes a thermionic electron gun, a prebuncher and a buncher. The sections performing at S-band working at 2856 MHz, and are powered by 4 klystrons Thomson TH2128C, with nominal output power of 45 MW, each one equipped with a SLED, the SLAC type pulse compressor device. The performances of the LINAC are summarized in Fig. 2.

	Design	Operational
Electron beam final energy	800 MeV	510 MeV
Positron beam final energy	550 MeV	510 MeV
RF frequency	2856 MHz	
Positron conversion energy	250 MeV	220 MeV
Beam pulse rep. rate	1 to 50 Hz	1 to 50 Hz
Beam macropulse length	10 nsec	1.4 to 300 nsec
Gun current	8 A	8 A
Beam spot on positron converter	1 mm	1 mm
norm. Emittance (mm. mrad)	1 (electron) 10 (positron)	< 1.5
rms Energy spread	0.5% (electron) 1.0% (positron)	0.5% (electron) 1.0% (positron)
electron current on positron converter	5 A	5.2 A
Max output electron current	>150 mA	500 mA
Max output positron current	36 mA	85 mA
Transport efficiency from capture section to linac end	90%	90%
Accelerating structure	SLAC-type, CG, 2π/3	
RF source	4 x 45 MWp sledded klystrons TH2128C	

Figure 2: The LINAC beam performances.

After an upgrade on the gun [3] all the parameters as bunch duration and the other gun parameters and RF power in the RF guide distribution and in the sections could be controlled by klystron voltage set and the low level RF input of each klystron (power and phase) and the prebuncher, buncher, capture section power and phases could be set.

The focusing system varies its conformation according to the requirements of the portion of the LINAC interested.

\* stefano.pioli@lnf.infn.it

Figure 3: The LINAC magnet elements and diagnostics.

An easy way to describe this system is to follow a particle beam from the gun up to the LINAC end. More than 30 quadrupoles and a network of more than 20 vertical and horizontal correctors, coupled on each of the accelerating section approximately, permits the LINAC orbit correction. All the power supply of this magnets system are controlled by the LINAC control system and part by DAFNE control system.

The LINAC beam diagnostics system which includes a total of 14 beam position monitors BPM, 4 beam current monitors (BCM) and 4 beam profile monitors (flags). The BPMs are acquired by a multiplexed PXI independent system and the WCM by oscilloscope by a HP Multiplexer.

The position monitors are of the capacitive type with four electrodes, see Fig. 3. The voltages induced by the beam on these electrodes, properly combined, give the transverse position of the beam.

The current monitors are of the resistive wall type. The vacuum chamber continuity is interrupted by a ceramic gap and several resistors uniformly distributed around the gap create a resistive bridge, where the beam image current on the vacuum chamber can flow through. By monitoring the voltage drop on the resistors it is possible to derive the current value. Moreover the frequency response of the monitor is sufficient to reproduce the shape of the macrobunch (10 ns) with a good fidelity. Several examples of the current monitor signal are showed in Fig. 3.

To check the energy and the charge of the beam at the end of the LINAC a pulsed magnet drive one of the 50 bunch each second in the hodoscope spectrometer.

## THE LINAC CONTROL SYSTEM

A distributed architecture has been chosen for the LINAC control system. These provide the feature to run all or part of the system individually for test and trouble-shooting, and being able to co-locate a subsystem with its controls.

Originally the control system is operated through a control computer located remotely from the LINAC. An Apple Mac II run National Instruments LabVIEW originally and after a few upgrade in 2013 a server DELL with a virtual machine where the original LabVIEW 3.0 software was upgrade to LabVIEW 2010 on CentOS 7. The control software provides GUI shown in Fig. 4 and the operator full control of all functions and communicate with the CAMAC control system

Figure 4: The LINAC control system GUI.

via an IEEE-488 (GPIB) fiber-optical data link to isolate the computer from the control system.

A remote manual control panel is provided to perform limited hardwire commands and includes hardwire interlock functions. The control computer allow data logging of the system parameters with no impact on system performance. A CAMAC based interface was selected in 1996 for this system on the basis of performance, module availability, and familiarity with programming and operation of CAMAC based systems.

The CAMAC crate and associated controller, GPIB interfaces, and all digital and analog modules are located in the local control rack. The Command and Control buses handles all of the system wide commands and response from all of the subsystems. The Auxiliary buses is used for subsystem specific specific commands and response for the various operational configuration. All of the analog control and monitor signals are not bus-connected, but run direct to/from the required location in the shielded twisted pair cables, using various interface chassis as terminations points. All the system under control are shown in Fig. 5.

The integration of all the systems and diagnostics are done following the schema represented in Fig. 6 follow the methodology presented in [4] to send and communicate with the Singularity AI. This system allows to integrate different data sources from the LINAC control system with the BPM system, WCM system and DAFNE control system [5] and to send the command with the same interface.

## THE REINFORCEMENT LEARNING APPROACH

According to Sutton's [6], Reinforcement Learning (RL) is a learning technique to map situations onto actions in order to maximize a numerical reward signal. The learner is not told which actions to perform, but must figure out through trial and error which actions yield the greatest reward by trying them. In the most interesting and challenging cases, the actions may affect not only the immediate reward, but also the next situation and through that, all subsequent rewards. These two characteristics (trial-and-error search and delayed

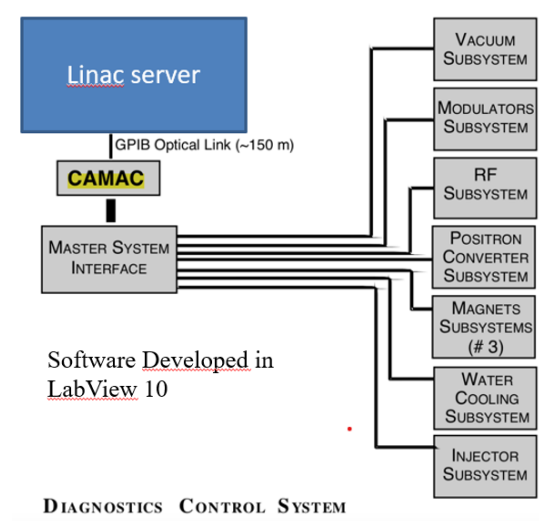

Figure 5: The LINAC control system.

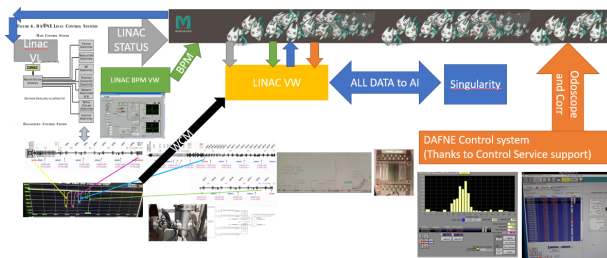

Figure 6: The LINAC control system and diagnostic acquisition.

reward) are the two most important distinguishing features of reinforcement learning.

Reinforcement learning is distinct from supervised learning, the type of learning studied in most current research in machine learning. Supervised learning is learning from a training set of labeled examples provided by a knowledgeable external supervisor. Each example is a description of a situation along with a specification (the label) of the correct action that the system should take in that situation, often to identify a category to which the situation belongs. The goal of this type of learning is for the system to extrapolate or generalize its responses so that it acts correctly in situations not included in the training set.

One of the challenges that reinforcement learning faces is the trade-off between exploration and exploitation that does not exist in other types of learning. To obtain a high reward, a reinforcement learning agent must prefer actions that it has tried in the past and found to be effective in obtaining a reward. However, in order to discover such actions, it must also try actions that it has not previously selected. The agent has to exploit what it has already experienced in order to obtain a reward, but it must also has to explore in order to make a better action selections in the future. The dilemma

is that neither exploration nor exploitation can be pursued exclusively without failing at the task. The agent must try a variety of actions and gradually prefer those that seem best to it.

Q-learning [7] is a form of model-free reinforcement learning. It can also be considered as a method of asynchronous dynamic programming. It provides agents with the opportunity to learn to act optimally in Markovian domains, Fig. 7, by experiencing the consequences of their actions without having to create maps of the domains. Learning proceeds similarly to Sutton's [6] method of temporal differences (TD): an agent tries an action in a given state and evaluates its consequences based on the immediate reward or penalty it receives and its estimate of the value of the state it is placed in. By repeatedly trying all actions in all states, it learns which actions are best overall, judged by the long-run discounted reward according to the Bellman transition function.

Figure 7: Markov Decision Process.

In this case, the learned action value function  $Q$  is a direct approximation to  $q^*$ , the optimal action value function, regardless of the strategy followed. This drastically simplifies the analysis of the algorithm and allows for early convergence proofs. The policy still has an impact as it determines which state-action pairs are visited and updated. However, all that is required for proper convergence is that all pairs continue to be updated.

Under this assumption and a variant of the usual stochastic approximation conditions for the sequence of step-size parameters,  $Q$  converge to  $q^*$  with probability 1. The Q-learning algorithm is presented below in procedural form in Fig. 8.

## CONTROL SYSTEM INTEGRATION & FAULT DETECTION

Mem-cached live data from LINAC control system is acquired from Singularity middle-layer while a REST communication channel allow to change devices setpoint.

In order to allow the proper data validation for ML algorithm, interlock signals are acquired from the CAMAC in order to break and restore operation when a fault happens. Anyway not all the fault trigger an interlock like RF anomaly that should be processed through a data analysis to identify breakdown phenomena and stop the autonomous operation while the issue is occurring.

### Q-learning (off-policy TD control) for estimating $\pi \approx \pi_*$

Algorithm parameters: step size  $\alpha \in (0, 1]$ , small  $\varepsilon > 0$

Initialize  $Q(s, a)$ , for all  $s \in \mathcal{S}^+, a \in \mathcal{A}(s)$ , arbitrarily except that  $Q(\text{terminal}, \cdot) = 0$

Loop for each episode:

Initialize  $S$

Loop for each step of episode:

Choose  $A$  from  $S$  using policy derived from  $Q$  (e.g.,  $\varepsilon$ -greedy)

Take action  $A$ , observe  $R, S'$

$Q(S, A) \leftarrow Q(S, A) + \alpha [R + \gamma \max_a Q(S', a) - Q(S, A)]$

$S \leftarrow S'$

until  $S$  is terminal

Figure 8: Q-learning pseudo-code iteration.

In order to handle this kind of RF events a Clustering algorithm have been involved to automatically recognize pattern inside the data so as to analyze the collected data without their labels. Using this advantage, a density based clustering fault diagnosis method have been used to deal with such RF breakdown issues, in which the labeled data are limited.

The Density-Based Spatial Clustering of Applications with Noise (DBSCAN) [8] algorithm requires two input parameters, a radius and minimum number used to define a density threshold in the data space. DBSCAN is an iterative algorithm which iterates over the objects in the dataset, analyzing their neighborhood. If there are more than certain number of objects whose distance from the considered object is less than the reference, then the object and its neighborhood originate a new cluster. DBSCAN is effective at finding clusters with arbitrary shape, and it is capable of identifying outliers as a low density area in the data space.

Figure 10: DBSCAN output in breakdown events which identify several clusters.

Figure 9: DBSCAN output in normal operation which identify one cluster.

Thanks to this unsupervised learning technique have been possible control n-dimensional system identified by the evolution of RF power signal and all the vacuum ion pumps current trends in order to identify breakdown. The algorithm is setup to expect one cluster made of a reasonable distribution of point from RF power and ion pumps current distribution, as in Fig. 9. The minimum number of point to identify a cluster is set one in order to allow the classification of fault when just one ion pump show an anomalous behavior. When a vacuum readback moves out from the cluster, as in Fig. 10, this is identified as a second cluster and trigger the identification of a breakdown event stopping the execution of RL algorithm. This process is performed for all the RF sources of the LINAC and all the related vacuum ion pumps.

## AUTONOMOUS OPERATION TOOLS

Two tools for autonomous operation have been developed in order to handle main tasks, really time consuming, which involves the operators team to reach required performances for the DAΦNE complex and the BTF.

As general comment, all the tools have been developed to be capable of machine independence from the accelerator layout and to be invariant to performance drift of aged devices. The combination of these two conditions allow to use these tools independently on different new-one or legacy accelerator just configuring the schematic lattice and operating parameter of each device. The algorithm, during the training phase, will learn how to drive each device identifying for each setpoint the contribute to reach the goal state.

### RF Sources Energy Tuning

According with definition of a Markovian Decision Process (MDP), the scope of this tool is the energy tuning of the LINAC beam through the control of two RF Sources (power and phase) after the positron converter and the monitoring the hodoscope at the end of the LINAC which provide the beam energy, as shown in Fig. 11.

Figure 11: Highlighted in red the RF sources and related distribution controlled by the RF energy tuning tool.

Figure 12: Score trend during each step of the 300 episodes training.

We identify for each variable of the environment operative ranges and the related accuracy. So the state-action matrix comes from the combination of all the possible action of the four variable parameters (power and phase of the two

Figure 13: Number of Steps during each one of the 300 episodes training.

RF sources) with all the possible states (hodoscope energy readback). The Q-learning agent provide variable reward in function of the different between the current beam energy and the target beam energy.

A simulated run with off-line data have been performed in order to test the algorithm over 300 episode. As shown in Figs. 12 and 13, the algorithm converge to  $Q^*$  within 1000 steps equivalent to about one day of training on the LINAC (taking in consideration the required time to perform and stabilize a command with the CAMAC control system).

### Beam Charge Optimization

The scope of this tool is optimize the charge of the LINAC beam through the control of 8 quadrupole magnets power supply, after the positron converter, and 2 beam current monitors (BCM) monitoring the beam current up to the end of the LINAC, as shown in Fig. 14.

Figure 14: Highlighted in red the distribution of quadrupole magnets while in blue the position of the BCMs controlled by the Beam Current Optimization tool.

We identify for each variable of the environment operative ranges and the related accuracy. So the state-action matrix comes from the combination of all the possible action of the 8 variable parameters (the current setpoint of each power supply) with all the possible states (percentage of current transported through the two BCMs). The Q-learning agent provide variable reward in function of the different between the ratio of current transported and the target beam current ratio.

A simulated run with off-line data have been performed in order to test the algorithm over 300 episode. As shown in Figs. 15 and 16, the algorithm converge to  $Q^*$  within 2000 steps equivalent to about two days of training on the LINAC

Figure 15: Score trend during each step of the 300 episodes training.

Figure 16: Number of Steps during each one of the 300 episodes training.

(taking in consideration the required time to perform and stabilize a command with the CAMAC control system).

## CONCLUSION

The work presented in this paper show the progress in the development of Machine Learning based middle layer

focused on Reinforcement Learning tool for automated operations.

Design of the DAΦNE LINAC control system, the first testing site, have been introduced together with the architecture of the Q-learning algorithm.

Validation process on off-line data highlight not only the feasibility of presented tools but also the capability to be trained on a LINAC with a small effort of few days of dedicated beam shift.

Next steps for the use of ML tools in operation will pass through a test shift to be scheduled in next months and an upgrade of the state-action matrix to a Deep Q-Network (DQN) to optimize memory usage.

## Abstract

Over the past several years machine learning has increased in popularity for accelerator applications. We have been exploring the use of machine learning as a diagnostic and tuning tool for the transfer line from the AGS to RHIC at Brookhaven National Laboratory. In our work, inverse models are used to either provide feed-forward corrections for beam steering, or as a diagnostic to illuminate quadrupole magnets that have excitation errors. In this paper we present results on using machine learning for beam steering optimization for a range of different operating energies. We also demonstrate the use of inverse models for optical error diagnostics. Our results are from studies that use both simulation and measurement data.

## INTRODUCTION

Machine learning (ML) has seen a significant growth in its adoption for widespread applications. In particle accelerators ML has been identified as having the potential for significant impact on modeling, operation, and controls [1,2]. These techniques are attractive due to their ability to model nonlinear behavior, interpolate on complicated surfaces, and adapt to system changes over time. This has led to a number of dedicated efforts to apply ML, and early efforts have shown promise.

For example, neural networks (NNs) have been used as surrogates for traditional accelerator diagnostics to generate non-interceptive predictions of beam parameters [3,4]. Neural networks have been used for a range of machine tuning problems utilizing inverse models [5,6]. When used in conjunction with optimization algorithms neural networks have demonstrated improved switching times between operational configurations [7]. Neural network surrogate models have also been demonstrated to significantly speed up multi-objective optimization of accelerators [8]. Additionally, ML has been of interest for anomaly detection, using autoencoders, for root cause analysis [9], and for outlier detection, using large data-sets of known good operational states [10].

In this work we seek to apply ML methods — for both tuning and anomaly detection — on the AGS to RHIC transfer line at Brookhaven National Laboratory. Specifically, we employ the use of inverse models for these applications. The application of inverse models for anomaly detection is a burgeoning area of research in many other fields that has not seen much attention in particle accelerators. Here we present our work towards implementing inverse models to detect errors in quadrupoles using only beam position monitors and corrector data. We will demonstrate the utility of

this approach using a toy model, and then show how it scales to a larger system such as the AGS to RHIC transfer line. We will then show results of training inverse models using data from the machine and discuss future work for this effort.

## THE ATR LINE

The transfer line between the Alternating Gradient Synchrotron (AGS) and RHIC, or the so-called the ATR line [11,12], must be retuned for different energies when RHIC changes its operating point. The transfer line controls the orbit matching, optics matching, and dispersion matching of the beam into RHIC. The transfer line is broken down into four sections. The U and W lines are seen by all beams entering RHIC while the X and Y lines are used for injection into the Blue and Yellow rings respectively. In this paper we focus our studies on the UW subset of the ATR line. The length of the transfer line presents challenges for tuning unto itself. The problem is further complicated by a 1.7 m vertical drop in order to get the beam from the AGS to RHIC.

The first part of the ATR (referred to as the U-line) starts with fast extraction from the AGS and stops before the vertical drop from the AGS to RHIC. The U-line consists of two bends. The first bend is  $4.25^\circ$ , consisting of two A-type dipole magnets. The second bend is an  $8^\circ$  bend consisting of four C-type combined-function magnets (placed in a FDDF arrangement), and thirteen quadrupoles. Optics in the U-line are configured to accomplish several goals. The Twiss parameters at the AGS extraction point must be matched, and provide achromatic transport of the beam to the exit of the  $8^\circ$  bend. The beam must be focused at the location of a thin gold foil which is placed just upstream of the quadrupole Q6 of the U-line. The Twiss parameters of the U-line must be matched to the ones at the origin of the W-line. Finally, the beam size should be kept small throughout to minimize losses.

The second part of the ATR (referred to as the W-line) introduces the vertical drop for injection into RHIC, and the matching sections for the injection lines. It contains eight C-type combined-function magnets that each make a  $2.5^\circ$  bend, followed by six quadrupoles. The eight combined function magnets form a  $20^\circ$  achromatic horizontal bend placed in a (F-D) configuration. The W-Line is also responsible for lowering the beam elevation by 1.7 m. This is accomplished using two dipoles in an achromatic dogleg configuration. Along the line there are also a number of BPMs and correctors that are required to match the orbit of the beam into RHIC.

## FODO TEST PROBLEM

Before applying inverse models for anomaly detection on the full UW line, we first demonstrate the efficacy of this technique using a toy problem. Our toy problem is a FODO lattice, containing BPMs and correctors, in addition to the quadrupoles. We built a model that predicts the corrector settings for a given sequence of BPM settings. Because the quadrupoles supply a dipole kick when the beam does not traverse them on axis, any error in the predicted corrector setting should be strongly correlated to an error in the quadrupole strength. Here we utilized a neural network based inverse model training on simulation data collected using MAD-X. A schematic of the beam-line used for this study is shown in Fig. 1.

Figure 1: Screenshot of Sirepo visualization of toy lattice used for studying inverse models for anomaly detection. Quadrupoles are shown in red, correctors are black, and BPMs are indicated by green flags.

The beam line is composed of four identical FODO sequences. Each segment has two BPM/corrector pairs followed by a BPM after the second quadrupole. Having a large number of BPMs available, ensured that the inverse model was easy to train, which will allow us to use it to detect errors in the quadrupoles.

The training data consisted of 5000 examples simulated by randomly changing corrector strength and the initial beam position. The NN architecture was optimized as a function of the number of layers as well as the nodes per layer to improve training loss without over-fitting. Gaussian noise was used as a regularizer which leads to an increased noise on the validation loss as the epoch increases. Figure 2 shows the loss as a function of training epoch for the training and validation data.

Here we see that The training loss is a bit above the validation loss which indicates we could train longer. However, Fig. 3 shows the model prediction compared to the ground truth for each of the correctors (kickers). The relationship is almost perfectly linear in all cases, indicating the model is well trained.

Next we test the model using data with systematically introduced errors in individual quadrupoles. We ran the MAD-X simulations with random corrector strengths and initial beam positions. Then, the BPM outputs were used as inputs to the NN model — trained without quadrupole errors — to predict the corrector settings. These predicted corrector settings were then compared to the actual corrector settings.

Figure 2: Mean squared error for the training and validation data as a function of the training epoch.

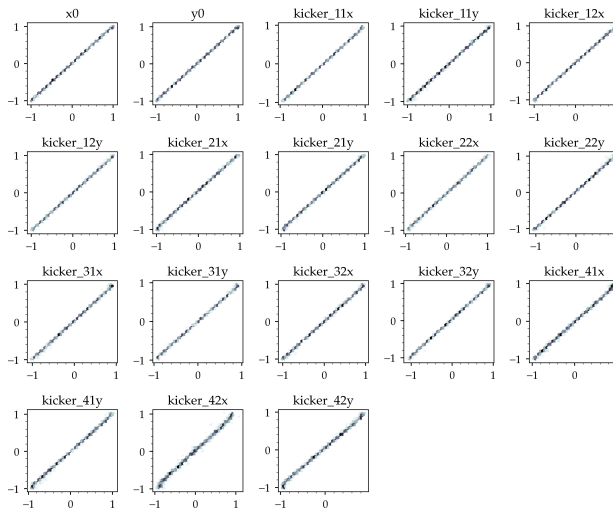

Figure 3: Predicted output vs. ground truth for the initial beam position and the kicker settings. The relationships are almost perfectly linear in all cases.

Figure 4 shows the predicted corrector setting versus the ground truth when testing the model using data generated with a strength error in one of the quadrupoles. Here it is very clear that the correctors in the first section of the beam-line (kicker\_11 and kicker\_12) are not well reconstructed while all the other correctors are well reconstructed. This points to quadrupole strength errors in the first part of the beam-line.

We then studied the prediction error for a wide range of quadrupole errors and compared our ability to reconstruct the corrector settings. Figure 5 shows the normalized prediction error vs corrector index for data with different quadrupole errors. For each test case we introduced a single quadrupole error at different points along the beamline and we observed prediction errors in both the horizontal and vertical corrector settings.

Here we see that for a given quadrupole there is a unique error signature for the correctors. Additionally, the corrector indices are arranged by their position in the beamline. As the quadrupoles that are varied move down the beamline so do the errors in the corrector predictions. This is likely because

Figure 4: Predicted output vs. ground truth for data with a single quadrupole strength error.

Figure 5: Normalized prediction error of corrector strengths given a range of Quadrupole errors. The dashed line is the horizontal corrector and the dotted line is the vertical corrector. The color indicates which Quadrupole was varied.

the BPM nearest the quadrupole with the error will be the most sensitive to this perturbation. Additionally due to the degenerate solutions in this type of model, it can be difficult to differentiate upstream errors from downstream errors. If we want to use this diagnostic for tuning, it is important to also examine the error in the corrector prediction as a function of the change in quadrupole strength. Figure 6 shows the normalized prediction error as a function of quadrupole strength error for a single quadrupole.

There is a clear quadratic relationship between the quadrupole strength error and the normalized prediction error. This means that we can clearly detect anomalies in quadrupoles using our inverse model trained on the BPMs and correctors. Moreover, this means that we can vary the quads to minimize the model error based on measured BPMs and correctors, allowing us to tune the lattice without using destructive beam optics measurements.

## ATR INVERSE MODEL

Given the success of this effort on the toy model we next applied this concept to the UW line in the ATR. The problem

Figure 6: Normalized prediction error as a function of quadrupole strength error for each kicker ( $\text{m}^{-2}$ ). The solid line is the horizontal kicker and the dashed line is the vertical kicker.

is a bit more complex as there are now not just quadrupoles, correctors, and BPMs, but also combined function bends and vertical bends. That said there are still comparatively few BPMs and correctors — only 26 and 14 respectively — making the model of similar scale to the toy problem. However there are 19 quadrupoles which significantly increases the complexity.

We trained the inverse model using 5000 samples, randomly varying the corrector strengths and beam initial positions. During our initial training of the inverse model four correctors (utv4, uth6, utv7, and wth1) were not well fit. This is likely due to the degenerate solutions that arise from the length of the transfer line. We attempted a wide range of solutions including sampling more data and working with image representations of the data 1-D convolutional layers. None of these methods were successful. When training inverse models there is always the possibility that the problem will not be fully invertible. In future work we will address this issue, however, for studies presented here we simply removed those four correctors from the prediction. Figure 7 shows the training and validation loss for the inverse model trained on the UW line.

Figure 7: Training and validation loss as a function of training epoch for the UW line.

Here we see very good agreement between the training and validation set. Additionally the loss continues to decrease, showing that we are not over-fitting. For this study the data

Figure 8: Root mean squared error on the training (blue) and validation (orange) datasets for the individual correctors.

were split into 80 % training and 20 % validation. Figure 8 shows the root mean squared error for each of the parameters individually.

The prediction error on the training and validation datasets are quite good. For this model we used 5 dense layers with 45 nodes each and Gaussian noise for regularization. The model used rectified linear units for the activation functions.

## INVERSE MODEL ERROR STUDIES

With a trained inverse model we moved on to the error studies. Quadrupoles were individually varied over a range of  $\pm 20\%$  of their design excitation. We then simulated the UW line with random initial beam positions and random corrector settings. The BPM output from these simulations was used to predict the corrector settings using the model trained on data with the design quadrupole strengths. These simulations were run in two configurations, one where the initial positions were also varied randomly and one where the initial positions were not varied. The goal here was to understand if the model can differentiate between these two cases. During operations it is likely that the initial position will be relatively static.

Figure 9 shows the predicted corrector settings vs the ground truth for the validation set without quadrupole errors (black), the test set with a single quadrupole error and random initial position errors (red), and the test set with a single quadrupole error without initial position errors (blue).

Here we can clearly see that some correctors have a significant error in the prediction compared to others. For example Uth2p2 has a nice linear relationship but with a clear jump near zero. While UTH3, on the other hand, has a general increase in the error, as compared with WTV6, where the errors are relatively low. The model also shows a lack of ability to distinguish between cases where the initial position is varying and is not varying. The spread in the errors appear consistent between the two data sets. Indeed, Figs. 10 and 11 — which show the sensitivity of each corrector prediction to a particular quadrupole error — demonstrate that there is negligible difference between the cases with and without initial position errors. Here sensitivity is defined as the model

Figure 9: Predicted corrector settings as a function of the ground truth for, the three test cases. Without quadrupole errors: black. A single quadrupole error and random initial position errors: red. A single quadrupole error without initial position errors: blue.

error divided by the fractional change in quadrupole strength. These figures also show that there is a unique signature for each quadrupole and that the model clearly identifies errors in these magnets without any explicit knowledge of their existence.

These results are promising for the adaption of this method on the machine. Especially because the UW line is designed to be linar, we expect the methods developed in simulation to behave similarly when transferred to the machine.

## MACHINE STUDIES AND BPM INVERSE MODELING

We are in the early stages of testing our method on the machine, and have collected BPM and corrector data for the nominal machine configuration. Working with the UW line allows us to take data between injections to RHIC, parasitic to operations. These studies took approximately four hours of beam time without any interruption to operations.

Our main goals with this first study is to answer two key questions 1) how much data do we need to train an inverse model for the transfer line and 2) establish the feasibility of a neural network based inverse model for detecting quadrupole

Figure 10: Sensitivity of each corrector prediction to individual quadrupole errors. In this case the initial position was randomly varied along with the correctors.

Figure 11: Sensitivity of each corrector prediction to individual quadrupole errors. In this case the initial position not varied.

errors in the ATR line. With these data we can evaluate the accuracy of the ATR line MAD-X model, study the ability to transfer our NN inverse model from simulation data to measured data, and finally test our ML models on real data from the machine.

Figure 12 shows histograms of the beam position monitor data collected on the ATR line. Note that our initial dataset is relatively small, and has regions where there are quite a few outliers. The outliers in the dataset make it difficult to effectively sample the space for training neural networks. This will present a challenge when training on machine data alone. We plan to overcome this by combining the measured data with simulation data prior to testing on the machine.

With this dataset we performed some initial studies in order to understand the limitations of the measurements, and to help identify areas for additional data collection, or where simulations would be particularly useful. We are focused on using inverse models that predict the corrector settings from the BPM readings.

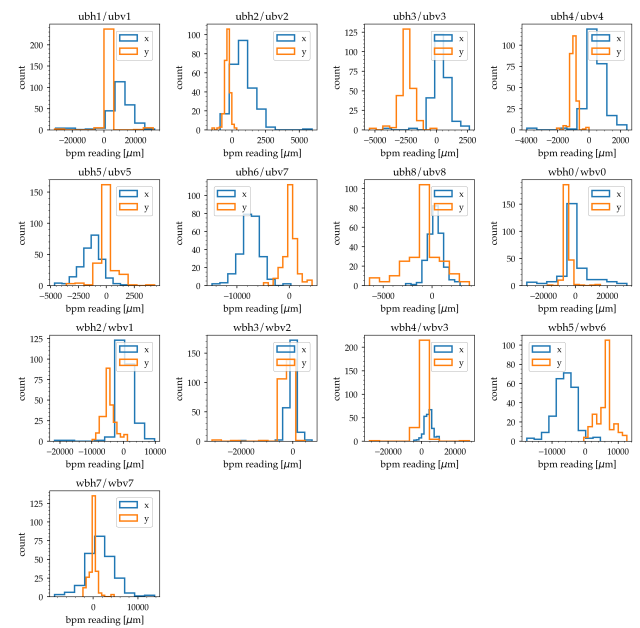

Figure 12: Histogram of BPM data collected from the ATR line. Horizontal (x) and vertical measurements are shown in blue and orange respectively.

For this study we varied numerous hyper parameters for the model, including: the number of nodes per layer, the number of layers, and the batch size. We also varied the regularization parameters to include both L2 regularization and Gaussian Noise. L2 regularization seeks to optimize the neural network architecture while simultaneously eliminating weights that are very small. The result is a more sparse network, but fewer nodes that are tracking noise in the data. Gaussian noise can assist the optimizer in getting out of local minima leading to a more robust solution. In the end, we trained on a batch size of 5 and aggressive Gaussian noise which helped the model fit such a small dataset. Figure 13 shows the training and validation loss as a function of training epoch for our neural network.

Figure 13: Loss curve for training and validation sets for the BPM data

The training and validation loss both decrease quite rapidly and then flatten out. The validation loss continues to improve slightly but does not change significantly after about 40000 epochs. With small datasets it is important to train for a long time in addition to restarting with different batch sizes to introduce perturbations to the network that allow it to generalize better. The large offset between the training and validation loss indicates that the network would benefit from more examples. The fact that the validation loss is not increasing indicates that we are not overfitting though. In spite of the relatively large discrepancy between the training and validation loss, the performance on the validation set is quite reasonable. Figure 14 shows the predicted corrector setting compared to the ground truth for the validation set.

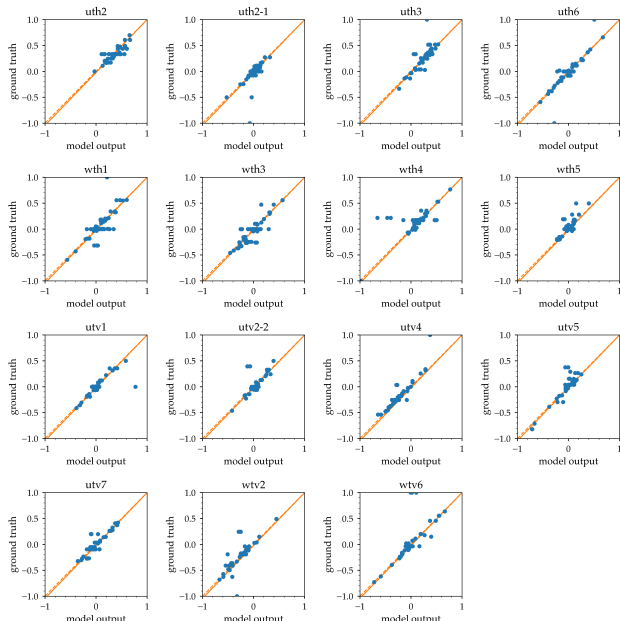

Figure 14: Fit results of the validation data for neural network trained on bpm on our study data

The solid orange line is the linear fit between the ground truth and the model output and the dashed line is the ideal fit should the model accurately reconstruct the corrector settings from the BPMs. In general the model performs relatively well, however as noted earlier it is clearly biased by small samples at extremes.

## CONCLUSION

In this paper we explore the use of inverse models to detect errors in quadrupole strengths using BPM and corrector data. We have demonstrated an initial test using a toy model consisting of four FODO cells. We then scaled this to the UW line on the ATR beamline at RHIC. Our results show that inverse models can identify quadrupole errors by comparing the predicted corrector setting to actual corrector settings. We also show that the each quadrupole strength error yields a unique signature. We have begun transferring our work for testing on the machine and have shown a neural network inverse model can be trained on real BPM data from the UW line.

## Abstract

ITER will produce large volumes of data that will need to be visualized and analyzed. This paper describes the development of a graphical data visualization and exploration tool, MINT (Make Informative and Nice Trends), for plant engineers, operators and physicists. It describes the early development phase from requirements capture to first release covering the mistakes, lessons learnt and future steps. The requirements were collected by interviewing the various stakeholders. The initial neglect of the architecture and user-friendliness turned out to be key points when developing such a tool for a project with a long lifetime like ITER. A modular architecture and clear definition of generic interfaces (abstraction layer) is crucial for such a long lifetime project and provides a robust basis for future adaptations to new plotting, processing and GUI libraries. The MINT application is based on an independent plotting library, which acts as a wrapper to the choice of underlying graphical libraries. This allows scientists and engineers to develop their own specific tools, which are immune to changes of the underlying graphical library. Data selection and retrieval have also been developed as a separate module with a well-defined data object interface to allow easy integration of additional data sources. The processing layer is also a separate module, which supports algebraic and user-defined functions. The development is based on Python [1] and uses Qt5 [2] as the visual backend. A first release of the 1-D trend tool (MINT) has already started and will be used for the ECH (Electron Cyclotron Heating) system commissioning. Other visualization tools will be developed in the future that build upon the same underlying modules.

## INTRODUCTION

ITER is already producing data which need to be plotted and analyzed quickly. This paper describes the requirements and challenges, the development phases and various lessons learnt.

## REQUIREMENTS

The top level requirement for data visualization is to be able to plot data for a time range or a pulse identifier.

## Stakeholders

To define the detailed requirements, the first thing was to identify the main stakeholders. We identified three basic categories of users:

- Plant engineers whose main objective is to make system investigations; some of them will also perform research activities.
- The science team whose main objective is to analyze pulses and carry out research.
- The operation team whose primary focus will be the analysis of pulses.

## Types of Data

The next step was to list the different data types of interest. After interviewing the stakeholders, the following list was constructed:

- Time and profile traces;
- Spectra;
- Fluxes (see Figure 1);
- Images and videos (see Figure 2)

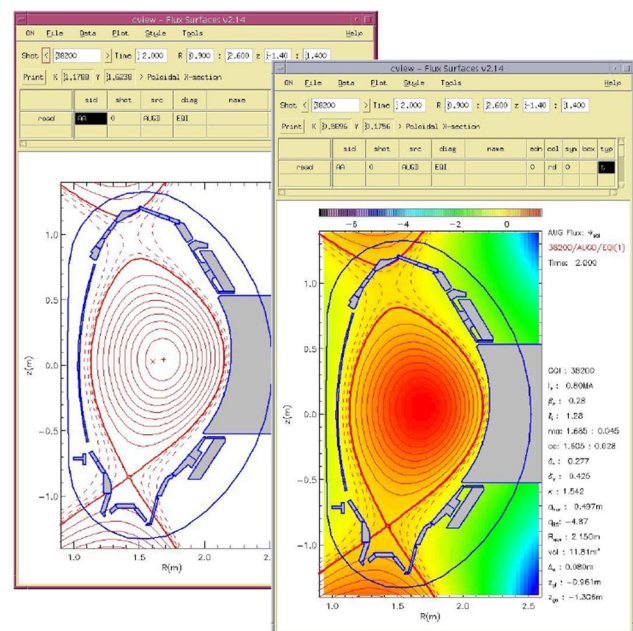

Figure 1: Example of magnetics flux surfaces as represented in CVIEW used at ASDEX (courtesy from G.Conway).

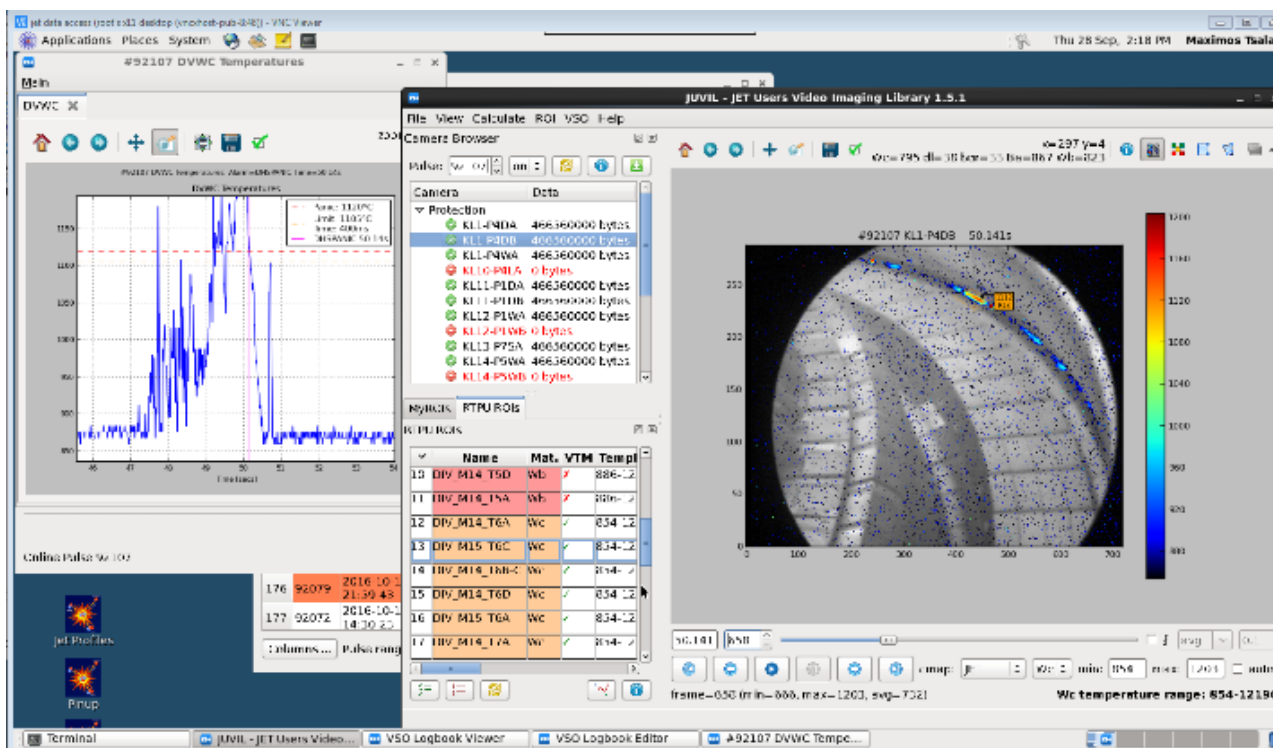

Figure 2: Example of image analysis (JUVIL used in JET).

### Collecting Requirements

In order to get more practical users' feedback, a prototype was developed based on existing similar tools. It enabled collecting more precise user requirements. By making various demonstrations to the stakeholders a set of requirements were collected, including:

- Be able to overlay data from multiple pulses in one plot
- Be able to plot quickly 100 signals in multiple plots
- Be able to update the colors, to mark the points, to control how two points are connected
- Zoom/pan interactively: ITER has very fast sampled signals (kB-GB/sec). Loading all the points in memory on the client side would be very resource intensive. So there is a need to be able to dynamically retrieve data during zooming/panning operations with acceptable performance
- Be able to apply basic processing on one or more signals

## DEVELOPMENT – PHASE I

### Agile Development

As stated in the previous section, an existing product based on C++/Qt5 was initially extended. An agile development approach was opted to add new features. Bugzilla was used to track all new features, SVN to store the code, and Jenkins as the continuous integration system. Resources (CPU and memory) and performance optimization were the main objectives besides feature implementation. Thanks to ECH and ICH team, we could simulate the acquisition of fast signals from 2MHz to 125MHz. The demonstration of zooming interactively a signal sampled at 125MHz was successful: the zooming was done until one was able to measure the distance between 2 points (8 ns). Figure 3 shows the layout of our prototype.

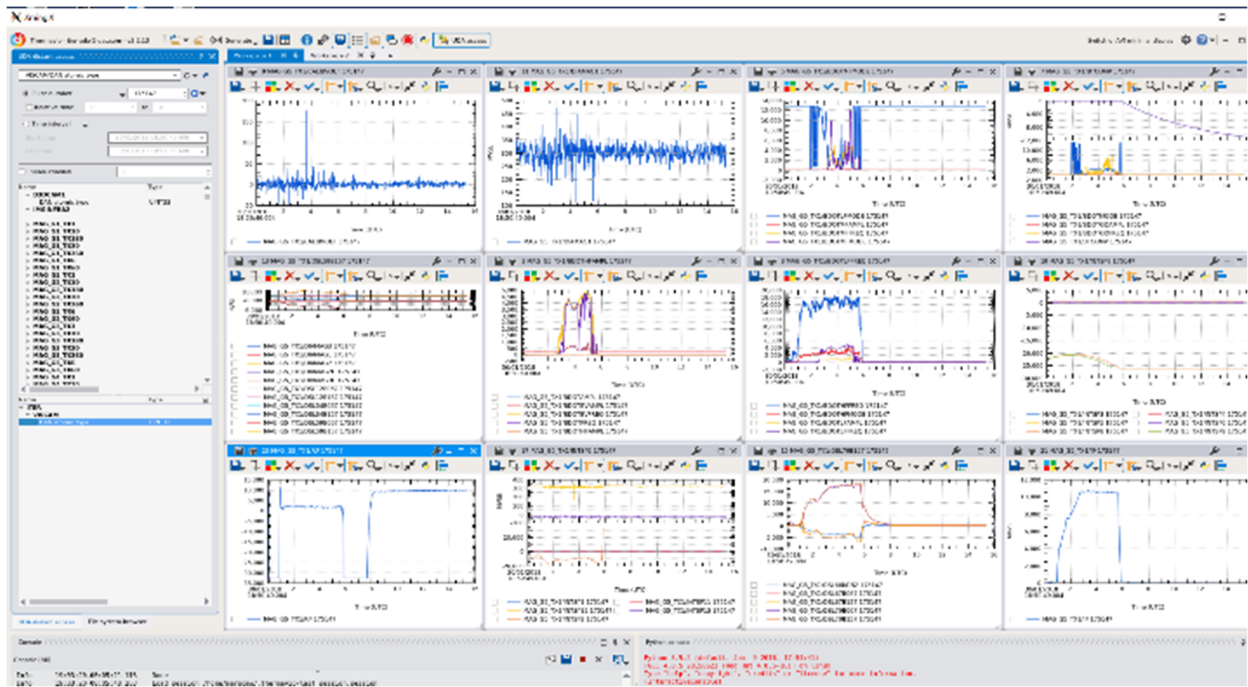

Figure 3: Look and feel of our first prototype based on Thermavip (tool used at CEA).

## Training Stakeholders

After several months of development, a training was given to the stakeholders through dedicated separate sessions. They were provided the tool and requested to plot data for a particular time range and for a particular pulse identifier.

The results were not so good. Many had difficulties to execute basic actions. None of them could plot data without our help.

Scientists also challenged the tool by wanting to add new data sources for data retrieval, something that was not easy to do as per the implementation of the existing tool. As a consequence, the chosen approach was reflected upon in detail and the way forward discussed.

## Lessons Learnt

During this initial development phase, it was realized that three key aspects were omitted:

- 1) Usability of the tool: non-developers shall be able to use the tool with very limited knowledge. When adding new features, the GUI became too complex and the main functionalities which needed to be kept simple, were not clearly identified.
- 2) Architecture: As a consequence of adopting an agile development approach, not enough thought was placed on the architecture, something that became clear when users requested to integrate a new data sources.
- 3) One big tool versus many tools: the initial concept was to have one big tool which could handle any data type and all stakeholders' views. Indeed it seemed attractive to provide users with one tool and then depending on their needs they can plot fluxes or profiles or time traces. With hindsight, it turned

out that the GUI was too complex in terms of usability and maintainability. A decision was thus taken to develop tools with a limited but well defined scope to ensure user-friendliness and improved maintainability.

With all this in mind, a new development strategy was implemented.

## DEVELOPMENT – PHASE II

### Review of Existing Tokamak Tools

It was decided to invest more time analyzing existing tools currently in use on other tokamaks and stellarators.

It was found that the visualization tools on most devices shared similarities:

- Multiple tools are often developed to cover different aspects of data visualization: one tool for time traces and limited support for images, surfaces; one tool for fluxes and another tool for image analysis
- The User Interface for the time traces is based on a table and not a tree: it allows to be agnostic to the data structure used for the experimental signals and also eases the configuration of the plots and their signals
- Plotting data versus a pulse or a time range, zooming/panning, displaying crosshair were very straight forward
- Importance of good default settings

### Architecture

As a result of the above review, a modular approach was subsequently adopted and it was furthermore decided to develop a plotting library so that scientists could reuse this layer to develop their own expert applications. Python and

PySide [3] where selected as the basis for the development, Python being a commonly used language for scientific visualization.

The current architecture is based on 4 blocks:

- **Logging** : module which allows logging to file/console
- **DataAccess**: module which allows retrieving data from various data sources. To add a new data source, it is sufficient to add a new Python class and implement method to retrieve data. The data object used in this class is generic.
- **Processing** module: this module is responsible for processing the data as required after it has been fetched. It is responsible for time-base alignment when an operation involves more than one signal. Note that the processing is reapplied in case of a zoom/pan operation.
- **Iplotlib**: module which is responsible to plot the data and react to events such as zooming/panning. To demonstrate that the interface is independent from the graphics backend (here Matplotlib [4]), a VTK [5] back-end has also been developed. This allows a user to choose to use ipplotlib either with Matplotlib (default) or VTK.
- **M.I.N.T.** (Make Informative and Nice Trends) is a tool that makes use of all the above modules. It is the primary tool for displaying time traces and analysis.

Current Status

Many features have been developed, as can be seen in Figure 4, such as plotting data for a given time range, or for a pulse identifier.

Features
View one or several 1-D trends (X axis is the time)
Support for pulse-based and time range data access (all the plots show the same time range/pulse)
Support for time range or pulse specialization at row level (allow comparing two plots side by side)
Support for pulse overlay
Support for interactive zoom
Support for crosshair (over multiple plots)
Support for envelope display
Support for pan interactive
Support for preferences update (color of a signal, draw-style (interpolated, stair), display points with markers)
Add a plot title
Support for automatic X-axis scale (if I zoom or pan on one plot, all the plots will be rescaled to the same time window).
Import/Export list of variables
Save/load configuration a plot
Support for streaming
Support for full-mode
Support for basic processing of one signal
Support for Y and X-axis label edition
Generate a screenshot given a preference file in an headless environment (to allow report automation)

Figure 4: List of main features which have been actually implemented.

The tool layout with both back-ends is shown in Fig. 5 and Fig. 6.

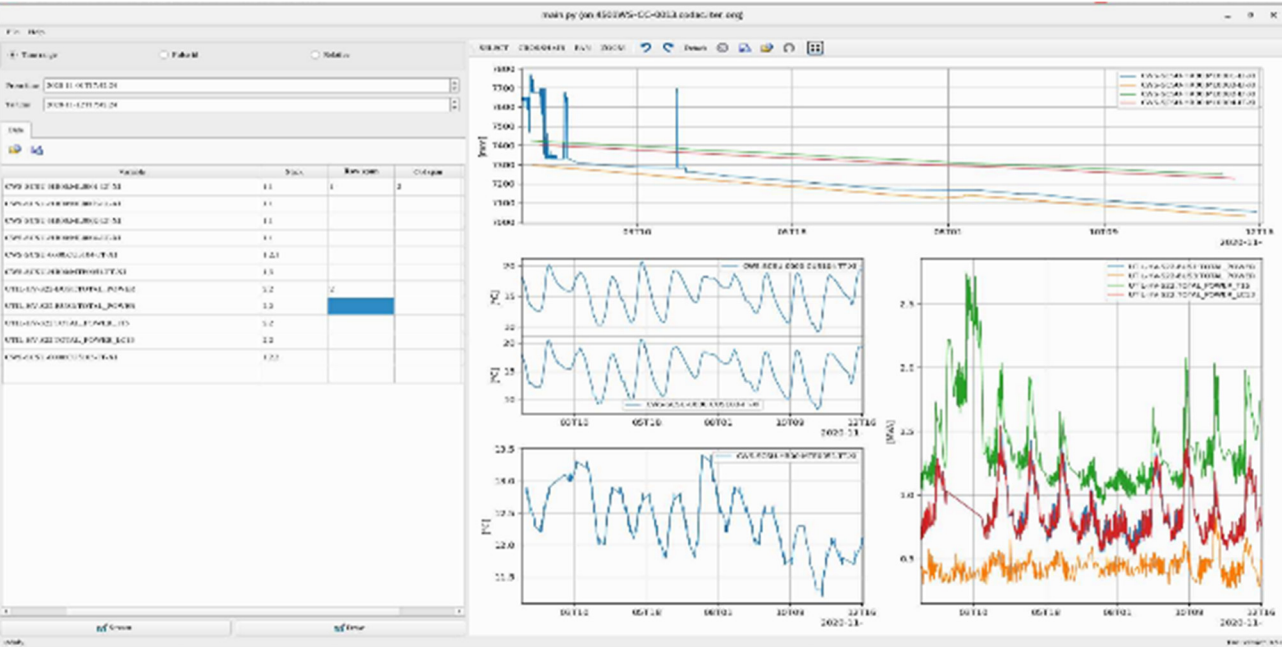

Figure 5: Layout of MINT (using Matplotlib back-end).

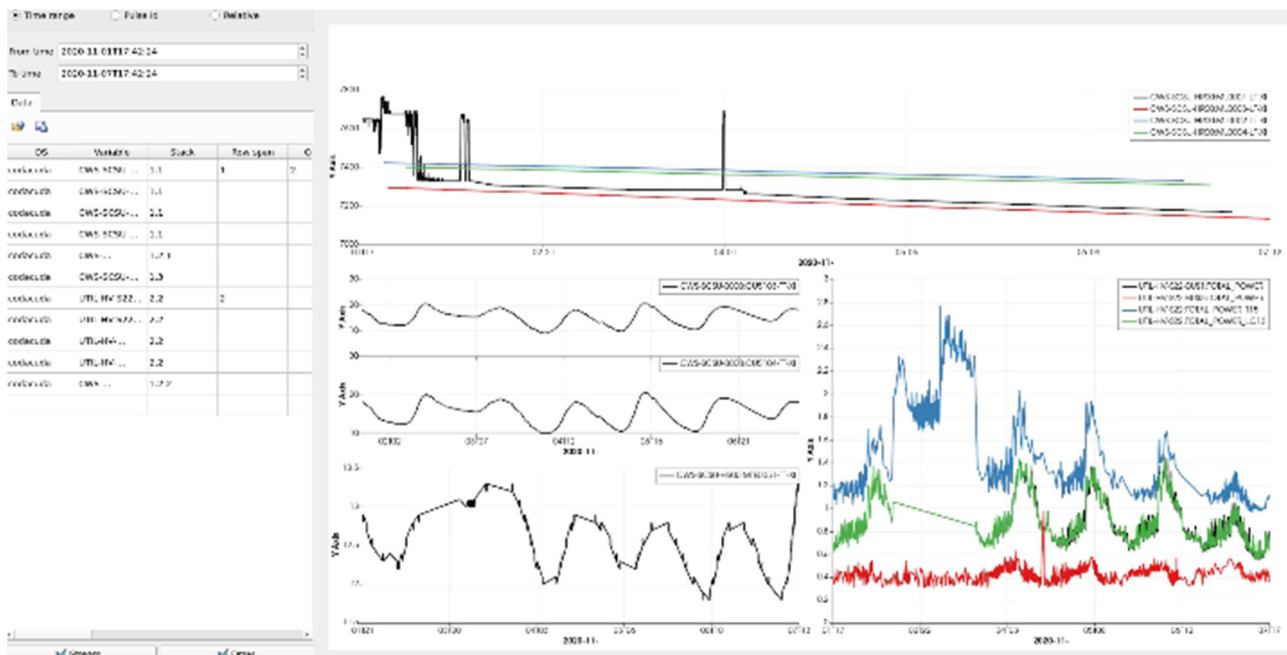

Figure 6: Layout of MINT (using VTK back-end).

## Next Steps

There are still important features to be implemented including:

- Extending the data processing to support the manipulation of multiple signals and support for user-defined functions
- Extending the ipyplotlib module to support new plot types such as surfaces, a 2-D slice of 3-D data chosen with a slider, histograms, etc.
- Implement a browsing plugin to search for variables and metadata to ease filling the table.

It is also important to note that the performance for this tool will be critical. If zooming is too slow, users will give up and seek alternatives. That's why one of the next big investments of effort will be to improve the data access layer.

## CONCLUSION

Good progress has been made on the development of a tool for data visualization. A lot has been learnt from the initial development experience and together with a more rigorous capture of the requirement this has provided a robust basis for subsequent development. The first version of the tool is now being actively used by the plant engineers (Cooling Water).

## ACKNOWLEDGEMENTS

We would like to thank all stakeholders Trevor Blackman, Laura De Frutos, Peter Des Vries, Fabienne Kazarian, Arthur Leveque, Victor Moncada, Marco Riva, Marc-Henri Sautenet, Mireille Schneider, Luca Zabeo and the management Mikyung Park, Anders Wallander, and Tim Luce for their support in this work.

The views and opinions expressed herein do not necessarily reflect those of the ITER Organization.

# AUTOMATED SCHEDULER SOFTWARE BASED ON METRO UI DESIGN FOR MACE TELESCOPE

Mahesh Punna, Sandhya Mohanan, Padmini Sridharan, Pradeep Chandra, Sagar Vijay Godambe  
BARC, Mumbai, India

## Abstract

MACE Scheduler software generates automated schedule for the observations of preloaded high energy gamma-ray sources. The paper presents the design of MACE Scheduler software covering; source rise/set time calculation algorithms; auto and manual schedule generation; various data visualizations provided for schedule and source visibility reports. The schedule generation for a specific period is automated using a filter workflow. The sources are selected for scheduling by processing the sources through a series of customizable user defined filters; source visibility filter, priority filter, priority resolution filter. The workflow provides flexibility to apply any user tailored filter criteria that can be loaded dynamically using XML schema. Loosely coupled design allowed decoupling the astronomical timing calculation algorithms from schedule preparation workflow. Scheduler provides metro UI based interface for source filtering workflow generating auto-schedule, updating the generated schedules. Tree-map visualization helped to represent hierarchical multi-dimensional schedule information for the selected date range. WPF flat UI control templates focused more on content than chrome.

## INTRODUCTION

Major Atmospheric Cherenkov Experiments (MACE) Telescope (Fig. 1) is a very high energy gamma-ray telescope set up by BARC, at Hanle, Ladakh, India for the study of gamma-ray emissions from various cosmic sources in the energy region of 20GeV-10TeV. The MACE

Figure 1: MACE Telescope.

Telescope Control System is a distributed control system which comprises of functionally diverse subsystems like Drive Control system, for moving the telescope towards specific sources at proper orientation; Mirror Alignment system, to focus the Cherenkov

light onto the camera; CAMERA system, which recognizes the onset of cosmic events of interest and records the signal acquired. It also consists of Sky Monitoring system, which quantifies the sky transparency level and checks the tracking accuracy of the telescope during observation; Data Archiving System (DAS), and Weather Monitoring system (WMS).

The MACE Operator console holds the responsibility for integrated control and monitoring of these subsystems to

conduct a successful observation run. Prior to the experiment an observation schedule selecting astronomical sources to be observed and the configuration of the various subsystems for the experiment is prepared by Astrophysicists.

The start-up sequence from the Operator console powers on the various subsystems in the required sequence and initialise the system and experiment configurations in each subsystem. This is done by running a sequence of commands (Fig. 2) from MACE Operator Console (OC), to bring the different subsystems to a ready state from where data acquisition can be started. These operation sequences are categorized into Initial run, Observation run, and Shut down run having associated pre-setup actions, experiment configuration, data acquisition and final shut down procedures respectively [1, 2]. The time required to carry out the initial run is accounted (X hours). The system automatically completes these activities and the Operator console starts the experiment X hours before the first observation.

## MACE SCHEDULER

The successful operation of the MACE Telescope for observing various high energy gamma celestial source by recording the Cherenkov events produced, highly depends on the schedule.

MACE Scheduler provides an interface to the Astrophysicists to generate observation schedule, which is required to streamline the observations of various sources with MACE telescope. A typical schedule contains 5-10 sources. It is the scheduler's task to create a realisable schedule that will then be used in the observations. The challenge is to select one of those possible schedules, which will lead to good results. The schedule file thus created consists of a set of different sources (astronomical) and their coordinates along with the time of observation. Scheduler software generates date-wise schedules and stores in a configured centralized location.

MACE OC loads the schedule file for the current date and picks one source at a time to conduct the Observation Run, wherein respective source co-ordinates are sent to the Drive Control System for positioning the telescope towards the source and data acquisition is done as per the time spec-

ified in the schedule. The schedule also chooses the experiment configuration to be loaded for each of the observation run.

### Design Basis

The scheduler software is designed to provide the following functionalities:

- It should provide facility to select the schedule duration, which can be planned for day, lunation, up to a year or any specified period
- It should provide default source list with default Azimuth and Zenith coordinates
- It should have a provision for manual schedule generation for the selected input configuration
- It should have a provision for selecting the visible astronomical sources to be observed
- The user should be able to automate the schedule preparation by using a filter set for selecting the sources
- It should provide various timing plots for Sun, Twilight, Moon Rise set times for deciding the dark period (the time span during which, there will be no background illumination from sun, moon, twilight) for observation
- It should provide report generation facility.

### Software Architecture

Scheduler software has been developed following layered architecture as shown in Fig. 3. Presentation layer handles user interface and implements custom controls, calendar controls, and tree map data visualization control. Application layer implements scheduler core modules like dark-period calculation and auto-scheduling controller and manual scheduling controllers. Algorithm layer implements rise and set time calculation algorithms for various celestial objects. Each layer defines an interface for the services it requires from the lower layer. The main aim of layered design [3] is the separation of concerns among the components. Application layer modules do not depend on lower layer concrete modules, instead they depend on the abstractions following Dependency Inversion principle. This helps to build loosely coupled software.

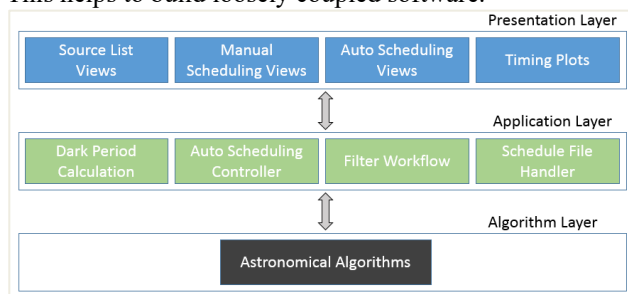

Figure 3: Software Architecture.

## SOFTWARE DESIGN

### Algorithms

The software implements the following astronomical algorithms [4, 5]:

- Calculating Rise/Set time for Sun, Moon and any custom source with defined coordinates
- Calculating Moon Phase
- Calculating the dark period for any day
- Calculating Azimuth and Zenith, given source coordinates and location

Astronomical algorithms are implemented following Adapter design pattern [6] (Fig. 4) and defines an algorithm interface for the application and makes it compatible with various algorithm implementations.

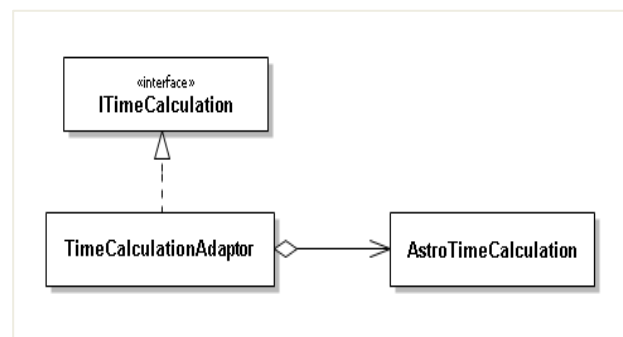

Figure 4: Adaptor Design Pattern for Astronomical Algorithms.

### Source List

The source list is organized into catalogues of various types (Optical, Gamma-ray etc.) and each source catalogue contains various source list with positional information (Right Ascension (RA) and Declination (DEC)) and priority. The source list data is stored in user configurable csv format. Source view provides the selected sources visibility information, polar view for Azimuth trend and Zenith trend plot for 24 hours of the selected day (Fig. 5). Selected source zenith trend plotted along with dark period helps to decide the observation period for the day.

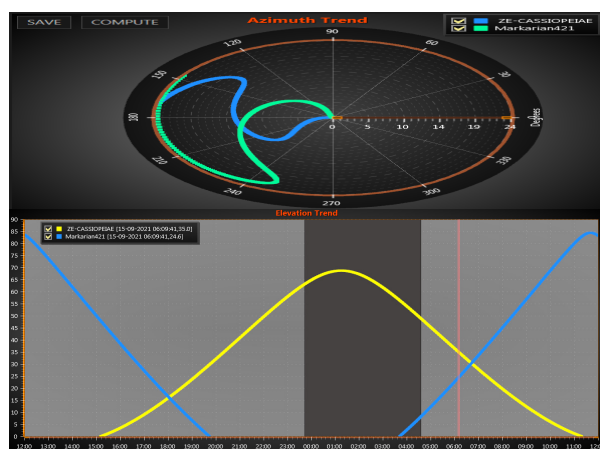

Figure 5: Selected source's azimuth and elevation trend along with dark period.

### Schedule Generation

The main responsibility of MACE Scheduler software is to enable the user to generate observation schedules for the

selected period and selected location. The software provides two modes for schedule generation; Auto, manual modes.

### Auto-Schedule Generation

Observation Schedule is automated by filtering and ordering the sources based on the user-defined criteria and scheduling the ordered sources as per the dark period window. Each source is configured to have a default scheduling period. Dark time available for the selected date is allotted to the ordered sources as per the source configured period.

The following are the steps for the auto-schedule generation.

1. **Input** Location coordinates (Latitude & Longitude), time zone, date selection, observation duration and source list are taken as input for auto-schedule generation
2. **Sources Selection** The sources are grouped into 4 categories; Optical (OP), Galactic (GA), Extra-Galactic (EG) and Positional (PO). The required source group or all groups or any user interested sources can be selected for scheduling
3. **Source Filtering** The sources are filtered and ordered from all the selected source list. To enable the user to control how the sources are filtered, a source reduction workflow has been created. The workflow projects intermediate filter results, enabling the user to see each filter output.

FilterContainer (Fig. 6) acts a Filter Factory that creates Filter Objects and builds filter workflow. Strategy Design Pattern helped to load the selected filters dynamically. The design adapts to new custom filters.

Figure 6: Filter Container.

The workflow consists of the following filters. Each filter takes input from previous filter and produces source list for the next filter input

- **Source Type Filter** The selected source list can further be filtered based on the source type (OP, GA, EG and PO)
- **Visibility Filter** Source observation is normally carried out during dark period. Hence the source should be visible within the dark period for the selected day. Rise/set time of previously filtered sources is calculated and checked if the source visible period overlaps with the dark time span. Thus, visibility filter produces a set of sources that can be observed during dark period.

- **Priority Filter** Each source is assigned a user-defined priority. Previously filtered sources will be ordered based on the priority. User can change the priority while building the workflow.
- **Priority Resolver** The same priority sources in the ordered source list can be resolved using a priority resolved criteria. Currently used criteria for resolving the priority is set time. The source that sets first is given more priority
- **Custom user filter** The workflow provides flexibility to apply any user tailored filter criteria. The user can define any customized filter and load it dynamically through structured XML schema as shown in Fig. 7.

For example, consider the following filter criteria:  
Source Azimuth > 50 and having 45 < Zenith < 90

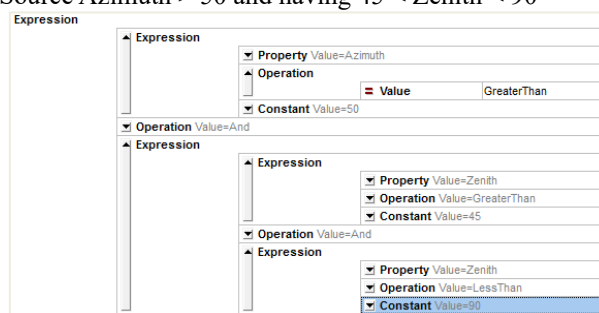

Figure 7: Custom Filter Expression.

Custom filters help to extend the software with various filter criteria depending on the requirements

- **Final Source List & Schedule Generation** The source list will be finally reduced to an ordered list for scheduling the observations depending on the Dark Period availability and a schedule for the selected day will be generated (Fig. 8)

Figure 8: Filter Workflow.

### Manual Schedule Generation

The software also provides manual mode for schedule generation. For the selected day, the visible sources having overlap with Dark Period are selected for scheduling. For the selected source, depending on the tracking mode (Wobble, On/Off), configuration is set. Rise Time plot (Fig. 9) displays Rise and Set timing for Sun, Twilight period, Moon and Dark Period. It also shows the selected source rise/set timings. The plot helps to properly schedule the sources as per the available dark time span. The software provides custom user control to select observation time span up to minute. Rise time plot shows scheduled/added observations

Figure 9: Rise set time plot.

The following Fig. 10 shows manual schedule generation UML sequence diagram [7].

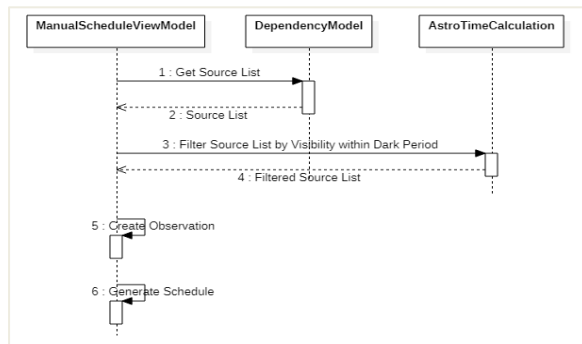

Figure 10: Manual Schedule Generation.

## Reports

The software provides different views for visualizing Sun, Moon, selected source visibility and schedule data. Schedule and visibility data can be exported to readable txt/excel formats. Visibility report (Fig. 11) contains dark period for the day and selected sources visibility for the selected date range.

NAME	01-09-2021	02-09-2021	03-09-2021
BLACK PERIOD	20:03-00:48	20:01-01:41	20:00-02:40
AL-ANDROMEDAE	23:21-04:04	23:17-04:00	23:13-03:56
BE-CASSIOPEIAE	00:20-03:10	00:16-03:06	00:12-03:02

Figure 11: Visibility report.

A schedule file contains the following information; Sources being observed, observation time span, dark time available, tracking mode information and configuration to be used. Schedule reports contain day-wise scheduled sources with the observation time span. Schedule information is shown in matrix layout, where each row contains date-wise scheduled sources. However, the matrix data is difficult to comprehend (Fig. 12) as the date range and number of sources observed increases.

10-09-2021	OP-ZE-CYGNI	08:41 09:11	GA-0FGLJ1958.1+2848	09:11 09:41	EG-BLLacertae	09:41 10:11

14-09-2021	OP-ZE-CYGNI	11:42 12:12				

Figure 12: Schedule Report.

To get better insight into the scheduling statistics tree map control (Fig. 13) has been developed. Tree map view [8] helps to flatten the hierarchical information and

presents multi-dimensional data. The view highlights the source has with highest scheduling period and positions it to the top left as indicated by the size of the block. For each source block, the date on which it got the highest schedule period is indicated by the size of date block. Color shows the dark period duration. The color intensity of a block is proportional to the dark period available to it.

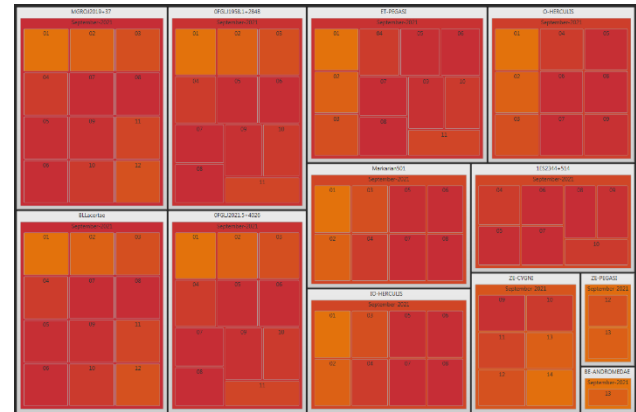

Figure 13: Schedule Info tree map visualization.

## Metro/Flat UX [9]

Scheduler user interface design has been developed following simple visual appearance, allowing the user to focus on content rather than chrome (colours, shadows etc.). Interface/custom control design has been inspired by Microsoft Design Language (MDL). It is also referred as Flat Design, which follows minimalistic approach using simple shapes, colours and icons for creating UI controls that are informative, thus avoiding the UI overload that comes from the visual effects. Flat UI design has been followed throughout the scheduler software.

## General Implementation

UI has been developed in WPF framework [10] and astronomy algorithms have been developed in C# following MVVM [11] architectural style, separating user interface logic from the application logic. Custom controls (ex: Custom Calendar control, auto schedule filter workflow control) are created by defining control templates to configure the control look and UX. Separating view logic from application logic helps to reduce coupling and improves application testability and maintainability. The following Fig. 14 shows the custom calendar control with orange markers to indicate if the schedule is prepared for that day.

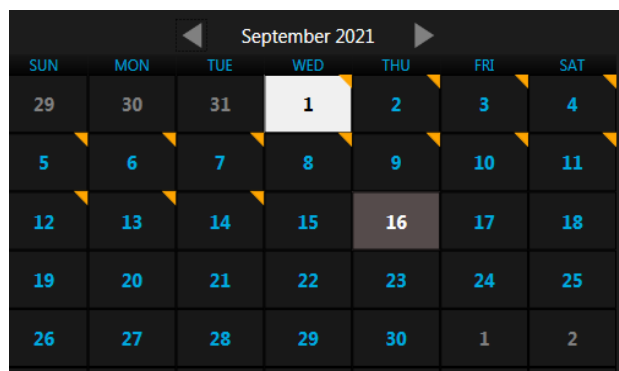

Figure 14: Custom calendar control.

## CONCLUSION

MACE Scheduler can automate the schedule generation through filter workflow for the selected date range and location. The software provides intuitive user interface for scheduling manual observations. The software consists of timing plots showing the available Dark Period and Sun, Moon, Selected Source's rise/set times, allowing the user to take a quick decision on schedule duration and time. The software design allows the scheduler extend to any custom developed astronomy algorithms. The software provides reports view using matrix form and tree map visualization for showing multi-dimensional schedule information. Schedule and Visibility information can be exported to readable format. MACE telescope has become fully operational in 2020 and scheduler has been used for preparing observations

## ACKNOWLEDGEMENTS

Authors would like to thank the colleagues from Astrophysical Sciences Division, BARC Mumbai for their suggestions and guidance.

# CONTROL SYSTEM MANAGEMENT AND DEPLOYMENT AT MAX IV

B. Bertrand\*, Á. Freitas, V. Hardion, MAX IV, Lund, Sweden

## Abstract

The control systems of big research facilities like synchrotron are composed of many different hardware and software parts. Deploying and maintaining such systems require proper workflows and tools. MAX IV has been using Ansible to manage and deploy its full control system, both software and infrastructure, for quite some time with great success. All required software (i.e. tango devices, GUIs...) used to be packaged as RPMs (Red Hat Package Manager) making deployment and dependencies management easy. Using RPMs brings many advantages (big community, well tested packages, stability) but also comes with a few drawbacks, mainly the dependency to the release cycle of the Operating System. The Python ecosystem is changing quickly and using recent modules can become challenging with RPMs. We have been investigating conda as an alternative package manager. Conda is a popular open-source package, dependency and environment management system. This paper will describe our workflow and experience working with both package managers.

## INTRODUCTION

The Controls & IT group, also called KITS, is responsible for the whole IT infrastructure at MAX IV. This includes everything from control system hardware and software to data storage, high performance computing, scientific software and information management systems. Within KITS, the Control System Software team manages all the software linked to the control system. With the accelerator and 16 beamlines, this represents more than 330 physical and virtual machines to configure and maintain. Ansible [1] was chosen for its simplicity of use as detailed in CONFIGURATION MANAGEMENT OF THE CONTROL SYSTEM [2] and is a great help to achieve this. The control system is made of many components that often have dependencies with each other: tango devices, controllers, GUIs. Building and being able to deploy each software individually without breaking another part is not straightforward. This requires some tools and is exactly why package managers were designed. One of their role is to keep track of dependencies between packages to ensure coherence and avoid conflicts. Using a package manager makes it easier to distribute, manage and update software.

## PACKAGE MANAGEMENT

### RPM

The RPM Package Manager [3] (RPM) is the package management system that runs on Red Hat Enterprise Linux, CentOS, and Fedora. As CentOS is the default Operating

System at MAX IV, using RPM to distribute internal software was an obvious choice.

RPM gives us access to a large numbers of high quality packages from the main CentOS repository and others like EPEL [4], the Extra Packages for Enterprise Linux. This provides solid foundation to build on and is one huge advantage of Operating System package managers.

**SPEC file** RPM creation is usually based on a SPEC file [5]. It is the recipe that rpmbuild uses to build an RPM. It contains metadata like the name of the package, version, license, as well as the instructions to build the software from source with all the required dependencies as seen in Fig. 1.

```
Summary:    Tango device for Linkam T96 heater
Name:       tangods-linkamt96
Version:    1.2.0
Release:    1%{?dist}.maxlab

```

Figure 1: RPM SPEC file (extract).

C++ projects are packaged using a SPEC file. RPM creation is handled by a GitLab CI [6] pipeline using maxpkg.

\* benjamin.bertrand@maxiv.lu.se

a MAX IV plugin to rpkg [7] for managing RPM packaging from a git repository.

**fpm** Most software at MAX IV are written in Python. *setup.py*, even if not recommended anymore [8], was the historical way to package a Python library or application with *setuptools* and is still widely used today. *fpm* [9] is a command-line program designed to help build packages. It can take different source types (directory, rubygem, python package...) and convert them to a target type, most common being "rpm" and "deb". Using *fpm* avoids having to write a SPEC file to create RPM. *fpm* can take the metadata required to build a package from the *setup.py* file.

```
fpm -s python -t rpm \
  --python-bin python3.6 \
  --rpm-dist el7 \
  -p results \
  --python-package-name-prefix python36 \
  --python-setup-py-arguments=--prefix=/usr \
  --no-python-downcase-dependencies \
  ${FPM_FLAGS} \
  --url $CI_PROJECT_URL --verbose .
```

Figure 2: Example of *fpm* command.

Figure 2 shows a typical command to create an RPM from a Python repository. It is automatically run by our Git-Lab CI pipeline. *fpm* takes the dependencies defined by *install\_requires* in the *setup.py* file and automatically adds the *python36* prefix to match the RPM naming convention. If a Python application had the following *install\_requires*=["*taurus*", "*PyYAML*", "*pytango*"], *fpm* would create a RPM with the dependencies *python36-aurus*, *python36-PyYAML* and *python36-pytango*. If there is a mismatch between the Python package and RPM name, it is possible to pass extra arguments using the *FPM\_FLAGS* variable and overwrite the RPM dependencies, i.e. *FPM\_FLAGS: '-no-python-dependencies -d python36-numpy,python36-dateutil'* could be used for a package depending on the *python-dateutil* library.

With the CentOS Project decision to shift its focus from CentOS Linux to CentOS Stream [10] and the uncertainty this created, migration to CentOS 8 was stopped. This forced us to remain on CentOS 7 and that started to create issues. CentOS is known for its stability, which is very important, but can become a problem when recent software are needed. Sardana [11] version 3 was very difficult to install as RPM due to the versions of the dependencies required. This is one of the reason we started to look at alternatives package managers like conda [12].

## Conda

Conda is an open-source package, dependency and environment management for any language. It is cross-platform and runs on Windows, macOS and Linux. By using anaconda compilers, binaries created with conda-build can run

on any modern Linux distribution. Being OS independent is an interesting feature that makes changing OS or migrating to a new one easier. With RPM, even when upgrading between two major releases of the same distribution, a rebuild of all packages is required. It's not the case with conda. The same package can be installed on CentOS 7 and 8 or even Debian.

Anaconda [13], the company behind conda provides some default channels with a large amount of packages. In the past years, conda-forge [14] became the de facto channel when using conda. Conda-forge is a community-led collection of recipes, build infrastructure and distributions for the conda package manager. It allows developers to automatically build recipe in a clean and repeatable way on Windows, Linux and macOS.

In 2021, the Tango community started to publish tango packages to conda-forge as mentioned in the THE TANGO CONTROLS COLLABORATION STATUS [15]. MAX IV also made available some packages that could be useful to the community like *dsconfig* or *svgsynoptic2*. Creating a recipe for conda-forge isn't very difficult but there is a review process done by volunteers that can take some time. For internal software we need a faster way to release packages and we deployed our own internal conda server based on Quetz [16].

Quetz is an open-source conda packages server. We use it to proxy external channels, like conda-forge, allowing conda packages to be installed without internet access. We also have some local channels to store packages created internally.

One complaint that people have about conda is that it can be slow. This is true when using large channels, and we even noticed a quite high memory usage (Fig. 3).

Figure 3: Sardana env creation with conda-forge.

The list of packages available in a channel is stored in a *repodata.json* file. It includes the description of all packages and their dependencies. That file needs to be downloaded and parsed to resolve an environment. The bigger that file, the more work for conda. As packages are never removed from a channel like conda-forge, the *repodata.json* file keeps growing. It is about 141MB today for the conda-forge linux-64 channel.

One way to improve performances is mamba [17], a re-implementation of conda in C++ for maximum efficiency. It was conceived as a drop-in replacement for conda, using libsolv for much faster dependency solving. Mamba is robust and fast (Fig. 4) but not 100% compatible with conda yet, especially for conda-env commands, meaning we couldn't rely on it for all operations.

Figure 4: Sardana env creation with mamba.

As conda performances depend on the channel size, we created our own local *mini-conda-forge* channel, a subset of conda-forge. Having a channel with only the packages we are interested in gives a big boost in performances, both in time and memory usage (Fig. 5). Using that channel, instead of conda-forge, solving an environment with sardana decreases the time from over 35 seconds to 1.4 seconds and memory usage from 1.2GB to only 45MB! The result is almost identical to using mamba. Note that those figures don't take into account the download of the repodata file, that was already cached, nor the download and installation of the packages.

Figure 5: Sardana env creation with mini-conda-forge.

To keep this channel up-to-date automatically, a GitLab CI pipeline is run on schedule every night. It downloads new packages, and their dependencies, from conda-forge and uploads them to mini-conda-forge. The packages to download are based on a list of environments we want to be able to install, that is defined in a text file (Fig. 6). Making new packages available only requires to update this packages specs file.

```
# We want to be able to install conda and mamba
conda
mamba
# Default packages for a sardana environment
python=3.9 sardana bitshuffle matplotlib spyder pytango taurus taurus_pyqtgraph h5py hdf5plugin icepap sockio
# lavue
python=3.9 lavue pytango h5py bitshuffle hdf5plugin
# silx
python=3.9 silx h5py bitshuffle hdf5plugin
# pymca
python=3.9 pymca matplotlib pyqt
```

Figure 6: Example of mini-conda-forge environments list.

Building a conda package requires a recipe, which is defined in a *meta.yaml* file, with the information needed to create the package. This is equivalent to the SPEC file for RPM. Figure 7 is a typical example of a pure Python package on conda-forge.

```
{% set name = "dsconfig" %}
{% set version = "1.6.0" %}

package:
  name: {{ name|lower }}
  version: {{ version }}

source:

```

Figure 7: conda-forge recipe.

To package software we develop internally we decided it was easier to make the conda recipe part of the source repository. This removes the need to have a second repository to maintain. Figure 8 shows an example.

conda-build provides a macro to parse the *setup.py* file. It can be used to get the version from that file as well as the runtime dependencies, making it easier to write and maintain the recipe.

Our GitLab CI pipeline template will automatically build and upload the conda package to our Quetz server if it detects a *recipe/meta.yaml* file in a repository.

## ANSIBLE

Ansible was chosen early at MAX IV as the solution to deploy and manage the control system.

## RPM Deployment

Ansible has a builtin *yum* module to manage packages with the *yum* package manager. This makes it easy to deploy RPM. For ease of use and consistency, a generic playbook was created to deploy internal software packages with RPM. The *packages\_stable* and *packages\_testing* variables define the list of packages to be deployed. Those variables are maintained in the Ansible inventory in the proper group or host variables file. The default version for each package is

```
{% set data = load_setup_py_data(setup_file='../setup.py',
from_recipe_dir=True) %}

package:
  name: tango_exporter
  version: {{ data.get('version') }}

source:
  path: ..

build:
  number: 0
  noarch: python
  script: {{ PYTHON }} -m pip install . -vv
  entry_points:
    - tango_exporter = tango_exporter:main

requirements:
  host:
    - pip
    - python >=3.6
  run:
    - python >=3.6
{% for dep in data['install_requires'] %}
    - {{ dep.lower() }}
{% endfor %}

test:
  imports:
    - tango_exporter
  requires:
    - pip
  commands:
    - pip check
    - tango_exporter --help

about:
  home: https://gitlab.maxiv.lu.se/kits-maxiv/app-maxiv-tangoexporter
  license: GPL-3.0-or-later
  license_file: ../LICENSE.txt
  summary: Prometheus exporter for a Tango control system.
```

Figure 8: local recipe.

centralized in the *all* group for consistency (Fig. 9a). Developers are encouraged to use this default version but can also pin it if needed or even use latest (Fig. 9b).

```
versions:
  python-aurus: 4.5.1-7.el7
  python-dsconfig: 1.4.0-1.el7
  python-facadedevice: 1.0.3.dev1-1.el7
  python-fandango: 14.3.0-1.el7
  python36-sdm: 1.6.1
  tangods-pathfixer: 1.5.7
  python-pyicepap: 2.8.1-1.el7
  python36-sherlock: 1.0.4

packages_stable:
  python-aurus: default
  python-dsconfig: default
  python-facadedevice: 0.9.0
  python-fandango: 10.9
  python36-sdm: default
  tangods-pathfixer: default
  python-pyicepap: default
  python36-sherlock: latest
```

(a) versions definition.

(b) packages definition.

Figure 9: RPM packages - Ansible inventory.

## Conda Deployment

Ansible doesn't have any builtin module to interact with conda. MAX IV has its own modules (Fig. 10) based on the ones developed by ESS [18].

- The *conda* module can install, update or remove conda packages. It works with a list of conda packages.
- The *conda\_env* module manages environment using an *environment.yml* file.

Mamba is used by default by the *conda* module but it's currently not compatible with the *conda\_env* one.

```
- name: install flask 2.0 and Python 3.9
  conda:
    name:
      - python=3.9
      - flask=2.0
    state: present
    environment: myapp

- name: create myenv environment
  conda_env:
    name: myenv
    state: present
    file: /tmp/environment.yml
```

(a) conda module.

(b) conda\_env module.

Figure 10: Ansible modules

Our *ans\_maxiv\_role\_conda* Ansible role installs and configures both conda and mamba. It can also be used to create a list of conda environments by setting the *conda\_envs* variable in the inventory. Conda environments are isolated by nature. You usually have to activate one to use it. To be transparent for the users, the role can create wrappers for command line applications. The wrapper is a simple script that activates the environment and runs the command from the env. Wrappers are deployed under */usr/local/bin*. Users don't have to know that the application they run is installed in a conda environment. Figs. 11 and 12 show how to define such an environment and the resulting wrapper.

```
conda_envs:
  - env_name: silx
    dependencies:
      - python=3.9
      - silx=0.15.1
    wrappers:
      - silx
```

Figure 11: conda\_envs definition.

```
#!/bin/bash

# Some cli need the env to be activated
source /opt/conda/etc/profile.d/conda.sh
conda activate silx

/opt/conda/envs/silx/bin/silx "$@"
```

Figure 12: /usr/local/bin/silx wrapper.

Conda is also used to deploy Sardana version 3. A specific Ansible role and playbook were developed to deploy it based on an *environment.yml* file. This format allows to define both conda and Python packages (installed with pip). The *yml* file is created from a template defined in the role and can be customized, to add extra packages, based on different variables in the inventory. Figure 13 shows an example of such a resulting environment. Wrappers are also installed under */usr/local/bin* for all sardana commands to make them globally available.

## CONCLUSION

Using a package manager to build, distribute and update software is a requirement in modern software development,

```
channels: [maxiv-kits, mini-conda-forge]
dependencies:
- pytango=9.3.3
- taurus=4.7.1
- taurus_pyqtgraph
- h5py
- hdf5plugin
- icepap=3.6.2
- sockio=0.15.0
- taurusgui-maxpeemenergy=0.2.2
- python=3.9
- sardana=3.1.2
- bitshuffle
- matplotlib
- spyder
- pytest
- pip
- pip:
  - --trusted-host repo.maxiv.lu.se
  - '-i http://repo.maxiv.lu.se/devpi/maxiv/prod'
  - taurusgui-scangui3==1.1.3
  - taurusgui-quickgui3==2.1.3
name: sardana
```

Figure 13: Sardana environment.

as git is for version control. There are different kinds of package managers that all have their strengths and weaknesses. RPM is by nature integrated with the OS. It's very stable and can be used to create systemd services for example. Conda is OS independent and creates isolated environments, avoiding the risk of dependencies conflicts, and giving more freedom in the packages that can be installed. Ansible, combined with RPM or conda, gives us a reliable and reproducible way to deploy and maintain the control system.

# EXPLORING ALTERNATIVES AND DESIGNING THE NEXT GENERATION OF REAL-TIME CONTROL SYSTEM FOR ASTRONOMICAL OBSERVATORIES

T. C. Shen\*, J. Sepulveda, ALMA Observatory, Santiago, Chile

P. Galeas, F. Huenupan, S. Carrasco, R. Augsburger, R. Seguel, U. de La Frontera, Temuco, Chile

## Abstract

The ALMA Observatory was inaugurated in 2013; after the first eight years of successful operation, obsolescence emerged in different areas. One of the most critical areas is the control bus of the hardware devices located in antennas, based on a customized version of CAN bus. Initial studies were performed to explore alternatives, and one of the candidates can be a solution based on EtherCAT technology. This paper compares the current architecture with a new proposal compatible with the existing hardware devices, providing the foundation for new subsystems associated with ALMA 2030 initiatives. The progress of a proof of concept is reported, which explores the possibility of embedding the existing ALMA monitor and control data structure into EtherCAT frames, using EtherCAT as the primary communication protocol to monitor and control hardware devices of ALMA telescope subsystems.

## INTRODUCTION

The ALMA Observatory was inaugurated in 2013; after the first eight years of successful operation, obsolescence emerged in different areas. One of the most critical areas is the control bus of the hardware devices located in antennas, based on a customized version of CAN bus. Initial studies were performed to explore alternatives, and one of the candidates can be a solution based on EtherCAT [1] technology. This paper compares the current architecture with a new proposal not only compatible with the existing hardware devices, but also provides the foundation for new subsystems associated with ALMA 2030 initiatives. This document reports the progress achieved in a proof of concept that explores the possibility to embed the ALMA monitor & control protocol into a EtherCAT protocol. The main goal of this phase is to obtain the technical assessment of the feasibility to implement the EtherCAT as the communication protocol to monitor and control hardware devices/controller in all the subsystems that comprises the ALMA telescope. This is a collaboration project between ALMA Observatory and the Universidad de La Frontera in the context of a QUIMAL fund (QUIMAL190009) [2], which is sponsored by Chilean National Agency for Research and Development (ANID). The main objective is to design, implement and evaluate an possible alternative of the existing antenna real time computer.

\* tshen@alma.cl

## THE ALMA DISTRIBUTED CONTROL SYSTEM

The ALMA control software is a distributed system that is divided into several subsystems, each focusing on different stages of the observation process. The subsystems provide software interfaces to transfer communication messages in a coordinated manner between them. Likewise, the control system is also responsible for coordinating, by means of events and/or command messages, all the activities involved in the different observation steps.

The main subsystems are Control, Correlator, Scheduling, Telescope Calibration, Executive and Archive. The software for each subsystem is implemented in one (or more) programming languages (C++, Java, Python) that support the ALMA common software (ACS) [3], CORBA-based framework. The official operating system is Red Hat Enterprise Linux Server release 7.6.

### *The Antenna Bus Master (ABM)*

The ABM is a dedicated real-time computer to monitor and control the antenna hardware devices. The purpose of this computer is to process low level messages from all antenna devices, using a particular implementation of the CAN communication protocol [4]. The scheme of monitor and control conducted by the ABM computer is accomplished with adoption of the ALMA Monitor Bus (AMB) specification. It is a particular ALMA protocol, based on a CAN bus, to communicate with hardware elements, which defines a unique master connected with several slaves in the same bus. The AMB specification promotes a configuration that converts the transaction of CAN messages in a deterministic communication of the command control messages. The master, in a timely manner, is the only agent on the bus that can sends messages and wait responses of the other elements involved in the CAN bus. Similarly, the ABM make uses of five independent ALMA Monitor Bus channels to communicate with the devices spread out in the antenna. In every channel the ABM real-time computer acts as the CAN master and antenna hardware devices are the slaves on the CAN bus.

### *Hardware Device Interface (AMBSI)*

The ALMA Monitor and Control Bus Interface (AMBSI) is a standard interface that defines, on the one side the physical connection of nodes on the bus, and on the other side, the application level protocol that nodes must conform to be monitored and controlled by a software control system. The AMBSI specification outlines that each ALMA device has

a node address (0-2030), a unique 64 bit serial number, the ALMA M&C bus (AMB) is a master/slave multi-drop serial bus. The ALMA specification is implemented in two standard interfaces, known as the ALMA Monitor and Control Standard Interface 1 & 2 (AMBSI1, AMBSI2). In addition, the standard also established that the low level protocol is Controller Area Network (CAN) serial bus operated in a master/slave mode by a dedicated bus master. The remote frame transmission request (RTR) is not used by the bus master to gather monitor data.

## Timing Event

The ALMA software infrastructure synchronizes the activities with the antennas by a common time base [5]. The time base definition is based on an electronic pulse signal with a period of 48 milliseconds, denominated as Time Event (TE) and absolute Gregorian time associated with each TE. The time system is provided by group of specialized hardware elements and software component denominated the Array Time. It is the main reference time for all machines connected in the ALMA system environment. This is a special coordination mechanism of the time that enables interactions between participants, in a time synchronized manner, according to a unique universal time provided by this dedicated time scheme. The coordination between different participants is performed by means of a time events.

The activities of monitor/control of hardware devices are completed in synchronization with the Time Events (TE). The Fig. 1 below shows a TE-related control/monitor command, the processing of this type control command may begin at the starts of every TE pulse. Any slave (hardware device) that receives a control command from the CAN master (ABM) must processes it in the first 24 ms of TE. In the same way, monitor commands are processed in a second window of 20 milliseconds of the 40 ms TE-window.

Figure 1: Time Event linked with control and monitor commands.

## THE PROPOSED DESIGN

The design take into account different parameters of open standards in control bus. The Table 1 shows the attributes of EtherCAT, CAN-Bus (CANOpen), RS-232, RS485 bus standards.

Different scenarios were analyzed for the observatory in the coming years, and these are the most relevant requirements and uses cases in the new control system:

- monitor and control of the existing hardware devices of the ALMA telescope.
- monitor and control of new hardware devices to be introduced mainly due to obsolescence problems.
- monitor and control of new hardware devices to be introduced by improvement and automation in the antenna remote recovery activities.
- monitor and control of new hardware devices of the ALMA 2030 developments.

Given the aforementioned scenarios, it was decided to explore a solution that could combine the EtherCAT, CANOpen and OPC UA protocols. The new design must be capable to combine, in the distributed control system, the different flavors of protocols and interfaces of existing design and also guarantee the future extension of the this new design. The resulting architecture must minimize the impact in the higher control software layer based on ACS. Additionally, the new design should provide a way to allow hardware engineers to be able to access the control bus for maintenance purposes, without the need to have the entire stack of control software up and running. This is an important aspect, because it prevent hardware and software engineers to work in parallel in different areas during the scarcely available technical time.

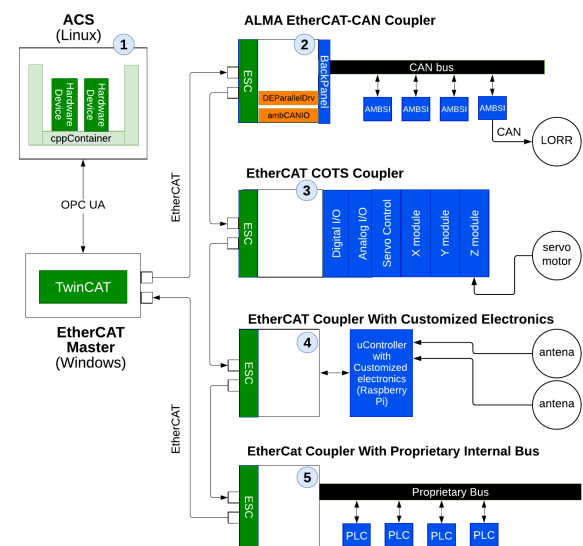

Figure 2: Control bus use cases in the coming years in ALMA.

The scenario or use cases displayed in the Fig. 2 are the following:

### ALMA Device Controller

The use case 1: The existing ABM's functionalities are separated into two parts. The first part represents the user-space (no real-time) to be executed in a Linux server with ACS. The existing "Hardware Device" components are adapted to use a OPC UA client driver, which sends (via Ethernet) messages to the second part (real-time) of the proposed system. Finally, an application must be developed to run within the IPC on top of TwinCAT 3, in order to verify

Table 1: Control Bus Comparison

	EtherCAT	CAN-Bus	RS232	RS485
Speed/Cable Length	100 Mbps at 100 m between two nodes for full speed	1 Mbps at 40 m from the start to end nodes	19,200 bps at 15 m from the start to end nodes	1 Mbps at 120 m from the start to end nodes
Cable Topology	Daisy Chain, Point-to-Point, Combination of the above	Daisy Chain	Point-to-Point	Daisy Chain, Point-to-Point
Max Number of Nodes	65535	128	1	32
Open Source Software	Yes	Most of CANOpen is proprietary	No predetermined protocol	No predetermined protocol
Required Hardware at master	Regular Ethernet adapter	PCI, USB, IC-type interface	PCI, USB, IC-type interface	PCI, USB, IC-type interface

the reception of the OPC UA messages and dispatch the message to the EtherCAT bus.

ALMA Current CAN Bus Device

The use case 2: This is the most important scenario for ALMA, because it tackles the current obsolescence problem of ABM real-time computers. In this scenario, the ACS components deployed in containers of the Linux Server running ACS will be able to communicate via EtherCAT with hardware devices connected to the CAN bus. The commands sent by hardware device component are processed by the OPC UA server and translated into EtherCAT frames, once the message is received by an EtherCAT-CAN coupler, it will convert the messages into the CAN messages compatible with the current implementation of ALMA control bus.

COTS EtherCAT Coupler with Digital, Analog I/O

The use case 3: This differentiates from use case 2 because it includes functionalities to interact with hardware module which are connected to the E-bus of the EtherCAT master or another EtherCAT coupler (i.e: Beckhoff ELK1100), for example, relays, temperature sensors, and servo motor driver, and encoder modules. This use case is the native usage of EtherCAT with hardware of the Beckhoff vendor.

EtherCAT Coupler with Customized Electronic

The use case 4: this scenario incorporates a development of EtherCAT slave that allow to attach customized functionalities implemented in a micro-controller.

EtherCAT Coupler Interfacing with a Sophisticate Subsystem

Use case 5: This is a generic case, in principle, it would be used to adapt future instruments with proprietary protocols to the EtherCAT infrastructure.

IMPLEMENTATION

It was decided to focus our effort and resource to demonstrate the use case 0 and use case 2, because their are the

most complicated and more likely scenario for the coming years. The use case 3 poses very low risks and is well demonstrated already in the industry. The use case 4 and use case 5 are variants of the use case 2.

The EtherCAT-CAN coupler will be implemented on top of a XMC4800 micro-controller [6], mainly because the XMC4800 has a MultiCAN controller that could support up to 5 independent CAN buses. Using the SDK of the XMC platform, the ALMA customized CAN protocol is implemented. The choice of the XMC4800 was heavily influenced by past experience of the team, but any micro-controller, FPGA with CAN transceivers could also be a possible alternative.

This design will cover all the different possible scenarios that ALMA may face in the next decade. It allows a coexistence of the different field bus protocols and a smooth transition of the existing architecture to a one that could also support ALMA2030 projects.

As shown in Fig. 3, the testing setup comprises the following equipment: i) a VM with ACS and TwinCAT development environment, ii) a Beckhoff CX2030 IPC EtherCAT master, iii) an Infineon XMC4800 microcontroller EtherCAT slave, iv) an ALMA AMBSI board representing hardware device of ALMA.

Figure 3: Physical connection of the test bench.

The objective is to reproduce the existing communication between of an ABM and a hardware devices through the AMBSI interface, but instead sending the customized CAN frame, the data structure will be embedded into a EtherCAT Service Data Object (SDO) frame.

The SDO protocol in EtherCAT allows to configure (write) and read back values of the Object Dictionary (OD) [7]. It establishes a client-server communication between the EtherCAT master (client) and a EtherCAT slave (server). The server (the XMC-4800 microcontroller) exposes an OD that defines the data structure and the related addresses for the SDO communication. If the amount of the entries of the OD requested by the client exceeds the maximum size, The SDO protocol will segment the data structures in multiples SDO frames. The simplified version of the OD was shown in Fig. 4.

5001:0	ALMA_CAN_Device1	RO	> 6 <
5001:01	AMBSI_SERIAL_NUMBER	RO	0x10e14f7e020800e7
5001:02	AMBIENT_TEMPERATURE	RO	0x10100038 (269484088)
5001:03	PROTOCOL_REV_LEVEL	RO	0x00000000 (0)
5001:04	CAN_ERROR	RO	0x000A0000 (655360)
5001:05	TRANS_NUM	RO	0x0000017F (383)
5001:06	SW_REV_LEVEL	RO	0x00020000 (131072)

Figure 4: Object dictionary.

In order to implement the use case 0 and use case 2, the data flow described in Fig. 5 was implemented, the main components are:

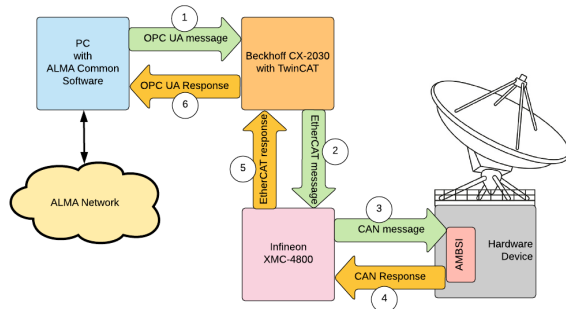

Figure 5: Data flow of the control bus.

## OPC UA Device Driver

The existing ALMA software uses Hardware Device Driver approach, in which according to the type of the hardware controller, the corresponding device driver must be developed. From the time being, the most common drivers are the AMBDevice driver and Ethernet Device Driver. For the OPC UA Device driver, the Ethernet Device Driver was extended, and additional OPC UA functionalities were added. As described in Fig. 6 This driver is essentially a OPC UA client that reads/writes data structure defined in OPC nodes hosted by an OPC server. For each entry of the OD, there is a specific node in the OPC server. Within this node, a sub-node is defined for receiving requests from the client (AMBMessage), additional the client subscribes itself to a second sub-node in order to receive the eventual response (AMBResponse).

## TwinCAT Application

A TwinCAT application was developed. This application is the EtherCAT master that runs inside of the Beckhoff CX2030. As shown in Fig. 7, the main objective of this application is to serves as a gateway between the OPC

Figure 6: Data flow: ACS to OPC UA section.

Figure 7: Data flow: TwinCAT to XMC section.

UA interface (external) and the EtherCAT bus (internal). This application implements the OPC UA server with a tree of nodes that represents the OD. Upon an reception of a OPC UA client request, the server queue the corresponding AMBMessage data structure in the control queue or monitor queue accordingly. Two messages processors (see Fig. 7) convert the AMBMessage into SDO data structure and dispatch this message in the EtherCAT bus. In addition, a state machine was implemented in order to separate the dispatch of messages in the queue according to the definition of the TE (see Fig. 1): in each windows of 48 ms, the first 24 ms are reserved for the control requests, and the next 20 ms are reserved for the monitor requests, then 4 ms of idle period follows. In each AMBMessage data structure, the address field maps the sub-index in the OD in a SDO frame. Once the EtherCAT slave (XMC4800) responds the SDO request, the data is extracted and filled inside of an AMBResponse structure which is updated in the corresponding OPC node in the tree of the OPC Server. The node trigger a notification to the OPC client (previously registered to this node) and the data is ready to be retrieved by the OPC client embedded in the OPC UA Device driver.

## EtherCAT Slave (XMC4800)

Inside of the micro-controller XMC4800, as shown in Fig. 8, an firmware is implemented to forward each SDO [8] request to the AMBSI card. Upon arrival of an SDO request, the firmware extract the relevant parameters and create an ALMA CAN frame and dispatch it in the CAN bus synchronously, once the respond of the AMBSI card returns, the XMC updates the content in its OD defined its EtherCAT Slave Controller (ESC), and the next EtherCAT frame will take care to bring it back to the EtherCAT master.

## RESULTS

The aforementioned implementation allow to generate an end-to-end communication between the logic layer inside of the ACS component and the hardware device located behind the AMBSI board by using COTS hardware and software.

Figure 8: Data flow: XMC to AMBSI section.

The performance tests consist on sending 10000 messages of 6 possible monitor points (see Fig. 4).

As shown in Fig. 9, we built a histogram with the time-of-fly of EtherCAT messages associated with six monitoring points (sub-index 01 to 06) of a hardware device in an antenna. We used the Wireshark software to analyze the TCP packets traffic between the CX2030 and the XMC4800. The packets were processes on a Jupyter notebook to calculate the time-of-fly of each EtherCAT packet. Given the limitations of the sampling time, it was not possible to obtain the EtherCAT propagation times. However, we estimated that it is in the order of nanoseconds, which is negligible for our measurement as the most time consuming in the communication process is related to the CAN communication between the XMC4800 and the AMBSI card. The mean values and the standard deviation of the times of each monitoring point were also calculated and shown in the Fig. 9. The monitor points defined in the OD at the sub-index 1,3, and 6 took 200  $\mu$ s in average, while the sub-index 2, 4, and 5 took 400  $\mu$ s in average. The differences between these two groups are because the implementation done inside of the XMC.

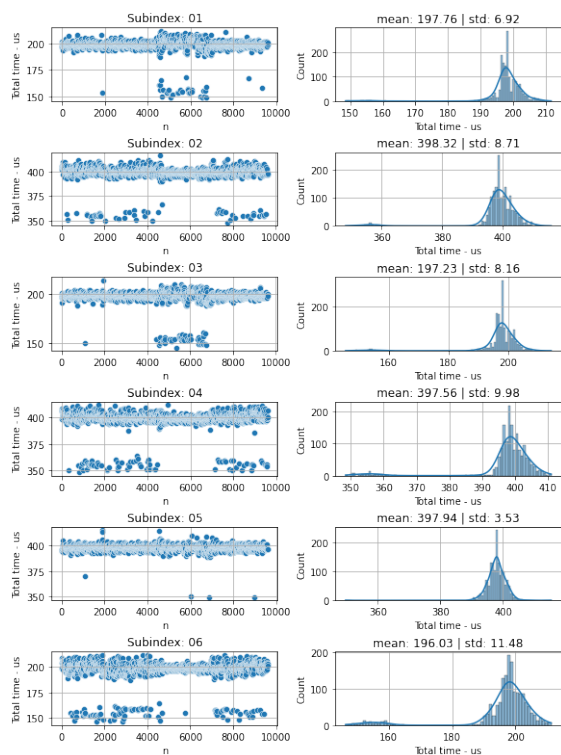

Figure 9: SDO traffic performance.

## CONCLUSION AND FUTURE WORKS

The proposed design demonstrated to be an viable alternative to replace the existing control bus in ALMA. Based on a open standard such as EtherCAT, it offers a ready to use framework to design the control interface of new hardware of the ALMA2030 projects, these hardware will behave as EtherCAT slaves. During the transition period, it was expected to have a combination of existing CAN based hardware device and EtherCAT based device in operation. This scenario can be supported by the design proposed in this paper. The feature of having an OPC UA interface between the Hardware Device Driver and the EtherCAT master (replacement of ABM) allows more efficient usage of the technical time between software engineers and hardware engineers in the observatory. The hardware engineers don't need to use the entire ALMA software for their specific hardware troubleshooting activities, which currently block the software testing activities of the software engineers in the observatory. Finally, the ALMA ICD definition fits perfectly in the concept of the OD dictated by the EtherCAT CoE, therefore minimal impact is expected in the Hardware Device layer.

Nevertheless, the SDO structure suits to the purposes of Monitoring and Control in the ALMA Control bus, we believe more performance can be achieved by using the PDO structure. The SDO can be reserved for setup commands, and low data rate monitoring points, such as temperature sensors. But the PDO structure can be reserved for high data rate monitoring points, such as, vibration sensors, encoders values, etc. The concept of using PDO is under analysis. Additionally, the TE infrastructure also needs to be improved in this design as same as the possibility to use the MultiCAN infrastructure of the XMC4800. Currently, only one of the possible six channels are being exploited.

# THE STATE OF CONTAINERIZATION IN CERN ACCELERATOR CONTROLS

R. Voirin\*, T. Oulevey, M. Vanden Eynden, CERN, Geneva, Switzerland

## Abstract

In industry, containers have dramatically changed the way system administrators deploy and manage applications. Developers are gradually switching from delivering monolithic applications to microservices. Using containerization solutions provides many advantages, such as: applications running in an isolated manner, decoupled from the operating system and its libraries; run-time dependencies, including access to persistent storage, are clearly declared. However, introducing these new techniques requires significant modifications of existing computing infrastructure as well as a cultural change. This contribution will explore practical use cases for containers and container orchestration within the CERN Accelerator Controls domain. We will explore challenges that have been arising in this field for the past two years and technical choices that we have made to tackle them. We will also outline the foreseen future developments.

## CONTAINERS IN CONTROLS SYSTEMS

### Containers in a Nutshell

Namespaces started being implemented in the Linux kernel in the 2000s. They provide isolation features on multiple levels: while the mount namespace prevents the process from accessing the rest of the Linux filesystem, the Process ID (PID) namespace creates an independent PID number space where the isolated process is given PID 1. There are eight namespaces in total: mount, PID, network, interprocess communication, time, time-sharing, user and cgroup.

Containers can be seen as industrialization of these isolation mechanisms, where the use of namespaces is concentrated in a single "containerization layer". A containerized application runs in an isolated manner, and requires its dependencies (libraries) to be embedded (Fig. 1).

The Open Container Initiative (OCI) provides three specifications defining how containerized applications are stored (the Image Format Specification), run (the Runtime Specification) and distributed (the Distribution Specification) [1].

### CERN Use Cases

Having been used in industry for some time already, it was clear that the benefits brought by containers could translate to CERN's Accelerator Control system. In April 2020, a project was launched to introduce containers to the Accelerator Controls landscape, in order to bring added value in a variety of areas.

Firstly, is the ability to decouple from the underlying host operating system and the flexibility this brings. At CERN,

Figure 1: Overview of a containerized software stack.

WinCC OA is used to manage many industrial SCADA systems [2]. Version 3.16 officially runs on CentOS 7 and Red Hat Enterprise Linux (RHEL) 7, while 3.18 will be made to run on Red Hat Enterprise Linux 8. Due to the massive number of WinCC OA applications, many of them for critical systems, migration from version 3.16 to 3.18 must be applied progressively. In contrast, the operating system upgrade from CentOS 7 to the next platform, will concern all hosts at once. For this case, deploying WinCC OA in containers will make it possible to run version 3.16 in a CentOS 7-based container, while the underlying host is already upgraded to RHEL 8 or a derivative.

Containerization is also becoming a *de facto* standard for companies to deliver software to their clients. For example, SourceGraph [3] is used in the CERN Controls software community to index code, quickly search through it, and create statistics. All deployment options for self-hosted instances of SourceGraph are container-based.

Other software are delivered in container images for simpler deployment and upgrades. This is the case for the Nexus Repository Manager, which is used at CERN to manage Python libraries [4].

Another advantage of container-based software delivery is the idempotent behaviour of a product between development and operational environments. This can translate into two ways: streamlining the creation of development and operational releases in a similar way, and easily providing a containerized test setup. For the LHC Orbit Feedback (OFB), the latter has proven cost and time effective. Instead of running many test instances on a dedicated server and configuring them via a database, it is possible to run a local containerized copy and feed it directly with the desired parameters.

Containers are also a way to distribute software that can easily run regardless of the Linux distribution, or even the

\* remi.voirin@cern.ch

operating system, as the Docker company created a desktop-oriented product for MacOS and Windows [5]. This has been successfully used for multiple PyQt training courses at CERN. It allows participants to run a particular Integrated Development Environment (IDE), faster, and with a lighter memory footprint than with a virtual machine.

Finally, there are many use cases where a clean and predictable software environment needs to be quickly generated, for instance in the context of Continuous Integration (CI) and Continuous Deployment (CD). A containerized environment is the most effective way to get this done.

### Issues and Limitations

The differences between a virtual machine and an OCI container can be summarized in the most simple terms by the fact that running a virtual machine implies executing a guest operating system (kernel). Nevertheless, even in the absence of a kernel, container images need to provide shared libraries and basic building blocks like libc in order for an application to run properly. These components are provided by a Linux distribution, which means that they need to be managed and kept up to date.

While most containers will run the CERN supported Linux distribution, external containerized applications are typically made with others like Alpine and Debian. Importing such containers is similar to adding computers running these alternative distributions in the Controls environment. It therefore implies a need to track and address security issues for a broader set of software.

Another issue is the growing complexity of the overall software stack. In case of unexplained latency, lost packets, or unexpected behavior, debugging involves more components to analyze. For instance, using containers implies having virtual interfaces to forward packets to them. Caping CPU and memory usage involves the use of cgroups, which need to be understood and mastered in the system administration team. Using additional debugging techniques may be required, like eBPF [6].

Containerization is efficient for scaling and reproducing software instances. However, when using proprietary software, careful attention needs to be given to ensure licensing terms are not violated.

### Required Components

In order to provide functional containerization in a Controls system, three components are required:

- a set of base images which will be used by developers as a foundation to package and deploy containerized software;
- a container registry to store images;
- a container engine, which is the piece of software made to run containers on hosts.

### BASE IMAGES

Base images are made to replicate a Controls host (technical console or server) running CERN CentOS 7 in a lighter fashion. The "acc\_cc7" base image is made from scratch

by setting up a few packages (e.g. the YUM or DNF package manager, a text editor) in a directory, then loading the directory into the OCI image format.

Figure 2: CERN CentOS 7 base images.

CERN Accelerator Controls images are configured to satisfy specific requirements, such as all Controls hosts running software from a set point in time called the "snapshot date" to give a homogeneous experience. This concept is applied within the container images thanks to a custom YUM repository configuration.

Images containing Java Development Kits (JDKs) are built on top of the acc\_cc7 base image in order to run Java-based software, either with the Oracle JDK 8 or with OpenJDK 11 (Fig. 2). This is done by running an Ansible playbook which sets up the relevant Java packages and their configuration files within a temporary container, then extracting the resulting directory structure and placing it in a clean container image.

The overall process is launched every day in a CI/CD pipeline. It is light enough such that when a new major version of RHEL/CentOS is available, minimum changes are required to update the image generation process.

## CONTAINER REGISTRY

Though the container registry can be described as simply as a repository of images, there are specific requirements that need to be satisfied. It must be able to store internal images (i.e. base images and containerized applications built on top), as well as images which come from public registries like the Docker Hub. Such images can not be pulled directly from Controls hosts, as they have no access to the Internet, hence the registry acts as curated proxy in this sense.

For security reasons, pushing images to the registry should be restricted to a specific process, while pulling should be done anonymously, allowing easy integration in automated software deployment processes. Following a market survey and discussing with other CERN teams working in this domain, it was decided to use the Harbor registry [7] (Fig. 3).

Harbor deployment is managed by the cloud infrastructure team within the IT Department. It fulfills the main functional requirements and it integrates well with additional security features such as an image validation policy and vulnerability scanning.

### Validation Policy and Vulnerability Scanning

The Controls computing infrastructure team has to find a balance between delivering a smooth experience to develop-

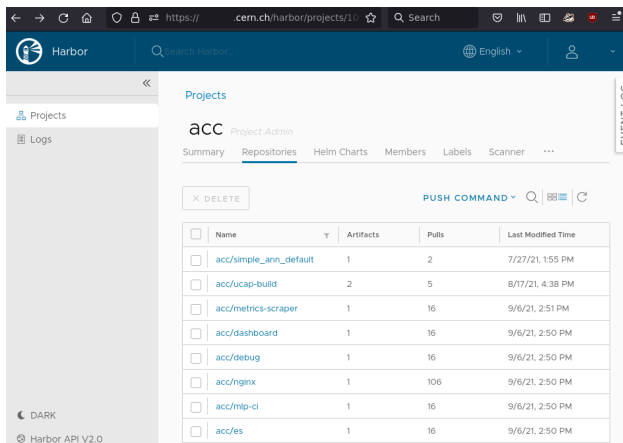

Figure 3: The Harbor registry.

Figure 5: Scan result of a critically vulnerable image.

ers, and at the same time, enforcing a security policy where only a certain set of images are allowed.

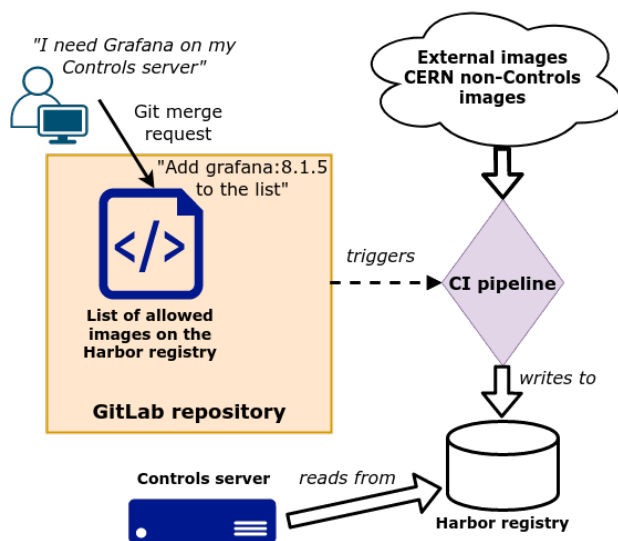

Figure 4: Image request and validation mechanism.

The Controls computing infrastructure team has designed a mechanism where developers can call a script which, after filling appropriate parameters, will create a merge request on a GitLab repository to add a new image to the Harbor-based Controls container registry (Fig. 4).

Only images that are relevant for operation are accepted. Later in the chain, vulnerability scanning is invoked from the Harbor registry, giving insight on the security status of the image. In 2021, Trivy [8] is the tool used to perform these scans (Fig. 5).

## CONTAINER ENGINE

When the use of containerization technologies exploded in the 2010s, Docker was the default choice for a container engine. Since then, the company behind Docker has adapted its business model, whereby the use of some products need to be paid for [9]. This change in policy, combined with the

potential for a sudden price increase, raises concerns when it comes to choosing a container engine for Controls, that must remain stable over the course of a full LHC Run (e.g. 5 years).

Docker revolves around a UNIX daemon running as root. It creates an additional attack surface on every Controls host where it would be deployed, and also consumes some RAM even when no container is launched. It becomes a single point of failure where containers are children of this process, and in case of any issues, they become orphans (PID 1 becomes the parent).

In the meantime, OCI alternatives have emerged, like Podman [10]. This software is supported by Red Hat and is included in the RHEL distribution and its derivatives.

Podman does not require a daemon, which addresses the problems stated above. Being daemonless allows easy integration with LUMENS, the Controls tool to manage and run user processes. With only slight adjustments, it is possible to treat container startup similarly to any other systemd service.

Podman can be configured to run rootless containers, which means that they run completely within the scope of a UNIX account. This provides an increased level of security and practicality, as root may not be involved at all.

## Rootless Containers

Even if all the required components are present (i.e. a recent enough Linux kernel supporting namespaces and the container engine to use them), some configuration is still required to enable rootless containers. First, user namespaces need be enabled. This is done thanks to the `max_user_namespaces` kernel parameter, which is set to 0 by default. A high enough value needs to be set to accommodate as many containers as a Controls host can support. At CERN, this is set to 8192 giving room to run a few hundred containers.

During the daily Ansible run, which enforces the general configuration on Controls hosts, the list of users who can run rootless containers will be extracted from LDAP. This list is then written in the `/etc/subuid` and `/etc/subgid`

files in the proper format: <username>:<start of subuid range>:<number of subuids>. To avoid collisions, subuids and subuids are calculated by shifting the user ID 8 bits to the left, and leaving the last 11 bits for subuids and subuids (Table 1). Therefore, the number of subuids and subuids is constant for all users:  $2^{11} - 1 = 2047$ .

Table 1: Example of subuid range for a given UID

User ID	Beginning of range	End of range
1000	1000 << 11 = 2048000	2050047

Finally, user-writable directories in /opt are created to store images, containers and their metadata. This is done by again taking the list of relevant users in LDAP, then making sure these directories exist for each one of them with proper Ansible tasks.

## CONTAINER ORCHESTRATION AND THE FUTURE OF THE ACCELERATOR DATA CENTER

### *Moving Away from Bare Metal*

The operation of the CERN Accelerator complex relies on a dedicated data center that was put in operation for the LHC start-up in 2008. A total of about 400 high-availability servers are used for the operation of critical LHC infrastructure systems such as Cryogenics as well as for all systems required for beam operation.

Over the years, this critical infrastructure remained as a 100% bare metal facility. Consequently, each process required for the operation of the CERN Accelerator complex runs on a dedicated server with a fixed IP address. So far this infrastructure offered excellent availability figures, however, it is clear that it can be optimized to make better usage of the overall computing power and to be more agile in terms of hardware maintenance effort (the current annual system administration effort takes up to 4 days). This is where virtualization and container orchestration technologies enter the game.

### *Relevance of Container Orchestration in Controls*

A simple way to summarize container orchestration is that instead of abstracting a single computer, an entire computing infrastructure is abstracted. An orchestrator takes care of the placement, scheduling, scaling, failover and health monitoring of containers. It also provides an API to interact with it, and accepts input with declarative configuration (generally in YAML format).

Stateless web services are one of the best use cases for orchestrated environments as they benefit from horizontal scalability, redundancy, and load balancing techniques without manual configuration of additional software like HAProxy and nginx.

Control systems are usually made of very diverse hardware and software with variety of monitoring and software

deployment methods. Since it is not feasible for Controls infrastructure to be entirely deployed in orchestrated containers, it means that multiple deployment and mechanisms must be maintained, resulting in a growing stack and overall, a more diverse and complex infrastructure to manage.

Another point of concern is related to security: lots of institutions prevent their Control systems from directly accessing the Internet. It means that the orchestrator has to be physically deployed on-site, and managed by a local team. While deploying software on orchestrators is convenient and eases developers' lives, the underlying infrastructure is quite complex. It implies dedicating additional time to maintain it, increasing total costs, unless orchestrated containers completely replace the legacy stack.

Finally, one of the best selling points for container orchestration in industry is complete scalability. When a company relies on microservices that need to be replicated to manage sudden load increases, and for which the computing power can be rented from one of the big cloud providers, it is easy to understand the interest in this technology. Benefits are less apparent when servers have to be physically provisioned on site (i.e. they have a fixed cost), and that computing resource don't need to be regularly redistributed to different applications over time.

### *Previous Studies*

There were two previous attempts at evaluating container orchestration for CERN Accelerator Controls in the late 2010s.

In 2018, the LHC Operations software team attempted to set up Kubernetes clusters to measure the performance of the LHC Coupling Analysis Service in containers [11]. Despite the use of infrastructure as code with Ansible, the complexity of deploying Kubernetes clusters in an environment without Internet connectivity was clearly highlighted.

Between 2018 and 2019, a study took place in the Accelerator Controls Group to evaluate container orchestration in a specific context, including the use of Nexus as an image registry, and creation of a proof-of-concept of base image. The conclusion, was that in-house deployment of Kubernetes was dismissed, due to human resources considerations and incompatibility with the accelerator schedule. Major Kubernetes versions were released every three months, whereas some Control system upgrades cannot be scheduled to take place more often than once per year. Upgrading Kubernetes on an annual basis could be quite risky, representing giant leaps across multiple versions.

### *CERN IT Container Orchestration Infrastructure*

Outside of Controls, OpenStack is used as the backbone of the CERN IT data center since 2012. The IT container deployment platform is based on OpenStack technology, together with an open-source component called Magnum [12]. Magnum is an Openstack API service developed by the OpenStack Container Team, with numerous patches from CERN contributors. It allows to run orchestrators such as Docker Swarm or Kubernetes. This section will give more

details on the Kubernetes use case, which is the main orchestrator in use. Nevertheless, it is important to note that Magnum templates can be added for different orchestrators, without changing the underlying architecture and hardware.

CERN OpenStack [13] offers a self-service solution to get an orchestrator running in the private cloud. CERN users can request a cluster with various storage, compute (CPU, GPU) or traffic routing options. On the storage front, CERN offers support for CephFS [14], CVMFS [15] and EOS [16], which are quite different from industry standards.

Magnum can spawn a cluster on virtual machines or the bare metal infrastructure thanks to the integration with other OpenStack APIs. Once created, CERN users have full control on their clusters and can use industry standard tools to access the Kubernetes APIs and deploy their applications. Around 650 clusters are running at CERN [17], using around 13,000 cores, 30 TB of RAM and more than 150 PB of local storage. Under the hood, the operating system is Fedora CoreOS, which is an automatically-updating, minimal operating system for running containerized workloads securely and at scale.

Helm [18] is a package manager for Kubernetes and gives users the ability to deploy existing sets of containers with almost no code or knowledge of the underlying infrastructure. Users are encouraged to store and deploy their applications using the CERN internal repository.

For monitoring, the IT Department largely relies on Prometheus [19] for gathering cluster metrics, which is provided by default. Users can also add their own custom metrics.

This paper wouldn't be complete without a mention of the HashiCorp product, Nomad [20]. Nomad is a modern, easy to install and lightweight workload scheduler. By creating a pool of compute, storage, and networking, Nomad can decide where it's most efficient to run tasks. The deployment consists of a single binary and the built-in task drivers plug-in allows to run all sorts of workloads to also bring orchestration benefits to existing services. A few teams in the IT Department have put in place self-managed solutions based on the open source version of Nomad.

As shown in this section, container orchestration is a complex subject and requires interactions with a lot of existing IT infrastructure components. The investment to have something working in an environment that spans servers, networks, storage and development processes is very challenging for small teams.

### *Container Orchestration and Accelerator Data Center Management*

In 2021, service continuity and recovery is considered as a high-priority topic with the CERN accelerator domain. One of the means to achieve this from the computing infrastructure perspective, is to allow critical services to easily recover, by starting them from a different data center.

Accelerator Controls back-end services are provided by around 400 servers in a single location. IP networks are

physically segmented in the data center, no anycast range is available, and enabling routing protocols up to the host isn't available. Storage is also provided by NFS servers that are single points of failure.

Prior to introducing technical solutions for computing service continuity and flexible data center management, it will be required to invest in an evolution of the network infrastructure, as well as deploying scalable storage.

The hardware team has identified: key servers to physically duplicate, required rack space, power consumption, and expected recovery times from daily backups. It was also crucial to focus on logical aspects and how services and data can be transferred, or kept in a working state, when moving from one data center to another.

Virtualization and container orchestration were analyzed (Fig. 6). To sum up, all these technologies solve the same problem which is, providing service continuity in the case of a catastrophic event in a data center. They also enable the hardware team to manage servers in a more generic way, by looking at a global set of systems instead of individual treatment for each of them. Thanks to virtualization and container orchestration, physical computing resources can also be shared, using a logical split for different use cases. Currently, a team requiring back-end resources needs to ask for a full server.

While orchestrators provide APIs to deploy applications and offer features like load-balancing and autoscaling, they can only be used to host cloud-ready applications. Currently, only a few use cases of specific Controls sub-systems are ready e.g. the Machine Learning Platform (MLP) [21] and the Unified Controls Acquisition and Processing (UCAP). Stateless web services could be easily transferred as well. However, many Controls applications would need significant architectural changes. Also, one third of Accelerator data center servers are dedicated to running WinCC OA back-ends to control SCADA systems, and this specific software won't be ready for orchestration for some years to come.

From the development and deployment perspective, CI/CD integration is better with orchestrators, but they imply rethinking process deployment and monitoring, currently done using LUMENS. CI/CD integration would be the same between current servers and potential virtual machines.

Kubernetes, as provided by the CERN IT Department, runs as a proof-of-concept. It would need further refinements in order to run mission critical applications, such as the ability to run multiple cluster masters to mitigate the impact of localized hardware failure. Currently, if one server fails, orchestrated applications still run but can't be easily stopped or restarted. Other orchestrators like OpenShift and Nomad can be deployed at an additional cost, as training / consultancy for the system administration team would be needed in order to deploy an optimal setup.

Container orchestration will not avoid the fate of non-cloud-ready applications in the case of a disaster in the CERN Accelerator data center. Given the large number of use cases that cannot be orchestrated in the foreseeable future, flexibility should come with the use of virtual ma-

Figure 6: Summary of options for computing service continuity and flexible data center management.

chines, for which floating IPs will allow services to quickly continue in a second data center.

## CONCLUSION

Containerization applies to different concepts and can be used on two different scales: plain containerization (by deploying on the current hardware and system stack), and container orchestration (by generically dedicating computing power to it).

At CERN, plain containerization is in place with fully functional base images, a container registry to store images, as well as a container engine configured to run rootless containers. It is used for operation and is fully supported.

Orchestration is deployed as a proof-of-concept, with software infrastructure provided by the IT Department, but it is currently not ready to run operational services. Introducing container orchestration on a massive scale implies a full review of software development practices. It can be used as a way to manage a data center in a more flexible manner, provided that the necessary techniques reach a critical mass adoption.

## ACKNOWLEDGEMENTS

The author expresses his sincere appreciation to Karim Ben Othman for helping set up containerization blocks and writing effective Python libraries.

The author thanks Frank Locci for his work on integrating Podman containers in LUMENS, as well as Steve Traylen for providing a solution for management of subuids and subgids.

# KUBERNETES FOR EPICS IOCs

G. Knap, T. Cobb, Y. Moazzam, U. Pedersen, C. Reynolds  
Diamond Light Source, Oxfordshire, UK

## Abstract

EPICS [1] IOCs at Diamond Light Source (DLS) [2] are built, deployed, and managed by a set of in-house tools that were implemented 15 years ago. This paper will detail a proof of concept to demonstrate replacing these legacy tools and processes with modern industry standards.

IOCs are packaged in containers with their unique dependencies included.

Container orchestration for all beamlines in the facility is provided through a central Kubernetes cluster. The cluster has remote nodes dedicated to each beamline that host IOCs on the beamline networks.

All source, images and individual IOC configurations are held in repositories. Build and deployment to the production registries is handled by continuous integration.

Development containers provide a portable development environment for maintaining and testing IOC code.

## INTRODUCTION

The approach presented here has 5 main themes:

1. **Containers:** package each IOC with its dependencies and execute it in a lightweight virtual environment. [3]
2. **Kubernetes:** centrally orchestrates all IOCs at the facility [4].
3. **Helm Charts:** deploy IOCs into Kubernetes and provide version management [5].
4. **Repositories:** Source, container and Helm repositories hold all of the assets required to define a beamline's IOCs.
5. **Continuous Integration:** source repositories automatically build containers, Helm charts and deliver them to package repositories.

An initial proof of concept (POC) has been implemented at DLS on the test beamline BL45P. All the source code for the proof of concept, plus documentation and tutorials can be found in the GitHub organization epics-containers [6].

## SCOPE

The POC initially targets Linux IOCs. This includes IOCs that communicate with their associated devices over the network, as well as those that connect to local devices through USB, PCIe etc. It does not include provision for Operator Interfaces (OPIs) as these vary greatly between facilities. Future plans include:

1. Support OPIs by having a 2nd container for each IOC instance that serves OPI files over HTTP.

2. Supporting RTEMS hard IOCs: using a containerised developer environment shared with soft IOCs.
3. Support Windows IOC development through a similar approach to RTEMS.

## CONTAINERS

A class of IOCs that connect to a particular class of device will all share identical binaries and library dependencies; they will differ only in their start-up script and EPICS database. Thus containerized IOCs may be represented as follows:

1. **Generic IOC:** A container image for all IOCs that will connect to a class of device.
2. **IOC Instance:** a Generic IOC image plus unique instance configuration. Typically the configuration is a single start-up script only.

This approach means that the number of container images is kept reasonably low and they are easier to manage.

## Image Layering

Container images are typically built by layering on top of existing images.

For the POC, an image hierarchy is used to improve maintainability as shown in Fig. 1 below.

Figure 1: Image hierarchy for the generic IOCs in the current proof of concept.

EPICS base [7] and essential tools are compiled inside one image; the most commonly used support modules (primarily Asyn [8]) and the AreaDetector [9] framework also have their own images. Generic IOC images are then

leaves in the hierarchy and are based upon the appropriate dependencies.

Images also have internal layering and every layer is shared between all instances of IOCs, both in image repositories and at runtime. Fig. 2 shows an example of this internal layering.

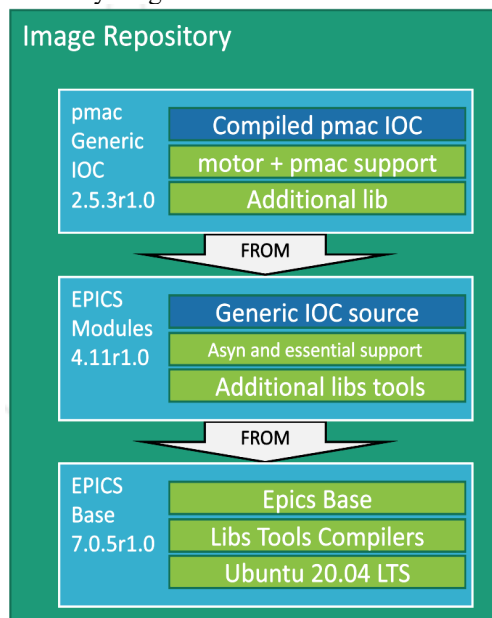

Figure 2: Example of the layered nature of a container image for the pmac motor controller generic IOC.

### Developer Container

To save on resources at runtime, all images are built using a staged Dockerfile [10]. There are two targets: a developer target which includes all of the compilers and tools used to build the runtime assets; and a runtime target containing the minimum assets to run the generic IOC.

The developer targets are used to provide an environment for developers to compile and debug the IOC and its dependent support modules. This provides a portable development environment and means there is no need to replicate the tool chain directly on developer workstations.

## KUBERNETES

A central Kubernetes cluster is used to orchestrate the IOC instances for all beamlines in the facility. It provides the following functionality that is typically handled by separate tools:

- Auto start IOCs when servers come up
- Manually Start and Stop IOCs
- Monitor IOC status and versions
- Deploy versions of IOCs to the beamline
- Roll back to a previous IOC version
- Allocate the server which runs an IOC
- View the current log
- View historical logs (via graylog at DLS)
- Connect to an IOC and interact with its shell
- Debug an IOC (by starting a bash shell inside its container)

## Cluster Topology

A single multi-tenant central cluster runs all of the worker nodes. This provides centralized management of all beamlines and other services. The High Availability (HA) control plane has 3 virtual servers distributed across 3 physical servers.

Each beamline has its own physical servers that are configured as remote worker nodes to the central cluster. This means that:

1. IOC instances are close to the hardware that they communicate with, avoiding network bottlenecks. This is important for high bandwidth IOCs such as area detectors.
2. IOC instances may be given affinity to a specific server and communicate directly with hardware connected to that server (e.g. a USB device)
3. IOC instances reside on the same subnet as the beamline's Channel Access (CA) clients and any network attached devices. This is a requirement for CA and some network attached devices (see below).

Each beamline has its own Kubernetes namespace and user id in which all the IOC instances will run. This provides isolation between the beamlines.

## Container Networking

Containers use namespaces to isolate their use of system resources. This is an important feature for building reliable, scalable and secure applications. However, EPICS IOCs rely on network protocols that may not suit network isolation because they do not easily pass through Network Address Translation (NAT). For this reason the POC foregoes virtual networks and uses the native networking of the host server.

Channel Access (CA) and pvAccess (PVA) are the primary protocols for communication between IOCs and clients. Both protocols require a broadcast in order to establish initial communication. The broadcast does not work via NAT to a virtual LAN.

Other protocols between IOCs and devices had issues with virtual networks. e.g. GigE Vision Stream Protocol (GVSP) establishes a connection by passing an IP address and port number in the application layer and therefore does not pass through a NAT.

Workarounds to the protocol issues were investigated on a case by case basis but it became clear that the only reliable solution was to use native networking within a single subnet. This is a slight concession to security, but is no worse than traditional IOC deployment. All other namespaces are applied to IOC containers and they are isolated from the host in all respects except network.

## HELM

The POC supplies a Helm Chart Library that describes all of the Kubernetes resources required to deploy an IOC instance to a beamline. Each Beamline has a source repository that specifies a Helm Chart for each of its IOC instances. The beamline source need only refer to the

Library and supply a few parameters to define the unique properties of the IOC instance – most notably its start-up script. The Library has templates for the following resources:

1. A Deployment [11] which makes sure 1 instance of the IOC Pod is always running.
2. The Pod [12] is described within the Deployment YAML. It includes a reference to the Generic IOC image it uses to launch the container.
3. A ConfigMap [13] which is mounted as a folder containing the unique configuration for the IOC instance. This typically contains only a start-up script.
4. A Persistent Volume Claim [14] which is mounted to provide persistent storage across IOC restarts and upgrades. This is used to hold autosave data.
5. Note that there is no Kubernetes Service [15] associated with the IOC since it uses native networking and is addressed via the host's IP address directly.

Helm command line functions are used to deploy IOC instances to a cluster and manage multiple versions of IOCs within the cluster.

Helm charts may be stored in a registry. For the POC the registry is provided by the epics-containers GitHub organization. New versions of IOC Helm charts are released to the registry and then deployed from it. Fig. 3 demonstrates this release process.

## REPOSITORIES

All of the assets required to manage a set of IOCs for a beamline are held in repositories. Thus all version control is done via these repositories and no shared file-systems are required. The classes of repository are as follows:

1. **Beamline Source:** (1 per beamline) holds the source for Helm charts for each IOC instance. Also hosts the continuous integration (CI) steps

to generate Helm charts and publish them to the Helm repository.

2. **Container Image Source:** (1 per Generic IOC) holds the Dockerfile that describes the contents of a Generic IOC. Also hosts the CI to generate an image from the Dockerfile and publish to the image repository.
3. **Helm Repository:** (1 per IOC Instance) holds the published IOC Instance Helm Charts ready for deployment to Kubernetes.
4. **Image Repository:** (1 per Generic IOC) holds the Generic IOC container images and their dependencies.

## CONTINUOUS INTEGRATION

All published assets in this process are generated via CI (see Repositories above). Every published asset has its own version number and its own source repository. When releasing an asset the developer will version tag the source repository. This causes the CI to build the source, publish the result and tag it with the same version number.

The POC uses GitHub Actions [16] to implement its CI and publishes assets to GitHub Packages [17]. However, during development GitLab CI [18] and Google Container Registry [19] were also tested.

## CONCLUSION

The POC demonstrates that it is possible to deploy and manage IOCs for a beamline using only standard open source tools such as Kubernetes, Helm and GitHub. The test beamline BL45P has successfully deployed its IOCs using this approach and required no custom software or scripts to do so.

DLS will continue to develop this approach as a possible site wide solution. The epics-containers GitHub organization will be continuously updated to track progress. The organization is also available for contribution from EPICS developers at other sites.

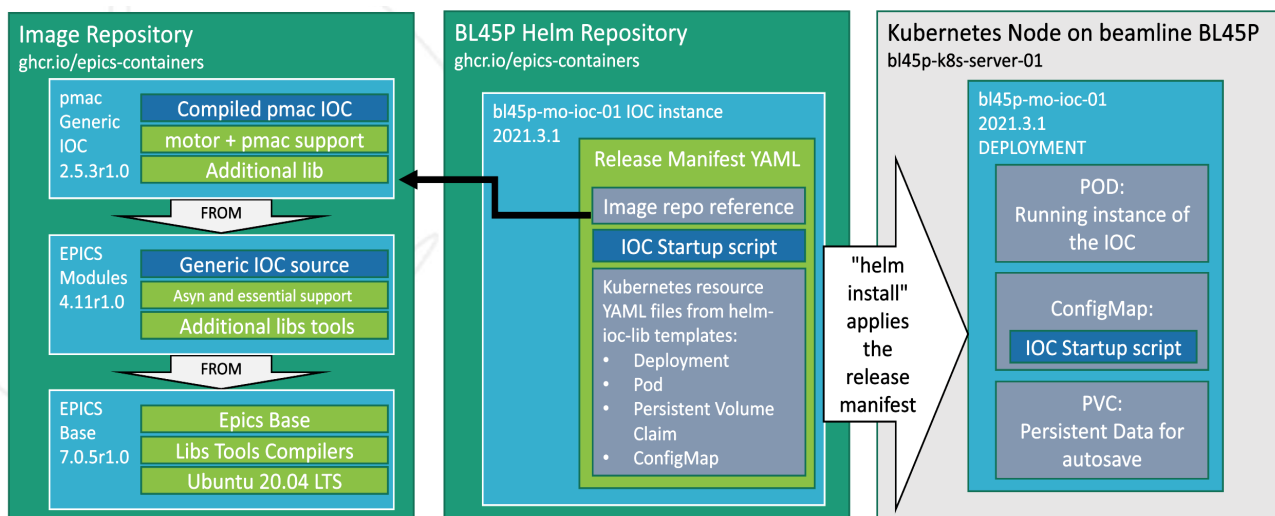

Figure 3: Example of a motion IOC (bl45p-mo-ioc-01) showing how the generic IOC image is built up, packaged with deployment details into a Helm chart, and then deployed to a Kubernetes node.

# RENOVATION OF THE TRIGGER DISTRIBUTION IN CERN'S OPEN ANALOGUE SIGNAL INFORMATION SYSTEM USING WHITE RABBIT

D. Lampridis\*, T. Gingold, D. Michalik<sup>1</sup>, T. Pereira da Silva,  
A. Poscia, M. H. Serans, M. R. Shukla, CERN, Geneva, Switzerland  
<sup>1</sup>also at Aalborg University, Aalborg, Denmark

## Abstract

The Open Analogue Signal Information System (OASIS) acts as a distributed oscilloscope system that acquires signals from devices across the CERN accelerator complex and displays them in a convenient, graphical way. Today, the OASIS installation counts over 500 multiplexed digitisers, capable of digitising more than 5000 analogue signals and offers a selection of more than 250 triggers for the acquisitions. These triggers are mostly generated at a single central place and are then distributed by means of a dedicated coaxial cable per digitiser, using a “star” topology. An upgrade is currently under way to renovate this trigger distribution system and migrate it to a White Rabbit (WR) based solution. In this new system, triggers are distributed in the form of Ethernet messages over a WR network, allowing for better scalability, higher time-stamping precision, trigger latency compensation and improved robustness. This paper discusses the new OASIS trigger distribution architecture, including hardware, drivers, front-end, server and application-tier software. It then provides results from preliminary tests in laboratory installations.

## INTRODUCTION

A common need among operators in the European Organisation for Nuclear Research (CERN) is to be able to observe, monitor and record the behaviour of equipment in the accelerator complex. Frequently, this behaviour is represented by analogue electrical signals which mirror physical phenomena, such as the current going through a magnet, the magnetic field, the horizontal and vertical position of the particle beam, and so on. Quite often, there is also the need to correlate these measurements, as for example in the case of transfer lines between accelerators where one might want to observe the currents going into the kicker magnets that are used to displace the beam, together with the beam position monitors detecting the beam passing to the next accelerator.

The Open Analogue Signal Information System (OASIS) [1–3] satisfies all of the above requirements by providing an oscilloscope-like user interface, which offers the possibility to select among more than 5000 available analogue signals, acquired from more than 500 multiplexed devices all across the CERN accelerator complex. This functionality implies the existence of a common trigger source, shared by all acquisition devices participating in a given measurement.

In fact, operators are interested in being able to trigger on different conditions, meaning that there is more than one trigger that needs to reach the acquisition devices. Today, OASIS counts over 250 such triggers which are mostly generated at a single central place, where they are also multiplexed. They are then distributed by means of a dedicated coaxial cable per digitiser, using a “star” topology.

This trigger distribution scheme has served OASIS well for many years, but it is beginning to show its limitations. Trigger multiplexers are located close to the central locations where the triggers are generated, while the connection between the multiplexers and the digitisers is done with long coaxial cables, especially since the digitisers are placed close to the analogue signal sources to preserve the integrity of the signals. Furthermore, there is no compensation for cable length differences, environmental conditions, etc. The fact that all triggers are generated at the same building creates a single point of failure. Last but not least, introducing new digitisers typically involves finding a free trigger multiplexer output and pulling the trigger cable from there to the digitiser, an expensive and not always feasible operation.

This paper presents a new trigger distribution architecture for OASIS based on White Rabbit Trigger Distribution (WRTD) [4, 5]. In this new system, triggers are distributed in the form of Ethernet messages over a White Rabbit (WR) [6, 7] network, allowing for better scalability, higher time-stamping precision, trigger latency compensation and improved robustness.

## BACKGROUND

### OASIS

OASIS is built using a 3-tier architecture:

1. The front-end tier controls the hardware modules (digitisers, multiplexers, etc.) and provides a hardware independent interface to the upper layer. It uses the Front-End Software Architecture (FESA) [8, 9] framework to provide the interface to the server tier.
2. The server tier consists of an application server that manages the resources provided by the front-end layer and assigns them to the connections requested by the clients (the third tier). The server tier intends to maximise the number of concurrent acquisitions based on a sophisticated priority algorithm.
3. The application tier, provides the users with a graphical user interface that displays the signals and their settings, in a familiar oscilloscope-like way.

\* dimitrios.lampridis@cern.ch

Figure 1: Typical signal monitoring session in OASIS.

OASIS provides the virtual oscilloscope abstraction. A virtual scope is a software oscilloscope that takes its data from different hardware oscilloscopes and displays it as if it all came from the same module. Thanks to this scheme, users are able to observe several signals distributed around the accelerator complex, as if they were next to each other. Figure 1 shows a typical signal monitoring session in OASIS, with seven signals combined in one virtual scope, triggered by the same trigger.

In order to be able to combine signals coming from different digitisers in a common virtual scope, the hardware needs to be triggered by the same pulse. Figure 2a shows the current trigger generation and distribution scheme used in OASIS. The yellow part on the left represents the central timing system, where timing events are distributed from the master devices (MTT) to numerous timing receivers (CTR) spread across the accelerator complex. The timing receivers in turn are programmed to generate trigger pulses upon reception of a particular timing event, with optional delays and resynchronisation to external clock(s). Once the triggers are generated, they are driven into the inputs of trigger multiplexers (CTC, in green), which also provide the possibility to delay and resynchronise the signal to external clock(s), separately for each output. Finally, each output of a trigger multiplexer is connected to the external trigger input of a digitiser (DAQ, in purple).

## WRTD

White Rabbit is a fully deterministic Ethernet-based network which provides sub-nanosecond accuracy. WR is based on the IEEE 1588 Precision Time Protocol (PTP) [10]. The improvements to PTP introduced by WR have been standardised as the High-Accuracy (HA) profile within the IEEE 1588 standard. WRTD provides a generic event distribution system on top of a standard WR network.

WRTD is a generalisation of a previous CERN development, the LHC Instability Trigger (LIST) [11, 12] distribution project. It is modelled after a group of so-called ex-

tended functions defined in the Local Area Network (LAN) eXtensions for Instrumentation (LXI) [13], namely the Clock Synchronisation [14], Event Messaging [15] and Timestamped Data [16] functions. The provided Application Programming Interface (API) mimics that of an Interchangeable Virtual Instruments (IVI) [17] driver, with a strong influence from the IVI-3.2 “Inherent Capabilities” [18] and IVI-3.15 “IviLxiSync” [19] specifications.

In WRTD, source nodes receive incoming pulses and distribute them to other nodes over WR in the form of network messages that carry the timestamp of the incoming pulse. The receiving (listening) nodes are programmed to take action (e.g. generate a pulse) upon reception of a particular message, potentially with some fixed delay added to the timestamp.

## SYSTEM ARCHITECTURE

The proposed solution makes use of WRTD to distribute OASIS triggers over WR and deliver them to the various digitisers. In this system, when a source node receives an incoming trigger pulse, it precisely timestamps its rising edge and distributes it over the WR network to all other nodes, in the form of a timestamp, accompanied by the unique identifier of the source node itself. All nodes that receive the network message and are actively listening for this identifier will add a fixed delay to the received timestamp and configure themselves to generate an output pulse at that precise moment. As long as the fixed delay added is greater than the upper-bound latency of the network (a fundamental feature of WR itself), this precise moment will be in the future and all output pulses will be produced at the same time, thanks to the sub-nanosecond synchronisation provided by WR.

Even though the above scheme will have all digitisers triggering at the same time, that time will still be in the future with respect to the timestamp that was recorded by WRTD at the source node. The solution is to modify the acquisition parameters of the digitisers, in order to have them record enough additional pre-trigger samples to cover the fixed delay that was added to the trigger timestamp, provided of course that the hardware has a large enough memory buffer. This last limitation is only an issue for some old OASIS digitisers with fast sampling rates and small memory and a new project has been launched to design a new equivalent digitiser [20]. Once the acquisition is complete, the acquisition window is rolled back around the original timestamp and the extra post-trigger samples are discarded.

Figure 2b presents a high-level view of the implemented architecture; Compared to Fig. 2a, triggers are still generated by the central timing system (in yellow) and go through the trigger multiplexer (in green), but the outputs of the multiplexer are now timestamped by WRTD source nodes, featuring Time-to-Digital Converters (TDC), which then distribute the triggers as messages over the WR network. At the receiving end, WRTD listening nodes equipped with Fine Delay pulse generators (FD) receive the messages, add

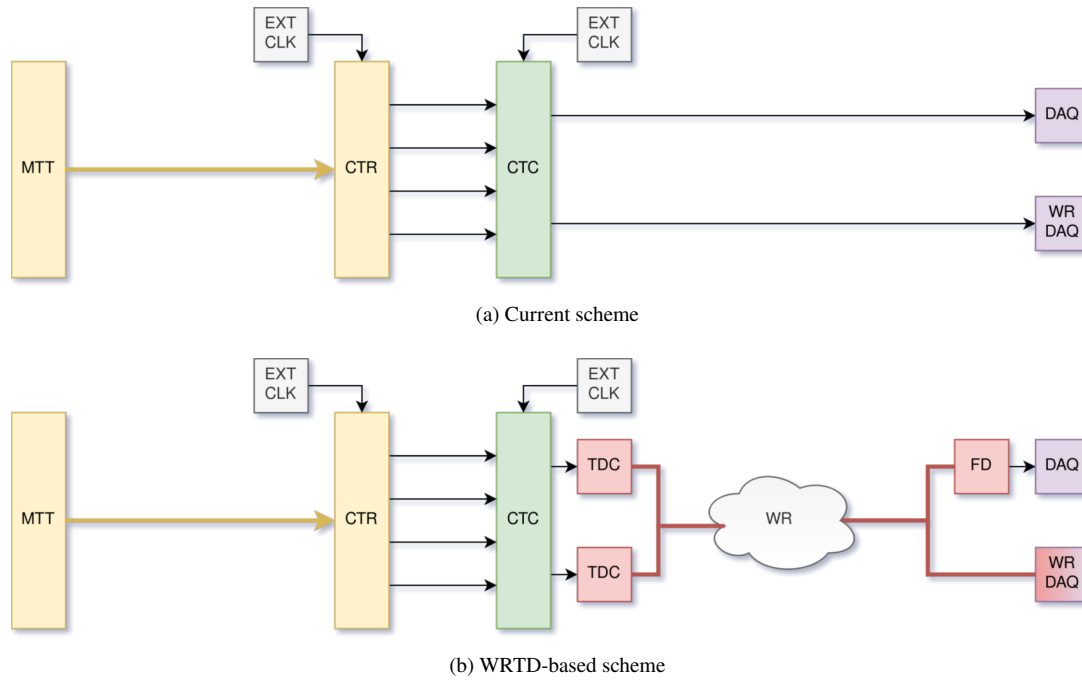

Figure 2: OASIS trigger distribution architectures.

the globally configured fixed delay and generate the output pulses that are then delivered to the external trigger input of the digitisers. In the special case of a WRTD-enabled digitiser, the FD is omitted since the digitiser is capable of triggering itself by retrieving the WRTD timestamp, taking into account the globally configured delay, and configuring itself to trigger internally at the specified time.

In the coming sections we discuss in more detail the developments performed at the various tiers of OASIS to implement this architecture.

## Hardware

The OASIS WRTD network infrastructure is built using standard WR network switches [21] and optical fibres. For the purpose of this project, three new types of WRTD nodes were developed, all of them reusing the WR-enabled Versa Module Europa (VME) dual Field-Programmable Gate Array (FPGA) Mezzanine Card (FMC) carrier, also known as Simple VME FMC Carrier (SVEC) [22] and combining it with existing FMC modules. The most important development in this case was the creation of new FPGA designs (also known as gateway), to provide the necessary WRTD-related logic.

The first WRTD node is a SVEC with the two FMC slots populated with TDC mezzanine cards [23] (“TDC” block in Fig. 2b). Since each TDC mezzanine provides five input channels, the whole WRTD node offers 10 input channels, capable of timestamping incoming pulses and transmitting WRTD events on the WR network.

The second WRTD node is a SVEC with the two FMC slots populated with FD mezzanine cards [24] (“FD” block in Fig. 2b). Since each FD mezzanine provides four out-

put channels, the whole WRTD node offers 8 output channels, capable of generating trigger pulses locally, at precise moments defined in WRTD events received from the WR network.

The third type of WRTD node is a SVEC with the two FMC slots populated with four-channel, 14-bit, 100 MHz ADC mezzanine cards [25] (“WR DAQ” block in Fig. 2b). This is an update to an existing piece of hardware, already used in OASIS, to add the possibility to trigger the ADC directly from WRTD events received from the WR network.

## Front-End Tier

FECs related to accelerator controls at CERN run real-time software developed with the FESA framework. Device controls are implemented in FESA classes and instantiated on each FEC, one instance per controlled device. Such an instance is also called a FESA device.

For the renovation of the OASIS trigger distribution system, two new FESA classes were introduced, the WRTD Event Source and the WRTD Event Listener. Even though the design is made with OASIS triggering in mind, the aim was to make it generic enough to be reused in other applications as well in the future. This is why the two new FESA classes do not include “OASIS” in their names and the use of the word “Event” is preferred over that of “Trigger”.

Additionally, two existing FESA classes, the OASIS Scope and OASIS Channel were extended.

**Global Delay Configuration** A global configuration delay value is stored in a configuration file and is made available to all WRTD Event Listener and OASIS Scope and Channel devices.

The purpose of this delay is to make sure that the trigger message is delivered to all WRTD Event Listener devices before the time to produce the trigger at the destination expires. As such, this value must always be superior to the worst-case trigger distribution latency (in the order of 100  $\mu$ s), which is guaranteed by the upper-bound latency of the WR network itself.

**WRTD Event Source** The WRTD Event Source FESA class is used to model devices that receive pulses locally, timestamp them and generate messages (Events) over the WR network containing a unique identifier for this device and the timestamp of the pulse. Typically, such devices are individual channels of a TDC.

Each WRTD Event Source device represents one input channel. Thus, a five-channel TDC (which from the hardware point of view is a single device with five input channels) will be mapped to five separate WRTD Event Source devices.

More often than not, the inputs of the TDC will be connected to the outputs of a trigger multiplexer. The trigger multiplexer will be generating the trigger pulses, which will be then timestamped by channels of the TDC. In a few cases, a trigger signal might be directly connected to an input of the TDC, without a trigger multiplexer in between.

**WRTD Event Listener** The WRTD Event Listener FESA class is used to model devices that receive over the WR network the messages (Events) generated by WRTD Event Source devices and generate pulses locally at a specific moment with respect to the timestamp contained in the received message. Typically such devices are channels of an FD.

Each WRTD Event Listener device represents one output channel. Thus, a four-channel FD (which from the hardware point of view is a single device with four output channels) will be mapped to four separate WRTD Event Listener devices. In practice, the outputs of the FD will be connected to external trigger inputs of digitisers, in order to trigger the acquisition of the digitisers at the moment specified by WRTD.

Apart from FD generators, another type of device that is modelled by the WRTD Event Listener is a digitiser that is capable of triggering directly over WRTD. Such a digitiser will also provide a single WRTD Event Listener to model its capability to receive the WRTD message and produce the local trigger pulse internally.

**OASIS Scope and Channel** The OASIS representation of a digitiser is based on the combination of two FESA device classes, the OASIS Scope and Channel. The first one handles all aspects of triggering and “horizontal settings” (sampling rate, number of samples, etc.), while the second one handles the “vertical settings” (full-scale range, offset, etc.).

In the context of this project, these two FESA classes have been extended, to allow for the triggering over WR. In particular, the following modifications were performed:

1. A new configuration option was introduced to specify whether this scope is triggered over WR or not.
2. If a scope is triggered over WR, the global delay configuration is taken into account, affecting the number of pre-trigger acquired samples, in order to allow for the trigger latency introduced by the WRTD network.
3. Once such a scope is triggered, the global delay configuration value is subtracted from the trigger timestamp, in order to point to the moment in time when the original trigger was generated at the source, not when it was actually received by the digitiser.
4. Following that, the acquisition window is adjusted once again, in order to discard surplus samples and return the data around the original trigger moment.

It is worth noting that these calculations and adjustments of settings happen at the front-end tier level. The OASIS server and the applications are not aware of them. Thus, if a user selects a particular trigger and asks for 1000 samples with 50% pre-triggering, the front-end tier will silently perform the necessary adjustments and in the end it will simply return 500 samples before and 500 samples after the selected trigger.

### Configuration Database

OASIS relies heavily on relations defined in the Controls Configuration Database (CCDB), to associate signals to signal multiplexers and digitiser channels, triggers to trigger multiplexers and digitisers, and so on.

In the context of OASIS WRTD, three new relations have been introduced and one existing relation has been reused:

**COUNTER2WRTD:** This new relation connects the output of a trigger multiplexer to a WRTD Event Source.

**TRIGGER2WRTD:** This new relation connects a trigger signal directly to a WRTD Event Source.

**WRTD2SCOPE:** This new relation connects a WRTD Event Listener to a digitiser.

**TRIGGER2MUX:** This existing relation connects a trigger signal to the input of a trigger multiplexer.

### Server Tier

For the OASIS server to be able to route a specific trigger signal to a digitiser, it needs to identify a route and then to configure the devices on that route. The server discovers that information using the relations defined in CCDB.

**WRTD Route Identification** To find a possible route for the trigger signal, the server first needs to discover which WRTD Event Source devices the trigger signal is connected to.

The actual route identification requires the following steps:

1. Discover to which trigger multiplexer(s) and on which input the trigger signal is connected (via a TRIGGER2MUX relation).
2. Identify all WRTD Event Sources connected to the trigger multiplexer(s) found in (1), remember to which output of the multiplexer each WRTD Event Source is connected (via a COUNTER2WRTD relation).
3. Alternatively, detect whether the trigger signal is directly connected to a WRTD Event Source, without any trigger multiplexer in between (via a TRIGGER2WRTD relation).

Thanks to this initial discovery phase, a set of candidate WRTD Event Sources to use to distribute the trigger on the WR network is obtained. Among those candidates, the server then finds the first one that matches all of the following criteria:

1. The WRTD Event Source is running and reachable.
2. The WRTD Event Source is free (i.e. it is not already used to route a trigger).

Once a WRTD Event Source is identified, the server queries the declared CCDB relations to find out to which WRTD Event Listener the digitiser is connected to.

At this point all the equipment that will be used to route the trigger signal has been identified. This includes:

- The WRTD Event Source
- The trigger multiplexer and the input and output to use
- The WRTD Event Listener

**WRTD Route Configuration** After a route is identified, it is necessary to configure the different devices so that the trigger signal is correctly routed to the digitisers. The following operations are performed by the OASIS server:

1. Trigger multiplexer: close the route from the trigger signal to the selected WRTD Event Source
2. WRTD Event Source: enable the device
3. WRTD Event Listener: enable the device and set the WRTD event to be listened to

Following these operations, the trigger signal will be routed to the WRTD Event Source that will publish the trigger to the WRTD network. The WRTD Event Listener will listen to the event published by that source device and trigger the digitiser accordingly. Finally, when the user has finished observing the signal(s), the OASIS server needs to turn off the WRTD Event Source and Listener devices and release the route that was used in the trigger multiplexer.

## Application Tier

Even though there are several applications that make use of OASIS, the most widely used one is the OASIS viewer (also shown in Fig. 1).

One of the core decisions taken during the planning phase of this project was to avoid any significant modifications and user interface redesigns of the OASIS viewer. Users of OASIS, CERN operators in particular, are accustomed to the current interface and the idea is to first renovate the trigger distribution system and then, slowly start introducing new features that would require an interface redesign, such as the possibility for a digitiser to trigger other digitisers, something that is not available with today's unidirectional trigger distribution system.

As such, the only modification that was done to the OASIS viewer was to add more information regarding the configured trigger path in the case of WRTD triggers (that is, the device names of the WRTD Event Source and Listener used).

## TEST SETUP AND FIRST RESULTS

A standard CERN VME FEC with all the necessary hardware was deployed in the laboratory from the beginning of this project. This test setup was used extensively during development, also as a part of a Continuous Integration (CI) flow. Currently, this setup is running released and deployed versions of all components and it is being used for the final validation of the full system.

A high-level diagram of the test setup can be seen in Fig. 3. Two trigger pulses are generated by the timing system, separated by a 400  $\mu$ s delay. Both triggers are fed into a trigger multiplexer. At the same time, the two trigger signals are also connected to analogue input channels of two scopes; the "normal" trigger goes to channel 1 of both scopes and the delayed trigger to channel 2.

Scope 2 is triggered directly by one of the outputs of the trigger multiplexer. Another output of the same trigger multiplexer is connected to a WRTD Event Source, and a WRTD Event Listener output is connected to the trigger input of Scope 1. Thanks to the trigger multiplexer, each scope can be triggered on either of the two signals, independently of each other. The WR network itself is made of two WR switches, separated by 10 km of rolled optical fibre. The global delay is configured at 400  $\mu$ s.

Figure 4 shows the OASIS viewer application, with the four signals connected. The yellow traces are from Scope 1, while the magenta traces are from Scope 2. The OASIS viewer is configured with two virtual scopes; the top one displays the signals from channel 1 of both scopes, while the bottom one shows the channel 2 signals. Both of the scopes are set to trigger on the signal that is also connected to channel 1. The acquisition window is set to 500  $\mu$ s (50  $\mu$ s/div) and there is a horizontal delay of 200  $\mu$ s applied. As it can be seen, there is no visible difference between the scope that is triggered by the pulse itself, and the scope that is triggered by the pulse passing first through the WRTD network, despite the latency of the network; the signals on both virtual

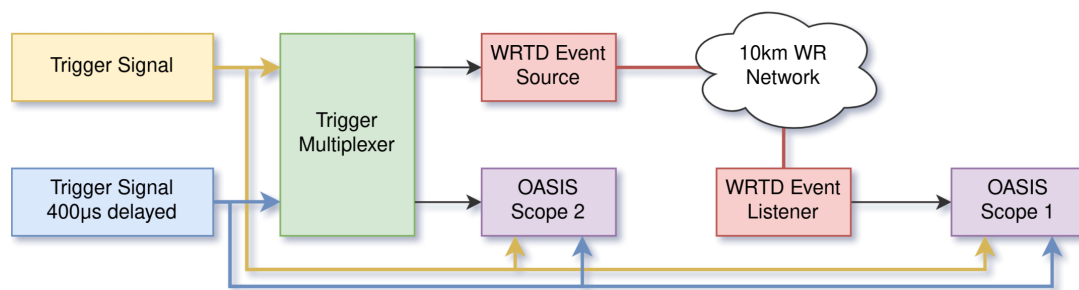

Figure 3: Laboratory test setup.

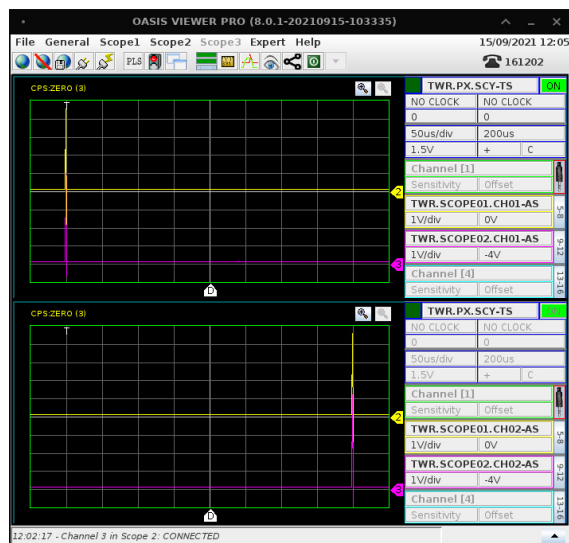

Figure 4: OASIS signal acquisition with WR triggers.

Figure 5: Zoom at trigger moment.

scopes are fully aligned, with the two sets of signals being 400 µs apart.

Figure 5 is a zoom in the moment of the trigger, using the two channel 1 signals from both scopes. The two digitisers are acquiring with a 100 MHz sampling rate (10 ns sampling

period) and the OASIS viewer is set to display a 200 ns window. As a result, one can see the 20 individual samples from each scope (each sample represented by a dot) and how they are aligned to each other, despite the fact that the two scopes are triggered in two completely different ways.

## CONCLUSIONS AND OUTLOOK

This paper has presented the new OASIS trigger distribution architecture based on WRTD. Currently, the development effort is almost complete, and the laboratory tests show that the full hardware and software stack is working and is well integrated inside the CERN accelerators' control system.

It is expected that the first operational OASIS triggers over WR will circulate before the end of 2021. Following that, a large campaign will take place to start replacing the complete trigger distribution installation.

There are also plans to further evolve the system, in three successive phases, with the work presented in this paper being part of the first phase. Figure 6 shows the proposed road-map, including a repetition of the block diagram from Fig. 2b to make the comparison between the three phases easier. In particular, the second phase involves the complete elimination of trigger multiplexers, in favour of direct timestamping of triggers by TDC channels. For this to happen however, new hardware developments are necessary, in order to provide a way to synchronise WRTD timestamps to external clocks, a feature provided today by the trigger multiplexer. This could happen for example with a new generation of TDC (NG-TDC in Fig. 6b), or with a module capable of receiving and reconstructing clock signals over a WR network (such as the WR2RF module [26] in Fig. 6b). In the third and last phase, that requires the complete central timing to be migrated to WR, there will be no more trigger pulses to digitise, and OASIS will be picking up timing events/messages from the WR network and using them for triggering its digitisers.

On another front, since WRTD itself is based on the existing IVI/LXI standards, it is foreseen to try to merge WRTD with these standards, in the same way that WR was merged and standardised within the IEEE1588 PTP standard. Such a development would allow instruments with an IVI driver and a WR interface to exchange events with each other. This

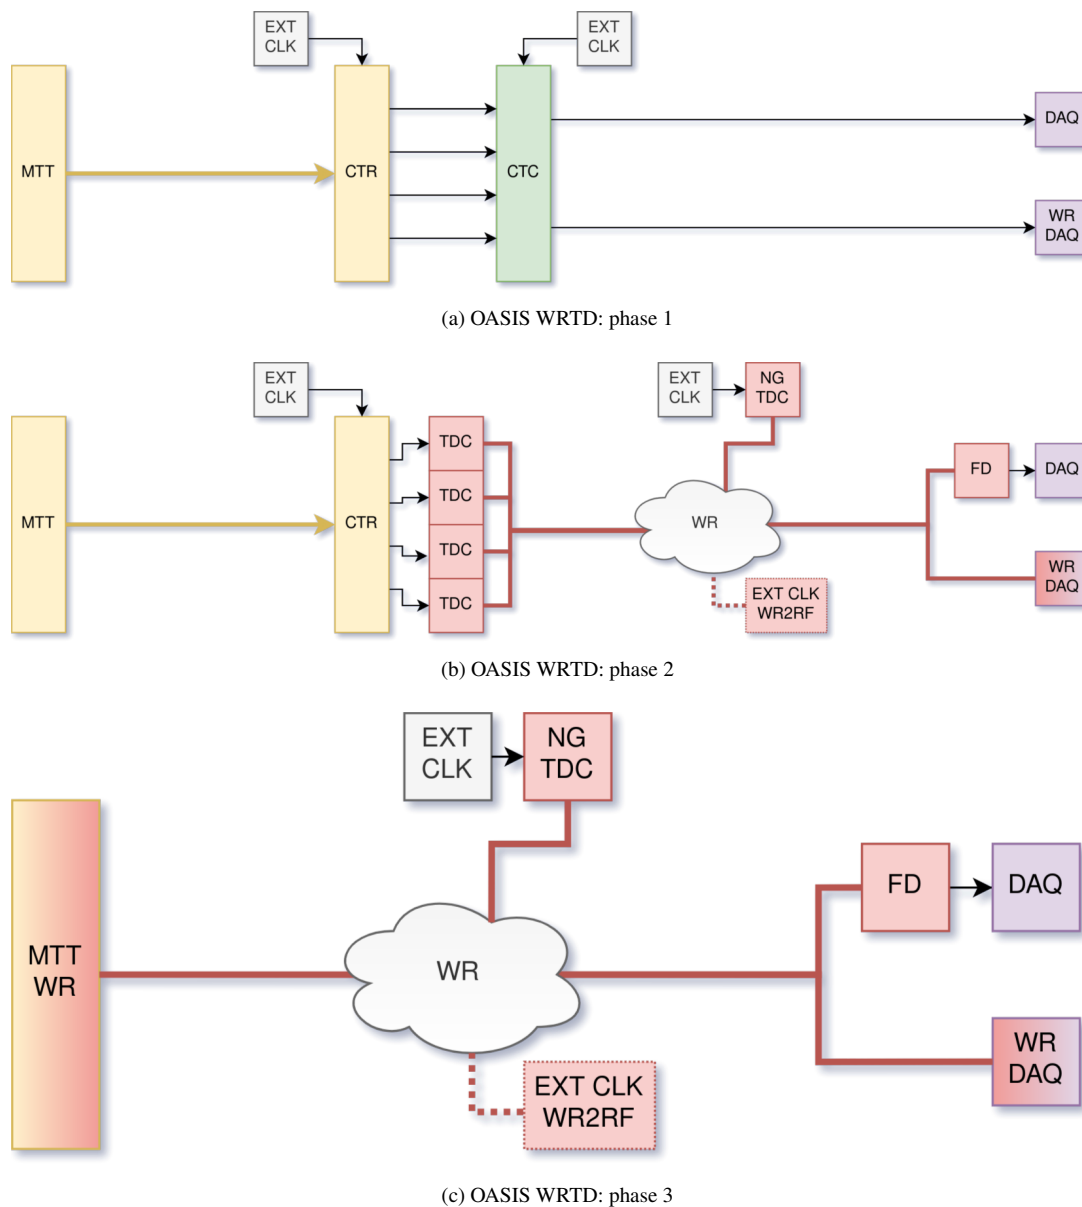

Figure 6: OASIS trigger distribution evolution road-map.

would also allow the industry to produce commercially available WRTD-enabled devices, which OASIS could then procure and use out of the box, with minimum integration effort.

## Abstract

The Super Proton Synchrotron (SPS) Low-level RF (LLRF) system at CERN was completely revamped in 2020 [1]. In the old system, the digital signal processing was clocked by a submultiple of the RF. The new system uses a fixed-frequency clock derived from White Rabbit (WR) [2]. This triggered the development of an eRTM module for generating very precise clock signals to be fed to the optional RF backplane in MTCA.4 crates. The eRTM14/15 sandwich of modules implements a WR node delivering clock signals with a jitter below 100 fs. WR-clocked RF synthesis inside the FPGA makes it simple to reproduce the RF elsewhere by broadcasting the frequency-tuning words over the WR network itself. These words are received by the WR2RF-VME module and used to produce beam-synchronous signals such as the bunch clock and the revolution tick. This paper explains the general architecture of this new LLRF system, highlighting the role of WR-based synchronization. It then goes on to describe the hardware and gateway designs for both modules, along with their supporting software. A recount of our experience with the deployment of the MTCA.4 platform is also provided.

## INTRODUCTION

The High Luminosity LHC (HL-LHC) project at CERN aims to increase the integrated luminosity of the LHC by a factor of 10 in the 10-12 years after its implementation in 2027. As a result of new requirements for the LHC beam, the whole CERN injector complex has undergone an extensive upgrade program. For the SPS, the synchrotron just upstream of the LHC, the new requirement for a beam intensity of  $2.3 \times 10^{11}$  protons/bunch with a bunch spacing of 25 ns resulted in a need to overhaul the complete accelerating system, including cavities, amplifiers and LLRF.

The new LLRF system needed to be ready in a short amount of time and required a significantly higher data transfer rate from the cards to the host PC than the legacy VME platform. A decision was therefore taken to capitalize on the effort of DESY and other institutes, as well as the Commercial-Off-The-Shelf (COTS) components using the MTCA.4 standard. Field Programmable Gate Arrays (FPGA) and System-on-Chip (SoC) solutions were used

extensively to speed up the development and provide the flexibility allowing the system to be reused in future applications.

White Rabbit (WR) timing technology plays a key role in several parts of the system:

- It is used to derive a very low-noise base clock signal which is then used to sample the cavity antenna and beam Pick-Up signals, and to synthesize the RF drive signals.
- It is the transmission medium through which the LLRF system receives bending magnetic field information in real time.
- Coupled with Direct Digital Synthesis (DDS) technology, it allows the LLRF system to transmit the RF signals not as physical signals but as messages containing Frequency-Tuning Words (FTW) which allow receivers to replay the RF in synchronism all around the accelerator. This allows distributing the reference RF phase with fixed and very stable latency.

This paper does not aim at describing the upgraded LLRF system in general, but just the synchronization aspects and the use of the WR technology therein. After a quick introduction to the general architecture of the system, we describe the low-noise eRTM14/15 clock signal generation and distribution module. We then move on to the module allowing regeneration of RF signals based on reception of FTWs, the WR2RF-VME. Finally, we share our experience as new users of the MTCA.4 form factor, hoping it can be useful to others in their exploration for optimal platforms to implement LLRF or other types of systems.

## GENERAL ARCHITECTURE

The overview of the SPS LLRF system architecture is shown in Fig. 1. Note that it focuses on the usage of WR in the system and omits many details of the RF part.

The renovated system drives six 200 MHz RF cavities and is implemented entirely in the MTCA.4 form factor. Each cavity has a dedicated Cavity Controller (CC), consisting of a Struck SIS8300KU card [3] and a DS8VM1 analog frontend/vector modulator RTM from DESY [4]. The CC's primary role is to maintain stable cavity power and phase, compensating the error introduced by the power amplifier (the Polar Loop) as well as handling the cavity beam loading

\* Tomasz.Wlostowski@cern.ch

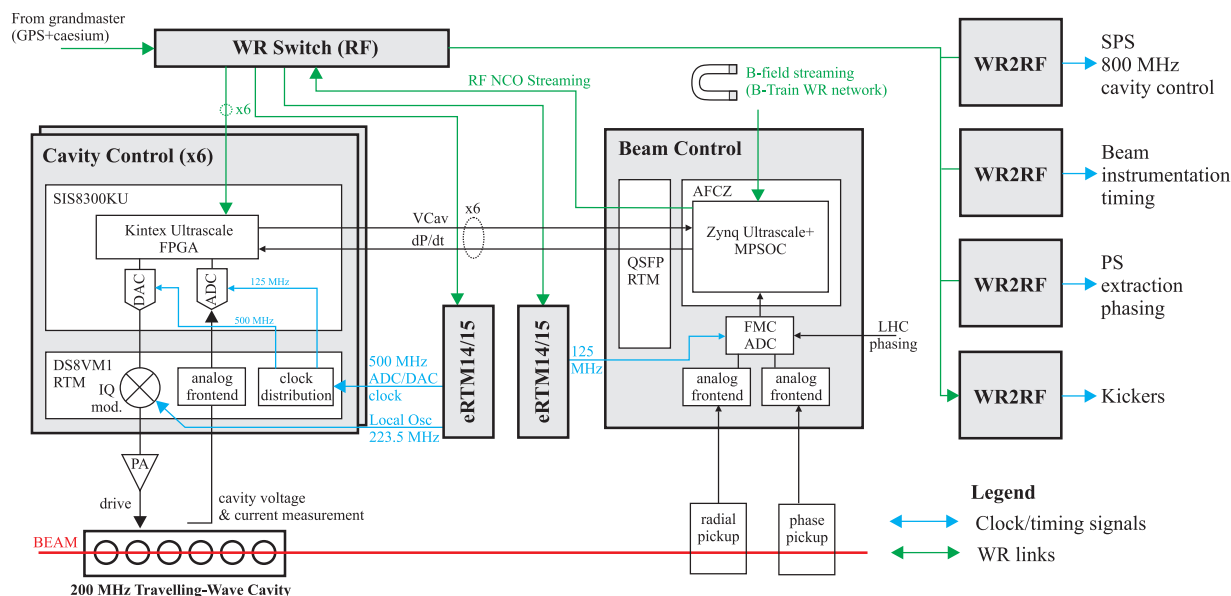

Figure 1: Overview of the WR-based SPS Low Level RF system.

and impedance effects (One-Turn Feedback). The measured cavity voltage information is streamed to the Beam Controller (BC) over dedicated gigabit links. Furthermore, the CC implements a monitoring and protection system which ensures safe operation of the high power RF equipment.

The BC uses the AFCZ board by Creotech [5] and two custom-made FMC mezzanines to interface with the power plant and the beam instrumentation. Its main task is calculating the instantaneous RF frequency and cavity voltage set-points for a particular beam (particle type, intensity and fill pattern) during the acceleration ramp. The most significant inputs for the BC are the beam's transverse position, phase, current and the magnetic field in the machine's magnets. The latter is provided by a WR-based B-Train system [6], also using a dedicated WR link. The frequency information calculated by the BC is broadcast with every beam turn over the WR network using a protocol similar to the B-Train system. More details are provided in the section about the WR2RF-VME module.

Timing-wise, each CC requires two clock signals: the Local Oscillator for upconversion of the RF drive output (223.5 MHz sine wave) and a 500 MHz ADC/DAC clock. Both clocks have stringent phase noise (PN) and stability requirements: PN of  $-130$  dBc/Hz at 1 kHz (carrier 223.5 MHz) and precision better than 13 ps (1 degree at 200 MHz). These requirements were set to minimize the detrimental effect of the RF noise during the long filling plateau for the LHC ions beams in the SPS. The clocks are provided by the eRTM14/15 module, described later. The BC needs a 125 MHz WR-synchronous clock for its ADCs, with similar noise and stability figures as the CC.

All six CCs share a single MTCA.4 crate (Schroff/nVent model 11890-170) with a single MCH/CPU set from N.A.T. [7] and a single eRTM14/15 module, whereas the BC resides in a separate MTCA.4 crate with its own CPU/MCH/eRTM boards. The crates are also equipped

with the CERN General Machine Timing receiver cards (not included in the drawing for the sake of clarity). The low-jitter clock connections between the eRTM board and the CCs are provided by the DESY MTCA.4 LLRF backplane (RFBP) [8].

As the new LLRF system distributes the frequency information in a purely digital form, a need arises for interfacing with the legacy systems (mostly VME-based) that require an analog cavity frequency and RF-related trigger signals (e.g. kicker magnets, beam instrumentation, Proton Synchrotron (PS) extraction synchro and the auxiliary 800 MHz SPS cavities). This task is performed by the WR2RF-VME cards, described in detail in the subsequent chapters.

## THE ERTM14/15 MODULES

The eRTM14/15 [9] is a MTCA.4-compliant WR receiver providing a variety of ultra-low jitter clock signals which are distributed over the RFBP:

- Two DDS clocks (named LO and REF in this paper), distributed to slots 4..12 of the MTCA crate and with two front-panel outputs for up/down-modulation of the RF analog signals.
- Two digital clocks (distributed to slots 4..12 and the front panel).
- 10 MHz and Pulse Per Second (PPS) input and output for interfacing with non-WR timing devices.

The module is made of two boards connected with a high speed board-to-board cable (Samtec QSH series), as depicted in Fig. 2. The board residing in slot 14 contains the FPGA (Kintex-7 XC7K70T) that implements the WR synchronization stack (the WR PTP Core - WRPC [10]), two redundant SFP uplink ports and basic ("low performance") WR local oscillators. Slot 15 contains the high performance oscillators and analog circuitry synthesizing the clocks listed above. Therefore, the eRTM14 can work alone as a basic

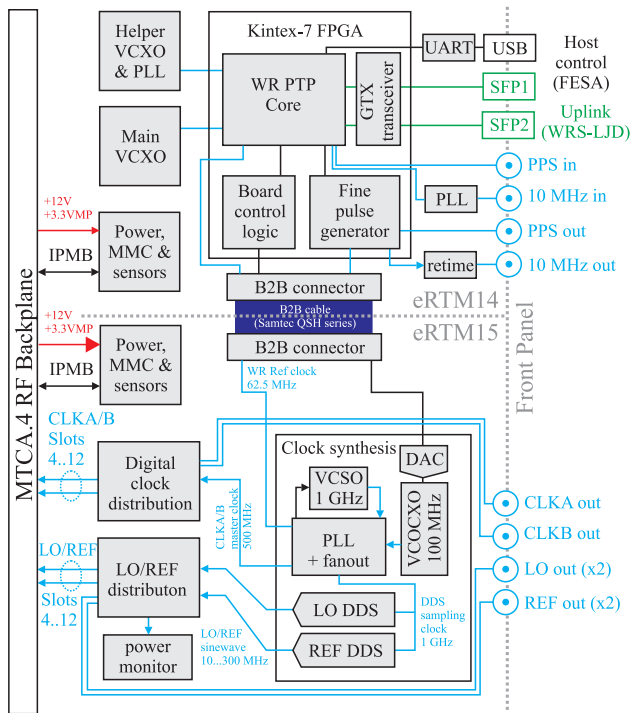

Figure 2: Simplified block diagram of the eRTM14/15 WR Receiver.

WR receiver or together with the eRTM15 with the full set of features.

To achieve the timing performance required by the SPS LLRF system, we had to develop novel techniques described in the two next subsections.

### WR Clock Synthesis

The WR clock recovery and synthesis was designed to meet a  $-130$  dBc/Hz phase noise figure at 1 kHz offset (carrier frequency 223 MHz) and less than 100 fs rms jitter (100 Hz - 10 MHz).

Meeting the latter requirement necessitated a local oscillator with sufficiently low PN in the low frequency range to match  $-100$  dBc/Hz, which is the noise floor of the Digital Dual Mixer Time Difference (DDMTD) phase detector used by WR at the offset of 50 Hz, much less than the bandwidth of standard WR PLL implementations (about 300 Hz). An Axtal AXIOM45 series OCXO has been selected, as a compromise between the performance and the price.

The OCXO provides a 100 MHz sinewave signal, finetuned within the range of a few ppm by a low-noise DAC (AD5660) controlled by the WRPC. This 100 MHz is multiplied by the subsequent PLL synthesizer (LTC6950) that delivers the 62.5 MHz WR reference clock (thus closing the WR clock recovery feedback loop), a 500 MHz master clock for the CLKA/B outputs and a 1 GHz sampling clock for the LO/REF DDS synthesizers. The PLL uses a discrete voltage-controlled SAW oscillator (Crystek CVCSO-914) to further improve the PN in the high frequency range and provide enough headroom for the additive PN of the DDS and clock distribution circuitry.

The LO/REF clocks are produced by two AD9910 integrated DDS synthesizers, capable of outputting up to 400 MHz with a tuning resolution of 0.23 Hz. The eRTM design allows them to be programmed to any arbitrary (non-modulated) frequency between 10 and 300 MHz. The output of each DDS is followed by a two-stage clock distribution network, each stage consisting of a Mini-Circuits GVA-81 amplifier followed by a passive 1:4 splitter. As the distribution network is partly passive, the outputs are coupled to the RFBP with individually programmable MEMS RF switches, terminating the unused slots. Each LO/REF RFBP output is also equipped with an RF power monitor. The module also allows to adjust (globally) the output power of the LO and REF chains between +9 and +19 dBm, achieved by digitally changing the DDS DAC bias current.

Furthermore, the DDS outputs can be phased together at an arbitrary moment of time through a message sent over the WR network. Such a message contains a TAI timestamp at which the Fine Pulse Generator core in the FPGA generates a pulse to reset the AD9910 phase accumulators, thus ensuring all the chips start producing the LO/REF signals at exactly the same phase. The SPS LLRF uses this feature at the start of each beam cycle to ensure the LO's in all WR nodes are correctly aligned.

The CLKA/B clocks are digital, differential (LVPECL levels) intended for driving ADC/DACs. They are derived from a 500 MHz master clock through two LTC6953 clock dividers/fanout buffers. The user can select from the frequencies of 62.5, 125, 250 and 500 MHz, each output capable of independent frequency, phase and on/off setting. To ensure the fixed phase alignment of the divided-down clocks across different nodes in the network, the FPGA's Fine Pulse Generator core provides PPS-aligned divider synchronization pulses for the LTC6953s.

The PN figures, measured for CLKA and LO channels

Figure 3: Phase noise of the CLKA (500 MHz) and LO (223.5 MHz) outputs of the eRTM.

Furthermore, for the eRTM to achieve the required performance, the upstream elements of the SPS WR network had to be improved:

- Changing the master GPS receiver to Microchip Sync-server S650 [11], as the previous receiver showed small phase jumps (few dozen ps), sufficient to disrupt the operation of the LLRF system referenced to it.
- Upgrading all the upstream WR Switches [12] to the Low Jitter Daughterboard (WRS-LJD) version [13], which offers lower additive PN and improved DDMTD tracking stability. More details can be found in [14].

### Phase Stability

The second requirement of the SPS LLRF that resulted in substantial development effort was the phase stability (precision) better than 13 ps. In other words, every time the system is switched on, the clock phases between all RF nodes must not change by more than 13 ps. Standard WR implementations offer a precision of around 100 ps, which we had identified to come from the internal clocking and Clock/Data Recovery (CDR) of the FPGA's Gigabit transceivers. We focused on the Xilinx's GTXE1 and GTXE2 transceivers, used, respectively, in the Virtex-6 and Kintex-7 series of FPGAs and improved their phase stability to better than 5 ps (std). The excessive phase error is caused by multiple effects:

- The RX/TX buffer bypass logic aligning the SerDes high clock with the FPGA fabric clock, which has been implemented as a tapped delay line, with the tap selected during the initialization of the link.
- Various clock dividers (most importantly, the RX SerDes bit clock to parallel word clock).

Figure 4: Phase stability comparison between LPDC and standard WR nodes.

These effects have been mitigated by instrumenting the transceiver internal clocks with a DDMTD-based phase measurement unit and repeatedly resetting the transceiver until the clock phases are fixed on previously calibrated values. The detailed information about the procedure is available in [15]. The WR devices which offer such improved phase stability, such as the version 6.0 of the White Rabbit Switch, are marked as Low Phase Drift Calibration (LPDC). Fig-

ure 4 compares the phase stability of a standard WR PHY implementation with the LPDC-enabled transceiver of the eRTM board.

### Digital and Software

All timing features of the eRTM module are controlled by the Kintex-7 FPGA, encompassing the WRPC, a set of I2C/SPI/GPIO interfaces to control all onboard chips and a Fine Pulse Generator core to produce the PPS output and the counter/phase accumulator synchronization pulses.

The WRPC contains an embedded CPU core (LM32) which runs a customized version of the WRPC software. The key differences between the standard WRPC and the eRTM are:

- Support for eRTM board-specific circuitry (PLLs, DDS, clock distribution).
- Improved regulation loops of the WR PLL (PI gain optimization, gain scheduling).
- Remote control and monitoring of the board through the front panel USB port. A library in C/Python is provided, which allows a remote PC to control the most important run-time parameters of the board (clock frequencies, channel assignment, etc.).

Being an MTCA.4-compliant module, the eRTM implements two MTCA Management MicroControllers (MMCs), one per board. These are STM32F3 series MCUs, running a customized version of the LNLS's OpenMMC firmware [16]. Their key responsibilities are monitoring the board health (voltages, currents and temperatures), power sequencing and MTCA.4 identification of the boards.

## THE WR2RF-VME MODULE

The WR2RF-VME card is a VME-compatible WR RF receiver, featuring:

- High performance WR receiver.
- x2 RF channels, each capable of reconstructing the modulated RF signal.
- x2 Programmable trigger outputs per RF channel.
- A number of standard timing I/Os (10 MHz/PPS) and general-purpose digital inputs/outputs.

The simplified block diagram of the WR2RF-VME is depicted in Fig. 5. As the board inherits the clock generation circuitry (OCXO, PLL and DDS) from the eRTM board, we will focus exclusively on the RF-specific features.

### RF Streaming and Reconstruction

The SPS Beam Control distributes Ethernet frames known as the "RF-train" over the WR network to Cavity Controllers and WR2RF-VME cards. These frames contain Frequency Tuning Words (FTW) that describe the setpoints for Numerically Controlled Oscillators (NCOs) implemented within the Kintex7 FPGA on the WR2RF-VME card. To ensure all receivers have the same NCO value, two things are necessary:

- Every frame from Beam Control is transmitted using WR Streamers, a feature of the WR-Core that guaran-

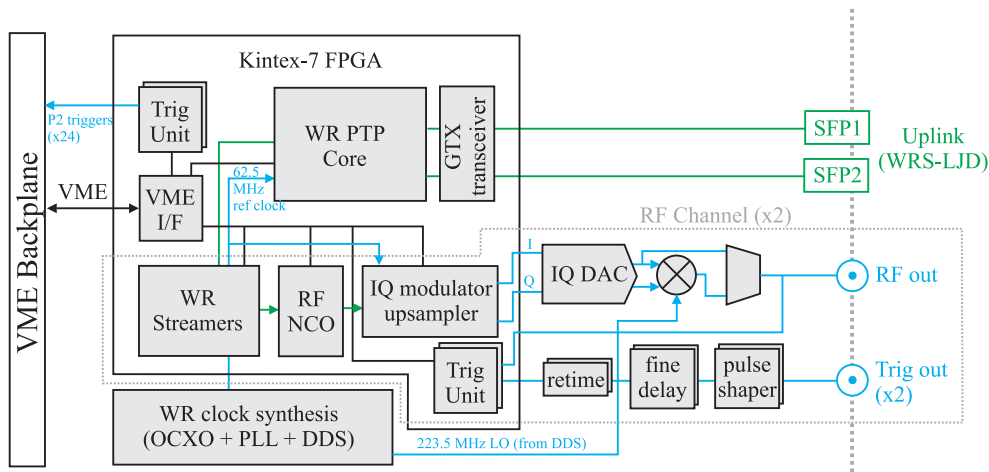

Figure 5: Simplified block diagram of the WR2RF-VME board.

tees a fixed latency delivery (the fixed latency must be larger than the worst case network latency).

- Each NCO is reset prior to starting a new accelerator cycle.

These features ensure that each NCO, in every receiver, has the same value on any WR clock tick.

The RF is reconstructed using a mixer approach. The FPGA uses the output of the NCOs to drive I and Q data lines for an AD9783 Digital to Analog Converter (DAC), with a varying frequency close to 23.5 MHz. The DAC generates the Intermediate Frequency (IF) for the LTC5598 mixer. Meanwhile, the Local Oscillator (LO) input of 223.5 MHz for the mixer is derived from an AD9910 DDS chip, as described for the eRTM modules. The output from the RF mixer is then filtered to accept the downside conversion and attenuate the LO and image frequency leakage close to 200 MHz. This is the reconstructed RF signal.

### Trigger Units

In LLRF systems at CERN, a Trigger Unit (TU) [17] is used to generate a pattern of pulses that are synchronized with an RF signal. These TUs, implemented in FPGA logic, are clocked by a digital version of the reconstructed RF signal to create an RF synchronous system. In the WR2RF-VME card there are two cascaded TUs, and typically they create:

- The revolution frequency or orbit clock.
- A bunch clock, which is a divided by 5 digital version of the RF signal.

Applications of these TUs are:

- Precise RF bucket selection to adjust the injection of particle bunches.
- Timing pulses to control systems responsible for dumping the beam.
- Signals for beam instrumentation and monitoring.

The output from the TU then drives a discrete pulse shaping and retiming circuit on the WR2RF-VME card, allowing for low jitter trigger signal generation and precise adjustment of trigger delay (10 ps steps).

## EXPERIENCE WITH MTCA.4

The SPS LLRF system is the first medium-scale deployment of the MTCA.4 platform in the Accelerator Sector at CERN. While MTCA.4 has easily met the project's requirements regarding the CPU processing power and the PCI Express bandwidth compared to the VME platforms, we identified several issues affecting the reliability and integration of the platform in the CERN Controls framework, in particular the LLRF backplane and the modules which utilize it. The list below applies only to the hardware models used at CERN and not the MTCA.4 ecosystem as a whole:

- Suboptimal thermal design of the MTCA.4 crate and fan speed management: the fans in the front were too powerful with respect to the fans in the rear. As the crate's cooling air inlet is in the front, the stock version of the fan unit would direct almost all of the airflow to the front part of the crate, thus causing overheating of the rear modules such as the Rear Power Modules (RPMs) and the eRTM board. We have observed temperatures of  $\sim 90^\circ\text{C}$  on the eRTM at an approximate power dissipation of 36 W (per 2 slots). Furthermore, the eRTM15 slot that dissipates the most heat in our system receives less airflow compared to other RTM slots. This is due to the placement of the fan too far from the slot.
- Unreliable Power Module (PM) firmware. The dedicated RFBP rear PMs would refuse to work with the eRTM module without indicating any error. We continued our development using standard PMs, but the MCH refused to recognize the eRTM boards (no IPMI/I2C communication).
- Bugs in the MCH, such as non-functional "upstream slot power delay" parameter causing PCIe enumeration issues for FPGA-based PCIe cards.
- CPU configuration process. The BIOS/UEFI settings of the CPU module are extremely complex and there is no recovery mechanism ("CMOS reset"). Incorrect settings can render the board permanently inoperable.

It is worth noting that after an intense, 4-month collaboration with the vendors, the above issues have been fixed or mitigated by the companies, thus making the MTCA.4 platform technically viable for current and future applications in the Accelerator sector at CERN.

On the non-technical side, the SPS renovation project's relatively short timespan required the RF team to choose from COTS MTCA.4 modules instead of the traditional in-house-developed electronics. Unfortunately, to obtain the basic information required to integrate one of the modules, a Non-Disclosure Agreement was needed. This is undesirable in a scientific environment and the long signature process even impacted the project planning.

## CONCLUSION

The MTCA.4-based SPS LLRF system has been in commissioning since April 2021 and has operated with physics beams since July 2021. After 6 months of successful commissioning, the results are very positive. We plan to use this novel solution for the prototype upgrade of the HiLumi LHC Accelerating and Crab Cavity LLRF systems.

The key highlights are:

- Timing performance previously reserved for analog RF distribution systems in a WR-network based solution.
- Proven RF distribution over WR, driving accelerating cavities in an operational machine (SPS).
- Compactness: taking two 9U MTCA.4 crates and one 19-inch rack with custom electronics instead of over ten 19-inch racks.
- Backplane connectivity for low-jitter clocks and RF signals reducing cabling cost and complexity.
- Bandwidth of the PCI Express fabric provided by MTCA.4 outperforming the legacy VME platform by two orders of magnitude and allowing for much more sophisticated beam diagnostics.
- Usage of COTS modules significantly shortened the development time (especially with the SIS8300-KU and AFCZ boards).

The SPS LLRF project also triggered the development of ultra-low phase noise and improved precision White Rabbit equipment: the eRTM14/15, WRS-LJD and WR2RF-VME which offer unprecedented performance among the available WR devices. These boards are available under the CERN Open Hardware Licence [18] and can be easily adapted to other LLRF systems as well as beam instrumentation or experiment electronics.

## ACKNOWLEDGMENTS

The authors would like to thank the CERN Electronics Design Office and Assembly Workshop, Creotech, N.A.T., Struck Innovative Systeme, Javier Serrano and Erik van der Bij for their support during the development and commissioning of the SPS LLRF project.

## Abstract

Shanghai High repetition rate XFEL and Extreme light facility (SHINE) is under construction. SHINE requires precise distribution and synchronization of the 1.003086MHz timing signals over a long distance of about 3.1 km. Two prototype systems were developed, both containing three functions: beam-synchronous trigger signal distribution, random-event trigger signal distribution and data exchange between nodes. The frequency of the beam-synchronous trigger signal can be divided according to the accelerator operation mode. Each output pulse can be configured for different fill modes. A prototype system was designed based on a customized clock frequency point (64.197530MHz). Another prototype system was designed based on the standard White Rabbit protocol. The DDS (Direct Digital Synthesis) and D flip-flops (DFFs) are adopted for RF signal transfer and pulse configuration. The details of the timing system design and test results will be reported in this paper.

## OVERVIEW

Owing to the wide range of applications of X-rays in the research fields of physics, chemistry and biology, facilities with the ability to generate X-rays were developed continuously in the last century. The free electron laser (FEL) is a novel light source, producing high-brightness X-ray pulses. To achieve high-intensity and ultra-fast short wavelength radiation, several X-ray FEL facilities have been completed or under construction around the world [1].

The first hard X-ray FEL light source in China, the so-called Shanghai High repetition rate XFEL and Extreme light facility (SHINE), is under construction. It will utilize a photocathode electron gun combined with the superconducting Linac to produce 8 GeV FEL quality electron beams with 1.003086MHz repetition rate.

\* Work supported by Shanghai Municipal Science and Technology Major Project

<sup>†</sup> yanyingbing@zjlab.org.cn

SHINE timing system is design to provide precise clock pulses (Trigger) for drive laser, LLRF, solid state amplifiers, kicker, beam and optical instruments, etc. It will ensure the electron beam is generated and accelerated to the design energy, to produce the free electron laser, while completing the beam and optical parameters measurement and feedback. The White Rabbit (WR) technology was evaluated and will be adopted.

## ARCHITECTURE

SHINE timing system is composed of one master node, WR switches and more than 500 slave nodes. The master node receives reference signal from the synchronization system. The switches distribute the clock to all the nodes in the network using a hierarchical architecture. The node basic functionality comes in the form of an IP Core called WR PTP Core. They can be standalone trigger fanout modules or FMC boards, which can be embedded in the DBPM and LLRF processor. The system architecture is shown in Figure 1.

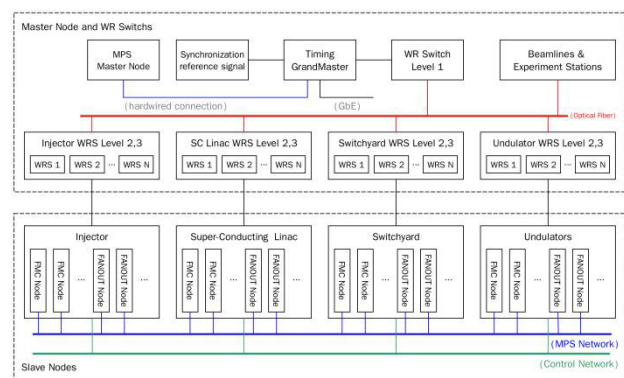

Figure 1: SHINE timing system architecture.

Three functions are designed: beam-synchronous trigger signal distribution, random-event trigger signal distribution and data exchange between nodes. The frequency of the beam-synchronous trigger signal need be divided according to the accelerator operation mode. Each output pulse need be configured for different fill modes.

SHINE requires precise distribution and synchronization of the 1.003086MHz (1300/1296) timing signals over a long distance of about 3.1 km. The beam-synchronous trigger signal distribution is the basic and priority function.

The standard White Rabbit network operates at 125/62.5MHz clock. If the repetition frequency of SHINE is 1.0MHz, 1300 MHz RF reference signal can be divided to 10MHz as the reference signal. The slave nodes output the trigger signals at the specified time, such as 1us, 2us, 5us, etc. But the repetition frequency is 1.003086MHz, we need to find the new technical routes.

### White Rabbit Trigger Distribution

White Rabbit Trigger Distribution (WRTD) is a generic framework for distributing triggers (events) between Nodes over a White Rabbit network [2]. WRTD nodes receive input events and distribute them to other nodes over WR in the form of network messages that are used to transfer the timestamp of the input event. The receiving nodes are programmed to execute some output event (action) upon reception of a particular message, potentially with some fixed delay added to the timestamp [3]. See Fig. 2:

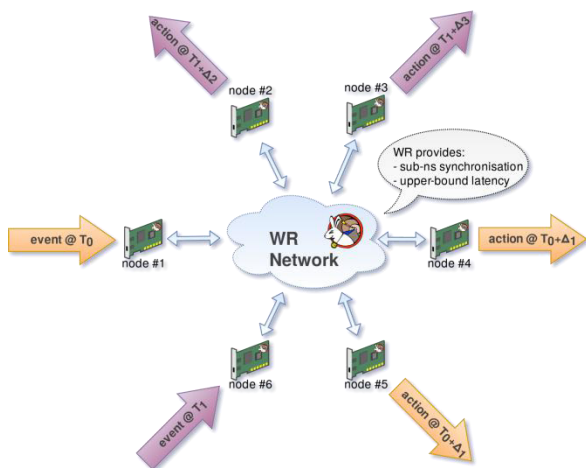

Figure 2: White Rabbit Trigger Distribution[2].

WRTD was used by CERN and SXFEL-UF (Shanghai soft X-ray Free-Electron Laser User Facility). The number of trigger sources in the system and the trigger repetition rate is limited by the network bandwidth and maximum acceptable latency requirements.[4] The SHINE beam-synchronous trigger signal could theoretically be distributed via WRTD, but the repetition rate too high. The 10 Gigabit White Rabbit switches are required, which are no commercial products yet.

The random-event trigger signal distribution is an extension function of SHINE timing system. It is used to distribute various event signals, such as beam loss, machine snapshot, etc. This function is achieved in our two prototypes by WRTD similar technology.

### RF over White Rabbit

In White Rabbit network all nodes have the same reference frequency and time. The master node phase locks its DDS (Direct Digital Synthesis) to the RF input, and broadcast the DDS control words including a TAI timestamp. All slave nodes update their DDSes with the received control word at the same moment [4,5]. See Fig. 3:

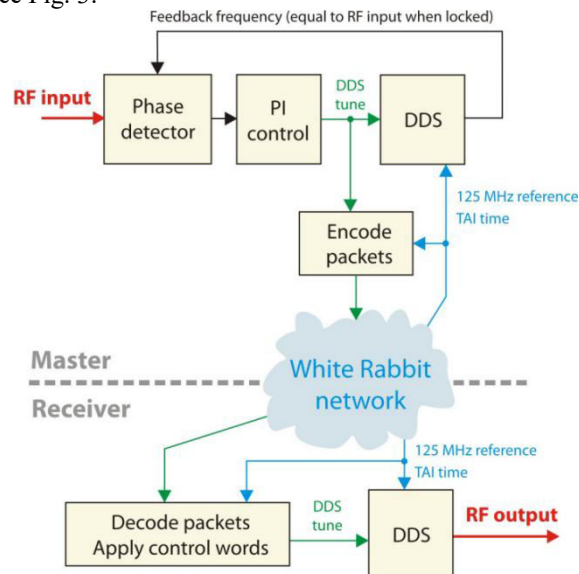

Figure 3: RF over White Rabbit[3].

This technology could be adopted for our beam-synchronous trigger signal distribution, but it needs further development. The slave nodes should output the low-jitter pulse signal. Meanwhile, it is expected that the pulses can be configured for different fill modes. We carried out the prototype (II) development with the state key laboratory of particle detection and electronics, University of Science and Technology of China[6].

### Non-Standard Clock Transmission

The repetition frequency of SHINE is 1.0030864MHz. If we build a customized White Rabbit network with non-standard PTP core, we can use the frequency division of 1300MHz as the reference signal instead of GPS/Cesium clock. This was originally just an idea, verified by the prototype (I, II) development. The prototype I was completed in cooperation with the department of engineering physics, Tsinghua University. This will implement the beam-synchronous timing system with more simpler architecture than RF over White Rabbit.

## PROTOTYPE I DEVELOPMENT

The standard White Rabbit network operates at 125/62.5MHz clock, using the external 10 MHz reference signal. The center frequency of VCXO (Voltage-Controlled Crystal Oscillator) is 25MHz. In order to minimize the modifications to the standard White Rabbit equipment, the initial solution was to replace the VCXO of the switches and nodes and shift the operating frequency to 67.708305MHz (1.003086MHz×135/2). The

system worked using the customized 27.083MHz VCXO, and less than 10ps jitters was achieved.

It is found that the frequency factor 135/2 is not conducive to the phase calculation and pulse delay. Therefore, the operating frequency was changed to 64.197504MHz ( $1.003086\text{MHz} \times 64$ ), which is easy to generate  $2^N$  divisions and thus obtain machine clock. Meanwhile, this frequency can be configured from the standard VCXO ( $25\text{MHz} \times 52/81$ ), not the customized VCXO.

There is a clear proportional relationship between the standard second and the pseudo-seconds ( $\sim 0.9969\text{s}$ ). The machine clock phase relationship is also determined.

Standard time format:

[ seconds : nanoseconds : sub-nanoseconds ]

Non-Standard time format:

[ pseudo-seconds : clock integer period : phase ]

The prototype master node and slave node are shown in figure 4 and 5. The master node receives the random-event trigger signal input. Different functions can be enabled or disabled via the digital signal from MPS (Machine Protection System). The level 1 WR switch is configured as the Grandmaster mode, which receives the external reference and PPS signal.

Figure 4: Prototype I master node.

Figure 5: Prototype I slave node.

The slave node is FMC board (FPGA Mezzanine Card), which follows the ANSI/VITA 57.1-2019 standard. There are two SFP ports and two SMA connectors on the front panel. One SFP port is used to connect to the White Rabbit network and the other is in reserve. It will be used to connect to the standard network for status monitoring in the future. One SMA connector outputs the beam-synchronous trigger signal, the other can be configured as interlock input. More signal outputs are developed through the FMC connector, including 8 independent

beam-synchronous trigger signal channels with adjustable delay and pulse width, 4 independent random-event trigger signal channels.

## PROTOTYPE II DEVELOPMENT

Prototype II implements both the two technical routes: the non-standard clock transmission and RF over White Rabbit. The details of the latter are described below.

The system architecture is shown in Figure 6. Based on the standard White Rabbit network, the master node converted the 9.027778MHz ( $1.003086\text{MHz} \times 9$ ) RF signal into the frequency and phase information. Then the data is transmitted to all slave nodes. The slave nodes use the received date to recover the clock and realize precise distribution and synchronization of the machine clock.

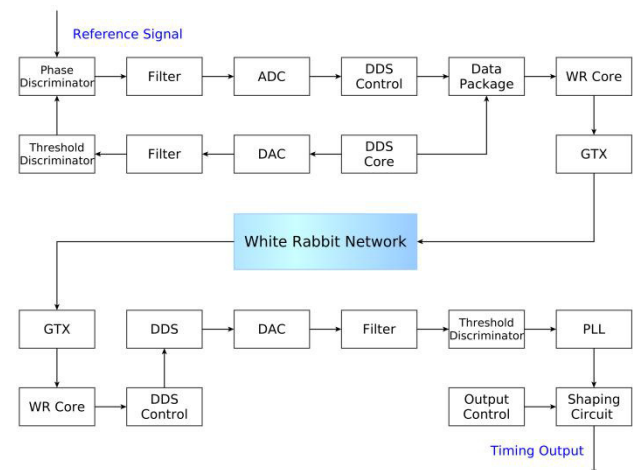

Figure 6: Prototype II system architecture.

The prototype master node and slave node are shown in figure 7 and 8. The master node is configured as the Grandmaster mode, which receives the external reference signal and random-event trigger signal. The standard WR switches are adopt to connect the slave nodes.

Figure 7: Prototype II master node.

Figure 8: Prototype II salve node.

The slave node is a non-standard FMC card. It is used to verify multiple functions, including signal recovery, pulse output, frequency division, delay adjustment and so on. The diagram of fan-out and shaping circuit is shown in Figure 9.

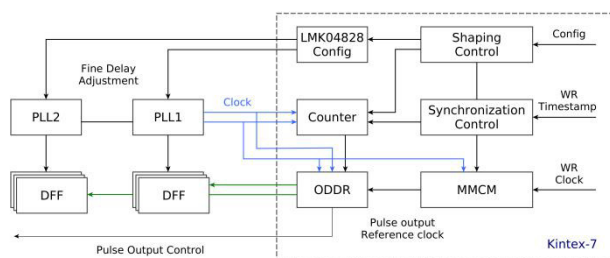

Figure 9: Fan-out and shaping circuit.

The circuit is mainly composed of the FPGA, off-chip PLL and DFF. The FPGA is responsible for frequency division, pulse width and coarse delay adjustment. The off-chip PLL is used for the signal fan-out and fine delay adjustment. The DFF latches the output of FPGA to ensure the quality and accuracy of the final pulse output.

## TEST RESULTS

A series of tests were carried out to confirm the performance of the prototype. The following parameters are verified for beam-synchronous trigger and random-event trigger signal distribution.

- Jitter between the output of slave node and the external reference signal.
- Jitter between the outputs from different slave nodes.
- Skews between two slave nodes after powering up and down.
- Delay and pulse width adjustment.
- Temperature drift.

### Prototype I Test

The test platform of Prototype I is shown in Figure 10 and 11. The GPS/Rubidium clock provides a stable 10MHz external reference signal for the arbitrary waveform generator, not for White Rabbit equipment. One channel of periodic square wave signal

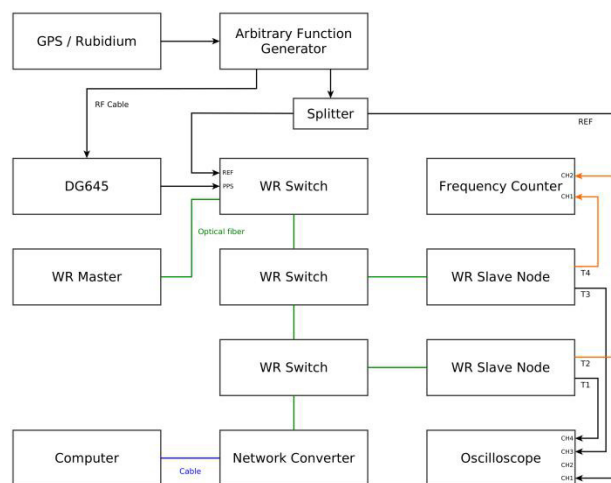

Figure 10: Prototype I test platform diagram.

Figure 11: Prototype I test platform.

For the beam-synchronous trigger signal distribution, the jitter between the output of slave node and the external reference signal is less than 10ps. The jitter between the outputs from different slave nodes is less than 5ps. The temperature drift test results are shown in the figure 12. For the random-event trigger signal distribution, the jitter between the output of slave node and the external reference signal is less than 60ps.

Figure 12: Result of the temperature drift test.

### Prototype II Test

The test platform of Prototype II is shown in Figure 13. The GPS/Rubidium clock provides a stable 10MHz external reference signal for the arbitrary waveform generator and WR switch. The master node is configured as the Grandmaster mode, which receives the RF signal (1.003086MHz×9). The computer is connected to the WR equipment via the standard network switch. The Keysight MSOS604A Oscilloscope is used to measure the output of slave node and the external reference signal.

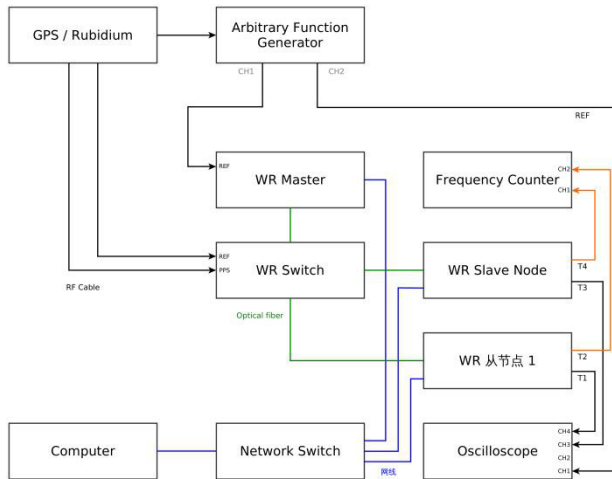

Figure 13: Prototype II test platform diagram.

For the beam-synchronous trigger signal distribution, the jitter between the output of slave node and the external reference signal is less than 20ps. The jitter between the outputs from different slave nodes is less than 10ps. For the random-event trigger signal distribution, the jitter between the output of slave node and the external reference signal is less than 35ps.

### CONCLUSION

Two prototype systems were developed, both containing three functions: beam-synchronous trigger signal distribution, random-event trigger signal distribution and data exchange between nodes. The non-standard clock transmission was proposed and verified. The prototype development has just been completed and

we will do further test and evaluation for the SHINE project.

### ACKNOWLEDGMENT

We would like to thank CERN colleagues of the Hardware and Timing Section, Beam Controls Group (BE-CO) for the discussions and suggestions.

# SUPERVISORY SYSTEM FOR THE SIRIUS SCIENTIFIC FACILITIES \*

L.C. Arruda†, G.T. Barreto, H.F. Canova, J.V. B. Franca, M.P. Calcanha,  
Brazilian Synchrotron Light Laboratory (LNLS) Campinas, Brazil

## Abstract

A general supervisory system for the scientific facilities is under development at Sirius, the Brazilian 4th generation synchrotron light source. The data generated by different classes of equipment are generally available via EPICS or industrial protocols such as OPC-UA provided by commercial automation systems. However, as the number of beamlines and laboratories expands, the effort to properly gather, display and manage this data also scales up. For this reason, an aggregating supervisory system is proposed to monitor the systems: power distribution, personal safety, beamline components, cryogenic fluids; mechanical utilities, air conditioning, among others. This work presents the overall system architecture, functionalities, and some user interfaces.

## INTRODUCTION

The general supervisory is a Supervisory Control and Data Acquisition (SCADA) system. It aims to provide a simplified web visualization and concentrate the creation of alarms notifications of Sirius' scientific facilities. The system final users are the facilities' support groups.

This article is divided into parts that discuss architecture, information organization, graphical user interface (GUI), and key performance indicators (KPIs).

## ARCHITECTURE

The parts that compose the system and the communication protocols used appear in Fig 1. The main server is the Siemens WinCC Unified Runtime [1] and it aims to exchange data with other devices, process information, handle alarms and communicate with the web clients. The Experimental and Industrial Control System (EPICS) [2] data server is used for concentrating the Epics Process Variables (PVs) data from the installations' EPICS servers and provide data to the main server using only one OPC Unified Architecture (OPC UA) [3] connection. The external communication server is intended to expand the way notifications can reach the user, in addition to the web clients alarms tables, providing services like sending emails, Telegram [4] and SMS messages. The SMS messages are sent by the Siemens 3G modem Scalance M874-3 [5] using a Socket protocol between the modem and the external communication server. The connection between the programmable logic controllers (PLCs) and the Main server uses a Siemens proprietary protocol based on TCP/IP, in these set of PLCs are included the equipment and personal protection systems [6].

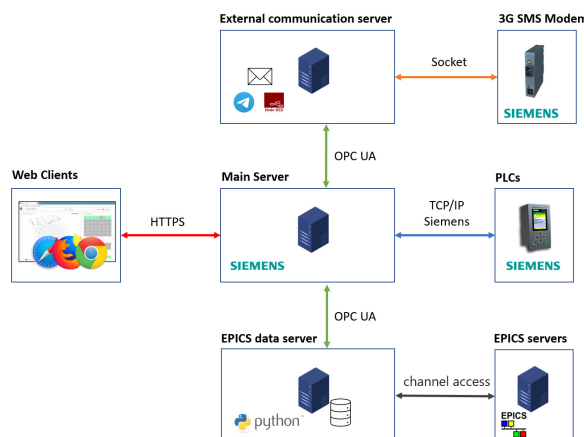

Figure 1: Architecture and communication schema.

Some of the Main server performance characteristics include the capacity to connect with 600,000 external tags, to have 200,000 internal tags, generate 200,000 discrete alarms, connect to 128 Siemens S7 SIMATIC PLCs, 10 OPC UA clients, and 100 web clients [7].

Access to the SCADA system uses password-protected authentication. The system is available only in the internal network, and user credentials needed are the same used to access other computational resources.

A software was developed to run on the EPICS data server using PyEPICS [8]. The update of data obtained from installation EPICs servers is configurable and is set to occur every second, this period is seen appropriated due to the absence of the need for quick diagnoses. Right after the PV is read, the OPC UA variable is updated.

To record trends and to perform more specifics diagnostics, when a correlation is needed, the tool used is the Archiver [9].

## INFORMATION ORGANIZATION

Usually, the users are interested in specific parts of the scientific facilities related to their expertise area such as electrical power distribution, mechanical utilities, vacuum, radiological protection, among others. Considering that support groups' work structure may be changed, the supervisory information was organized by the facilities subsystems and the user is responsible for finding their interest area.

The GUI hierarchy pattern is shown in a general form in Fig. 2. The screens are currently grouped in the general view, infrastructure, beamlines, safety, statistics, and support labs. Inside each group, there is a division by subsystem and inside each subsystem, there are one or more personalized screens related to the subsystem and one

\* Work supported by the Brazilian Ministry of Science, Technology and Innovation

† lucas.arruda@lnls.br

screen used to view and configure the alarms and other notifications.

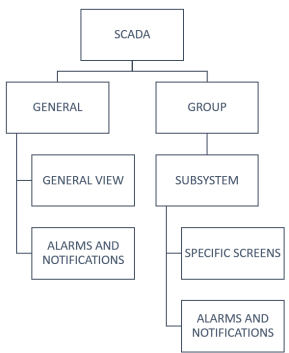

Figure 2: GUI hierarchy pattern.

Alarms and notifications screens by subsystem were designed to allow the group of people responsible for each subsystem to manage the configuration and acknowledgment of alarms and notifications.

### GUI

The Sirius' general screen, radiological protection, electrical power distribution, and alarms are currently in beta version or in development and are presented to show some of the GUI possibilities. In addition, the screens for components, vacuum, utilities, HVAC (heating, ventilation, and air conditioning), cryogenic systems among others are predicted.

### Sirius General

The Sirius' general screen plans to provide a simplified view of the hutches' status, beamlines, and subsystems. This screen is in Fig. 3.

In this screen, the hutches' status can indicate: Fail (Beam is not allowed in hutch), beam on (allowed beam on the hutch), and power off (a failure related to electrical power distribution has occurred). On the right, two matrices show the status of the beamlines, subsystems, and beamlines' gamma shutter authorization to open. Besides providing a simplified diagnostic, the existence of these matrices facilitates the view if the user uses a smartphone.

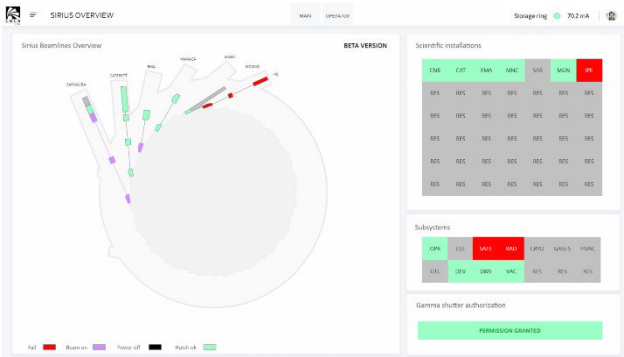

Figure 3: The Sirius' general screen showing the status of beamlines, hutches, subsystems, and authorization to open front-ends' gamma shutters.

### Radiological Protection

The radiological protection screen follows the same principle used in Sirius general screen, the main difference is that the status change to the radiological protection context. The screen is in Fig. 4.

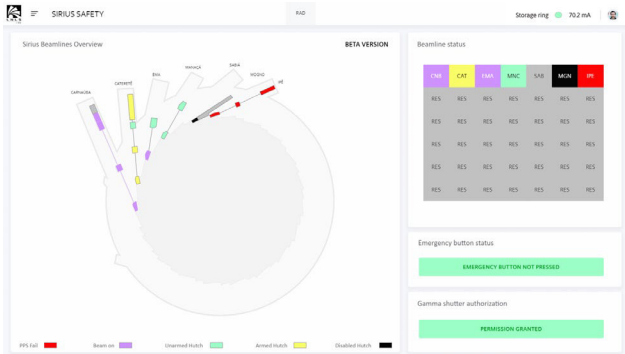

Figure 4: The radiological protection screen showing the status of beamlines, hutches, emergency buttons, and authorization to open de front-ends' gamma shutters.

### Power Distribution

The screens related to electrical power distribution are divided into two parts: A general view and the beamlines screen. The General view is in Fig. 5 and an example of the beamlines screens is shown in Fig. 6.

The general view indicates the status of beamlines, the building power distribution panels, emergency buttons, and power consumption. The overview part shows the power being consumed by the 220 VAC, 380 VAC, and 220 VAC provided by the uninterruptible power supply (UPS). The Sirius mini-map indicates the hutches' status and the power distribution panels indicating their locals in the installation.

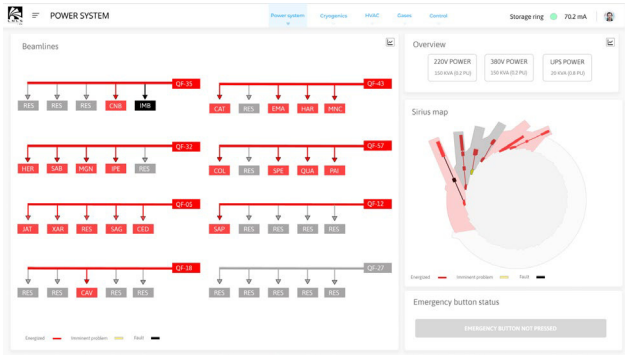

Figure 5: The electrical power distribution general screen showing the status of beamlines, hutches, emergency buttons, and building power panels.

The beamlines screens have a unifilar diagram that indicates the energized and de-energized regions, currents and allows to select a device to view more detailed information about the device in "Component data". In "Overview" is available the total amount of power being consumed in real time by the alternated current circuits. In "UPS" region is shown the status of the central 220 VAC UPS and the 24

VDC UPS that feed the emergency light and other emergency circuits related to reset the safety relays for example.

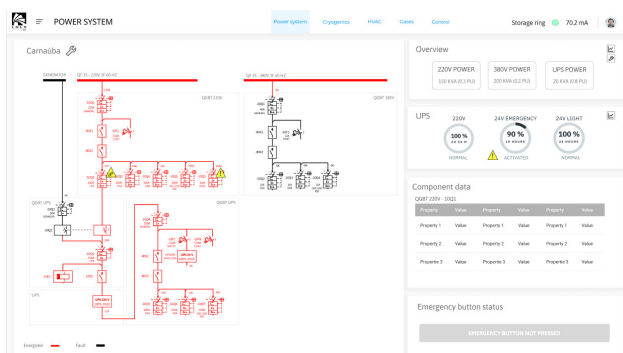

Figure 6: The beamline electrical power distribution screen showing the unifilar diagram, power consumption and status of UPS and emergency buttons.

If there's any condition that requires the user attention, a warning symbol is shown to direct then.

## Notifications

The notification screen is divided into two parts: The "Attention required", which manages the alarms and allows to configure notifications settings, and the "Log" which shows the recorded data of all events of interest related to the subsystem. The notifications screen is in Fig. 7.

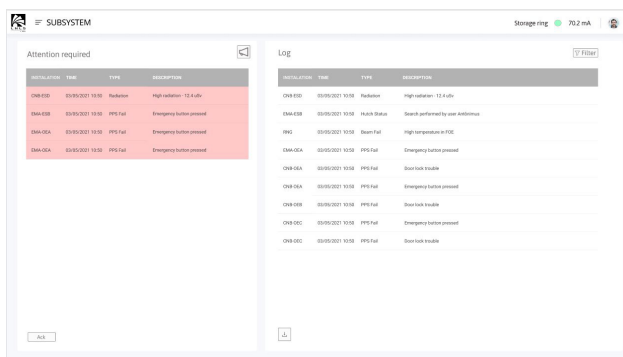

Figure 7: The subsystems' notification screens indicating the alarms that require user attention on the left and the log data on the right.

In "Attention required" exists a button on the lower part of the screen that is used to acknowledge the events and clear the stack. Using a button in the superior part of the screen the user can upload a configuration file that contains the notifications settings that can only be made by authorized users. All alarms configured to be shown in the "Attention required" region generate notifications.

In "Log" there is a button on the superior part of the screen that can be used to filter the data shown in the log table, the main filter parameters are beamline and the period. Using the button on the lower part of the screen, the user can download a file that contains the filtered log data.

## KPI

The KPIs aim to measure performance. These indicators are very dependent on the activity type and are used in the decision take process. In the supervisory system, the KPIs are planned to be implemented in the future.

In the beamline's context, the main parameter of interest is the beam availability to experiments during the programmed beamline operation period while the subsystems has nominal conditions. If the availability in these conditions is not satisfied, there's also interested to know which subsystem was not available, the local of the problem, and the period. These measurements allow directing the maintenance and the improvements by the support groups.

In addition to the availability, other parameters are being considered for beamlines and subsystems are the Meantime Before Failure (MTBF) and the Mean Time To Repair (MTTR).

## CONCLUSIONS

The SCADA system is complex by involving a high number of signals provided by different sources, to demand detailed knowledge of the facilities and by considering the user's interest from different areas. The possibility of a high number of connections, simplified GUI visualization, performance indicators, and the web access present in this work are key points to achieve the system's requirements.

## ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge the funding by the Brazilian Ministry of Science, Technology, and Innovation and the contribution of the LNLS team involved in the development of this supervisory system.

# OPEN-HARDWARE KNOB SYSTEM FOR ACCELERATION CONTROL OPERATIONS

E. Munaron, M. Montis, L. Pranovi, INFN-LNL, Legnaro, Italy

## Abstract

Nowadays technologies in LINAc facilities brought the common Human-Machine Interfaces (HMIs) to be more aligned to the standards coming from the information technology (IT) and the operators started to interact to the apparatus with the common computers' instruments: mouse and keyboard. This approach has both pros and cons. In order to minimize the cons and with the idea of providing an alternative to interact with HMIs, we tried to design and realize an open-hardware knob system solution.

## INTRODUCTION

In the market, in addition to the standard devices (such as keyboard, mouse, and so on), there are several HMI controllers used to interact with personal computers. This kind of hardware is based on encoders and buttons and it needs dedicated drivers for specific operating systems (OSs) or software to work.

Sometimes software tools and applications adopted by the control system environment can introduce limitations and constraints in the usage of these commercial devices.

To overcome this limitation (in terms of drivers and OS interface), the need for a new technical solution would be suitable.

## THE OPEN-HARDWARE KNOB CONTROLLER

Because of the heterogeneous situation in terms of hardware and software solutions adopted for the different functional systems composing the facilities at INFN National Laboratories in Legnaro, the new controller should guarantee to be easily interfaced with several kinds of instruments and devices. According to this assumption and based on the talk by Kerry Scharfglass during KiCon 2019 [1], we started to study and design a new knob controller equipped with an encoder and buttons which has to achieve the following goals:

- Easy to configure
- Multi-platform
- Cost-optimized
- Adopt public licenses for both hardware and software

Unlike many proprietary solutions, this hardware interface can be recognized as a USB keyboard from any kind of device and is virtually compatible with any modern operating system. Key buttons and encoder can be programmable and dynamically reconfigurable by the user if needed.

In addition to the technical assumptions previously mentioned, we've chosen to release the project under Open Hardware License (OHL) [2] and GNU General Public License version 3 (GPLv3), so any developer or user interested in this work will be free to reproduce, develop, customize and share his product.

## ELECTRONICS

The hardware (Figure 1) has been structured on a Printed Circuit Board (PCB) where the following parts are mounted:

- 9 Cherry-MX type keys
- 1 mechanical encoder
- 1 microcontroller

The keys are used to simulate, at the firmware level, the pressure of one keyboard button or a combination of them. Each key is equipped with anti-bounce circuitry and adequate ESD protection (Human-Body Model - HBM) to prevent a malfunction or breakdown of the electronics.

The microcontroller is devoted to managing the USB HID communication to the target system (such as a personal computer or a control device). To have multiple options in terms of hardware solutions for the microcontroller, the PCB has been realized to be compatible with both ARM STM32 microcontroller [3] and Teensy LC module [4]. This degree of freedom is very useful because it let developers select the preferred software toolchain for firmware implementation: for example, the Teensy LC module

Figure 1: The open-hardware knob controller prototype.

is compatible with Arduino Integrated Development Environment (IDE) [5], the famous opensource solution used to write and upload programs to Arduino compatible boards or, with the help of third-party cores, other vendor development boards.

Following the open-source philosophy adopted for the entire project, the PCB schema has been built using KiCad open-source software [6].

### MECHANICAL COMPONENTS

Under the mechanic aspect, the main goal the project wanted to achieve was to provide a complete system buildable from scratch, minimizing the cost in terms of components. For this reason, different parts have been designed to be realized through 3D printers and Fused Deposition Modeling (FDM) technology. Among the different 3D printing solutions, FDM technology has been considered the best choice because it is suitable for creating robust, durable, and dimensionally stable components, with the highest degree of accuracy and repeatability with low costs. As a matter of fact, 3D printers are quite diffused in several professional heterogeneous environments and among makers because of the commercial costs for devices, tools and raw materials.

Based on this choice, key covers and encored knob have been designed to be produced using FDM technology as visible in Figure 2, while the entire device cover has not been finalized due to the fact that additional ergonomics studies on the entire controller are ongoing.

The entire set of 3D models have been done with FreeCAD [7] (Figure 3), according to the philosophy adopted by the project.

Figure 2: Mechanical parts realized with FDM technology.

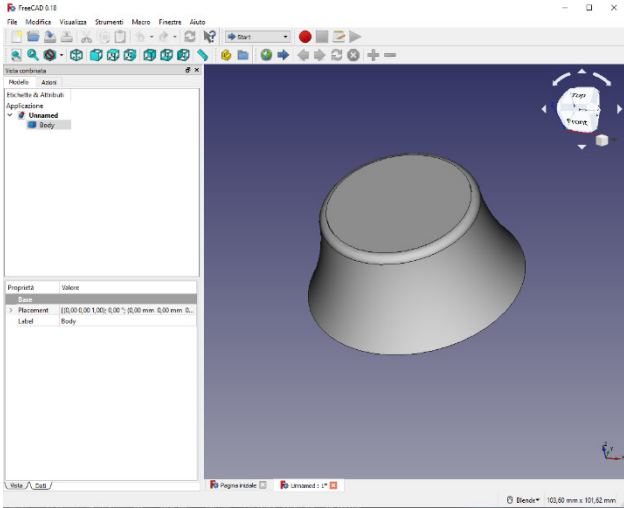

Figure 3: FreeCAD knob schematics.

### FIRMWARE

Based on the microcontroller used, the preliminary firmware version has been defined using Arduino IDE and Teensyduino add-on [8] as software toolchain (see Figure 4).

This simple application is composed of the main Arduino sketches file (Arduino program language based on C/C++) and an external C header file. In particular:

- The main sketches file is devoted to establish the serial port communication and manage the events;
- The C library defines the maps for the key buttons and the knob controller. In this place it is possible, for example, to customize the response in case of buttons pressed combinations;
- Additional standard Arduino libraries.

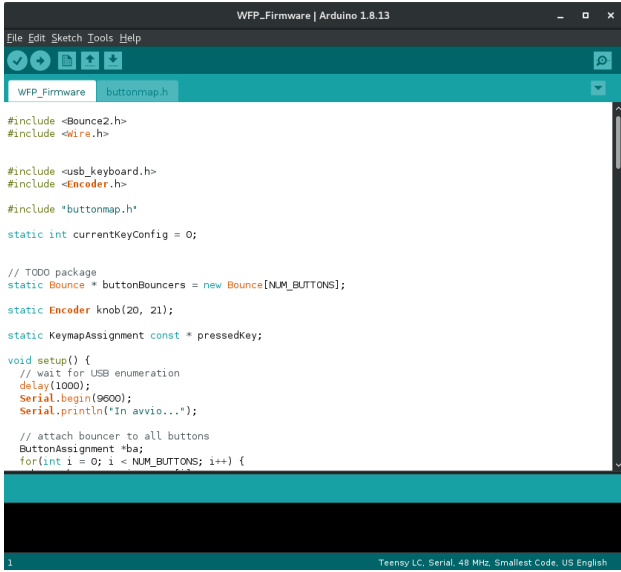

Figure 4: Firmware code realized with Arduino IDE and Teensyduino packages.

## FIRST TESTS

Preliminary tests on different operative systems let us verify the correct functionality in terms of electronics and firmware: in every setup, the device has been automatically recognized as a USB keyboard. Trying to use a heterogeneous set of applications (word processors, draw applications, etc.), the device substituted the normal keyboard without any issue (according to the buttons map pre-loaded in the Firmware).

## FURTHER DEVELOPMENTS

After the preliminary R&D performed and the test results obtained, further developments will be focused on two different areas of interest:

- Optimize the electronics and the mechanical parts to simplify schematics for PCB production and 3D printing processes
- Further investigations in ergonomics of the device, taking into account the feedback coming back from the beta testers, to realize a comfortable controller for end-users experience

In addition to that, a long-term goal the project wants to achieve is an advanced integration with the programs and software used for the control system; as consequence, deeper studies and tests with control system HMI applications will be performed, in order to adopt this hardware solution as a standard for INFN-LNL linear accelerators facility.

## CONCLUSION

The need for a simpler and more intuitive solution for beam transport and experimental control has been the starting point to design and develop a new controller for linear accelerators.

The prototype realized is a multi-platform, easy to configure solution where most of the costs have been minimized through the usage of fast prototyping technologies, such as 3D printing. In addition to that, the product follows the open-source philosophy, and all the design parts are freely available under OHL and GPLv3 licenses.

First feedbacks coming from the test are very promising and let us confirm the technology assumptions made during the design stage; at the same time, further development will be done to optimize different aspects (electronics, mechanics, performances) and realize a more efficient and comfortable control device.

# VIRTUAL REALITY AND CONTROL SYSTEMS: HOW A 3D SYSTEM LOOKS LIKE

L. Pranovi, M. Montis, INFN-LNL, Legnaro, Italy

## Abstract

Virtual Reality (VR) technology and its derivatives are mature enough to be used in environments like a nuclear research laboratory, to provide useful tools and procedures to optimize the tasks of developers and operators. Preliminary tests were performed [1] to verify the feasibility of this technology applied to a nuclear physics laboratory with promising results. Since this technology is rapidly diffusing in several different professional heterogeneous environments, such as medicine, architecture, the military and industry, we tried to evaluate the impact coming from a new kind of Human-Machine Interface based on VR.

## PRELIMINARY WORKS

In a complex environment like a nuclear facility, many tasks can be difficult to execute because of the limitations (in terms of time and availability) due to the normal operations. In this scenario, the usage of Virtual Reality Technology can be an extraordinary way to overcome these limitations.

Among the several possibilities offered by the daily work, we focused on three main aspects: data collection (used to verify the incoherencies among the data provided by the groups involved in specific tasks and projects and to correct them on design and documentation), training (used to train operators to work in parts of the particle accelerator, giving them the opportunity to familiarize with the system despite its real availability) and machine maintenance.

The studies executed and the proof of concept designed and implemented verified the maturity and the versatility of this technology: the application developed gave us preliminary good feedbacks for the areas of interest previously mentioned and the results were very promising and pushed us to extend studies and application functionalities of the prototype, embracing different hardware solutions and integrating heterogeneous data and information.

At the same time, the work done has been consolidated and extended: the training based on VR technology has obtained several good feedbacks (Figure 1) and, accordingly, a new VR experience for radioprotection staff is under discussion.

## VIRTUAL REALITY AND AUGMENTED REALITY TECHNOLOGIES

In the last decade, the mayor IT companies invested a lot of effort in VR technology and, as results, several products arrived on the market.

Figure 1: Beta tester for VR training.

At the same time the cost related to this kind of products become more attractive for the end user. In these last years, while VR devices are becoming quite common, first AR (Augmented Reality) type controllers are going to be available on the market (with high costs) [2].

These two kinds of technologies have different characteristics and, as consequence, offer different experiences to the user. Comparing them, it is possible to analyse VR in an interactive computer-generated experience taking place within a simulated environment, that incorporates mainly auditory and visual, but also other types of sensory feedback. It is rapidly diffusing among several different professional environments, such as medical, architecture, military and industry, with different level of interactions, based on the experience required. On the other hand, AR technology is defined as “an interactive experience of a real-world environment where the objects that reside in the real world are enhanced by computer-generated perceptual information, sometimes across multiple sensory modalities, including visual, auditory and haptic, somatosensory and olfactory. AR can be defined as a system that incorporates three basic features:

- a combination of real and virtual worlds
- real-time interaction
- accurate 3D registration of virtual and real objects.

The overlaid sensory information can be constructive (i.e., additive to the natural environment), or destructive (i.e., masking of the natural environment). This experience is seamlessly interwoven with the physical world such that it is perceived as an immersive aspect of the real environment” [3]. It is possible to say that augmented reality alters one's ongoing perception of a real-world environment, whereas virtual reality completely replaces the user's real-world environment with a simulated one.

However, AR technology has a distinct disadvantage compared with virtual reality: visual immersion. While VR completely covers and replaces your field of vision, AR

can only project images in a limited area in front of your eyes. This aspect must be kept into account when AR applications are going to be developed for supervision and control.

Figure 2: Panels in AR added as additional virtual desktop in the main control room.

## AR IN NUCLEAR FACILITIES

The technology is designed for free movement, while projecting images over whatever you look at, with the possibility of introducing additional information.

For our preliminary study, HoloLens 2 display by Microsoft® [4] were used as AR device: it is a combination of waveguides and light projectors which are inside the enclosure above the brow. HoloLens 2 uses laser light to illuminate the display [5].

HoloLens 2 has been designed as a tool useful in a heterogeneous set of environments and operations, such as manufacturing shop floors, field services, construction sites, remote work, sales, teaching and so on. In a facility like a nuclear plant, the introduction of this kind of device can increase performances and help operators in numerous tasks:

- provide an easy way to recall information during apparatus maintenance
- communicate with colleagues and teams through dedicated communication apps
- introduce a new concept of Human-Machine Interface (HMI) where the classical control panels are extended with virtual ones

The principal user case has been the definition of a virtual console used by operators working with the cyclotron apparatus at LNL. A renewal process is ongoing, in parallel with normal operations, in order to upgrade the apparatus high-level control interface. In this scenario, additional screens are reproduced in AR next to the normal control monitors (Figure 2). This configuration lets users have the main screens devoted to monitor and supervise the machine provided in AR while the normal computer-based HMI can be used to interact with the control (sending command and execute procedures).

The AR screens are a reproduction of the console panels, optimized for HoloLens device. This approach

simplifies the machine conduction because all the graphical user interfaces are harmonized among them.

Under technical aspect, Unreal Engine [6] software has been used. The choice of this tool has been based on two factors:

- the experience acquired with the work done with VR experiences
- the availability of dedicated Software Development Kit (SDK) optimized for AR technology.

It is important to underline that all the screens defined in AR are devoted only for monitoring: no commands or machine's procedure can be executed via AR technology. This condition has been adopted to guarantee safety and reliability for users and apparatus.

Further studies and tests are ongoing to provide control information during maintenance: the goal we want to achieve is to provide at least the same control panels available to operators working close to the machine during local supervision. Preliminary tests have been done (Figure 3) with promising results (i.e., touchless controls maximize the cleaning of environment and tools), but more effort must be invested in this task.

Figure 3: Preliminary tests with AR technology for maintenance operations.

## FURTHER DEVELOPMENTS

The work done and exposed is a preliminary test for a more stable solution of virtual monitoring and it requires further development regarding reliability and usability. The main goal we want to achieve is to extend the usage of virtual desktops not only for supervision but also for control: this step can have an important impact in terms of space optimization and portability.

Concerning this goal, additional studies and investigations are required to evaluate the effort required to realize multi-user and multi-platform solutions.

As the number of AR tools is on the rise, it is also critical to evaluate and select additional tools and software needed to develop more AR experiences.

## CONCLUSION

Augmented Reality technology is rapidly becoming an important asset in many professional fields. In an environment like nuclear facilities, it has the potential to redesign the concept of Human-Machine Interface and it can extend the usage of control parameters outside the classical control room. The preliminary tests done realizing new control panels in AR confirmed the huge potential of the tool, but further effort is required to fully integrate this technology in an heterogenous system (in terms of software and applications) like the one nuclear facility represents.

# DESIGN OF REAL-TIME ALARM SYSTEM FOR CAFe

N.Xie,Y.H.Gua, R.Wang, B.J.Wang, IMP, LAN Zhou 730000, P.R. China

## Abstract

In accelerator control, the alarm system is a very important real-time monitoring and control system. In order to find specific failures of accelerator-related equipment in time, improve the high availability of the equipment, and ensure the long-term operation of the accelerator. An accelerator alarm system based on Kafka was designed and built on the CAFe. The system uses Phoebe for architecture deployment. Kafka is used as the streaming platform of the alarm system, which effectively improves the throughput of the system and realizes real-time alarms. In order to realize the function of remote monitoring of data in the central control room, CS-Studio is used to draw the opi interface to deploy to the enterprise WeChat platform to realize remote data monitoring. This system greatly improves the response speed of fault handling and saves a lot of valuable time for accelerator fault handling.

## INTRODUCTION

China Initiative Accelerator Driven System (CiADS) plays an important role in the safety of spent fuel handling. This is a global challenge that has not yet been resolved by our country and the international nuclear energy community. Chinese ADS Front-end Demo Linac (CAFe) as a CiADS prototype. Figure 1 is the layout of the CAFe superconducting linear accelerator, which consists of nine parts. CAFe as a prototype of CiADS. Its research purpose is to develop clean, efficient and safe nuclear fission energy, and to solve the future energy supply. Therefore, the stable operation of the CAFe equipment is particularly important for the debugging and stable operation of the beam experiment.

Figure 1: Layout of CAFe Superconducting Linear Accelerator.

## SYSTEM STRUCTURE

Figure 2 is the overall framework of the alarm system, which is mainly composed of the control layer, the alarm service layer, the Kafka layer and the application layer.

### Control Layer

IOC (input output controller) is the executor of control tasks[1]. It is used to obtain the data of the monitoring

Figure 2: Framework diagram of an alarm system based on Kafka.

equipment and define the alarm threshold of the equipment. The sending of alarm information is based on the setting of the threshold. Each record in the IOC has multiple fields, "SEVR", "ACKT", "STAT" and "ACKS" are related fields of the alarm and can be customized.

### Alarm Service Layer

Alarm Server connects all PVs and obtains the records that need to be monitored through the CA protocol and configuration files. At the same time, Alarm Server collects the command information from the upper application "Acknowledge" in the topic "CAFeCommand" in Kafka to confirm the alarm. When the alarm status changes in the records, the Alarm Server will generate a new alarm to update the content in the "AcceleratorState". AutoConfigurator obtains the recorded configuration information and delivers alarm configuration information to the topic "CAFe".

### Kafka Layer

The Kafka layer generates 4 themes: Accelerator, AcceleratorState, AcceleratorCommand, and AcceleratorTalk. Alarm Server obtains current alarm configuration information, real-time alarm status, Acknowledge commands, and voice alarm records from the above 4 topics respectively.

## Application Layer

Phoebus subscribes to Kafka Topic to realize visualization of alarm information. It can display Alarm Tree, Alarm Table, Alarm Area Panel, Logger and Annunciator user interface. The staff in the central control room can know whether the accelerator is operating normally according to the alarm interface.

## Phoebus

Phoebus is a new version of Control System Studio, which eliminates the dependence on Eclipse RCP and SWT, which is conducive to the development of control system users. Phoebus is the graphical interface of EPICS control system. It provides a simple and easy-to-operate alarm interface for the central control room. The alarm module components are divided into server and client. The Alarm Server component on the server side monitors the status changes of the PV in the IOC, and sends data to Kafka based on the previous configuration and status of the PV. The server subscribes to the topic in Kafka, and displays the alarm interface on the Phoebus architecture: Alarm Tree, Alarm Table, Alarm Area Panel, Alarm Logger, and Annunciator. The functions are shown in Table 1.

Table 1: Alarm

Application	Function
Alarm Tree	Display hierarchical alarm data flow, record the type and severity of alarms
Alarm Table	Display real-time alarm information of process variables in tabular form
Alarm Area Panel	Display the name of the top alarm layer, which can be used to display the basic alarm status indication interface
Alarm Logger	Record all statuses associated with the service archive and the alarm server
Annunciator	Display the alarm time, alarm security level and the description of the alarm PV and send out the alarm voice

## HARDWARE

Figure 3 is a diagram of the hardware architecture of the control system. The operator interface uses Linux operating system to run Phoebus to realize alarm visualization and complete the human-computer interaction process. IOC provides a physical interface for the device and communicates directly with the underlying device[2].

IOC uses records to limit the description of the controlled device, so that the value obtained by the controlled device is divided into alarm levels. LAN realizes the communication between OPI and IOC. IOC and OPI adopt CA (Channel Access) channel access mechanism. CA includes client CAC (CA Client) and server CAS (CA Server), which provide application interface libraries for OPI (Operator Interface) and IOC respectively[3]

Figure 3: Hardware architecture of control system.

## REAL-TIME REMOTE INTERFACE

### Remote Real-time Interface Deployment

In order to realize the function of remotely accessing the interface of the central control room, the enterprise WeChat is adopted. At the same time, in order to ensure data security, the server and enterprise WeChat account are deployed to the intranet and the extranet respectively. The deployment process is shown in Figure 4. Intranet: The opi interface drawn by CS-Studio is deployed in the Tomcat application server on the intranet[4]. Write the configuration file config.php to connect to the enterprise WeChat, which mainly includes CorpId, TxIdSecret and AppSecret. Extranet: Deploy enterprise WeChat account, and log in to the enterprise WeChat account through the administrator's authorization for staff in the office. Enterprise WeChat obtains real-time data from the central control room through the firewall. The staff of the institute can view the real-time remote interface anytime and anywhere to understand the experimental situation.

Figure 4: Remote real-time interface deployment.

### Real-time Mobile Terminal Alarm Interface

Figure 5 shows the remote real-time data interface. The value of the alarm can be marked in red by setting the control rules of the OPI interface. The user group can view the relevant on-site real-time interface through the enterprise WeChat, which is helpful for the staff to understand the on-site operation in time and deal with the failure in time.

Figure 5: Real-time remote interface.

## CENTRAL CONTROL ROOM ALARM INTERFACE DISPLAY

### Alarm

The alarm interface of Phoebebus is shown in Figure 6. The alarm interface mainly includes four parts: Alarm Tree , Alarm Area Panel and Alarm Table[5].

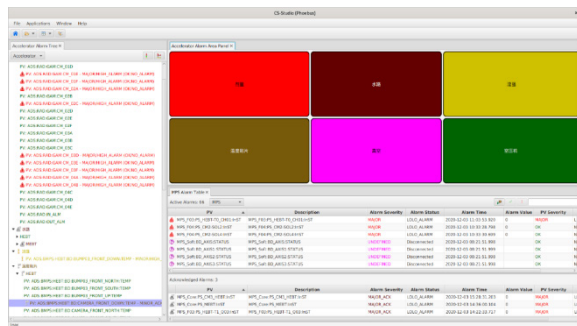

Figure 6: The alarm interface of Phoebebus.

### Alarm Tree

The alarm tree is mainly used to configure the alarm system, add PV and define the detailed information of the alarm. The tree-like hierarchical structure is used to record the PV that needs to be monitored. The tree structure mainly includes three parts: root, branch and leaf. Root represents the top-level domain name, branch represents the subsystem under the top-level domain name, and leaf represents the monitored process variable[6]. As shown in Figure 7, there are 6 top-level areas, namely dosage, waterway, flow intensity, temperature patch, vacuum and air compressor. Subsystems can be divided under each area, such as HEBT and MEBT in the waterway, and PV can be classified under the sub-system. The top-level domain name shows the most serious alarm status among all PVs under the domain name. The hierarchical view allows the operator to quickly find the affected subsystem or area.

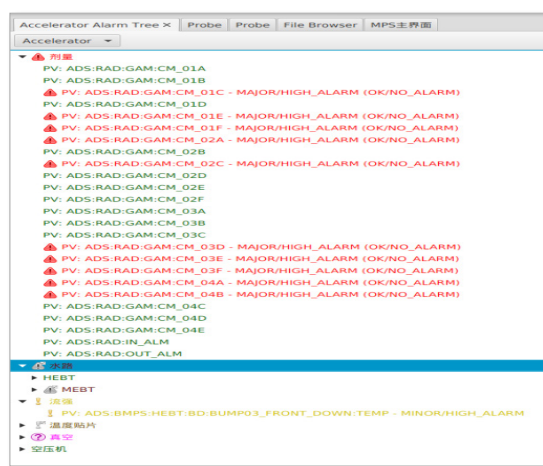

Figure 7: The interface of the Alarm Tree.

### Alarm Area Panel

The Alarm Area Panel displays the most serious alarm level, and the panel color is colored according to the high-

### Alarm Area Panel

The Alarm Area Panel displays the most serious alarm level, and the panel color is colored according to the highest alarm in the area. Different colors represent different levels of alarms, and each alarm domain corresponds to the top-level alarm of the Alarm Tree. As shown in Figure 8, the red is the MAJOR alarm state, the red is the MAJOR alarm state and the operator confirms that the alarm is received, the yellow is the MINOR alarm state, the yellow is the MINOR alarm state and the operator confirms that the alarm is received, the purple is the INVALID disconnection state, and the green is the normal state.

Figure 8: The interface of the Alarm Area Panel.

### Alarm Table

As shown in Figure 9, the Alarm Table is empty under normal conditions. When an alarm occurs, the alarm PV will be listed in the table, and the user can sort by PV name, description, alarm time and alarm level.

Figure 9: The interface of the Alarm Table.

### Alarm Log Table

The Alarm Log Table records historical alarms and is updated every 10 s, which can be used to query historical alarm information, as shown in Figure 10.

Figure 10: The interface of the Alarm Log Table.

# Annunciator

When the PV alarm information that exceeds the threshold in the topic “AcceleratorState” is sent to the Alarm Server, the topic “AcceleratorTalk” will send the alarm to the Annunciator. The Annunciator interface will display the alarm time, alarm security level and the description of the alarm PV, as shown in Figure 11. By default, the central control room receives the alarm voice once/15 s, and the voice is the content of the description, and it broadcasts until the alarm PV returns to the normal threshold.

Figure 11: The interface of the Annunciator.

## COMPARISON OF THROUGHPUT PERFORMANCE BETWEEN Kafka AND ActiveMQ

Kafka and ActiveMQ are streaming media platforms, both of which can process streaming data. The old version of the alarm system uses ActiveMQ. The alarm system of this report uses Kafka as an intermediate message plug-in. As shown in Figure 12 and Figure 13, JMeter is used to test the throughput of Kafka and ActiveMQ, both of which use a single thread to obtain 1000 data for multiple tests. The experiment shows that Kafka throughput is 6188119/minute, ActiveMQ throughput is 739153/minute. Kafka's perform-

Figure 12: The throughput of Kafka.

Figure 13: The throughput of ActiveMQ.

ance far exceeds ActiveMQ. Kafka has high throughput and is more efficient for processing real-time data streams from accelerators. Moreover, Kafka can be used not only as a message intermediate plug-in, but also as a database cache data. There is no need to install the database separately, which simplifies the installation process. Therefore, it is more effective to use Kafka as the streaming platform of the alarm system.

## CONCLUSION

CAFe alarm system was built based on Kafka streaming media platform. Phoebus adds the PV to be monitored and displays the running status. Phoebus provides an interface for stable monitoring of PV status and real-time alarm function. Using Kafka can effectively increase the data throughput rate and ensure the high availability of the server. And use the remote real-time interface to improve the cross-regional alarm function. The entire control system has been deployed and put into operation in the central control room. The interface is simple and easy to operate, works well and is easy to maintain, which saves troubleshooting time and increases the maintainability of CAFe.

# FAST CREATION OF CONTROL AND MONITOR GRAPHICAL USER INTERFACE FOR PEPC OF LASER FUSION FACILITY BASED ON ICSFF

Li Li<sup>†</sup>, Jun Luo, Zhigao Ni

Institute of Computer Application (CAEP) China Academy of Engineering Physics, MianYang, China

## Abstract

Plasma electrode Pockels cell (PEPC) is the key unit of the multi-pass amplify system in laser fusion facility, whether the PEPC is effective determined the success rate of the facility experiment directly. The operator needs to conduct remote control and monitor during the facility is running, also can automatically judge whether the pulse discharge waveform is regular online. In traditional design and realization of control and monitor software, the fixed GUI cannot adapt frequent changes of the experiment requirements, and it will consume time and resources once more. We have designed a software framework (ICSFF) that loads all GUI widget elements related to control and monitor into board through plug-ins, and then by setting the respective properties, data source and built-in script of each widget achieve patterns like point control, flow control and other complex combined control, can also achieve data acquisition and varied display effects. It allows the operator drag and drop widget freely and configure the widget properties through the interface in a non-programming mode to quickly build the GUI they need. It not only apply to PEPC in facility, but also to other system in the same facility. ICSFF supports Tango control system right now, and more control systems will be supported in the future.

## OVERVIEW

The control system of large-scale scientific experiment equipment is usually a heterogeneous system, including multiple subsystems with special functions, and PEPC of laser fusion facility is also a complex system, which contains a variety of hardware devices with different communication protocol interfaces. The typical large-scale control system like Figure 1. In the past, when developing remote integrated control system, we needed to design different interfaces for each different hardware protocol and design different operating interfaces for users. However, the solidified interface and interface design have great limitations. They are neither adapted to the frequently changing user operation requirements nor to the frequently changing hardware interfaces of experimental systems. Designers often need to spend a lot of time on the repetitive work of modifying and debugging code.

In order to change this situation, we have designed a software framework (ICSFF) that allows users to simply drag and drop and configure control properties through the interface in non-programming mode, and then quickly build the GUI what they need. This is not only applicable

to the remote integrated control of the PEPC in facility, but also applicable to other systems in the facility.

## FRAMEWORK INTRODUCTION

As mentioned above, we have developed a general control system framework for the integrated control system design of this large-scale facility, and provide editable functional modules for monitoring, control, data acquisition and storage functions with general requirements. The ICSFF software framework is a component-based distributed control system, mainly for non-real-time systems.

The software framework is suitable for the following network systems, and hardware devices are connected to the system through the network. The software of the control layer is deployed on the server or embedded controller to provide the control and data interaction of the hardware device. The monitoring layer software is deployed on the console computer to provide integrated operation, monitoring and other functions.

Figure 1: Typical large-scale scientific device control system structure.

The ICSFF software framework is divided into three layers: device service layer, system service layer and integrated monitoring layer [1]. See Figure 2.

The integrated monitoring layer provides a unified integrated operating environment for the control operation of the entire facility, enabling centralized control, monitoring and data management of the entire facility; the integrated monitoring layer can be divided into three different dimensions of integrated control functions according to actual needs: facilities, systems, groups.

The system service layer provides a combined control function for a single system under a bundle group, which is a large-scale control function aggregation of the device service layer, and this layer provides parameter delivery and experimental data archiving.

<sup>†</sup> lili\_top@163.com

The device service layer provides software mapping for independent devices to implement device control, status acquisition, device diagnostics, and self-test, using device drivers. Therefore, all heterogeneous devices implement the unification of software interfaces and provide consistent standard services on network protocols [2].

Figure 2: ICSFF software framework.

## COMPONENT-BASED CONTROL AND MONITORING GUI DESIGN

Here we mainly discuss the GUI design of the software framework. To make the software framework have a flexible operation mode that can be configured at runtime, it is need to solve the problems of abstraction of the UI layer, separation of data and UI, and editability at runtime.

Direct interaction with users requires a variety of functional modules. Currently, our software framework provides login module, log module, panel module, service management module, scheme module, element module, and attribute editing module. A complete user integrated monitoring system can be built from these modules.

### Element Module and Attribute Editing Module

Let's start with the smallest element module. At present, our element library contains 23 optional controls, including flow nodes, buttons, text edit boxes, multiple selection boxes, text displays, LCD digital displays, status lights, progress bars, Ring marquee, pump, valve, pipe, image, curve, time and other types. Currently supports Qt controls, Iocomp controls and Quc controls.

Each type of element contains its own different attributes, which include styles, data access interfaces, and data display styles. element properties can be edited. Users can edit the basic styles of the element such as the size, color, border, and font according to the needs of the display. Element style editing is shown in Figure 3, which shows the style editing interface of several element.

The purpose of separating the data I/O interfaces separately is to separate the data from the element, so that the software framework can adapt to more requirement. To configure the data in and out interface for each element, whether it is a button to send a command, or a status light, pump, etc. displayed by receiving data, you only need to select the interface provided in the corresponding service from the left side of Figure 4, and pass on the right side.

Edit the script language file to realize the connection between the control and the data. The script language can also provide more complex calculations, so that the received raw data can be processed through calculations and then displayed on the element.

Figure 3: Element property editing interface.

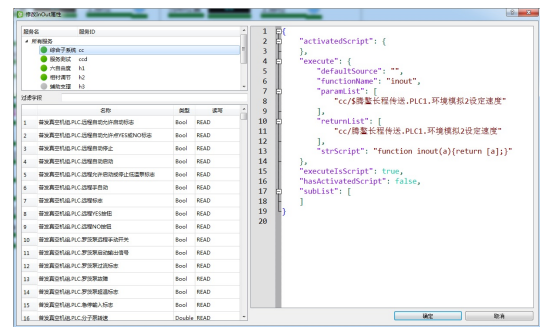

Figure 4: Data interface property configuration.

Data display style editing is shown in Figure 5, it realizes that certain controls, such as status light data, will undergo different color changes according to the received data. This is done by configuring keywords and values. Especially when the data types and data meanings defined by different manufacturers are different, users can uniformly set according to their own needs, which is conducive to the unification of the interface without changing the code.

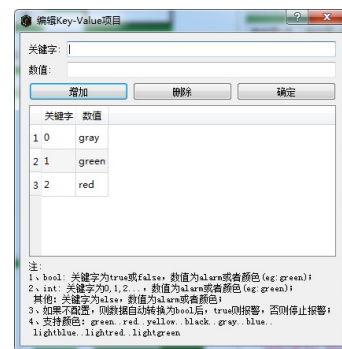

Figure 5: Data display style attribute configuration.

The data flow of the element is shown in Figure 6. The data input and the data received in the interface are all translated through the script language, and then sent and received by the FRTDB interface, which realizes the separation of the control and the data.

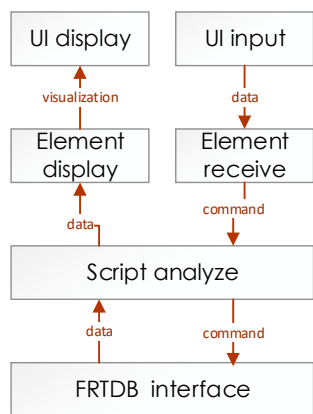

Figure 6: Data flow through element.

### Panel Module and Scheme Module

A scheme is a container of controls, and a scheme can become a system interface with independent functions. The panel is a container for loading solutions. Programs provide users with the ability to build any system or sub-system, and programs can be nested. So, users can create multiple schemes to facilitate the use and management of the control system.

The panel provides program editing and running functions, it shown in Figure 7. User drags the elements into the schemes, and arranges the elements in the editing function provided by the panel. In order to realize the editability of the program, all the contents of the program need to be stored persistently, including the general attributes such as the position, size, and color of the control, as well as the configuration of the data in and out interface. The panel provides functions such as saving scheme to database, saving to file, loading scheme from file, and loading scheme from database. At the same time, it also provides convenient functions such as copying of controls, replacing control data in and out interfaces, so that users can create schemes more quickly.

Figure 7: Panel editing function.

Through the application model of this software framework, our development model has changed, the amount of code is reduced, the focus is more focused on the difficult points, the debugging efficiency is greatly improved, and the operation and maintenance cost are greatly reduced. Figure 8 shows our current working mode: after confirming the requirements with the users, confirming the interface requirements with various manufacturers, and then using the reuse of the ICSFF software framework to build the control system, and directly convert the fully reusable parts such as login, log, panel, etc. Utilize, some reusable parts such as program editing, attribute editing, etc., are changed according to user needs, and some functions and elements that are not available in the framework need to change the framework code or add new elements to meet user needs, and at the same time Reverse enriches the

connotation of the software framework. After the iteration of unit testing and integration testing, the control system has completed the basic creation.

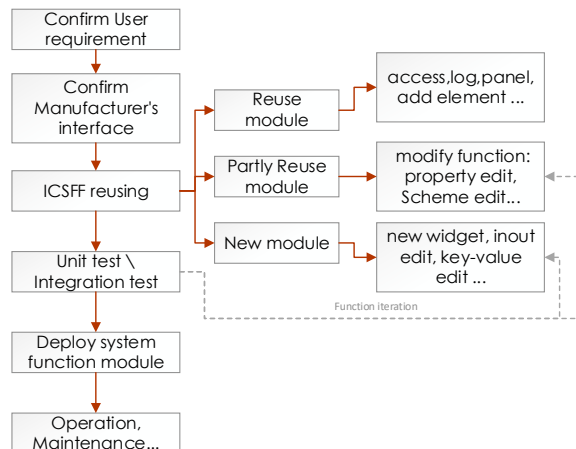

Figure 8: Software framework reuse process.

## APPLICATION

The application of ICSFF in the software framework in the plasma switch control system is shown in Figure 9. As described in the previous chapter, the system framework is built through the software framework, and the required controls are added, and the properties and control data in and out of the interface content are edited. Complete the system. Compared with the actual time of our implementation and deployment, the previous system debugging and code modification took 1~2 man/month, while the current model only needs 0.5 man/month to debug and modify.

Figure 9: PEPC control system.

## CONCLUSION

The ICSFF software framework contains many other components. This article only shows the application in the user interface. The goal of the software framework is to provide an open, scalable and reliable integrated control platform that can provide long-term operation and maintenance capabilities for various large and small systems and scientific experimental devices. In the future, we will conduct more exploration and research on the intelligent direction of the software framework, and add more intelligent modules to promote the current growing demand for data analysis.

# WEB GUI DEVELOPMENT AND INTEGRATION IN LIBERA INSTRUMENTATION

D. Bisiach<sup>†</sup>, M. Cargnelutti, P. Leban, P. Paglovec, L. Rahne, M. Škabar, A. Vigali  
Instrumentation Technologies doo, Solkan, Slovenia

## Abstract

During the past 5 years, Instrumentation Technologies expanded and added to the embedded OS running on Libera instruments (beam position instrumentation, LLRF) a lot of data access interfaces to allow faster access to the signals retrieved by the instrument. Some of the access interfaces are strictly related to the user environment Machine control system (EPICS/TANGO), and others are related to the user software preferences (Matlab/Python). In the last years, the requirement for easier data streaming was raised to allow easier data access using PC and mobile phones through a Web browser. This paper aims to present the development of the web backend server and the realization of a web frontend capable to process the data retrieved by the instrument. A use-case will be presented, the realization of the Libera Current Meter Web GUI as a first development example of a Web GUI interface for a Libera instrument and the starting point for the Web GUI pipeline integration on other instruments. The HTTP access interface will become in the next years a standard in data access for Libera instrumentation for quick testing/diagnostics and will allow the final user to customize it autonomously.

## INTRODUCTION

In the accelerator environment, the data access is usually performed with well-established and standard access using EPICS, TANGO, Labview, and Matlab interfaces. This software does not allow only access to data but also integrates the control system and safety interlocks to prevent damage to the accelerator block unit.

The drawback of this reliable and safe type of implementation is that any new instrument that is placed in the accelerator environment needs to be configured on the server-side and usually this procedure requires time and effort since the connection is not immediate.

The need for a faster way for evaluation and testing of new devices triggered the attention to the Web interfaces that were already developed in-house by the Red Pitaya project [1] that integrates a fast and easy to access interface that can be used for quick data acquisition.

## INTERFACE BETWEEN INSTRUMENT AND APPLICATION SOFTWARE

The access to the setting and the data provided by the instrument is allowed by the software structure reported in Fig.1. The lower layer is tightly bonded to the hardware interface and is responsible to communicate at a lower level with the FPGA and the CPU processes. The second

layer called Machine Control Interface (MCI) connects all the user interfaces by providing APIs that enable the servers to access the configuration parameters, the status information, and the data acquired by the instrument. The server-side applications expose through the network to the client-side different application protocols: libera-ioc (EPICS), libera-ds (TANGO), libera-telnet (Labview/Matlab), libera-cli (user access with the bash) and, as a new feature described in this paper, the libera-http interface that enables the Web access.

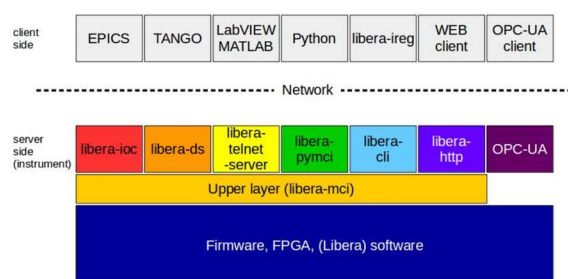

Figure 1: Application stack layer.

Some of these protocols can run in parallel (e.g. EPICS, bash, and HTTP) which makes the troubleshooting of the instrument much easier and more efficient.

## HTTP APPLICATION ARCHITECTURE BASED ON REST API

As mentioned in the previous paragraph, access to the instrument can be performed by any device that can access the same network using the HTTP protocol. A typical use case is reported in Fig. 2 where the instrument is accessible using the wired and wireless network:

Figure 2: Access to the instrument in a local network.

The system architecture is based on the REpresentational State Transfer (REST) software architectural style and provides the services through Application Programming Interfaces (API) that allow the programmer to easily implement access to the instrument internal interfaces.

The server interface starts during the boot of the instrument and opens a port that is accessible to the other devices

<sup>†</sup> danilo.bisiach@i-tech.si

connected to the same network environment. The Libera instrument acts as a server, and any local device acts as a client. The communication API uses the JavaScript Object Notation (JSON) to exchange the data between the server and the client is reported in Fig. 3 and Fig. 4:

Figure 3: HTTP REST API application architecture.

The requests are performed on the client-side by sending desired parameters in JSON format to the REST API. The server will then return the requested node in JSON format that will be processed by the client and presented in a human-readable format on the WebGUI.

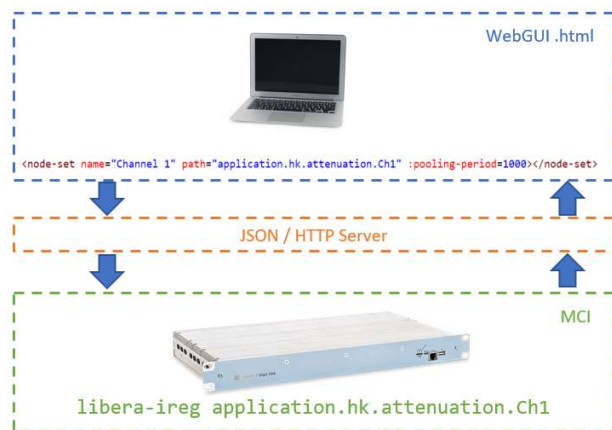

Figure 4: HTTP REST API application architecture node detail.

The integration of the HTTP server on different instruments is almost immediate since the building of the application is fully automated by the existing revisioning and building system. Different instruments, so different software applications, can share the same code for the server application and this feature allows high scalability of the server application.

The only part that needs to be customized development for every new application is the WebGUI code which includes the path to the application nodes. All the settable nodes on the instrument are specified by the node-set labels where the path of a specified node can be accessed as reported in Fig. 5:

The node-set tag is composed by the name we want to give to the variable in the WebGUI, by the path label that is representing the target node in MCI application and allows access to a specific settable variable or a data stream on the instrument, and by the polling-period which specified the refresh time in the WebGUI application.

```
<div class="ireg-node-container">
  <div class="ireg-node-set-name">
    ATTENUATION
  </div>
  <table>
    <node-set name="Channel 1" path="application.hk.attenuation.Ch1" :pooling-period=1000></node-set>
    <node-set name="Channel 2" path="application.hk.attenuation.Ch2" :pooling-period=1000></node-set>
    <node-set name="Channel 3" path="application.hk.attenuation.Ch3" :pooling-period=1000></node-set>
    <node-set name="Channel 4" path="application.hk.attenuation.Ch4" :pooling-period=1000></node-set>
  </table>
</div>
```

Figure 5: Code snippet with the implementation of a node readout from the system.

## HTTP APPLICATION ARCHITECTURE BASED ON WEBSOCKET

An additional high-performance interface based on WebSocket technology was integrated into the Libera software.

The interface is compliant with the RFC 6455 and compatible with the HTTP protocol by allowing a full-duplex communication between the client and the server running without the need to re-establish the communication at every request but by keeping it open to facilitate the real-time data transfer and data streaming over TCP. Figure 6 reports the architecture implemented with the WebSocket architecture:

Figure 6: WebSocket application architecture.

The main benefit of this implementation is to allow a maximum performance on data exchange with minimum overhead, and this can make the difference with the REST/API.

It was chosen for the implementation of the 12 Channel Libera Current Meter WebGUI interface which can handle and plot the data acquired from the instrument with minimum latency and high robustness.

## EXTENSION AND CUSTOMISATION OF THE HTTP USER INTERFACE: DEVELOPMENT AND INTEGRATION OF A 12 CHANNEL CURRENT METER

One of the main benefits of the HTTP implementation is to allow the final user to customize and integrate the application.

The extensions of the WebGUI can consist of the simple addition of buttons/graphical effects or also of some more consistent improvements. The realization of the 12 Channel Current Meter GUI interface was a very extensive customization of the user software that consisted in the implementation of really demanding features listed below:

1. Capability to perform calculations on the data acquired such as mean values and standard deviation for the acquired signals.
2. Continuous backup of the acquired data in .csv file format.

3. Integrate the data acquisition from 3 independent 4-channel acquisition instruments as a 12 channel acquisition instrument.
4. The ability of the WebGUI to run smoothly for 1-month operation, without any loss of data and by keeping the measurement going during the operation.

These features required a high number of additions, testing, and revision of the actual HTTP server implementation. Due to these features, the decision was to implement all the communication based on WebSockets.

All the 3 integrated instruments were acting as an independent device with 12 channels by maintaining a constant synchronization between the 12 channels. The implemented architecture is reported in Fig. 7 where one 4-channel Libera Current meter unit is acting as the master unit which includes the HTTP server on which the client will access the acquired data. The two other 4-channel Libera Current meter are synchronized with the master unit and continuously provide the acquired data stream:

Figure 7: 12 Channel Libera Current meter integration. 3 independent instruments are acting as one on the WebGUI interface side.

The WebGUI screenshot of Fig. 8 reports the final result of the implementation.

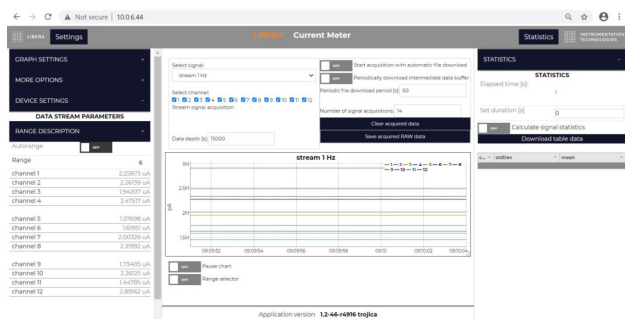

Figure 8: 12-Channel Libera Current meter integration WebGUI.

The most critical point was the testing of the user interface by checking the ability to run smoothly for one month time. These tests were performed by adding to the application software many additional data exchange requests and to stress the memory consumption of the Web browser. The interface was demonstrated to work smoothly for 30 consecutive days with this additional workload on Microsoft Edge (based on the Chromium engine). The main parameters were constantly monitored using the Web browser diagnostics features such as the task manager and the performance options in the Web browser developer mode. The use of the WebSocket architecture allowed the interface to run smoothly even if a lot of data were continuously accumulated and plotted.

As a first experience and proof of concept about the use of WebGUI interfaces based on Javascript for instrument data acquisition, the decision is to integrate the Selenium plugin for Python into the future projects to automate the GUI regression tests and scalability during the QC operations.

## RESULTS AND CONCLUSIONS

The development of an HTTP REST API and WebSocket interfaces required a lot of effort in terms of system implementation, integration, testing, and debugging. One of the main benefits is that such a system can be easily accessed by any final user without the need for any control system software (EPICS, TANGO) or proprietary software (Matlab, Labview) already running on the data acquisition system. These features made it very reliable and the first choice of use during system troubleshooting and installation.

The other benefit was to introduce high scalability of the interface: many instruments can benefit from this implementation since the HTTP server is available as a quick add-on for all the Libera instruments with minimal effort dedicated to porting. The performance of the WebSockets can make a difference when a large amount of data needs to be retrieved from the instrument.

Another future implementation within the HTTP or WebSocket can be the GRPC [2] Node-based implementation, which will unify high performance in an easy-to-use platform.

As an ending note, we can confirm that the developed HTTP REST API and WebSocket interface has now become one of the first choice data access interfaces for the testing of the instruments.

# SCALING UP THE ALBA CABLING DATABASE AND PLANS TO TURN INTO AN ASSET MANAGEMENT SYSTEM

I. Costa<sup>†</sup>, A. Camps Gimenez, R. Cazorla, T. Fernández Maltas, D. Salvat\*  
ALBA-CELLS Synchrotron, Barcelona, Spain

## Abstract

The “Cabling and Controls Database” (CCDB) is a central repository where the different teams of ALBA manage the information of installed racks, equipment, cables and connectors, and their connections and technical specifications. ALBA has modernized this web application for sustainability reasons and fit new needs detected throughout the last years of operation in our facility. The application has been linked to Jira to allow tracking problems in specific installed equipment or locations. In addition, it also connects to the ALBA Inventory Pools application, the warehouse management system, where the stock of physical equipment and components are maintained to get information on the life cycle of the different devices. These new features, integrated with proprietary products like Jira and Insight, aim to become ALBA's asset management system. This paper aims to describe the main features of the recent application upgrade, currently in continuous development.

## INTRODUCTION

During the ALBA's design phase back in 2006, the Management Information Systems section (MIS), under the Computing Division, started to develop the “Cabling and Controls Database” (CCDB) [1]. Since then, this web application has been used as a central repository to keep information of all racks, equipment, connectors and cables used in ALBA. At its early stage, the application was very useful for the cabling tender and the installation phase. Subsequently, other features were implemented in order to ease the maintenance of the Tango Control System [2] and the Equipment Protection System (EPS) [3] by the Controls group, who gets the data through an API or directly from the web interface.

This in-house development has been evolving for years, and in 2019 started a process of technological upgrade. In this upgrade new features have been included, such as the integration between equipment instances and Jira, and also their integration to the ALBA Inventory Pools system. These integrations aim to become a new ALBA's Asset Management System.

## CCDB UPGRADE

In origin, the “Cabling and Controls Database” was integrated in the ALBA's Intranet and built in python Plone/Zope which acted as the web interface to ease the visualization of the data stored in a MySQL database. The

CCDB provides also an API, which has also been upgraded to a RESTful system.

Along the last years of usage, the Electronics section of ALBA, managers of the application, detected new needs and proposed new features to be developed. Without a first modernization of the technology these new features could not be developed.

## Technological Upgrade

Starting on January 2019, the original CCDB application was redefined and migrated to Django Framework [4], a Python-based free and open-source web framework that follows the model–template–views (MTV) architectural pattern. Like in the old application, the new database is also a MySQL.

This upgrade was necessary to decouple the application from the outdated Plone ALBA's Intranet, following the tendency of the other applications developed by the MIS section. In the same direction, the new application's look and feel meets the style guide of the MIS' applications, based on Bootstrap [5] (see Fig. 1).

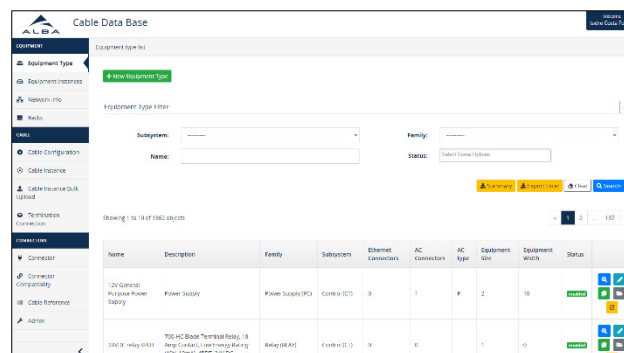

Figure 1: View of the CCDB web application.

To carry out the migration, the new application was developed from scratch and, after a period of coexistence between both the old and the new system, finally on February 2020 all the data was migrated to the new CCDB Django application and the old version was disabled.

## New Features

Among the new features introduced after the migration of the application we should highlight two of them, that enable the application to be part of a future Asset Management System.

The first of these features requested by Electronics was the tracking of equipment instances and location using Jira, our issue tracking system. This feature allows to detect dysfunctional equipment or hot locations.

<sup>†</sup> icosta@cells.es

\* on leave

The other requirement was the interconnection between the CCDB and the ALBA's Inventory Pools application, our warehouse management system. This integration gives users the opportunity to inform which physical equipment from the warehouse is installed in the equipment instance of the CCDB.

## ISSUE TRACKING OF EQUIPMENT

### *The Concept of Equipment Instance*

An equipment instance is an object created in the CCDB that represents an instance of an equipment type model. The equipment type is a template that contains a set of channels, each channel has associated a connector type that has already been created in the CCDB [1]. Furthermore, every equipment type has associated its documentation, like technical specifications and manuals.

When a user creates a new equipment instance in the CCDB, he/she is virtually placing an equipment of the chosen type in a particular location of the facility. In addition to the location and the type, user should select a system and subsystem from a list, to add a functional attribute to the equipment instance. The result of this combination of fields is an equipment code, which will be a unique identifier in the whole CCDB. In Fig.2 there is an example of equipment instance code and how it is structured.

**SR-CT-CPCI-RKA04B01-01**

**System-Subsystem-Family (Eq.Type)-Location-Code**

Figure 2: Example of equipment instance code.

### *Jira Service Desk and Insight Application*

In 2016 ALBA adopted Jira as its Service Management System, given that it fulfils all the needs of the organization, not only in terms of service but also in terms of project management [6]. Since the implementation of this commercial software the creation and management of different types of issues to different Service Desk teams has been centralized in a unique Customer Portal. With the support of the MIS section, every team has configured their workflows and processes according to their needs to handle their service desk requests.

As it is well known, there are a large number of plugins and applications in the market that can be installed in Jira. Some teams of ALBA started to use an application called Insight, which is fully integrated in the Jira Service Management. Insight is used for asset and configuration management [7] and it is very versatile, since any organization can completely configure its schema according to their needs.

Due to the high accessibility of the API provided by Jira, it is not difficult to make interact our own applications with Jira or Insight. However, in order to centralize all these interactions, the MIS section developed an internal REST API built in Python called jira-rest-service.

### *Integration of CCDB and Jira*

Regarding to the equipment instances, one of the new requirements raised by the Electronics group was to allow

users to create Jira issues from the CCDB web application relating directly the equipment instance. This feature enables the detection of dysfunctional equipment or hot locations.

The Jira issues are listed in every equipment instance detail page (see Fig. 3), or are easily reachable directly in the Jira Service Desk, where users can manage the issues at their convenience (see Fig. 4).

The screenshot shows the 'Equipment Description' page for 'BO-PC-BM-RKA15A02-01'. It includes fields for Equipment type, Description, Subsystem, and Alpha code. Below this is a 'Jira Issue History' section with a table of issues.

Type	Key	Summary	Status	Created	Last Update

Figure 4: Jira Service Desk search page filtering by the Equipment instance showing the list of issues.

To allow this integration between CCDB and Jira, an object schema in the Insight application had to be created and configured. This schema is composed by all the possible location places that could occupy an equipment instance in CCDB, formed by combinations of fields location, number, row id and row position. Furthermore, every equipment instance created in CCDB, currently 8764 elements, are created also in Insight and related to its location place. When a new equipment instance is created in CCDB, the internal jira-rest-service API is requested to create its equivalent object to Insight, keeping the integrity of the data between both systems.

This equipment instance object of Insight is fully accessible from Jira Service Desk, since it has been defined as a custom field and added to the screens of the Electronics group Service Desk.

## INVENTORY POOLS SYSTEM

The ALBA's Inventory Pools is an in-house web application developed by the MIS section that allows the different groups of ALBA the management of the inventory of their items as well as the booking and lending of the material by other users.

Technologically, it is built in a back-end / front-end architecture, using Django and AngularJS that interacts each other through the back-end REST services.

In a nutshell, Inventory Pools gives every group of the organization the opportunity to create their own pool, where they can manage their catalogue of materials, stocks and locations in the different warehouses or labs in the facility. To manage this information in the pool, every group assign different roles to particular users, such pool managers or pool operators, to be able to do different actions according to their responsibilities.

### Booking System

Every pool can be public or not, depending if their items can be borrowed by any member of the ALBA staff. This is one of the main features of this application, indeed this was its original motivation. Figure 5 shows a page of the booking system.

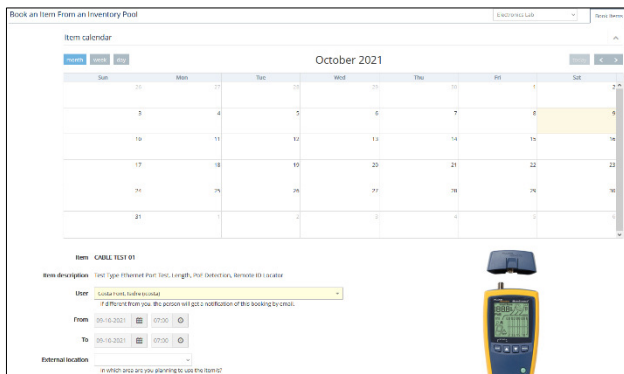

Figure 5: View of the Inventory Pools web application.

### Warehouse and Inventory Management

To ease the management of the material stock, managers and operators of every pool can set up the locations in the system where the items are actually placed in their warehouse.

Every item of the pool has its unique barcode, provided by the system or by the pool manager. This barcode can be printed in a label and posted to the item or to its location. Teams are free to let users to get the material directly from their warehouse. In this case, a set of devices (touchscreen, barcode reader and an access card reader) controlled by a raspberry pi is installed in the warehouse (see Fig. 6). User should pick up the item, read the barcode and the item will be displayed in the system. After authenticating himself with his/her ALBA's access card through the card reader he/she can get the item recording it automatically to the system. An option to search the location of the item is also available as well as an option for the pool members to manage the material directly in site.

### INSTALLATION OF ITEMS IN CCDB

As it is explained before, an equipment instance of CCDB is the representation of the specific location of the facility that will be used to place an equipment of a particular type for a determined purpose or functionality.

Figure 6: Set of devices installed in the ECS warehouse.

But until now, the specific physical device with its own barcode, that will occupy that equipment instance is not known. This is the need that the Electronics group detected throughout the last years of operation in our facility.

### Integration of Inventory Pools and CCDB

To fulfil this need, the MIS section has customized the generic Inventory Pools application in order to allow the interconnection of the Electronics Critical Stock (ECS) with CCDB. Thus, users can install physical devices or components from Inventory Pools to CCDB.

If a pool, like ECS, is configured to interact with CCDB some differences are applied in its features. The barcode field becomes the "Alba Code" field, with the same purpose of identifying the item. A new field "Equipment Instance" is included for each item in the list and filter page.

To install the item in the equipment instance, user is able to do it in the equipment instance of CCDB or alternatively using the warehouse feature of the Inventory Pools. For that purpose, user can go to the warehouse of ECS take the item from its location, read the barcode and inform the system that he/she is going to install it physically in the selected equipment instance of CCDB (see Fig. 7).

When user performs this operation, the item becomes unavailable for other users, because it is being used in the installation. Besides, the managers and operators of the pool can see the code of the equipment instance where the item has been installed in the list of items.

From the CCDB point of view, users can do the same operation, getting a list of items that can be installed in the equipment instance. It is allowed to install multiple items in the same instance, because an equipment instance can be composed by multiple components. In fact, there is a new feature in CCDB, still to be developed, to give the

possibility of splitting the equipment instances in sub-equipment. Doing this, users would be able to install all the components one by one in each real location within an equipment instance.

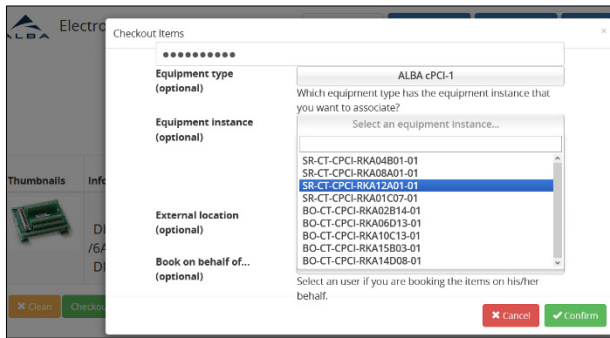

Figure 7: Example of how to select an equipment instance from the warehouse using the Inventory Pools application.

### Asset Product Object in Insight

In the integration between CCDB and Inventory Pools the same CCDB object schema of Insight has been used. A new object called Asset Product has been created. When a manager or operator of the ECS pool creates a returnable item, this item can be created to Insight as an Asset Product. Internally, this time from Inventory Pools, the jira-rest-service API is requested to create the new object in Insight. The only data necessary to do it is the Alba Code and the item's name.

An item is considered returnable when it is a non-fungible material, when it is unique and identifiable with its own serial number. An Alba Code will be assigned to it in our system, which will be the code used to be identified also in CCDB.

When an item is installed in an equipment instance, regardless where this operation is being done, from CCDB or Inventory Pools, the jira-rest-service API will relate both objects in the Asset Product of Insight. On the opposite, an item can be uninstalled from the equipment instance in CCDB, in this case our API will remove their relationship. In Insight, an historic of events is stored for every object, so a tracking of operations in the Asset Product can be obtained.

## ASSET MANAGEMENT

The integration between both applications, CCDB and Inventory Pools with Jira and Insight can be considered as a first step to build a new Asset Management System, since the combination of these systems covers all the four aspects that every asset needs to be unique (functional, product, geographical location and life cycle) (see Fig. 8).

**Functional Aspect** This aspect gives information about what is the functionality or purpose of the asset. Normally, an asset belongs to a system and sub-system that can be translated as its functional position. This is a mandatory information for the creation of the equipment instances in CCDB.

**Product** Information about what type of product the asset is. Types can be grouped by families to ease the categorization of products. Also, the serial number or barcode, that allow the identification belong to this aspect. Stored in both CCDB and Inventory Pools there are information and documentation about the item type. While the barcode, the serial number and other manufacturer information are maintained in Inventory Pools.

**Geographical Location** Regarding to this aspect, when an equipment instance is created in CCDB, user should provide a location of the facility, formed by the combination of fields location, number, row id and row position. This combination is the part of the equipment instance code related to its location (i.e. RKA12A01).

**Life Cycle** The integration with Jira can help users to manage the life cycle of items, keeping the history of changes or problems throughout its usage in the facility.

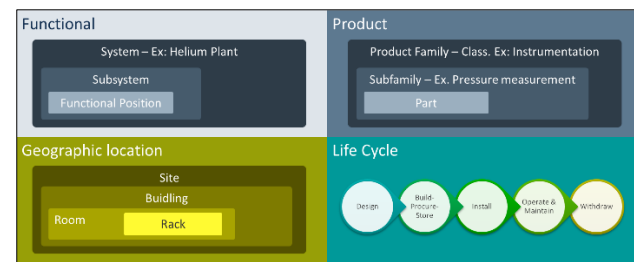

Figure 8: The four aspects of an asset [8].

### Future Roadmap

The base of this incipient asset management system has been implemented successfully, but there are new features that need to be developed in order to complete it.

First, a definition of the process of a standard life cycle of an asset is needed to be implemented in Jira and Insight. Now, users can only install or uninstall items in the equipment instance, but the life cycle is much more than this.

And also, the multi-equipment feature in CCDB is needed to provide a complete break-down of components in each equipment instance.

## CONCLUSION

The “Cabling and Controls Database” (CCDB) has been migrated to a new system for sustainability reasons, but also new features have been implemented. One of them is the integration with Jira in order to allow users the issue tracking of the equipment instances which can ease the detection of dysfunctional equipment or hot locations. Other remarkable issue is the integration with the Inventory Pools application, which enables the installation of physical equipment to the CCDB equipment instances.

These integrations are the first steps to build a new asset management system that combine the functional and geographical information provided by CCDB, the detailed information of the products from items of Inventory Pools and the tracking of the asset extracted from Jira and Insight.

There are still some features needed in order to make it more functional. Since the migration was finished, CCDB is in continuous development, not only from the asset management point of view.

# NOTIFICATIONS WITH NATIVE MOBILE APPLICATIONS

B. Bertrand\*, J. Forsberg, MAX IV, Lund, Sweden  
E. Laface, G. Weiss, European Spallation Source ERIC, Lund, Sweden

## Abstract

Notifications are an essential part of any control system. Many people want to be notified of specific events. There are several ways to send notifications: SMS, e-mails or messaging applications like Slack and Telegram are some common ones. Those solutions frequently require some central configuration to record who will receive messages, which is difficult to maintain. ESS developed a native mobile application, both for iOS and Android, to manage notifications. The application allows the users to subscribe to the topics they are interested in, removing the need for a central configuration. A web server is used as gateway to send all notifications following Apple and Google protocols. This server exposes a REST API that is used both by clients to send messages and mobile applications to retrieve and manage those messages. This paper will detail the technical implementation as well as the lessons learnt from this approach.

## INTRODUCTION

The European Spallation Source (ESS) is under rapid development in Lund, Sweden. More and more parts of the control system are put into place, which means a growing number of messages and alarms are triggered. People want to be notified to keep track of what is happening and to know if any action is required. There were several ways to send notifications depending on the application. IT had a service to send SMS, some applications were relying on e-mails. We also developed Telegram and Slack bots. The Telegram bot was quite popular as users could check messages on their phone via the native mobile application. The issue was that the configuration was centralized: each new user had to be added manually with the list of topics he was interested in. That was demanding to maintain and didn't scale well. The other problem was the inclusion in existing applications which wasn't trivial. We wanted a general purpose solution that would be easy to use from any application and would unify the user experience.

## CONCEPTS

We wanted users to be able to subscribe themselves to the notifications they are interested in. This would remove the need for a central configuration that is laborious to manage. To achieve this, notifications have to be grouped in categories named *services*. The number of *services* doesn't have any limit in theory. In practice, too many services would make it difficult to decide which to subscribe to. With too few services, there is a risk that the user will receive many unwanted notifications. Some services used at ESS are called Logbook On-Call, Logbook TS2, OpenXAL and

Prometheus CSI. Those examples show that a service can be linked to an application (like OpenXAL), but that one application can also send messages to different services (like the LogBook).

Smartphones are part of an infrastructure that makes it easy to dispatch notifications. We chose to develop a specific mobile application that we could customize to our need. This application would be used to subscribe to the *services*, receive notifications and read messages. Two clients are available, one for Apple iOS devices [1] and one for Android users [2].

Sending notifications to a mobile phone can be done relying on Apple and Google infrastructure. We decided to design a REST API that is used both to communicate with the mobile clients and to forward the notifications received from the system. Sending a notification only requires a POST to this central server, named Notify server [3], making the integration in existing application simple.

## NOTIFY SERVER

The Notify server was developed with FastAPI [4], an async Python web framework, that quickly became very popular in the past years. It is based on Starlette [5], a lightweight ASGI framework, and Pydantic [6], a data validation library using python type annotations. PostgreSQL [7] is used as database. FastAPI was designed to make writing API easy and is based on OpenAPI standard [8]. It automatically generates an interactive API documentation with exploration via Swagger UI [9]. This interface, showed in Fig. 1, is used by admin users to perform basic operation, like creating new services.

### Message Sending

As described earlier, a notification has to be linked to a *service*. Only admin users can register a new service. When creating a new service, a UUID is generated and used to identify the service. This id has to be used by clients to send a notification associated to that service. This is done by sending a POST to `/services/{service_id}/notifications` with the fields *title*, *subtitle* and *url* in the body. Only the title is required. Other fields are optional. The subtitle usually contains a longer description. The URL can be used to redirect to a specific website, like a LogBook entry, to have more details. This link will make the messages clickable in the mobile app. Figure 2 and Figure 3 show how to send a notification using curl or Python.

As there is no authentication, a filtering based on IP address is performed to avoid receiving messages from an untrusted source. Once received, the message is forwarded to all users who subscribed to this service using Apple and Google push infrastructure.

## Communication with Mobile Clients

Mobile clients need to authenticate to access the REST API. To login, username and password are sent to the server and checked against an Active Directory service. If the credentials are correct, the server sends back a JSON Web Token (JWT). This token shall be included in the header of any future request. It is valid for a limited number of days and the user will only be forced to authenticate again when it has expired. This solution allows to not store any credentials in the phone or server.

Once logged in, the mobile app can use the API endpoints to get the list of services, subscribe or unsubscribe and read notifications linked to the current user. For notifications to be sent to that phone, the app must send a token to identify the device. This is done via the `/users/user/device-token` endpoint. This device token is associated to the user and saved on the server. This is the token used to send notifications via Apple or Google services.

The workflow to send a notification is depicted in Fig. 4:

1. An application sends a message to the Notify server (the message is linked to a service).
2. The server sends a notification to both Apple Push Notification service [10] and Firebase Cloud Messaging [11] (depending on the device token type) for all users who subscribed to that service.
3. The notification is sent by Apple and Google cloud services to the user device.
4. When the user opens the notification, the full message is read from the Notify server API.

Figure 4: Notification workflow

The Notify server is deployed using docker in a Virtual Machine at ESS and on Kubernetes at MAX IV. All site specific parameters can be defined in a configuration file.

## APPLE IOS CLIENT

The iOS client is a GUI for the REST API described previously. Once installed it will contact the server through a link that is hard coded in the application. In our current version we support two possible links and customizations, one for ESS server and one for MAX IV server as in Fig. 5. As described previously, upon successful login a JSON Web Token is stored in the app and will be used for future authentications.

The app will also ask the user to accept notifications and in case of an affirmative answer it will request to Apple a push token that is sent to the Notify server. This token is stored in the profile of the user and used to push any new notification to the phone through the Apple Push notification API.

Once the app is properly registered on the server the available services can be selected for subscription (Fig. 6). The app will communicate to the server which service the user wants to subscribe to and the server will associate the push token of the user to the service. In this way every time a new message is delivered to a service, all the subscribers will be notified about the new message (Fig. 7).

When the app is opened, the main screen will display the list of available notifications (Fig. 8a), these are downloaded from the server at every startup of the app or if a new notification arrives and the app is running on the phone. The notifications are marked with a red dot if unread, and a badge

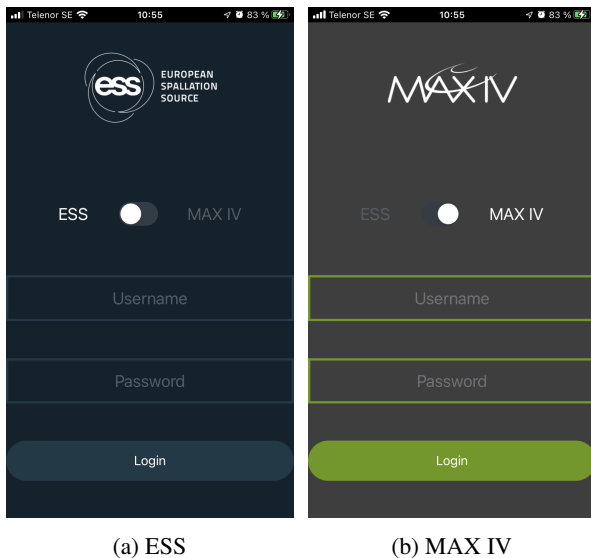

Figure 5: Login Screen

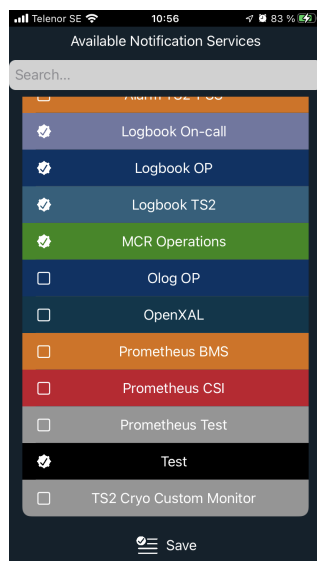

Figure 6: Services

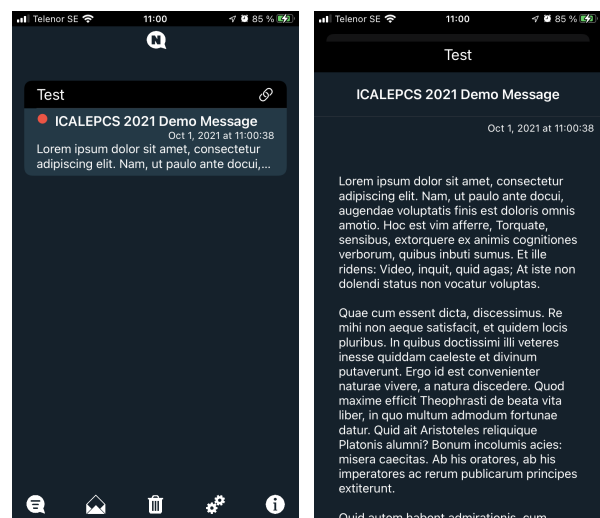

Figure 7: Push notification alert

(a) Messages list

(b) Single message view

Figure 8: Main Screen

with the number of unread notifications is shown on the icon of the app. The top bar of the notification contains the name and the color of the service that is notifying, and on the right corner there is a button with a link to the URL sent together with the message, if present.

Tapping on a notification is possible to expand the text and read the full content (Fig. 8b).

## Deployment

To be able to send push notifications to an Apple device the developer needs to request a push key that has to be used in order to send the notifications to the app. This is the reason why we developed a unique app with two possible logins (ESS and MAX IV), because in this way we can use the push key registered under the ESS license to push messages also from MAX IV. The alternative is that MAX IV register

its own developer on the developer program of Apple and requests a key for push notifications that is set in the Notify server settings. This is under consideration for the future.

Apple offers multiple way to deploy applications. The most common way is to use the App Store, but our application has an access restriction to the users of ESS and MAX IV and Apple forbids the distribution of restricted applications on the App Store. The solution that we adopted to distribute the app is then through the Mobile Device Management (MDM) system. The whole process is exactly like to distribute the app through the App Store, it means that the app must be signed with the distribution signature generated on the Apple Developer portal and sent to the App Store Connect, that is the website that Apple uses to manage the distribution of apps. Once the app is on the portal and all the relevant information for distribution are filled, the app is

sent to Apple for review as Private. A normal app in general is sent as public, but because we do not go to the App Store but we will stay within our MDM, the app has to be marked as private.

Apple will then verify the application running it, this means that together with the app they will require a demo account to test the functionalities, so we created in our LDAP server a test account that we enable every time we submit a new revision of the app for approval. After the checks of Apple the application is marked as Ready for Sale and appears automatically to the registered Business web page connected to our license for distribution. For ESS we use the Self Service application to distribute internal apps.

This process, except the push key that is always the same, has to be repeated for each version of the app submitted to Apple.

## ANDROID CLIENT

The Android client was initially developed after the iOS counterpart, consequently the functionality and user interface (UI) were copied to be basically identical. Some minor difference in the UI layout exist, though. Figure 9 shows the lock screen showing a test notification message.

Figure 9: Push notification alert

The Android client does not support selection between ESS and MAX IV, it currently only supports the ESS use case. To be used at MAX IV, the application was recompiled after changing the Notify server url. This was enough for testing purpose. More customization is planned to make the theme MAX IV specific.

The current code base of the Android client requires a minimum version of Android 7.0, which was released August 2016.

## Deployment

Development of Android apps is free of charge, as are development tools. Installing an Android app by downloading

an apk (Android application PacKage) file to any compatible target device - or using USB tethering - is possible and does not incur any limitations to the app usage. ESS has however opted for distribution over Google Play due to its simplicity. The Google Play approval process is slightly simpler compared to the process used by Apple, e.g. there is no test account needed in order for Google to be able to login to the application. This distribution will be considered by MAX IV when the app is customized.

In order to publish apps on Google Play one needs to register a developer account, currently priced at \$25 (one-time charge). The developer account must be linked to a Gmail account.

## APPLICATION INTEGRATION

As we saw earlier, sending a notification only requires a POST request to the Notify server. ESS integrated this system in several applications: LogBook, OpenXAL, EPICS alarms and Prometheus are some examples. Integration can be done in different ways depending on the application. For Prometheus, a bridge [12] was created to forward and curate messages from the Alert manager to the Notify server. EPICS alarms are sent via Kafka, which makes it quite flexible. A client is used to listen to the desired Kafka topics and forward alarms to the server. At MAX IV, preliminary tests were performed successfully with Achtung, a new alarm management system for Tango.

## CONCLUSION

The solution put in place at ESS relies on modern tools and native mobile applications for both iOS and Android. The management of who will receive notifications is delegated to the users themselves, which removes the need for a central configuration that can be fastidious to keep up to date. This is really beneficial to the users who can subscribe and unsubscribe as they want, from their phone. It gives an unified way to receive notifications from different systems. The implementation is generic and can be re-used. The Notify server was straightforward to deploy at MAX IV and the concept was tested successfully. The customization of the mobile clients requires a bit more work but nothing major.

<sup>2</sup> University of Malta, Malta

The Large Hadron Collider (LHC) collimation system is designed to protect the machine against unavoidable beam losses. The collimation system for the LHC Run 3, starting in 2022, consists of more than 100 movable collimators located along the 27 km long ring and in the transfer lines. The cleaning performance and machine protection role of the system critically depend on the accurate positioning of the collimator jaws. The collimation control system in place enables remote control and appropriate diagnostics of the relevant parameters. This ensures that the collimators dynamically follow optimum settings in all phases of the LHC operational cycle. In this paper, an overview of the top-level software tools available for collimation control from the control room is given. These tools range from collimator alignment applications to generation tools for collimator settings, as well as collimator scans, settings checks and machine protection sequences. Amongst these tools the key upgrades and newly introduced tools for the Run 3 are presented.

The CERN Large Hadron Collider (LHC) accelerates and collides two counter-rotating beams towards the unprecedented design centre-of-mass energy of 14 TeV [1]. It is made up of eight arcs containing superconducting magnets and eight straight sections that are referred to as insertion regions (IRs) [2].

The quench limit of the LHC superconducting magnets is of the order of 10–30 mW/cm<sup>3</sup> [3] and the damage limit of metal is of a few hundred kJ per cm<sup>3</sup> [4], to be compared to the stored beam energy of more than 300 MJ planned for Run 3. Therefore, a high-performance and robust collimation system is installed to safely dispose of beam losses in the collimation regions, providing a cleaning efficiency of 99.998% of all halo particles [5].

A total of 123 movable collimators are installed in the LHC for the start of Run 3 in 2022, whereby 14 betatron collimators, 6 injection protection collimators and all 12 transfer line collimators have been newly installed/replaced and 2 crystal collimators are planned to be replaced. The LHC ring collimators are mainly concentrated in two dedicated cleaning insertion regions (as shown in Figure 1); IR7 is dedicated to the betatron cleaning, and IR3, where the dispersion is larger, provides off-momentum cleaning [6]. Other collimators are installed in the experimental region to protect the inner triplet magnets, and in the high-luminosity regions IR1 and IR5, to dispose of the collision debris.

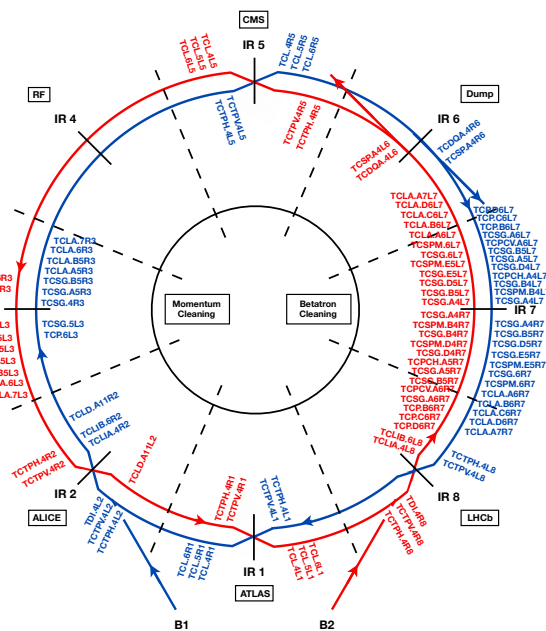

Figure 1: The Run 3 LHC ring collimation system layout.

The collimators have different designs, orientations (horizontal, vertical or skew) and roles for cleaning and protection (refer to Table 1); (1) Primary, secondary collimators, and shower absorbers are located in IR3 and IR7, (2) Tertiary collimators protect the super-conducting triplet quadrupoles in all experimental regions, (3) Injection protection devices (TDI, TCLI) protect the machine in case of injection errors (also the transfer line (TCDIL) collimators), (4) Dump collimators protect against asynchronous or unclean beam dumps in IR6, (5) Crystal collimators, in IR7, enhance ion beam cleaning, (6) Fixed aperture, passive collimators in IR3/7 shield specific magnets from high radiation doses (TCAP).

Table 1: Movable LHC Ring Collimators

Collimator	Description	Number

## BACKGROUND

### Collimator Design and Control

A collimator is made up of two parallel absorbing blocks, referred to as *left* and *right* jaws, which are typically positioned symmetrically around the beam, except for the 2 one-sided TCDQ. Each jaw is controlled by two stepping motors to precisely adjust the jaw position and angle with respect to the beam [7]. The maximum and minimum possible angles are  $\pm 2$  mrad [8]. The collimation coordinate system is displayed in Fig. 2, whereby the jaw corners are referred to as left-up (LU) and right-up (RU) when they are upstream of the beam and left-down (LD) and right-down (RD) when they are downstream of the beam (or at the end of the beam).

Figure 2: (a) The collimator coordinate system and (b) the jaw tilt angular convention as viewed from above, from [9].

Each collimator has Four Linear Variable Differential Transformer (LVDT) sensors and resolvers to independently measure the position of the collimators' axes in real-time at 100 Hz [10]. An additional 2 LVDTs are installed for direct collimator gap measurements, resulting in a total of 6 LVDTs per collimator used for jaw position interlocking [11, 12]. Moreover, the tanks housing 60 of the collimators have an additional motor, resolver and non-interlocked LVDT, to move the entire collimator in the orthogonal plane. This feature allows exposing a fresh surface to the beam in case of suspected collimator damage from beam losses. Finally, 33 collimators have 2 Beam Position Monitoring (BPM) pick-up button installed in each jaw, to provide a direct measurement of the beam orbit at the collimator location [13]. A third BPM is mounted on the collimator vacuum tank of 13 of these collimators, to measure the beam position on the axis orthogonal to the cleaning plane.

The tightest settings of  $5\sigma$  for the TCPs correspond to gaps of  $\sim 1$  mm at 7 TeV, requiring  $\sim 20\mu\text{m}$  position accuracy. To ensure that, in static and dynamic conditions, the jaw positions stay within safe operational windows, a complex system of threshold functions has been implemented [7]. The limits are defined as functions of time, beam energy, and  $\beta^*$  functions that express the amplitude of the beam oscillation in the IP (or beam size) [4].

Four limit functions (inner and outer dump and warning limits) can be defined for each LVDT, for a total of 24 func-

tions. If the measured axis position violates any of the dump limits, which are always active in parallel, the low level control system requests an immediate abort of the circulating beams. The interlocks per collimator for jaw position and gap measurements include; limits versus time (inner and outer thresholds for 6 degrees of freedom, i.e. 12 limits), maximum allowed gaps versus beam energy (2 limits) and gap thresholds versus  $\beta^*$  (inner and outer thresholds for 2 gaps, i.e. 4 limits). The energy and  $\beta^*$  dependent limit functions catch failures in triggering the start of time functions at the start of energy ramp: a beam dump is eventually requested if the collimator gaps are not scaled down as needed by smaller beams [7]. The list of key parameters for the collimation system is presented in Table 2 for a typical LHC operational cycle that includes separate functions for the energy ramp, betatron squeeze and collision process. Injection protection collimators require a simple implementation, as they do not need to be controlled through functions of time.

Table 2: Collimation System Parameters (excluding TCDQ)

Parameters	Number
Movable collimators in the ring	109
Transfer line collimators	12
BPM pick-ups	145
Stepping motors	544
Resolvers	536
Position/gap measurements	786
Interlocked position sensors	726
Motor settings Vs Time	1452
Threshold settings Vs Energy	242
Threshold settings Vs $\beta^*$	484

### Collimation Controls Software Technologies

The collimation controls are used for all LHC ring and transfer line collimators. The controls consist of various software applications, each one providing a different set of user functionality, ranging from; collimator alignments and settings' controls to loss map and machine-protection check tools.

Various programming languages and tools are involved in developing the controls, including: Java for user interfaces, Front-end software architecture (FESA) [14] for device control, Python and SWAN [15] for machine learning and data analysis, LHC Software Architecture (LSA) [16] with Oracle for operational settings management, Next CERN Accelerator Logging Service (NXCLS) [17] for data logging and Apache Spark for data processing.

## COLLIMATOR ALIGNMENTS

At the start of each year, the LHC goes through a commissioning phase to ensure that all collimators are correctly set up and ready for nominal operation [18]. During the commissioning phase various alignment campaigns [19] take

place at different machine states, to set up the correct collimation hierarchy. Collimator alignments are performed with “setup beams” i.e. low intensity, which at the LHC typically corresponds to 3 bunches at  $10^{11}$  p/beam. The collimator settings are monitored along the year as the beam orbit may shift over time [20], thus potentially requiring the collimators to be realigned. Moreover, different collimator setups are required when the machine parameters are changed.

Two types of beam instrumentation are available to align collimators (refer to Fig. 3); the Beam Loss Monitoring (BLM) and the in-jaw collimator Beam Position Monitoring systems. Each collimator has a dedicated BLM installed outside the beam vacuum, immediately downstream. BLMs are used to detect beam losses generated when halo particles impact the collimator jaws, such that the recorded losses are proportional to the amount of intercepted beam, measured in units of Gy/s. Meanwhile, BPMs directly embedded in the collimator jaws, allow for a faster alignment by analysing the electrode signals, without needing to touch the beam [13].

Figure 3: (a) BLM attached to LHC cryostat (yellow device) [21] and (b) BPM pick-up button embedded in collimator jaw [22].

### BPM Alignment Controls

BPM collimators are aligned using a successive approximation algorithm. This takes into account a calibration of the nonlinear BPM sensitivity to beam displacement and an asymmetry of the electronic channels processing the BPM electrode signals [23].

The BPM controls allow users to monitor the electrodes and the beam position. The user can automatically align collimators by defining the minimum collimator gap (mm), the target alignment error ( $\mu\text{m}$ ) for alignment precision when equalizing the electrodes, and the time interval(s) between each step of the successive approximation algorithm.

The BPM-based alignment procedure aims at finding the jaw positions and angles, where the beam orbit is centred, at both the upstream and downstream sides of the collimators, individually. The algorithm works by moving both collimator jaws in steps, keeping the same gap, until the signals from electrodes are equalized as shown in Fig. 4 [22].

The entire procedure is automated, able to align a single collimator at the optimal angle in  $\sim 10\text{--}20$  s. In addition, all BPM alignments can be performed in parallel [13]. The method is not invasive and does not cause any beam loss.

Figure 4: BPM electrode signals during a BPM-based alignment in 2017, from [13].

### BLM Alignment Controls

All collimators can be aligned using the beam loss signals recorded by their respective BLM located directly downstream. A beam-based alignment (BBA) procedure [24] is used to align collimators with BLMs. This involves creating a reference halo with the primary collimators, then moving the collimator jaws separately towards the beam in steps of  $5\text{--}20\ \mu\text{m}$ . A collimator is said to be aligned when both jaws are centred around the beam after touching the beam halo. The alignment of any collimator relies on BLM signal distinction between alignment and spurious spikes: a collimator must continuously move towards the beam ignoring any spurious spikes, until a clear alignment spike is observed. Throughout the procedure, the jaws are kept parallel to each other with a zero tilt angle with respect to the collimator frame. The procedure can be extended to measure the jaw angle with respect to the beam [19].

The BLM controls allow users to monitor the BLM signals and the collimator position. Since 2018, the entire BBA procedure has been automated [25, 26] by introducing supervised machine learning to classify alignment spikes [27] and other algorithms [28]. The user can start an automatic alignment by selecting the list of collimators to be aligned and the software will align all collimators and save the settings.

This new automatic software is able to align a single collimator in  $\sim 1\text{--}2$  mins [29, 30], depending on the machine state. When aligning collimators with BLMs, a maximum of two collimators can be aligned in parallel, one from each beam. However, the two collimators must be specifically selected, as one must consider possible cross-talk, i.e. having multiple BLMs around the ring detecting the losses generated by a single collimator [31].

Having the foundations for an automatic BBA opens the possibility for further research and development [32]. It also allows introducing more complex alignment techniques and changing the collimation hierarchy more frequently throughout an operational year, to provide tighter settings.

**Angular Alignment** The current operational settings for the betatron cleaning hierarchy requires a  $1.5\ \sigma$  retraction between primary and secondary collimators in IR7, corresponding to  $\sim 300\ \mu\text{m}$ . Tighter collimator settings with smaller retractions might be used in the future to improve the LHC performance and achieve a smaller  $\beta^*$  [33]. Keep-

ing collimators with a zero tilt angle with respect to the beam will not be adequate to operate the system with retractions below  $1.5 \sigma$  [34]. Moreover, possible tank misalignments are a source of error that could jeopardize the performance of the system if not corrected. Aligning collimators at an angle will allow for tighter collimator settings. However, this procedure is longer, as it involves performing the standard BBA at different angles to find the most optimal one.

The angular alignment controls allow users to monitor the BLM signals and the positions of the 4 collimator jaw corners. Angular alignments are implemented on top of the BBA, therefore they have also been automated in 2018. The user can automatically align collimators at an angle by setting the start and end angles ( $\mu\text{rad}$ ) to define the angular range to be explored, and the angle step size ( $\mu\text{rad}$ ) to tilt the collimator between each alignment. The user can then select one of the 3 angular alignment procedures developed in [35], depending on the specific error encountered; (1) The first method aligns the collimator at different angles (keeping the jaws parallel). This is used to determine the optimal angle for the collimator tank in cases where there is an offset. (2) The second method aligns the upstream and downstream jaw corners individually, to determine the corresponding centres. The optimal angle is taken to be the average of the two. (3) The third method individually aligns the collimator jaws at different angles and aligns the other jaw (with zero tilt) to act as a reference. This method is useful in cases of asymmetries within the collimator itself, as the optimal angles for both jaws are determined independently.

At injection, methods 1 and 3 require a similar amount of time  $\sim 13$  minutes, whilst method 2 requires  $\sim 3$  minutes [36]. Since angular alignments rely on BLMs, one must consider possible cross-talk when aligning collimators in parallel.

## LOSS MAP ANALYSIS FRAMEWORK

The collimation system performance is monitored when the configuration is changed, and at most every three months of operation, as the beam orbit may shift over time. This is done by inducing slow (multi-turn) beam losses, such that a large number of particles are purposely sent onto primary collimators in a controlled way, and the resulting electromagnetic showers can be detected by BLM devices around the LHC ring. A beam loss map, showing the spatial distribution of the measured losses along the LHC ring (Fig. 5), can then be generated to validate the collimator setup [36]. Specifically the losses in IR7 provide information on the collimation hierarchy and halo cleaning performance. In case of a degradation in performance, the collimators might need to be re-aligned to generate a new setup for the current beam state. This could be observed as a degradation of the cleaning in the dispersion suppressor of IR7, or a difference in the pattern of the beam losses at the collimators [37] or by the observation of anomalous loss locations.

A new framework was developed for Run 3, providing an automatic way to validate loss maps generated throughout the year. It allows users to import loss map metadata

Figure 5: Proton full ring loss map performed at injection in the horizontal plane for beam 1, from [36].

as new loss maps are generated, including; start date/time, plane info, beam energy, and loss map type (betatron or off-momentum). This metadata is then used to automatically extract the loss map data logged in NXCALs. The user then has the option to plot individual loss maps depicting the distribution of losses across the full ring or in specific IRs. Alternatively the user can plot multiple loss maps at a particular IR, stacked for comparison. This framework also integrates the necessary tools for automatically calculating the collimation hierarchy inefficiency by analysing the losses in the dispersion suppressor.

## SETTINGS GENERATION APPLICATION

Once the collimation hierarchy is validated, the next step is to generate the collimator settings for operation [38]. As previously mentioned, the collimator settings obtained following the BBA are saved to file. A new application was developed for Run 3 to automatically extract the relevant data and calculate and import these settings into the control system defined in LSA. A mathematical framework for defining these functions, which will now be automatically calculated by the system, can be found in [38]. This application replaces the scripts that were used in the past, creating a central and homogeneous procedure for settings' generation.

The user can automatically generate the settings by selecting the BBA results file, the list of collimators, the LSA parameters to update and the collimator settings to be used. In addition, the user can manually edit any of the settings loaded into the application and save the modified settings to a new file for future use.

## SETTINGS CHECK APPLICATION

Following their generation in LSA, the settings must be validated to ensure they are consistent with the expected collimator positions. The setting-check application requires the user to select the LSA configuration, the start and end time, and the list of collimators to check their settings. This application automatically compares the settings defined in the following locations: 1) the selected LSA configuration, 2) the settings calculated by the application based on data stored in LSA, 3) the data logged in NXCALs for the selected time period, 4) the real-time positions of the collimators.

## MACHINE PROTECTION SEQUENCE

The precise control of the jaw positions versus time and beam position has important relevance for machine protec-

tion (MP) of the LHC. As part of MP procedures, the collimation MP sequence, independently of the beam, checks that for every scenario, the interlocks are correctly triggered (recall Table 2). MP tests ensure the correct behaviour of interlocks to guarantee a beam abort in case of potentially critical situations, i.e. if a collimator moves beyond the safe limit [39]. A dedicated MP sequence for LHC collimators forms part of the collimation controls. It is an application which automatically tests all interlocks associated with a collimator. This application is used when new collimators are installed or replaced, and, after each long shutdown in order to test all collimators before starting a new LHC run.

To begin the testing sequence, the user simply selects a collimator. The collimator is moved sequentially to each of its limits to ensure the interlocks are correctly triggered, whilst the user monitors the results. This typically takes less than 10 minutes per collimator. Multiple sequences can be started in parallel for collimators that are not connected to the same interlock units (typically one interlock unit per IR).

## BPM-CALIBRATION APPLICATION

This application is used to measure BPM non-linearities, by characterizing the BPM readout for selected jaw gaps and beam offsets, in order to validate the BPM calibration. This is achieved by performing an automatic scan which measures the beam position at different gaps and different collimator offsets, to ensure the centre is proportionate [23].

Before starting the scan the user must first align the collimator using the feedback from the BLM, to centre the jaws around the beam. To begin a scan, the user must define; the maximum offset ( $\mu\text{m}$ ) to avoid beam scraping, the jaw step size ( $\mu\text{m}$ ), the gap step size ( $\mu\text{m}$ ), the initial and final gaps ( $\mu\text{m}$ ) defining the range to be explored, and the waiting time between each movement(s).

The scan begins by opening the collimator jaws to the starting gap. The jaws are then continuously shifted by the predefined jaw step size, waiting the requested time between movements. When one of the jaws reaches the predefined limit, the jaws are moved back to the starting point and the jaw gap is reduced by the predefined gap step size. The procedure is repeated until the minimum jaw gap is reached. The jaw positions and BPM electrode signals are automatically saved to a file for offline analysis.

## CRYSTAL COLLIMATION CONTROLS

The crystal collimation scheme uses bent crystals as primary collimators. These are used to channel beam halo particles and deflect them onto a single secondary collimator per beam and plane, further downstream, as opposed to the present multi-stage collimation system. The crystal-based collimation system improves the overall cleaning inefficiency in the IR7 dispersion suppressor and along the ring, with respect to the standard collimation system [40], for heavy-ion beams. In order to determine the optimal channelling angle, angular scans are performed by changing the crystals' orientation angle with respect to the beam envelope. Crystal

channelling is achieved when a reduction in the local beam losses is observed in the corresponding BLMs [41].

The crystal controls allow users to control the goniometer that houses the crystal, whilst monitoring the signals of neighbouring BLMs and the linear crystal position. The user can align the crystal linearly using the BBA similar to one-axis collimators, and can perform an angular scan of the crystal to determine the optimal channelling angle for operational use [42].

Linearly aligning each crystal requires  $\sim 5$ – $10$  minutes depending on the machine state, as the automatic alignment is not yet available for crystals. Moreover, as this alignment relies on BLMs, one must consider possible cross-talk when aligning crystals in parallel. Scanning the largest angular range available of  $20$  mrad can take longer than an hour. Angular scans cannot be done in parallel, as any cross-talk would make it difficult to determine the optimal channelling angle.

## GLOBAL MONITORING DISPLAYS

Given the numerous collimators, various global monitoring displays are available to provide an overview of their status. Four dedicated fixed displays are available for the collimators in beam 1, in beam 2, in the transfer lines and for crystals. An additional display for collimator settings is available to monitor the collimation hierarchy in case of incorrect settings. Finally, the number of BPM collimators have doubled for the start of Run 3. Therefore, a dedicated display for them is being developed to provide an overall status, comparing the collimator centre and the beam centre measured by the BPMs in real-time.

## CONCLUSION

The LHC makes use of a high-performance collimation system to protect its sensitive equipment from unavoidable beam losses. A total of 123 movable collimators are readily installed in the LHC for the start of the Run 3 in 2022. This paper presents the control system of the LHC collimators that provide the functionality required to handle high-intensity beams. The system underwent a significant upgrade to improve the functionality in light of the recent system upgrade for Run 3. An overview is given of the software tools available for collimation, including; BPM alignments, BLM alignments, BLM angular alignments, loss map analysis, generation of settings, machine protection sequence, BPM calibration, crystal collimation and global monitoring. These tools ensure precise jaw positioning during all the phases of LHC operation. The occurrence of unsafe conditions is minimized by making sure that all the critical degrees of freedom stay within safe operational windows. All these tools are readily available for the start of Run 3.

## ACKNOWLEDGEMENTS

This work is presented on behalf of the LHC collimation team (BE-ABP-NDC), with special thanks to the LHC OP crew (BE-OP) and the collimation HW team (BE-CEM).

# WRAP – A WEB-BASED RAPID APPLICATION DEVELOPMENT FRAMEWORK FOR CERN’S CONTROLS INFRASTRUCTURE

E. Galatas\*, A. Asko†, E. Matli‡, C. Roderick§, CERN, Geneva, Switzerland

## Abstract

To ensure stable operation of CERN’s accelerator complex, many Devices need to be controlled. To meet this need, over 500 custom Graphical User Interfaces (GUI) have been developed using Java Swing, Java FX, NetBeans, Eclipse SWT, etc. These represent a high maintenance cost, particularly considering the global evolution of the GUI technology landscape. The new Web-based Rapid Application Platform (WRAP) provides a centralized, zero-code, drag-n-drop means of GUI creation. It aims to replace a significant percentage of existing GUIs and ease new developments. Integration with the Controls Configuration Service (CCS) provides rich infrastructure metadata to support application configuration, whilst following the associated equipment lifecycle (e.g. renames, upgrades, dismantling). Leveraging the CERN Accelerator Logging Service (NXCALs) and the Unified Controls Acquisition and Processing (UCAP) platform, allows WRAP users to respectively, create GUIs showing historical data, and interface with complex data-stream processing. The plugin architecture will allow teams to further extend the tool as needed. This paper describes the WRAP architecture, design, status, and outlook.

## INTRODUCTION

Over the past decade, a large number of expert applications have been developed to provide a way of controlling and monitoring thousands of Devices present within the CERN accelerator complex. The need for control and data visualization applies not only to production equipment, but is also essential for developing and testing new Devices. However, the ecosystem of technologies and platforms used for the development of such applications is quite fragmented. A lot of applications evolved organically based on individual needs. At the same time, the desktop graphical application tool kits traditionally used at CERN have evolved, whilst in parallel facing a major decline of community interest over the years. The Java Swing toolkit has been used since the late 90’s, with Java FX coming on the scene several years ago. Most recently, given the direction of Oracle’s support for Java as a graphical user interface solution, PyQt has been adopted for some graphical applications [1]. Unsurprisingly, the proliferation of custom Graphical User Interfaces (GUI) combined with an relatively rapid evolution of GUI technologies has lead to a worrying situation backed by extensive technical debt.

Instead of forcing a large and diverse community at CERN to continue learning new GUI technologies and develop their

own applications, the following question was raised: ”Can we turn the situation around and provide a central, data-driven GUI platform, which experts can use to configure their applications, based on their domain knowledge, without worrying about how to develop, build, deploy, and maintain it, using technologies which will undoubtedly continue to evolve?”. A new Web-based Rapid Application Development Framework (WRAP) was designed as the answer to this question, and aims to replace many of the legacy applications over time. WRAP will provide a centralized solution around a common platform, integrated with core Controls sub-systems such as the Accelerator Logging Service (NXCALs) [2] and Controls Configuration Service (CCS) [3]. Since the inception of this project comes after years of application development in the organization, there is a large data-set of use-cases, feedback, and design decisions to analyse and improve upon. Leveraging this knowledge can shape WRAP into a single, unified solution for the vast majority of use-cases.

## PROJECT GOALS

There are currently over 500 custom Graphical User Interfaces (GUI) relating to Device control and corresponding to different needs of Operation. Since WRAP encompasses many diverse use-cases and clients, it is important to have a clearly defined set of goals, based on which, decisions can be made regarding individual features.

The most vital attribute WRAP must exhibit, is ease of use. An intuitive User Interface (UI) is required, and beyond improving user productivity, it must encapsulate the complexity of Device modeling and communication. Wherever possible no-code, drag-and-drop configuration should be preferred, allowing experts without a programming background to work at a higher level. This level of abstraction must not, however, come at the cost of performance. Many parallel, real time visualizations should be supported.

Being a centralized service concentrates a lot of complexity on the platform itself, creating a barrier that may inhibit contributions from other teams. To offset this, contributions will instead be supported through a plugin architecture. A stable public application programming interface (API) will be made available giving access to the core functionalities of the platform. Those must in turn have high test coverage and be very conservatively altered.

Lastly, WRAP should leverage device metadata from the CCS to the highest possible degree. Not only does this remove redundant configuration steps, but also enables the restriction of configuration options to only those that are compatible with any given Device. This will help users to configure applications within WRAP whilst avoiding configuration compatibility errors that typically stem from a lack

\* epameinondas.galatas@cern.ch

† anti.asko@cern.ch

‡ aemnuele.matli@cern.ch

§ chris.roderick@cern.ch

of detailed knowledge of the underlying Device interfaces and behaviour.

## ARCHITECTURE OVERVIEW

The WRAP architecture (Fig. 1) needs to accommodate the goals mentioned above, whilst also ensuring that it can scale in terms of functionality, complexity and performance. A clear separation between the rendering logic and underlying data management has to exist, while delegating some key points of complexity to relevant CERN Controls sub-systems.

The platform's front-end (user interface layer), is created using web technologies rather than as a native desktop application. Running in a web browser removes cross-platform compatibility concerns, simplifies distribution and updates, and facilitates use from mobile devices. JavaScript's ever improving speed also removes the need for performance trade-offs in order to facilitate the WRAP platform use cases. Thanks to its immense popularity, the web stack appeals to a lot of potential candidates applying to CERN, it provides mature frameworks and UI design systems, and incorporates comprehensive debugging tools. A high degree of flexibility is also present; while the platform and most graphical widgets are being developed in the Angular framework, 3rd party widgets can utilize any preferred solution. These widgets can then be bundled and integrated as native Web Components. Web Components can encapsulate presentation and behaviour in a custom HTML element, creating the basis of a plugin architecture. Each widget has a specific, predefined structure that is modeled in the WRAP database. This model is used to validate widget states and to provide constraints on what types of data can be visualized.

In order to provide actual Device data to be rendered and processed, a variety of other Controls sub-systems are used. The information about the available Devices and their data structures is managed within the Controls Configuration Service (CCS) [3] from where it is served to WRAP via a REST API. After the desired Devices and their Properties are identified, the WRAP back-end subscribes to live updates of data values, using the CERN Java API for Parameter Control (JAPC) [4]. As values become available, they are aggregated and propagated from the WRAP server to corresponding WRAP clients via HTTP/2 push events.

### Device Evolution

As operational needs or underlying hardware evolve, corresponding Controls software Devices follow. This can mean a simple change of Device name or a more complex change of Device interface. A requirement for WRAP is to be resilient to such events by design. This is achieved by integrating with the CCS and its Controls Configuration Data Lifecycle (CCDL) manager [5]. Knowing the dependencies between Device data and WRAP widgets, throughout all applications configured within WRAP allows a WRAP API to be exposed to the CCDL. Using this API, the CCDL can interrogate WRAP to check for compatibility of CCS changes

to Device configurations and, in most cases propagate the changes to WRAP - automatically keeping the applications working over time. Very complex changes such as data type alterations or Device deletions will at least result in notifications to the relevant application owners in order that they can make a manual intervention.

### Historical Data

The architecture explained so far is able to visualize live Device data, however historical values are also important. For example, a graph widget would require data for the displayed time window to be pre-filled, before receiving updates based on current values. The visualisation of historical data is possible thanks to the integration with the CERN Accelerator Logging Service (NXCALs) [2], providing a unified solution for logging of time-series data acquired from accelerator Controls Devices.

### Data Processing

For some use cases, Device data requires some form of processing before being displayed. This processing can range from simple filtering of specific values to aggregations that involve a large number of data subscriptions and require complex computations. The Unified Controls Acquisition and Processing (UCAP) [6] framework provides a means to facilitate and streamline acquisition and processing of Controls data. Data from multiple Devices are processed with pre-existing or user defined Python or Java code, with incoming values aggregated based on the desired event sourcing strategy. The result is then exposed as a Virtual Device, for which WRAP can utilize the standard infrastructure explained above to access Device metadata, live data and historical values.

### Fault Tolerance

Given the foreseen critical nature of WRAP as a service (e.g. exposing critical GUI applications), it must have a high degree of fault tolerance. The WRAP front-end is received by the client as a Single Page Application (SPA). When loading a user application instance within WRAP, metadata has to be fetched in order to: render the included widgets, establish data source subscriptions, and fill historical values where necessary. Once initialized, WRAP applications only depend on the back-end infrastructure to exchange values, for which the corresponding server nodes are highly redundant. In the event of failure, such as a Device disconnection, wrong metadata, missing history, etc. parts of the application can fail gracefully, providing appropriate information to the user, without breaking the application as a whole.

## CURRENT STATUS

WRAP development has now entered its second year. The processes for structuring and saving user applications have stabilized, and development is focused on adding editor features and extending the widget library. In this section, some

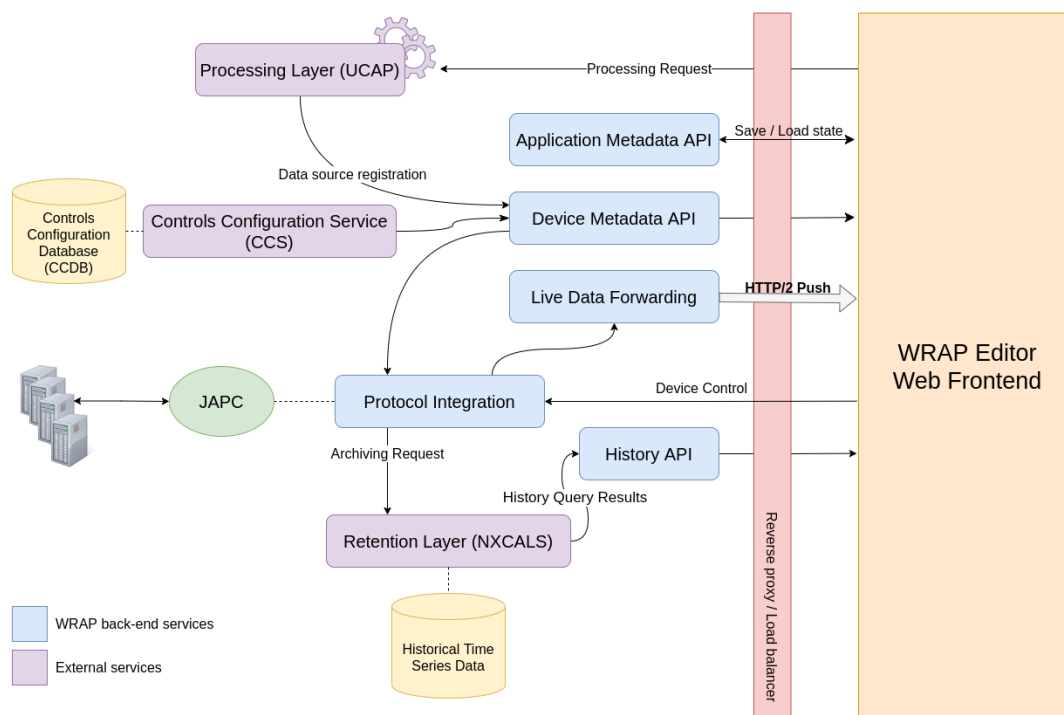

Figure 1: WRAP architecture overview.

of the existing capabilities will be highlighted coupled with some examples of finished products.

Figure 2 shows the WRAP editor. On the top, a tab-like list of recently visited applications is present. These tabs allow a fast navigation between applications. They also include information about the application title and owner, as well as an option to make a new copy - helpful when starting a new application based on an existing one. When an application owner enables the edit mode, a blue bar appears below with options to alter the application name and description, make it publicly visible, undo/redo functionality, and an option to enable a scroll-able / report-like view (instead of being limited to one screen).

On the left side is the Entry Point menu which allows the lookup of Devices (with some additional filters). Once a Device has been selected, a list of it's Properties appear, indicating the data type and additional flags dictating its behaviour. A Property value can either be used to instantiate a new widget that references it, or it can be assigned to an existing widget. In both cases, constraints are applied based on the correlation between the Property value type and corresponding widgets (e.g. boolean, string or enum can be shown on status indicators, numbers may be plotted on a chart, etc.).

Selecting a widget on the central application canvas will open a panel on the right side, from where the related attributes can be modified. Widgets can also be grouped together, with the resulting group having a union of the aspects of its children (Device source, colours, relative dimensions, etc.). This effectively enables bulk copying, moving and editing of related widgets. The bulk features around groups can make it very efficient to configure applications showing

multiple aspects, of multiple Devices, of a similar type. For such cases, the user configures the individual widgets for a single Device, groups them together, copies them, then changes the Device binding in bulk for all widgets in the new group. Currently, the implemented widgets include graphs, labels, and status indicators, with many others foreseen.

## ADOPTION

At CERN there are around 60 so-called "Fixed Displays" or "Vistars" which are applications that typically display important information about the status of accelerator operations and specific systems. These critical applications, are based on an aging custom framework, legacy Java Swing technology, and domain specific code. They are under the responsibility of a diverse group of people, who are only involved with software as an occasional, part-time activity, typically during periods of accelerator shutdown. It is not feasible for such people to learn the latest graphical technologies in their spare time. This is one of several reasons that it is foreseen to migrate all of these Fixed Display applications to the WRAP platform, thus lowering the technical debt and limiting the responsibility of the people associated with the applications to the domain knowledge and not the software maintenance.

A progressive migration of the Fixed Displays is already underway. Figure 3 shows one such application related to the LHC experiments. The applications created so far, aggregate data from multiple Devices via UCAP, and then visualize the resulting Virtual Device data from within WRAP. Currently, an effort is placed on evaluating how these new applications behave in the operational environment, while additionally

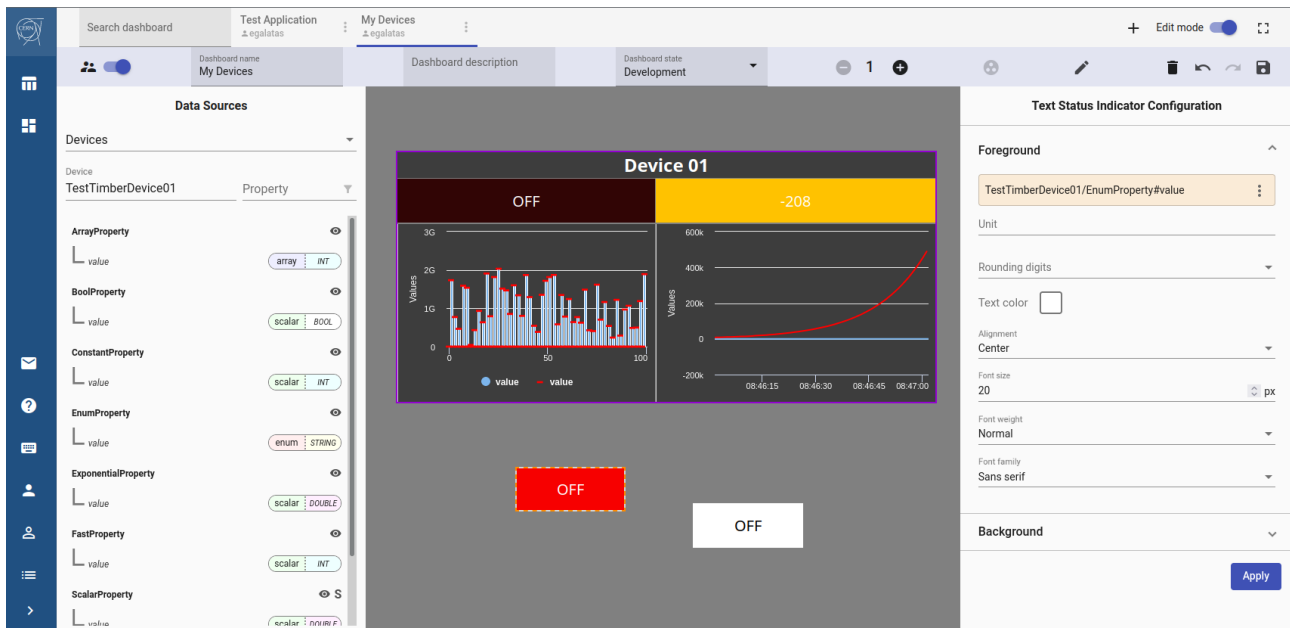

Figure 2: WRAP application builder.

evaluating possible cases of performance degradation or improvements with respect to the legacy ones. In order to give a desktop like experience, it is foreseen to evaluate technologies such as Electron [7], in order to avoid launching the WRAP applications via a full-blown web browser.

## MAJOR CHALLENGES

As a system that combines many different services and provides solutions for very diverse use cases, WRAP presents a number of technical challenges that have to be addressed. Some of the most notable challenges currently experienced when developing WRAP are listed below.

### Scalability and Performance

CERN's accelerator complex consists of hundreds of thousands of Devices, some of which emit very large data sets at very high frequencies. Creating visualizations that can cope with such cases requires optimizations both on data delivery and front-end (user interface) performance. Any inefficiency in either, however small, will be magnified and create bottlenecks in sufficiently complex user applications. A number of strategies have been employed to counter this, such as avoiding duplicate data subscriptions and bundling rendering events. Despite this, thorough regression testing will have to be incorporated for all widgets and major editor features in order to guarantee consistent performance across subsequent WRAP builds.

### Evolving Technologies

Achieving stability on an evolving technological landscape is a challenge faced in all software. WRAP is particularly exposed to this problem, as it has to follow the evolution of not only 3rd-party front-end web frameworks and back-end technologies, but also the CERN Controls sub-systems with which it interacts. A consistent and well documented

API between different parts of the platform, and a modular design across the entire stack, helps alleviate this problem. Even if breaking changes cannot be avoided, affected parts can be addressed separately, containing the scope of any potential refactoring and improving the accuracy of related cost estimations.

### Web Limitations

As mentioned above, the web as an application run-time provides a number of advantages with respect to native applications, including efficient development times, easier debugging (especially around the visual elements), and a trivial distribution of the final product. There are however, some trade-offs that have to be considered.

The performance of complex applications on aging hardware can degrade the user experience. For WRAP this problem will become more apparent as more features are requested and more sophisticated applications are created. Solutions like Web Assembly and Web Workers have been considered and seem promising in eliminating these problems in the future.

Web applications might sometimes be limited due their inability to access native desktop features. They are also perceived differently by end-users, when faced with loading and running in a browser, instead of being installed as a standalone application available via a shortcut. However, all these point can be addressed by bundling WRAP with Electron [7] allowing the same behaviour and access to native APIs as a traditional desktop application. This also enables individual applications created within WRAP to be accessible via distinct shortcuts.

Finally, some problems are inherently more difficult to solve on the Web compared to native applications. For example, installation and communication across multiple windows, while possible, is a lot more involved. Creating multi-

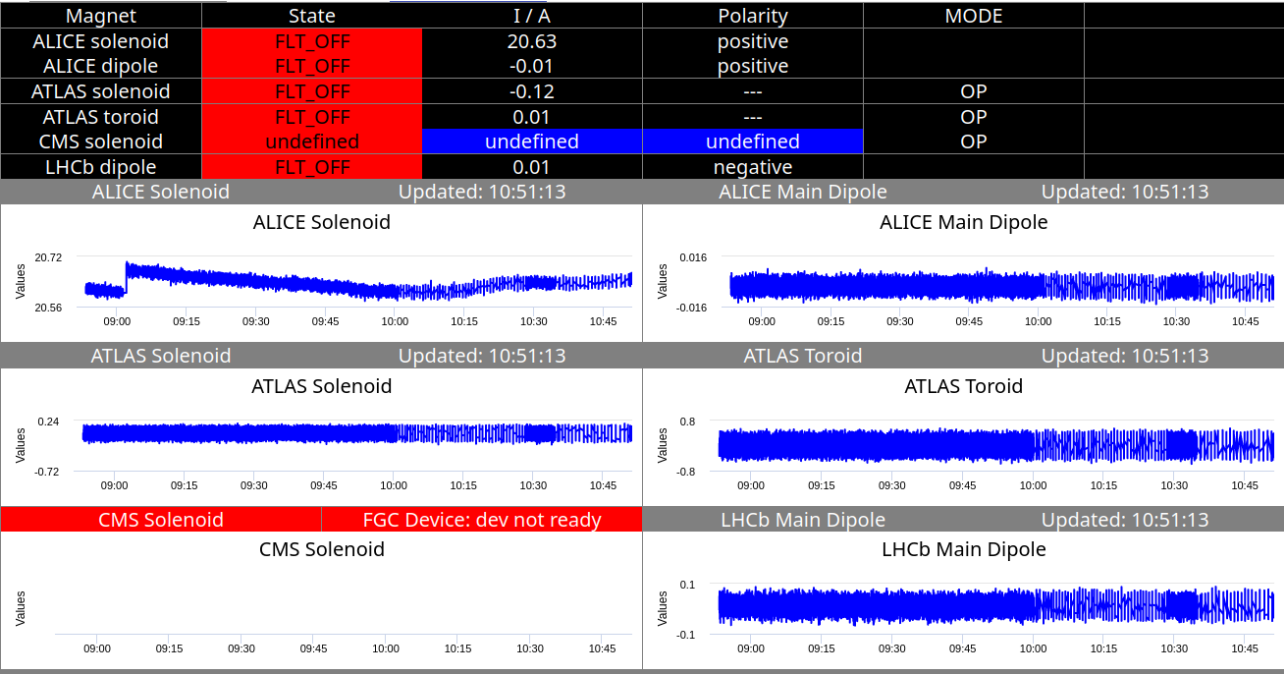

Figure 3: Example LHC Fixed Display implemented in WRAP.

windowed applications via WRAP is presenting a significant challenge. However, the easier development of most of the other parts of WRAP on the Web does, so far, greatly offset the small subset of features that prove problematic. Choosing any technology to build a sufficiently complex software will invariably highlight some deficiencies in some aspects of it.

NEXT STEPS AND FUTURE OUTLOOK

The aim is to use WRAP to replace as many as possible of the hundreds of CERN accelerator controls standalone graphical applications. From the outset, it is clear that WRAP, which is a data-driven application, will not be suited to replace the most complex legacy applications. Nevertheless, based on an in-depth analysis performed in 2020, it is expected that between 40-70 percent will be suited to WRAP. This will clearly require a lot of features to be present in the WRAP editor together with significant expansion to the widget collection. It is expected that the gradual adoption of WRAP by a large community will help establish collaborations with other teams (certainly inside CERN, and hopefully outside), which in turn can contribute improvements, extensions or even just valuable feedback to help WRAP become a more complete and useful end-product.

SUMMARY

WRAP introduces a new paradigm of developing applications for control and visualization of Device data. The new platform has received a lot of interest from the user community and, while development is at an early stage relative to the ambitious goals that were initially set, early adopters have shown promising results on the long-term viability of

the solution. The overall architecture, consisting of modern and tested industry practices, coupled with the use of open-source software used by large communities, will help ensure the stability of the overall platform. WRAP is on-track towards its objectives and it is expected that this endeavour will pay off, helping to substantially reduce technical debt, and minimising the need for diverse experts to acquire new software application development skills, in order to develop and maintain their graphical applications.

# ADOPTING PyQt FOR BEAM INSTRUMENTATION GUI DEVELOPMENT AT CERN

S. Zanzottera, S. Jensen, S. Jackson, CERN, Geneva, Switzerland

## Abstract

As Java GUI toolkits become deprecated, the Beam Instrumentation (BI) group at CERN has investigated alternatives and selected PyQt as one of the suitable technologies for future GUIs, in accordance with the paper presented at ICALEPCS19.

This paper presents tools created, or adapted, to seamlessly integrate future PyQt GUI development alongside current Java oriented workflows and the controls environment. This includes (a) creating a project template and a GUI management tool to ease and standardize our development process, (b) rewriting our previously Java-centric Expert GUI Launcher to be language-agnostic and (c) porting a selection of operational GUIs from Java to PyQt, to test the feasibility of the development process and identify bottlenecks.

To conclude, the challenges we anticipate for the BI GUI developer community in adopting this new technology are also discussed.

## INTRODUCTION

The software section of the Beam Instrumentation Group at CERN (SY-BI-SW) has a mandate, to provide expert GUIs allowing hardware experts to manage and diagnose instrumentation. As explained in detail in our preliminary evaluation[1], the software stack consists of several layers, where the most high-level ones, including the GUIs, have been traditionally implemented in Java. However, as Java GUI technologies age and become deprecated, efforts[1,2,3] were made to identify suitable, more modern replacements. As these evaluations concluded, no alternative Java framework could be identified, leading to the option of PyQt.

Adopting PyQt is not trivial: Firstly, tools, services and frameworks must be developed for integration with CERN's control system. Secondly, existing GUIs cannot simply be migrated – they must be rewritten. This represents a massive effort in terms of redesigning and reprogramming. In addition, developers will have to adopt Python as a programming language, which is a challenge in itself, as Python is fundamentally different from Java in many aspects.

As integration with CERN's control system is addressed by another team at CERN, we have been able to focus on the GUI programming aspect itself (GUI management tools, widgets, proof of concept GUIs) and also on the adaptation of our decade-old Java-oriented GUI development workflow to a more language-agnostic one, supported by more generic tools.

## PYTHON TOOLS FOR EXPERT GUIs

### *Devtools: bipy-gui-manager*

Previous integration efforts resulted in a set of tools and environments under the name of Acc-Py[4]. However, none of these tools are oriented towards GUI development: they all target a generalised Python codebase, favouring in practice CLI applications and libraries. Consequently, we proceeded to define a set of best-practices to be followed in order to develop Expert GUIs with PyQt and embarked on the creation of a specific tool, the “bipy-gui-manager” to encourage (and partially enforce) them.

Upon invocation, this command line utility collects some basic project information (project name, author name, author email etc...) and then creates a template project in the desired location, pre-configured with its own GitLab repository (created on the fly), a dedicated virtual environment, a template for Sphinx-based documentation and a workflow that provides Continuous Integration, Continuous Deployment and Continuous Documentation for the project. As a consequence, the setup effort required from the developer to get a fully standard project is close to zero. Even the README is pre-written by compiling a template README with the information gathered by the tool at setup time.

The bipy-gui-manager enables us to enforce group-specific conventions and promote best practices in general. This is valuable in homogenizing the code produced, given the number of short-term developers in the section and their different backgrounds.

One example is how bipy-gui-manager deals with GitLab repositories. In the past, the section had problems with critical pieces of software not checked into version control, or not having their repositories synchronized with the code that was effectively in production. The bipy-gui-manager addresses the issue by 1) setting up the repository for the developers, so even if they don't know or have no time for version control, the tool takes care of it, and 2) by not allowing the developers to use its simplified release function unless they commit all their changes to GitLab. It is important here to note that bipy-gui-manager does not really block the developer from releasing uncommitted code: a slightly more expert person can still do a release in a single (although longer) command. However, we believe that such small hurdles will make programmers follow conventions, which in turn will help lower our code hand-over and maintenance efforts. This is especially true for projects made by newcomers and interns, who are often tasked with developing or maintaining expert GUIs as a way to

familiarize themselves with systems they will eventually be working on.

The bipy-gui-manager is already in use in the section for our first Python Expert GUIs.

### RAD Tools: ComRAD

Along with the development of Acc-Py, the team produced another interesting tool for Rapid Application Development (RAD), called ComRAD[5]. This paper will not go into detail about the implementation details of this zero-code GUI tool, but rather highlight how it has contributed to our PyQt efforts.

While initially aimed only at prototypes and fixed-display (non interactive) applications, its scope has been gradually expanded, and it has eventually become an interesting tool for general Expert GUI development.

Therefore, we decided to perform an evaluation of this tool and understand which role it could take in our standard PyQt development workflow. Our requirements for a successful evaluation of this tool included:

- Do not limit the developers from using the full capabilities of PyQt. This is important to allow Expert GUIs to grow in complexity if the need arises.
- Allow the use of custom widgets, to be able to extract components and reduce the development time.
- Be able to package and deploy ComRAD applications on our NFS file system as a regular Python application.
- Have some actual benefit over bare PyQt. This was important to avoid adding unnecessary complexity to our tools without any effective gain.

Our analysis was generally positive: ComRAD matched all our requirements and exceeded them by cutting development time for simple Expert GUIs to hours rather than days.

Consequently, ComRAD was added to our workflow. Such an addition was performed by adapting bipy-gui-manager, which is now capable of creating both PyQt and ComRAD oriented Expert GUI projects.

This operation also reinforced the relevance of bipy-gui-manager for controlling our workflow: the tool was easy to adapt to the new standard, and enabled all our developers to develop ComRAD based applications almost immediately at the end of our evaluation and the decision to make it available to developers.

## A LANGUAGE-AGNOSTIC LAUNCHER

One pillar of our Expert GUI ecosystem is the AppLauncher[6] (Figure 1), a tool which provides two main functionalities: a) it lets us manage user access to expert GUIs, and b) it provides users a centralized catalogue of the expert GUIs a user has access to.

On the operational computers in CERN's Control Center, the console managers point not to the application's binary itself, but to the AppLauncher executable, with a parameter set to the desired application name. This layer of abstraction allows on one side the operators to have a reliable entry point to find applications, and on the other hand gives the developers more freedom on where and how to install their applications for operational use, so long as they can be registered in the AppLauncher and be launched on the target machine.

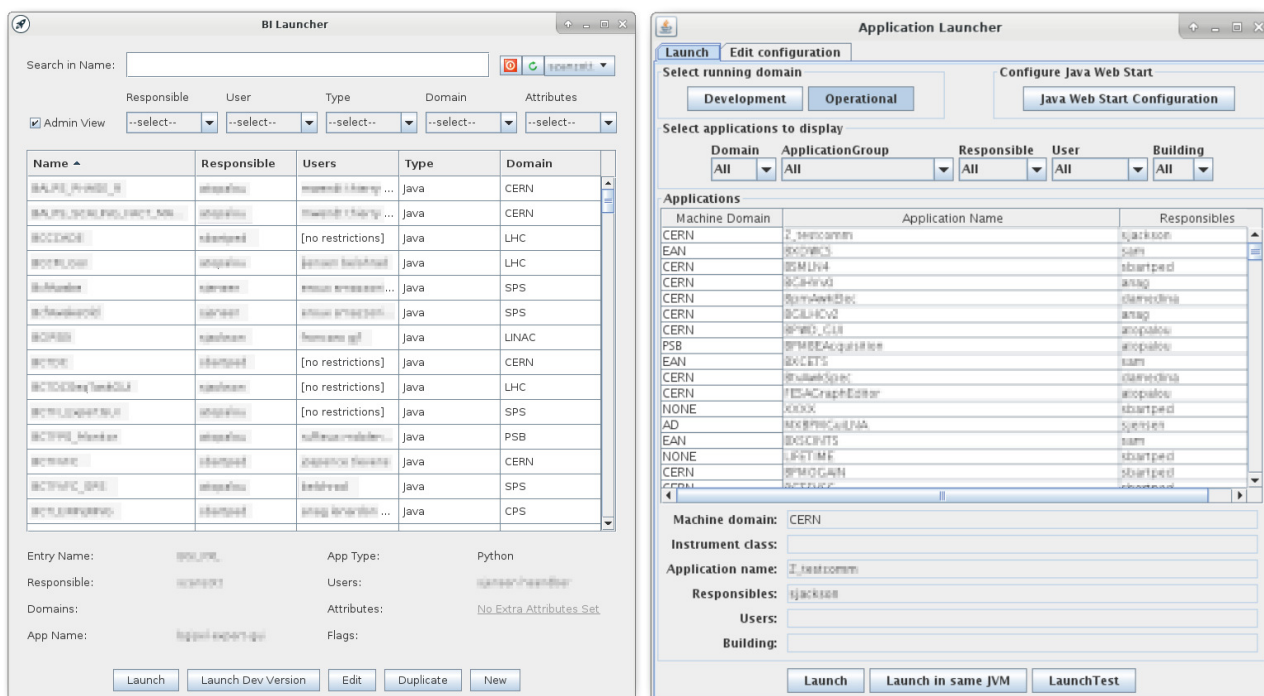

Figure 1: The BI Launcher (left) and the old AppLauncher (right).

Given the nature of expert GUIs, accidental misuse could lead to serious equipment damage; however, the AppLauncher did not enforce any strict access control, and it was rather oriented towards helping users find the correct GUI faster access rather than limiting access to them. In addition, being designed to support Java applications only, it was relying at its core on the Java Web Start system, which has been preserved at CERN after its demise by Oracle as an in-house tool called JWS. The AppLauncher, although rather simple, could not be repurposed to support any other language, and therefore this option was excluded in favour of a more radical one: a full rewrite. The new AppLauncher, now called simply BI Launcher, is a new Java Swing application that imitates to some degree the look and feel of its predecessor, while fundamentally rethinking its internals. By adopting more modern Java standards and reducing the features to what the section mostly uses this tool for, the BI Launcher ended up as a simpler application with a compact codebase, able to launch Java (though JWS), Python (through Acc-Py tools) and Web pages (through the browser) from the same interface. It also modernised the security aspects of accessing the application catalogue, by utilising CERN's widely used role-based-access system (RBAC[7]).

The old AppLauncher was eventually decommissioned in September.

## FIRST PYTHON EXPERT GUIS

### PyQt Expert GUIs

In parallel to the work detailed above, we also ported a few Expert GUIs to PyQt to use them as a proof of concept, and to identify potential blocking issues that we might have overlooked. Candidate GUIs for this role had to match the following requirements:

- *Be small*: in order to be able to quickly iterate in case of issues, a good candidate GUIs should be small, both in the expected codebase size and in the interface.
- *Be thin*: we are not interested at this stage in GUIs that contain a lot of logic unrelated to the interface (like complex calculations or domain-specific algorithms). We need GUIs that do nothing more than allowing the user to read, write and monitor values.
- *Already due for a rewrite*: some GUIs were already in need of a full rewrite. For example, we have a number of JavaFX-based GUIs which we want to migrate, due to the fact that JavaFX is no more a recommended technology for GUIs. Other examples include GUIs based on Swing or Qt (C++), developed by other teams but assigned to our section for maintenance.
- *Include commonly used widgets*: expert GUIs tend to include common widgets, like plots, timing displays, log viewers, toggles, etc. Testing the new technology on these components was mandatory.

- *Be actively used*: the ultimate test is operational use. We opted for GUIs being actively used, rather than made-up test cases.

After an inspection of the collection of GUIs that matched the above requirements, we selected a couple of them for the initial port. The chosen applications were:

- A medium-small application already partially ported to PyQt by an intern in a previous evaluation of the technology, which we are going to identify as “BGI App”;
- A very small JavaFX application with some interesting features and plot customizations, which we are going to refer to as “BCF App” (Figure 2).

We began the process from the BGI App in an attempt to define a good project template to be followed by other applications. We defined the features at a project level (GitLab repo, test suite, CI, README, code structure, etc) but also at a visual level (mandatory widgets like the log panel at the bottom of the window, timing bar at the top, etc...) and used the resulting template in the bipy-gui-manager to ensure uniformity for future applications.

Once this step was complete, we moved on to the BCF App, the first real port from scratch. In this case we started with the newly created template, and we verified that the bipy-gui-manager was an effective tool for the task. Then we proceeded with the actual port and succeeded in producing a fully functional application which replicated faithfully all the features present in its JavaFX counterpart.

In the process of porting both application we also produced a number of reusable PyQt widgets that, especially once repackaged in BE-CSS widget libraries, are going to make building future PyQt applications even faster and simpler than it was for these ones. Examples of these widgets include the Timing Bar, a widget that displays timing information of a selected accelerator, the Log Console, a highly customizable widget that receives, displays and filters the logs, the crosshair, that was added to the basic plots widget after our example, plus several others that are still being evaluated.

### ComRAD Expert GUIs

Shortly after porting the two Expert GUIs mentioned above, ComRAD became ready for evaluation. As a test case, we chose to migrate and simplify a C++ Qt-based application called “PXL App”.

Our experiences with ComRAD were considered highly successful, due to a series of benefits that we identified while working on the application:

- *Faster development*. The initial iterations of the GUI were very fast and required barely any code, due to the great amount of Qt UI files that could be reused from the C++ based counterpart. In addition, ComRAD provides useful CERN-specific widgets which facilitated shorter iterations.

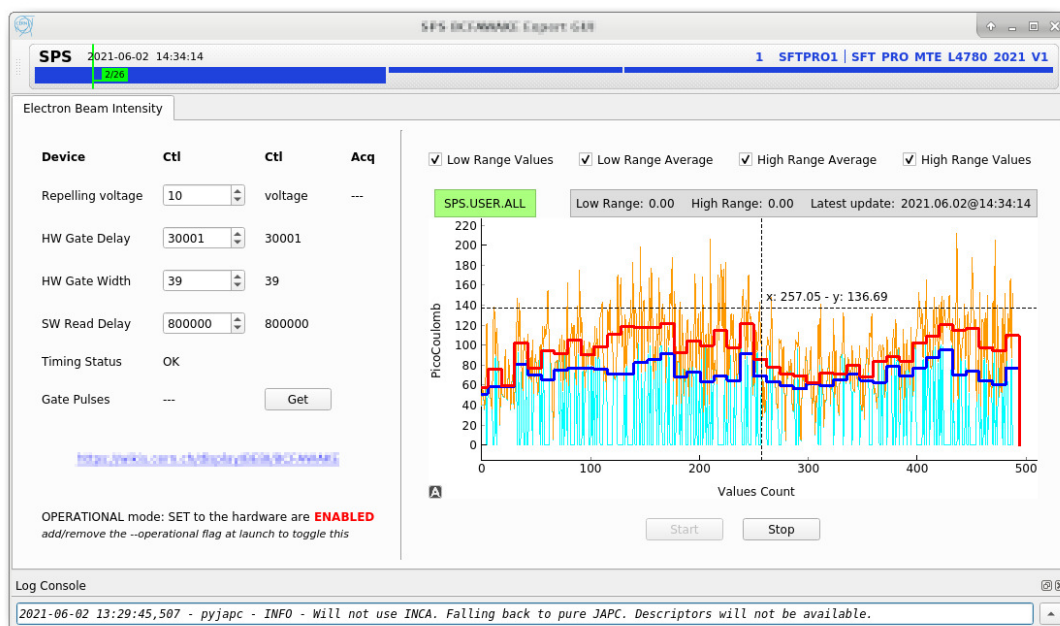

Figure 2: Example of an expert GUI ported to PyQt from JavaFX: the BCF App.

- *Decoupling interface design and interface logic.* ComRAD enabled us to design the interface with no boilerplate code to support it, through enhancements made on the Qt Designer. This decoupling allowed us to first build an application with no connections to the middleware and iterate on the design without the need to think about the code.
- *Progressive wiring.* ComRAD allowed us to progressively connect widgets from the simplest to the most complicated. In addition, for the majority of the widgets, it required no code at all to connect to the control system. This code-less approach could be used also in simple plot widgets, and code was required only for the most complex ones.
- *Allows pure PyQt code.* ComRAD was designed to allow developers to fall back to a pure PyQt-style application where needed, while allowing the rest of the application to benefit of its RAD facilities. In fact, while ComRAD has its own enhanced Designer files, it can read and manage regular Qt Designer interfaces too; while it has its own highly automated system to connect to the middleware, it also allows developers to use their own connections, and so on. This is a very strong feature, as it means that the framework will not hinder the developer if they need to implement something different from what ComRAD was designed for, which means that it will be easier to support in the long-term, and even to replace at a future date if the need arises.

### Performance Assessment

One of the most worrying concerns of porting our Expert GUIs to Python-based technologies was the performance of some demanding widgets, for example

tables and plots. While we met no performance bottlenecks during the development and operation of the first two PyQt GUIs, we finally faced the problem with the PXL App, when we ported it to ComRAD. This app was initially written in C++, and not in Java, due to several reasons: some demanding plots, hundreds of widgets to display, and a special C++ library being used in the backend. Although simplified in its ComRAD version, this GUI still featured a plot that was required to fully re-render up to 1.048.576 points (1024 lines with 1024 data points each) in less than a second in order not to freeze or skip updates.

We soon realized that such requirement could not be satisfied, and that the GUI would be able to barely deal with 400 such lines (409.600 points). However, after presenting the issue to the users of this application, we realized that there was no need to display the entire bulk of the data and that displaying a subset of 100 lines was sufficient. With this new concession, the application was able to run smoothly.

### FUTURE WORK

Now that the technology is proven and some GUIs have been successfully ported, the next steps involve primarily the port of all the remaining GUIs that need a rewrite. This port will not be simply a translation of the old codebase into a new one: at every iteration we plan to assess which components can be transformed into generic widgets, extract them, package them, and release them to be reused as ComRAD widgets for the following applications.

We believe this process will benefit both ourselves, by speeding up the development of more complex application, and the wider PyQt and ComRAD community at CERN.

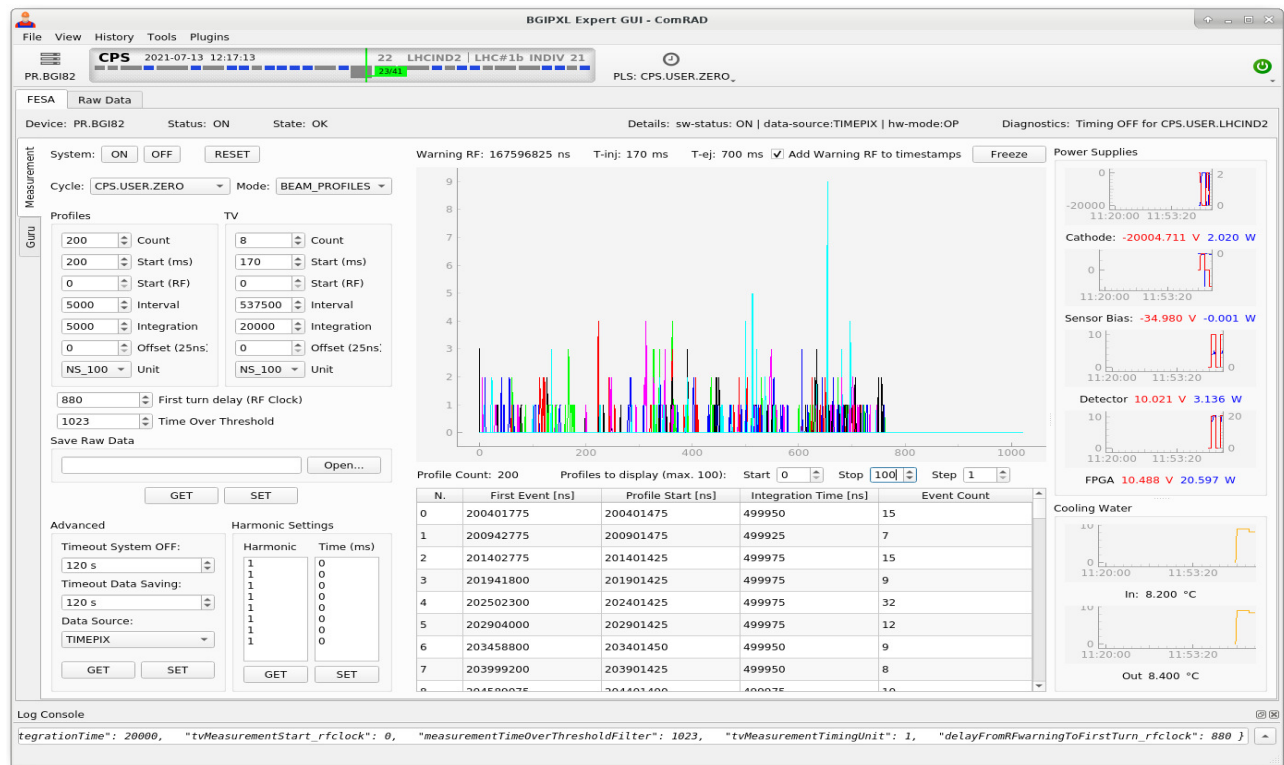

Figure 3: Example of an expert GUI ported to ComRAD from C++ Qt: the PXL App.

## CONCLUSION

Adopting PyQt as the main framework for Expert GUIs development in our group was not a straightforward task. Most of the assumptions made in the past about the applications had to be re-evaluated to allow non-Java based GUIs to enter the scene. With the help of another team (BE-CSS) which took care of the middleware integrations, we progressively cleared the path for seamless PyQt GUI development by: a) modifying the AppLauncher to enable launching of any type of GUI application, b) developing the bipy-gui-manager to promote standardization and best practices within our team c) porting two pilot GUIs to PyQt, d) porting one GUI to ComRAD and e) assessing the performance capabilities of the plots in a demanding real use-case.

While the future for PyQt as the main technology for future GUIs is still not fully clear, it is clear that PyQt will be a key technology for RAD purposes. In this context, the work put in place to maintain, control and catalogue these efforts will be valuable regardless of whether we decide to move our entire portfolio of GUIs to PyQt technologies or not, and we expect this workflow to serve us well in the years to come.

# NEW TIMING SEQUENCER APPLICATION IN PYTHON WITH Qt DEVELOPMENT WORKFLOW AND LESSONS LEARNT

Z. Kovari, G. Kruk, CERN, Geneva, Switzerland

## Abstract

PyQt is a Python binding for the popular Qt framework for the development of desktop applications. By using PyQt one can leverage Qt's aspects to implement modern, intuitive, and cross-platform applications while benefiting from Python's flexibility. Recently, we successfully used PyQt 5 to renovate the Graphical User Interface (GUI) used to control the CERN accelerator timing system. The GUI application interfaces with a Java-based service behind the scenes. In this paper we introduce the generic architecture used for this project, our development workflow as well as the challenges and lessons we learnt from using Python with Qt. We present our approach to delivering an operational application with a particular focus on testing, quality assurance, and continuous integration.

## TIMING CONTROL APPLICATION

### Accelerator Timing System

CERN continuously delivers particle beams to a range of physics experiments (end-users), each posing strict, detailed requirements with respect to the physical characteristics of the particle beam to be delivered. Hence, particle beams traverse a number of accelerators while being manipulated in various ways. For this to happen, the accelerators repeatedly “play” pre-defined cycles, which usually consist of an injection-acceleration-ejection sequence. This in turn involves many concurrent beam manipulations including particle production, bunching, cooling, steering, acceleration and beam transfer – all of which must occur at precise moments in time, often with microsecond or even nanosecond precision. The role of the Timing system is an orchestration of all these activities, ensuring that the accelerator complex behaves as expected as a function of time.

Each accelerator at CERN is associated with a Central Timing system (CT) which, based on the configuration provided by the operators and dynamic input such as external conditions, calculates in real time so-called *General Machine Timing (GMT)* events that define key moments in the accelerator cycles such as beginning of the cycle, injection, ramp, extraction, etc.

GMT events are then transmitted to *Front-End Computers (FECs)* via a dedicated cabled network known as the *GMT network*.

On the FEC side, the GMT cables are connected to *Central Timing Receiver (CTR)* modules, which decode the received GMT events and allow generation of derived local events (with optional delay) in the form of software interrupts and physical pulses for the accelerator hardware.

## Timing App Suite

The control of the timing system is done via a dedicated GUI application that allows operation crews to define a collection of cycles composing a so-called *beam* (see Fig. 1). A Beam is executed by the central timing to transfer and accelerate a particular particle beam from the source, through the intermediate accelerators, up to the final experiment. Beams are then used to build a *Beam Coordination Diagram (BCD)* that defines sequencing of different particle beams sent to different destinations as illustrated in Fig. 2.

Following the renovation of the central timing itself, it was decided to also renovate the 20-year-old application used to control it, modernizing its architecture, improving usability aspects and taking advantage of the new features provided by the central timing.

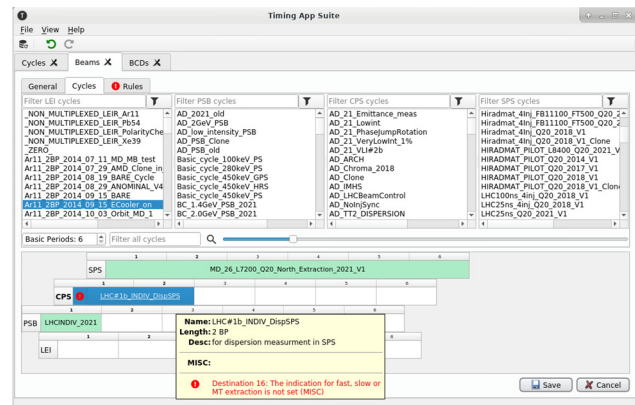

Figure 1: Timing Beam editor.

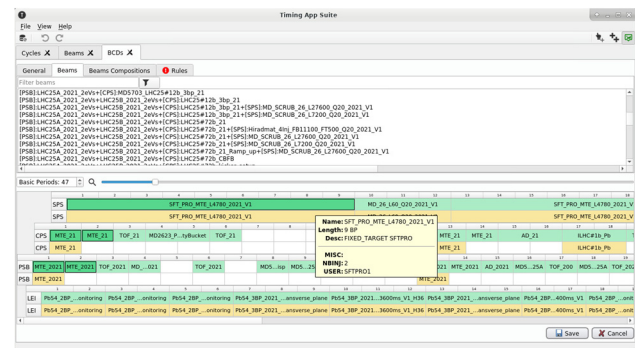

Figure 2: Beam Coordination Diagram editor.

## ARCHITECTURE

The application was designed and implemented in a 3-tier architecture (see Fig. 3): a GUI, implemented in Python using PyQt toolkit, communicating via HTTP with RESTful services implemented in Java, and with the Cen-

tral Timing process (C++) via PyJAPC [1] a Python wrapper over the Controls Middleware (CMW) [2] communication library.

The Java server relies on Spring Boot and several features provided by the Spring framework such as REST controllers or JPA database access, along with dependency injection and configuration services.

Figure 3: Timing App Suite architecture.

The server is completely stateless allowing simple deployment of two instances with an Nginx [3] proxy server in front, and enabling rolling updates.

## GRAPHICAL USER INTERFACE

The GUI application is split into four different layers:

- **Data:** Qt independent CERN-related domain classes representing the Timing ecosystem.
- **Model:** Qt model layer responsible for mapping Data to the View [4].
- **View:** the User Interface widgets [4].
- **Controller:** optional intermediate layer between view and model, typically handling signal and slot connections that need more sophisticated business logic and cannot be connected directly between the view and the model.

### Model

The model layer in Qt's architecture has two responsibilities. On the one hand, it maps the Data objects to the View, basically saying which data item should be displayed at which index (*QModelIndex* [5]). On the other hand, it also tells the View component how that data should be rendered, e.g., in which font, background color, and with what tooltip or icon.

### View

In most cases, the user interface was designed in Qt's built-in editor, *Qt Designer*, which is also easily accessible through the *pyqt5-tools* [6] Python package. *Qt Designer* is a simple-to-use editor that allows dragging and dropping Qt widgets and creating user interfaces without any programming.

Such created panels are then saved to *.ui* files, which are re-used in the Timing Control Python application. There are two ways to do that:

- Using PyQt's *uic* module to load the generated UI files [7].
- Generating Python code from the UI files [8].

The 2nd solution was used, as this approach provides content assists in the *PyCharm* IDE, and in general,

helped to better integrate the View components into the source code (e.g. finding usages throughout the entire source code).

The drawback of such an approach was that an additional step was needed between editing the UI in *Qt Designer* and then using it in the application. The *pyqt5ac* 3rd party library was used for code generation to automatically convert multiple UI files into Python [9].

## Communication Between Model and View

The model layer in Qt handles many aspects of what is displayed, and how, from *Data* to *View*. Due to this close connection, it is also simple to directly handle user interactions between view and model by connecting the necessary signals from the view to the model's slots, and vice-versa. That being said, an additional controller layer was introduced to handle some of the more complex signal-slot connections. This also allowed to further modularize the application and re-use some of the view, model, or even controller components in other panels.

## Testing

One of the great benefits of using Qt/PyQt was automated testing. Using the *pytest-qt* Python library [10], over 500 test cases were implemented that verify the user interface. The *pytest-qt* package provides a *qbot* object that can be used to spawn and interact with the GUI application, e.g., clicking buttons, selecting, or even dragging and dropping elements. Behind the scenes, the package uses Qt's *QTest* namespace [11] with some additional features extended (e.g., "stop" method [12]).

## TIMING JAVA SERVER

The server side follows the classical pattern with three layers [Fig4]: (1) the data access layer consisting of JPA repositories and corresponding entities mapped to the database tables, (2) the service layer that uses one or more repositories to perform CRUD operations and does the translation between entities and Data Transfer Objects (DTOs), and (3) the REST controllers layer that handles HTTP requests, relying on services.

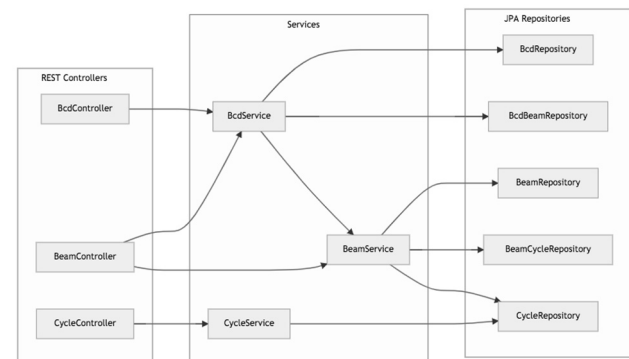

Figure 4: Simplified diagram of Timing server components.

## CONTINUOUS INTEGRATION

CERN's self-hosted *GitLab* instance was used to host the application's code repository and set up automated pipelines [13] for continuous quality assurance.

Each time a commit is pushed to the Git repository, a *GitLab* pipeline (see Fig. 5) runs and automatically verifies the codebase of that specific commit. Verification means the following:

- GUI tests run automatically on *GitLab*. To run UI tests in a container, Xvfb [14] (a virtual framebuffer X server that can run on machines with no display) was configured.
- Static code analyzer tools (such *flake8* [15], *pylint* [16], and *mypy* [17]) are used to analyze the correctness of the code. These tools can detect non-standard code usages that violate PEP-8, or even potential problems such as missing arguments or missing imports. Based on the development experience, these tools are easy to set up and do help to elevate code quality but don't replace frequent code reviews and testing.

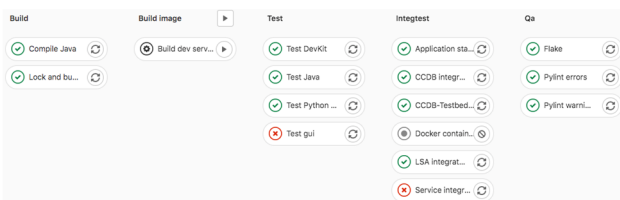

Figure 5: Pipeline to build, test and analyse the code.

## CONTINUOUS DEPLOYMENT

On the same *GitLab* pipelines that verify the code, the application can also be deployed to different environments, as illustrated in Fig. 6.

Figure 6: Deployment part of the pipeline.

To track the environments (such as DEV, STAGING, RC, PROD) the *GitLab* built-in environments feature is used [18]. *GitLab's* environments panel allows to track which commits are deployed to which environments. Furthermore, a deployment pipeline can also be quickly triggered from the same panel, and likewise a roll back to a previous version if necessary.

Application deployment is carried out with *Ansible* [19]. The Python application's wheels [20] are built on *GitLab CI*, dependencies are locked, and then with *Ansible*, binaries are transferred to the deployment server where the Python virtual environment is re-created and the application deployed.

The deployment of the backend server is also triggered from the same pipeline. The server and application code are stored in the same repository, which allows to version and deploy them together to production.

*Docker* images are built which contain the backend server's binaries and then deployed with *Ansible* to the various environments (DEV, STAGING, RC, PROD). One such environment comprises a *Podman* pod [21] with three running containers: two for the server to facilitate rolling updates, and one *Nginx* container to delegate the incoming requests between the two other containers.

## CHALLENGES AND LESSONS LEARNT

### Python for GUI

From the end of 90's until 2020, the vast majority of CERN Controls desktop applications were implemented in Java, for many years using the Swing toolkit, and more recently JavaFX.

For the new Timing application, it was decided to switch to Python and PyQt. The decision was not easy and was mainly dictated by the announcements made by Oracle for deprecation of Swing and discontinued support for JavaFX. Both frameworks are unlikely to disappear within the next few years (Swing will still remain a part of the JDK at least over the next few years), however their future beyond the time frame of 8-10 years is very uncertain. The lifetime of CERN controls applications (including Timing App Suite) is typically beyond 20 years, therefore for the development of new GUI software, requiring significant investment, it was preferred to switch to a framework that is actively developed and maintained, and whose future seems to be much more reassuring.

Python is a powerful, flexible, easy-to-learn and easy-to-use language. One needs less lines of code to perform the same task when compared to other major languages like C++ or Java, which turns into a better productivity. These advantages apply also to GUI programming. The biggest issue confronted when developing the application comes from the flexibility of the language i.e. dynamic typing and lack of compilation checks.

While the codebase of the application was growing, many internal modifications were applied, such as renaming classes, functions and variables, moving parts of the logic from one place to another, replacing one class with another etc. *PyCharm* is dealing with most of the refactoring quite well, but occasionally was failing to properly identify the type of a variable and not applying the requested change. After realizing this, type hints were consistently used all over the code, paying particular attention to function declarations i.e. parameters and return types.

The static analysis tools came in very useful to catch various issues related to the code refactoring, however the ultimate safety net to protect from these kinds of risks was the high coverage of the code by automated tests.

## PyQt Toolkit

Qt provides all standard components designed following the model/view architecture, therefore their usage did not pose any major problems. The concept of signals and slots for establishing communication among various components permits flexibility when dealing with GUI events and results in a smooth codebase.

PyQt is one of the most used UI frameworks for Python therefore there is a relatively big community behind it. There are many learning resources for Qt and PyQt, however a complete and up-to-date PyQt beginners tutorial, with simple and more advanced code examples was found to be missing. Answers to most specific questions could be found, but this required browsing through different forums and blogs, and often applying solutions given for C++ Qt or PyQt4, to the PyQt5-based application.

There is a certain learning curve, especially when it comes to a bit more advanced usage of UI widgets, although once foundations were established and the concepts became familiar, the Qt API documentation was deemed satisfactory most of the time.

The documentation of the testing library, pytest-qt, is rather modest, so learning it and setting up bases for UI tests required a bit of time to experiment and browse Qt forums.

On several occasions segmentation faults (coming from the Qt widgets) were encountered. At first these were not straightforward to understand, but with time they could be interpreted, and it quickly became possible to identify their source.

## Architecture

Implementing the GUI in Python and the backend in Java did not pose any issues. The advantages of both languages and corresponding frameworks could be leveraged to develop the adequate logic in the most efficient way.

What comes as a drawback in this kind of approach is the duplication of domain objects (or Data Transfer Objects) as they are needed in both languages. The Timing API is relatively small and the domain objects quite simple, therefore implementing and maintaining them in Java and Python was a negligible effort.

## CONCLUSIONS

After two decades of developing desktop controls applications using Java, it was decided to change the programming language to Python with PyQt selected as the widget toolkit. The choice was not obvious, but the end result is more than satisfactory, and the same approach is now foreseen for some other applications e.g. the CERN developed Front End Software Architecture [22] diagnostic tool (known as the FESA Navigator).

Efficiency and flexibility, while preserving readability of Python-based applications as compared to Java, comes along with the lack of compile time verification of the codebase. Therefore, a rigorous approach to Continuous Integration performing static code analysis, together with high coverage by automated testing is deemed indispensable for any operational application.

# TATU: A FLEXIBLE FPGA-BASED TRIGGER AND TIMER UNIT CREATED ON CompactRIO FOR THE FIRST SIRIUS BEAMLINES

J. R. Piton, D. Alnajjar, D. H. C. Araujo, J. L. Brito Neto,  
L. P. do Carmo, L. C. Guedes, M. A. L. de Moraes,  
Brazilian Synchrotron Light Laboratory (LNLS), Campinas, Brazil

## Abstract

In the modern synchrotron light sources, the higher brilliance leads to shorter acquisition times at the experimental stations. For most beamlines of the fourth-generation source SIRIUS (the fourth-generation particle accelerator in Campinas, Brazil), it was imperative to shift from the usual software-based synchronization of operations to the much faster triggering by hardware of some key equipment involved in the experiments. As a basis of their control system for devices, the SIRIUS beamlines have standard CompactRIO controllers and I/O modules along the hutches. Equipped with an FPGA (Field Programmable Gate Array) and a hard processor running Linux Real-Time, this platform could deal with the triggers from and to other devices, in the order of ms and  $\mu$ s. TATU (Time and Trigger Unit) is an FPGA/real-time software combination running in a CompactRIO unit to coordinate multiple triggering conditions and actions. TATU can be either the master pulse generator or the follower of other signals. Complex trigger pattern generation is set from a user-friendly standardized interface. EPICS (Experimental Physics and Industrial Control Systems) process variables [1], by means of LNLS Nheengatu [2], are used to set parameters and to follow the execution status. The concept and first field test results in at least four SIRIUS beamlines are presented.

## INTRODUCTION

LNLS Tatu (Timing and Trigger Unit), being mostly FPGA code running in a CompactRIO (CRIO) device (NI CRIO models 9045/9049/9035/9039), combines C-Series I/O modules to work as trigger detectors, pulse generators and a recorder of analog and digital input readouts. Tatu manages digital signals to detect events and to produce actions for synchronized operations at a beamline. That comprises sequences of operations on shutters, motorized devices and detectors, allowing the data acquisition at beamlines to be as fast as possible (also known as “fly-scan”). An example of signal combination to produce different outputs is shown in Figure 1.

Some premises that have been considered in the pursuing of this project are as follows:

- it was already decided that each hutch in a SIRIUS beamline would count on at least one device to make available TTL signal input/output and CompactRIO was the selected standard.

- additional small pieces of software, either in FPGA or Real-Time, could be included for dedicated jobs (like filtering analog readouts), in parallel to the triggering management.
- the access to the configuration parameters would happen through Nheengatu [2], so their manipulation would be immediately made available under EPICS.
- at least for the initial operation of the first beamlines, a maximum pulse rate of 4 kHz would fully meet the requirements.
- it should be highly flexible to let different conditions and outputs to be combined, just by software configuration (no FPGA recompilation needed).

Figure 1: Two cases of output in IO4 port (pulses or “on”) depending on the combination of two input ports IO0 and IO1.

## THE HARDWARE

Tatu is embedded in an 8-slot CompactRIO controller, under a Real-Time Linux operating system and a programmable FPGA (through LabVIEW). Tatu has been implemented in four different models:

**9045** (or 9035) – 1.30 GHz Dual-Core CPU, 2 GB DRAM, Kintex-7 70T FPGA

and the larger

**9049** (or 9039) – 1.60 GHz Quad-Core CPU, 4 GB DRAM, Kintex-7 325T FPGA.

The chosen CompactRIO chassis can host C-series modules, a suite of interfaces that provide several analog or digital I/O channels, in a range of different sample rates.

One of two modules can be used under Tatu:

**9401** – a 5 V/TTL digital module with 8 bidirectional I/O channels. Four channels are set to input (IO0 to IO3) and four channels to output (IO4 to IO7). In this configur-

ation, the maximum signal switching frequency for the module is 16 MHz per input channel and 10 MHz per output channel [3].

or the larger (but 70 times slower) module

**9403** – a 5 V/TTL digital module with 32 bidirectional I/O channels. The first block of four channels is set to input and the next four channels are set to output and so on (IO0 to IO3, IO8 to IO11 and IO16 to IO19 as inputs, IO4 to IO7, IO12 to IO15 and IO20 to IO23 as outputs). Only 12 of 16 input ports and 12 of 16 output ports have been implemented so far, to save FPGA resources. The signal switching frequency is about 150 kHz. [4]

The nominal maximum switching frequency as described in the specification of 9401 and 9403 modules is not reached by Tatu, as its flexibility in the signal management consumes FPGA some clock cycles. Also, our selection of the CRIO chassi model depends on the I/O modules to be used, as they require different demands for FPGA resources. Resource usage and achieved performance in each case is listed in Table 1.

Table 1: CompactRIO FPGA Use and Module Rates

CRIO model	I/O model	FPGA use (Total slices)	I/O rate
9049	9401	24.7 %	10 MHz
	9403	49.2 %	140 kHz
9045	9401	86.8 %	10 MHz

## SIGNAL MANAGEMENT

### *Tatu as the Master Signal Generator*

There are some cases where the synchronization of the devices can be provided by Tatu as the signal manager, identifying the status of each involved device and providing trigger signals at the right time, to coordinate their operations as previously set by the user. In this situation, Tatu is said to be in the *Master* mode. Tatu produces a series of internal “master” trigger signals (defined by a given number of pulses, with a duration and periodicity, all previously set by the user). That determines the pace of the operation, being followed by Tatu itself and/or replicated to other devices involved in the data acquisition.

### *Tatu as a Signal Follower*

There are cases where some devices mandatorily require the use of its proprietary software. In such scenarios, the device is the “master” giving the pace of the acquisition operation and Tatu is just another device in the chain. Tatu is set to wait for some external signal and occasionally to replicate it to third parties, other devices in the acquisition. This is the case of Tatu being in the *Follower* mode.

## TATU OPERATIONS

When Tatu is deployed, an EPICS IOC (Input Output Controller) is configured and it runs under the Linux RT CompactRIO operating system. It provides several EPICS PVs (process variables) to set and monitor the Tatu operations.

For each input port (IO0...IO3) a trigger state can be detected. The Input Trigger detection modes currently available are:

- an *Up* or *Down* state
- a *Falling edge* or a *Rising edge*
- *under* or *over an Analog threshold* (of a channel in an associated C-series analog module)
- just following the internal *Tatu Master Pulse*
- otherwise, the input is ignored

If one of the *edge* trigger modes is selected, a secondary parameter can be used – *EdgestoTrig*. Then, the triggering condition for input port *n* is satisfied only after the detection of a given number of the specified edge (falling or rising) at that port.

When the input readout meets the trigger mode defined for an input port *n*, the corresponding *Pn* state goes true.

Three different cases *c0*, *c1* and *c2* can be defined for operations on each output port (IO4...IO7). This way, an output port can be turned on in a specific situation and turned off only when another specific condition is present. Each case for an output port has its own *Condition* parameter, whose values are:

- a *Forced* action, as the defined operation should happen regardless of any condition
- the operation should happen as soon as the *Master Pulse* is present
- the operation should happen if any of the P states is true (*P0 ~ P19*)
- the condition is given by a logical combination of *Ps*, so the additional parameter *ConditionCombo* should be inspected to determine the condition; the *ConditionCombo* parameters can be set to one of the logical operations, limited to P0 to P3:
  - *P0 and P1 / P0 and P2 / P0 and P3*
  - *P1 and P2 / P1 and P3*
  - *P2 and P3*
  - *P0 and P1 and P2*
  - *P0 and P1 and P2 and P3*
  - the same combinations with an *or* operator
- otherwise, no output happens

The output will happen after a specific amount of time that can be set (in microseconds) by the *Delay* parameters,

for each case and each output port. The type of output or action (also for each case and each output port) is defined by the *Output* parameters, which can be set to one of the following choices:

- set this output port to 0 (*Off*)
- set this output port to 1 (*On*)
- produce a pulse by setting the port to 1, then to 0 for a given time and to 1 again (*Falling pulse*)
- produce a pulse by setting the port to 0, then to 1 for a given time and to 0 again (*Rising pulse*)
- *Copy* a given value to the output port
- *Copy the inversion* of a given value to the output port
- *Trigger* the scalers readouts and keep them

Whenever the *copy* or the *copy the inversion* is selected, yet another parameter is taken in consideration to define the output operation: which input condition state is to be copied. The *OutputCopy* parameter can bear one of the following values:

- copy the *master pulse* value to the output port
- copy the *P0* state or any of the other 19 states to the output port (P0 ~ P19)
- otherwise, no output should be produced

Finally, whenever the output port should produce a falling pulse (or a rising pulse), the duration in microseconds of its low (respectively high) state is given by the *Pulse* parameter.

Tatu operates and produces output only when it is put in the *active* state, through an EPICS PV. From then on, any changes in the PVs for Tatu settings are ignored and the input raw data PVs are not updated anymore. All efforts are put in the Tatu execution, and the follow-up must happen through Tatu status Pvs.

The *master pulse* is an internally produced reference. A user example of Tatu parameters set (in CompactRIO1 of hutch B, Manacá beamline) is shown in Figure 2. That would produce a train of four 250-microsecond pulses in the output port IO7 every half second, 10 times.

```
$ caput MNC:B:RIO01:9401H:Activate Off (or: 0)

$ caput MNC:B:RIO01:9401H:MasterMode On (or: 1)
$ caput MNC:B:RIO01:9401H:Zeropulses On (or: 1)
$ caput MNC:B:RIO01:9401H:MasterPulseNumber 10
$ caput MNC:B:RIO01:9401H:MasterPulseLength 1000
$ caput MNC:B:RIO01:9401H:MasterPulsePeriod 500000

$ caput MNC:B:RIO01:9401H:InputTriggerIO0 Follower (or: 7)
$ caput MNC:B:RIO01:9401H:ConditionIO7:c0 Master pulse (or: 2)
$ caput MNC:B:RIO01:9401H:OutputIO7:c0 Rising pulse (or: 4)
$ caput MNC:B:RIO01:9401H:PulseIO7:c0 200
$ caput MNC:B:RIO01:9401H:DelayIO7:c0 50

$ caput MNC:B:RIO01:9401H:Activate On (or: 1)
```

Figure 2: EPICS PVs used to configure Tatu in the *master mode* (time units in microseconds).

As soon as Tatu is in the *activate* state, that produces pulses in the output port IO7 (Figure 3).

Figure 3: The port IO7 producing output pulses at the master pulse pace.

There are watchdog PVs to show that RT-side and FPGA-side software is running. As Tatu gains new features after each new beamline, it may be helpful for the users to check the version control identifier embedded in the FPGA. That can be inspected through an *ai* EPICS PV, a longint number consisting of eight digits *yyyymmdd* (representing *year, month, day*); for instance, the number **20210131** represents “**January 31<sup>st</sup>, 2021**”.

A small piece of software can be connected to the CRIO to provide a debugging tool, with live values shown (Figure 4).

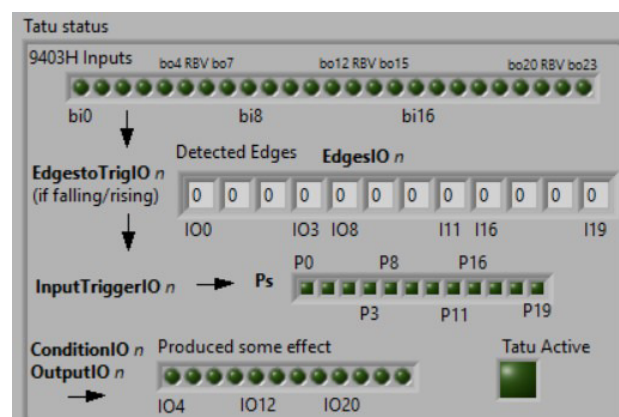

Figure 4: Debug tool for Tatu status.

## APPLICATION AT THE BEAMLINES

All beamlines now in commissioning at SIRIUS have one or more Tatu units.

In the commissioning of *Tarumã*, an experimental station at *Carnaúba* (Coherent X-ray Nanoprobe) beamline [5], Tatu has been used for instance in the scanning of areas as small as 80 μm x 80 μm and 800 nm steps. Tatu gives 500 μs pulses along 10100 points, in a total time of 30 seconds for the whole acquisition. [6]

*Manacá* (Macromolecular Micro and Nanocrystallography) beamline has Tatu in the follower mode, coordinating the shutter opening (1 ms pulse) and the trigger to start the detector in the beginning of an acquisition. This beamline was the first open to user projects [7].

As of Oct. 2021 *Ema* (Extreme condition Methods of Analysis) beamline will start to use Tatu during the energy scanning operations of its high dynamic double-crystal monochromator [8].

## CONCLUSION

The premises for such a solution at SIRIUS beamlines were satisfied and Tatu was available in time for the initial tests at SIRIUS *Mogno* beamline (X-ray Micro- and Nanotomography). In sequence, it has been applied for fast data acquisition during the commissioning of the next released SIRIUS beamlines – *Manacá*, *Cateretê*, *Carnaúba*. The flexibility to set parameters and operation modes in Tatu allowed the technical staff to quickly include new input signals and distribute triggering signals to additional devices on demand. An improvement is to admit one or more additional digital I/O modules to increase the number of available ports by keeping the performance observed with just one 100 kHz module. The solution proved successful given the time requirements. Where a better time performance will be needed, the Tatu can be purportedly redesigned, giving up flexibility for the sake of speed. Furthermore, in the future some beamlines will certainly face time requirements too strict to be met by the CompactRIO hardware platform and novel solutions will be selected.

## ACKNOWLEDGEMENTS

The authors would like to thank their colleagues among the Brazilian Synchrotron Light Laboratory (LNLS) staff, specially at the groups: SOL-Beamline Software, COL-Beamline Controls and Integration, IEA-Beamline Automation, GIE-Electronics Instrumentation and PLL-Beamline Design for the technical support and advice. During the tests, the contributions of Fernando Henrique Cardoso (GIE), Cassiano Correa Bueno (PLL), Gabriel Schubert (Mogno), Lucca Campoi (Mogno), Andrey Nascimento (Manacá), Tiago Araújo Kalile (Cateretê), João Paulo Zerba (Cateretê), Marcio Paduan Donadio and Gabriel Fedel were much appreciated.

# MRF TIMING SYSTEM DESIGN AT SARAF

A. Gaget<sup>†</sup>, CEA Saclay IRFU, Gif sur Yvette, France

## Abstract

CEA Saclay Irfu is in charge of an important part of the control system of the SARAF LINAC accelerator based in Tel-Aviv. It's including among other the control of the timing system (synchronization and timestamping). CEA has already installed and used successfully timing distribution with MRF on test bench for ESS or IPHI, so it has been decided to use the same technologies. The reference frequency will be distributed along the accelerator by a Rhode & Schwartz oscillator and the UTC time will be based on a Meridian II GPS, these 2 devices, to synchronize MRF cards, will be connected to the Event Master (EVM) card which is the main element of the timing system architecture.

The MRF timing system [1] thanks to an optical fiber network allows to distribute downstream and upstream events with a  $\mu\text{s}$  propagation time. Currently we are working on development to also use it for the machine protection system of the accelerator.

In this paper I will present the hardware used, timing architecture, developments and tests we have performed.

## INTRODUCTION

SNRC and CEA collaborate to the upgrade of the SARAF accelerator to 5 mA CW 40 MeV deuteron and proton beams (Phase 2) at 176MHz. The timing system is a key part of the accelerator as the machine protection system. The CEA control team is in charge of them and we have selected the MRF products to provide an integrated solution.

## TIMING SYSTEM ARCHITECTURE

### Overview

The SARAF timing system main functionality is to distribute:

- Trigger events
- Timestamping
- Reference frequency

The main EVM is in charge of distributing these 3 above topics. This EVM generates the trigger events from sequencers, multiplexed counters or external inputs. The timestamping will be defined by the Meridian 2 GPS [2] that distributes the UTC time by NTP and the Pulse Per Second signal (PPS). The PPS consists of a signal sent to the EVM to increment the second of the timestamp with an accuracy of 10ns. The GPS also distributes a 10MHz with ultra-low phase noise to the master oscillator that distributes itself the reference frequency (176MHz) of the accelerator to the EVM and to the RF devices.

### Propagation Time

For machine protection system or PostMortem analysis, we use the upstream propagation of events. For machine

protection system, the event propagation time associated to a machine issue is an important point to be able to ensure that the system performance is suitable to the requirements. To test this feature, we built a test bench to measure the propagation of an event. The principle of the test is generating a signal on one input of an EVR, and measuring the time for the system to generate an output signal on any other EVR of the bench (see Fig. 1). On this test bench, the propagation time is about 700 $\mu\text{s}$  for each additional floor of EVM fan-out.

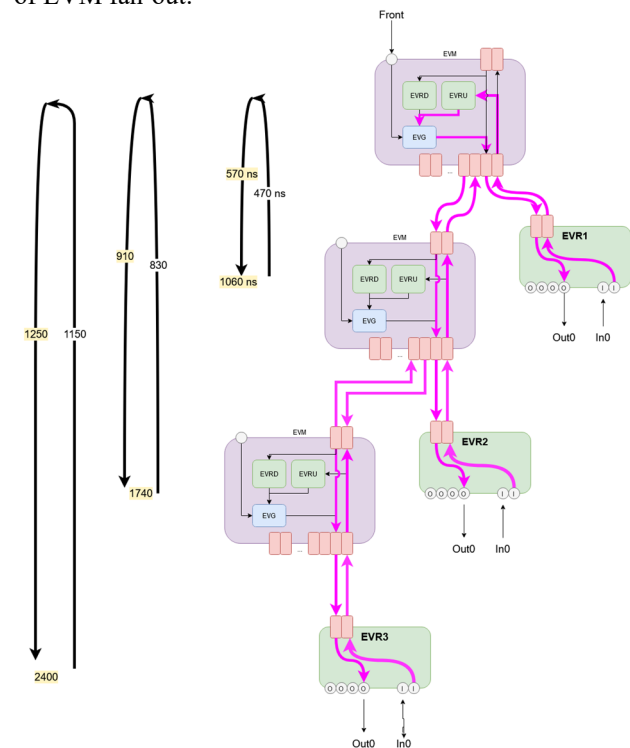

Figure 1: Test bench and result of event propagation.

### Topology

The main topology is represented in Figure 2. Due to the propagation time described in the previous paragraph, we need to have as less as possible floors of EVM fan-outs. Therefore the distribution has been divided into 3 distinct parts: Injector, MEBT and SCL.

The Injector EVR has a direct link to the main EVM because it has an important role in protection and has to receive trigger events as soon as possible.

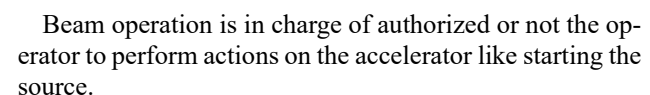

The MEBT (Medium Energy Beam Transport) part is controlled essentially by one EVM fan-out that will only be used as fan-out during beam operation. However for RF conditioning, it will produce events for RF to let cavities as independent as possible.

For the same reason in the SCL (Super Conducting Linac) part, each cryomodule will have a devoted EVM fan-out.

<sup>†</sup> alexis.gaget@cea.fr

MTCA-EVR-300U has 4 LVTTTL outputs, 2 TTL inputs and 2 slots to plug universal modules. Thanks to MTCA.4 this EVR can also use backplane lines of the MTCA.4 bus from the line 17 to 20 (see Fig. 4), meaning 8 channels can be configured as outputs or inputs.

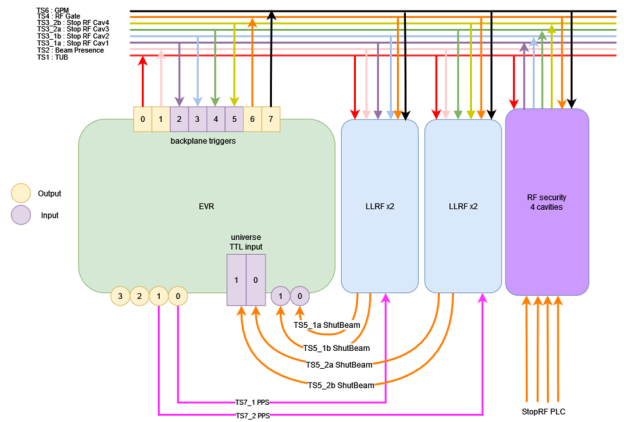

Figure 5: Distribution of signals on LLRF EVR.

For beam operation, we will use one of the sequencers of the EVM. The sequencer will trig events corresponding to the RF Gate, the chopper and the beam presence as shown in Figure 6.

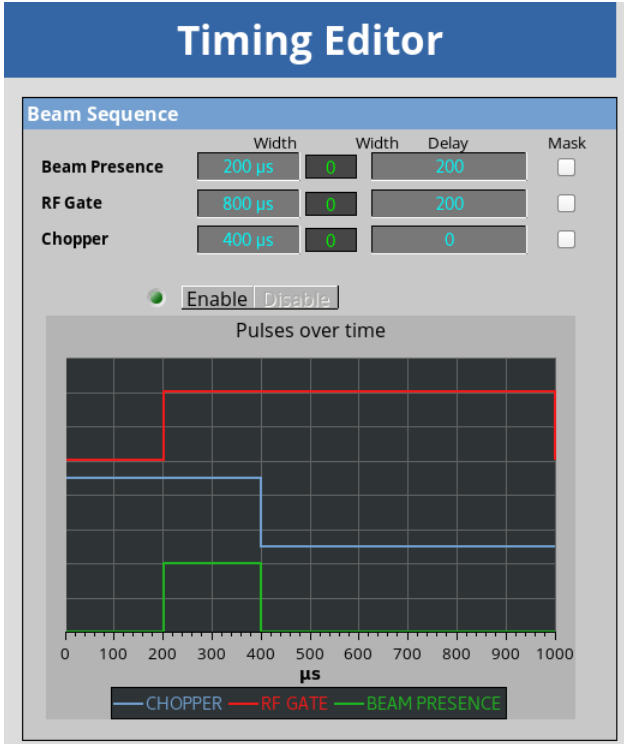

Figure 6: Graphical interface on CSS for the control of the sequencer.

We have different states during this operation:

- Pilot Beam: if the injection of beam is possible, the sequence is enabled and can send 3 different event triggers to manage the beam.
- Stop Beam: the sequence status is still on, but using the mechanism of mask of MRF, we mask the chopper event and then magnetron and RFQ are still on but the beam is not produced. It happens when we want to change the destination of the beam.

- Start Beam: the sequence status is still on and we unmask the chopper event trigger to generate the beam, it happens when the destination of the beam has been changed.
- Reset Beam: the sequence is stopped and no beam is produced.

### RF Conditioning Operation

The sequence of the RF conditioning is handled by another EPICS application, but it uses the timing EPICS application to apply a new width to the RF Gate and to change the frequency period. As seen in Figure 7 in RF conditioning mode, the main EVM will not produce the trigger events, it's each sub EVM fan-out that will manage the RF trigger events for the conditioning of cavities. Meaning that each EVM will provide the same RF Gate for its cavities:

- EVM MEBT : RFQ and 3 rebunchers
- EVM CM1: 6 equipped cavities
- EVM CM2: 7 equipped cavities
- EVM CM3: 7 equipped cavities
- EVM CM4: 7 equipped cavities

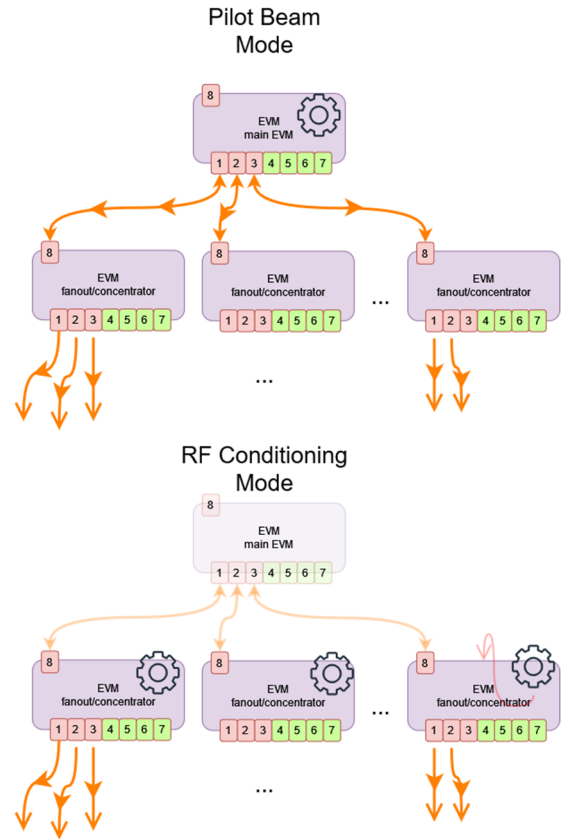

Figure 7: Timing distribution modes.

### MACHINE PROTECTION SYSTEM

The machine protection system is the system that will shut down the beam and protect the accelerator from material damages. Based on ALBA accelerator experience [6], we've decided to delegate a part of the MPS to the MRF system. Thanks to the EVM-300, it's now easier to have an

upstream configuration. Indeed, the EVM integrates 2 internal EVRs (see Fig. 8) that can handle upstream events and associate the reaction of the EVM.

As seen in Figure 8, a signal detected on the input of an EVR can upstream to the EVM and be submitted to the EVRU (for EVR Upstream). From there, like any other EVR, the EVRU can be configured to act on the reception of an event and trig the event in the integrated EVG of the EVM and then redistribute events to the whole EVRs of the accelerator. We use among others this method to propagate a “shut beam” event to the whole accelerator when a critical default is detected by a device.

Figure 8: Upstream and propagation of an event to the whole MRF tree architecture.

## EPICS APPLICATION

The EPICS timing application is based on mrfioc2 driver developed by Michael Davidsaver and a fork developed by ESS ICS [7]. We have modified the ESS driver to add mask functionalities of the sequencer [8]. We use the Irfu EPICS Environment (IEE) for EPICS development and deployment [9].

An SNL sequencer is implemented to handle the different Operation mode described earlier. Each EVR and EVM configuration will have an interface in order to operate simply the timing but an expert interface is also proposed for MRF developers. In the simplified interface (see Fig. 9), the user can modify the width and the delay of pulses produced by the EVR and have an overview of the status of pulses.

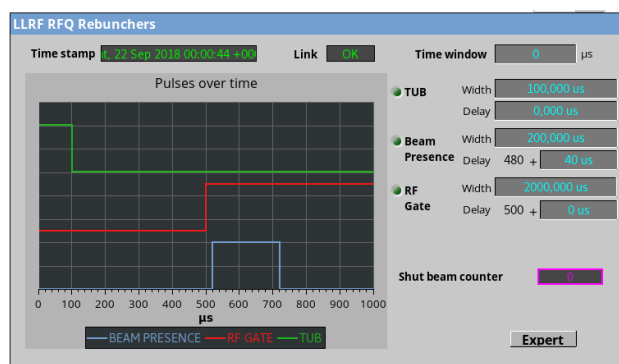

Figure 9: Example of simple interface for EVR LLRF.

## CONCLUSION

We have completed the test of the MRF solution for the Timing and Machine Protection Systems at CEA Saclay in 2021. Due to the fact that those functionalities are transversal, they have been progressively installed at SOREQ this year.

## ACKNOWLEDGEMENTS

The author would like to thank Jukka Pietarinen from MRF, Javier Cereijo Garcia and Jerzy Jamroz from ESS for their technical help.

# A NEW TIMING SYSTEM FOR PETRA IV

T. Wilksen<sup>†</sup>, A. Aghababayan, K. Brede, H.T. Duhme, M. Fenner,  
U. Hurdelbrink, H. Kay, H. Lippek, H. Schlarb,  
Deutsches Elektronen-Synchrotron DESY, Germany

## Abstract

The currently ongoing PETRA IV project at DESY proposes an upgrade of the PETRA III synchrotron light source towards a fourth-generation, low emittance machine. The goal is to provide X-ray energies in the regime of 10 keV bringing the electron beam production to its physical limits with respect to the smallest achievable source size, and thus approaching the diffraction limit.

The realization of this new, challenging machine implies a new design of the timing and synchronization system because requirements on beam quality and controls will become significantly more demanding with respect to the existing implementation at PETRA III. Furthermore, the PETRA IV baseline for the fast front-end electronics read-out will be based on the MTCA.4 standard. Given the success of the at DESY developed MicroTCA.4-based timing system for the European XFEL accelerator, it has been chosen to utilize the MTCA.4 technology for the PETRA IV timing system as well.

We present in this paper general concepts of the timing and synchronization system, its integration into the control system as well as first design ideas and evaluations of the major timing system hardware component, a MicroTCA.4-based AMC.

## THE PETRA IV PROJECT

The PETRA IV project [1] comprises the replacement of the existing 3rd generation synchrotron radiation source PETRA III with a state-of-the-art ultra-low emittance storage ring. This includes the upgrade of the storage ring infrastructure with a circumference of 2304 m as well as the redesign of the current pre-accelerator chain and construction of new beamlines. The 6 GeV storage ring will be operated at an RF frequency of 500 MHz as PETRA III. Currently, the PETRA III facility can run in either the timing mode with 40 equally distributed electron bunches at 100 mA stored beam or in brightness mode with 480 equally distributed bunches and 120 mA of beam current. The bunch pattern options are being under discussion since recent modifications of the lattice design allow now for patterns more similar to the PETRA III ones rather than what was proposed in the PETRA IV CDR.

The present booster synchrotron DESY II will be replaced by a new one, DESY IV, to meet the requirements of a low emittance beam injected into PETRA IV. While the LINAC section will be kept, the gun will be upgraded as well as the transfer section with the PIA accumulator has to be revised. The option of keeping DESY II for test beam production has to be taken into account when designing the

timing and synchronization system even if this is not considered to be part of the baseline layout of the PETRA IV project. The entire facility is shown in Fig. 1.

Furthermore, the front-end electronics for diagnostics and instrumentation will be completely overhauled and based on the MTCA.4 standard. At the same time, it has been decided to change over the existing PETRA III control system using the TINE framework to a DOOCS-based one as used at the DESY FEL accelerators. This effectively leads to the necessity to redesign the entire timing and synchronization system and its controls for the storage ring as well as for the pre-accelerator chain.

Figure 1: The PETRA IV facility layout with its existing, its new experimental halls and its pre-accelerators.

## THE TIMING SYSTEM DESIGN

The overall concept of the new timing and synchronization system has to provide services to at minimum four individual synchrotron, booster, accumulator or LINAC facilities. Namely, the new PETRA IV storage ring, the new DESY IV booster ring, potentially a PIA II accumulator and a LINAC. If it is desired to continue to provide test beam services through DESY II fed by the same new LINAC and PIA II, one has to make sure, these are well enough synchronized with respect to the RF, timing and controls with the pre-accelerator chain for PETRA IV. The idea being pursued at the moment is to provide individual main oscillators and main timing system components for each of the major installations PETRA IV, DESY IV, DESY II and LINAC with PIA together. This would allow for a most flexible way of providing the different required RF frequencies and synchronization signals. Beamlines and experiments would be served by the timing system of PETRA IV, test beams by the DESY II one. The challenge

<sup>†</sup> Tim.Wilksen@desy.de

here will be to synchronize not just the RF reference signals but also the timing information itself, i.e. cycle numbers and such to uniquely tag the data across facilities for later analysis.

## THE TIMING SYSTEM HARDWARE

### Baseline

The hardware for the new timing and synchronization system will follow this baseline:

- MTCA.4 [2] will be used as the standard for the timing system electronics specifically for the transmitter and receiver module.
- Since MTCA.4 has been successfully introduced and established when constructing and commissioning the European XFEL accelerator timing system, the design of its transmitter and receiver Advanced Mezzanine Card (AMC) [3] will be used as a basis for the new PETRA IV MTCA.4 timing module.
- The design will be kept such that adaptations and modifications of the overall functionality can be implemented easily during the life-cycle of the accelerator.
- Essential to a successful realization is the expertise from both the machine beam controls and machine controls system groups, being the developers of the timing and synchronization systems for the FEL and synchrotrons at DESY.

### Key Requirements

The key requirements for the timing and synchronization system of which the latter is crucial for the proper RF reference and signal distribution are given as follows:

- Distribution of a continuous RF reference signal
- Provision of low-jitter clocks for ADC sampling
- Distribution of timing signals, clocks and trigger events
- Provision of beam-synchronous data such as:
  - High-resolution timestamp
  - Revolution counter(s)
  - Beam modes i.e. timing or brilliance mode
  - Bunch pattern
  - Bunch current (PETRA IV)

Further, it has been proven at the EuXFEL that a common MTCA.4 module acting as a transmitter and/or as a receiver is a quite flexible and convenient concept.

A dedicated optical fiber network with drift compensation along the lines will be used. The topology follows the storage ring layout to make use of temperature-controlled media shafts and facilities. The storage ring, the booster and the LINAC with its gun will have its own timing system, however, being synchronized across the overall facility. Beamline experiments will have the possibility to connect to the PETRA IV timing system via the same MTCA.4-based AMC module.

### Integration into The Control System

An important part of the PETRA IV control system will be to provide all relevant data not only to control and monitor the entire accelerator but also to analyze its performance and proper functioning. This requires the timing system to provide the corresponding functionality. Beam-synchronous information like a high-resolution timestamp, revolution counters and a bunch pattern might be utilized by:

- Post-mortem analysis
- Transient recorder
- Event archives
- Bunch-resolved data acquisition (for detailed analysis)
- Experiment controls and its beamline data acquisitions

## PROJECT STATUS

### Organization

The timing and synchronization system project is well embedded into the overall PETRA IV project management. A work-breakdown structure as well as a product-breakdown structure with all of its deliverables have been set up. The PBS represents a hierarchical view of all PETRA IV components:

- Define the scope “What will be built?”
- Organization of design and specification data
- Integration of the subsystem into the overall project

Requirements are derived for each PBS item and classified:

- Design, Interface, Functional
- Design can be validated against requirements
- Requirements are linked to PBS items

As of now requirements from accelerator subsystems, accelerator work packages as well as beamline experiments are being collected, discussed and evaluated. This is an iterative process and will continue throughout the TDR stage. Eventually reviews will lead to a final design for the TDR documents.

### MTCA.4 Hardware Design

Currently an evaluation phase is ongoing and accompanied by lab pre-tests. This is done with the existing x2timer AMC hardware as installed at the DESY FEL machines and shown in Fig. 2 but also with a potentially new hardware based on the MPSoC-enabled Xilinx Zynq technology. For this, a Xilinx Zynq evaluation board as shown in Fig. 3 is being evaluated.

The primary goal here is to test the clock and trigger generation function, as used in PETRA III, and to measure the jitter quality of generated clock and trigger signals at the output. Using a dual loop PLL clock cleaner is being investigated as an improvement to the output jitter.

At the same time components for the distribution of the incoming and outgoing clock and trigger signals on the AMC-Card are being researched and tested. Those components must have a very low additive jitter as well. Therefore, a test stand for measuring its signal jitter has been set up in the lab.

Figure 2: This figure represents the setup of the MTCA system with an x2timer AMC for tests and evaluation.

Figure 3: Shown in this picture is the measurement and FPGA evaluation board setup.

New concepts for the advance delay calculation which is required to target individual buckets inside the PETRA ring have to be developed as well as different kinds for the FPGA control system interface.

The next major step will be the integration of the aforementioned functionality into the existing DAMC-FMC1Z7IO AMC-Card. This MTCA.4 component is being developed by the DESY MSK group and the DESY MTCA Technology lab.

Since the overall distribution of the timing system information is using a distributed optical fiber topology, the clock recovery mechanism as well as drift compensation mechanisms have to be tested, too.

Eventually, the development has to yield in a design of a Zynq architecture-based successor AMC of the x2timer,

currently being called x3timer. The design of this card is already in the specification phase and will be based on results of the requirements engineering in progress.

## OUTLOOK AND ROADMAP

The next milestones within the TDR phase until mid of 2023 are:

- Collect requirements and derive specifications
- Develop MTCA AMC- and RTM-Card architecture and interfaces according to the specifications
- Adapt AMC- Design for x3timer demonstrator
- Hardware development and production
- Firmware development for the x3timer AMC
- Front-end controls development, i.e. server applications for controls

## CONCLUSION

The renewal of the timing system for PETRA IV is without any choice however challenging. Given the excellent experience made with MTCA.4-based solutions specifically for the timing system hardware at the DESY FEL accelerators FLASH and the European XFEL, we are confident that this technology choice will serve the PETRA IV project quite well, too.

Our goal within the TDR phase is to fully specify the requirements of the PETRA IV timing and synchronization system and produce a fully functional demonstrator of the x3timer AMC hardware until 2023.

## ACKNOWLEDGEMENTS

We acknowledge DESY (Hamburg, Germany), a member of the Helmholtz Association HGF, for its support on providing resources and infrastructure. Furthermore, we would like to thank all colleagues of the MSK and MCS groups as well as the PETRA IV project team and management for their contributions to this work and help in preparing this paper.

# APPLICATION OF THE WHITE RABBIT SYSTEM AT SuperKEKB

H. Kaji\*, High Energy Accelerator Research Organization (KEK), Ibaraki, Japan  
Y. Iitsuka, East Japan Institute of Technology (EJIT), Ibaraki, Japan

## Abstract

We employ the White Rabbit system to satisfy the increasing requests from the SuperKEKB operations. The SuperKEKB-type slave node was developed based on the SPEC board and FMC-DIO card. The firmware was customized slightly to realize the SuperKEKB needs. The device/driver for EPICS was developed. The five slave nodes have been operated since the 2021 autumn run. The delivery of the beam permission signal from the central control building to the injector linac is taken care of by new slave nodes. The timing of the abort request signal and the trigger for the abort kicker magnet are recorded with the distributed TDC system. More slave nodes will be installed in the next year to enhance the role of the distributed TDC system.

## INTRODUCTION

There are two types of modern timing systems for the large-scale accelerator. One is the event-base system. Its most famous hardware is Event Timing System (EVT) [1]. The other is the timestamp-base system. The famous hardware in this case is White Rabbit (WR) [2].

Both EVT and WR enhance their roles because of the increasing requirements from the accelerator operation. The synchronous control of the distant hardware is indispensable to improve the performance of accelerators.

The SuperKEKB collider [3] at KEK utilizes EVT for the injection control including the delivery of the timing-triggers towards the beamline. It successfully implements the transcendental scheme in the position injections [4,5].

We consider introducing WR in addition to EVT for taking care of the increasing requirements to the SuperKEKB control system and to replace the devices which close with their lifetime. We especially plan to develop the distributed data acquisition system (distributed DAQ).

## NETWORK-BASED CONTROL SYSTEM

In the operation of the modern accelerators, fast and robust communication between the separated hardware is indispensable. In such a case, the accelerator control is realized by synchronously operating modules that are connected via the dedicated optical cable. Often, the cable length becomes more than a kilometer in the large-scale accelerators. Recently, the roles of the timing system are increased for this purpose.

The network-based control system is summarized in Table 1. The module that is employed at SuperKEKB is listed together with the future possibilities of EVT and WR for those purposes.

Table 1: List of network-based control systems: the module that is employed at SuperKEKB is listed together with the future possibilities of EVT and WR. “Commercial” is a commercial product. “Original” means an original product that is developed at KEK.

	SuperKEKB	Possibility
Trigger delivery	EVT	EVT or WR
Bucket Selection	Commercial	WR
Abort system	Original	EVT or WR
Beam permission	Original	WR
Distributed DAQ	None	EVT or WR

In the case of SuperKEKB, the trigger delivery for the beam injection is taken care of by EVT. The commercial distributed shared memory is utilized for Bucket Selection [6]. The original modules were individually developed for the Abort Trigger System [7] and the beam permission system.

On the other hand, the WR system has several kinds of modules so that they can take care of all listed systems. We consider replacing the “Commercial” and “Original” devices with WR. Then, all network-based control systems are developed with EVT and WR. Note, the best way is to develop everything with one system. However, to develop with two systems is still better. And this experience becomes important knowledge for future colliders like Higgs factory.

## APPLICATION TO SuperKEKB

In this section, we report the WR application at SuperKEKB. The entire system is discussed after introducing the specification of the SuperKEKB-type slave node.

### Slave Module

Figure 1 is the pictures of the slave modules which we developed at KEK. The SPEC board [8] is selected as the slave node of WR. Only the FMC-DIO card [9] is employed in the SuperKEKB operation, so far. Two types of nodes are produced at a low cost.

The module in the upper picture of Fig. 1 is a homebuilt computer with a 2.9 GHz 6 core CPU, 8 GB of RAM, and 2.5 inch SATA III SSD. We chose the small-size commercial barebone kit with the PCIexpress slot to mount the SPEC board. All parts are mass-produced goods and can be supplied easily. The size of this module is  $20 \times 25 \times 8 \text{ cm}^3$ .

The firmware and software of the starting kit [10] are utilized with small customization. The transition timing of the input or output signals is informed in both higher or lower transitions while that is informed only in higher transition with the original firmware. The software runs on the Ubuntu 18.04 OS. We developed the device/driver for EPICS.

\* E-mail: hiroshi.kaji@kek.jp

Figure 1: Pictures of the slave node: the upper picture is SPEC on the homebuilt computer. In the lower picture, SPEC is housed in the 19-inch box with 1U height. It can be operated from RaspberryPi.

Followings are the functions of SuperKEKB-type slave node:

- Detect the transition of the TTL level signal for both input and output channels and inform the GPS synchronized timestamp.
- Transport the status of an input signal to the other nodes and enforce output.
- Output the TTL level signal according to the status of the received signal from other nodes.
- Output the pulse-per-second (PPS) signal which is synchronized with GPS.

The module in the lower picture of Fig. 1 is SPEC with RaspberryPi. In the 19-inch rack box, the SPEC board and the RaspberryPi 3 model B+ are assembled with the power supply units. This system utilizes the standalone feature of SPEC. The SPEC board is controlled via a mini USB port. It is successfully configured as the slave node. The test operation under the WR network at SuperKEKB was successfully carried out. However, the development of the EPICS device/driver is still ongoing.

### Installation to Beamline

We installed the five SPEC nodes and two WR switches [11], so far. Their location is indicated in Fig. 2. Three SPEC nodes and one WR switch were installed at Central Control Building (CCB). For the WR switch as the grand-master module, the PPS signal and 10 MHz reference clock are provided from the rubidium clock which is synchronized with GPS. The slave nodes measure the arrival

Figure 2: Map of the slave nodes at SuperKEKB: The WR modules were installed at D4, CCB, and LINAC buildings.

timings of the abort request signal at CCB and the delivery timing of the TTL triggers to the abort kicker magnet. The Beam Gate signal is input into one of the slave nodes. It is transferred to the injector linac (LINAC) [12]. Besides, the 99176 divided revolution signal ( $\sim 1.002$  Hz) is produced.

The SPEC node at the D4 building provides the PPS signal to the beam size monitor for the electron ring (X-ray monitor) [13]. Since the PPS signal from the WR slave node is synchronized with GPS, it indicates the absolute time of the measured data of the beam size monitor. The system is being tested in the 2021 autumn run.

Figure 3 is a picture of WR modules at LINAC. One WR switch is installed as the boundary module. One SPEC node is installed under this boundary module. It is utilized to receive the Beam Gate signal and delivers the TTL level control signal to the LINAC components such as the electron guns. In the future, more slave nodes will be installed under this boundary module to understand the LINAC hardware status with the common clock.

## BEAM GATE SYSTEM “D0D0”

Beam Gate is a part of the beam permission system. The beam permission system permits or inhibits the provision of the beam pulse from LINAC. In general, the system monitors the accelerator hardware and inhibits the injection when some hardware is in an abnormal condition.

In the case of Beam Gate at SuperKEKB, the injection is enabled and disabled dynamically by the operator. It is managed to keep the beam current at two main rings (MR). The stored beam at MR is decayed and the operation beam current is decreased gradually. Beam Gate is opened and

Figure 3: Picture of LINAC node: the WR switch and SPEC node were installed near the master IOC of EVT.

implements the beam injection when the operation beam current becomes the lower acceptable limit. Then, Beam Gate is closed when the operation beam current reached the target value of the experiment.

The beam permission signal is delivered from MR to LINAC via 800 m optical cable. It is inputted to the SPEC node at CCB and transferred to that at LINAC. This new system is named “D0D0”. The name of the system is decided from the setting of the FMC-DIO card at LINAC<sup>1</sup>.

One of the advantages of the D0D0 system is to know the accurate timing of both enabling and disabling the beam injection with GPS time. It is reliable information when we inspect the relation between the injection and problems which happened at MR.

The slave node can transfer the input signal to more than one node. So, in the future prospect, the Beam Gate signal can be delivered not only LINAC but the injection and extraction control of the damping ring (DR). In that case, the extraction system of DR must be controlled at least 40 ms later than the injection system. The signal transfer with the SuperKEKB-type node can take care of such kind of delay.

Besides, all beam permission logic can be included in the FPGA of SPEC. The Mock Turtle framework may complicate the management.

<sup>1</sup> It is “iD0D0”. Note, the setting of channels 2 and 4 is zero and is not the capital letter “O”. However, we pronounce our system like “doudou”.

Figure 4: Measurement of correlation between abort response time,  $\Delta T_{\text{kicker}}$ , and the revolution,  $\Delta T_{\text{rev}}$ : the details of the setup of this measurement are explained in Ref. [15]. The results for both the positron and electron rings are shown in the left and right plots, respectively.

## DISTRIBUTED TDC

The distributed Time-to-Digital Converter (distributed TDC) is one part of the distributed DAQ. The key technology of the distributed DAQ is the timestamp synchronization among the data acquisition devices which are distributed along the long beamline of accelerators. The utility of the timestamp synchronization among the separated beam monitors was demonstrated with the injection archiver of SuperKEKB [14].

The WR system is a strong tool to take care of timestamp synchronization. By using the SuperKEKB-type slave node as TDC, we can measure the timing of events that occur in the entire accelerator and can sort them in the time order with the accuracy of 8 ns.

We plan to measure the timestamp of the TTL reference-signal from the individual Abort Trigger modules [7] with the SuperKEKB-type slave node. The Abort Trigger System collects the request signal of the beam abort from the accelerator hardware and monitors. Therefore, we can make the time order of abort requests and know which component launches the abort request firstly. They are valuable data to diagnose the source of the problem. The time resolution of the abort request measurement will be 8 ns and becomes much precise than that in the current system<sup>2</sup>. We installed the slave node only at CCB, so far, and all modules will be installed in the next year.

The feasibility of the WR system in the abort timing measurement is demonstrated in Ref. [15]. In this case, only two modules were installed at the D2 building and CCB. Figure 4 is the update of the result with more large data set. The correlation between the abort kicker timing and the revolution was clearly observed. The variation of the abort response time can be explained by the timing of the abort gap.

<sup>2</sup> Note, the low accuracy part still remains in the upgrade system. The accuracy of the timestamp comparison among the channels on the same Abort Trigger module is 100 ns. It comes from the internal clock rate of 10 MHz.

We are discussing further improvement. We plan to receive the signal directly from the beam loss monitor which has a high time resolution and will be installed soon.

## TRIGGER DELIVERY

The trigger delivery from the WR node is the other valuable method to configure distributed DAQ. Since the WR node knows the precise timing of signal output, WR can fetch the GPS synchronized timestamp to data taken with its trigger. So far we can provide the following two kinds of triggers.

### Pulse-to-Pulse

All slave nodes with SPEC and FMC-DIO can provide the PPS signal which is accurately synchronized with GPS. We provide the PPS signal to the X-ray monitor for the electron ring at the D4 building. It is the first step for this kind of distributed DAQ. The operation test is ongoing in the 2021 autumn run.

### One-Herz Revolution

The 99176-divided revolution signal can be delivered from the WR slave node. Note the revolution of SuperKEKB is  $\sim 100$  kHz. Therefore, the rate of this signal becomes  $\sim 1.002$  Hz. The DAQ rate of some monitors at SuperKEKB is quite less than the revolution and is from 1 Hz to 10 Hz. This signal can use a such kind of case.

The signal is made from the 2254-divided revolution which is the source of the injection trigger. It is inputted into one of the WR slave node at CCB. Further 44 times division is implemented on the CPU process. The signal transfer to other nodes is implemented once in the 44 inputs while that process is vetoed in the remaining cases.

The trigger resolution in the current system is 8 ns. And there is a possibility of a future upgrade with FMC-TDC and FMC-DLY. In this case, the resolution of the revolution signal becomes less than a nanosecond. It will advance machine commissioning and the study of beam physics. For example, if we carry out the bunch-by-bunch measurement at SuperKEKB, the time resolution must be smaller than 4 ns.

## CONCLUSION

The operation of WR has been started at SuperKEKB. The SPEC and FMC-DIO are employed as the slave node. By applying the small customization to firmware and software, the SuperKEKB-type slave node provides a lot of benefits to the accelerator operation. The Beam Gate system “D0D0” provides a more smooth operation of SuperKEKB. The dis-

tributed TDC system plays important role in the beam loss diagnostic.

The development of the distributed DAQ system with WR is continued and it will provide large benefits in the accelerator operations.

# ANALYSIS OF AC LINE FLUCTUATION FOR TIMING SYSTEM AT KEK

D. Wang\*, K. Furukawa, M. Satoh, H. Kaji, H. Sugimura, Y. Enomoto, F. Miyahara, KEK, Japan

## Abstract

The timing system controls the injection procedure of the accelerator by performing signal synchronization and trigger delivery to the devices all over the installations at KEK. The trigger signals is usually generated at the same phase of an AC power line to reduce the unwanted variation of the beam quality. This requirement originates from the power supply systems. However, the AC line synchronization conflicts with the bucket selection process of SuperKEKB low energy ring (LER) which stores the positron beam. The positron beam is firstly injected into a damping ring (DR) to lower the emittance before entering desired RF bucket in LER. A long bucket selection cycle for DR and LER makes it difficult to coincide with AC line every injection pulse. This trouble is solved by grouping several injection pulses into various of injection sequences and manipulating the length of sequences to adjust the AC line arrival timing. Therefore, the timing system is sensitive to drastically AC line fluctuation. The failure of timing system caused by strong AC line fluctuation and solutions are introduced in this work.

## INTRODUCTION

The electron/positron collider, SuperKEKB, is upgraded from the KEKB project since 2010 at KEK, whose goal is to update the world highest luminosity record and discover new particle physics by Belle II experiment [1]. The timing system at the 700-m long injector linear accelerator (LINAC) is responsible for the injection of all accelerator complex which consist of a 7 GeV electron high energy ring (HER), a 4 GeV positron low energy ring (LER), a 2.5 GeV Photon Factory (PF) and a 6.5 GeV PF-AR ring (see Fig. 1). During the phase-2 operation in 2018, a 1.1 GeV positron Damping Ring (DR) is constructed at the middle of LINAC to lower the positron beam emittance [2].

Figure 1: Overview of LINAC, SuperKEKB, and PF/PF-AR.

The event-based timing system at LINAC is required to switch the beam properties at 50 Hz by changing the event codes and additional control data. Totally 12 kinds of beam

modes are defined to perform the pulse-to-pulse modulation. The master trigger signal of the timing system comes from the AC line to follow the fluctuation of power line and keep the beam energy stable. The bucket selection is implemented by adding delays to the master trigger signal. However, a long bucket selection cycle which caused by the DR makes it difficult to coincide with the AC line. A scheme called sequence shift is developed to synchronize with the 50 Hz AC line [3]. With the growth of the system complexity, several failures of timing system are observed and analyzed based on the fault diagnosis system [4].

In this paper, the reason of such failures are identified and some efforts to improve the reliability and stability of timing system are introduced.

## BUCKET SELECTION FOR LER

The primary task for bucket selection is to provide the ability to select an arbitrary RF bucket in the ring for a single injection pulse. This can be achieved by adding a proper delay time to the gun triggering signal after defining the fiducial bucket in the ring. As the stable phase of RF cavity coincides based on the common frequency (CF) between LINAC and two main rings (MRs), the injection is performed based on the period of the CF [5]. After  $h$  times injection, all RF buckets are filled. The period during which all ring RF buckets can be filled is defined as a bucket selection cycle (BSC) and the period of BSC can be represented as

$$T_{BSC} = h_{MR} * T_{CF} \quad (1)$$

where  $h$  is the harmonic number (i.e., the number of RF buckets),  $T_{CF}$  is the period of common frequency between LINAC and MR.

According to the requirements of RF synchronization, several significant frequencies for timing system can be calculated in Table 1. Note that the BSC for DR only is practically useful when performing DR-injection-only mode for beam study.

Table 1: Bucket Selection Frequencies at KEK LINAC

Frequency	Period	Remarks
2856 MHz	350 ps	RF frequency for LINAC
508.89 MHz	1.97 ns	RF frequency for DR & LER
114.24 MHz	8.75 ns	Event clock
2.21 MHz	452 ns	DR revolution frequency
99.39 kHz	10.06 $\mu$ s	LER revolution frequency
45.15 kHz	22.15 $\mu$ s	BSC for DR only
2.03 kHz	493 $\mu$ s	BSC for LER only
88.19 Hz	11.34 ms	BSC for DR and LER
50 Hz	20 ms	Beam repetition rate

\* sdcswd@post.kek.jp

The harmonic number  $h_{MR}$  at two MRs are 5120, and the injection opportunity arises at the common frequency of 10.385 MHz between LINAC and the SuperKEKB MR (i.e., every 96.3 ns). According to the Table 1, all RF buckets can be selected within 493  $\mu$ s, and the bucket selection process can be easily accomplished every 20 ms. Nevertheless, if DR is considered, the complexity of the bucket selection system grows. The harmonic number at DR is 230 and the least common multiple between the DR and LER harmonic numbers is 117760; thus, the BSC for DR and LER becomes 11.34 ms (i.e., 88 Hz).

## AC LINE SYNCHRONIZATION

It is usually necessary to maintain the beam intensity and quality on the same level for consecutive triggers. Some devices are sensitive to the AC line phase and might not satisfy the stability requirement when working at different AC line phases. The klystron is a good illustration of this. Some klystrons use the AC-powered filament or heater to heat the electron cathode, and the changing AC phase might generate a magnetic field that eventually affects the velocity modulation process of the klystron. The frequency of the AC line is not ideal 50 Hz. The Tokyo Electric Power Company, which supplies AC power for KEK, adjusts the frequency of the AC power line within  $50 \pm 0.2$  Hz to balance the supply and demand requirement of the electricity market [6]. The timing system is required to follow the drift of AC50.

For HER injection, the BSC is 493  $\mu$ s and the gun timing can be calculated based on the coincidence between AC50 and BSC. However, for LER injection with DR, the BSC is longer and to be 11.34 ms, so it cannot coincide with AC50 every 20 ms. Therefore, a method called sequence shift is utilized to deliver the triggers at the same phase of AC50, while it is also synchronized with the BSC.

## SEQUENCE SHIFT

A set of injection pulses are grouped as an injection sequence. By shifting the length of the sequence, the synchronization between BSC and AC line becomes possible.

### 8/9 Pulses Sequence Shift

For HER injection, the BSC is 493  $\mu$ s and the gun timing can be calculated based on the coincidence between AC50 and BSC every 20 ms. However, for the positron injection process, the bunch is first injected from LINAC into DR and then extracted from DR into LINAC after a pre-defined storage time. Hence, the BSC for the combination of DR and MR is 22.68 ms; therefore, synchronization with AC50 at every pulse is impossible. Consequently, an 8/9-pulse injection sequence was developed.

As shown in Fig. 2, the core ideology of the 8/9-pulse sequence is to define the 50 Hz fiducial point and record the AC50 arrival time and BSC timing. Inside the 8/9-pulse injection sequence, the bucket selection delay value for the positron can be acquired based on the fiducial point and current pulse number. After an 8-pulse sequence (i.e., 160 ms),

Figure 2: By shifting the injection sequence, the BSC for DR and MR injection can synchronize with the 50-Hz AC50.

the next sequence can synchronize with the BSC again if the next pulse starts 1.25 ms early. Similarly, launching the next pulse 1.4 ms after 9 pulses (180 ms) also meets the synchronization requirement (see Fig. 3). Using this method, the fiducial value for the BSC in every pulse can be calculated using the pulse number, and it is possible to operate the injection into DR and the extraction from DR at different pulses. The determination of the next sequence length is based on the AC50 value, which is measured by TDC for every pulse.

Figure 3: AC50 position in a pulse is manipulated by the sequence shift.

### 16/18 Pulses Sequence Shift

The DR operation is carried in 2018. To achieve a satisfactory damping effect, a DR storage time of at least 40 ms is required. There also exists a restriction of the maximum storage time in the DR. The injection and extraction delay are calculated together, and both follow the AC line phase at the injection pulse. Thus, the extraction timing trigger has a larger discrepancy at the downstream LINAC for a long storage time. The difference between the extraction timing and AC50 arrival timing at extraction pulse becomes larger when the storage time increases. Consequently, the maximum storage time is chosen to be 200 ms, while the minimum storage time is 40 ms. To supply the requirement of the maximum DR storage time (200 ms), the sequence length is doubled to apply the 16/18-pulse sequence shift in 2018, and the sequence shift values are enlarged to 2.5 and 2.8 ms [2].

### Sequence Shift Algorithm

The algorithm of the sequence shift is based on the AC50 timing of the previous pulse and uses it as an estimation the AC50 value in the near future. A reference value is also required to act as a comparison point. Obviously, there are only two sequence types, i.e., 16-pulse sequence and 18-pulse sequence. Therefore, the AC50 shift value, i.e., 2.5

and -2.8, can be used to represent the sequence types 16 and 18, respectively. Because the program operation requires some time, the sequence shift decision should be done at the start of the current sequence. It is then easy to calculate the next sequence type based on the current sequence type and the AC50 timing of the starting pulse. The detail of the sequence shift algorithm can be referred from [7].

## TIMING SYSTEM FAILURES

The timing system, which satisfies the requirements to operate the DR for the positron injection, was installed and commissioned in 2018 [2]. As the growth of the system complexity comes from the bucket selection and 16/18-pulse sequence shift, several failure modes of the timing system are observed. An event code log system, which monitors and saves all event codes received in EVR, is developed to diagnose the failure modes in 2019 [4]. The severity of some timing system failures is minimal because the trigger signals for devices are masked and inhibited by beam gate system [8] when some abnormal events are transmitted. On the other hand, a timing system failure that stops the delivery of event codes for a few minutes is severe for the physics run because it usually triggers the beam abort system to dump all the beams at SuperKEKB. It normally takes 10 minutes for the operator to check the status of the devices and restart the injection. The occurrence of such kind of failure is rare (i.e., 9 times) in 2020. However, the number of failures increases to 18 times in a month since the 2021 spring, and the beam operation is frequently interrupted. Thus, it is urgent and significant to understand the failure cause and stabilize the operation. By analyzing the event code log system and auxiliary timing data, such malfunction of the timing system is caused by strong AC50 drift.

Figure 4: If AC50 arrives too early or too late in the 20 ms pulse, the logic of timing system may fail

As Fig. 4 shows, every pulse the timing system needs some time to process the data. If AC50 drifts continuously, the AC50 arrival time may come too early or too late. Therefore, the timing system logic may fail.

## STABILIZATION OF TIMING SYSTEM

As Fig. 5 shows, compared with the 16/18-pulse injection sequence, the 8/9-pulse injection sequence increases the

robustness of the sequence shift algorithm. Switching to the 8/9-pulse injection sequence is a possible method to solve the timing failure because the AC50 adjustment speed is faster.

Figure 5: Comparison of AC50 arrival timing between 16/18-pulse sequence and 8/9-pulse sequence.

The restriction of the sequence length originates from the DR storage time and the root reason is the coupling of DR injection and extraction calculation. Shifting the RF phase at downstream LINAC is an efficient way to increase the DR extraction opportunity and relieve the stress of long sequence management. The DR extraction delay is calculated based on the shifted RF phase at downstream LINAC. Under these circumstances, the dependency between DR and MR injections can be removed. The operation of 8/9-pulse sequence shift is possible as the DR injection and extraction delay calculations can be separated. More descriptions about RF phase shifting can be found in [9].

Apart from the 8/9-pulse sequence shift, the sequence shift algorithm can be further improved by considering the AC50 drift value. Currently, the estimated AC50 arrival time is used to determine the next sequence type. If strong AC50 drift happens, the estimated value has a large deviation from the real value. The timing system could enter race conditions when an inappropriate sequence type is selected. To avoid such a situation, the sequence shift algorithm is modified and the average AC50 drift value in recent pulses is utilized to help the sequence shift algorithm to estimate the AC50 arrival time. The new estimation becomes closer to the real value even when AC50 fluctuates strongly.

According to our simulation, the new algorithm can handle an AC50 drift ranging from  $-156\mu\text{s}$  to  $158\mu\text{s}$ . Figure 6 shows a timing system failure which is caused by the strongest AC50 drift situation that we have recorded during the past two years. The data was recorded by TDC in 2019. The AC50 drift value reached  $120\mu\text{s}$  and lasted for several seconds. Figure 7 compares three sequence shift schemes, 16/18-pulse sequence shift which is currently using, 8/9-pulse sequence shift, and 8/9 pulse sequence shift with the functionality of using the past AC drift value. The results show that the new algorithm can handle the most significant AC50 drift situation.

The 8/9-pulse sequence operation with AC50 drift compensation has been planned from the 2021 summer.

Figure 6: Extremely strong AC50 drift recorded by TDC.

Figure 7: Comparison of different sequence shift schemes.

## SUMMARY

The timing system failures that happened at LINAC frequently interrupt the operation of SuperKEKB. We analyzed the algorithm of the injection sequence shift, the timing system failures caused by strong AC50 fluctuation are solved after upgrading the sequence shift by applying short sequence length and performing a reliable AC50 estimation. The simulation results show that the new method can handle the most severe AC drift situation we have ever met in the last two years. The analysis procedure and solution for a timing

system with a long bucket selection cycle can be referred to for the design of future circular accelerators.

# DEVELOPMENT OF TIMING READ-BACK SYSTEM FOR STABLE OPERATION OF J-PARC

M. Yang<sup>†</sup>, N. Kamikubota, K.C. Sato, N. Kikuzawa, J-PARC Center, KEK&JAEA, Japan  
Y. Tajima, Kanto Information Service, Tsuchiura, Japan

## Abstract

Since 2006, the Japan Proton Accelerator Research Complex (J-PARC) timing system has been operated successfully. However, there were some unexpected trigger-failure events, typically missing trigger events, during the operation over 15 years. When a trigger-failure event occurred, it was often tough to find the one with the fault among many suspected modules. To solve the problem more easily, a unique device, triggered scaler, was developed for reading back accelerator signals.

The performance of the module has been evaluated in 2018. In 2021, we measured and observed an LLRF signal as the first signal of the read-back system for beam operation. After firmware upgrades of the module, some customized timing read-back systems were developed, and successfully demonstrated as coping strategies for past trigger-failure events. In addition, a future plan to apply the read-back system to other facilities is discussed. More details are given in the paper.

## INTRODUCTION

J-PARC (Japan Proton Accelerator Research Complex) is a high-intensity proton accelerator complex. It consists of three accelerators: a 400-MeV H- Linac (LI), a 3-GeV Rapid Cycling Synchrotron (RCS), and a 30-GeV slow cycling Main Ring Synchrotron (MR) [1-2]. Since the initial beam in 2006, J-PARC has been improving beam power. Concerning MR, recent beam power is about 500-kW (50-kW) by fast (slow) extraction, respectively [3].

There are two time cycles used in J-PARC: A 25-Hz rapid cycle is used at LI and RCS, a slow cycle is used at MR. When MR delivers proton beams to the NU and HD facilities, 2.48-s (fast extraction mode (FX)) and 5.20-s (slow extraction mode (SX)) cycles are used, respectively. Because the slow cycle determines the overall time behavior of the accelerators, it is also called a “machine cycle.”

The control system for J-PARC accelerators was developed using the Experimental Physics and Industrial Control System (EPICS) framework [4]. In addition, a dedicated timing system has been developed [5-6]. The J-PARC timing system consists of one transmitter module and approximately 200 receiver modules. Both types of modules were developed as in-house VME modules. Event-codes, which have information on beam destination and beam parameters, are distributed from the transmitter module to the receiver modules. A fiber-optic cable network is used for event-code distribution using several optical-to-electrical (O/E) or electrical-to-optical (E/O) modules. According to

the received event-code, each receiver module generates eight independent delayed trigger signals.

Since the first beam use began in 2006, the J-PARC timing system has contributed to a stable operation of the accelerator beam [6]. Nevertheless, some timing trigger-failure events have occurred during beam operation. During each recovery process against a failure, it was often difficult to find a definite module among the many modules suspected. Such experiences have prompted us to develop a new module that can read back signals generated by the J-PARC timing system. We developed a new module, called a triggered scaler module, for this purpose [7-8].

In this paper, using one of trigger-failure events occurred in J-PARC MR as a case, the working principle, a usage in beam operation, and firmware upgrades of the triggered scaler module, are described. Moreover, a customized read-back system is introduced, followed by a discussion on the plan for future.

## PAST TRIGGER-FAILURE EVENTS

Since 2006, we experienced some unexpected trigger-failure events during beam operation [8-9]. Herein, one case is given as an example, a 25-Hz irregular trigger event.

From November to December 2016, an O/E module, which was used to send a 25-Hz trigger signal from RCS to MR, started to produce irregular triggers (Fig. 1). Because the irregular triggers affected a critical beam diagnostic system, the accelerator operation was suspended several times per day [7]. It took 2 weeks to identify the troublesome O/E module.

Figure 1: The normal and irregular 25-Hz trigger signals monitored by an oscilloscope during beam operation.

## TRIGGERED SCALER MODULE

### Introduction

A unique device, triggered scaler (hereafter TS), was designed by J-PARC control group for reading back timing signals. It is a scaler to count number of pulses in a specified accelerator cycle, and it stores the counts in a momentary array [7-8]. The differences between a TS module, a digitizer, and a simple scaler are shown in Fig. 2. Contrast to the simple scaler, the uniqueness of the triggered scaler

<sup>†</sup> yangmin@post.kek.jp

module is that it has an external trigger input and an output data as a digitizer, and its output is a data buffer with 192 elements. It was designed as a Yokogawa (FA-M3/e-RT3) PLC-type, which can fit the standard I/O form in J-PARC MR.

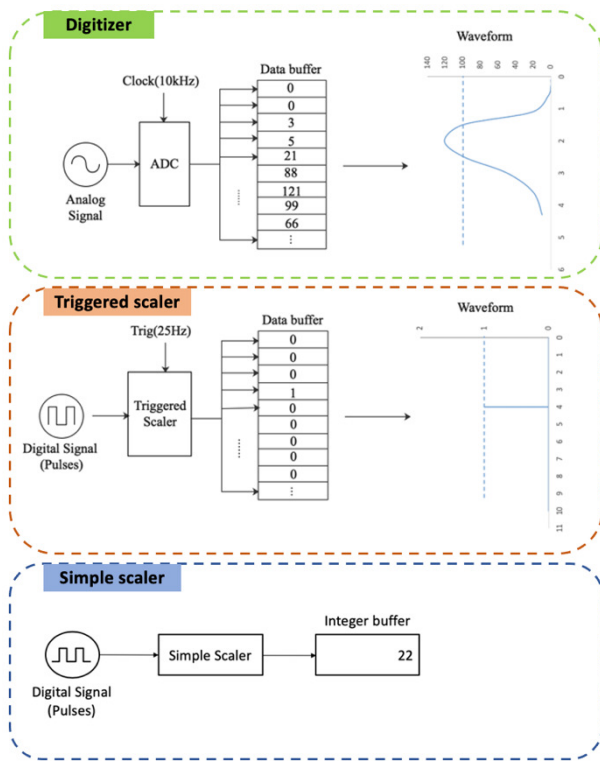

Figure 2: The comparison of digitizer, triggered scaler, and simple scaler.

There are two types of the module: the MR-type and the LI-type. The hardware appearances of the two types are shown in Fig. 3. The LI-type TS module was designed to find a missing trigger event of the LI accelerator. The module checks the pulse count in the rapid cycle (25-Hz), and outputs an error signal when an error is detected. In turn, the MR-type checks the pulse counts in the last slow cycle (2.48-s or 5.20-s) and raises an error flag. Both require the start signals of the slow cycle (“S”) and the rapid cycle (“Trig”), provided by the J-PARC timing system. The MR-type has four input channels and no output channel, while the LI-type has two input channels and two error-output channels. There is a dual ring buffer (192 cells  $\times$  2 for MR-type, 448 cells  $\times$  2 for LI-type, 16 bit/cell) for each channel.

Figure 3: The hardware appearances of two types of the triggered scaler module.

### Working Principle

In principle, each channel of the TS module works as a scaler. Two internal FPGA logics are shown in Fig. 4. The first logic (FPGA\_1) counts the input pulses. When the “S” signal arrives, FPGA\_1 starts to increase the count in the first cell of the first memory buffer. Each time the “Trig” signal arrives, FPGA\_1 shifts the pointer to the next cell. When the following “S” signal arrives, the pointer is moved to the first cell of the second memory buffer. In other words, each cell keeps several trigger pulses received in a 40-ms bin (as the “Trig” signal is 25-Hz). This scheme enables retrieval of the numbers of counts during the last machine cycle. The second logic (FPGA\_2) reads the memory buffers, checks whether trigger faults exist or not, and outputs an error signal for LI-type or sets an error flag for the MR-type, if necessary. The LI-type module can output an error signal directly through the output channels.

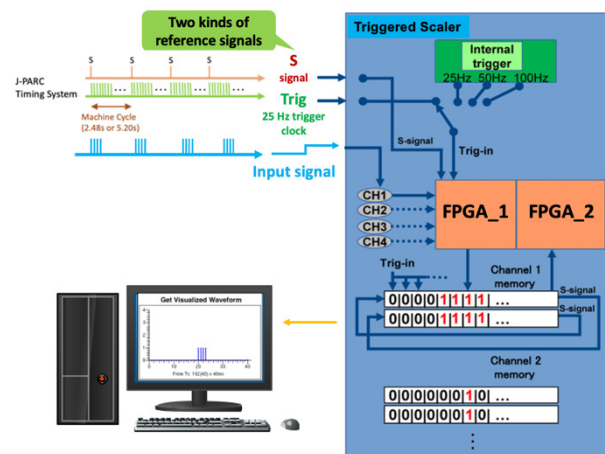

Figure 4: The conceptual design of the triggered scaler module.

## For Beam Operation

The performance of the module was confirmed and reported in 2018 [7]. Early in 2021, a setup for beam operation was prepared as shown in Fig. 5. It consists of a CPU module, a TS module, and a power supply module. All of them are standard Yokogawa PLC modules. Linux and EPICS IOC are running on the CPU module.

Figure 5: Test setup of triggered scaler module.

In May 2021, we started to observe an LLRF signal (MR circulation signal) by the setup, as one of the first operational surveillance to read-back signals. LLRF patterns in 30-GeV and in 8-GeV are visualized as shown in Fig. 6 (a). An EPICS PV (Process Variable) for the MR energy, which is deduced from the observed LLRF patterns, was developed and has been recorded by an archiver (as shown in Fig. 6 (b)).

Figure 6: (a) Measurement of an LLRF signal, (b) MR energy from an archiver.

## Firmware Upgrades

Based on experiences of module measurements, we identified small problems in the TS module. In 2020 and 2021, we upgraded the firmware of the MR-type module as follows (details are given in [9]).

1. Synchronize the internal trigger with the “S” signal. In the old firmware, the cell position of the received signal sometimes shifted to the next position.
2. Add preset-delay function for “Trig” signal. This function is to adjust the arrival time of the “S” signal relative to the external “Trig” signal.
3. Add 30-Hz, 60-Hz, and 120-Hz internal triggers to use in western Japan and other countries.
4. Clear data buffer each time when “S” signal comes.
5. A bug in counting the last cell of the data buffer was fixed. This bug has caused zero count in the last cells (62nd or 130th) when we had measured the RF signal.
6. Enlarge the LED flushing duration up to 10-ms, for better visibility in field works.

The issues 1 and 5 were caused by unsynchronized internal trigger. With the new firmware, the internal trigger is synchronized with the “S” signal. The issues 2 and 3 are essential upgrades to use the module in other facilities. The issues 4 and 6 were updated for user’s conveniences.

This firmware upgrade was significant to shift the module status from a test to an operational phase. The firmware upgrade of the LI-type module is planned.

## CUSTOMIZED TIMING READ-BACK SYSTEM

It has been demonstrated that the TS module can measure and visualize accelerator signals with the relationship of accelerator cycle. Several customized timing read-back systems were developed based on the module, as the countermeasures against the past trigger-failure events [9]. Here shows one example: a read-back system of 25-Hz trigger.

The 25-Hz trigger from RCS is important for the beam diagnostic system of a fast-current transformer (FCT), which observes the in-coming protons into MR. The past trigger-failure event in 2016, as shown in Fig. 1, caused a critical problem.

The read-back system of 25-Hz trigger observes the signal at the MR side since May 2021. The system realizes remote monitoring of the signal as shown in Fig. 7. Thus, we can find the same failure event immediately.

Figure 7: The observed 25-Hz trigger signal from RCS in a machine cycle (5.20-s) by the read-back system.

## FUTURE PLAN

The current read-back system assumes the use of the computer resources of the J-PARC control system. Thus, it is unavailable elsewhere, but on the J-PARC site. We would like to develop a standalone read-back system, which is available for other accelerators.

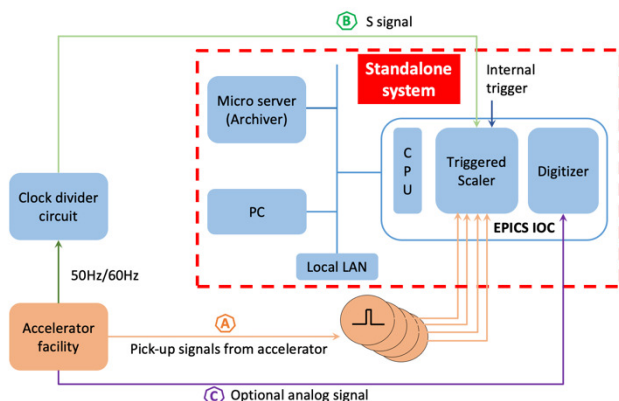

Figure 8: A standalone read-back system for other accelerators.

Fig. 8 shows a planned design of standalone read-back system. The system requires the start signal “S” from the target facility, which is needed to start the TS module. If there is no “S” (or similar) signal, a clock divider circuit would be used to simulate the signal from 50-Hz/60-Hz. The internal trigger of the TS module is to be used. Thus, no external trigger clock is needed. With additional I/O modules like a digitizer, the system can meet to various cases in other accelerator facilities. The unexpected trigger-failure detection of the target timing signal could be customized by updating the EPICS IOC software upon request. A portable micro-server is expected to work as an archiver to analyse faulty events.

If the portable standalone read-back system is successfully developed, it can be exported to other facilities.

## CONCLUSION

A triggered scaler module was developed to read back the signals of the J-PARC timing system. The module is capable of detecting accelerator signals as well as visualizing beam based on the relationship with the accelerator cycle. The first read-back system by the TS setup started operational surveillance for an LLRF signal. Then, a customized read-back system for the 25-Hz trigger is introduced. It is demonstrated as a countermeasure against the trigger-failure event in 2016.

An idea to develop a standalone read-back system has been discussed. We expect the development of the standalone system will contribute to the accelerator timing fields in the future.

## ACKNOWLEDGEMENTS

We express our best thanks to Noboru Yamamoto and other J-PARC accelerator staff members for their encouragement and suggestions during system development.

Dresden, Germany

### Abstract

The ELBE center for high power radiation sources is operating an electron linear accelerator to generate various secondary radiation like neutrons, positrons, intense THz and IR pulses and Bremsstrahlung. The timing system, that is currently in operation, has been modified and extended in the last two decades to enable new experiments. At the moment parts of this timing system are using obsolete components which makes maintenance a very challenging endeavour.

To make the ELBE timing system again a more homogenous system, that will allow for easier adaption to new and more complex trigger patterns, an upgrade based on Micro Research Finland (MRF) hardware platform is currently in progress. This upgrade will enable parallel operation of two electron sources and subsequent kickers to serve multiple end stations at the same time. Selected hardware enables low jitter emission of timing patterns and a long-term delay compensation of the distribution network. We are currently in the final phase of development and with plans for commissioning to be completed in 2022.

### SYSTEM DESCRIPTION

#### Hardware

The new timing system uses hardware from Micro Research Finland [1]. MRF hardware allows a modular approach with highly flexible topology with event master modules (EVMs), which are responsible for timing event generation and distribution, and event receiver modules (EVRs), which are responsible for setting the state of a physical outputs based on the received event.

For the majority of the system hardware used shall be of the MicroTCA form factor wherever possible, but certain user/experiment stations will use PCIe cards, which allow for up to 10 trigger outputs in a smaller package and are more cost effective.

Each of the two ELBE injectors will have an EVM, which will be responsible for generating independent timing pattern, allowing for both independent operation in separate beamlines and also common emission into ELBE accelerator.

Beam diagnostics, low level frequency control (LLRF) and other devices that need coordinated triggering will be connected to the EVRs via MicroTCA backplane trigger lines (if device lives in the same crate as EVR and supports triggering on a backplane signal), front panel output (if TTL level is needed) or through any of the Universal Modules that provide variety of optical and electrical level triggers.

As the number of outputs is limited to 8 per EVR, 4 front panel TTL trigger signals and 4 signals from Universal

Modules, MRF offers to extend the number of trigger signals via rear transition module (RTM), where 10 additional trigger output signals can be configured and routed. Type of the input or output signal from the RTM is determined by the type of the Universal Input/Output (I/O) module selected as shown in Figure 1.

Figure 1: Micro Research Finland timing receiver rear transition module equipped with universal output modules.

All MRF boards (EVMs and EVRs) from the 300 series provide a delay compensation feature, where event propagation delay through whole distribution network is continuously measured and EVRs adjust their internal delay to match a programmed desired target delay. Each of the EVRs can have a different target delay setpoint, but adjusting target delay on an EVR will hold you back for approximately 15 minutes while the measurement and the loop-back mechanism stabilizes.

To synchronize new timing system with the accelerator RF we plan to lock the internal oscillator of the master EVM to an externally provided frequency of 130 MHz through the dedicated input on front panel of the master EVM. This external reference frequency will be locked to both 1.3 GHz RF frequency and 26 MHz thermionic gun master oscillator and it will provide a 130 MHz event clock rate with which timing events will be distributed from the EVMs to the EVRs.

ELBE has multiple beamlines (as shown at Figure 2) but at the moment only one kicker is used to split the beam into two beamlines. For each beamline branch a dedicated bunch pattern has to be generated and sent to appropriate gun. A combined interlock and logic block interleaves the pulse trains and allows the machine interlock system to disable individual gun clock signals. As an upgrade to the machine protection system (MPS), an upgrade is foreseen where it will be able to react on interlock events after the kicker and only disable the corresponding pulse train.

Figure 2: Topology of ELBE beamlines.

A possible ELBE upgrade scenario is to extend capabilities for simultaneous multi-user experiments; new timing system has a requirement to support parallel injection of the two electron sources. Selected timing hardware already has these capabilities. To make use of this feature to its full potential, injector sections of ELBE have to be modified to be susceptible for beams at different energy.

### Software

Software for the new timing hardware is implemented in EPICS [2] control system framework with support of the mrfioc2 [3] and s7plc [4] modules. It allows a creation of required timing event patterns based on a requested operation mode, like continuous wave (CW), macro pulsed or single pulsed beam. These predefined operation modes

simplify the operation of the timing system for the end users, and allow for high level of automated parameter settings which is the core part of development effort.

The timing system can be configured using two graphical user interfaces (GUI). While EPICS GUI is mainly for expert control and debugging, the main control will be done by WinCC SCADA system which includes all ELBE machine controls.

All user entered machine parameters and operation mode dependent derivatives are checked by verification part of the timing software and by a master programmable logic controller (PLC) which is the main interface for MPS.

While in development a simulator written in Python is used to test connection and interaction between the timing system software and master PLC.

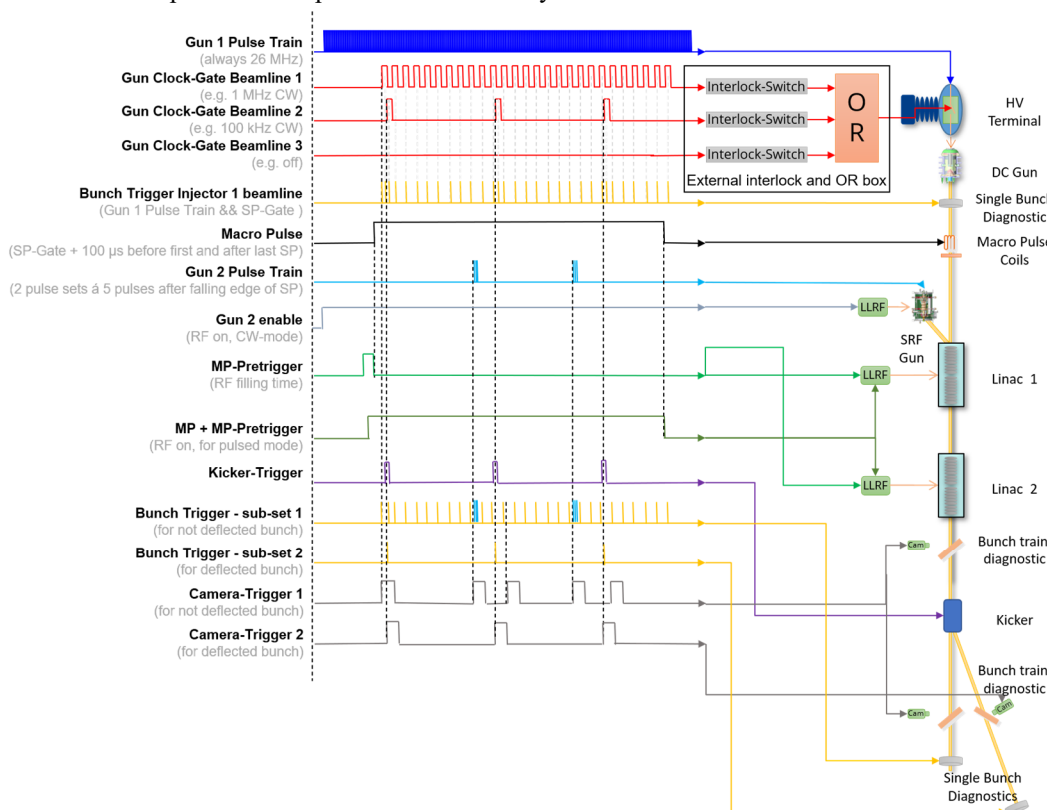

Figure 3: Example of a timing structure at ELBE using two guns and a subsequent kicker to generate bunch pattern.

Figure 4: Output performance of a UNIV-LVPECL-DLY output module.

### Pattern Generation - Example

Figure 3 illustrates an example of a more complex operation mode than could be applied after the timing system upgrade. Here both injectors emit electron pulses into the ELBE accelerator. A kicker is used to split the beam of the first gun into two beamlines. For each beamline section the corresponding gun emission triggers are generated and later the single bunch diagnostic triggers (e.g., for BPMs and ICTs) as well as the bunch train diagnostics (e.g., cameras).

The phase between the emission triggers can be set manually while the system automatically avoids gun emission triggers in the same RF bucket.

### Output Jitter Performance

The output jitter was measured with two different MRF Universal I/O modules, one with UNIV-LVTTL and second with UNIV-LVPECL-DLY module using a Rohde & Schwarz FSWP8.

Measurements with UNIV-TTL module show jitter of 4.5 ps rms in an interval of 1 Hz to 1 MHz, while measurements with UNIV-LVPECL-DLY module show jitter of 7.8 ps rms in an interval of 1 Hz to 1 MHz as shown in Figure 4.

## WORK IN PROGRESS

The system is currently under development on a test bench. It consists of two MicroTCA chassis equipped with two EVMs and four EVRs. In addition, a computer system is set up to test the PCIe event receiver modules. The generated patterns are analysed by three oscilloscopes.

The last of the main operation modes (dark current suppression, combination of macro pulse and single pulse) is being implemented and debugged at the moment. For stand-alone operation a GUI in Control System Studio GUI has been developed over many iterations and will serve as an expert GUI when the system has been commissioned at ELBE.

Main part of developed GUI is shown in Figure 5 and it enables the user to set up the timing system parameters through set of EPICS variables and also check what parameters are configured through WinCC GUI and under which what parameters timing hardware is currently operating. It also enables configuration of individual outputs on EVRs with selection of the predefined logic pulse patterns or with a pattern based on individual event, delay and width.

Status of the individual timing system hardware components is monitored and also displayed in dedicated GUI.

In addition to the implementation of operation modes the hardware is being tested and the long-term stability monitored.

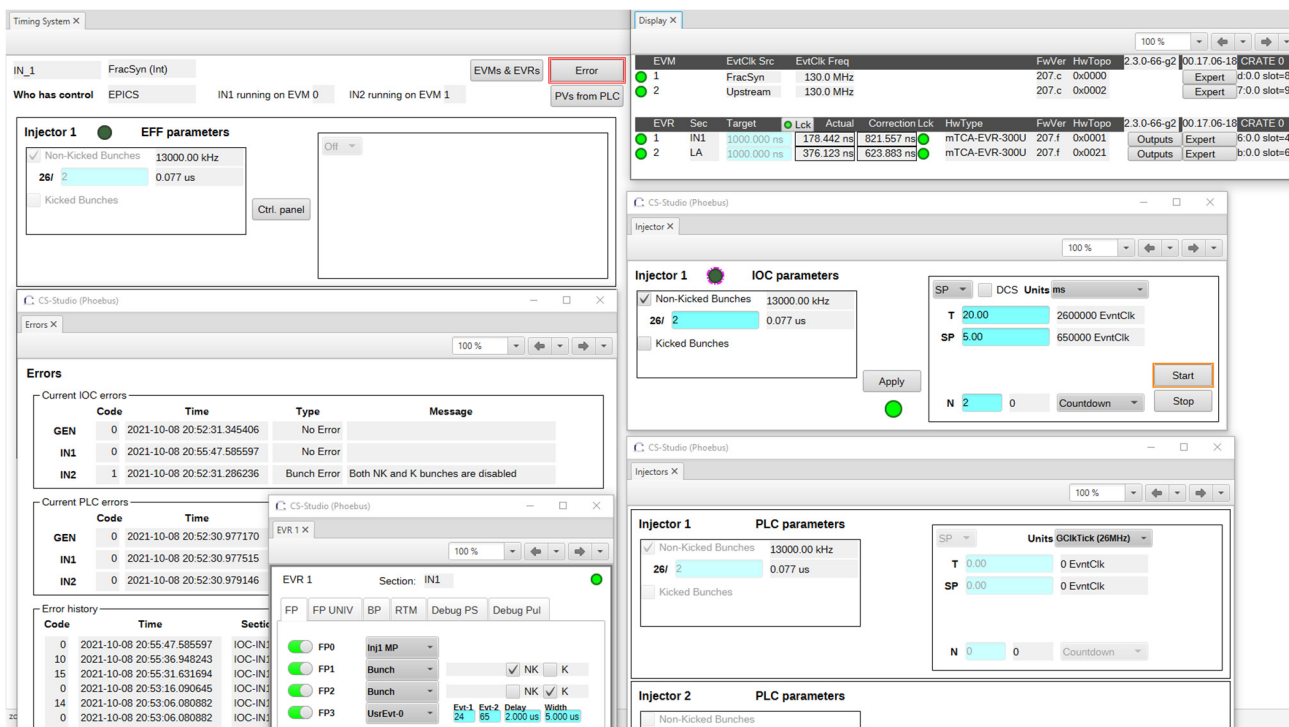

Figure 5: Timing system expert GUI.

## CONCLUSION

A new flexible timing system is being developed for the ELBE accelerator. The system allows flexible bunch pattern generation for two injectors operated in parallel.

The system is currently set up on a test bench which is used for performance tests and debugging. First tests with the ELBE accelerator are planned for beginning of next year which will then follow by a stepwise transition from the legacy timing system to the new timing generation and distribution.

# THE DEMONSTRATOR OF THE HL-LHC ATLAS TILE CALORIMETER

Pavle Tsotskolauri<sup>†</sup>, on behalf of the ATLAS Tile Calorimeter System\*  
Tbilisi State University, Tbilisi, Georgia

## Abstract

The High Luminosity Large Hadron Collider (HL-LHC) has motivated R&D to upgrade the ATLAS Tile Calorimeter. The new system consists on an optimized analogue design engineered with selected radiation-tolerant COTS and redundancy layers to avoid single points of failure. The design will provide better timing, improved energy resolution, lower noise and less sensitivity to out-of-time pileup. Multiple types of FPGAs, CERN custom rad-hard ASICs (GBTx), and multi-Gbps optical links are used to distribute LHC timing, read out fully digital data of the whole TileCal, transmit timing and calibrated energy per cell to the Trigger system at 40 MHz, and provide triggered data at 1 MHz. To test the upgraded electronics in real ATLAS conditions, a hybrid demonstrator prototype module containing the new calorimeter module electronics, but still compatible with TileCal legacy system was tested in ATLAS during 2019-2021. An upgraded version of the demonstrator with finalized HL-LHC electronics is being assembled to be tested in testbeam campaigns at the Super Proton Synchrotron (SPS) at CERN. We present current status and results for the different tests done with the upgraded demonstrator system.

## Introduction

The upgrade of the Large Hadronic Collider (LHC) to the High-Luminosity Large Hadronic Collider (HL-LHC) is aimed to deliver up to ten times peak luminosity [1]. HL-LHC is designed to deliver collisions at the luminosity of  $7.5 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$  and up to 200 simultaneous proton-proton interactions per bunch crossing. This environment necessitated a Phase-II upgrade of the ATLAS detector [2]. The Tile Calorimeter (TileCal) is the central section of the hadronic calorimeter of ATLAS. It plays an important role in the measurements of jet and missing transverse momentum, jet substructure, electron isolation, energy reconstruction and triggering, including muon information. To meet the requirements of HL-LHC, upgraded electronics were tested by using The Hybrid Demonstrator in real conditions. The Hybrid Demonstrator combining fully functional upgraded Phase-II electronics with analog trigger signals to be compatible with present and legacy ATLAS interface. Demonstrator comprises four prototype mini-drawers, each equipped with 12 Photo-Multiplier Tubes (PMT) with 3-in-1 cards, Mainboard, Daughterboard and high voltage regulation board. Finger Low Voltage Power supply (fLVPS) is powering all four mini-drawers with 10V. The Hybrid Demonstrator is connected to an off-detector Pre-Processor module with a patch panel. PreProcessor

modules provide data and control interfaces between on-detector electronics and both legacy and Phase-II Trigger and Data Acquisitions interface (TDAQi) [3].

## Photo-Multiplier Tubes

At every bunch crossing light produced by scintillator plates is transmitted by wavelength shifting fibres. PMTs are responsible for converting this light coming from TileCal cells into analog signal and transfer it to the next stage of a signal chain. Every PMT is equipped with a High Voltage Active Divider (HVAD). The function of HVAD is to divide high voltage coming from high voltage system to 8 PMT dynodes. The high voltage for PMTs is in the range of 600-900 Volts. HVAD is also responsible for linear PMT response. PMT Block consists of PMT, HVAD and 3-in-1 card. For individual PMTs and PMT Blocks, there are two different test benches to ensure their performance and correct functionality. Before PMT Blocks are assembled each PMT is tested to ensure their physical properties. After this PMT Blocks are tested with Portable Readout Module for Tile Electronics (PROMETEO) system which ensures the correct functionality of PMT blocks alongside other demonstrator modules [3].

## 3-in-1 Card

The 3-in-1 card is part of the PMT Blocks, see Figure 1. They are responsible for shaping, amplification and integration of signal coming from PMT. 3-in-1 cards feature a 16-bit dynamic range, 50ns full width at half maximum (FWHM) time constant, fast readout with two gains (low gain and high gain), integrated slow readout, charge injection for continuous calibration over full dynamic range. Low-gain signals are summed into trigger towers (adder cards) and sent to off-detector electronics. It also consists of an analog trigger to be compatible with the current ATLAS architecture. Data from 3-in-1 cards are read by FPGAs from The Mainboard.

Figure 1: 3-in-1 Card [3].

## Mainboard

The Demonstrator consists of four mainboards. The picture of The Mainboard is shown in Figure 2. Currently, Mainboard went through four revisions. The Mainboard is responsible for data transfer between PMT Blocks and Daughterboard. Each of them is connected to 12 PMT Blocks using Field Programmable Gate Arrays (FPGA).

<sup>†</sup> pavle.tsotskolauri@cern.ch

\* Copyright [2021] CERN for the benefit of the ATLAS Collaboration. Reproduction of this article or parts of it is allowed as specified in the CC-BY-4.0 license

Each FPGA reads out 3 PMT Blocks. For The PMT Block readout, The Mainboard uses 12-bit ADC at 40 Msps and 16-bit ADC for slow integration. The Mainboard is designed to be reliable and redundant, therefore it is divided into two sections called A- and B- Side. Each section is completely independent with each side having +10V LVPS supply bricks. In order to prevent failure caused by LVPS or total failure each side is connected with a “Diode-Or” connection to make the power supply more redundant. Other functions of The Mainboard are to provide timing signals for low- and high-gain Charge Injection (CIS) calibrations. Mainboard V4 is the final revision that will be used in HL-LHC.

Figure 2: Mainboard [3].

### Daughterboard

The Daughterboard is an on-detector communication board that interfaces between front-end electronics and back-end Tile Pre-Processor (TilePPr) module. The Daughterboard is shown in Figure 3. This is 4th version of The Daughterboard. It sends PMT data and Detector Control System (DCS) and detector readout data to TilePPr over multi-gigabit links. Like The Mainboard, The Daughterboard is also divided into two sections for reliability and redundancy. Redundant optical fibres are also used for protection against single link failure. CERN-developed GBTx protocol chip is used for FPGA configuration, LHC clock distribution and to receive DCS and run commands from off detector PreProcessor module. The Daughterboard version 6 is available and is being tested at CERN test beam facilities. Replacement with the latest version on The Demonstrator is under consideration.

Figure 3: Daughterboard [3].

### PreProcessor

The PreProcessor (PPr) is a core module of off-detector electronics. PMT Digital samples are transferred to The PPr every bunch crossing. A picture of the PPr is shown in Figure 4. The PPr has bi-directional communication with front-end electronics. It provides DCS commands, Timing, Trigger and Control information and the LHC Clock to the front-end electronics. From front-end electronics, The PPr receives PMT data which is stored in pipeline buffers waiting for trigger decision. In parallel, The PPr provides reconstructed energy information to the trigger system at 40MHz. After the trigger decision, The PPr sends buffered data to legacy Read-Out Driver (ROD) and processes in the same way as for current modules (backward compatibility).

Figure 4: Tile PreProcessor [3].

### Trigger and Data Acquisition interface

Trigger and Data Acquisition interface (TDAQi) communicates with off-detector electronics. It is responsible for constructing the trigger primitives and interfaces with trigger systems. The Trigger FPGA calculates trigger objects such as jets, muons, electrons with different granularity and energy resolution and results are transmitted through low latency optical links to the first level of the trigger. TDAQi is designed for HL-LHC and currently is not used for Demonstrator.

### Low Voltage Power Supply

The Tile Calorimeter Low Voltage Power Supply (LVPS) provides power to all front-end electronics and provides control and feedback to the monitoring system and can be seen in Figure 5. Previous LVPS modules were generating eight different voltages for various sub-circuits of front-end electronics. In Phase-II upgrade each super-drawer is powered by one LVPS module which now provides 10V supply to all the front-end. As the result, TileCal has 256 LVPS boxes. Each LVPS box consists of eight bricks which converts 200V input voltage to 10V output. For redundancy eight bricks are grouped into four sets of two. Diode-Or design is also implemented for improved reliability.

Figure 5: Low Voltage Power Supply [3].

### High Voltage Power Supply

High Voltage Power Supply (HVPS) must supply high voltage to all PMTs in the system. it also needs to monitor, control and report values to DCS System, as shown in Figure 6. There is a total of 256 high voltage regulation boards each equipped with an ethernet interface.

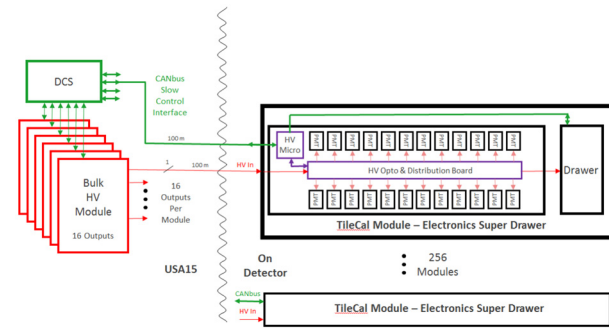

Figure 6: High Voltage Power Supply System [3].

## Test Beam Results

The TileCal modules equipped with The Hybrid Demonstrator, with Phase-II upgrade electronics together with modules equipped with the old electronics, were exposed to different particles and energies in 7 test beam campaigns at CERN SPS North Area, during 2015-2018 [3].

The uniformity of the test module, which is segmented into three longitudinal layers (A - Figure 7 BC - Figure 8 and D - Figure 9), was evaluated using muon beams.

Figure 7: Longitudinal layer A [4].

Figure 8: Longitudinal layer BC [4].

Figure 9: Longitudinal layer D [4].

Figure 10 shows the distribution of the total energy deposited in the calorimeter obtained using experimental and simulated electron data.

Figure 10: Total energy deposited in the calorimeter obtained using electron beams was also studied [4].

Detector energy response and resolution were studied using the hadron beams with different energies. The results obtained using muons, electrons and hadrons are in agreement with the calibration settings, as shown in Figure 11.

Figure 11: Energy response ratios, measured experimentally (red circles) and predicted by simulation (black squares) as a function of beam energy obtained using pions [4].

Figure 12 shows the stability of the laser over time with low and high gains.

Figure 12: Stability of Laser over time.

Figure 13 and Figure 14 show a comparison of noise between The Demonstrator and Legacy Module.

Figure 13: The Demonstrator low gain RMS noise.

Figure 14: Legacy Module low gain RMS noise.

The above test beam results indicate that The Demonstrator Module performs at least as good as Legacy Module.

## SUMMARY

The Tile Demonstrator Module is a prototype for an upgraded readout system and is compatible with current and legacy systems. The Tile Demonstrator is fully integrated into upgraded in the ATLAS Trigger and Data Acquisition and Detector Control systems. It was extensively tested during 2015, 2016 and 2017 test beams and demonstrated good performance. New tests will take place in November 2021 in order to validate new on-detector electronics in the radiation environment and associated off-detector electronics. The Tile Demonstrator module will also be present in Tile Calorimeter during the Run-3 period.

# REUSABLE REAL-TIME SOFTWARE COMPONENTS FOR THE SPS LOW LEVEL RF CONTROL SYSTEM

M. Suminski\*, K. Adrianek, B. Bielawski, A. C. Butterworth, J. Egli, G. Hagmann, P. Kuzmanovic, S. Novel Gonzalez, A. Rey, A. Spierer, CERN, Geneva, Switzerland

## Abstract

In 2021 the Super Proton Synchrotron has been recommissioned after a complete renovation of its low level RF system (LLRF). The new system has largely moved to digital signal processing, implemented as a set of functional blocks (IP cores) in Field Programmable Gate Arrays (FPGAs) with associated software to control them. Some of these IP cores provide generic functionalities such as timing, function generation and signal acquisition, and are reused in several components, with a potential application in other accelerators.

To take full advantage of the modular approach, IP core flexibility must be complemented by the software stack. In this paper we present steps we have taken to reach this goal from the software point of view, and describe the custom tools and procedures used to implement the various software layers.

## INTRODUCTION

The new LLRF system for the SPS has largely replaced old VME-based hardware with a modern installation designed around microTCA crates using PCI-express as the bus.

The update has brought many benefits, one of them being higher hardware density: what used to take a VME crate filled with modules, now is replaced with one or two microTCA cards. It has also affected the control system, as component size has shrunk from a card to an IP core.

Previously, each component was implemented as a VME module, with its own driver, user-space library and application. With the new hardware, the said approach was no longer applicable, therefore a new solution had to be defined.

## WORKFLOW

This section will illustrate typical steps needed to develop reusable firmware and software. Overview of the layers constituting a component is presented in Fig. 1.

### Memory Map

The process begins with hardware interface definition, starting with individual IP cores and ending with the top level map containing all components used in a card. The interface is called memory map since it defines mapping registers and memories to offsets in a card memory space. Memory map serves as the primary data source for both firmware and software developers.

Each register is described by a number of attributes, such as name, access mode (read-write/read-only), bit width,

valid value range or conversion functions between raw register value and physical units.

Figure 1: Example of a card implementation with several components. The white block (C library) is common to all cards and components. The grey blocks (Linux driver & address decoder) are card specific. The remaining colors show parts of reusable component stacks, each color representing a different component.

Registers may have subcomponents called fields, providing a way to give different meaning to a set of bits belonging to a particular register. This method is frequently used for status and control registers, where each bit represents a different part of the logic.

Each memory map may also include other memory maps, allowing the designer to reuse existing ones and establish a tree-like structure. The latter method is commonly applied for composing IP cores to define a card interface, also known as the top level map.

Memory maps are edited using a dedicated tool named Reksio (former Cheburashka [1]). The tool offers a graphical user interface aiding the users in memory map creation and validation. It also provides straightforward access to external tools, such as generators for various layers of the component stack.

\* maciej.suminski@cern.ch

Once a memory map is finished, it serves as the source to generate several layers of the component stack:

- FPGA firmware template
- Linux driver
- C++ library

Generated components will be discussed in detail in the following sections.

### *FPGA Firmware Template*

The firmware designer begins with executing the Cheby [2] tool to generate skeleton code in VHDL, creating the foundation for firmware development. The obtained code supplies a bus interface used for data transfers and a set of signals directly representing registers. The latter part is used by the firmware designer to implement the actual component logic.

This step may be executed at the component level, resulting in self-contained, component-specific code or at the top level in order to generate an address decoder for a card.

### *Linux Driver*

Another part of the toolset is the Encore Driver Generator (EDGE) [4], which translates a memory map file to Linux driver source code.

While in certain cases it would be possible to bypass the driver by directly accessing memory-mapped device registers, having a driver brings certain benefits. In a microTCA module, the driver is needed to enable Direct Memory Access (DMA) transfers or handle hardware interrupts.

Apart from driver generation, EDGE also provides a user-space shared C library to communicate with the hardware. The library interface allows the software developer to access any register by its name, using a driver specific memory map file. Thanks to that, the library is common to all components and is not included in the component stack.

It is worth mentioning that EDGE supports both PCI/PCI-express and VME, which is especially convenient when a component needs to be migrated to a different platform.

Please note that the Linux driver is card specific and does not belong to any particular component.

### *C++ Library*

The next layer of the software stack is a C++ library, also generated from a memory map. It uses the EDGE library for accessing the hardware, and as such requires a driver generated with the aforementioned tool. While the C++ library is not strictly required for the application development, it facilitates the software development process.

First of all, generated C++ libraries provide a user-friendly interface, where the tree-like hierarchy of a memory map is reflected in a set of classes, each representing a submap, register or field. Such an approach allows the developer to easily traverse the structure by accessing appropriate fields in the generated classes.

Moreover, the generated library takes advantage of certain properties defined in the memory map:

- Data type (bit width and signedness): ensures correct register value interpretation.
- Valid value range: prevents setting registers to values which are not considered correct.
- Functions to convert between raw register values and physical units: enables writing application code using values expressed in physical units without any additional effort.

### *Real-Time Application*

The last layer of the software stack is the real-time application. At CERN, such applications are developed using the Front-end Software Architecture (FESA [5]) framework with C++ as the programming language.

Most applications built using FESA consist of two parts:

- Server: used for communication with the user or higher level applications. It provides a way to specify new settings or read data acquired from the hardware.
- Real-time: controls the hardware synchronously to the timing system. This part most often configures the card for a particular accelerator cycle and reads back data from the hardware.

Application code might also be generated, but the interface would correspond directly to the memory map. In most cases, applications are expected to implement a user-friendly interface and not one that gives a direct access to the hardware. Usually this layer takes most time to implement.

## **VERSION VALIDATION**

It is usual for components to evolve as new requirements arise. If a change is made to hardware, then it needs to be propagated through each layer upwards in order to avoid unexpected behaviour, which is often difficult to analyze.

For this reason it is essential to verify if all layers of a component are compatible with each other. The simplest way to achieve that is by assigning each layer a version number. In the new SPS LLRF system, the numbers are assigned in accordance with semantic versioning [5] scheme, which defines clear rules regarding which versions are compatible with each other.

For hardware, it has been decided that the first registers in each memory map constitute a standard header providing firmware and memory map version numbers. This is true for both top level and component memory maps.

The Linux driver version is expected to match the firmware version of the card. EDGE offers a way to specify an automatic version check by specifying a register and its expected value range. If the register value is outside of the range, the driver will refuse to load. This step assures memory map compatibility between software and hardware domains.

The user-space EDGE library (libedge) executes another test. When a device is opened, the library reads its driver version and loads the corresponding memory map file, which will be used for obtaining register offsets. At this stage the library also computes the memory map file checksum and

compares it with the one stored in the driver. Further access to the card is possible only when the two numbers match.

Finally, each user-space application is also expected to validate the hardware version. Normally this is done by comparing the component firmware version against the version supported by the application.

## EXAMPLES

During the SPS LLRF upgrade, several common components have been developed to be applied in Cavity Controllers and Beam Control microTCA cards:

- Timing generator core: programmable timer generating pulses with requested delays.
- Acquisition core: generic component for sampling data inside the FPGA and transferring it to a memory.
- Resampler core: converts acquired data between fixed sampling rate and beam synchronous rate.
- Function generator core: delivers time series data according to a programmed pattern.
- Numerically controlled oscillator core: generates samples corresponding to a sine wave at the requested frequency, with certain customizations for application in accelerators.
- Gigabit link core: controller for a gigabit serial link used for data transfer.

Each of the above components has an implementation in all the presented layers apart from the Linux driver, which is card specific. If one of them needs to be instantiated in another system, the whole stack can be reused.

## CONCLUSION

The described workflow has been successfully applied during the SPS LLRF renovation. The process has delivered several self-contained components, covering all layers from hardware to software application. The components have been reused in two cards without any modification and are potentially applicable in other systems, including non-microTCA ones.

The new approach has improved task coordination in the development process, since several components could be developed independently and tested with any available hardware.

# LASER DRIVER STATE ESTIMATION ORIENTED DATA GOVERNANCE

J. Luo<sup>†</sup>, L. Li, Z. G. Ni, X.W. Zhou, Institute of Computer Application, China Academy of  
Engineering Physics, Mianyang City, China

## Abstract

Laser driver state estimation is an important task during the operation process for the high-power laser facility, by utilizing measured data to analyze experiment results and laser driver performances. It involves complicated data processing jobs, including data extraction, data cleaning, data fusion, data visualization and so on. Data governance aims to improve the efficiency and quality of data analysis for laser driver state estimation, which focuses on 4 aspects — data specification, data cleaning, data exchange, and data integration. The achievements of data governance contribute to not only laser driver state estimation, but also other experimental data analysis applications.

## INTRODUCTION

Laser driver state evaluation is an important part of the business process of a laser shooting experiment, which mainly includes physical experiment results evaluation and driver performances evaluation. The energy, pulse power waveform and near-field results of the experimental process are extracted by using the measurement data obtained by acquisition equipments such as energy card meters, oscilloscopes and CCDs in the diagnostic system, and the energy dispersion, power imbalance and other results of a shooting experiment, as well as the gain capacity, output capacity and output stability of the driver are calculated, to evaluate the effectiveness of physical experiments and the performance status of the laser driver.

By adopting the Oracle relational database platform, all the experimental measurement data of the facility are stored [1, 2]. The early database design defined the physical structure and logical structure specification of experimental data storage, but there were no constraints on the storage format of experimental data, so there existed inconsistencies in the storage format of the same type of experimental data. Secondly, there are invalid measurements or missing measurements in the process of experimental data measurement, but such measurement data are not screened when the experimental data are stored in the database, resulting in experimental data quality problems such as missing or abnormal data items. In addition, with the laser facility putting into experimental operations, a large number of experimental measurement data are accumulated, and multiple application systems involving experimental data processing and storage are generated. For these late emerging application systems, most of them do not follow the early database design specifications in terms of data storage. Therefore, the experimental data

relationship of the whole facility is complex.

The operational process of a shooting experiment is described in Figure 1. As an important asset of the facility, the increasingly accumulated experimental data has played an important role in the operation control optimization of the facility in recent years, and the state evaluation of laser driver is one of the main contents. However, limited by the above problems such as inconsistent experimental data storage format, missing experimental data items, abnormal experimental data and complex experimental data relationship, data preprocessing consumes a lot of time, and application systems involving experimental data processing and analysis reveal common problems, such as slow development progress, repeated processing of experimental data, low computational efficiency, and uncertain analysis results, which coincides with the current situation of data preparation mentioned in literature [3].

Data governance aims to improve the efficiency and quality of data analysis and plays an important role in the whole big data analysis process [4]. In recent years, with the rapid development of big data analysis and application research, data governance has played a very significant role in enterprise big data mining, government public data sharing, industrial big data analysis, scientific research data management and other industries [5-12]. The state estimation of a laser driver involves a lot of jobs, like experimental data extraction, transformation, joint calculation and visualization. Considering the current situation of the experimental data quality and the problems faced by the data processing application system, we utilize a framework consisting with data governance and data visualization to implement the laser driver state estimation system. This paper mainly introduces and summarizes our work about the data governance part.

The next section provides an overview of laser driver state estimation. Section III illustrates the data governance. The computation of state parameters of laser driver is discussed in section IV. Finally, we conclude this paper in section V.

## LASER DRIVER STATE EVALUATION

The main purpose of state estimation of laser driver is to evaluate the compliance of physical experiment and the performance of the laser driver. The energy, pulse power waveform and near-field results of the experimental process are extracted from the original measurements. And the key technical parameters such as power imbalance, output beam quality, output stability, gain capability and third harmonic efficiency of the laser driver are calculated. Furthermore, their evolution law is visually analyzed.

<sup>†</sup> luoj1987@caep.cn

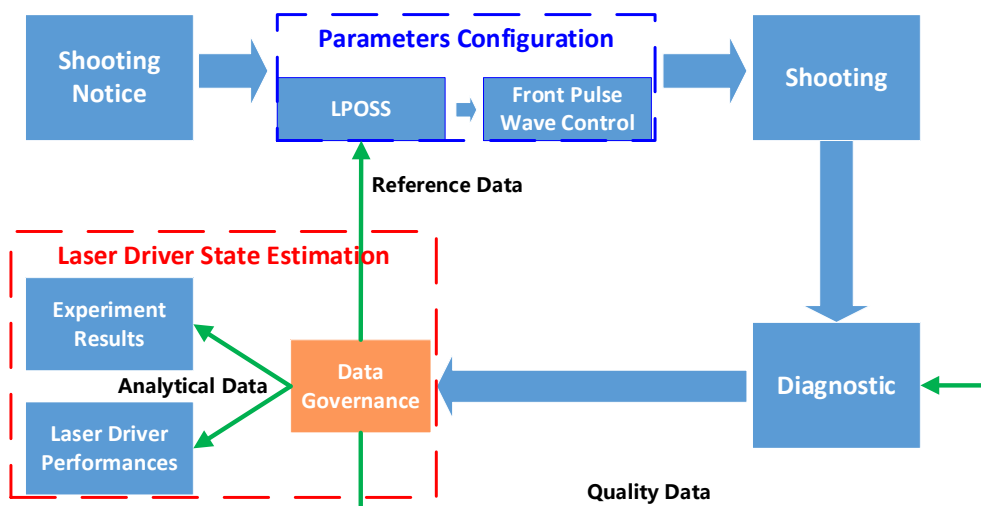

Figure 1: Business process of a shooting experiment.

## Evaluation Contents

The state evaluation of the laser driver mainly includes two aspects: the evaluation of physical experiment results and the evaluation of laser driver performance.

- State of physical experiment results: including output energy and pulse power waveform of each laser beam, total output energy, energy dispersion of each beam set, total average power and power imbalance. Among them, energy dispersion and power imbalance are two important criterion to judge whether the physical experiment meets the target or not, and they are also key factors to indicate the energy and power balance of the laser driver.
- State of laser driver performance: including driver gain capability, output capability and output stability. Among them, the gain capability includes the main amplification gain and pre amplification gain, the output capability mainly refers to the peak power of each laser beam, and the output stability includes the frequency conversion efficiency and the energy deviation of each laser beam.

## Functional Architecture

The laser driver state estimation system mainly consists with two functional parts, namely data governance and data visualization, as shown in Figure 2.

Data visualization is mainly responsible for the interface display of driver state parameters, while data governance realizes the whole process of data extraction, cleaning, calculation, transformation and storage integration, as well as the functions of analysis and processing algorithm management and anomaly detection.

## Technical Architecture

The laser driver state estimation system is composed of a hierarchical architecture, including data application layer, data management layer, data computation layer and data sources layer. The technical architecture is shown in Figure 3. Data governance mainly covers the data computing layer and the data management layer.

- Data sources: in the process of experimental operation, the original experimental data is generated and stored in Oracle database. The data forms are diversified, including numerical value, text, picture and other data.
- Data computation: extracting the original measurement data from the data source system, then cleaning the source data, detecting the abnormality and mark the quality of the measured data. Finally, combined with the statistical analysis algorithm, the state evaluation result data of the laser driver are obtained.
- Data management: according to certain physical structure, logical structure and data format specifications, the analyzed state parameters are stored in the data warehouse for centralized management. In the data management layer, data is stored in Oracle relational database.

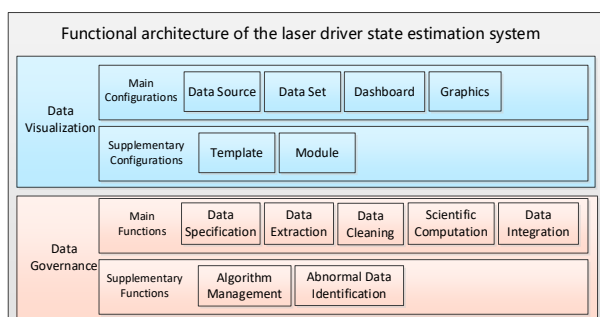

Figure 2: Functional architecture of the laser driver state estimation system.

- d. Data application: providing the data in the data warehouse system to the end user in the form of chart through the web interface. According to the analysis needs of users, report, query, multi-dimensional analysis and other functions are used to display data.

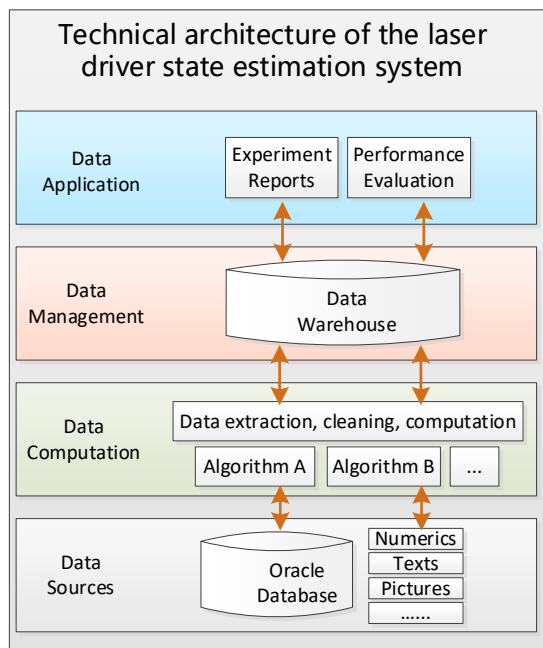

Figure 3: Technical architecture of the laser driver state estimation system.

## DATA GOVERNANCE FOR LASER DRIVER STATE EVALUATION

The data governance is the process of reviewing and transforming data in order to make data better serving data analysis. It is the most energy consuming part in the whole data analysis process [3]. Although the original motivation of conducting the data governance is to conveniently serve the laser driver state evaluation system, once the data governance is carried out, it becomes a task of dynamically constructing data processing process for various business systems. Data governance pre-processes data for specific problems, adopts different data processing algorithms for different problems, and some data governance achievements can be shared among multiple applications. The final result of data governance for laser driver state estimation can serve all relevant data users in the whole facility, as shown in Figure 1.

Data governance mainly includes four aspects: data specification, data cleaning, data exchange and data integration. The work in these four aspects is described in detail below.

### Data Specification

Aiming at the problem that the data formats of the same type of data are inconsistent, the data formats of pulse

power waveform data and CCD image data are designed uniformly.

Pulse power waveform data is represented by [time column, power column] two-dimensional double array. The background measurement results outside the effective time window in the original measurement waveform are no longer retained, and only the part within the effective time window in the original measurement waveform is selected, as depicted in Figure 4.

Figure 4: Example of pulse waveform data (red rectangle indicates the effective time window).

CCD image data is represented according to integer pixel matrix. Each element in the matrix represents the pixel gray-scale value at the corresponding position of the image. In order to facilitate subsequent data analysis, CCD image data is divided into two types, original measured and intended clipped. The matrix dimensions of these two types are different. The original measurement is fixed at 1024 \* 1024 scale, and the pixel matrix dimension of the clipped image depends on the effective illumination range during actual imaging, as shown in Figure 5.

Figure 5: Example of CCD image data (red rectangle indicates effective illumination range).

### Data Cleaning

Data cleaning is a necessary step for most data-driven tasks. Data cleaning refers to detecting and correcting possible errors from data to ensure the quality of data and

comply with domain related integrity constraints. The data cleaning mainly refers to the integrity and anomaly detection of the original measurement data. Integrity detection is to judge whether the laser beam participating in the experiment has energy, waveform and near-field measurement results at all positions based on the experimental configuration parameters. Anomaly detection is to judge whether there is a serious mismatch between the measurement results and the actual output, which will significantly affect the state evaluation results.

### Data Exchange

A data governance service named "report and performance calculation process" is established to exchange data through the database read-write interface.

The service reads the experimental measurement data from the original database of the data source layer through the database interface, realizes the functions of data extraction, data cleaning, analysis and calculation in combination with the algorithm, and stores the analytical results in the data warehouse of the data management layer, for the visualization function module to directly read the data and display the charts.

The "report and performance calculation process" service is integrated into the main operation workflow. It is called by the centralized control system. After each shooting experiment, the experimental data governance of the shot is started to calculate the state parameters of the laser driver.

### Data Integration

Data integration is the physical or logical integration of heterogeneous, distributed and autonomous data to provide users with a unified access interface, so that they can access data sources transparently, so as to realize comprehensive data sharing [3,4]. There are two common schemes for data integration, one is pattern integration method, and the other is data replication method, such as data warehouse. This paper utilizes the data replication method, based on the logical model of experimental number, laser beam number, experimental configuration parameters, experimental measurement results and state evaluation results, constructs the data warehouse of driver state evaluation. The visualization function module directly reads data from the data warehouse and displays a variety of charts.

## CALCULATION OF LASER DRIVER STATE PARAMETERS

The contents of laser driver state estimation are described in Section 2.1, mainly including physical experiment results and laser driver performances. In order to calculate these data, we need to focus on two important issues: the data flow and the calculation algorithm.

### Data Flow

The relationship between experimental configuration parameters, original measurement data and state parameters data is shown in Figure 6.

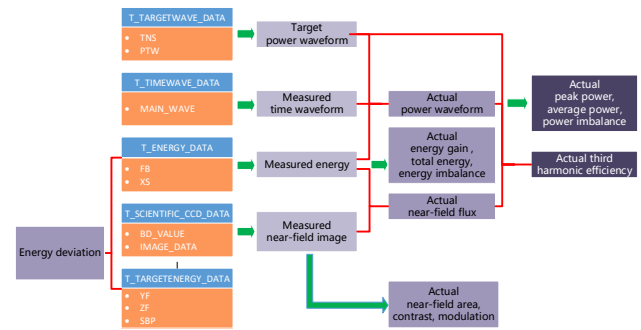

Figure 6: Data flow of calculating state parameters.

### Algorithm Integration

The data governance service for the laser driver state estimation follows the software architecture and integration specification of the centralized control system, and is coded in C++. Data governance service involves various data processing algorithms in data extraction, data cleaning, analysis and calculation. By weighing the difficulty of algorithm implementation and the time efficiency of calculation, the matlab is mostly used. These algorithms are encapsulated into dynamic link library files for data governance services to call. According to the data relationship as shown in Figure 6, the data input and output interfaces of each algorithm are almost fixed. In case of algorithm upgrade, we only need to replace the corresponding algorithm dynamic link library file and rebuild the data governance service.

## CONCLUSION

This paper summarizes the data governance work for the application of laser driver state estimation from four aspects: data specification, data cleaning, data exchange and data integration. The final result can serve all relevant data users in the whole laser facility.

Data governance involves various data processing algorithms. As a supplement to traditional algorithms, artificial intelligence algorithms increasingly show a big potential. Our future research will be carried out in the development and integration of intelligent algorithms to gradually optimize the effect of data governance.

# THE IMPLEMENTATION OF THE BEAM PROFILE APPLICATION FOR KOMAC BEAM EMITTANCE\*

Jae-Ha Kim<sup>†</sup>, Young-Gi Song, SungYun Cho, Seunghyun Lee, Sang-Pil Yun  
Korea Multi-purpose Accelerator Complex, Korea Atomic Energy Research Institute, Gyeongju, Korea

## Abstract

Korea Multi-purpose Accelerator Complex (KOMAC) has been operating a 100 MeV proton linear accelerator that accelerates a beam using ion source, a radio frequency quadrupole (RFQ), 11 drift tube linac (DTL). And the accelerated protons are transported to target rooms that meets the conditions required by the users. It is important to figure out the beam profile of the proton linac to provide the proper beam condition to users. We installed 8 wire scanners to measure beam emittance of KOMAC at beam lines. And beam profile application to measure beam emittance has been implemented using EPICS and python. This paper will describe the implementation of the beam profile application for KOMAC beam emittance.

## INTRODUCTION

KOMAC has been operating five beamlines and five target rooms for clients. A proton beam that clients require is transported to a target room through a beamline. So it is important to identify the characteristics for the proton linac and a proton beam to provide and appropriate beam. Therefore KOMAC installed Beam profile measurement devices that are Beam Position Monitor, Beam Loss Monitor, Beam Phase Monitor to measure beam characteristics and eight wire scanners at beamlines that are TR23, TR103, TR104, TR105 and straight beamline to figure out the beam profile of the proton beam. Following Fig. 1 shows layout of KOMAC linac and beamlines.

Figure 1: the layout of KOMAC linac and beamlines.

KOMAC control system based on Experimental Physics and Industrial Control System (EPICS) framework has been implemented to control the 100 MeV linac and peripheral devices at the control room [1]. Figure 2 shows the block diagram of KOMAC control system.

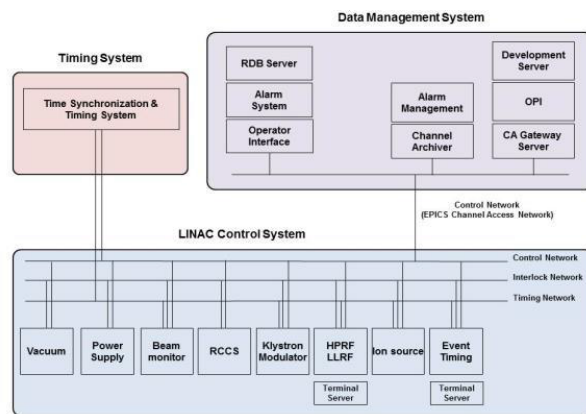

Figure 2: Block diagram of KOMAC control system.

We adopted Control System Studio (CSS) for user interface and Archiver Appliance for data saving system [2], [3]. And we have been developed high level applications that can communicate with the control system to study the beam profile of the linac. To integrate the wire scanner into KOMAC control system, the wire scanner control system was implemented using EPICS to control wire scanner and pyEPICS for data process [4].

## WIRE SCANNER

The wire scanner has been developed to measure beam emittance of the KOMAC linac. The specification of the wire scanner is shown in Table 1.

Table 1: The Specification of The Wire Scanner

Specification	
Wire material	W tungsten
Wire diameter	0.1 mm
Moving speed & Range	100 mm/s, 50 mm (± 25 mm)
Spatial accuracy	0.05 mm
Spatial resolution	0.1 mm
Mounting Flange	6" CF

The wire scanner control system is divided into two part: driving wire scanner; data analysis. The layout of the existing wire scanner control system is shown in Fig. 3.

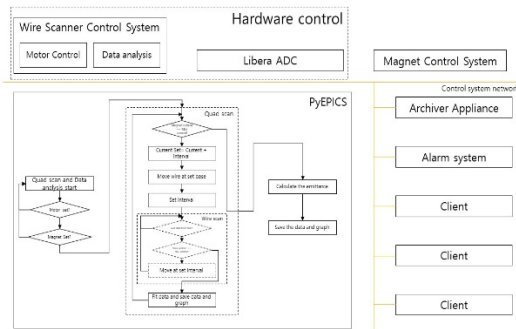

Figure 3: The existing wire scanner control system.

The part of driving wire scanner controls a position of the wires using the motor and gets the current data from the wires using libera ADC. The data process part analyses the obtained data from wire scanner.

### Wire Scanner Control System

EPICS IOC controls a motor to move a position of a wire in wire scanner by communicating with a motor controller. A Libera digit electronic captures data whenever a beam passes the wires and delivers the data to EPICS IOC. For the convenience of managing the wire scanners, a wire scanner control unit that is made up of two motor controllers and a libera digit electronic, is created and installed as shown Fig. 4 and Fig. 5.

Figure 4: The wire scanner control units.

Figure 5: The wire scanner control units installed at KOMAC linac.

### Quad Scan Interface with pyEPICS

pyEPICS that can access the EPICS IOC using Channel Access protocol was adopted for the quad scan interface. the quad scan interface using pyEPICS based on Python programming language takes data from EPICS IOC in synchronization with the beam repetition rate. The algorithm diagram of quad scan and data analysis is shown in Fig. 6.

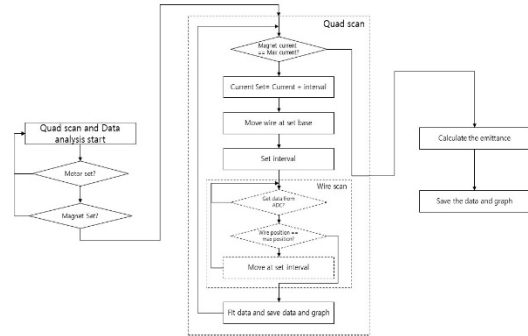

Figure 6: The algorithm diagram of the quad scan interface.

After quad scanning, the quad scan interface delivers the processed data to the EPICS IOC, and all the data are archived by the Archiver appliance that is chosen for the KOMAC data archiving system. In addition, the processed data are saved in file and picture format. However, quad scan interface must be running in the background as a daemon. And when a modification occurs, we need to modify both EPICS IOC and python code

### Quad Scan Interface with sscan and asub Record

To simplify the process of the quad scan and wire scan, All the process has been integrated into the EPICS IOC. So for implementation of the quad scan interface, sscan EPICS modules and asub record were adopted [5], [6]. The sscan module performs the quad scan algorithm previously implemented by pyEPICS. The EPICS database for quad scan is shown in Fig. 7.

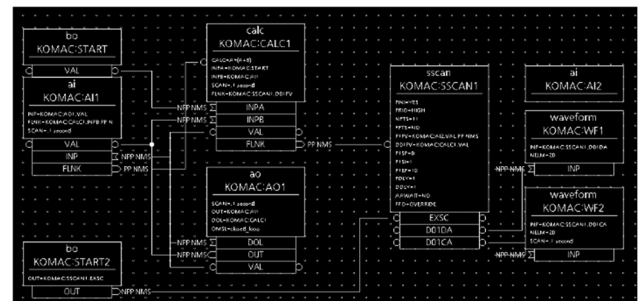

Figure 7: The block diagram of the EPICS database for the quad scan.

Quad scanning is started with the start button and the sscan module moves the wire and acquire data of a proton beam according to a beam repetition until the wire is moved at the set position. The obtained data are passed to the waveform record and are shown on CSS in real-time.

After scanning, all the data are delivered to asub record and are analyzed. Figure 8 shows the raw data and the fitted data after quad scanning.

Figure 8: The raw data da fitted data from quad scan.

The obtained data are saved in text and graph file format. And asub record reads all the text file resulted from quad scan and calculated the rms beam size versus Field gradient that is shown in Fig. 9.

Figure 9: The rms beam size versus Field gradient.

The beam emittance of the 100 MeV proton linac is then obtained from the rm beam size versus field gradient. Following Fig. 10 shows the beam emittance in test environment.

Figure 10: The beam emittance of the linac in test environment.

## CONCLUSION

The beam profile application for the KOMAC beam emittance has been integrated into KOMAC control system. The wire scanner control system performs the quad scan and data processing automatically. By using sscan and asub record, the process of the quad scan has been reduced. The program shows the wire scan data in real time and then calculated the fitted data and beam emittance after quad scanning. In the future, the beam profile application is applied to KOMAC 100 MeV proton linac to conduct the test.

## ACKNOWLEDGEMENTS

This work has been supported through KOMAC (Korea Multi-purpose Accelerator Complex) operation fund of KAERI by MSIT (Ministry of Science and ICT).

# PLUG-IN-BASED PTYCHOGRAPHY & CDI RECONSTRUCTION USER INTERFACE DEVELOPMENT

Sang-Woo Kim\*, Kyung-Hyun Ku, Woul-Woo Lee  
Pohang Accelerator Laboratory, Pohang, South Korea

## Abstract

Synchrotron beamlines have a wide range of fields, and accordingly, various open source and commercial softwares are being used for data analysis. Inevitable, the user interface differs between programs and there is little shared part, so the user had to spend a lot of effort to perform a new experimental analysis and learn how to use the program newly.

In order to overcome these shortcomings, the same user interface was maintained using the Xi-cam framework [1], and different analysis algorithms for each field were introduced in a plugin method. In this presentation, user interfaces designed for ptychography and cdi reconstruction will be introduced.

## INTRODUCTION

With the development of technology, the amount of data from detectors used for synchrotron radiation facilities is rapidly increasing. Diverse programs for processing the massive data are being developed individually at synchrotrons and universities with various languages such as python, matlab, labview, etc. In this situation, Xi-cam [1] proposed to jointly develop data analysis software with standardized framework and to utilize the developed program in other research institutes. Analysis programs using standardized framework have the advantage of being able to easily add necessary functions by loading plugins while maintaining a unified user interface. In addition, since the Xi-cam program handles GUI and analysis code execution, it is possible to focus on the implementation of core functionality. For this reason, we created a ptychography and cdi data processing program using Xi-cam's framework.

Ptychography and CDI are two types of coherent X-ray imaging techniques. As the focused and coherent X-rays pass through the sample, an interference pattern is created and this pattern is recorded by the detector. By using the interference pattern, the wavefunction of the probe, the density distribution of the sample, and the strain information could be obtained. The method estimates the wave function of the probe and the distribution of the sample at the beginning, and repeats the process of updating the probe and sample information to match the measured interference pattern while repeating propagation and backward propagation to obtain a value close to the actual probe and sample. Propagation is mathematically equivalent to a Fourier transformation. When CPU is used to repeatedly perform FFT and inverse FFT of large image data, it takes a long time to obtain a result,

whereas GPU could significantly reduce operation time because multiple cores can operate in parallel.

Ptychography and CDI operations were performed using the PyNX [2] developed by ESRF. PyNX was chosen because it is designed to increase the operation speed by using cuda cores of GPU and is designed based on mathematical operator so that the user can modify the application of the algorithms to suit their data. Although PyNX provides a script that can apply the reconstruction algorithm from the command line, a graphical user interface was created so that general users who are not familiar with command-line can utilize it.

## PTYCHOGRAPHY

Figure 1 shows the initial screen of Xi-cam. A list of installed plugins is displayed in the upper right corner. Currently, ptychography and cdi plugins are displayed, and plugins can be added on demand. Figure 2 is the screen displayed when the Ptychography plugin is selected. Tabs are arranged in the order of data processing, Preprocessing, STXM Viewer, Reconstruction, and Result Viewer. Similarly, CDI plugin (Fig. 6) consists of Preprocessing, Reconstruction, and Result Viewer.

Figure 1: The initial screen of the Xi-cam. Installed plugins can be selected from the upper right corner.

## Preprocessing

In preprocessing, meta data such as energy and the distance between the sample and the detector is read from the header file and average, background, subtraction, crop, re-size, denoising, etc. are performed and then saved as a cxi file. The cxi file format [3] is used as a standard in the field of coherent X-ray imaging and is supported by many programs. Thousands of images are compressed and stored in a single

\* physwkim@postech.ac.kr

file, so the efficiency of management and data transmission is increased.

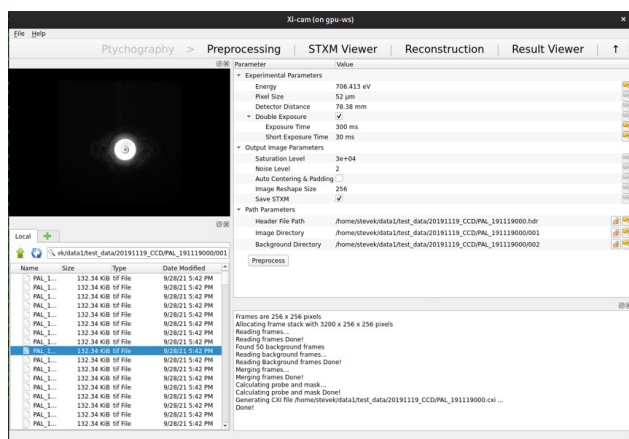

Figure 2: The first screen displayed when the Ptychography plugin is selected. The tabs are arranged in the order of Preprocessing, STXM Viewer, Reconstruction, and Result Viewer workflow.

## Reconstruction

In the Reconstruction tab (Fig. 3), the initial probe size and shape are determined, and reconstruction is performed by combining algorithms to be applied. Reconstruction may not work well depending on the direction in which the camera is mounted. In this case, it is possible to find the condition for good reconstruction when the image is transposed or flipped. On the right side, there is a window that updates the amplitude and phase of the sample and the amplitude and phase of the probe while the calculation is in progress. The black square box displayed on the object indicates the area where the actual scan was made. In the lower right log window, the name of the currently running algorithm, the error value, the elapsed time, and the size of the probe finally obtained are displayed.

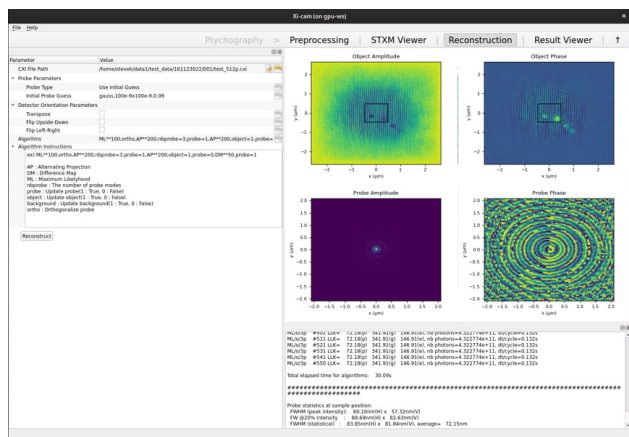

Figure 3: Ptychography reconstruction panel is shown. In the left setting window, the initial probe size, and reconstruction algorithm could be changed.

Since the wave function of the probe can be obtained through the ptychography, it has the advantage of accurately grasping the size and shape of the beam. In addition, if this data is applied to the next operation, a good reconstruction result could be obtained with much fewer operations.

## Result Viewer

Figure 4 shows the Result Viewer tab. In this tab, the reconstruction results can be immediately checked and exported or captured. The left panel shows the hierarchy of a cxi file. Not only the reconstruction result, but also meta data such as pixel size and energy and the wave function of the probe could be accessed. The right panel shows the amplitude of the reconstructed sample. The black square box indicates the area where the actual scan was made.

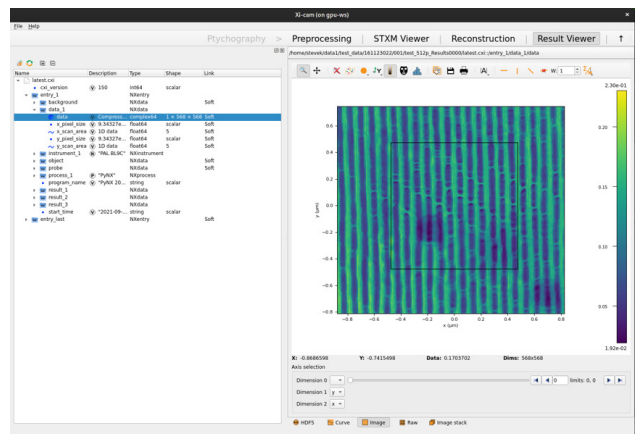

Figure 4: The Result Viewer tab of the Ptychography Plugin. The hierarchy of the Cxi file resulting from the reconstruction is shown on the left, and the operation result image is shown on the right. The black box indicates the scan area.

Figure 5 shows the STXM (a) and Ptychography reconstruction results (b) of measuring a zoneplate with defects. STXM data were measured in 50 nm steps when the beam size was 60 nm (FWHM). In the reconstruction result, the pixel size was reduced from 50 nm to 9.3 nm, and the noise seen in the STXM data was also greatly reduced in the result. Since the image quality can be improved through the reconstruction, it has many advantages when performing 2D XANES and Tomography experiments using the STXM technique. The soft X-ray beamline 10A1 and the hard X-ray beamline 9C are using the Ptychography plugin.

## CDI

Unlike the case of ptychography, the wavefunction of the probe cannot be obtained through CDI reconstruction. Instead, designate an arbitrary support area that is slightly larger than the actual sample and perform the reconstruction until it approaches the actual sample while narrowing or increasing the support area. Through this support update, when the boundary of the actual sample and that of the support match, the error is minimized and the information of the sample could be obtained.

Figure 5: The result of measuring the zoneplate at PLS-II 10A1 beamline is shown. The left (a) is the data measured by typical STXM, and the right (b) is the result obtained after performing the Ptychography reconstruction. The pixel size of (a) is 50 nm, and the pixel size of (b) is 9.3 nm.

The Bragg CDI technique can obtain the 3 dimensional characteristics of the sample in real space by using the interference pattern obtained from the rocking curves around the diffraction peak. The images obtained through rocking measurement is converted into q-space during preprocessing to obtain diffraction patterns in reciprocal space.

## Reconstruction

Figure 6 shows the reconstruction tab of the CDI plugin. The parameters of support type and size and reconstruction algorithm setting screen are located on the left. On the right screen, the amplitude and phase of the sample, the reconstructed interference pattern and the measured interference pattern are shown. The sample distribution in real space was revealed through CDI reconstruction of interference patterns in 3D q-space.

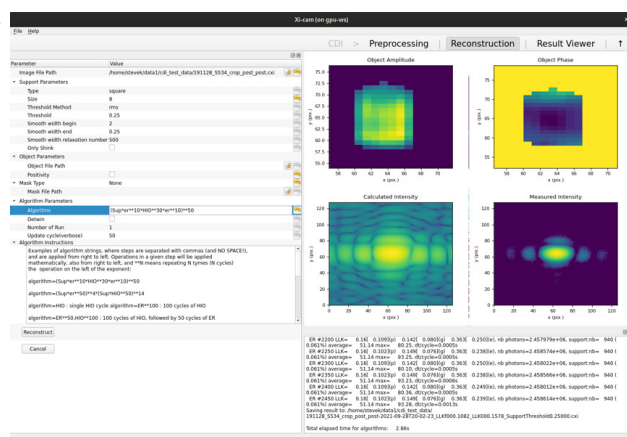

Figure 6: The reconstruction tab of the CDI plugin. Setting parameters and status results are displayed.

## Result Viewer

Figure 7 shows the result viewer tab where the CDI reconstruction result can be viewed as a 3D image. The 3D

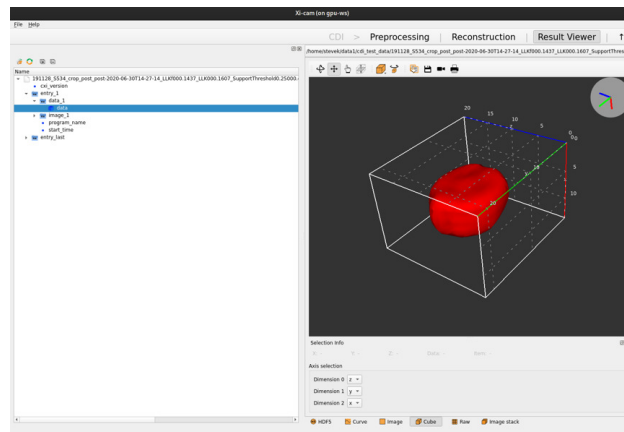

Figure 7: Result Viewer tab of CDI plugin. A three-dimensional image of the reconstructed sample is displayed.

image was displayed using the image viewer of silx [4], and the cross-sectional image of the sample can be displayed.

## CONCLUSION

Using Xi-cam as a standard framework for data analysis, Ptychography [5] and CDI [6] plugins were made. The unity of the user interface has been increased, and the efficiency has also been increased as it is possible to focus only on the production of core functionalities.

The Ptychography and Bragg CDI plugins were applied to the hard X-ray and soft X-ray beamlines. It is confirmed that image quality can be improved with ptychography compared to stxm and 3D sample information could be obtained through Bragg CDI.

# NEW MACHINE LEARNING MODEL APPLICATION FOR THE AUTOMATIC LHC COLLIMATOR BEAM-BASED ALIGNMENT

G. Azzopardi\*,<sup>1</sup>, G. Ricci<sup>1,2</sup>

<sup>1</sup> CERN, Geneva, Switzerland,

<sup>2</sup> Sapienza Università di Roma

## Abstract

A collimation system is installed in the Large Hadron Collider (LHC) to protect its sensitive equipment from unavoidable beam losses. An alignment procedure determines the settings of each collimator, by moving the collimator jaws towards the beam until a characteristic loss pattern, consisting of a sharp rise followed by a slow decay, is observed in downstream beam loss monitors. This indicates that the collimator jaw intercepted the reference beam halo and is thus aligned to the beam. The latest alignment software introduced in 2018 relies on supervised machine learning (ML) to detect such spike patterns in real-time. This enables the automatic alignment of the collimators, with a significant reduction in the alignment time. This paper analyses the first-use performance of this new software focusing on solutions to the identified bottleneck caused by waiting a fixed duration of time when detecting spikes. It is proposed to replace the supervised ML model with a Long-Short Term Memory model able to detect spikes in time windows of varying lengths, waiting for a variable duration of time determined by the spike itself. This will allow for further speeding up the automatic alignment.

## INTRODUCTION

The CERN Large Hadron Collider (LHC) is the largest particle accelerator in the world, built to accelerate and collide two counter-rotating beams towards the unprecedented design center-of-mass energy of 14 TeV [1]. The LHC is susceptible to beam losses which can damage the state of superconductivity of its magnets [2]. A multi-stage collimation system, consisting of 123 collimators [3], is installed in the LHC. Each collimator consists of two parallel absorbing blocks, referred to as jaws, inside a vacuum tank. The collimators must be aligned with the beam by symmetrically positioning the jaws on either side. This provides a 99.998 % cleaning efficiency of halo particles, preventing any LHC damage [4]. Each year of LHC operation begins with a commissioning phase which involves aligning all collimators and ensuring the correct settings for nominal operation [5].

This paper presents an analysis of first-use performance of the latest alignment software, that makes use of machine learning. A comparison with the previous alignment software resulted in identifying a bottleneck that restricts alignment efficiency. This is followed by a detailed analysis of a Long-Short Term Memory model that can be introduced to further improve the performance of the new software.

\* gabriella.azzopardi@cern.ch

## BACKGROUND

### *Recap. of Collimator Alignments*

Collimation alignment at the LHC is essential for beam performance and is based on different beam-based techniques developed for the specific LHC conditions [6]. While the new generation of collimators feature a design with embedded beam position monitors for a rapid alignment to the circulating beam [7], most of the LHC collimators do not have this feature. For the latter, the alignment relies on dedicated Beam Loss Monitoring (BLM) devices positioned outside the beam vacuum, immediately downstream from each collimator [4].

Collimator jaws are moved towards the beam with a step precision of 5  $\mu\text{m}$ , and the BLMs are used to detect beam losses generated when halo particles impact the collimator jaws. The recorded losses are proportional to the amount of beam intercepted and are measured in units of Gy/s. Collimators are aligned with respect to a reference halo cut generated with the primary collimators. A collimator jaw is considered aligned when a movement produces a clear beam loss spike in the BLM [8]. The observation time to evaluate the quality of the signal and to assess if the spike corresponds to a correct alignment can vary from  $< 1$  s to  $> 10$  s depending on the machine conditions and beam properties. Aligning collimators with BLMs is referred to as the beam-based alignment (BBA), which involves aligning collimators one by one, by moving one jaw at a time towards the beam.

Before moving each jaw, the losses produced by the previous alignment must have decayed in order to decrease possible cross-talk effects between the collimators, whereby the BLM losses at a specific collimator are affected by the signal produced by other collimators around the LHC [9]. A complete alignment campaign at the LHC requires moving each collimator jaw several times, which can produce more than 1000 observation spikes. Therefore, improving the time needed to classify these spikes has a direct impact on the system's alignment time.

### *Semi-Automatic Beam-based Alignment*

Since 2011, LHC collimators have been aligned using a semi-automatic procedure. This involves having the user to select the collimator to align, including the required settings and BLM threshold. The collimator will then automatically move towards the beam until the BLM losses exceed the threshold selected. At this point, the collimator automatically stops moving and the user must determine whether

the collimator is aligned or not by classifying the loss spike recorded in the BLM signal.

### Fully-Automatic Beam-based Alignment

The fully-automatic alignment was introduced and used in 2018 for all collimator alignments. As the name suggests, this fully-automates the entire procedure by automating the user's tasks in the semi-automatic alignment [10]. The three main user tasks have each been replaced with dedicated algorithms, such that:

- The collimator to align is automatically selected to avoid cross-talk (if any) [11].
- The BLM threshold (to stop the jaw movement during alignment) is automatically selected based on the real-time losses detected at the collimator [12].
- The BLM loss spikes are automatically classified using supervised machine learning into two classes; alignment spike or spurious spike [13]. This is possible by waiting a fixed duration of time to extract the features required for classification, from the BLM loss spike. Based on experience, the classification is set to wait 4 s at injection and 6 s at flat top.

These algorithms are developed as individual modules within the fully-automatic alignment software package [14], allowing for any improvements/upgrades. This paper focuses on the upgrade of the machine learning module.

## ANALYSIS OF SEMI- AND FULLY-AUTOMATIC BBA

Data were collected from collimator alignments performed using the semi-automatic alignment software in 2016 injection commissioning and the latest parallel fully-automatic alignment software in 2018, during a dedicated beam test replicating injection commissioning conditions [15]. The logged data includes the alignment of 75 collimators in 2016 and 77 collimators in 2018, both at a frequency of 1 Hz. Table 1 lists the details of the two alignment campaigns, resulting in the fully-automatic procedure able to align the collimators at injection in one third of the time required by the semi-automatic one [16].

One can observe that the moving time of the collimator jaws during both campaigns is approximately 38 % of the total time ( $\pm 10$  % assuming a 0.5 s error on each jaw alignment due to the 1 Hz logging precision). This indicates that the fully-automatic alignment can be further sped up by decreasing the waiting time (62 %). The main contribution to the waiting time is the spike classification which is currently set to wait a fixed 4 s, at injection, for the BLM signal to decay before classifying it.

### Decay Time Analysis

The actual time required for the BLM signal to decay at injection and flat top was analysed to identify possible gains in the overall alignment time by reducing the duration of

Table 1: Details of two alignment campaigns at injection using the semi-automatic alignment in 2016 and the fully-automatic alignment in 2018.

	Semi-Automatic	Fully-Automatic
Collimators	75	77
Total time	2h 31m 59s	49m 17s
Moving time	58m 13s	18m 14s
Total alignments	1903	637
Moving time	38.3 %	38.0 %
Alignments/Coll	25.37	8.27

the decay observation. The decay time was analysed for 1550 alignment spikes collected during 2016-2018 alignment campaigns, which includes 719 alignment spikes at injection and 831 at flat top.

The decay rate is modelled as an exponentially falling distribution, with optimal losses achieved after 6 half-lives, as shown in Figure 1. As a result the optimal decay time is the latency required for the BLM losses to fall to 1/64 of the maximum value. Figure 2 displays the distribution of the decay latency at the two machine states such that the mean decay time is 0.61 s at injection and 2 s at flat top.

Figure 1: An example of a short decay observed in the BLM signal of an alignment spike at flat top.

Figure 2: BLM signal decay time distributions at injection and flat top.

This highlights the fact that a dynamic adjustment of the observation time can speed up the overall alignment, as it is

not necessary to consistently wait 4 s at injection or 6 s at flat top. As an example, Figure 1 displays an alignment spike at flat top with a short decay that lasts 0.96 s. Moreover, this will allow for adjusting the observation window in the case of longer decays, although they do not happen frequently.

## LSTM-RNN FOR SPIKE CLASSIFICATION

In order to continuously classify spikes in real-time and automatically detect their decay, the proposed solution is to train a Long Short-Term Memory (LSTM) - Recurrent Neural Network (RNN) [17]. This may enable the spike classification after a variable duration and minimize the waiting time of the automatic collimator alignment.

The entire data set gathered during 2016-2018 consists of 2973 samples collected when the BLM losses exceeded the predefined threshold, i.e. the moment when the observation of the BLM signal starts. The collected data samples were individually analysed and labelled into the classification classes; 1550 alignment spikes and 1423 spurious spikes. Each sample is a 7.5 s time series of length 188 and contains two signals; the BLM signal logged at a frequency of 25 Hz and the collimator jaw positions logged at a frequency of 1 Hz.

The input used to train the LSTM combines the two signals in each sample by scaling the BLM signal with the collimator position in sigma at the time the threshold was exceeded. Z-Score ( $z = \frac{x-\mu}{\sigma}$ ) is then used as the normalization technique to re-scale the features such that they have the properties of a standard normal distribution.

The network architecture was developed using the deep learning library Keras [18], with TensorFlow [19] as the back-end, see Figure 3. It consists of two LSTM layers, followed by a dropout and dense layer. The model was trained over 75 epochs using an Adam optimizer [20] with a learning rate of  $3e^{-4}$ . Binary cross-entropy is used as the loss function.

Figure 3: The LSTM network architecture. Two layers containing 128 and 64 hidden neurons, respectively, process the learning data produced by the preprocessing unit. Following is a dropout layer with rate of 0.4, then a dense layer with one neuron and sigmoid activation function.

The results of the two LSTM layers were outputted solely on the final time step, such that each layer generated a 2D

array: Layer 1 output size:  $188 \times 128$ , Layer 2 output size:  $64 \times 1$ . Following this, the dropout layer outputs a 1D array of size 64, and finally the dense layer outputs the final probability used for spike classification.

In order to ensure the correct alignment of collimators, false detection of an alignment spike is more grievous than not detecting an alignment spike. Therefore, precision is used as the main performance metric to avoid false positives [13].

The results are collected over a 10-fold cross-validation randomly stratified 30 times, to handle lucky splits. The results are displayed in Figure 4, highlighting that the train and test loss curves stabilized with a minimal gap between the final values, thus indicating that a good fit has been found after 75 epochs. Overall, the model obtained an average precision of 94 % on the testing sets (and 94 % accuracy).

This precision was calculated by evaluating the classification probability at the end of the available sample, whereby a classification score with a probability larger than 50 % is classified as an alignment spike. Further analysis will aid to determine the best moment to predict the spike class and the ideal probability threshold, to possibly improve the model's precision.

Figure 4: Loss and precision curves obtained by the LSTM on the training and testing data, in terms of mean and standard deviation.

## Spike Classification Analysis

The trained LSTM model was used to continuously classify each sample at each time step, starting from the moment when the collimator stopped moving, until the end of the 7.5 s window.

An overview of the classification probabilities obtained for the two spike classes at injection is displayed in Figure 5. A clear distinction can be made between the spike classes at a latency of  $\sim 1.5$  s, at which point the probability gradient for alignment spikes falls below 0.2. Taking a closer look at the classification probabilities of the two classes at a latency of 1.5 s in Figure 6, one can observe that there is no overlap at 80 % probability. Moreover, Figure 7 displays the latency required to obtain the maximum probability for each spike class. One can observe that the  $\sim 98\%$  of spurious spikes obtain their maximum probability within the first 1.5 s, whilst

Figure 5: Spike classification results displayed as (i) the evolution of the classification probabilities in time for the two machine states, and (ii) the gradient of change in the classification probabilities. The two plots are displayed in terms of mean and standard deviation.

Figure 6: The probabilities obtained by the two spike classes at 1.5 s latency after the collimator stopped moving.

all spurious spikes remain below the 80 % classification probability threshold.

As a result, the LSTM can be set to make a classification once the probability gradient decreases below 0.2, which, as shown in Figure 5, occurs within a latency of ~1-1.5 s, at injection. If the probability at this point is below 80 %, then the BLM losses can be classified as a spurious spike, and the next alignment can begin. When the losses form an alignment spike, the next step is to determine the optimal BLM decay time to begin the next alignment. In this case an exponential function can be fit (as shown in Figure 1) to determine when ~98.5 % of the BLM signal decays (6 half-lives), which on average would have already decayed (mean of 0.61 s).

An analogous analysis was performed at flat top, showing similar results, i.e. classifications can rely on the 80 % probability threshold when the probability gradient decreases below 0.2, which at this machine state occurs within a latency of ~1.5-2 s.

### Classification Results

Classifying the BLM signals as proposed by the presented analysis increases the classification precision on the data set to 98 % (with 90 % accuracy). In addition, the time taken for the LSTM to classify the data set into the two spike

Figure 7: The distribution of the maximum probabilities achieved by the two spike classes and the required latency. The majority of alignment spikes obtain a probability above 80 % whereas all spurious spikes remain below.

classes resulted in a mean latency of 1.07 s at injection and 1.54 s at flat top, whereby 88 % of the observation spikes were classified within these times. Table 2 summarises the classification results at the two machine states, indicating a factor of 4 speed-up compared to the present implementation using supervised ML with fixed observation times.

Table 2: The latency results obtained when classifying the data set using the LSTM model. The classification was started at 1 s for injection and 1.5 s for flat top.

State	Start time	Mean	Stand. dev.	Max.
Injection	1 s	1.07 s	0.1 s	1.72 s
Flat top	1.5 s	1.54 s	0.06 s	2.04 s

**Results with Ion Beams** A data set was collated with 254 samples (192 alignment spikes, 62 spurious spikes) from the ion run in 2018 during the collimator alignment campaign in collisions. The mean decay time for the BLM losses to fall to 1/64 of the maximum value is 1.08 s.

An analogous analysis was performed with ion beams resulting in a similar environment for classifications, such that an 80 % probability threshold and 0.2 probability gradient after a minimum of 2 s latency, are ideal. The LSTM model trained on proton beams was used to classify this data set and obtained 97 % precision (and 87 % accuracy). The mean latency required to classify these samples is 2.08 s.

A summary of the results obtained at the different machine configurations analysed in this paper, is collected in Table 3.

Table 3: Results obtained at different LHC configurations.

	Proton beams		Ion beams
	Injection	Flat top	Collisions
Decay time	~0.61 s	~2 s	~1.08 s
Prob. threshold	80 %	80 %	80 %
Prob. gradient	0.2	0.2	0.2
Class. latency	~1.07 s	~1.54 s	~2.08 s
<b>Class. precision</b>	<b>98 %</b>		<b>97 %</b>

## THEORETICAL IMPROVEMENT OF ALIGNMENT TIME WITH LSTM

The time performance of the automatic BBA using supervised machine learning is displayed in Table 1, taking into consideration the following assumptions [11]:

- A clear alignment spike is achieved the first time the threshold is exceeded.
- Two clear alignment spikes are achieved after ~10 steps per jaw.
- The primary collimator was aligned in a previous alignment and both jaws achieved an alignment spike the first time the threshold is exceeded.

Table 4: Theoretical minimum time required to align a collimator [11].

Step	Action	Time (s)
1	Move both jaws to 4 mm	~8
2	Wait for losses to decay	$x$
3	Classification delay	1
4a	Align Left Jaw	$2 \cdot (0.1 + x + 1)$
4b	Align Right Jaw	$2 \cdot (0.1 + x + 1)$
5a	TCP before (Left Jaw)	$0.1 + x + 1$
5b	TCP before (Right Jaw)	$0.1 + x + 1$
6	TCP after (Left + Right)	$2 \cdot (0.1 + x + 1)$
<b>Total</b>	<b>17.8 + 9x</b>	@Inj $x \geq 4$ @FT $x \geq 6$

The proposed LSTM model is capable of dynamically classifying alignment spikes of varying lengths in real-time. Therefore, this will decrease the time waiting for the losses to decay ( $x_1$ ) to an average of 1.07 s at injection and 2 s for alignment spikes at flat top. This indicates that the theoretical minimum time required to align a single collimator at injection is 27.43 s, assuming that every spike is an alignment spike. Therefore, on average, aligning 79 collimators at injection would require a minimum of 36.1 mins.

On the other hand, if the collimator jaws encounter one spurious spike in Steps 1, 4a and 4b, then an addi-

tional  $3 \cdot (0.1 + x_0 + 1)$  seconds are required per collimator, i.e. 1.07 s at injection and 1.54 s for spurious spikes at flat top. This results in an additional average of 6.51 s at injection, increasing the average time required in this case to 44.7 minutes.

Table 5: The average theoretical minimum time to sequentially align LHC collimators, calculated using Table 4.

Case studied	Supervised ML	LSTM-RNN
1 coll @Inj	53.8 s	27.43 s
+1 spurious spike	69.1 s	33.94 s
79 colls @Inj	70.84 mins	36.12 mins
+1 spurious spike	90.98 mins	44.69 mins
1 coll @FT	71.8 s	35.8 s
+1 spurious spike	93.1 s	43.72 s
79 colls @FT	94.53 mins	47.14 mins
+1 spurious spike	122.58 mins	57.56 mins

Table 5 summarises the theoretical minimum time required to sequentially align the collimator cases discussed, at injection and flat top. In 2018, the automatic alignment was upgraded to align the collimators in the two beams in parallel, resulting in 79 collimators aligned in 50 minutes at injection [15, 16]. Therefore the possible introduction of LSTM can theoretically align the collimators in ~24.56 minutes, speeding-up the automatic alignment by ~50 %.

## CONCLUSION

The 123 LHC collimators are aligned automatically using supervised ML, provided by the latest fully-automatic software introduced in 2018. This paper analysed first-use performance of this software and identified a bottleneck caused by the fixed observation window used by the ML model to classify the BLM loss signal. This classification determines if the collimator jaws reached the correct alignment position.

In this paper a Long-Short Term Memory model was trained to continuously classify BLM signals. This allows classifying the losses into a spike class within 1-2 s of a collimator stopping its movement, once the rate of change in classification probabilities is below 0.2. Following each alignment spike classification, the suggestion is to fit an exponential function to the losses to determine whether the next alignment can begin. On average, the losses at injection would have already decayed (mean of 0.61 s), whereas decays at flat top may require a longer time (mean of 2 s).

This work allows for classifying BLM signals independent of whether the losses decayed or not, thus solving the bottleneck in the fully-automatic alignment process. Overall, this research could decrease the alignment time by ~50 %. The LSTM is readily available to be incorporated into the alignment software for testing during the LHC Run 3.

# INNOVATIVE METHODOLOGY DEDICATED TO THE CERN LHC CRYOGENIC VALVES BASED ON MODERN ALGORITHM FOR FAULT DETECTION AND PREDICTIVE DIAGNOSTICS.

A. Amodio, P. Arpaia, Y. Donon, F. Gargiulo, L. Iodice, M. Pezzetti, CERN, Geneva, Switzerland

## Abstract

The European Organization for Nuclear Research (CERN) cryogenic infrastructure is composed of many equipment, among them there are the cryogenic valves widely used in the Large Hadron Collider (LHC) cryogenic facility. At present time, diagnostic solutions that can be integrated into the process control systems, capable to identify leak failures in valves bellows, are not available. The authors goal has been the development of a system that allows the detection of helium leaking valves during normal operation using available data extracted from the control system. The design constraints (inaccessibility to the plants, variety of valve models used) has driven the development towards a solution integrated in the monitoring systems in use, not requiring manual interventions. The methodology presented in this article is based on the extraction of distinctive features (analyzing the data in time and frequency domain) which are exploited in the next phase of machine learning. The aim is to identify a list of candidate valves with a high probability of helium leakage. The proposed methodology, which is at very early stage now, with the evolution of the data set and the iterative approach for the test phase presented in the last paragraph, is aiming toward a cryogenic valves targeted maintenance in the LHC cryogenic accelerator system.

## INTRODUCTION

The maintenance purpose is to reduce, as far as possible, the occurrence of undesirable events and, consequently, the corrective maintenance interventions. The maintenance campaign of large accelerator systems, such as the LHC at CERN, represents an important factor in terms of financial and manpower resources. At CERN, a large fraction of the cryogenic installation and its control systems are located in areas inaccessible during physic run campaigns. Due to the high complexity of the accelerator, the cryogenic system needs high levels of reliability for its operations. [1]. The cryogenic valves are widely used in the LHC cryogenic facility. The design constraints, such as the inaccessibility to the plants and the variety of valve models used, have driven the development of an integrated solution in the monitoring systems in use, not requiring manual interventions. The authors motivation has been the development of a system that allows the detection of helium leakage during valves operations using available data. In the past, several diagnostic approaches have been developed concerning compressors, electrical motors and cryogenic instrumentation [2, 3]. In literature, diagnostic solutions that can be integrated into the process control systems using only the available data, to identify leak failures in valves bellows, are not available

at this time. Although the solution proposed in [4] based on Support Vector Machine (SVM) reaches a very interesting level of accuracy (97 %), it unfortunately requires the use of vibration sensors making this method inapplicable in contexts where the valves are numerous and difficult to access. The state-of-the-art solutions for failure prediction in control valves, cannot fit the context whose constraints are described.

## PROBLEM OF CRYOGENIC VALVE BELLOWS LEAKAGE

The helium used in cryogenic systems can, due to its physical characteristic, escape through micro-cracks originated from valve bellows movements after years of operations. The main purpose of the presented work is the development of an innovative tool for maintenance diagnostic. The described algorithm produces a list of designated valves that could potentially present the helium leakage problem. The selected valves are investigated, by cryogenic operators, using local helium sniffing devices and if the leak is validated, a mechanical repair action is undertaken. The cryogenic system uses several valve models for the regulation and the control of cryogenic liquefied gases, being able to be fully functional both at temperatures as low as 1.9 K and at various pressures required by the cryogenic process. The system presented below is focused on these control valves of the cryogenic types (see Fig. 1) fabricated in stainless steel (AISI 316L). The control valve model used at CERN is driven by a Siemens Sipart PS2® positioner which gets a setpoint by the industrial Profibus® PA or by a 4-20 mA current signal (supporting HART® protocol). The control valve has a chamber divided into two parts by a diaphragm.

Figure 1: Example of LHC Cryogenic control valve [5].

The desired state of the valve is achieved by varying the air pressure in the two areas of the chamber. The pressure difference moves the diaphragm, and the stem tuning the valve opening. The valves are sealed to air using metallic bellows forming a cylinder shape junction between the fixed and movable part of the valve. The bellows shape is designed in order to be flexible and to follow the stem actions. The authors have analyzed a subset of 174 out of the 1357 control valves.

## PRIOR KNOWLEDGE MODEL

The valve failures, causing helium leakage, are mainly related to the metallic bellows fatigue due to the workloads within the tens of thousands of elongations cycles [6]. The study turns into a binary classification problem in which the fatigue phenomena is used to identify if the valve is close to a failure caused by stress. The fatigue phenomena is described using the Wöhler diagram (see Fig. 2). It represents the number of cycles at which a breakage is expected to happen. According the diagram, the relationship between stress  $\sigma$  and critical number of the cycles  $N$  is:

$$\sigma^M \cdot N = \text{constant} \quad (1)$$

where  $M$  is a constant.

Figure 2:  $\sigma - N$  diagram of stainless-steel bellows [7].

During normal operation, the mechanical effort on the component is characterized by different values of stress intensity. To combine them and estimate the general cumulative damage of the material, Palmgren-Miner's rule is used [8].

$$\sum_i \frac{n_i}{N_i} = \text{damage condition parameter} \quad (2)$$

where  $n_i$  and  $N_i$  are the number of performed and the critical cycles of the  $i$ -th value of stress applied to the bellows. The damage condition parameter indicates an estimation of the cumulative damage and is used to compare the health status of the valves. Values under the unit mean that the fatigue limit is not reached.

## DATA COLLECTION

The history of the valves position is extracted from the logging files, and the parameters reported in the Table 1 were gathered for each valve. The dataset is built from log files using a Python® script and the CERN/TIMBER® application querying of the CERN Accelerator Logging Service. The extracted information were then organized as a vector for each valve. The history covers the interval of time between 2008 and 2019.

Table 1: SIPART PS2 Positioner® Parameters

STRKS	Number of complete strokes from 0% up to 100% and back
CHDIR	Number of times a change of direction has occurred
HOURS	Number of hours worked since initialization
SSUP	It defines the upward variation within which the valve in the Slow Step zone is operated. In this condition, the actuators are piloted by a PWM signal to avoid overshoots.
SSDN	Similarly to the SSUP parameter but with regard to the downward movements.

After having studied the problem from a physical point of view and collected the data, the authors have divided the procedure into two main steps: i) Pre-processing phase where distinctive features are extracted by considering breaking phenomena; ii) Machine Learning (ML) model training, for the classification of broken valves. While the leak problem is tackled, the reliability of the ML model obtained will improve because of the growing number of broken valves dataset.

Figure 3: Representation of algorithm approach development.

## PRE-PROCESSING FOR FEATURES EXTRACTION

Starting from the vector of the valve position over time, two features were extracted to be used in the subsequent ML model training. The extraction of these two features takes place in the two phases explained below:

## Time Domain

This phase aims to identify which valve bellows had the most stressful regulation due to the widest elongation and compression. Considering the bellows as a spring, the Hook's law can be used to find a relation between the amplitude and the force applied to compress or stretch the bellows (and indeed stress):

$$\sigma = \frac{-k \cdot \Delta L}{S} \Rightarrow N \propto 1/\Delta L^M \quad (3)$$

where  $k$  is the elastic constant of the material,  $\Delta L$  is the excursion performed by the bellows and  $S$  is its section area. In according to fatigue theory, larger movements of the valves (opening or closing) drastically reduce the lifetime of the bellows. The evaluation of the correct amplitude is mandatory because of the exponential relationship between the critical number of cycles and the amplitude of the movement. The series of movements are filtered and then processed with logical operations to obtain the extremes mono directional variation. This operations not only allow to reduce the vector size by discarding all the value between two extremes, but they also reduce the computational effort for all the subsequent operations. The little changes in directions are removed using the local Gaussian smoothing. At the end, only the extremes of the wide variations are extracted. The purpose is to build a matrix from the dataset in order to have a synthetic representation of the movement history. The Stochastic matrix is a square matrix in which the rows and the columns represent respectively the initial and the final position of the movement. The matrix is filled with the number of movements relative to the row-column pair. A mask matrix is then adopted in order to assign a weight to the excursions according to the change of position importance (more or less burdensome). According to Palmgren-Miner's rule, the mask coefficients are the reverse of the maximum number of expected cycles and are obtained by the Wohler diagram of stainless steel bellows. At CERN, the information from broken valve dataset is extracted in order to improve the analysis with experimental data. The dataset of broken bellows valve and healthy valve are considered, and a stochastic matrix is extracted and calculated for each of them. All the stochastic matrixes are weighted with the coefficient of the mask and are clustered using an unsupervised classifier (ML technique in which the users do not need to intervene manually to label the dataset model) to identify for each coefficient of the matrix a centroid of the broken valve set. All these centroids are collected in a matrix and each value is divided by the mean value of stochastic matrix of the broken valve dataset. The unsupervised classifier used is  $K - means$ . The outcoming matrix is used as weights matrix for the analysis of each new checked valve. A final output parameter is extracted for each valve to test. The parameter is the sum of all the coefficients of the matrix obtained by multiplying the coefficient of the stochastic matrix and the second weight matrix. This parameter, according to previous formulas, is proportional to the estimation of the accumulated bellows damage.

## Frequency Domain

The second phase is based on spectral analysis performed to evaluate the dynamic of the movements. The time series data extracted from log file are non-uniform sampled. Before passing to the frequency domain, an interpolation must be performed. The interpolation must fill the missing values discarded during the the storing in log files (due to avoiding the replication of similar values in log files). Considering a common time base for all valves, a previous neighbor interpolation to replicate the non-sampled values is performed. Other interpolation approaches are avoided in order to do not alter the original values. The spectral analysis is performed by calculating the energy of the envelope of the module of the Fast Fourier Transform (FFT) of valve trace movements. The extracted feature is the ratio between the energy of the last quarter of the frequency spectrum and the total energy.

## MACHINE LEARNING PERFORMANCE MEASURES

To assess the quality of the classification model, different performance indices were considered. The accuracy index (explained below), when the size of the minor class represents only a small percentage of the data set size, is not suitable because the minority class has very little influence on accuracy. The results of binary classification can be defined in four different values: true positive (TP), true negative (TN), false positive (FP) and false negative (FN).

Table 2: Confusion Matrix for Binary Classification

		Predicted class	
		Positive	Negative
True Class	Positive	TP	FN
	Negative	FP	TN

By these values the confusion matrix was built as shown in Table 2. Different quality indexes can be calculated:

$$Accuracy (ACC) := \frac{TP + TN}{TP + TN + FN + FP} = \frac{TP + TN}{P + N}$$

$$Recall (REC) := TP_{rate} = \frac{TP}{TP + FN} = \frac{TP}{P}$$

$$Precision (PREC) := \frac{TP}{TP + FP}$$

$$False Positive Rate (FRP) := \frac{FP}{TN + FP}$$

where  $P$  refers to the total number of broken valves and  $N$  refers to the total number of healthy valves.

The TPR and the PRECISION values are summarized in the F-score parameter defined as:

$$F = 2 \frac{Precision \cdot TPR}{Precision + TPR}$$

These indices are useful to give a measure of performance and to make comparison between the models.

## EXPERIMENTAL RESULTS

In the processing phase, different binary classification models were explored [9]. The choice of the model is driven by the performance indices explained in the section "Machine Learning Performance measures". The input dataset is composed of the observations collected for each valve, whose features are the elements in Table 1 and the time and frequency domain features extracted as described above. In the first experiment 174 valves, of which 8 were broken, were used as input data (training set), . The choice of the valves is driven by the similar mechanical characteristics, in order to make them comparable using Wöhler diagram. Due to the small dataset, the K-fold cross-validation is chosen with k=8 to have at least 1 broken valve for each validation subset. To train the model, only the predictors with low correlation are chosen. The selected predictors were the two features extracted in pre-processing step, CHDIR and STRKS. The model was trained with these features obtaining as best result, in terms of accuracy, the "Gaussian SVM" with an accuracy of 96.6 %. The broken valves recognized were two out of eight, with a TPR of 25.0 %. Even though Kernel Naïve Bayes model has an accuracy lower and equal to 94.8 %, it had a TPR for the broken class of 75.0 % identifying six out of eight broken valves. The F-score is equal to 57.1 %. Good results were obtained although the dataset is highly unbalanced with a TNR of 95.8 % and a TPR of 75.0 %. Different techniques were analyzed to overcome the disproportion between the positive and negative class [10].

### Cost-sensitive Learning Technique

Two different costs for the wrong classification are assigned. The aim is to penalize the wrong classification of positives samples more than the wrong classification of negatives samples, hence a higher cost to FN is applied [11]. The CFN denotes the cost of predicting negative instead of

Table 3: Misclassification Costs Matrix

		Predicted class	
		Positive	Negative
True Class	Positive	0	CFN
	Negative	CFP	0

positive, and CFP the cost of predicting positive instead of negative. To move the attention of the model to the broken valves, a script was written to maximize the F-score varying the CostRatio and, at the same time, minimize the cost function [12]. Different models achieved good results as shown in Table 4. In this case, the best solution is the Quadratic Discriminant model, which accomplished a TPR=87.5 % recognizing 7 out of 8 broken valves and a TNR=95.8 %.

### Resampling Techniques

Operating before the training, a dataset already balanced in the classes has been provided to the Classification Learner App®. There are two different techniques :

Table 4: TPR and TNR with a different CostRatio [9].

	TPR(%)	TNR (%)	CR	New TPR (%)	New TNR (%)
Linear Discriminant	50	98.2	6	62.5	96.4
Quadratic Discriminant	75.0	96.4	3	87.5	95.8
Subspace Discriminant	50	98.2	23	75	94.0
Linear SVM	25.0	98.2	9	75.0	96.4
Medium SVM	25.0	100	23	62.5	95.2
Coarse Gaussian SVM	0	99.4	18	75	93.4
Kernel Naïve Bayes	75.0	95.8	9	87.5	92.2

- "Undersampling" which purpose is the reduction of the samples in the majority class to balance the data. The technique was not performed due to the small number of samples in the minority class.
- "Oversampling" which purpose is the increment of the samples of the minority class to balance the data. This result can be achieved either randomly or with synthetic data. These techniques can be then adopted, but overfitting risk need to be handled.

Synthetic data are added to the dataset by means of the following oversampling techniques:

- Synthetic Minority Over-sampling Technique (SMOTE): New synthetic samples are obtained by selecting randomly one of the  $K - nearestneighbors$  of a sample casually picked from the minority class. Then, through a random number  $\delta \in [0, 1]$ , the point is placed along the line between the selected minority class sample and the nearest neighbor chosen [10]:

$$X_j^{SMOTE} = x_i(\tilde{x}_{i,k}^{Knn} - x_i) * \delta_j \quad (4)$$

where  $\delta \in [0, 1]$  is a random number.

In this case study, an oversampling of 8 broken valves

Figure 4: Synthetic data SMOTE.

was processed, in order to prevent the model from being performed only on the synthetic data, leading to a completely distorted model. Factor  $K=3$  and a 16-cross validation are chosen obtaining as best result the “Quadratic Discriminant” with an accuracy of 95.1 % with the confusion matrix in Table 5.

Table 5: SMOTE Confusion Matrix

		Predicted class	
		Positive	Negative
True Class	Positive	14	2
	Negative	7	159

### Cross-validation and Overfitting

If the oversampling of the minority class is done before cross-validation, the oversampling can lead to overfitting. Because in the Smote algorithm  $\delta_i$  could be equal to 0 or equal to 1, if the oversampling is applied before the cross-validation, one or more samples could be equal to the original dataset points [13]. In Fig. 5 the same minority samples (in blue) are in both validation and training set. The overfit-

Figure 5: Oversampling and Cross-validation.

ting can be avoided if in each iteration: i) dataset is divided into validation and training set, then ii) SMOTE algorithm is applied only to the training dataset and iii) performance measures are evaluated with the validation set [13] as shown in the Fig. 6. Applying this structure, there has been a degradation in the performances of the SMOTE algorithm with a TPR=75.0 % recognizing 6 out of 8 broken valves.

### ITERATIVE APPROACH FOR THE TEST PHASE

Since this is a novel study of the helium leakage of the cryogenic valves, the test phase is conducted by applying the ML models introduced by authors, to the valves of a certain sector of the LHC. The valves are then manually

Figure 6: Cross-validation and Oversampling.

checked for damages. This approach allows to evaluate the performance of the model and improve it at each step. Due to the low number of broken valves, one of the first algorithm attempts, then rejected, presented the problem of overfitting as the performance in the test phase was much worse than in the training phase. For this reason, the authors decided to consider several dataset manipulation techniques and ML solutions towards the highest level of performance. The authors are confident that the combination of the increasing number of broken valves and the iterative approach to the test phase will lead to a more reliable model for the correct recognition of broken valves.

### CONCLUSION

The authors present in this paper an innovative solution for fault detection of cryogenic valves bellows installed in the CERN LHC accelerator. The development was focused to produce a solution able to be easily applicable to the data from the existing cryogenic control system. The solution consists of a pre-processing step in which a features extraction is performed and a ML phase for the data drive modelling. The dataset, for the training and validation step, is composed of recorded data characterized of 174 valves by different features. Several classifiers were validated and best performances, exploiting the oversampling of broken valves, were reached by means of Quadratic Discriminant. The Quadratic Discriminant model has accomplished good performances both with oversampling and cost-sensitive learning technique. The presented results were obtained using an unbalanced dataset of heterogeneous types of bellows-sealed control valves. The work presented in this manuscript will constantly evolve when more dataset become available to improve the training and validation steps and perform the iterative test step.

# EVOLUTION OF THE CERN BEAM INSTRUMENTATION OFFLINE ANALYSIS FRAMEWORK (OAF)

A. Samantas, M. Gonzalez-Berges, J-J Gras, S. Zanzottera, CERN, Geneva, Switzerland

## Abstract

The CERN accelerators require a large number of instruments, measuring different beam parameters like position, losses, current etc. The instruments' associated electronics and software also produce information about their status. All these data are stored in a database for later analysis. The Beam Instrumentation group developed the Offline Analysis Framework some years ago to regularly and systematically analyze these data. The framework has been successfully used for nearly 100 different analyses that ran regularly by the end of the LHC run 2. Currently it is being updated for run 3 with modern and efficient tools to improve its usability and data analysis power. In particular, the architecture has been reviewed to have a modular design to facilitate the maintenance and the future evolution of the tool. A new web based application is being developed to facilitate the users' access both to online configuration and to results. This paper will describe all these evolutions and outline possible lines of work for further improvements.

## INTRODUCTION

Several thousand instruments are installed in the CERN accelerator complex to measure beam parameters (e.g. position, losses, intensity, etc). Table 1 gives an approximate overview of the types of instrument per accelerator. Each instrument is typically composed of a monitor that can be inserted in the beam pipe or installed outside, an analogue/digital electronics system and a software layer.

The complex itself spans over several kilometres, with most of the accelerators installed underground. The regular operation of these instruments is a major challenge. They need to be available for the run periods and their performance has to be guaranteed.

Table 1: Approximate Number of Main Types of Instruments per Type and Accelerator

	LHC	SPS	PS complex	Other
Position	1300	300	300	50
Losses	4200	10	50	30
Intensity	20	10	80	10
Profile	40	10	80	30

The Offline Analysis Framework (OAF) [1,2] was developed some years ago to deal with this challenge. The instruments produce beam physics data as well as status information. Both sets of data are used to monitor

the instrument performance and its evolution through time. Our final aim is to fine tune the instruments' performance and introduce predictive maintenance on their mechanics and electronics parts.

## CURRENT USAGE

All these instruments measure, regularly or on demand, the different beam observables. Then, they send these values, together with relevant status and setting registers, to the CERN Control Room for the real time operation of the machines and into a centralized logging database (NXCAL) [3] for future offline analysis (Fig. 1).

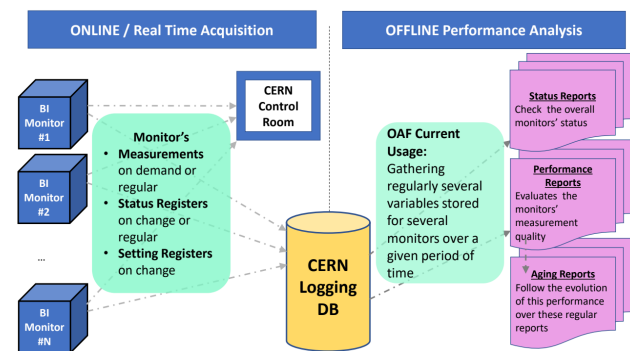

Figure 1: Standard usage workflow.

All this logged information contains too much data to be analysed properly manually. So, in 2013, we decided to develop the Offline Analysis Framework [1] in order to regularly monitor the records stored and automatically produce 3 kinds of reports:

- Status reports that focus on the state of the instrument and monitor humidity, temperatures, logging frequency and more, raising alarms whenever necessary.
- Performance reports will monitor and assess the quality (accuracy, resolution, stability) via device comparisons or regular calibration sequences.
- Aging or long term evolution reports will survey the evolution of the quality evaluations made in the daily performance reports.

Most of these analyses can be derived from the raw DB records via standard data treatment and plotting functionalities directly supported by OAF. However, some analyses require ad-hoc computations or specific plots. To cover these non-standard requirements, OAF offers the possibility, whenever necessary (i.e. when the need is not covered by the build-in OAF features), to add expert python code to this specific analysis that will be

executed at the end of the standard OAF process with a direct and simple access to:

- The extracted raw DB data and all subsequent data produced by the OAF associated treatments.
- The OAF programmable interface which allows the expert graphs, tables and alarms produced to be included in the reports.

## ARCHITECTURE REDESIGN

Although stable and capable of running reliably for years, the original software architecture of OAF had some flaws that made working with its codebase difficult.

For example, adding new types of analyses to be run on the collected data was very complex: it required the original author to write lots of code, and it was not modular, meaning that no code could be reused from one analysis to the other. As a result, over the years the source inflated due to the code duplication, and became very hard to maintain and develop further.

An additional issue we found was that users did not find the user interface understandable enough to use it, and required constant assistance from the original author to use the system.

Recently, CERN adopted NXCALS as its central logging database, forcing OAF to adapt to this new interface. Due to the need to perform this upgrade, we took the opportunity to review the entire system, and we decided to perform a nearly complete redesign. The aim of this redesign was:

- Make OAF modular and maintainable.
- Make OAF easier to use for the end users.
- Make the creation of new analysis types easier.
- Review which of the existing analysis were still being used, and which ones could be dropped.
- Clean up and simplify the codebase heavily.
- Strongly improve the performance on some of the analysis.

As a plus, we also agreed that the output of OAF could be improved by adding more output mediums. From the original PDF-over-email report (Fig. 2), we decided to add several others: a web application, a raw data file, and we plan to add Python notebooks as well, to allow users to explore the results further (Fig. 3).

Figure 2: Original architecture of OAF.

One more incentive to the redesign was that the original OAF has been developed in Python 2. This fact meant that a full rewrite was not necessary, but large chunks of the old code could be kept in the new architecture with minimal or no changes.

During the redesign, we identified several logic units and split the codebase into meaningful modules, which were then reconnected over a more explicit API. This process proved to be very helpful to the codebase simplification goal we identified earlier.

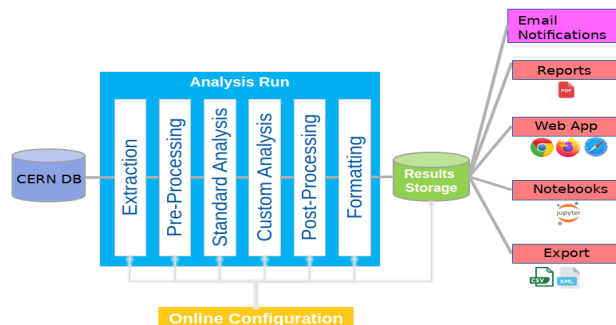

Figure 3: OAF architecture after the redesign.

In between the last step of the analysis and the output, we also introduced the concept of *results storage*, a temporary store for the processed data. This storage was critical to make our web interface capable of showing the analysis' results without having to re-run the analysis itself from the original logged data. This storage, though, also represented a challenge, as we wanted to avoid data duplication with the database as much as possible. We finally decided to use HDF5 files for storage, due to the format's properties and its capability to efficiently store complex data structures.

Along with the intermediate storage, we also developed a small utility library to act as an interface between the raw files and the Python code, called *oaf-commons*, which could be shared between the proper OAF pipeline and the web application without incurring in more code duplication.

As a result of the redesign the runtime architecture completely changed. This can be seen in the Figure 4. The users interact with the system through a web application that will be described in the next paragraph. For complex analysis where custom code is needed it will be placed directly in Gitlab. The OAF engine gets from Gitlab all the configuration and the custom code. It queries the logging database and produces results in a distributed file system. Then, the web application can access these results and display them.

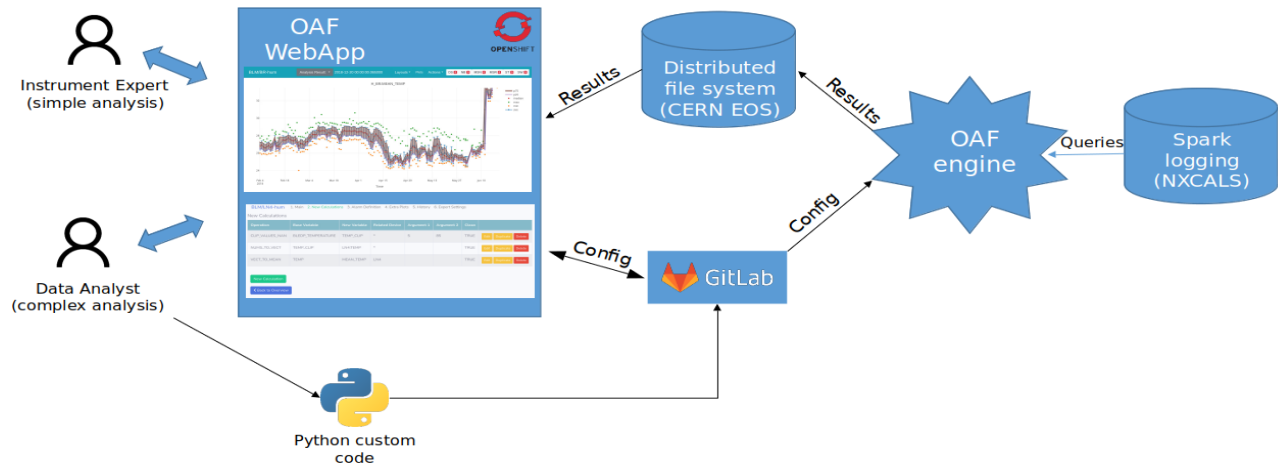

Figure 4: Runtime architecture.

## OAF WEB APPLICATION

The OAF Web Application (Webapp), is a web based application in Python using Django Framework for both visualization of BI data results and analysis configuration.

### Visualization of Results

All the HDF5 files that contain the different instrument analysis results are saved in a specific directory. In the Webapp, a list of different instrument analysis where we can browse between results from different dates is generated. By default one plot is visualized but there is also the option to visualize two or four plots the same time (Fig. 5).

Figure 5: OAF Webapp instrument analysis example.

There are several alarms, various plot types and categories. OAF can raise an alarm in the following instances:

- MISSING: Alarm raised in case of missing entities.
- NB\_REC: Alarm raised when number of records is not as expected.
- DISCRETE: Alarm raised if values do not belong to the given list of values.

- MEASURE: Alarm raised if values do not remain within given range.
- STATUS\_BIT: Alarm raised if the state of status bit register does not correspond to the nominal state of each bit.
- SWITCH: Alarm is raised each time a value is changed.

The following plot categories that are already implemented are:

- Default Plots: Input data used for the analysis coming from NXCALs.
- Extra Plots: Produce more complex plots and tables combining default plots or custom ones on demand.
- Historical Plots: Show evolution of parameters across different analysis executions.
- Admin Plots: Monitoring and analysis of OAF itself.
- Info Plots: Summary of alarms and other info.

Each of these categories can produce different types of plots. These types can be value over time, value over value, Histogram, Num-box, Tables and many more.

Quite often we need to transform the displayed results in order to understand better the measurements. The most common conversion types (statistic calculations, FFTs, KDE) have been identified and are made available to the user. Different plot features are already implemented, providing like this a deeper, more specific and accurate analysis according to the users' needs.

An overview of all the alarms that were detected the last 24h in each of the available instrument analyses is provided in a table (Fig. 6).

[Back to Overview](#)

Figure 7: OAF Webapp configuration wizard.

## Analysis Configuration

Apart from the visualization of results in the Webapp one can define the configuration of the analysis. Until today the user had to configure excel files without hints and error control. In the Webapp version we provide a user friendly interface guiding the user through a wizard.

Configuration is achieved by the modification of different tables (Fig. 7) that are stored in an internal database. This allows the configuration of many features of the framework. The instrumentation experts do not have to provide any code for a common usage case. The different table categories are the following:

- Main: General information.
- New Calculations: Declaration of new variables based on extracted ones.
- Alarm Definition: The criteria for the alarms.
- Extra Plots: Creation of complex plots combining default ones based on the already existing variables or the new ones that are declared in the New Calculations table.
- History: Evolution of parameters over a long time span.
- Expert Settings: The user can add expert code in order to include more functionalities than we already provide.

Different analysis management options are already available. Through these options the user can deploy the configurations to the production server, import existing configurations, compare if there is a difference between the current modifications and the production server and finally re-run the analysis. A new user can also create an analysis for an instrument by initially adding an empty one or importing an existing one. An overview table with the current status of all the analyses gives details about the production state, including inconsistencies between development and production configuration.

## Technologies Involved

The Webapp is running in the local network of CERN with limited access to the CERN users only with a Single-Sign-On (SSO). For the development we use Django [4], an open source web application framework written in Python. The data analysis code is written in Python using libraries such as Plotly, NumPy, SciPy, Pandas. Using Gitlab's CI/CD tool the Webapp is deployed on Openshift after every change in the code, once the unit test have passed.

## EXAMPLE USE CASES

We have selected two use cases to illustrate where the OAF is being used today. A full list would be too long to be covered in the paper. At the end of the LHC run 2 (end of 2018) there were nearly 100 use cases running daily.

The ability to measure luminosity on an absolute scale is essential for CERN's Large Hadron Collider (LHC) physics experiments [5]. The dominating contribution to the final uncertainty of the absolute luminosity calibration originates from the bunch current normalization. Thus, one important use case of OAF has been to assess and monitor our current different measurement performance. We are systematically cross-checking the measurements of the four DC BCTs (Beam Current Transformer) and the two fast BCTs to detect deviations between them. The calibration of all these instruments is compared with lab measurements to make sure that the absolute values are correct.

A second simpler example is the regular surveillance of the control of the water cooled racks temperatures hosting our Beam Position measurement electronics to prevent calibration changes caused by the building temperature variations (Fig. 8). We have to make sure that the temperature variations are below 1°C so that the orbit calculations are not affected.

Figure 8: Temperature evolution envelop (min, max, median and a box from 1st quartile to 3rd) of the different sensors located in LHC building SR1.

## EVOLUTION

We have several ideas to improve OAF in the short term. For the whole life cycle of an analysis, it is still necessary to open different tools. Our goal is to have a single entry point application that will allow to configure all the required steps (data logging, data preprocessing, data queries, analysis configuration, visualization, export).

We are also looking to have a full Python code base. Today we still need some Java functions to query the Spark based Accelerator Logging (NXCALS).

In the medium term, we want to improve and modernize the analysis capabilities of OAF to be able to cover new use cases. We are currently surveying the needs of users in the Beam Instrumentation group.

## CONCLUSION

The Offline Analysis Framework was developed some years ago to systematically analyze beam instrumentation data. The tool has helped diagnose and solve numerous issues so far. In the meantime, the technologies it is based on have evolved and opened new possibilities. This paper

presents a first step towards this direction by introducing a web-based self-service tool for the users to configure their analysis and visualize the results. A second future step will be to focus on the extensions of the analyses algorithms that can be used within the tool.

## ACKNOWLEDGEMENT

We would like to thank our colleagues in the hardware teams of the Beam Instrumentation group for their input of new features needed for OAF. We would also like to thank our colleagues in the Controls Group for providing the infrastructure that OAF requires to run.

Engineering, Old Dominion University, Norfolk, Virginia, USA

### Abstract

Field emission control, mitigation, and reduction is critical for reliable operation of high gradient superconducting radio-frequency (SRF) accelerators. With the SRF cavities at high gradients, the field emission of electrons from cavity walls can occur and will impact the operational gradient, radiological environment via activated components, and reliability of CEBAF's two linacs. A new effort has started to minimize field emission in the CEBAF linacs by re-distributing cavity gradients. To measure radiation levels, newly designed neutron and gamma radiation dose rate monitors have been installed in both linacs. Artificial intelligence (AI) techniques will be used to identify cavities with high levels of field emission based on control system data such as radiation levels, cryogenic readbacks, and vacuum loads. The gradients on the most offending cavities will be reduced and compensated for by increasing the gradients on least offensive cavities. Training data will be collected during this year's operational program and initial implementation of AI models will be deployed. Preliminary results and future plans are presented.

### INTRODUCTION

The Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Lab is a high power, continuous wave recirculating linac that completed an energy enhancing upgrade to 12 GeV in 2017 [1]. This upgrade included the installation of 11 additional higher gradient cryomodules, named C100s for their capability of producing a 100 MeV energy gain. Field emission (FE) is a well-known phenomenon in superconducting radio-frequency (SRF) cavities that can have deleterious impact on accelerator hardware, cryogenic heat loads, and machine operations. Field emitted electrons can be accelerated similarly to CEBAF's electron beam and can generate neutron and gamma radiation on impact. Managing FE in CEBAF's C100 cryomodules has emerged as an on-going operational challenge since the 12 GeV upgrade (Fig. 1).

CEBAF recently designed, built, calibrated, and installed neutron dose rate meters (NDX) [2]. The NDX monitors are deployed around CEBAF with a majority of detectors placed near the newer higher gradient cryomodules. This new system allows for more detailed measurements to be made of the radiation response to RF

configurations and is currently being used to minimize the FE-based radiation through manual gradient optimizations.

Figure 1: CEBAF schematic denoting the location of C100 cryomodules. One north linac C100 was removed for refurbishment during the time of this study.

Several beam studies were conducted during CEBAF restoration that leveraged the NDX system to measure FE-related radiation response to changes in cavity RF gradients. This data provides an ample training set for the development of artificial intelligence (AI) models to aid operations in maintaining a lower radiation environment. Preliminary attempts at modeling radiation as a function of gradient appear successful.

### NDX SYSTEM

Installation and commissioning of the NDX system was completed in August 2021. The system has 21 detectors positioned at strategic locations in the CEBAF tunnel. The majority of these detectors are positioned around the newer higher gradient cryomodules with names corresponding to the adjacent downstream cryomodule. These detectors are primarily designed to measure neutron radiation, but as an ancillary and necessary feature, they also provide measurements of gamma radiation dose rates. The NDX system is now the primary tool for measuring FE-related radiation at CEBAF.

Electrometers associated with the detectors measure the current signal over a variable integration time period, typically set to one second. These signals are converted to

<sup>†</sup>adamc@jlab.org

dose rates, presented over CEBAF's standard EPICS control system, and stored in the control system archiver.

## PROBLEM OF FIELD EMISSION

SRF cavity walls may emit electrons when exposed to a sufficiently high RF gradient, which are subsequently accelerated by the same RF field. Electrons are emitted with an exponential response to increases beyond this onset threshold. Many of these electrons quickly impact the cavity and are reabsorbed, potentially causing increased cryogenic heat load or radiation. However, some FE electrons are captured by RF fields and transported long distances ( $>100$  m) through adjacent cavities and cryomodules either upstream or downstream [3]. These electrons eventually collide with accelerator hardware producing much higher radiation levels at the new location.

This radiation has several deleterious effects on CEBAF operations. For example, hardware can be damaged requiring early replacement, components can become activated which present hazards for nearby work, and the increased radiation and field emission can increase the number of machine trips or lower the maximum operational gradient ("operational drive high") that can be achieved. These issues all contribute to increased CEBAF downtime and lowered energy reach. Field emission control, reduction, and management is critical for reliable, high gradient operation at CEBAF.

Field emission during CEBAF operations is largely impacted by contamination on the cavity wall surface. SRF cavity fabrication uses state-of-the-art surface processing and assembly techniques to control FE, however, particulates may be introduced through activities such as vacuum valve operations or installation work [4, 5]. Trace gasses may freeze on to cavity wall surfaces and activate or degrade existing field emitters [5]. These gasses may also be removed during warm-up events or over time during RF operations.

Ideally, all cavities could be run below the FE onset gradient. However, CEBAF's experimental requirements demand that many cavities are set beyond this threshold in order to meet the target energy of experimenters. Thus the question becomes how to best distribute gradient in order to reduce FE across a linac. CEBAF operations staff already have tools available for automatic gradient distribution to optimize for common cavity faults and other operational criteria. Our goal is to first develop AI tools to help operators better leverage the existing toolkit, rather than replace the existing automated gradient distribution process.

During summer 2021, operations staff used manual investigations of FE-related radiation response to changes in gradient to achieve large-scale reductions in radiation while maintaining linac energy gain. Use of machine learning (ML) models and advanced optimization techniques may be able to surpass these manually found settings. Additionally, operational conditions evolve and change during an experimental run. Existing field emitters may degrade or new ones appear. Operational limits on cavity gradients change as hardware fails or is repaired. As

such operations would need to continue fine tuning this optimization throughout a run as time and manpower allow. AI may be able to provide similar functionality without the need for time consuming manual efforts.

These operational characteristics raise interesting questions regarding the management of FE:

1. Given a machine configuration, can the cavities that are the leading contributors to FE-radiation be identified? This would allow for off-line optimization work to be performed without interrupting beam delivery.
2. Can changes in existing field emitters be detected and localized? This would allow degraded or improved field emitters to be identified for manual operator intervention or possibly to inform updates to existing ML model regarding the previous question.
3. Can the appearance or elimination of field emitters be detected and localized? Completely new field emitters would likely pose a challenge for ML models trained on old data. Quickly identifying these would alert users that the model needs to be re-trained, and improve the rapidity of manual interventions.

Currently, these questions can be answered manually by invasively adjusting cavity gradients to explore the machine response. However, this process can take hours. This level of effort and beam studies time is difficult to obtain during experimental runs. Providing non-invasive AI methods to replace or enhance existing manual optimizations could enable CEBAF to maintain a lower level of FE during operations.

## DATA COLLECTION METHODS

Our initial approach to these problems is to focus on the response of the C100 cryomodules at the end of the north linac. Two types of data were collected during beam studies, the radiation onset for C100 cavities, and radiation responses to a range of operational C100 gradient settings. First, the radiation onsets of C100 cavities were determined under pseudo-operational conditions. This is subtly different, but closely related to, a cavity's FE onset. The radiation onset measurements determine the highest gradient a cavity can achieve before the NDX system can definitively detect an increase above background radiation in a configuration approximating normal beam operations. Secondly, we measured the radiation response across the linac using the NDX system while scanning a range of gradients consistent with normal operations.

### *Radiation Onset*

Automated radiation onset measurements were performed via software on one cryomodule at a time. First we turn off RF in at least the adjacent four cryomodules on either side to remove radiation generated by other cavities. Then all cavity gradients in the cryomodule of interest were increased as much as possible without causing a noticeable rise in radiation.

Once this elevated baseline was achieved, each cavity was individually walked up in 0.125 MV/m steps until a significant increase in radiation was observed. Determining if radiation levels exceeded background was done using a statistical comparison. Unconverted NDX detector current signals were sampled for ten seconds at the start of the scan to establish the background. Then similar samples were taken after each step. A difference in average currents of ten standard errors was considered statistically significant. Our statistical approach typically corresponded to a dose rate increase on the order of 1-10 mrem/h. This automated onset scanning procedure requires approximately one hour to find the radiation onsets for the eight cavities in a cryomodule. However, we believe there is opportunity for considerable speed enhancements.

### Gradient Scan

A gradient scan was conducted by setting the entire linac to RF settings consistent with an energy gain used during experimental runs. This process sets all C100 cavities to their operational maximum gradients (drive high limits). From this starting point, we systematically stepped all of the C100 cavities' gradients down.

Each stage of a gradient scan consisted of stepping down individual cavity gradients in identical step sizes and in a randomized order. After turning down a cavity, we waited several seconds for the cryogenic system to settle, then allowed several seconds for dedicated radiation measurements. Data was collected for both the settle and dedicated measurement periods as radiation responses appear to be similar during both phases.

Figure 2: A single gradient scan using three 1 MV/m steps (top). The measured neutron (middle) and gamma (bottom) dose rates (rem/h) show the reduction in radiation as cavity gradients are lowered.

Figure 2 shows a single gradient scan and its radiation response. Notice that the reduction in radiation is a mix of plateaus and steep declines. This likely indicates that specific cavities were the primary field emitters as

radiation levels dropped with small changes to gradient. In this example, radiation is practically eliminated while gradients have been indiscriminately reduced 15-20% below their standard operational settings. A more optimal approach could likely achieve similar radiation reductions while sparing much of the gradient losses.

A single gradient scan consisted of several such identical stages. A typical scan with three stages could be completed in approximately 20 minutes. As was the case with onset scans, there are opportunities to speed up the process by either collecting fewer samples per step, requiring less wait time after gradient change to collect data, or by algorithmic enhancements.

Multiple scans were performed at various step sizes ranging from 0.1 MV/m to 1 MV/m, and were performed starting at various offsets from the C100 cavities' maximum gradients. This allowed for a range of gradient combinations covering the highest 3 MV/m range of each cavity to be explored. All gradient scan data collection was managed by CEBAF's EPICS control system archiver, with the data collection software maintaining an index file for later retrieval.

### DATA EXPLORATION

The gradient scans produced 17,940 samples (10 samples for each of the 1,794 gradient combinations explored during the scans). After data cleaning, 17,610 samples remained. The gradient scans produced a broad range in radiation mimicking dose rates that will be seen during operations (Fig. 3). Higher dose rates are possible but not achievable during beam studies without exceeding the current operational limits.

Figure 3: Radiation dose rate measured by NDX detectors during gradient scan studies. Each dot represents a single one-second integrated measurement. Six detectors (1L22-1L27) are positioned near C100s in the north linac.

C100 gradient settings were very positively correlated with individual radiation readings and radiation readings

were highly correlated amongst detectors near the C100 cryomodules (Fig. 4). Positive correlations were expected between gradients and detector readings given that, in general, higher gradients lead to higher radiation. Readings between detectors were also expected to be positively correlated as they occupy the same linac tunnel. However, it is possible that the structure of the gradient scans, where all C100 cavity gradients were stepped down in stages, exaggerated the correlations between detectors. Future gradients scans should keep this concern under consideration and allow additional randomness in the scanning procedure.

Figure 4: Dose rates were very positively correlated among the C100-adjacent NDX detectors. Correlations between other detectors were likely due to changes in non-C100 configurations between beam studies. Note that the same cryomodules are listed twice, once for gamma radiation and once for neutron.

## MODELING RESULTS

We developed a preliminary model to address the first operational FE problem, i.e., identifying cavities that are leading offenders. Our initial approach is to directly model the radiation produced at all C100-adjacent detectors as a function of C100 cavity gradients and radiation onset values. Given a sufficient model, standard “black box” optimization techniques can be used to optimize the gradient settings, or an automated procedure can check which gradients will have the most anticipated impact on radiation production.

Preliminary attempts at modeling the radiation readings as a function of cavity gradients and radiation onset values used a multi-output random forest regressor [6] trained on 12,302 examples and tested on 5,308 examples for a 70/30 split. Examples taken from repeated measurements of a gradient configuration were grouped exclusively into the training or testing set to ensure the test data was unseen during training. Model development was performed using the scikit-learn python package [7].

Early attempts to model radiation using solely untransformed cavity gradients were unsuccessful.

However, providing a feature set that more closely mimics the described physical process proved effective [3]. For this model, the following five features per cavity were engineered:

1. Surface FE:  $g_i = 2^{max(gmes_i - rad\_onset_i, 0)}$
2. Upstream energy gain:  $u_i = \sum_j(gmes_j)$  where cavity j is upstream of cavity i
3. Downstream energy gain:  $d_i = \sum_j(gmes_j)$  where cavity j is downstream of cavity i
4. Upstream interactions:  $u_i g_i$
5. Downstream interaction:  $d_i g_i$

Where  $gmes_i$  is the measured cavity gradient of cavity i, and  $rad\_onset_i$  is the radiation onset gradient of cavity i found during beam studies. These features, while crude approximations of the physical processes, are sufficient as the model achieved an R-Squared score of 0.978 using these features. Figure 5 shows the difference in observed and predicted neutron dose rates detected upstream of 1L25 as the aggregate C100 gradient changed. Table 1 gives additional metrics for model performance.

Figure 5: Testing results of the random forest model predicting neutron dose rates at detector 1L25. The model maintains small errors across the range of gradients.

A significant drawback of this approach is that the model will need to be retrained on new data when there are changes to active field emitters (i.e. if they are processed away or their onset changes). Additional work will investigate alternative modeling approaches or mitigations of this shortcoming, such as developing procedures for rapid or non-invasive data collection.

The initial modeling results provide confidence that the data from the NDX detectors, along with machine learning

techniques, can be leveraged to address the three operational questions highlighted earlier.

Table 1: Performance Metrics of the Multi-Output Random Forest Regressor

Metric	Training	Testing
R-Squared	0.999	0.978
MSE	0.001	0.052
MAE	0.013	0.115

SUMMARY

We have begun leveraging the NDX system to develop AI models capable of enhancing the management of field emission during CEBAF operations. Initial data collection and modeling efforts show promising signs that this is an effective tool to apply for that purpose. Our future work aims to refine this work with more advanced deep learning techniques and to expand the scope of the problems investigated.

# VIRTUALIZED CONTROL SYSTEM INFRASTRUCTURE AT LINAC PROJECT PINSTECH

N. U. Saqib<sup>†</sup>, F. Sher\*  
LINAC Project, PINSTECH, Islamabad, Pakistan

## Abstract

IT infrastructure is backbone of modern big science accelerator control systems. Accelerator Controls and Electronics (ACE) Group is responsible for controls, electronics and IT infrastructure for Medical and Industrial NDT (Non-Destructive Testing) linear accelerator prototypes at LINAC Project, PINSTECH. All of the control system components such as EPICS IOCs, Operator Interfaces, Databases and various servers are virtualized using VMware vSphere and VMware Horizon technologies. This paper describes the current IT design and development structure that is supporting the control systems of the linear accelerators efficiently and effectively.

## INTRODUCTION

LINAC Project, PINSTECH aims at developing indigenous RF linear accelerators for medical and industrial purposes. Along with progressive research in this field, prototypes of 6 MeV Medical and Industrial (NDT) linear accelerators are being developed. IT infrastructure provides computing, network and storage resources, as well as several services to the accelerator control system, and also to engineers and scientists involved in research and development tasks. An Ethernet based Local Area Network (LAN) is deployed at LINAC Project. The overall LAN is divided into two segments: *Technical Network* and *Office Network*. Both networks are isolated and contain independent IT infrastructure. Measurement and control devices including commercial-off-the-shelf equipment and related devices are connected to the *Technical Network* while *Office Network* consists of users related devices including scientists' and engineers' PCs, printers, scanners, test equipment etc. For compute resources, Dell EMC PowerEdge servers are configured and installed to provide reliable services for both the networks. Servers are managed remotely via Integrated Dell Remote Access Controller (iDRAC) which eliminates the need of physical presence of server administrator to configure/reconfigure a server. For network resources, Allied Telesis Gigabit Ethernet network switches are installed to provide network connectivity and high bandwidth data transfer between nodes in the networks. Three types of network switches are utilized: unmanaged, web-smart and managed according to purpose of utilization. As multi-core processors become common, virtualization is an important technology to implement full utilization of hardware resources and reduce their footprint [1]. Virtualization enables running multiple virtual PCs simultaneously on one physical machine and allows multiple operat-

ing systems to work at the same time and on the same machine. Main advantage of virtual machines is that hardware resources such as processor, memory, hard disk, device controllers, network cards etc. can be dynamically increased or decreased according to the requirements.

## SERVER VIRTUALIZATION

Server virtualization divides a physical server into multiple virtual machines by means of a software layer called hypervisor. Virtualization fully utilizes a physical server by distributing workload on virtual servers. Additional benefits include less hardware to buy and manage, more efficient resources usage and improved resilience. Dell EMC PowerEdge servers [2] are virtualized using VMware vSphere 6 [3] technology which is a data center virtualization solution. VMware vSphere consists of two components: VMware ESXi which is a type 1 hypervisor installed on bare metal server and vCenter Server which provides centralized management platform for ESXi hosts, virtual machines and other dependent components. Two Dell R740 servers are deployed in the *Office Network* and one Dell R630 server is deployed in the *Technical Network*. Specifications of both types of servers are provided in Table 1 and Table 2 respectively.

Table 1: Specifications of Dell R740 Server

Component	Specification
CPU	Intel Xeon Silver @ 2.1 GHz x 2
RAM	64 GB (32 GB x 2)
HDD	8 TB (2 TB x 4)
OS	VMware ESXi 6.7

Table 2: Specifications of Dell R630 Server

Component	Specification
CPU	Intel Xeon Silver @ 2.1 GHz
RAM	32 GB (16 GB x 2)
HDD	6 TB (2 TB x 3)
OS	VMware ESXi 6.7

## TECHNICAL NETWORK

All components related to control system consisting of servers, desktop computers and commercial-off-the-shelf equipment are connected to the *Technical Network* to pro-

<sup>†</sup> najm.control@gmail.com

<sup>\*</sup> falaksher@gmail.com

vide isolation, security and reliability [4]. Dell EMC PowerEdge R630 virtualized server deployed in the *Technical Network* and shown in Fig. 1 provides the following services:

### EPICS IOCs

EPICS (Experimental Physics and Industrial Control System) is a software toolkit to develop distributed control systems[5]. EPICS IOCs (Input/Output Controllers) deployed in our control system are soft IOCs operating in open source CentOS 7 operating system. IOCs are suitable to be run in virtual machines because none of the devices are directly attached to the hardware. Also, serial interfaces are converted to Ethernet by means of MOXA and USB-IOT Serial-to-Ethernet converters wherever possible.

### Operator Interfaces

Operator Interfaces (OPI) are developed in Phoebus Control System Studio (CSS) which is a set of tools and application for developing Graphical User Interfaces (GUI) [6]. CSS is installed in a virtual machine and OPIs are designed and developed on it. OPIs are then deployed to *Operator Computer* in the *Control Room*.

### Data Archiver and Alarm Services

Data archiver for recording history of process variables is implemented using CSS Best Ever Archive Toolset, Yet (BEAUTY). Alarm services for notifications about events is implemented using CSS Best Ever Alarm System Toolkit (BEAST). Both of these services are configured in CentOS 7 OS based virtual machine.

### Database

Relational database for data archiver system is provided via MySQL server running in Microsoft Windows virtual machine.

### Network Services

Domain controller residing in a virtual machine provides essential network services such as Active Directory Domain Services (ADDS), Domain Name System (DNS), Dynamic Host Configuration Protocol (DHCP), Windows Deployment Services (WDS) and File Transfer Protocol (FTP) servers.

Figure 1: Technical Network Virtualization.

## OFFICE NETWORK

General network consists of personal computers of engineers and scientists, workstations for simulations, servers for services and other equipment such as printers, scanners, test equipment etc. Two Dell EMC PowerEdge R740 servers deployed in the office network are virtualized using VMware ESXi 6.7 as shown in Fig. 2. These servers provide the following services:

### vCenter Server

Open SUSE OS based vCenter Server appliance for managing ESXi hosts, virtual machines, network and storage.

### Network Services

Domain controller provides essential network services such as ADDS, DNS, DHCP, WDS and FTP servers.

### VMware Horizon Server

Microsoft Windows Server 2016 VM contains VMware Horizon View 7.11 Connection Server for providing Virtual Desktop Infrastructure (VDI). It provides a web based client interface to manage VDI. Adding/removing desktop pools, assignment of virtual machines to the pools and adding/removing of users' entitlements are few of the several important tasks managed through the client.

### Nextcloud Hub

Centos 7 VM for Nextcloud Hub [7] provides collaboration platform for scientists and engineers. It provides many features such as file sharing, storage, announcements, chat, contacts, photos etc.

### GitLab Server

CentOS 7 VM for GitLab server provides version control system and much more. It is a private server consisting of five users and is being tested currently. After testing, it will be integrate into the system soon as it provides essential services for software development.

Figure 2: Office Network Virtualization.

## VIRTUAL DESKTOP INFRASTRUCTURE

Virtual Desktop Infrastructure refers to desktop hosting environment on a central server that manages and allows access of desktop and server operating systems running in virtualized machines, and deploys them to end-users on requests [8]. VMware Horizon 7 is used to provide desktop virtualization environment at our facility. Currently, main purpose of VDI is to provide internet access, and to provide remote workstations to scientists and engineers for helping out in their research and development tasks. Access to internet services is provided to users through a virtual machine that contains a dedicated network interface to a public network. HP Zero Clients and Horizon client software for Windows are used at end-user side to connect remotely to these desktops. Other desktops configured include dedicated user PCs for some users. Figure 3 presents layout of the deployed system.

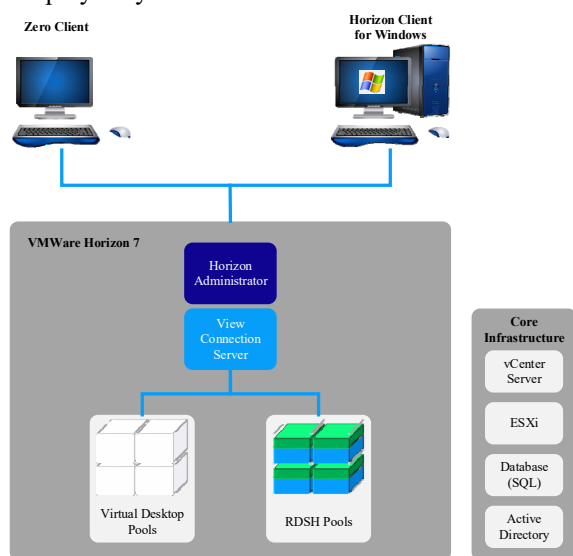

Figure 3: VDI Layout.

## CONCLUSION

Virtualization technology has greatly improved development & deployment of the control system and services in terms of stability and reliability. Office Network is providing services as well as a collaboration platform for scientists and engineers. There is a room for a lot of improvement including new hardware and software technologies. We are gradually moving in the right direction but are limited with manpower and expertise. We expect significant upgrades in near future.

# STATUS OF HIGH LEVEL APPLICATION DEVELOPMENT FOR HEPS\*

Xiaohan Lu<sup>†</sup>, Qiang Ye, Hongfei Ji, Yi Jiao, Jingyi Li, Cai Meng, Yuemei Peng, Gang Xu,  
Yaliang Zhao

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

## Abstract

The High Energy Photon Source (HEPS) is a 6 GeV, 1.3 km, ultralow emittance ring-based light source in China. The construction started in 2019. In this year, the development of beam commissioning software of HEPS started. It was planned to use EPICS as the control system and Python as the main development tools for high level applications (HLAs). Python has very rich and mature modules to meet the challenging requirements of HEPS commissioning and operation, such as PyQt5 for graphical user interface (GUI) application development, PyEPICS and P4P for communicating with EPICS. A client-server framework was proposed for online calculations and always-running programs. Model based control is also one important design criteria, all the online commissioning software should be easily connected to a powerful virtual accelerator (VA) for comparison and predicting actual beam behaviour. It was planned to use elegant and Ocelot as the core calculation model of VA.

## INTRODUCTION

The High Energy Photon Source (HEPS) is a 6 GeV, 1.3km, green-field 4<sup>th</sup> generation storage ring light source [1]. For this light source, the lattice design and related physics studies were basically finished [2-6], and the construction started in mid-2019. The machine commissioning of LINAC is expected to start in mid-2022. By this time, the high level applications (HLAs) for beam commissioning are indispensable.

To achieve this goal, the development of HLAs started this year. Before the start of development, we investigated the HLA schemes of almost all the running light sources. Most of them use the Matlab Middle Layer Toolkit (MML) [7, 8] as the main commissioning tools, and part of them developed new specific commissioning tools, such python-based aphla of NSLSII [9], and python-based HLA of Sirius [10]. Recently, python becomes more and more popular in every walk of life, due to its powerful modules and easy-to-learn characteristic. And more and more labs use python as the main development tools for control software and data analysis tool. In consideration of future development, economic and time cost, for the HEPS python was chosen as the main development tools, and EPICS as the control system. Python has very rich modules to meet the demands of HLA. PyQt5 was used to develop GUI app, will be update to pyqt6 in near future, PyEPICS and P4P were used as the communication tools. The HLA of HEPS is model-based, we decided to use Elegant [11] and Ocelot [12] as the core calculation models. A client-

server framework was proposed for online calculations and always-running programs. All the online commissioning software should be easily connected to a powerful virtual accelerator (VA) for comparison and predicting actual beam behaviour.

## APPLICATIONS FRAMEWORK

The development of HLA is collaborative work between the control group and physics group. The whole control system framework is shown in Fig. 1, all the applications were classified into three categories: parameter display and hardware controls, algorithm-based applications for tuning or measurements, model-based applications. The accelerator physics group is responsible for the development of the algorithm-based and model-based applications (the green part in Fig.1), and the control group is responsible for the development of the rest of applications and the construction of the low-level control applications (the blue part in Fig. 1).

The control group chose Control System Studio (CSS) [13] and python display management (PyDM) to build the parameter display and hardware control applications. The accelerator physics group is responsible to develop a brand new platform python accelerator physics application set (Pyapas) to build the HLA, as shown in Fig.2 with the aim of including all necessary tools and modules.

Pyapas is not only a set of applications, but also designed as a platform for the rapid development of HLA. Pyapas learns design philosophy from PyDM [14] and OpenXAL [15]. There are three principles of Pyapas, the first one is that all the applications are physical quantity based. The parameters we work with should be physical quantity. For example, when we do the orbit correction, we should change the magnetic field rather than the current of the correctors. The second one is that most of the applications should be server-based, the calculation process could be running in the background. The third one is that the applications should be model-based, all the applications could be connected to the VA, use the simulation results to tune and predict the behaviour of the beam.

According to the design principles, a clear roadmap was made to develop Pyapas. The drag-and-drop way should be implemented to develop GUI applications quickly. To develop server-based application, a robust and convenient client-server framework is indispensable. The model-based applications and VA require powerful physical models, for the moment we decide to use the exist mature simulation code Elegant and Ocelot as the core physical model. To

\*Work supported by NSFC (12005239)

<sup>†</sup> luxh@ihep.ac.cn

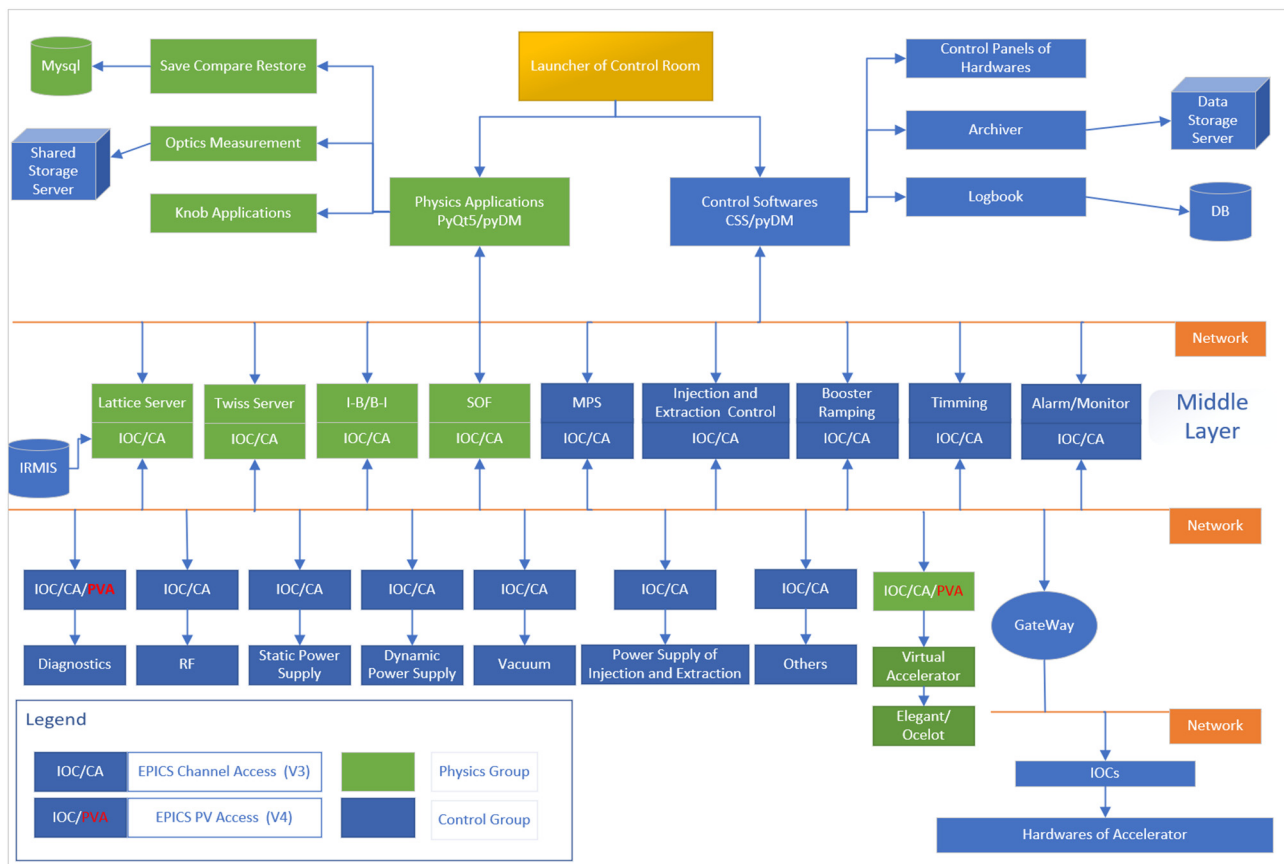

Figure 1: The structure of the control system.

make the development of model-based application intuitive, a new structure will be developed to describe the whole accelerator. For example there will be a magnet class to describe a real magnet, and an instance of this class will hold all the information of one magnet include channels and connector to call tracking algorithm. With these classes it is convenient to control machine and setup simulation, even control the machine based on simulation results. And the channel class based on EPICS for communication with machine should also be embedded. The adaptor for connecting to database is also on the development list.

The above development list describes the core elements of Pyapas, but it's not the ultimate goal. Machine learning is also on the development list, data acquisition and model training modules will be added to Pyapas. With trained model it will be easily to predict and control the actual machine through Pyapas.

To achieve the above goals, lots of development tasks have been started and some were already done. Extended QtDesigner was added to Pyapas as GUI development tool. Many customized widgets were embedded for rapid development, such as plot widgets, table widget with filter. The connectors were developed to connect to elegant and ocelot used as the core physical model. RPC and mDNS were implemented to build service applications, and adaptor for MySQL was also added to connect the database.

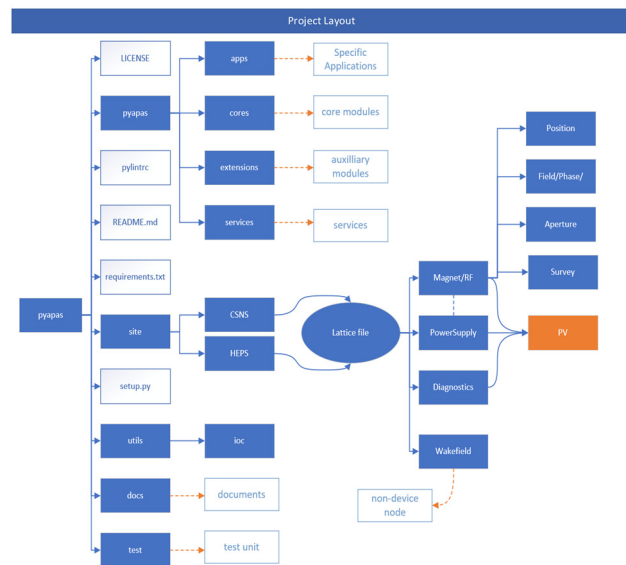

Figure 2: The structure of Pyapas.

## APPLICATIONS UNDER DEVELOPMENT

For the requirements of the upcoming LINAC commissioning, the necessary applications are already under development, includes launcher, orbit correction, phase scan, emittance measurement, beam based alignment, energy and energy spread measurement, virtual accelerator and so on.

As shown in Fig. 3, the launcher application is service-based. All the applications of Pyapas will register itself on the local network through mDNS, and the launcher could monitor the status of all the launched applications and do the close and launch actions.

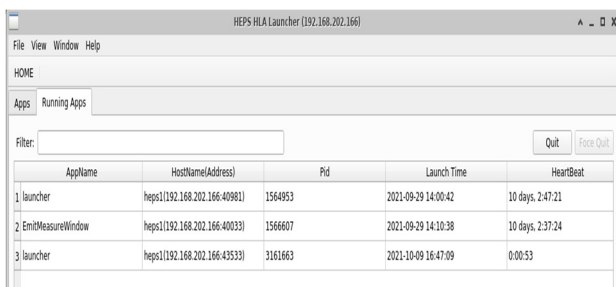

Figure 3: The snapshot of launcher.

The virtual accelerator shown in Fig. 4 is also service-based. There is a virtual IOC system which hold the same records of the real machine but start with prefix 'V'. The calculation engine built based on elegant and ocelot will supply the simulation values to the virtual IOC. For the commissioning software, the VA is same as the real machine, together with some auxiliary modules, we could also get the Twiss parameters in real time.

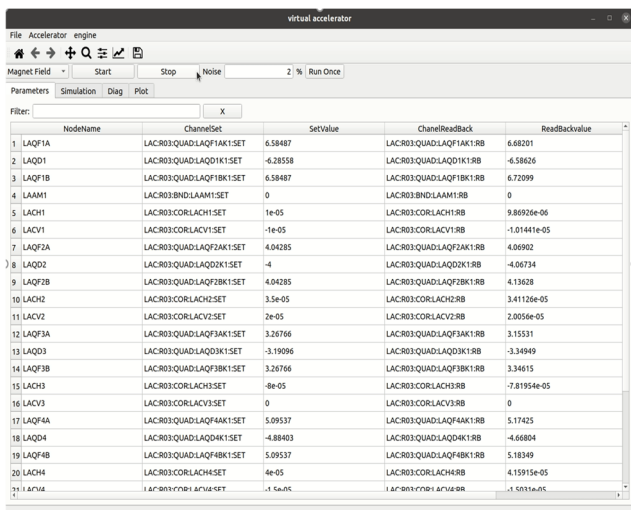

Figure 4: The snapshot of virtual accelerator.

## CONCLUSION

The development of HLAs for HPES started this year. A new python-based flexible framework Pyapas is proposed to build HLA of HEPS. Pyapas is positioned as a platform for rapid development of beam commissioning software, it will be as convenient as CSS. Different from CSS for building display and hardware control applications, Pyapas is designed to build model-based applications. We keep adding new features and modules to it to make it more powerful.

To meet the requirements of upcoming beam commissioning of LINAC, the necessary applications are under development.

# NOVEL CONTROL SYSTEM FOR THE LHCb SCINTILLATING FIBRE TRACKER DETECTOR INFRASTRUCTURE

M. Ostrega, M. Ciupinski, S. Jakobsen, X. Pons  
CERN CH-1211 Geneva 23, Switzerland

## Abstract

During the Long Shutdown 2 of the LHC at CERN, the LHCb detector is upgraded to cope with higher instantaneous luminosities. The largest of the new trackers is based on the scintillating fibres (SciFi) read out by Silicon PhotoMultipliers (SiPMs). The SiPMs will be cooled down to  $-40^{\circ}\text{C}$  to minimize noise. For performance and integration compatibility, the cooling lines are vacuum insulated. Ionizing radiation requires detaching and displacing the readout electronics from Pirani gauges to a lower radiation area. To avoid condensation inside the SiPM boxes, the atmosphere inside must have a dew point of at most  $-45^{\circ}\text{C}$ . The low dew point will be achieved by flushing a dry gas through the box. 576 flowmeters devices will be installed to monitor the gas flow continuously. A Condensation Prevention System (CPS) has been implemented as condensation was observed in previous detector operation tests. The CPS powers heating wires installed around the SiPM boxes and the vacuum bellows isolating the cooling lines. The CPS also includes 672 temperature sensors to monitor that all parts are warmer than the cavern dew point. The temperature readout systems are based on radiation tolerant multiplexing technology at the front-end and a PLC in the back-end.

## INTRODUCTION

### SciFi Tracker

The SciFi tracker consists of three stations each with four detection planes. The detector is built from individual modules ( $0.5\text{ m} \times 4.8\text{ m}$ ), each comprising 8 fibre mats with a length of 2.4 m as active detector material. The fibre mats consist of 6 layers of densely packed blue-emitting scintillating fibres with a diameter of  $250\text{ }\mu\text{m}$  (see Fig. 1). The scintillation light is recorded with arrays of state-of-the-art multi-channel silicon photomultipliers (SiPMs). A custom ASIC is used to digitize the SiPM signals. Subsequent digital electronics performs clustering and data-compression before the data is sent via optical links to the DAQ system. To reduce the thermal noise of the SiPM, in particular after being exposed to a neutron fluence of up to  $10^{12}\text{ neq/cm}^2$ , expected for the lifetime of the detector, the SiPM arrays are mounted in so called cold-boxes and cooled down by 3D-printed titanium cold-bars to  $-40^{\circ}\text{C}$ . The detector is designed to provide low material budget (1 % per layer), hit efficiency of 99 % and a resolution better than  $100\text{ }\mu\text{m}$ . These performance figures must be maintained over the lifetime of the detector which will receive radiation dose up to  $35\text{ kGy}$  near the beam pipe. The full detector, comprising 590 000 channels, is read out at 40 MHz [1].

## Detector Infrastructure

Three control systems have been developed in order to allow the operation with correct environmental parameters for the SciFi infrastructure were developed. In this paper, the vacuum system, condensation protection system and flowcells monitoring system were described.

Figure 1: LHCb SciFi Tracker assembly.

## VACUUM SYSTEM

### System Overview

The SciFi vacuum system consists of two subsystems that serve two detector sides (A & C). Each subsystem consists of a scroll pump (primary) and two turbomolecular pumps connected parallel for redundancy purposes. “Turbo” pumps set is connected to the central manifold, where are the manual valves. Those valves can insulate every C-Frame in case of maintenance. There are 48 vacuum lines (12 supply and 12 return lines per side), connecting two main manifolds with the 12 detector C-frames.

Figure 2: Turbomolecular pumps shielding.

Both vacuum subsystems are connected by the primary vacuum bypass valve, which allows the whole system for operation in case of one primary pump failure. In such a situation, both turbomolecular pumps (side A & C) runs with the same primary pump. This increases the whole system's redundancy (two turbomolecular pumps per side and two primary pumps).

Turbomolecular pumps are located on both sides, in close proximity of the detector and required to be protected against magnetic field. To allow safe operation, pumps, electro valves and two pressure gauges have been placed in the 2-layer iron shielded case (see Fig. 2). Additionally, pump drivers have been detached and located in the PLC (Programmable Logic Controller) rack in the LHCb service cavern.

### Vacuum System Controls

Each of the 12 C-Frames has two vacuum gauges for the upper manifold and lower manifold, 24 Pirani sensors in total. The presence of ionising radiation, cumulating to 50 Gy over the lifetime of the experiment, requires detaching the readout electronics from those Pirani gauges that are mounted on the manifolds (see Fig. 3). Two 3U racks (one per side) with 12 readout electronic PCB are located in the safe distance from the detector (in the bunker area). Tests shows that detaching electronic and sensor adds small offset on the readout value, which is acceptable.

The SciFi Vacuum Control System is based on Siemens S7-1500 PLC technology. It operate the system in the automatic and safe mode as well it assure the readings of the Pirani probes. The PLC program follows the UNICOS framework which allows the PLC program software connection to the WinCC OA SCADA software used in the Supervisor Layer [2][3].

THPV048

Figure 3: Pirani gauge electronic.

## CONDENSATION PREVENTION SYSTEM

### System Overview

Even though the good operation of the vacuum system, the collaboration has decided the implementation of high complex temperature measurement and heating system to avoid the condensation that may endanger the correct operation of the detector. This system, called CPS (Condensation Prevention System) consists in the installation of high-density temperature measurement network in the strategic places in the detector.

The CPS allows the monitoring, and the survey of 672 temperature sensors, Pt100 type, that are connected to radiation tolerant electronic interfaces, multiplexed and connected to a PLC, which collects all the information that is sent, a posteriori, to the Detector Control System. In case of condensation a heating wire that has been wrapped around the cooling transfer lines and the box housing the SiPMs. The heating wires can be powered by means of external power supplies. The heating power is distributed by the same electronic interfaces used for temperature measurements, in addition all the power consumption values of each circuit is measured by same interface through the PLC and sent up to the DCS for its control.

Each C-frame module (24 per C-frame) is equipped with one electrical heater and two Pt100 sensors. On each C-frame quadrant (4 per C-frame) there is one multiplexer box, which is responsible for reading 12 Pt100 signals and the measurement of the current of 6 electrical heaters. Additionally, on the MUX board, there is a power distribution and electrical protection (fuses) for six electrical heaters. One of the MUX installed on the C-frame, called MUX Master, will consist also additional multiplexer to multiplex all C-frame signals (see Fig. 4). Power to each heaters group is supplied by the MARATON power supplies. All the temperature signals (48 per C-frame, 576 in total) and heater power signals (24 per C-frame, 288 in total) are connected to the PLC located in the service cavern. Additionally, CPS monitor also cooling water temperature, which at the end gives total amount of 672 signals. All the MUX boards are based on electronics with sufficient radiation tolerance to cope with the radiation expected in the live time of the detector.

### CPS Controls

The CPS control system is based on Siemens S7-1500 PLC technology commonly used and supported at CERN.

The PLC control program follow the CERN BE-ICS control system standards (UNICOS-COMM) which allows the PLC program software connection to the WinCC OA SCADA software used in the Supervision Layer (i.e. the SciFi Detector Control System or DCS). The WinCC OA software also archive all the relevant data in an ORACLE database.

Figure 4. CPS Master multiplexing board.

## FLOWCELLS DAQ SYSTEM

### System Overview

The SiPM photodetectors are attached to cold bars through which Novec at about  $-40^{\circ}\text{C}$  is flowing. The low temperature operation of the SiPMs mitigates radiation-related dark noise. To avoid condensation and frost formation inside the cold box, in particular on the SiPM arrays, the atmosphere inside the box must be free from humidity down to a dew point (DP) of approximately  $-50^{\circ}\text{C}$ .

A complete sealing of the cold boxes is practically impossible, because the boxes need to ensure direct optical contact of the SiPMs to the scintillating fibres and also the passage of the SiPM signals via kapton flex cables to the electronic cards.

The low dew point will therefore be achieved by flushing a dry gas through the box. A small overpressure will compensate for potential leaks which could let humid air diffuse into the box. Flowmeter devices are installed on the outgoing line of each cold box in order to monitor continuously the gas flow. To insure a reliable measurement a fully redundant flow measurement is made with two flowmeters by outgoing line.

### Controls

All the flow cells signals (48 per C-frame, 576 in total) are connected to two patch panels boxes, where power is distributed (two independent power supplies) and signals are separated (normal & redundant). The patch panel is connected with the DAQ rack using 12 MCA50 cables with the length around 60m each. The readout system is based on a 12 multiplexing boards (see Fig. 5). To preserve the redundancy, flow signals are separated into two multiplexers sub-racks. Multiplexed signals are connected to the SIEMENS S7-1500 PLC.

The PLC control program follows the CERN control system standards (UNICOS) which allows the PLC program software connection to the WinCC OA SCADA software used in the Supervision Layer. The WinCC OA software will also archive all the relevant data in an ORACLE database.

The PLC is installed in a dedicated 19'' rack for the dry gas DAQ system, which also contain the two multiplexers crate and two DC power supplies. Rack is also shared with the CPS PLC.

Figure 5. Flowcells multiplexing circuit.

## SUMMARY

The multiplexing technology, used in the CPS and flowcells systems might be an interesting solution for the slow controls or monitoring systems. In the SciFi CPS system, almost 1000 channels are multiplexed and read by the PLC which is equipped with one DO (Digital Output) card and only three AI (Analog Input) cards. The multiplexers are installed on the detector which significantly reduces the number of cables between the experimental and service cavern, where the PLC is located. In the flowcells system, 12 multiplexers boards are installed in the accessible area, 576 signals are connected to the three AI cards, which reduce the signal readout time. The use of the Pirani gauges, with the detached electronic, reduced the cost of the vacuum system. Tests show that detaching the electronic has an acceptable effect on the readout vacuum pressure. It

might be also an interesting solution for the systems with a high number of readouts points, where vacuum sensors are affected by radiation.

# VIRTUALISATION AND SOFTWARE APPLIANCES AS MEANS FOR DEPLOYMENT OF SCADA IN ISOLATED SYSTEMS

P. Golonka<sup>†</sup>, L. Davoine, M. Zimny, L. Zwalinski, CERN, Geneva, Switzerland

## Abstract

The paper discusses the use of virtualisation as a way to deliver a complete pre-configured SCADA (Supervisory Control And Data Acquisition) application as a software appliance to ease its deployment and maintenance. For the off-premise control systems, it allows for deployment to be performed by the local IT servicing teams with no particular control-specific knowledge, providing a "turnkey" solution. The virtualisation of a complete desktop allows to deliver and reuse the existing feature-rich Human-Machine Interface experience for local operation; it also resolves the issues of hardware and software compatibilities in the deployment sites. The approach presented here was employed to provide replicas of the "LUCASZ" cooling system to collaborating laboratories, where the on-site knowledge of underlying technologies was not available and required to encapsulate the controls as a "black-box" so that for users, the system is operational soon after power is applied. The approach is generally applicable for international collaborations where control systems are contributed and need to be maintained by remote teams.

## MOTIVATION

For the past two decades industrial controls technologies have been applied with success at CERN to build control systems for a vast range of applications, ranging from laboratory setups through technical infrastructure up to the ones for accelerators and large particle detectors counting millions of I/O channels. Applying the standardized stack of industrial technologies (WinCCOA SCADA [1]), enhanced with in-house developed frameworks [2,3] allowed for rapid development and effective maintenance of hundreds of complex control system across the organisation. However, this wouldn't be possible without centrally supported IT services and infrastructure. In particular, provisioning of secure network connectivity, computing server hardware, installation of operating system and software, high capacity database service, shared file-systems, consoles in the control rooms or terminal servers for secure remote access have been essential for reliable day-to-day operation. Harmonized efforts of numerous expert teams, ensured the maintenance and upgrades of applications and infrastructure [4] throughout the life-time of control systems.

In general, production control systems are hosted on centrally maintained infrastructure, remain highly homogeneous in terms of technologies and assume the availability of services and also experts. Nevertheless, this may not be achievable for international research collaborations, where the development and precommissioning of the control system may be performed in collaborations, where the development and precom-

missioning of the control system may be performed in a different place than the final location of the equipment. The local infrastructure, available expertise and policies at the deployment site may differ, making the integration and maintenance of such control system seemingly impossible.

## LUCASZ CO<sub>2</sub> Cooling Stations

LUCASZ [5], *Light Use Cooling Appliance for Surface Zones*, is a medium size I-2PACL CO<sub>2</sub> cooling system developed at CERN with 1kW cooling power at -35°C. It was designed with the purpose of cooling down small and medium sized light tracking detector structures and supporting detector-assembly. A number of research institutes collaborating with CERN needs to build their own replicas of the LUCASZ system to proceed with their activities and commitments related to the phase-II upgrade of the LHC Experiments.

The control system for LUCASZ employs the standard CERN UNICOS [3] technology stack with a Schneider M580 PLC. To facilitate the local operation for non-expert users LUCASZ has a detachable *LocalBOX* featuring an industrial touch-panel. However, its functionalities are limited: for instance it is not suitable for long-term storage of historical data, hence it may not be considered a replacement for a complete, PC-based UNICOS SCADA.

Provisioning a stand-alone cooling system to be operated outside CERN is a technical challenge and requires expertise in several domains not always available in the institutes. Indeed, in addition to cooling, mechanical engineering also the expertise in deployment and configuration of control systems would be required.

## PROBLEM AND PROPOSED SOLUTION

Difficulties in deployment and maintenance of control systems, requiring specialized skills, may hinder the effective collaboration and prevent possible re-use of existing instruments or technologies. A solution allowing for the control system to be deployed in form of a "black box" next to the equipment, with the purpose of acting as the *local control station* is demanded.

Unlike for the PLCs, deploying the full UNICOS SCADA application on top of undefined IT infrastructure remains a complex task requiring specific knowledge. In what follows we propose a solution allowing to package a complex SCADA application together with the necessary environment, and at the same time address the problem of the infrastructure compatibility.

## Virtual Software Appliances

To address the class of practical problems of lack of local domain-specific technical expertise the IT industry applies a pattern of *software appliances* [6]: self-contained

<sup>†</sup> Piotr.Golonka@cern.ch

assemblies of software tailored and configured for specific use and easy to deploy through well known and practised IT procedures.

Virtual machines (VMs) are a widely used method to implement software appliances, supported by IT industry. By virtues of *isolation* and *emulation* they allow to decouple the physical computing infrastructure from the one required by the software embedded in the appliance.

Instances of VMs are created from *VM image files* comprising all the software, the operating system and settings. The image files are the standardized [7] way of distributing the appliances from vendors to end-users.

### Local Desktop Virtualisation

Addressing the primary requirement of *local* operation of SCADA, the proposed solution adopts the approach of *local desktop virtualisation* to provide a complete desktop session to the operators using the VM running in a local desktop PC located close to the controlled equipment (see Fig. 1).

Figure 1: The architecture of proposed solution that employs local desktop virtualisation.

This approach draws from a decade of authors' experience with virtualisation of Linux-based desktop developer environments using the multi-platform and open-source *VirtualBox* hypervisor [8]. Image files containing pre-configured tools and services allow to quickly instantiate new and ready-to-use VMs to be used by developers, in particular those with no experience with configuring a Linux desktop machine. It enables them to develop and test the Human-Machine Interface (HMI) with the user experience similar to real operator consoles, considering aspects such as colour themes, available fonts or pixel-exact rendering. The VMs behave identically regardless of the operating system (Windows, MacOS, various Linux distributions) installed on their desktop machine or a laptop (hence prove the capability of this technology to address the requirement of decoupling the appliance from the hosting infrastructure).

In practice, the perceived performance of VMs hosted in modern desktop machines equipped with SSD storage and enough RAM (extra 4 GB per VM) is most often indistinguishable from the non-virtualised environments. However it is essential to activate the acceleration of virtualisation (VT-d, IOMMU) in the computer's setup – options which are usually disabled by default.

The VM images are based on the currently recommended version of the operating system and applications (CentOS 7, WinCC OA 3.16). New releases containing updates/patches applied are delivered on a regular basis and their

import takes around 2 minutes. Desktop session (KDE Plasma) is started immediately after the machine boots, ready to be used in less than 30 seconds. The users appreciate simplicity of use and additional features: auto-adjusting the VM's screen resolution upon its window resize, clipboard synchronization, access to host files, and adequate functionality even without a network connection.

Using these already existing images as a starting point we were able to prototype a "black-box" SCADA appliance for LUCASZ with not much effort. The initial experience clearly indicated that the approach would fit the needs remarkably well, while reusing the already existing work.

### Approach to Computer Security

Through the *isolation* features, virtualisation may significantly enhance the security of deployed appliances, if configured correctly. In what follows we assume that the security of the host machine: not only the OS but also the hypervisor software (e.g. *VirtualBox*) is assured adequately (security and functionality erratas, etc.).

To reduce the potential surface for vulnerabilities the amount of installed software and enabled services in the appliance is reduced to strict minimum. This also allows to reduce the VM startup time and the size of the distributed image (2.5 GB).

The appliance does not require any external *online* resources and could be operated in complete isolation.

A direct connection to the PLC using a dedicated Ethernet network port of the host PC is required. The VM configures it in *bridged mode* for its own use and it should not be available for any other purpose by the host. The MAC address of the network port is pre-configured by the VM, and static non-routable IP addresses are configured for the PLC and the VM's network stack.

If necessary, inter/intra-net connectivity from VM may be enabled: a separate network connection is preconfigured in the VM to provide routed networking through the host's networking stack working in the NAT (*Network Address Translation*) mode. When enabled, it provides the security similar to those of a home router, disallowing incoming connection to the VM, and having all outgoing connection handled by the host's internet connection, respecting all security policies configured by its administrators.

The operation of the appliance is primarily through the main window of the *VirtualBox* application, which displays the contents of virtualised screen, and passes the mouse and keyboard events to the VM. Remote assistance or operation to the session in which the VM executed may be provided either by the standard tooling or via a commercial *VirtualBox Extension* providing direct RDP access to its console.

The appliance is ready for operation within 30 seconds from its start. Once the VM loads the operating system it auto-starts the SCADA and opens the main HMI Window allowing to visualize the state of the control system. The SCADA-level access control mechanisms are employed requiring the operator to log in to enable commanding on the controlled hardware.

## Storage for Historical Values Data

To store the history of the value-changes the SCADA in the self-contained appliance may not assume the availability of large centrally-managed databases, as these typically used at CERN, and needs to fall back to the local file-based mechanism available in WinCC OA. This requires careful parametrisation of data-retention and data-reduction policies to balance the period of available data, its granularity and consumed storage space.

In the proposed solution a dedicated disk image file, with (self-expanding) capacity of up to 100GB is attached to the VM and auto-configures itself to become the storage space for the archive data. The image may be freely detached from one VM and re-attached to another allowing for upgrades of the VM without the loss of archives. In addition, detaching it prior to a VM snapshot allows to exclude the historical data and reduce its size.

## Reliability and Recovery Procedure

The reliability of a VM depends of the hardware it runs on. For stand-alone control systems it is not optimal to deploy high-end server hardware. Often a cheaper PC may be sufficient, even though their reliability is lower, provided that a quick and straightforward recovery procedure is available. In case one needs to change the PC, it is sufficient to load the same VM *image* used for the original installation, which takes a few tens of seconds. It is also possible to re-connect the storage of historical values. In addition, standard functionality of VM *snapshots*, which themselves could be exported as images, provide a robust solution for backups.

## Update Scenarios

In spite of being a “black box” solution, the appliance needs to be managed through the lifetime of the LUCASZ system. To assure proper support, the major versions of the SCADA and OS of the appliance need to be kept in line with those used at CERN. The envisaged scenario is to prepare and deliver new versions of the image on, with updated components on a regular basis (once per year). The new image may be imported as a new VM working *alongside* the one used in production allowing for its local commissioning and smooth roll-back scenarios. At the moment of writing we have no experience yet with executing an upgrade of the image in production.

## Discussion of Alternatives

The presented choice of approach and technologies may not be the only one allowing to address the use case. In what follows, let us present the reasons for not having followed some of other possible solutions.

Remote access to appliances hosted in the on-premises or *cloud* data centres is the most widely known provisioning method for desktop virtualisation. At CERN it is used to provide remote operation of the applications using Terminal Servers hosted on the local “*openstack*” cloud infrastructure.

However, the essential part for the cloud models (Infrastructure/Platform/Software/Desktop as a Service) is the

availability of network communication between the user and the hosting site. Concerns about the privacy and non-locality of data may arise due to internal policies. The requirement of vicinity (direct connection) of the self-contained operator station to the operated plant may be hard to address. In addition, the efforts and skills related to provisioning and configuration of such services for a single appliance may exceed those needed by the presented solution.

*IIoT* and *edge* solutions are very popular trends in industrial controls these days. However, they are not applicable to the discussed problem, as there is no need for storing and processing data in a central place anyway.

Containers are amongst the most popular methods of deployment for reusable software appliances, also applied for Linux-based control systems at CERN [9]. The upcoming enhancements in MS Windows container subsystem allowing to run Linux containers with GUI may become a viable alternative, with advantage of significant reduction in the size of distributed image and startup time, yet at the cost of reduced level of isolation.

Centralized deployment and maintenance of controls applications are being addressed by the SCADA vendors too. For WinCC OA the “*On Premise Administration*” feature (part of *IOT Suite* [10]) has recently become available, yet at the moment of this writing we have no practical experience with it yet.

The fall-back solution is the provisioning of the physical PC, configured with all the software to be installed in the remote location. However, remote expert interventions may be restricted by local IT policies.

Numerous available software products allow for effective virtualisation of GUI desktops in local machines, with efforts for standardization and interoperability [7]. Our choice of Virtual Box was motivated by its availability on numerous platforms and being an open source project. We are convinced that in a general case, other products could fit the same purpose.

## EXPERIENCE OF FIRST DEPLOYMENT

The deployment of a virtualised SCADA has been successfully completed for the first time with the LUCASZ installation at DESY in Hamburg, Germany (Fig. 2).

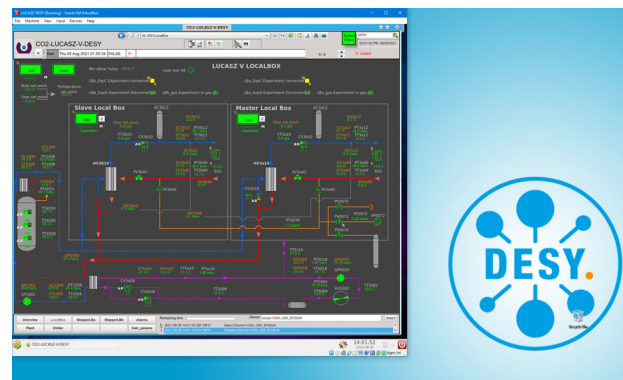

Figure 2: Operator screen of the *CO2-LUCASZ-V-DESY* appliance visible in the VM window of a desktop PC.

Prior to the deployment, the image of the appliance has been prepared by the experts at CERN. Firstly, a *multipurpose image* with latest versions of SCADA software, OS patches, and a complete generic unparameterized UNICOS application and preconfigured networking parameters (for the PLC communication) was prepared. Based on that the LUCASZ control engineers instantiated a VM, configured the SCADA application (import device instances, I/O addresses, application-specific customizations and operator panels), validated it with a PLC and hardware. Then the VM was exported as the *final image* and delivered to the IT team in the remote institute to be instantiated in the local PC. The same image may be used (with minimal adjustments) for all other instances of the LUCASZ cooling plant.

The initial deployment at DESY resulted in successful operation: after loading and connecting the PLC (with CERN remote assistance), the communication with SCADA was established immediately. The deployment and hand-over to the local team for operation was completed in less than a day, which is very encouraging for the future.

## APPLICABILITY

The presented solution addresses primarily the need for an easy-to-deploy standalone local control system to be used for replicas of highly specialized equipment, built from engineering *blueprints*. However, the scope of the use for this approach is wider.

Large and complex research equipment is often built through a collaborative effort partitioned to work-packages distributed worldwide. Some of the contributions may be delivered as complete “turn key” systems to bring also the *operational experience* (e.g. gas system for KEK contributed by CERN). Their controls technologies may differ from the ones used widely by the collaboration whereas re-engineering is not feasible. Virtualised appliances allow to overcome this inhomogeneity and ease the integration.

Recently the appliance has been used to implement a small portable laboratory setup at CERN for tests of CO<sub>2</sub> long vertical transfer lines recording data from a few pressure sensors wired to a PLC. It took less than 3 hours to set up the PLC and the SCADA appliance running in a laptop. Numerous CERN groups have already expressed their interest for this type of portable SCADA deployments to be used in instrumentation of test stands.

## CONCLUSIONS AND OUTLOOK

The use of virtualisation to provision self contained SCADA systems in form of easy-to-deploy software appliances has been carried out successfully for the first remote instance of LUCASZ system in DESY, with subsequent ones already scheduled for NIKHEF and INFN. The same approach is envisaged to provide control system for the Gas System to be contributed by CERN to the T2K-ND280 experiment in Japan. After a decade of the internal use of desktop virtualisation for software development, we found the approach to be effective for production and lab setups to deliver the full functionality of SCADA. We expect it to be used more

## CONCLUSIONS AND OUTLOOK

The use of virtualisation to provision self contained SCADA systems in form of easy-to-deploy software appliances has been carried out successfully for the first remote instance of LUCASZ system in DESY, with subsequent ones already scheduled for NIKHEF and INFN. The same approach is envisaged to provide control system for the Gas System to be contributed by CERN to the T2K-ND280 experiment in Japan. After a decade of the internal use of desktop virtualisation for software development, we found the approach to be effective for production and lab setups to deliver the full functionality of SCADA. We expect it to be used more and more not only internally at CERN but also for contributions to international research collaborations.

We believe that the presented solution is generally applicable also for other control system technologies and will further enable the reuse of unique hardware across research community, also beyond physics.

# THE Laser MegaJoule FACILITY STATUS REPORT

H.Cortey, CEA/DAM CESTA, Le Barp, France

## Abstract

The Laser MegaJoule (LMJ), the French 176-beam laser facility, is located at the CEA CESTA Laboratory near Bordeaux (France). It is designed to deliver about 1.4 MJ of energy on targets, for high energy density physics experiments, including fusion experiments. The first bundle of 8-beams was commissioned in October 2014 [1]. By the end of 2021, ten bundles of 8-beams are expected to be fully operational.

In this paper, we will present:

- The LMJ Bundles Status
- The main evolutions of the LMJ facility since ICALEPS2019
- The result of a major milestone for the project: ‘Fusion Milestone’

## INTRODUCTION

The laser Megajoule (LMJ) facility, developed by the “Commissariat à l’Energie Atomique et aux Energies Alternatives” (CEA), is designed to provide the experimental capabilities to study High Energy Density Physics (HEDP). The LMJ is a keystone of the Simulation Program, which combines improvement of physics models, high performance numerical simulation, and experimental validation, in order to guarantee the safety and the reliability of French deterrent weapons. When completed, the LMJ will deliver a total energy of 1.4 MJ of  $0.35 \mu\text{m}$  ( $3\omega$ ) light and a maximum power of 400 TW.

The LMJ is sized to accommodate 176 beams grouped into 22 bundles of 8 beams. These will be located in the four laser bays arranged on both sides of the central target bay of 60 meter diameter and 40 meter height. The target chamber and the associated equipment are located in the center of the target bay.

The first bundle of eight beams has been commissioned at the end of 2014. The second bundle has been commissioned at the end of 2016 following the same commissioning process. Seven additional bundles are now operational since the end of 2020, and the first physics experiments using the 56 operational beams took place in the second semester of 2019.

The PETAL project consists in the addition of one short-pulse (0.5 to 10 ps) ultra-high-power (1 up to 7 PW), high-energy beam (1 up to 3.5 kJ) to the LMJ facility. PETAL offers a combination of a very high intensity petawatt beam, synchronized with the nanosecond beams of the LMJ [2].

The first phase of nuclear commissioning of LMJ has been achieved to take into account high-energy particles created by PETAL, and neutron production from D-D fusion reaction. A subsequent phase will take into account tritium targets.

This paper describes the LMJ facility status and the new target diagnostics. A milestone physics experiments is presented to illustrate the facility capacity to realize the first thermonuclear fusion by implosion of a  $\text{D}_2$  capsule in a cavity.

## LMJ BASELINE

The 176 beams ( $37 \times 35.6 \text{ cm}^2$  each) are grouped into 22 bundles of 8 beams. In the switch-yards, each individual bundle is divided into two quads of 4 beams, the basic independent unit for experiments, which are directed to the upper and lower hemispheres of the target chamber.

Basically, an LMJ laser beam line is composed of three parts: the front-end, the amplifying section, the switch-yard and the final optics assembly.

The front end delivers the initial laser pulse (up to 500 mJ). It provides the desired temporal pulse shape and spatial energy profile.

Figure 1: Laser beamline schematic diagram.

The initial pulse leaving the front end is amplified four times through two amplifiers, in order to obtain the energy required for the experiments (up to 15 kJ at 1  $\omega$  per beam). Positioned between the two amplifiers, focusing lenses, associated to a diaphragm (spatial filter pinhole), take out the parasitic (noise) beams that may arise. Beyond the two amplifiers is a reflecting mirror (M1), making the four passes possible through angular multiplexing, as shown on Fig. 1. The surface of this mirror is deformable (being controlled by electro-mechanical actuators), allowing beam wavefront distortions to be controlled.

The 8 beams coming from the amplification section are divided into two quads. Each quad is transported over more than 40 meters into the target bay and is directed to the upper or lower hemisphere of the target chamber using six transport mirrors per beam. Each quad arrives into a frequency conversion and focusing system (SCF). Inside the SCF, the beams frequency is changed from infrared (1,053 nm) to ultraviolet (351 nm). The frequency conversion is realized by two KDP crystals, with a global efficiency of about 60%. The beams are focused on target using a 3  $\omega$  focusing grating. This specific component allows spectral separation (to ensure only 351 nm wavelength reaches the target).

## LMJ BUNDLES STATUS

The completion of the LMJ facility (176 operational beams, full target bay equipment, ...) requires a long period of time. During this period, we need to assemble the bundles, commission the assembled bundles, but also realize experiments addressing different physics domains with the operational bundles, in order to control the ignition process.

Today, Nine LMJ bundles (18 quads) are operational since the end of 2020. Before the end of the year, one more bundle will be operational and four more bundles should be assembled. At the end of 2021, 80 beams will be operational.

## LMJ & PETAL TARGET DIAGNOSTICS

Fourteen target diagnostics are now operational around the target chamber, and two new diagnostics will be operational at the end of 2021. Table 1 summarizes the different functions and the main features of these diagnostics. Some diagnostics are insertable using a SID (System for Diagnostics Insertion). A SID is a telescoping system that provides a precise positioning of a diagnostic close to the center of the target chamber. It moves a 150 kg diagnostic with 50  $\mu$ m precision. Four SID are operational: three in the equatorial plane of the target chamber, and one in a polar position on the upper hemisphere. Three more equatorial SID will be operational at the end of 2021, in 2022 and 2023.

## PETAL: A PETAWATT CLASS LASER INSIDE THE LMJ FACILITY

The PETAL project consists in the addition of one short-pulse (0.5 to 10 ps) ultra-high-power (1 to 7 PW), high-energy beam (1 to 3.5 kJ) to the LMJ facility (see Fig. 2).

Table 1: Target Diagnostics Description

Diagnostic	Function(s)	Insertable	Operational
GXi-1	Hard gated X-ray middle resolution imager	Yes	Yes
DMX	Multi-channel X-ray diagnostic: broadband X-Ray spectrometer + laser entry hole imager & soft-X-ray spectrometer	No	Yes
mini-DMX	Broadband X-Ray spectrometer	Yes	Yes
SSXi	Soft X-ray spectro-imager	Yes	Yes
GXi-2	Large field of view Hard X-Ray imager	Yes	Yes
SPECTIX	Hard X-Ray spectrometer	Yes	Yes
CRACC	Proton radiography (part of SEP-AGE)	Yes	Yes
SESAME 1&2	Electron spectrometers	No	Yes
SEPAGE	Electron & ion/proton spectrometer & proton radiography	Yes	Yes
FABS	Full aperture scattering measurement station	No	Yes
SHXI	Streaked Hard X-Ray Imager (time resolved 1D image)	Yes	Yes
Neutron pack	Neutron yield measurement, neutron Time of Flight measurement	No	Yes
EOS pack	Velocity measurement (Visar), Shock Break Out/pyrometers	Yes, partly	Yes
DEDIX	Heterodyne velocimetry	Yes	Yes
Nbi	Near Backscattering Imaging System	No	2021
UPXi	LEH imager	No	2022
HRXi	High Resolution X-Ray imager	Yes	2022
HRXS	High resolution X-Ray spectrometer	Yes	2023
HRXi	High Resolution X-Ray imager	Yes	2022

The PETAL beam is focused in the equatorial plane of the target chamber.

### PETAL Architecture

PETAL laser is based on the chirped pulse amplification (CPA) technique combined with optical parametric amplification (OPA). The front end consists in a standard Ti:Sap-

Figure 2: Implementation of PETAL. The PETAL beam is focused in the equatorial plane of the target chamber.

phire mode locked oscillator delivering 3 nJ, 100 fs, 16 nm pulse at 77.76 MHz and 1053 nm wavelength. The initial pulse (3 nJ, 100 fs, 16 nm) is stretched to 9 ns in an Offner stretcher in eight passes. Then the pulse is sent to the Pre-Amplifier Module (PAM) including OPA stages and pump laser to reach 150 mJ.

The PETAL amplifying section has the same architecture as the LMJ using a single beam instead of the 8 beams of an LMJ line. It uses 16 amplifier laser slabs arranged in two sets and delivering up to 6 kJ (1.7 ns, 3 nm). The main differences with the LMJ amplifying section baseline are the wavefront and chromatism corrections.

The compression scheme is a two-stages system. The first compressor, in air atmosphere, reduces the pulse duration from 1.7 ns to 350 ps. The output mirror is segmented in order to divide the initial beam into 4 sub-apertures which are independently compressed and synchronized into the second compressor under vacuum. These sub-apertures are coherently added using the segmented mirror with three interferometric displacements for each sub-aperture. The pulse duration is adjustable from 0.5 to 10 ps.

After a transport under vacuum, the beam is focused in the equatorial plane of the LMJ chamber via an off-axis

parabolic mirror with a 90° deviation angle, followed by a pointing mirror.

### PETAL Performances

The first high energy test shots in the compressor stage of PETAL were performed in May 2015. They demonstrated the Petawatt capabilities of PETAL with a 1.15 PW power shot (850 J energy and 700 fs duration) [3]. This Petawatt power has then been brought to the LMJ target chamber center in December 2015, and a test shot coupling LMJ and PETAL has been performed at the same date.

The commissioning of focal spot on target and the main performance on target has been performed during the first campaigns (2nd semester 2017 to 1st semester 2019), see Fig. 3.

It concerns:

- The alignment of the sub-aperture compression stages in order to optimize the pulse compression (the mean duration was 685 fs for the 2018 shots in ps regime, the best 2018 value being 570 fs),
- the intensity on target of  $9.2 \times 10^{18}$  W/cm<sup>2</sup> in 2019 (intensity inferred from measurements at the end of the compressor for the 358 J @ 690 fs shot and confirmed by the TwIST measurement [4],

Figure 3: Focal spot (left) for the 358 J @ 690 fs shot giving  $9.2 \times 10^{18}$  W/cm<sup>2</sup>, focal spot (right) optimized for the shot on the 25  $\mu$ m wire with 396 J @ 3 ps and  $10^{18}$  W/cm<sup>2</sup>. They are measured on the compression diagnostic table TDC during shot.

- the alignment performance (positioning, pointing) and demonstration of the first associated LMJ and PETAL laser shots on target.

Specific optimizations have been made to deliver 10 ps pulses on target and to shot for the 1st time on PETAL on a 25  $\mu\text{m}$  wire.

The next improvement of PETAL performances will concern:

- the upgrade of optics under vacuum in order to increase the transported energy (ongoing action),
- the improvement on damage threshold,
- the temporal contrast measurement
- and the focal spot optimization and characterization.

## EXPERIMENTS: “FUSION MILESTONE”

At the end of 2019 a major milestone has been reached with the fusion milestone. It was the first fusion experiments in cavity with 6 laser bundles in an indirect drive scheme. By this way, we are able to provide more than 150 kJ and 55 TW on target. Goals of this experiment were

- the realization of a thermonuclear fusion by implosion of a  $\text{D}_2$  capsule in a Rugby cavity,
- the measurement of produced neutrons,
- the design robust to laser illumination asymmetry,
- the good capacity of prediction from our simulations.

The experiment is described on Fig. 4. The ten experiments provided a rich set of measurements for the validation of the 3D simulation code. Some of the experimental results are presented on Fig. 5.

Figure 4: Experimental set-up.

## X-Ray imager measurements

Figure 5: Hydrodynamics measurement of the cavity walls.

## CONCLUSION

At the end of 2021, The LMJ facility will be operational with ten LMJ bundles (80 beams) and with PETAL, a Petawatt class laser.

The combination of PETAL and LMJ extends the versatility of the laser facility.

From its commission in 2014, the capacity of the facility is constantly growing up. The assembly of new bundles go on following a rhythm of 2 bundles per year.

### Abstract

DISCOS is the control software of the Italian Radio Telescopes and it is based on the Alma Control Software. The project core started during the construction of the Sardinia Radio Telescope (SRT) and it further developed to support also the other antennas managed by INAF (National Institute for Astrophysics), which are the Noto and the Medicina antennas. Not only DISCOS controls all the telescope sub-systems - like servo systems, backends, receivers and active optic system - but it also allows users to exploit a variety of observing strategies. In addition, many tools and high-level applications for observers have been produced over time. The development of this software follows test-driven methodologies, which, together with real hardware simulation and automated deployment, speed up testing and maintenance. We here describe the status of the DISCOS project and of the related activities, also presenting its ongoing upgrades.

### INTRODUCTION

The Italian National Institute for Astrophysics (INAF) manages three single-dish radio telescopes: The Sardinia Radio Telescope (SRT), the Noto and the Medicina radio telescopes. These are open sky facilities; the international scientific community is invited to submit observing projects through calls for proposal, published twice a year [1]. The telescopes cover radio bands from 305 MHz up to 26.5 GHz, allowing many research topics to be explored. Examples are pulsars, astrochemistry, extragalactic sources, space weather. SRT and Noto are already provided with an active surface, allowing for observations at much higher frequencies; Medicina is planned to have it installed within spring 2023.

The control software plays a key role in an observing facility, allowing the users to perform the needed observations by using proper strategies and modes, while ensuring the quality of the acquired data. Therefore, in 2004 we started developing NURAGHE, the SRT control software. In 2007 we parallelly began the ESCS (Enhanced Single-dish Control Software) project, devoted to the Medicina and Noto radio telescopes. Eventually, in order to optimize the efforts, in 2015 the three development lines were unified in DISCOS, a common control software for all the three telescopes.

DISCOS is built on top of the Alma Common Software, which is based on CORBA [2]. This framework allowed us to realize a modular software mostly made of common code-base, reused and deployed at all sites, as much as possible. Considering this, only a small part of the codebase (23%) is telescope-specific, essentially in the low-level and no-logic

control of the devices and of the telescope hardware [3]. In 2017 we refactored part of the code, in order to adapt it to the upgrade of the framework to a newer version of ACS [4]. Also, we chose Github [5] to track issues and manage version control.

Equally important is the development strategy. We followed guidelines in the adoption of an approach called Behavior Driven Development (BDD) [6] which aims to test the software behaviour and it is used together with Test Driven Development (TDD) and unit testing strategies [7].

In the following sections we show the ongoing and planned DISCOS upgrades. In particular we present the integration of new instrumentation, such as new receivers and backends, a new simulated environment of the SRT hardware devices, a middleware DISCOS wrapper called SURICATE and a simple web-based monitoring and alarm system.

### TELESCOPES UPGRADE

In 2019 INAF was granted a PON (National Operational Program) funding to upgrade the Sardinia Radio Telescope and its infrastructure toward higher frequencies (up to 100 GHz). Within this scope, up to a 15% of the overall funding was aimed to also upgrade the Medicina and Noto radio telescopes. The funded project includes the acquisition and the installation of new receivers on the telescopes:

- Three coaxials receivers K/Q/W band (18–26 GHz, 34–50 GHz, 80–116 GHz). for Medicina, Noto and SRT.
- 16-Beam W Band receiver (70–116 GHz) for SRT
- 19-Beam Q Band receiver (33–50 GHz) for SRT
- A bolometric millimetre camera for SRT operating in the 77–103 GHz made of 408 detectors.

Furthermore, the PON project includes, as concerns the SRT, the procurement of three digital data acquisition systems (backends), a new state-of-the-art metrology system, an HPC system and laboratory instrumentation. Also, the telescope minor servo system, which is responsible for the proper positioning of the telescope optics, will undergo a refactoring and a major upgrade.

It is worth noting that new receivers and new backends will need a big effort in order to integrate them in the control software. To do this, we exploited the ACS architecture and the DISCOS modularity. Not only the new receivers have the same interfaces, but also the communication protocols are the same of the SRT first-light receivers.

\* sergio.poppi@inaf.it

The availability of new instrumentation will allow users to exploit additional observing modes, so we are also upgrading BASIE (the schedule creator), which is a fundamental tool to plan and execute the observations. BASIE was designed to create the schedule files required by DISCOS to carry out continuum and spectroscopy observations, according to different strategies - like on-the-fly scanning, on-off and nodding [8]. Thanks to this tool, users do not need to deal with the writing of the complex schedule files: they are only asked to specify a combination of receiver and backend, providing basic information on the celestial sources to be observed, the desired strategy and the configuration of the devices.

## SIMULATORS

Writing a simulator helps the developers in writing more reliable code for the actual control software of the radio telescope, the DISCOS control software. Being able to test the code without having to rely on the hardware represents a huge advantage in the development and maintenance processes. It speeds up the development of new features and the bug fixing, keeping under control the codebase through the adoption of continuous integration practices. Both unit and functional tests are cleaner and shorter, no code mocking is required, they work both over simulators and real hardware. In addition, the integration of new components is easier and more reliable, and the hardware itself can be verified by running the simulator tests over it. A suite of simulators, capable of reproducing different scenarios, can be exploited to write and execute a great variety of tests whenever a modification to the control software code gets pushed to the main repository. All these considerations led us to change our process to integrate new devices, so that the writing of its simulator is now the mandatory first step. To improve and speed up our capability to add simulators to our environment, we developed a simulator framework. The framework for the simulators is written in Python and is composed of two layers. The topmost layer is in charge of handling network communications, it behaves as a server, listening for incoming connections from clients and relaying every received byte to the other layer of the framework, the simulation layer. This layer is where received packets are parsed and executed. It can faithfully replicate the behavior of the hardware, or it can simply act as a protocol interpreter by providing back proper answers. [9]

Furthermore, the framework allows to test how the control software code reacts under expected error conditions. In fact, it provides an easy way to simulate unlikely scenarios that are very difficult or, in some cases, impossible to replicate by only using the hardware. This allows the developers to write more reliable and robust code, likely permitting the recovery from an error condition without having to resort to a complete reboot of the system.

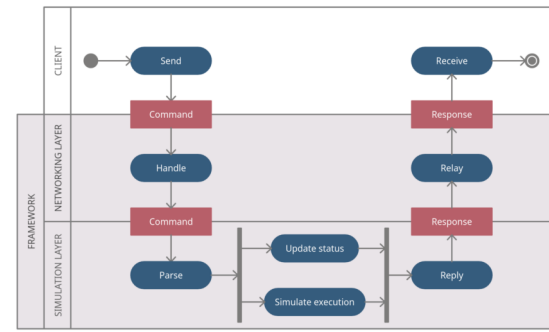

Figure 1: Simulators framework layers and communication behavior.

## DEPLOYMENT

An automatic Ansible [10] pipeline creates users, configures the network, sets up the shared file system, installs all the required dependencies (i.e.: Alma Common Software), installs all the required observing tools and finally the DISCOS software, creating a fully-configured working environment. Having an automated deployment means that both development and production environments are aligned, all the process is automatically documented and the system can be easily updated and restored. Not only Ansible allows the deployment on physical machines, but it can also provide, through Vagrant, virtual machines based on Oracle VirtualBox.

A DISCOS installation is basically composed of:

- A manager hosting ACS services and maintenance tools
- A console, providing the user interfaces and accounts for all the allowed observing projects
- Storage cluster, mounted with LustreFS

The deployment scripts allow to select which telescope the installation is specific for and which branch or the tag from the Github repository is to be provided [11].

In summary, all the DISCOS instances are well aligned among all the installations. This allows us to speed up maintenance and bug tracking.

## SURICATE

Suricate [12] is a middleware which exposes APIs to the clients and offers an abstraction from the control system and the programming language. Moreover, it allows DISCOS to be easily extended bypassing the framework on which it is based, getting advantage of new technologies.

It is composed of a sampler that collects from DISCOS the telescope status, its configuration and relevant parameters, writing them in on a in-memory database (redis-db). Then a different module, the db-filler, gets the data from the redis-db to save them into a persistent SQL database. A HTTP server gets requests from clients and reads the values from the database, returning a JSON answer. Also, the HTTP server

receives user commands from clients, forwarding them to DISCOS.

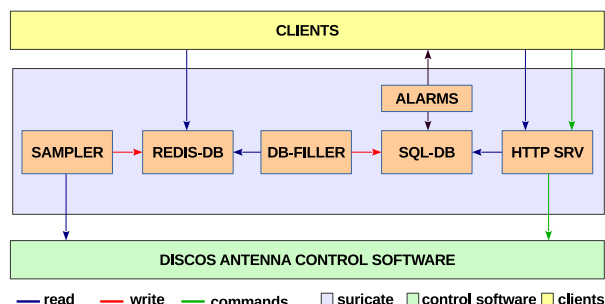

Figure 2: Suricate is a middleware which offers API and abstraction from the operating system and the programming language.

## CONCLUSIONS

DISCOS is continuously evolving as new instrumentation is installed on the Italian radio telescopes. One of the major upgrades we are performing is the integration of new high-frequency receivers and data acquisition backends into the control software.

Such upgrades are made easier by the development choices the team previously made. The automatic deployment and software provisioning, together with the hardware simulators, allow us to add new features while keeping software robustness, speeding up maintenance and bug fixing. The Suricate middleware, thanks to its abstraction from the underlying control software, allows us to produce new applications (e.g. GUIs) exploiting also technologies that are not supported by the ACS framework.

## ACKNOWLEDGEMENTS

The Sardinia Radio Telescope is funded by the Ministry of University and Research (MIUR), Italian Space Agency (ASI), and the Autonomous Region of Sardinia (RAS) and is operated as National Facility by the National Institute for Astrophysics (INAF). The Medicina and Noto radio telescope are funded by the Ministry of University and Research (MIUR) and are operated as National Facility by the National Institute for Astrophysics (INAF).

The Enhancement of the Sardinia Radio Telescope for the study of the Universe at high radio frequencies is financially supported by the Programma Operativo Nazionale (PON) del MIUR “Ricerca e Innovazione 2014-2020” Avviso D.D. n° 424 del 28/02/2018/ per la concessione di finanziamenti finalizzati al potenziamento di infrastrutture di ricerca, in attuazione dell’Azione II.1 - Proposta Progettuale PIR01\_00010.

# CRYOGENIC CONTROLS TODAY AND TOMORROW

M. Pezzetti, P. Gayet, CERN, Geneva, Switzerland

## Abstract

The CERN cryogenic facilities demand a versatile, distributed, homogeneous and highly reliable control system. For this purpose, CERN conceived and developed several frameworks (JCOP, UNICOS, FESA, CMW), based on current industrial technologies and COTS equipment, such as PC, PLC and SCADA systems complying with the requested constraints. The cryogenic control system nowadays uses these frameworks and allows the joint development of supervision and control layers by defining a common structure for specifications and code documentation. Such a system is capable of sharing control variables from all accelerator apparatus. The first implementation of this control architecture started in 2000 for the Large Hadron Collider (LHC). Since then, CERN continued developing the hardware and software components of the cryogenic control system, based on the exploitation of the experience gained. These developments are always aimed to increase the safety while improving, at the same time, the performance. The final part will present the evolution of the cryogenic control toward an integrated control system SOA based, using the Reference Architectural Model Industrie 4.0 (RAMI 4.0).

## INTRODUCTION

The CERN cryogenic infrastructures for accelerators, detectors and test systems include large and complex facilities able to cool the equipment down to 80 K with liquid nitrogen ( $LN_2$ ), to 4.5 K with liquid Helium ( $LHe$ ) and to 1.9 K with super fluid helium. These facilities are placed in dedicated test facilities, experimental areas and around the 27 km LHC. The complexity of the cryogenic facility requires an automated and homogeneous control system that must be flexible, reliable and distributed around the entire CERN LHC cryogenic line QRL [1]. Today, for the High luminosity (HL-LHC), era some adaptations will be applied to fully automate the control development and to prepare the integration of the control system with the existing Maintenance Management Software (MMS) and the operational support environment from the conception stage to the daily operation. Tomorrow, a new generation of large accelerators is forecasted, making the story far from finished. Hence this article will also present additional thoughts and potential developments proposals.

## CRYOGENIC CONTROL SYSTEM TODAY

Currently, the cryogenic control system follows the standard automation pyramidal structure of the International Electrotechnical Commission (IEC-62264) and is based on industrial components deployed in all control layers (see Fig. 1):

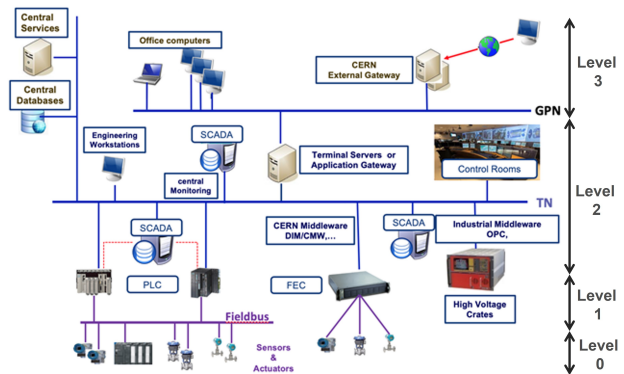

Figure 1: CERN Industrial Control Ecosystem.

- Instrumentation layer (IL): The cryogenic instrumentation needs a significant number of industrial sensors to collect data, electronic conditioning units and actuators to execute commands. To ensure the correct communication with the devices, both copper cable connections and a protected and dedicated Ethernet network or industrial field-buses are used. In the LHC, where the environment is hostile, radiation resistant instruments and fieldbuses were chosen.
- Control layer (CL): The control duties are executed within PLC, with safety interlocks either cabled in the electrical cabinets or programmed in local protection PLCs. In radiation exposed area radiation tolerant crates and field-bus are used, coupled with standard CERN Front End Computer (FEC). The long-distance integration site to site or toward the supervision layer, relies on the CERN Ethernet Technical Network (TN) whereas the local ones (internal to a cryogenic site) are implemented on field-buses using both fibres and copper cables or direct cabled to the cabinets.
- Supervision layer (SL): All cryogenics systems are supervised through Data Servers (DS) running the WinCC-OA® SCADA system within off-the-shelf's Linux machines. The Human-Machine Interface (HMI) clients allows operators to monitor and act on the cryogenics facilities using Linux PC deployed within the control rooms. In addition to the classical SCADA features, several functionalities have been added in the last decade: visualisation of the process hierarchy, access to the interlocks per devices, control loop auto tuning, direct access to device documentation, etc. This layer provides also interfaces to the Management Layer, and a dedicated connections toward the CERN central alarm system and the LHC experiments control systems.
- Maintenance & Operation Management System layer (ML): The central long-term logging database (NX-CALS), the CERN CMMS (Infor-EAM) and the Accelerator Fault Track application (AFT) are parts of this

layer. They monitor the whole process and integrate it into the campus environment. These applications are currently being integrated with the present cryogenic control system and the next run will be a good opportunity to validate them.

- The Company Overall Management layer (CL): At CERN, this level is filled with Administrative Information Services (AIS) applications. Up to now there are few ad-hoc integrations with ML components for specific CERN groups. However, the complete vision is lacking and there is not yet a well coordinated development.

## Cryogenic Control Applications

The cryogenic process control system uses the first implementation of the UNified Industrial Control System (UNICOS), a CERN-made framework to develop of industrial control applications that integrates the development the SL and the CL in PLC and SCADA as it's done in a Distributed Control System (DCS). The main benefit of UCPC applications (UNICOS coupled with the Continuous Process Control package) [2, 3] is to ease the operator's ability to follow the evolution of the process and to understand the dynamics of a situation as well as the role of each physical component. It also helps to identify the origin of a failure, predict what could happen in the near future, etc. To achieve these duties, operation teams have access to classical SCADA tools (process synoptics, time stamped alarms, events lists, trend curves with long term storage, etc.), but also to the visualisation of the process hierarchy, the interlocks per devices, the control loop auto tuning, and the device documentation, etc.

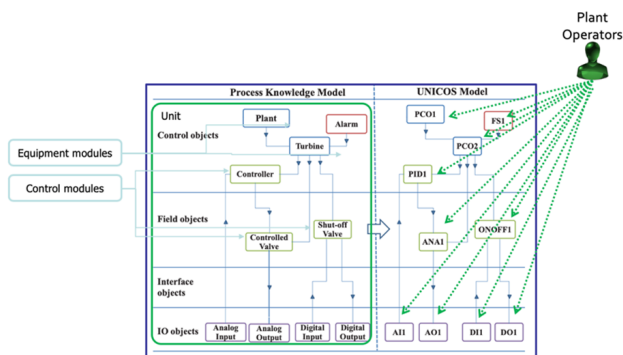

Figure 2: cryogenic device hierarchy according to IEC61512-1 decomposition and its equivalence in UCPC.

The UCPC model is based on the IEC61512-1 model that decomposes (see Fig. 2) the cryogenic plant in smaller components (Equipment Modules (EM) or Process Control Object (PCO) for UCPC) down to the smallest possible equipment module. These EM are structured in Control Modules (CM) representing the sensors and actuators or regulators and alarms connected to the process through inputs and outputs. The UCPC device model permits the concurrent access from the supervision and process control hierarchy to the devices with the mechanism as exposed in Fig. 3. It

allows the operators to intervene at the right place without side effects to the other components.

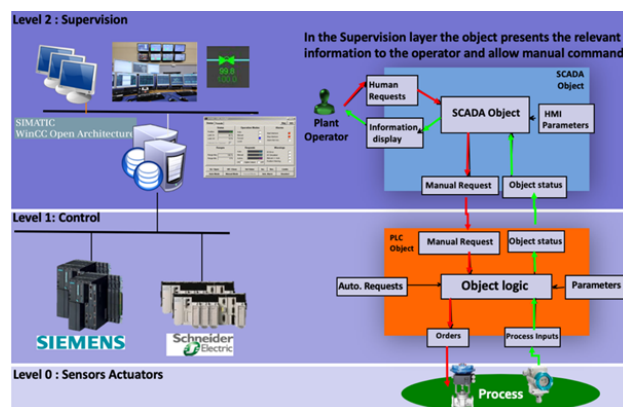

Figure 3: UCPC Control & supervision layer integration.

## Application Development

To achieve the delivery of high-quality control system applications within a certain cost and time constraints, a generator, using a step-wise development methodology (as shown in Fig. 4), has been elaborated by CERN. This 5 part process makes the development team's life easier:

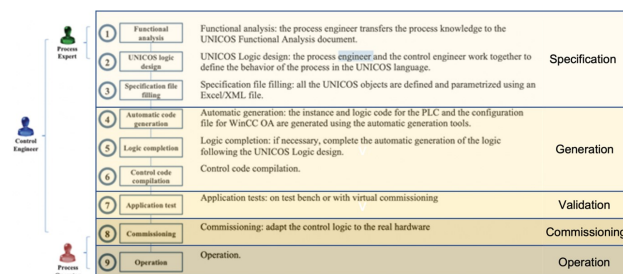

Figure 4: UCPC development methodology.

- a) Specification: To produce the initial specification (step 1, 2, 3 in Fig. 4) the process experts use a common set of basic documentation elaborated during the design phase of the project:

- The electrical schemas, the Process & Instrumentation Diagrams (P&ID) and the instruments lists together with their associated data to validate the conformity with the cryogenic group prescription for construction and protection principles;
- The P&ID to elaborate the Process Flow Diagram (PFD), to identify the functions and the completeness of the proposed instrumentation to ensure the requested duties. They permit also to validate if the tag names proposed are in conformity with CERN required standards;
- The instruments lists to identify the conformity with the prescriptions of the components choices and to validate the availability of the necessary process data.

From these documents it is possible, in collaboration with a control expert, to prepare either manually or automatically:

- The devices description specifications as XML format sheets to describe all devices to be used within an application;
- The functional and logic specifications based on text templates used to code the needed PLC function placeholders in a standardised way using pre-defined templates;
- The supervision configuration data and synoptics that can be either drawn manually or generated using standardised templates.

A quality testing of the data validity can then be conducted to maintain the maximum reproducibility and to reduce the commissioning time (comparison of the parameters stored in the databases together with the parameters extracted from the production system). Today the non LHC cryogenic systems and the LHC cryoplants are manually developed whereas the cryogenic tunnel applications are automatically generated.

- Generation: When generating the applications (step 4, 5, 6 in Fig. 4), the XML inputs files describing the devices as well as their properties and the python templates for PLC codes and SCADA panel, are processed and combined by the UNICOS Application Builder (UAB). Its internal plugins follow semantic rules to produce the application files to be loaded directly in PLCs and SCADA. If at this stage templates are missing, the control expert must either manually complete the control logic placeholder in the PLC or draw the process synoptics with the SCADA drag & drop tool.
- Application Validation or Virtual Commissioning (step 7 in Fig. 4) can be performed to validate the implemented logic:
  - Application validation : A mirror PLC with automated or semimanual features, to control the different thresholds for the interlocks logical transitions, is used [4];
  - Virtual commissioning : A cryogenic model using a dynamic simulation model based on Ecosim-Pro® and a Cryogenic library developed at CERN is exploited to validate the control loops through the UCPC decomposition, allowing a complete virtual commissioning of the system.
- Final Cryogenic Commissioning (step 8 in Fig. 4): After the completion of the previous validation tests, process experts can proceed to the actual commissioning to adapt the application to the process.
- Operation: In this last step the operators use the SCADA User Interface (UI) to take over normal operation. In case of failure, they can obtain detailed information about the entire process and controlled devices. For instance, they have the access to diagnostic

panels to investigate the origin of interlocks (mechanical, electrical, hardware, control software, etc.) in order to take quick corrective actions to overcome problems and reduce potential downtime.

### *Automation of the Application Generation*

The complexity of the cryogenic control system and the frequent updates carried out for optimisation or regular maintenance have made the follow-up of the control software complicated and time-consuming with high demand for complex Information Technology (IT) tools. To elaborate automatically the UAB inputs files and improve the quality of the cryogenic control applications, an adapted generator using the design principle of the “Continuous Integration” model has been developed [5]. This generation process uses a shared project control repository, with the XML devices fill, the process logics and generic panels implemented in Python templates easing the replication and automates all the steps to build new projects including the new code testing. Hence, since it’s implementation the applications controlling the LHC tunnel, have been regularly updated, with excellent results in terms of efficiency and reliability such as the reduction of the necessary time for the code review. The different languages semantic and the lack of inter-operability between PLC brands and the integration of PLC-SCADA with common protocols were the main limitations of industrial control systems. The use of UCPC solved a large part of these limitations. Applications generation for the various brand of PLC are homogeneous since they are based on a common control model. The PLC-SCADA communication configuration is automated and the communication from PLC to SCADA uses a Time Stamped Push Protocol (TSPP) adapted to the PLC brand. All the application generation processes have been automated and implemented.

## **CRYOGENIC CONTROL SYSTEM EVOLUTION IN THE NEAR FUTURE**

Beside the process control applications needs continuous to be update in both the supervision and control levels to follow the operation requested evolution (synoptic evolution, new trends, new alarms, etc.), to implement the logic modifications related to the hardware protection evolution, to follow the evolution of the requested logic & presentation and to develop additional process operation features. The goal is to facilitate the operators duties to improve the application software productivity, to reduce the critically of several components improving the hardware availability, and to simplify the preventive maintenance reducing the costs [1].

### *Supervision Level Evolution to Facilitate the Operator’s Duties*

A new version of WinCC-OA® and the UCPC SCADA framework package will be introduced [6], in addition to a new archiving technology compatible with the NXCALs storage and a new alarm list with additional functionalities. The new version offers a large integration with ML layer

information tools from each device (e.g., CMMS data, Control Logic, Electrical Drawing) that will be extended in the coming years.

### *Improving Application Software Productivity*

A recent extraction of the control devices has shown that around 280000 UCPC devices are already deployed and used for the various cryogenic controls systems at CERN. This gives a total of more than 13 million fields to be maintained. Since in the specification phase of UCPC, technical documents contain all the technical information needed to develop the cryogenic control system applications. Therefore, the needed evolution is to make the complete set of technical data contained in those documents available. Thereby, the various stakeholders will be able to access all necessary information to develop, operate or maintain the cryogenic system [7]. Besides this work, a Control Specification Generator including a new database as well as a set of generic software components to extract the information to produce the XML input files for UAB will have to be developed [7, 8]. An official request to the CERN Industrial Control group to prepare the generation database and develop the tool has been filled, accepted and noted in the Road-Map. However, the development is presently on hold.

### *Other Generators*

With a similar approach, an evolution of UAB and the development of adapted python templates and rules should be generated for new projects or renovation of existing ones:

- EcosimPro® & CryoLib, cryogenic simulation models;
- Cryogenic Maintenance plan for MMS (procedure, frequency, checklist, etc.);
- Data driven schematics;
- Intelligent electrical schemas;
- Intelligent mechanicals P&ID

### *Improving the Control and Instrumentation Availability*

To enhance the availability of the control and instrumentation hardware there is a need to eradicate the root causes of failures, to reduce the fault diagnostic time and to minimize the equipment variability, eliminating at the same time unnecessary equipment to limit the annual maintenance costs. This goal will be achieved by using industrial fieldbus, standard cabinets and removing outdated plugs and installing push terminals:

- The PROFIBUS® communication will be updated with the migration to Ethernet-based technology for PROFIBUS® DP long distance Network, and the replacement of PROFIBUS® PA I/O board to introduce additional redundancy.
- The 400 V distribution design will be modified to simplify the distribution and protection. Main maintenance switches will be installed on the cabinets to facilitate and accelerate the recovery in case of failure.

- The 24 V devices will be supplied with a bus to enhance the flexibility, ease the diagnostic and improve the availability in case of a component failure.

### *Radiation Tolerance Consolidation*

The LHC cryogenic system has operate during 2 physics Runs without radiation induced failures. However, in the coming years, with the increment of the luminosity in the frame of the HL-LHC, this aspect must be considered to avoid failures that will lead to unplanned downtime. Several solutions have been explored (i.e. transfer the cryoplants to a surface building or to existing underground protected locations or creation of a new service caverns) The most suitable solution seems to shield by a wall between the source of the radiation and the sensitive equipment, in order to reduce the numbers of events [9]. The problem of this installation is the crowded environment and the thickness of the wall to achieve the right reduction of radiations as an attenuation by a factor of 5 is the goal to achieve when the luminosity will rises to  $50 fb^{-1}/y$ .

## **CRYOGENIC CONTROL SYSTEM TOMORROW**

This chapter is based on real concepts studied and, for a part of them, already in practice in the contemporary control community. First of all, the groups do agree with many assertions presented in the [10] (chapter 5.10) and in particular with those going in a direction, particularly true and necessary for the control systems, to make the choice of homogeneous solutions for the various control systems (infrastructures, accelerators & detectors) and to open large cooperation with industrial, research and institutional partners. Strong partnership with industrial providers can be a key to the success of a project. Indeed, specific requirements that drastically differ from those of industry (scale of the applications, integration with external or exotic systems, flow control and ultra-fast real time constraint) have to be offered. For the evolution of the control systems, the cryogenic group preference, is to remain as compatible as possible with its present implementation and follow the state-of-the-art. Then, many components or services will have to be developed and maintained by the appropriate entities: IT department, controls groups. The plan is to collaborate as much as possible to develop the most adapted solutions.

### *Architecture Evolution*

Today the buzzwords for the future of industrial automation are Internet of Things (IoT) and Service Oriented Architecture (SOA). Internet of things applies to the devices/components found in the control system [11]. With IoT the control devices are no longer at the lowest level of the control pyramid but they are the node of interactions with several services across the levels such as presented in Fig. 5:

- Service-oriented automation : The application domain is the source of knowledge. Several techniques can be used to describe the available information (e.g. the use

Figure 5: IoT Device model.

of semantics, ontology), besides the intrinsic capabilities provided by web service technologies to capture them in an automated way;

- Plug & play is the ability to connect devices to a network with minimal need of configuration as they are able to integrate themselves and will be ready to work. It uses dynamic discovery, dynamic configuration, uniform description of the device functions and use of standard interfaces;
- Engineering represents the methodologies and tools to make the controlled system run and behave in accordance to what is expected. Services engineering covers every aspect from the initial analysis phase to the operation & maintenance phase;
- Integration covers not only the integration of devices with others, but also their interaction with other levels (e.g., entire production systems, Business);
- Distributed orchestration, since the coordination of activities is not viewed in a central manner, the collaboration between separated units need the use of complex interactions such as orchestration and composition of control to achieve the global objectives.
- Run-time features: When the system is running, there is a continuous monitoring of several useful features to automatize the process to improve the maintenance and to take actions as soon as possible failures occur. The distinctive features are considered to be re-configurable, adaptable, intelligence, auto-sustainable.

In Service Oriented Architecture (Fig. 6), the hierarchical communication of the classical layered architecture, is replaced by a flat exchange of information. The services used in the process can be easily modified with a cross layer integration to improve the inter-operability. The embedded services incorporated in the system operate independently [12]. For this reason, adding or modifying new services and processes will become easier. As result, the process is no longer constrained in a specific platform, but it can be considered

as a component of a wider process and therefore reused or modified.

Figure 6: Next generation of industrial control system, service based, and flat information driven interaction [12].

### Evolution of the Control Architecture

The transition to SOA technology has already been implemented in the highest layer of the enterprise system (CL) for many years. It is also used for the integration between CL and ML with solutions available on the market. The downward spread to SL, CL and IL is progressing today thanks to some initiatives such in Industry 4.0 and existing industrial protocols covering a large part of the necessary services such as OPC-UA (Fig. 7).

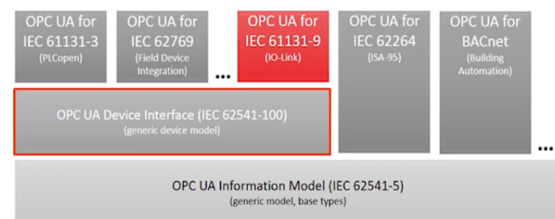

Figure 7: OPC-UA information model that can already be used as generic middleware for slow control systems.

To develop a SOA based control system, the Reference Architectural Model Industries 4.0 (RAMI 4.0) presented in Fig. 8 could be considered. The hierarchy level axis may integrate the accelerators and detectors equipment (field devices and control devices) with the system levels (connected world, enterprise, workcentre, station). Consequently, services, interfaces and integration guidelines shall be used to allow the aforementioned components to interact with the different functional levels (business, functional, information, communication, integration and asset). Ultimately, the life cycle management framework shall be used by the development process to span from concept over requirements, design, implementation/procurement, transition to operation, maintenance and retirement.

This model is an ideal reference to establish the control and data acquisition architecture for an entire project, limiting internal project developments to the only parts that cannot be covered by existing products, services, standards and guidelines.

Figure 8: Reference Architectural Model Industrie 4.0.

## Migration from the UCPC Cryogenic Control System

To adapt the cryogenic control layer to the SOA architecture, the following challenges must be faced [13]:

- One of the strengths of the cryogenic control architecture is the tight link between the HMI and the control execution with the operator's intervention restricted to the chosen devices. Hence, further break down of the hierarchy shall not affect the functional integration. In addition, the choice of an adapted middleware such as OPC-UA will offer additional features.
- Group the devices: Within a given system, it must be determined which device can be migrated to SOA as devices and which devices shall be grouped together and then migrated to SOA as a group.
- For process control execution the present architecture allows an excellent integration between devices if the expected behaviour by the process expert has been implemented. However, in case of unexpected event, adapted behaviour will have to be automatically initiated from the lowest level possible and propagated with automation services (such as OPC-UA for IEC61131.3).
- Preserve real-time control: The real time control execution, which, in the legacy system, is secured in the controllers, must be preserved [14]: As example, a sub-system using feedback and regulation might require legacy interfaces due to real-time needs. For such a group of devices the SOA interface will be implemented using a Mediator for the entire group and this part of the system will be handled as a black-box.

## Hardware Evolution from High Luminosity LHC to Future Circular Collider (FCC)

Hardware for the cryogenic control systems should be able to support the software evolution towards IoT and SOA. At the low level of the pyramid, PLCs were the best choice for systems such as cryogenics, cooling, ventilation, vacuum, etc. because they are simple, with an efficient programming language, high level of availability and reliability. However, they lack the capabilities to run parallel equation solving algorithms or high level programming languages necessary to implement the IoT and SOA complex capabilities such as dynamic discovery and configuration adaption with process conditions typical of IoT devices or the interconnection of services (configuration, maintenance data exchange, etc.) necessary for SOA. Even though the features just mentioned can be obtained thanks the LHC Front End Computer (FEC), their reliability is not as high as that of the PLC. New solutions, such as the Beckhoff Twincat PLC, must be investigated to obtain a product compatible with the new concepts with a very high reliability. Today the low-level devices used in cryogenic systems do not integrate complex capabilities such as dynamic discovery and configuration adaption with process conditions typical of IoT devices. However, some of IoT compatible devices already exist (such as IO-link compatible devices). In addition, Industrial Control Middleware such as OPC-UA proposes a mediator for the interconnection of services (configuration, maintenance data exchange, etc.). For the communication to the process interface at the lowest level of the pyramid, the main concerns are related to the electronic control components located inside the accelerator tunnel, due to the harsh conditions. For the FCC, a FLUKA model of the collider arc has been created. The results obtained, show increment factors of about 500 time compared to the LHC for the stochastic and the cumulative effect respectively. But the same model shows that shielded alcoves radiation levels are such that they can host electronics devices with a proper lifetime and with stochastic effects reduced to an acceptable rate. However, some electronic components will have to be implemented close to the accelerator. As a consequence, the major concerns of the cryogenic control system for this level, will be the data acquisition and the powering means between the sensors/actuators located in the vicinity of the beams and the processing/driving activities that will be in the alcoves. The FCC design report proposes to study the hardening of a cabled Ethernet based solution by applying the recommended "The FCC-hh Radiation Hardening Availability (RHA)", founded on a full-availability approach based on moving the processing tasks away from the equipment under control, introducing functionalities for self-diagnosis of failure, online hot swapping, remote control and remote handling.

A potential solution could be to use a CERN custom-made module, the Distributed I/O Tier (DI/OT). In this solution, a generic low cost customisable and reusable communication intermodule is deployed (see Fig. 9) to achieve the needed for radiation-exposed and radiation-free areas. This platform

is based on compact PCI serial communication. It allows the designers to use standard elements and standard voltages. The hardware kit includes different interchangeable modules ("1" for radiation-exposed areas and "2" for the free radiation areas) [15]:

Figure 9: Distributed I/O Tier hardware [15].

- Power supply:
  - "1" RaToPUS: hardened 100 W AC/DC switched mode power supply ;
  - "2" Off-the-shelf CPCI-S power supply: 300 W switched-mode power supply.
- Monitoring module Monimod to monitor simple functionalities such as voltage, current, temperature or the control of an additional fan tray temperature and speed in radiation exposed area ;
- FPGA based system board with replaceable fieldbus communication mezzanines to allow different communication protocols:
  - "1" WorldFIP and Ethernet-POWERLINK
  - "2" White Rabbit and PROFINET

In addition, considering the burden (resources, planning and costs) faced by the LHC cabling campaigns for each LS, wireless communication and power supply from the alcoves to the sensors/actuators, would be an excellent solution. It has been proposed in the FCC week 2015 [16] and since then, two initiatives WADAPT [17] and The "Smart Diagnostics" from the FuSuMaTech project [18] have presented the same type of proposal based on 60 GHz wireless CMOS Chips including IoT features for the second one

### Responsibility Sharing for Future Large Projects

For future projects, the sharing of responsibilities must be organized at the laboratory level. Hence, the CERN control community will be able to address the challenges proposed by the evolution of technologies. To achieve this goal the project need to profit of the experience at CERN labs or within successful control collaborations and last but not least to setup large collaboration frameworks for hardware and software.

## CONCLUSION

The LHC cryogenic control is the result of years of experience with this highly demanding process that can induce very long accelerator downtime in case of failure. To achieve the present availability, an automated and continuously updated cryogenic process was considered and implemented thanks to a good synergy between the cryogenic group and the accelerator controls groups.

Today, the ongoing CERN HL-LHC upgrade project requests the cryogenic system to be more reliable, versatile, and still easy to implement. These goals will be achieved with the collaboration of a large part of CERN control community spread in at least 5 CERN departments.

This evolution must start with a serious consciousness of the experience within successful control collaborations (e.g. Tango, EPICS), the integration of versatile procedures and protocols in parallel with several open and active collaboration frameworks (for hardware and software parts). It will be crucial to set the right balance between open solutions, solutions based on open standards, off the shelf's components and proprietary solutions. Special attention must be given to keep strategical domains under control, avoiding vendor lock-in issues and allowing a fair knowledge transfer between partners. This new architecture shall cover all the levels of the ancient control pyramid and offers all necessary services proposed by the SOA approach.

To integrate the presented technological breakthrough and not miss any technological rupture the CERN (infrastructures, accelerators systems, experimental physic, and the information technology) control community shall be included together with CERN research partners and partnership with the industry to federate the efforts. Our recommendation for the needed collaboration frameworks is to start as soon as possible (I.e., the hardened hardware components) with a strong management support.

# THE CONTROL SYSTEM OF THE NEW SMALL WHEEL ELECTRONICS FOR THE ATLAS EXPERIMENT

P. Tzanis<sup>\*,1,2</sup>, on behalf of the ATLAS Collaboration

<sup>1</sup> National Technical University of Athens, Athens, Greece

<sup>2</sup> Brookhaven National Laboratory, Upton, NY, USA

## Abstract

The present ATLAS Small Wheel Muon detector will be replaced with a New Small Wheel (NSW) detector in order to cope up with the future LHC runs of high luminosity. One crucial part of the integration procedure concerns the validation of the electronics for a system with more than 2.1 M electronic channels. The readout chain is based on optical link technology connecting the back-end to the front-end electronics via the FELIX, which is a newly developed system that will serve as the next generation readout driver for ATLAS. For the configuration, calibration and monitoring path the various electronics boards are supplied with the GBT-SCA ASIC and its purpose is to distribute control and monitoring signals to the electronics. Due to its complexity, NSW electronics requires the development of a sophisticated Control System. The use of such a system is necessary to allow the electronics to function consistently, safely and as a seamless interface to all sub-detectors and the technical infrastructure of the experiment. The central system handles the transition between the probe's possible operating states while ensuring continuous monitoring and archiving of the system's operating parameters.

## NEW SMALL WHEEL

In order to efficiently handle the increased luminosity that will be provided by the High-Luminosity LHC (HL-LHC), the first station of the ATLAS [1] muon end-cap system (Small Wheel, SW) will need to be replaced. The New Small Wheel (NSW) [2] will have to operate in a high background radiation region (up to 22 kHz/cm<sup>2</sup>) while reconstructing muon tracks with high precision as well as providing information for the Level-1 trigger. The detector technologies to be used come from the family of gaseous detectors, the first is called small-strip Thin Gap Chambers (sTGCs), and the second comes from the category of micro-pattern gas detectors and is named Micromesh Gaseous Structure (Micromegas (MM)) [3]. The new experimental layout will consist of 16 detection layers in total and 8 layers per detection technology (8 layers sTGC and 8 layers Micromegas), as shown in Fig. 1. The sTGC detectors are designed to provide fast trigger and high precision muon tracking under the HL-LHC conditions. On the other hand, Micromegas detectors have a small conversion region (5 mm) and fine strip pitch (0.45 mm) resulting in excellent spatial resolution and are primarily used for precise tracking.

## ELECTRONICS OVERVIEW

The NSW electronics for the trigger and Data Acquisition (TDAQ) path of both detectors is divided into two major categories, on-detector and off-detector electronics, as shown in Fig. 2. On the left-hand side, the front-end boards that

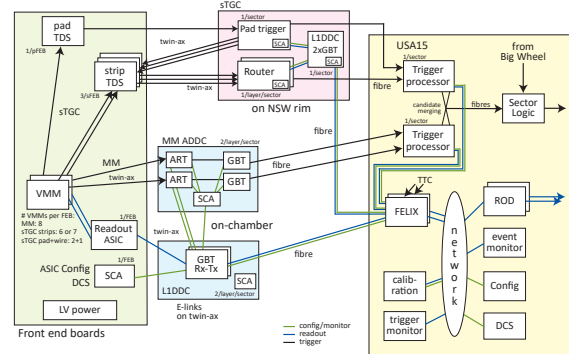

Figure 2: Overview of the NSW electronics scheme. The front-end detector boards are depicted on the left (for MM and sTGC), the data-driver cards (L1DDC, ADDC) in the middle while the back-end electronics can be seen on the right. [4]

are attached to the chambers bear VMMs, SCAs (Slow Control Adapter) and ROCs (Read Out Controller), while for the sTGCs they also host TDS chips. The ROC aggregates L1 data from many VMMs [5] and sends them to (Front End Link eXchange (FELIX) [6] via the GBTx [7]. FELIX also sends trigger signals to the front-end electronics via the ATLAS TTC system. It also sends tracking data from the ROC to the swROD (here depicted to send the data fragments to the HLT), and communicates with the Detector Control System (DCS) [8] for slow control purposes. The Micromegas trigger data are collected from many VMMs by

the ART ASIC, which sends them towards the Micromegas trigger processor, alongside geographical and timestamp information. The TDS chips on the other hand, handle the sTGC trigger primitives, and alongside the Pad Trigger and Router boards, are part of the more complex sTGC trigger chain, which has the associated trigger processor FPGA on the back-end as a final destination of its data-flow. Both FPGAs create muon candidates that are then transmitted to the SL. The NSW on-detector electronics (Front-End boards (MMFE8), Level-1 Data Driver Card (L1DDC), ART (Address in Real Time) Data Driver Card (ADDCC)) will be placed inside the cavern (detector area with radiation and magnetic fields) and consists of custom-made boards mainly using radiation-tolerant Application Specific Integrated Circuits (ASICs). The communication between these boards will be established with the use of mini Serial Attached Small Computer System Interface (SCSI) cables. The off-detector electronics FELIX, trigger processor, sector logic and services running on commercial server computers like Read Out Drivers (ROD), Detector Control System (DCS), event monitoring, configuration, trigger monitor and calibration) will be placed outside the cavern in an area that is called USA15.

## FELIX

The keystone of the ATLAS DAQ system will be the FELIX which is an FPGA-based system housed by a commercial server. FELIX will essentially be a bridge between the front-end electronics of all ATLAS detector subsystems, and their corresponding back-end components, which will mostly be software-based, as shown in Fig. 3. Situated in

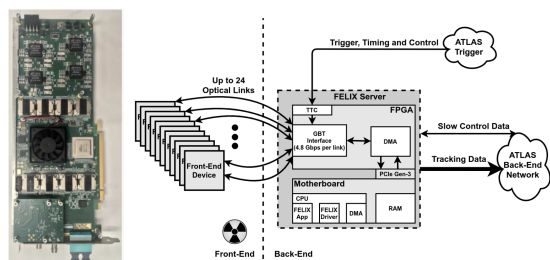

Figure 3: Left: The FELIX BNL712 FPGA board, which the NSW will use for its needs. It features a Xilinx® Kintex Ultrascale XCKU115 FPGA, a PCIe connector to interface with the CPU and the back-end network, and an optical coupler supporting up to 24 links. A dedicated mezzanine board receives the reference clock and the trigger information from the ATLAS TTC system. Right: FELIX and its relationship with other parts of the DAQ system.

the USA15, FELIX connects to the front-end electronics of the ATLAS cavern via optical links, or GBT links, each one of which is running at 4.8 Gb/s. For the NSW case, FELIX will interface with the front-end nodes over 24 optical links. These links carry the GBT frame, which is 84-bit wide. The Giga-Bit Transceiver (GBT) protocol is a transmission scheme that involves radiation-tolerant ASICs that

are capable of handling the large amounts of data of high energy physics experiments.

## GBT-SCA

The GBT-SCA ASIC (Giga-Bit Transceiver - Slow Control Adapter) [9] is an integrated circuit built in a commercial 130 nm CMOS technology and is the part of the GBT chipset which purpose is to distribute control and monitoring signals to the front-end electronics embedded in the detectors. It connects to a dedicated electrical port on the GBTx ASICs through an 80 Mbps dual redundant bidirectional data-link; namely the e-links. In order to meet the requirements of different front-end ASIC in various experiments, the SCA provides a number of user-configurable electrical interface ports, able to perform concurrent data transfer operations. The user interface ports are: 1 SPI master, 16 independent I2C masters, 1 JTAG master and 32 general-purpose IO signals with individual programmable direction and interrupt generation functionality. It also includes 31 analog inputs multiplexed to a 12 bit ADC featuring offset calibration and gain correction as well as four analog output ports controlled by four independent 8-bits DACs. An illustration of the different blocks are displayed on Fig. 4.

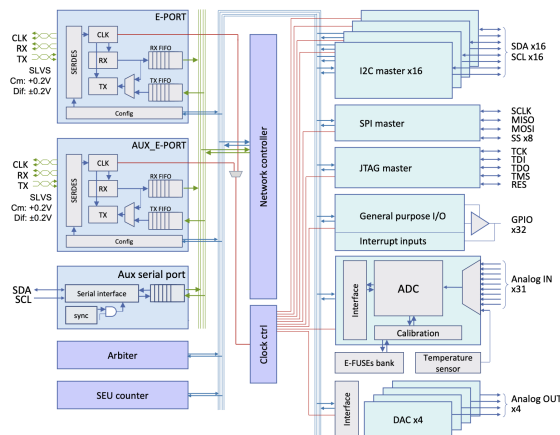

Figure 4: Overview of the GBT-SCA block diagram. [9]

## SCA OPC-UA SERVER

For the NSW project alone,  $\approx 6400$  SCAs will be used to configure and monitor various ASICs that are part of the general DAQ scheme. All of these SCAs communicate with the back-end (i.e. FELIX) via the GBTx, which implements the GBT protocol in its logic, while FELIX implements the GBT-FPGA core in order to communicate with the aforementioned package. The SCA-to-GBTx interface is the E-link, a serial differential line running at 80 Mb/s over HDLC encoding. The protocol defined by the SCA's requirements is request/respond that is, for every packet received by the SCA, the back-end that originally transmitted the packet awaits for an associated reply by the SCA. In this SCA-GBTx-FELIX communication chain, the last two components can be viewed as data mediators, so there is one piece missing: the back-end logic that actually

builds the packets-to-be-transmitted to the SCA, and handles the inbound traffic from the ASIC. This is a software suite, which is a dedicated Open Communications Platform Unified Automation (OPC-UA) server. Overview of the on/off-detector electronics and the DCS, Configuration and Calibration path via the SCA, the FELIX and the SCA OPC UA Server is illustrated in Fig. 5. A common readout path and a separate trigger path are developed for each detector technology. The communication chain starts in the control room with an OPC-UA client, which is the first step into our detector control system. Configuration and monitoring data is requested and sent from here to the OPC-UA server and next to the FELIX PCs, which lie in the underground service area. Then, through radiation-hard fibers, we reach the GBTx chips, which implement the optical links, to finally arrive to the SCA.

Figure 5: Representation of the on/off-detector electronics and the DCS, Configuration and Calibration path via the SCA, the FELIX and the SCA OPC UA Server [4]

## ATLAS DETECTOR CONTROL SYSTEM

The ATLAS DCS has the task to permit coherent and safe operation of ATLAS and to serve as a homogeneous interface to all sub-detectors and the technical infrastructure of the experiment. The DCS must bring the detector into any desired operational state, continuously monitor and archive the operational parameters, signal any abnormal behavior. The DCS was designed and implemented within the frame of the Joint Controls Project (JCOP), a collaboration of the CERN controls group and DCS teams of the LHC experiments. Standards for DCS hardware and software were established together with implementation guidelines both, commonly for [10] and specifically for ATLAS. It combines common standards for the use of DCS hardware based on SCADA system Siemens, WinCC Open Architecture, also known as PVSS with its older name, where it serves as the basis for all DCS applications. Figure 6 depicts the architecture of DCS which can be divided into Front-End (FE) equipment and a system Back-End (BE).

FE includes equipment DCS, including customized electronic systems and related services such as high voltage power supplies and cooling circuits. The BE system uses the software WinCC, integrating front-end control systems into the framework components to facilitate the integration of standard hardware devices and the implementation of homogeneous control applications. The two ends of DCS

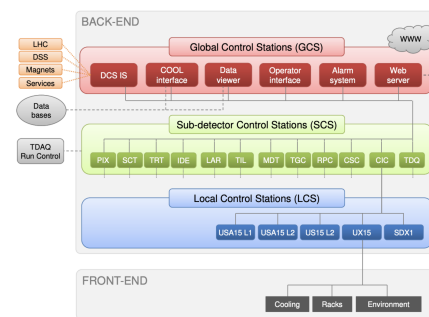

Figure 6: Graphical representation of the DCS architecture of the experiment ATLAS divided into 3 levels: GCS, SCS and LCS. [8]

communicate mainly through the industrial protocol bus CAN, while the communication standard OPC is used as a communication software protocol. The system BE is organized hierarchically on three levels, the Local Control Stations (Local Control Stations (LCS), the Sub-detector Control Stations (SCS)) and the Central Control Stations (Global Control Stations (GCS)). In total, BE consists of more than a hundred computer stations connected to a distributed system. Communication between subsystems of the system is handled by WinCC via a local area network. A distributed finite state machine, Finite State Machine (FSM), represents the complete hierarchy of the BE system as it integrates more than 10 million data elements into a single tree structure and ensures proper operation and efficient handling errors in each operating layer. The most important element of this system is the structure data point (DP), which plays the role of the global variable network. Each element of this structure has a unique name and configurability, and special DPs are used to read data from the hardware components updated by the interface OPC client-server communication.

Figure 7: Operator interface (FSM Screen) showing the detector in STANDBY configuration during LHC ramp-up. The top hierarchy level object is shown together with its children objects (top left) and the associated main panel (bottom right). The UI allows the navigation to any FSM object and associated panel within the whole ATLAS DCS hierarchy. On the top right, a list of objects with non-OK Status allow shortcut navigation to problems. [8]

Each node FSM has a unique name based on the subsystem name and its functionality following the conventions of ATLAS DCS and the state in which they are specified by a corresponding internal DP. The type of object FSM which defines the basic functionality of the node and its components, depends on the functional purpose and position of the element in the DCS architecture hierarchy. The main graphical user interface of ATLAS DCS with all subsystems integrated into a hierarchical structure FSM is illustrated in Fig. 7. The FSM is based on a strict hierarchical structure that constitutes parent-child relationships, where in tree construction commands are passed from parents to children, and situations from children to parents. This way, when some action is required on all children it is extremely efficient to command a higher node and correspondingly the status of the higher node summarizes the status of all nodes of any generation. All nodes are in a predefined state and only accept predefined commands as defined in the FSM type to which they belong. The DCS is operated from two primary, remotely accessible user interfaces – the FSM Screen for operation of the detector Finite State Machine hierarchy (see Fig. 7) and the Alarm Screen for alarm recognition and acknowledgment. Static status monitoring is provided by web pages on a dedicated web server allowing to quickly visualize all high level FSM user interface panels world-wide and without additional load of BE control stations.

## NSW DETECTOR CONTROL SYSTEM

Due to its complexity and long-term operation, the NSW requires the development of a sophisticated Detector Control System (DCS). The use of such a system is necessary to allow the detector to function consistently and safely as well as to function as a seamless interface to all sub-detectors and the technical infrastructure of the experiment.

### Architecture

The NSW DCS architecture and its integration with the ATLAS DCS have been finalized and projects will closely follow the existing look, feel and command structure of Muon DCS, to facilitate the shifter and expert operations. The current plan is to have 2 new sub-detectors, MMG (Micromegas) and STG (sTGC). The top node of both MMG and STG will propagate its state and receive commands from the ATLAS overall DCS. An overview of ATLAS MUO DCS structure with NSW DCS integration and brief structure of the sub-detector node structure is displayed in Fig. 8. The overview of the NSW structure and project/server allocation is displayed in Fig. 9.

## ELECTRONICS CONTROL STATION

### System Setup

The electronics system setup will consist of 28 FELIX servers, 12 for MMG and 16 for STG accordingly. The FELIX-SCA OPC UA Server granularity will be 1-to-1 meaning that we will have 1 SCA OPC UA Server per sub-detector sector. An example is illustrated on Fig. 10.

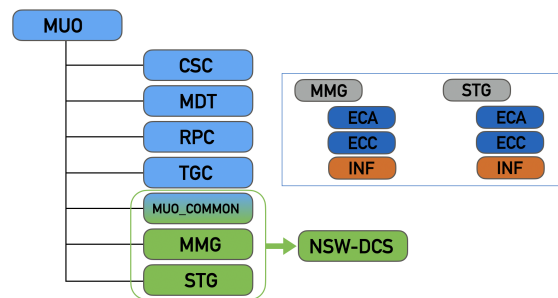

Figure 8: The overview of the ATLAS MUO DCS structure with NSW DCS integration and brief structure of the sub-detector node structure.

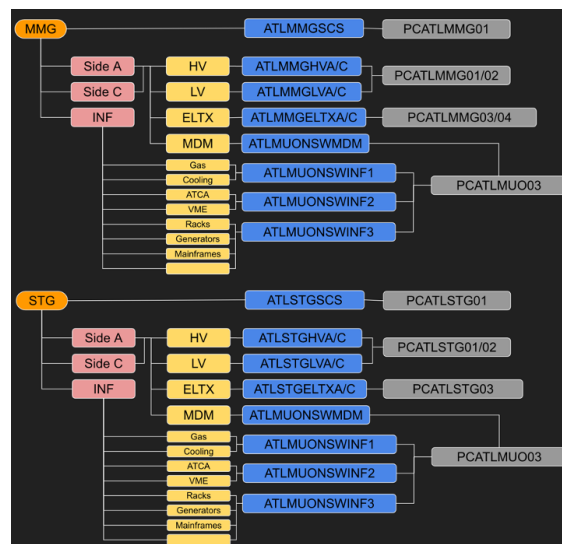

Figure 9: The overview of the NSW structure and project/server allocation.

Figure 10: An illustration of the FELIX-SCA OPC UA Server granularity mapping.

For the system operation, automated sequence has to be settled up on the FELIX machine in order to perform the GBT e-link configuration, the FELIX API initialisation and the SCA OPC UA Server automatically in the FELIX machine boot.

### Configuration

The NSW is a fully autonomous trigger and tracking detector system, adequately supported by an advanced electronics scheme and ready to handle the challenges of increased instantaneous luminosity at the High Luminosity LHC. It

includes more than 60k front-end ASICs and a few tens of FPGAs, which need to be configured before every run of the experiment. This process needs to be efficient and quick, since it needs to happen a few times per day. The main ASIC to be configured is the VMM, the front-end signal pre-processing chip that can readout 64 channels. A few kbytes of configuration data include thresholds for each channel, but also global registers to define the gain, time-to-amplitude conversion and many others. For this procedure we need to use the SCA's SPI master to communicate with the 8 SCA's SPI slaves in the VMMs. Also, the SCA's GPIO interface is required, to act as an enable signal. Moreover, a similar scheme using the SCA's I2C interface is used for configuration of the TDS chip, which is used for timing and trigger.

## Calibration

The calibration procedure consists of various timing and charge calibrations of the front-end electronics. Gain calibration is done by varying the signal input using the internal pulser of the chip. A specific configuration file needs to be loaded on the VMM chips, which is done with the SCA. Calibration of a time-to-amplitude converter is done by skewing the input clock, which is performed by re-configuring the specific on-board with different settings. Baseline and noise level is defined by reading out each channel output with the ADC when no collisions are occurring.

## Monitoring

Due to its complexity and long-term operation, the ATLAS detector requires the development of an advanced DCS for the electronics monitoring using the SCA chip, which is installed on the 8000 front-end boards of the NSW. The use of such a system is necessary for the safe operation of the detector as well as to act as a homogeneous interface to all the sub-detectors and the technical infrastructure of the experiment. This system gives us the ability to monitor more than 100000 parameters which include all the power/temperature sensors, on-chip temperature and information, which are connected to the SCA on all the front-tend boards of the NSW. In order to achieve the electronics monitoring via the FELIX-SCA and the SCA OPC UA server chain some steps must be performed in advance. The first step is the creation of the SCA OPC UA Server XML file, which the various sensors connected to the SCA ADC channels are specified. Then, the second step is the initialisation of the FELIXcore and the SCA OPC UA Server, services which are running into the FELIX machine. The third step is the subscription to the SCA OPC UA Server via a WinCC-OA OPC UA Client. Then, another step is the creation of the SCA OPC UA Server XML items into DPEs inside the WinCC-OA. And finally, the monitor of the board parameters is accessible via the SCA electronics control station. The electronics control station has been developed, following the existing look, feel and command architecture of the other Muon sub-systems, in order to facilitate the shifter/expert operations. It is mapped onto a hierarchy of Finite State Machine (FSM)

elements using the toolkit. For each individual layer, a main panel has been developed, providing the user with useful information, reflecting the state and status of the detector, its vitals displayed in trendplots; while a secondary panel provides supplementary details. A general view of the graphical user interface of the top FSM nodes and their constituents is shown in the Fig. 11 and Fig. 12.

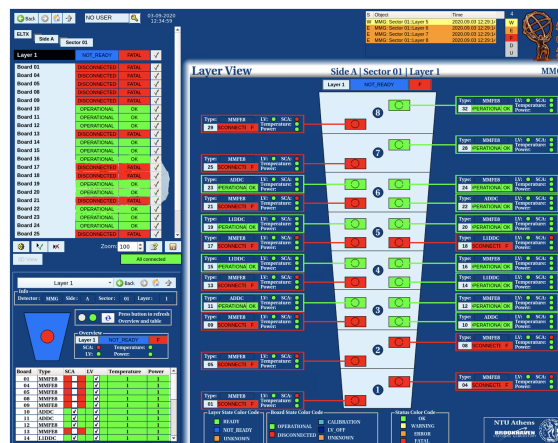

Figure 11: The interface of the Electronics control station and in particular the layer view of the sector which user can navigate and see in a glance the electronics status.

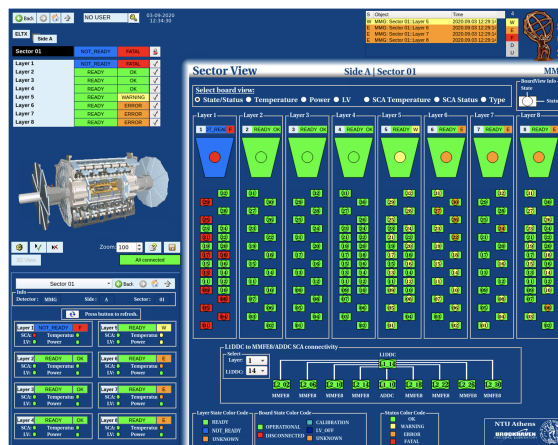

Figure 12: The sector view of the Electronics control station.

Each board's monitoring and conditions can be displayed on the panel. The state and status of the board depends on the status data point element of each board's temperature and power sensors and the communication validity of the SCA OPC UA server. The projects were validated through daily usage from shifters in the commissioning site at a first stage and then through the NSW control in ATLAS Control room.

## DCS-DAQ Interaction

As already mentioned above, DCS, calibration and configuration share the common SCA OPC UA Server path for the SCA. Although, the front-end boards which are equipped with the VMM, are using the same SCA ADC input channel

for both monitoring and calibration purposes. During the Physics run, the VMM monitor output is equivalent to the VMM temperature but during the Calibration run, the VMM monitor output will display the baseline measurement which is used for the board noise calibration measurements. Thus, during calibration run, VMM shows fake temperature values so a interface plugin between DCS-DAQ should be implemented in order to prevent the DCS to trigger several alarms and warnings. The solution found via the common SCA OPC UA Server and the FreeVariable status which is mainly a user defined OPC-UA item which can be controlled and monitored both by DCS and DAQ back-ends applications. Thus, during the Calibration run, the DCS will monitor the configuration status for this specific VMM of the FEB and the alarm will be disabled corresponding FEB's VMM, as shown in Fig. 13. In addition, more DCS-DAQ interaction tools are on-going in order to monitor the FELIX status, the GBTx alignment information and various FELIX infrastructure parameters.

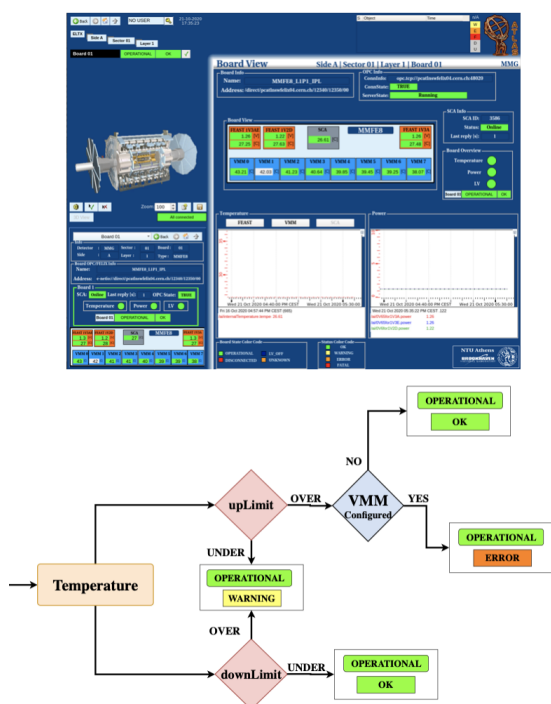

Figure 13: Top: Overview of the board panel of the electronics control station which shows the VMM temperature alarm disabled using the configuration status of the FEB's VMM via the SCA OPC UA Server. Bottom: A flow chart of the logic for the status and state definition based on the VMM temperature and the configuration status.

## ACKNOWLEDGEMENTS

This work was funded in part by the U. S. Department of Energy, Office of Science, High Energy Physics under Contracts DE-SC0012704, DE-SC0009920.

We acknowledge support of this work by the project “DeTANet: Detector Development and Technologies for High Energy Physics” (MIS 5029538) which is implemented under the action “Reinforcement of the Research and Innovation Infrastructure” funded by the Operational Programme “Competitiveness, Entrepreneurship and Innovation” (NSRF 2014–2020) and co-financed by Greece and the European Union (European Regional Development Fund).

# MACE CAMERA ELECTRONICS: CONTROL, MONITORING & SAFETY MECHANISMS

Saurabh Kumar Neema, Shikha Srivastava, Hariharan J., Sandhya Mohanan,  
Saju Joy, Padmini S., Anita Behere  
Bhabha Atomic Research Centre, Mumbai, India

## Abstract

MACE Telescope installed in Ladakh Region of India comprises of many functionally diverse subsystems, Camera being the most important one. Mounted at the focal plane of 21 m diameter parabolic reflector dish, event driven Camera system comprises of 1088 PMTs, with 16 PMTs constituting one Camera Integrated Module (CIM). Central Camera Controller (CCC), located in Camera housing, manages and coordinates all the actions of these 68 Modules and other camera subsystems as per the command sequence received from Operator Console. In addition to control and monitoring of subsystems, various mechanisms have been implemented in hardware as well as embedded firmware of CCC and CIM to provide safety of PMTs against exposure to ambient bright light, bright star masking and detection and recovery from loss of event synchronization at runtime. An adequate command response protocol with fault tolerant behaviour has also been designed to meet performance requirements. The paper presents the overall architecture and flow of camera control mechanisms with a focus on software and hardware challenges involved. Various experimental performance parameters and results will be presented.

## INTRODUCTION

The MACE Telescope is a 21m diameter gamma ray telescope installed at Hanle in Ladakh, India at an altitude of 4270m above sea level, the highest for any Imaging Atmospheric Cherenkov Telescopes (IACT) based telescope. Primary objective of such IACT's is to detect High energy cosmic gamma rays emanating from various galactic and extragalactic sources. MACE Telescope detects very faint and narrow (5-10 ns) Cherenkov light generated by Extensive Air Shower when High Energy Gamma rays (20 GeV – 10 TeV) interact in the earth's atmosphere. The Imaging Camera is an essential subsystem of the Huge Telescope system and has been designed with state-of-the-art technologies for High Speed Data acquisition within the constraints of space, weight and power in such a way that the entire electronics for analog signal processing, digitization, triggering and event building is fully integrated into the camera body. Only Power supply and Network cables are connected between Ground station and Camera. Control and monitoring aspects of highly compact camera electronics is discussed in the current paper. Figure 1 presents the latest photograph of MACE Telescope during observation.

Figure 2 describes the block diagram of various subsystems of Camera Electronics. Second level trigger Generator (SLTG) detects time-space coincidence across nearby

Figure 1: MACE Telescope during observation.

pixels in trigger regions based on the first level Trigger information from various CIMs and generates system-wide Trigger signal. After receiving the Trigger signal, CIMs start acquisition and send event data to the Data Concentrator (DC). Efficient data processing algorithms [1] have been implemented in CIM and accumulated charge data for each pixel along with profile of hit pixels is formed in the CIM data packets. DC collects these data packets from all the CIMs and prepares camera event packets. Event data from camera is sent via 1 Gbps Ethernet link to the Ground station. The co-ordination, control and monitoring of various subsystems in a reliably deterministic manner is a challenging task.

Other subsystems which are part of the camera electronics are Lid Controller, Temperature monitoring system and LED/Sky Calibration system.

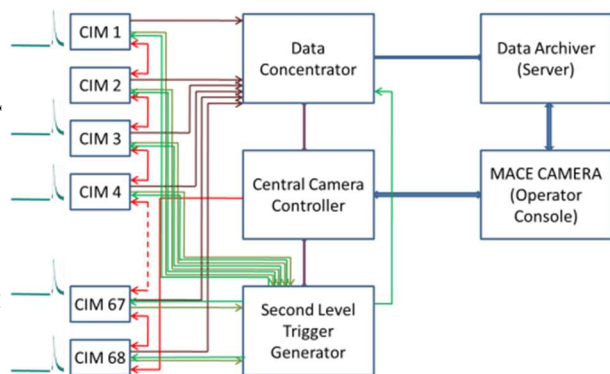

Figure 2: MACE Camera block diagram.

## MACE CAMERA CONTROL SYSTEM ARCHITECTURE

### Requirements of the System

The main requirements of MACE Camera Control system is to set system configuration, monitor operating parameters, coordinate all functions through command/ response protocol and take corrective/ recovery action to ensure safe and stable operating conditions during a sky observation.

The settable configuration parameters include pixel related settings like Bias voltage, Discrimination Threshold etc. within CIM. For STLG the configuration includes Trigger Configuration, Trigger mode etc. and for DC it includes Acquisition mode, Active data modules etc. The operating parameters such as Anode Current (AC), Single Channel Rate (SCR) etc. that indicate light seen by the PMTs are monitored at higher rate of 5sec to ensure corrective action to limit exposure of PMTs to excessive light. Set parameters such as PMT Bias Voltage (HV), Temperature, Power Supply Status etc. are monitored at 1min to ensure stable operating conditions.

Other operation involves Lid controller to safe and reliable shutter open/close based on the command from ground station and Temperature monitoring to monitor temperature at different locations inside the camera.

### Hardware Implementation of the System

Each Camera Integrated Module (CIM) contains programmable HV generation module, Pre-Amplifiers, Amplifiers, Pulse discriminators, Scalar counters for individual channels [2]. Each module also houses First Level Trigger generators, scalar counters and Digitization circuits. Extensive Data acquisition, Control and monitoring analysis has been carried out on CIM modules [3]. All these 68 Modules and other subsystems are controlled by Central Camera Controller (CCC) [4]. CCC receives control commands from ground station over Ethernet and accordingly controls various subsystems of Camera Electronics and transmits regular Health monitoring information to the ground station.

Camera Shutter open/close mechanism is also implemented in CCC embedded software as well as FPGA firmware. Two shutters (2m x 1m each) are moved by DC Brushless motors, which are controlled by CCC FPGA firmware in Voltage control mode. It regularly checks for various limit switches and varies the speed of motor to optimize the time to open/close. Various failsafe mechanisms are implemented in firmware to avoid deadlock condition. There is also a mode to operate shutters manually during maintenance schedule. Figure 3 shows the rear view of MACE Camera Electronics.

There are two control links between CCC and CIM modules, which are connected in multi-drop topology. First control link, based on RS485 standard, is used to sense the status of Input power supplies to CIM and accordingly

Figure 3: Rear view of MACE Camera Electronics.

Switch ON/OFF of CIMs can be performed. CIMs can be reset using this link. This link is used for sequential powering of CIMs, which reduces sudden power surge associated with powering of all CIMs together. Second control link is based on I2C protocol and it is used to control overall functioning of CIM module including individual channel HV values, Discrimination threshold for each channel, First level Trigger logic modes, Digitization modes etc. This link is also used to collect and send health parameters of the CIM including HV read back value, Anode current, Discrimination Threshold read back, Scalars of various input channels, readings of 5 temperature sensors inside CIM etc. I2C bus operates at 100 kbps speed. Local microcontroller firmware controls various functions of the CIM. Detailed description of the firmware is given in the next section. The control link between CCC and Data Concentrator is RS-232, operating at 115200-baud rate; through this link, DC is set into proper mode of operation and various status flags are read at regular interval. Control link between CCC and STLG is based on SPI Interface operating at 1 MHz clock; through which STLG is set into particular operation mode and various status flags are read at regular interval. Figure 4 describes the block diagram of various control links.

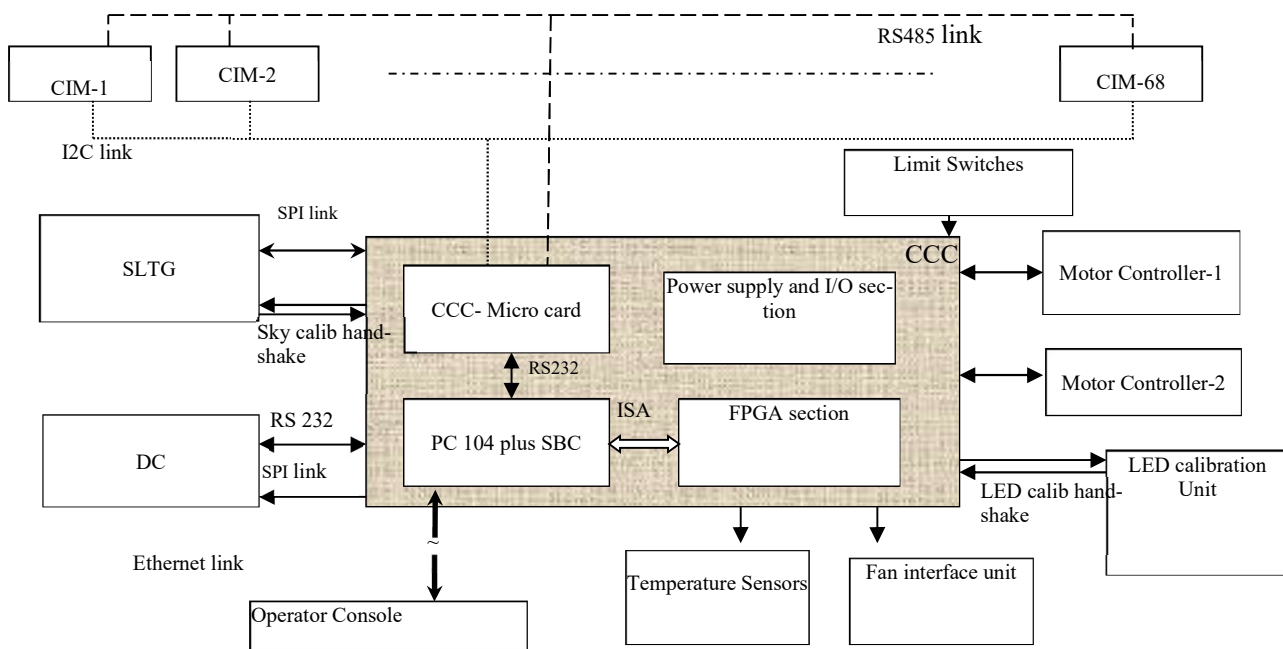

Figure 4: Control and monitoring system of MACE Camera.

## Software Implementation

For control and monitoring of various subsystems and to provide overall safety of MACE Camera, embedded firmware of CCC and CIM plays an important role.

Each CIM has a controller card, referred to as LTC Micro board, which controls various functions of CIMs. It monitors telemetry parameters of the CIM like Anode Current, SCR, HV, DT, board temperature etc. Additional functions of control of PMT HV bias and LVDS link for event data transmission to data concentrator and sequential powering up of camera electronics are also performed. The LTC Micro module communicates with CCC on a multi-drop, differential I2C network with CCC acting as master and CIM as slave. System and experimental configuration settings are received upon initialization of the CIM. Post configuration, different telemetry parameters are acquired from the CIM at regular intervals on request-response basis.

The Microcontroller firmware is designed to be multi-tasking in order to effectively monitor the critical parameters of CIM and to service asynchronous telemetry data requests and other commands from the CCC. Periodically, CIM parameters of HV, DT, AC and SCR are acquired from the respective hardware modules. A correction algorithm is run on the acquired data, which analyses the current data with set limits for each parameter from the pre-loaded configuration. The algorithm iteratively evaluates and sets each pixel's state based on the current value of monitored parameter. Based on the algorithm, a pixel identified to be persistently in an abnormal state for a set duration is permanently disabled to safeguard the PMT. Concurrently, a dedicated task responds to commands from CCC.

ISR for controlling I2C operations has been designed and exhaustively tested to handle all conditions of the bus state [5]. However, in situations where the CIM becomes unresponsive over the I2C network, a RESET command from CCC can be sent over an auxiliary link to reset the microcontroller to its initial state.

Central Camera Controller (CCC) is the central entity that manages and coordinates all the actions of the camera. The CCC interfaces with the subsystems for control, configuration, monitoring, error handling, and recovery to ensure that fault tolerant and reliable observations are obtained. CCC software has a layered architecture consisting of Managers dedicated for specific functionality at each level, which interact among themselves through event notifications. The top layer consists of important modules like Command Parser, Telemetry Manager, Sky Calibration Manager and Sync Loss Manager for carrying out dedicated functionalities like managing actions on Camera subsystems by parsing the command received from MACE OC, and serializing the final response to MACE OC after execution; periodic health monitoring of CIMs, collection of diagnostics information from all the subsystems and sending them to OC; facilitating the sky calibration cycles during data acquisition; and error handling and recovery of Camera during event data acquisition from synchronization errors. Managers at top layer uses the lower level Subcommunication Managers for interaction with different subsystems involved.

Apart from basic functionalities of control and monitoring, CCC software also provides fault tolerance, error handling and recovery of Camera at runtime [6]. To ensure high availability of the entire telescope, CCC allows failures of certain number of CIMs, within acceptable limits that is user configurable. On error response from CIMs, on

timeout or incorrect response, after 3 retries of the command, it disables and power off the faulty module. The scheme allows the telescope to continue to operate with useful data collection making the system fault tolerant in nature. It provides error handling mechanism by categorizing different types of errors for each of the sub-actions involved for Commands from OC including timeout and communication error. Some of the errors are handled and recovered by retries of command, while others are reported at OC.

An adequate command response protocol between CCC and CIM has been established to meet the stringent performance requirement of acquiring periodic telemetry requests from 68 CIMs every 5 seconds. CCC sends some of the commands for CIMs over I2C link in a Broadcast mode for parallel execution of the commands, wherein one of the active CIMs, set as an acknowledgement module, responds with the result of the command. This broadcast scheme highly increased the responsiveness of the system by reducing the effective system response time for overall observation run.

## CONTROL AND MONITORING FEATURES

### *Bright Star Masking*

In the field of view of certain Gamma ray sources, various bright stars are also visible. These bright stars emit light, which create very high Single Channel Rates (SCR) in few of the nearby pixels, resulting in generation of spurious triggers from the Trigger Generator and compromising the recording of actual gamma ray events. In order to avoid such spurious triggers, a Bright star masking Algorithm has been implemented in the firmware of CIM. This algorithm monitors SCRs of each pixel every second, and if the value crosses a set Threshold limit, the particular pixel is disabled from participating in generation of First Level Triggers. This way the pixel remains active and collects charge information during actual gamma ray event caused by other pixels without generating spurious triggers. Hysteresis of 70 % has been implemented in the Algorithm itself, due to this the pixel starts participating in trigger generation when the SCR values reduces to 70% of set Threshold value. The following graph shows the pattern of Bright start masking in the case of pixel no. 855 during the observation of source MrK501 on 29/08/2021. For the day's experiment, Threshold for Bright star masking was kept as 1 MHz. During the observation period, the algorithm got activated for few of the pixels. For the sake of simplicity pattern of only one pixel is presented in Fig. 5.

### *PMT Light Exposure Protection*

Photo multiplier Tubes are an indispensable part of Camera electronics and it is of paramount importance to preserve them from overexposure to unwanted light, which may reduce their productive life. During the source observation, various vehicular movements or bright stars cause drastic increase in Anode currents of individual PMT based

pixels. In order to protect PMTs from exposure to unwanted light sources, an algorithm has been implemented in the firmware of CIM which continuously monitors Anode current (AC) and SCRs of individual pixel every second. If any pixel crosses the set value of AC for a particular number of times called UCT, the algorithm temporarily disables the particular pixel by reducing the bias voltage to a safe value. The algorithm re-enables the pixel after a set time interval called Reactivation Time (RT) and checks for AC again for UCT and accordingly takes a decision to keep it enabled or temporarily disabled. Few such attempts are carried out which are set by Maximum Retrial Count (MRC), after that the pixel is permanently disabled for the day's observation. Graph in Fig. 6 describes the behaviour of the pixel protection algorithm. Here, the y-axis describes the PMT Anode current and x-axis describes the Telemetry sample number. The threshold for Anode current is set at - 5  $\mu$ A. Value of UCT and RT is set as 4 and 30 seconds respectively.

### *Event Data Synchronization Loss Detection and Recovery*

After receipt of Master Trigger signal from SLTG, all the CIMs acquire event data independently and transfer the event data in a predefined packet format through unidirectional point to point LVDS links to DC. DC Firmware then reads the event data from individual channel buffers and builds the Event data packet. It is of paramount importance that DC event packet shall have all the event packets from CIM, which are due to the same cosmic event and the corresponding event numbers across all CIMs are synchronized. To ensure that there is no event misalignment due to any data corruption during transmission or processing, Event synch-loss detection and recovery mechanism has been implemented in DC and CCC. Data Concentrator checks for event marker at every DC event in order to detect any data processing error. Additionally, DC regularly checks for CIM Event packet nos. for all the CIM event packets in a DC event packet. If there is any mismatch in the CIM event nos., then DC informs Loss of Data Synchronisation to CCC. On receipt of Synch loss info from DC, CCC stops the ongoing data acquisition and restarts a fresh data acquisition after resetting all event counters. This automatic recovery of Synch loss takes approx. 5 seconds and it is a very rare phenomenon in actual observations. Even if it occurs, it gives advance indication to some hardware related issue like data cable malfunction or other hardware issues that can be sorted out with pro-active fault diagnosis.

### *Regular System Calibration*

During the course of the observation, there is huge variation in night sky background light due to various factors. For better resolution of acquired charge on the PMT during source observation, effect of this background light on pixel accumulated charge has to be considered. Regular system calibration runs are carried out during the source observation every 5-15 min interval so as to assess the extent of

Figure 5: Bright Star Mask algorithm trend on pixel number 855.

Figure 7: POST Status on operator console of MACE Telescope (08/07/2021).

variation of night sky background light. At the set Interval, CCC gives commands to SLTG, which in turns generates fix number of self-triggers at a set frequency due to which all the pixels record charge collected due to background light and such events are tagged as SKY calibration events in DC Event data packet. Similarly, PMT gain calibration is also carried out at a regular interval just after the SKY Calibration cycle, during this CCC instructs LED driver (mounted at the centre of reflector dish) to generate fix number of LED pulses at a set frequency. All the PMTs collect charge due to LED pulses fired from the centre of reflector dish. Gain of all the PMTs is calibrated with respect to the charge calculated in the Reference PMT.

### Safety & Diagnostics Features of the System

Due to harsh weather conditions in Hanle, Temperature in winters can go up to -30 degrees Celsius. CCC is designed to operate in such harsh environments and initially only CCC is powered on. It acquires the temperature from 8 Temperature sensors mounted inside the camera body and 2 mounted on the outer body of Camera. Temperature reading from all these is taken into consideration before powering ON of other subsystems of the camera in winter season. Passive heaters are provided inside the Camera to bring Camera Temperature to an operating range. Only after attaining the operating temperature, various subsystems of camera are switched ON. At the time of powering ON

of Camera electronics, each subsystem performs its own Power on Self-Test (POST). After power ON CIM checks for various memory locations, setting and read back of discrimination voltages, ADC baseline read back, firmware version mismatch, Temperatures etc. If there is any error in POST STATUS from CIM, the particular CIM is switched OFF and does not participate in observation. One such scenario is presented in Fig. 7 where one of the board firmware version information of CIM 64 was not recorded correctly at the time of POST so CIM 64 was switched OFF for the particular experiment. The system also performs various link tests like Auxiliary Link Test, I2C link test and Data link test etc. and takes corrective actions before proceeding to the observation schedule. Regular health parameters of CIM are recorded and sent to the ground station. There are 5 Temperature sensors inside each CIM. CCC monitors each of them at regular intervals, if the temperature of any CIM crosses the set value, CCC can take corrective actions.

## CONCLUSION

MACE Telescope is operational since early 2021 and regular trial source observations are being carried out. Initially stability of various configuration parameters was verified by long trial runs in close lid conditions and parameters were found to be stable over a long period of time e.g. 4-5 Hrs. various control and monitoring features of Camera

Electronics have been rigorously tested in real source observation condition. Implemented algorithms like self-diagnostics, safety, PMT protection and Telemetry monitoring etc. are performing as per the design specifications.

## ACKNOWLEDGEMENTS

Authors would like to thank the colleagues from Astrophysical Sciences Division, BARC Mumbai for their support in various activities related to MACE Camera Electronics. Authors would also like to thank the staff of MACE Telescope site, Hanle for their support in carrying out the observations in the challenging weather conditions.

## Abstract

The remote control and monitoring of accelerators and experimental setup has become essential when remote work has become the norm for the last two years. Unlike the desktop user interfaces which have been developed for the use from physical workstations, web application are naturally accessible remotely via the ubiquitous web browsers. On the other hand, Web technology development requires a specific knowledge which has yet to be disseminated in the control system engineering and desktop frameworks still have the benefit of rapid, and easy development even for the non-specialist. Taranta Suite is a collection of web applications jointly developed by MAX IV Laboratory and the SKA Observatory, for the Tango Control System. In line with the "no-code" trend for the users, truly little knowledge of web technologies is needed. An operator can create a graphical user interface on-the-fly and can share it instantly. Authentication and authorization ensures that the right access level is given to the user. This paper will describe the system, the details of its implementation, and the first usage at the different facilities.

## INTRODUCTION

There is no doubt about the usability and the optimised user experience of web interfaces and applications in everyday life situations. The last decade has seen an explosion of these kind of developments. New tools, new frameworks and new wide-spread applications have gained fame and number of users and slowly displaced traditional desktop applications. However, scientific environments are usually built on traditional and well known infrastructure, lagging behind software innovation and trends. MAX IV and SKA facilities were pushing and promoting the usage of web applications in their respective communities and in 2019 they joined efforts and gave birth to Taranta, a web application for building user interfaces in a Tango ecosystem [1]. The tango community renamed it from the previous Webjive name [2].

This new application is profiting from recent years of development in User Experience (UX) and User Interface (UI) web frameworks. It provides an out of the box, modern and stylish environment for accessing the most important functionality of a Tango device, from what is called the Device View [2]. Simple and powerful enough for fast access, however, the most remarkable functionality is the Dashboard

View. This element is where the user can create its own user interface by drag and drop components (which are called Taranta Widgets) and easily configure and link them to Tango devices. This is where the idea of No-Code plays a fundamental role, Taranta leverages the UI development to the end user.

## NO-CODE PARADIGM

The lead time to get a new user interface is usually very long. The software development and UI design have to follow a number of established stages starting from the user requirement gathering to the usage of a final product. The no-code trend define a way for any end-user to develop their own software and then to make it available immediately to a larger audience of the same end-user group [3]. This way, user of a no-code system doesn't need to be knowledgeable in software development and how the software is deployed to be able to add value into the system. All the infrastructure is completely transparent and does not prevent fulfilling their will.

There is a lot of advantage for the users to bypass the traditional software development chain. First of all, as users themselves, they know exactly what the software should look like and which feature is expected. The users own the requirements like in any development method, although in a no-code system many filters are avoided since the users develop their own product. Writing down the requirements, understanding the specification and code development throughout different persons are some examples of filters which attenuate the original idea.

The concept of accelerating the software development has started years before the no-code trend arrived. Prototype generated by sketch of the Graphical User Interface (GUI) in the Rapid-Application Development (RAD) [4] made a step closer to the final product by developing only the functionalities. An extension of the same concept appears in the early 2000s for the creation of UI based on the definition of the domain i.e in the model development driven (MDD) all the structure of the software (Model) and part of its implementation is generated from the requirement. Visual programming language helps the power-users with enough software skills to design a system rapidly for their local applications i.e workbench like LabView can produce application with no manually written code code. The dissemination to a larger group of users can be delegated later to the software engineers.

\* mikel.eguirau@maxiv.lu.se

In our Scientific Facilities and in particular in the Control System, the software development has followed the same trend all the long to the industry standard evolution. Application like Taurus Designer [5] for the Tango Control System and Control System Studio for EPICS [6] allows to leverage the skills of the scientist to create GUI on top of their Control System. No-code introduces another level of independence for the user and rely on them to also publish their software to an entire group of people without involving any IT staff for the deployment, which is a large cost of a software. Not only can the end-user benefit from this possibility but also the they can leverage the use of technologies traditionally separated, e.g. web technologies and control system frameworks.

The No-code platform are designed from the web technology for its low-cost of deployment of application. Only one computer server running a web application is necessary to allow many clients to access the program. On the contrary, a desktop based application has to be deployed on every single workstation which is usually a long and not user-friendly process.

Although No-code is completely oriented to simplify the end-user development, the software developers are still needed to program the elementary bricks of the application.

TARANTA

A Taranta application is composed of two main elements: the backend and the frontend application. The backend provides a GraphQL API to a Tango control system. The client is a web application that provides a generic tango device application, but it also provides a dashboard. A blank canvas for the users to build their User Interfaces.

Figure 1 displays how Taranta components are linked together. It is composed of several applications, or micro-services, this way each component is developed and tested independently. The next sections will describe the most relevant aspects of the main elements.

TangoGQL

GraphQL is a modern query protocol for the application layer developed by Facebook [7]. It provides a unified interface between the client and the server for performing data oriented actions e.g fetching and manipulation. It removes the need of having multiple endpoints for data manipulation to/from the server and instead returns the data what the client asks for over a single API endpoint. The advantage of this approach is that the client asks explicitly for what it needs. In addition, due to its schema-based implementation, the extension of the API does not change the API interface so that compatibility between versions is simplified.

TangoGQL [8] is an implementation of GraphQL over Tango. It provides a communication based on web-socket [9] for subscribing to asynchronous attribute value events, and a GraphQL interface to the Tango database. The standard operations over a Tango device are supported, for example

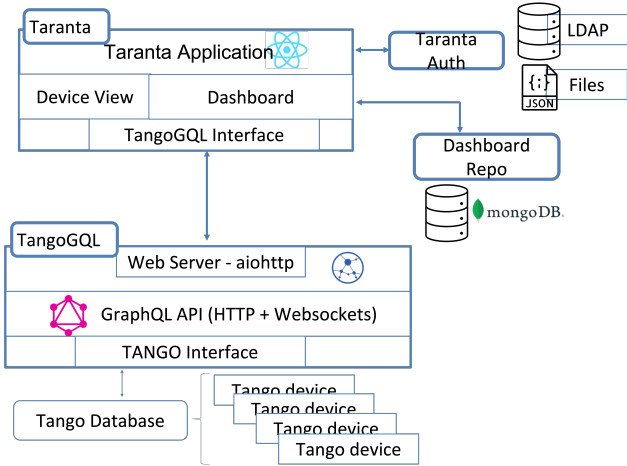

Figure 1: Structure of Taranta, at the bottom and connected to the tango ecosystem there is the TangoGql interface, to which the Taranta web application talks to. Together with the authentication and repository database systems, Taranta suite is complete.

read/write access to device properties and attributes, and command executions. It is developed in Python 3.9.

Front-End

The front-end of Taranta is a React [10] application that is used both to browse, inspect and control Tango devices and to create and run dashboards, each composed of widgets. It accesses the Tango Control System through the TangoGQL API, the communication between Taranta and TangoGQL is managed by an appropriate frontend component. The first developed component was the Device Viewer, Figure 2,

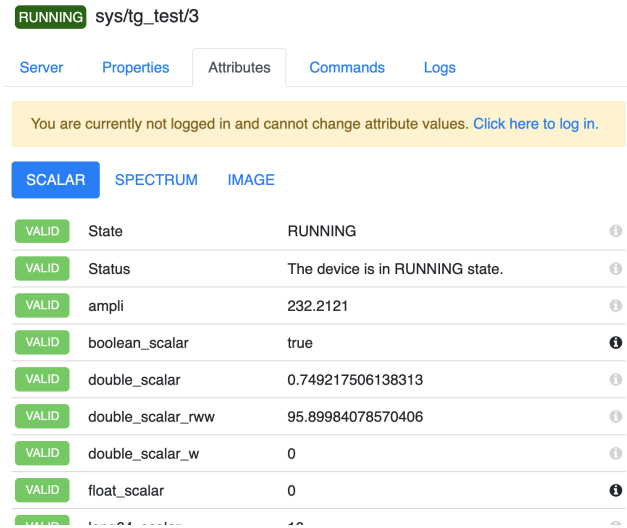

Figure 2: Generic Tango device viewer. Several tabs are available for displaying different types of information, device properties, attributes, commands and logs. The attribute view is further split into the different data types present in the given attribute.

which provides a generic view for any tango device running in the system. It has a search section, which aims at helping the user navigating the full tango device tree hierarchy. Once the desired device is selected, the right section of the page will display several navigation tabs for accessing device properties, attributes (further split based on the data format), commands and logs. Any user can see everything, but only logged in users can modify attributes or execute commands. The values of the attributes are updated at real time. In addition, the selected device name is appended to the page url, thus, it can be shared with others colleagues to access the same view.

As monitoring tool the Device Viewer is a very fast way to access a Tango device, but it lacks of any kind of customization. In order to provide a configurable user interface the Dashboard View was developed. It belongs to the Taranta front-end but it is a very different user interface. As opposed to the static device view, here the user can create their User Interface starting from a blank page and simply dragging and dropping widgets into it. Each widget comes with its own configuration, depending on the purpose of the widget, but they all provide a Tango device (or attribute) selection.

**Taranta widgets** A widget is a dashboard component to serve the function of interacting with Tango devices. There are different types of widgets. A command can be sent to tango device through command related widgets. An attribute can be read/write through specific attribute widgets. Using widgets, users are able to monitor attribute changes and take remote control operations.

**Available widgets** The available widgets fall into different categories according to their functions: labels, attributes, commands and plotting. The label widget is mainly used to display static information. It is basic and also flexible with a hyperlink feature, that can be configured by the user to switch between different dashboards. It enables well-structured dashboards.

The attribute widget family is used to display the value of interested attributes, which also includes the device status. The displayed information and text size can be customized to user settings. Several different widgets are available depending on the data type of the attribute (numeric, boolean, etc.), but also some widgets provides extra functionality for example the SimpleMotor and SardanaMotor widgets, where movement steps can be defined and move commands issued.

A command widget enables users to send commands with parameters to tango devices. It also enables users to customize widget settings based on their needs. Again, several widgets are available for different command arguments and data types.

The array type attributes have its own set of widget. For example, a spectrum widget is a special attribute widget, which allows plotting of 2-dimensional attributes. Multiple spectrum attributes can be plotted on the y-axis against one spectrum attribute on the x-axis. The plots are updated when a new attribute value is pushed in by its associated

tango device. The rendering of plot is achieved through Plotly [11], which enables user interaction with the plots including zooming, extracting specific graph parts, and also axes resetting. Several widgets are available providing different visualization options for example heatmaps, scatter plots, table like view, a few others.

The variable selector widget is a new feature which enables the interaction between a widget and a dashboard variable. A dashboard variable allows users to create a parametric dashboard where a running device can be replaced by a variable in widget configuration. Users can associate a device to a dashboard variable and change device in run mode. All widgets having this device which subscribed to this variable will be updated with the new device value.

Currently 25 different widgets are available, and more coming regularly due to requests from our user community. Moreover, development is ongoing to allow users to create new widgets from the existing ones.

**Creating a new widget** A widget is composed of a definition (also called a widget definition) and a React component. The definition is a declarative object describing the characteristics of the widget and the inputs that it receives.

A widget definition starts with a JSON object. An example of a definition is as follows:

```
const definition = {
  type: "OUR_NEW_WIDGET",
  name: "Our New Widget",
  defaultWidth: "10",
  defaultHeight: "15",
  inputs: {
    device: {
      type: "device",
      publish: "$device",
    },
    position: {
      type: "attribute",
      device: "$device",
      attribute: "Position"
    },
    ...
  }
}
```

In this example a new widget is defined with some styling options as well as the required input fields, in this particular case a tango device must be defined and which attribute of that device should be considered position. In addition, Table 1 describes a brief description about required widget definition keys.

Different types of inputs can be defined through their corresponding input definition interfaces. For example, an attribute can be defined with *AttributeInputDefinition* where the bounded device and attribute name as well as other characteristic keys are set. Different from other inputs, the device name can be published to a variable which is available for other inputs. For TypeScript implementation, the widget inputs can be obtained through *WidgetProps* type mapping, which makes the process much easier to develop a new widget and avoid type inaccuracy [12].

Table 1: Description of Widget Definition Keys

Key	Type	Description
type	string	Type identifier for the widget. Must be unique (e.g. "ATTRIBUTE_PLOT").
name	string	The name of the widget shown to the user (e.g. "Attribute Plot").
defaultWidth	number	Default width (in number of tiles)
defaultHeight	number	Default height (in number of tiles)
inputs	object	An object where the keys are input names and the values are corresponding to their input definition.

In the corresponding React component, the declared inputs are made available through a prop named *input*. A minimal example of a React component for our new widget would as follows:

```
class OurNewWidget extends Component{
  render() {
    const {
      position
    } = this.props.inputs;

    return (
      <div>
        Position: {position.value}
      </div>
    );
  }
}

export default {
  component: OurNewWidget,
  definition
}
```

This minimal example describes how to create a basic widget. All the rest of the required interaction with the dashboard page as well all the communication with the tango device is already handle by Taranta, no additional development is required. Figure 3 shows the newly created widget in action, in both editing mode for selecting a tango device as well as in running mode displaying an attribute value.

### Taranta Dashboard Repository

The dashboard repository is an API for fetching and storing the dashboards. It is crafted from ExpressJS and communicates with MongoDB to store and fetch dashboards. Few endpoints are open to provide data to anonymous users, for example, fetching the dashboards. Whereas other endpoints are restricted and require a valid JWT (JSON Web Token) to perform the respective function.

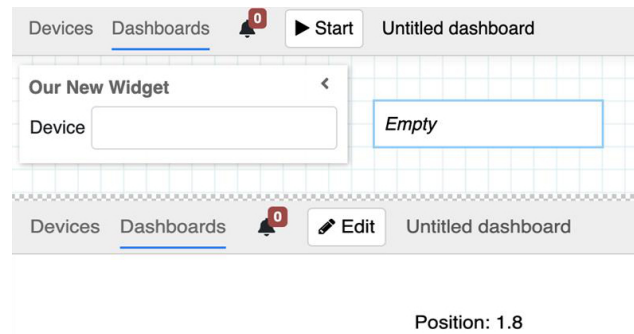

Figure 3: A minimal widget example. The top view displays the widget in editing mode where the users selects the tango device. The bottom view shows the widget in action.

### Taranta Auth

Security of web applications has been recently gaining enormous popularity. This could be due to its nature of being accessible from various end-points and therefore of potentially being an entry point to malicious attackers. Furthermore, it could also contain sensitive data and years of progress and their loss can be catastrophic. Several industry standard protocols could be followed at application-level as well as organization-level to enhance the security of web applications and to ensure the data integrity. The Taranta Auth is a micro-service based on NodeJS and provides an authentication service to be use by the Taranta suite for authenticating and authorising users and identifying their shared groups. It uses JSON Web Tokens [13], an open standard to digitally sign information for being transmitted between services. Taranta Auth access an LDAP repository or a JSON file to manage users or to retrieve user information. An anonymous user can run dashboards and can browse and inspect devices. However, to be able to send commands to devices, to change their attributes and to create or modify dashboards, an authentication is required.

### USAGE

All facilities involved in the development have a very different experience using Taranta. This is partly due to the stage in which each facility is. MAX IV is in a stable user operation phase while SKA is in building stage. Despite these differences on the particular situation on each facility the development has benefit for both experiences.

### MAXIV

Almost every system in MAX IV uses Taranta in one way or another, from accelerator operators to the beamlines, including the whole range of support groups. The operators use dozens of dashboards to monitor the insertion devices, RF and water cooling systems in the LINAC, and also for the status of the personal safety system. These dashboards are primarily focused on monitoring usage, but they also provide control functionalities, e.g. set-point adjustment of the motor movements.

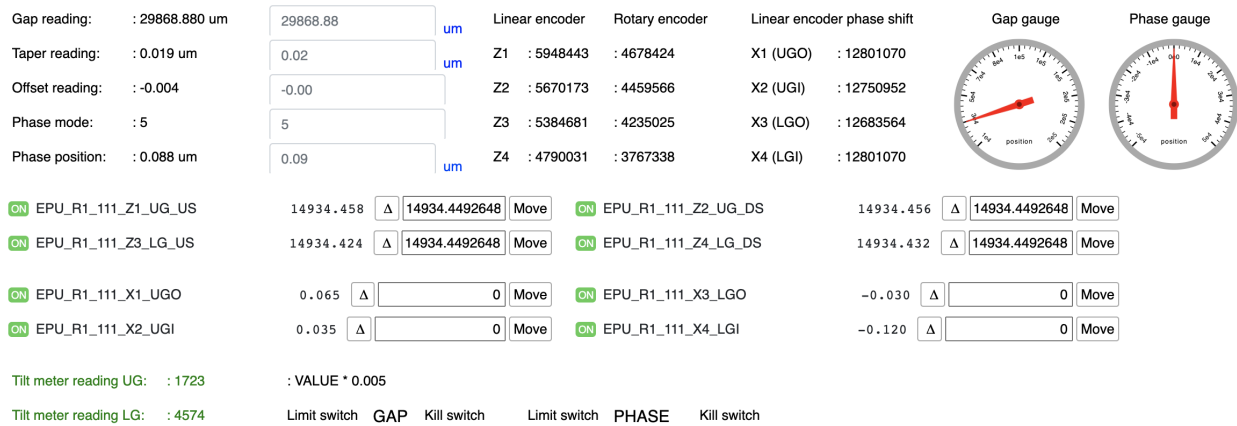

Figure 4: Example of a dashboard for monitorization and control of MAX IV insertion device for a beamline.

Figure 5: Example of a dashboard for monitorization of cooling systems in the Linac. There is one like this for every klystron.

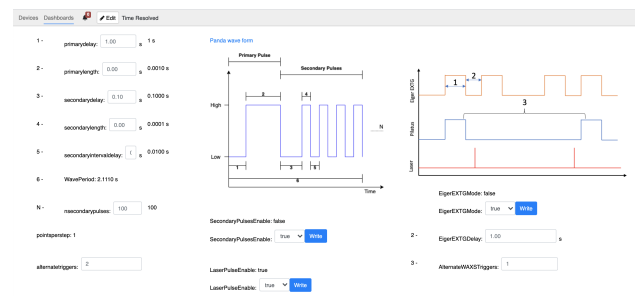

Figure 6: Dashboard for configuration of the timing strategy for the data acquisition at Cosaxs beamline.

Figures 4 and 5 show working examples of production dashboards. The usage approach is different, the first example is more focused on the moveable elements of an insertion device and thus, the user wanted to have the possibility of driving those axis. The second example is oriented towards cooling water trends over time, link widgets above the plot allows to switch to different dashboards.

On the beamline's side, the usage is focused on one hand to provide a simplified overview of equipment by adding into a dashboard only the most critical tango attributes of an equipment. On the other hand, it is also used to provide users with an easy to use interface to configure parts of the experiment. Figure 6 displays a dashboard to configure the timing pulse diagram for the data acquisition in Cosaxs beamline.

There was a slow start with the adoption of Taranta, but thanks to a few early adopters in the machine operators group that provided valuable feedback as well as bug reporting, Taranta is gaining popularity quickly. In addition, the knowledge of widgets development has been improved so we are able to provide new widgets faster than before, which helps gaining trust from our user community.

## SKA

Taranta is seen as a tool with a lot of potential within SKA. At the current stage of the project's development, there are

different categories of target users for Taranta. First, there are control system developers who create the dashboards and use them to inspect, debug and verify the devices they are developing; secondly, other teams who want to verify the behaviour of a component and use dashboards provided by the team who developed them; and lastly, managers or engineers who may want to check the current status of the system or are tasked with testing the Minimum Viable Product (MVP). Often, Taranta dashboards are used for showcasing the progress in the development of the control system during demos. Depending on their envisaged use, dashboards are expected to have different lifetimes and to require different levels of analysis before realising them.

Figures 7 and 8 show two examples of dashboards realised by SKA teams. The dashboard in 7 has been created by the team that is developing Taranta after some interactions with developers belonging to other teams. It allows to switch ON/OFF the Central Signal Processor (CSP) subsystems as well as to control them by configuring the set of resources to be used and for sending a set of commands for executing a scan (atomic part of an observation).. It also gives fast feedback on the state of subsystems. 8 shows a dashboard that is mainly used for checking the "state readiness" of the MVP for executing certain tasks (and allowing recovery of inconsistent states where possible) whilst conducting interactive end to end test development.

The close interaction with users of Taranta often promotes the development of new widgets or functionalities, such as the timeline widget, or triggers some usability improvements for the tool. Moreover using this dashboard helped developers in other teams to early detect needed changes in the control software and identify bugs.

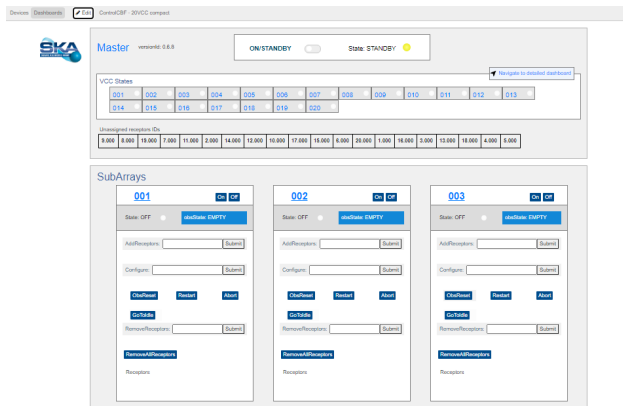

Figure 7: Example of a dashboard for monitoring and control SKA CSP.

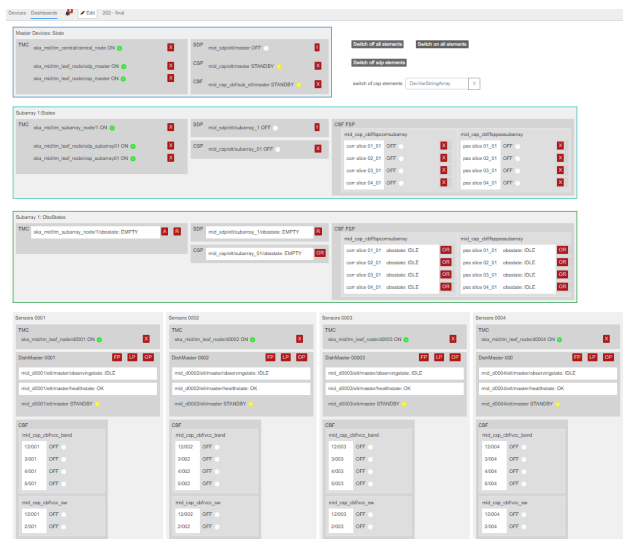

Figure 8: Example of a dashboard to monitor the status of various resources that are part of the SKA MVP.

## FUTURE WORK

By the increase of user feedback a lot of new improvement can be done in Taranta. The increased number of available widgets requires a redesigned widget library element, possibly with searching and sorting by type functionality. This

would make the life of our users a little bit easier. In addition, several new widgets are under development. For example, a grouping widget, onto which one can drop different widgets and then group it into one entity. This would make designing the interface layout smoother as well as give the users the possibility to create their own widgets. Another interesting widget under development is the synoptic, which aims at displaying svg images and linking svg elements to tango devices [14]. Moreover, optimisation on how and when the application sends updated values to the client, as well as data formatting improvements, specially for images, are on the list. Last but not least important, there will be new widgets coming to complement running the experiments, i.e. moving into web current functionality nowadays scattered over desktop applications and command line applications.

## canone3: A NEW SERVICE AND DEVELOPMENT FRAMEWORK FOR THE WEB AND PLATFORM INDEPENDENT APPLICATIONS\*

G. Strangolino, L. Zambon, Elettra, Trieste, Italy

### Abstract

On the wake of former web interfaces developed at ELETTRA [1] as well as in other institutes, the service and development framework for the web and platform independent applications named PUMA (Platform for Universal Mobile application) has been substantially enhanced and rewritten, with the additional objectives of high availability, scalability, load balancing, responsiveness and customization. Thorough analysis of WebSocket limits led to an SSE (Server-Sent Events) based server technology relying on channels (Nchan over NGINX) to deliver the events to the clients. The development of the latter is supported by JQuery, Bootstrap, D3js, SVG (Scalable Vector Graphics) and QT and helps build interfaces ranging from mobile to dashboard. Ultimate developments led to successful load balancing and failover actions, owing to the joint cooperation of a dedicated service supervisor and the NGINX upstream module.

### DESIGN RATIONALE

The system consists of a cluster of servers, thereafter synonymously named services, and two client side development environments. One is based on web technologies on browsers. The second is a C++ client library to build native Qt applications. The main objectives of the service design are reliability, security, scalability and accessibility. To satisfy them, a set of state of the art technologies and software serve as the groundwork of the system.

### RELIABILITY

The design rationale identifies the principles of a reliable service as follows. The system shall work:

- from any place and platform;
- at any time;
- regardless the number of clients
- included when part of the system is unavailable
- included when the network performance is suboptimal or even subject to charges.

The first requirement ruled out the *WebSocket* technology after an accurate analysis of its assets and liabilities.

### WebSocket

WebSocket is a computer communications protocol, providing full-duplex communication channels over a single TCP connection. The WebSocket protocol was standardized by the IETF as RFC 6455 in 2011, and the

WebSocket API in Web IDL is being standardized by the W3C. [2]

WebSockets are widespread and efficient when handling huge amount of messages from both ends, where duplex communication is continuously involved: Massive Multiplayer Online (MMO) and messaging applications.

The list of liabilities is nevertheless long in our situation:

- WebSockets can be potentially blocked by proxies;
- CORS (Cross-Origin Resource Sharing) [3] related concerns;
- no multiplexing over HTTP/2 (implementing it on both ends is complicated);
- no load balancing;
- susceptible to DoS;
- problems already taken care of in HTTP must be solved ad hoc;
- operational overhead in developing, testing and scaling is increased.

Some proxy servers are transparent and work fine with WebSockets; others will prevent them from working correctly, causing the connection to fail. In some cases, additional proxy server configuration is required.

Load balancing is very complicated. When servers are under pressure and new connections need to be created and old ones closed, the actions that must be taken can trigger a massive chain of refreshes and new data requests, additionally overloading the system. It's not possible to move socket connections to a different server to relieve one under high load. They must be closed and reopened. It turns out that WebSockets need to be maintained both on the server and on the client.

Multiplexing is usually handled by front end HTTP proxies that cannot be handled by TCP proxies which are needed for the WebSockets. Connecting to the sockets and flooding servers with data is a possible eventuality.

Concerning the last weakness in the list, we observe that mobile devices would maintain a WebSocket open by keeping the antenna and the connection to the cellular network active. Battery life would be reduced, heating increased, and, where applicable, extra costs for data usage applied.

### SSE

Server-Sent Events (SSE) is a server push technology enabling a client to receive automatic updates from a server via an HTTP connection, and describes how servers can initiate data transmission towards clients once an initial connection has been established. They are commonly used to send message updates or continuous data streams to a browser client and designed to enhance native, cross-browser streaming through a JavaScript API called EventSource, through which a client requests a

\* inspiration by Alessio Igor Bogani, Elettra, Trieste, Italy

particular URL in order to receive an event stream. The Server-Sent Events EventSource API is standardized as part of HTML5 by the W3C [4].

Server-Sent Events technology analysis underlined some disadvantages; most of them do not appertain to our environment:

- SSE is unfit for duplex communications;
- binary data cannot be sent;
- the number of connections on a web browser is limited;
- mono-directional by nature, additional approaches are required for duplex synchronous operations.

The third limitation in the record must be addressed in web browser based applications, while it does not affect clients of different nature.

Nevertheless, in our context the opportunities offered by SSE outweigh the weaknesses:

- SSE is based on HTTP, posing no issues with proxies;
- multiplexing is implemented in HTTP/2
- messages bear an *id*: the server is aware if the client misses one;
- data exchange requires a smaller number of connections;
- on failure, the *EventSource* reconnects;
- the connection stream is based on events, it is read only and goes from the server to the client;
- arbitrary events can be sent.

PUMA framework combines SSE with a channel based event streaming (*Nchan* [5]), thus enforcing the connection economy mentioned in the fourth item in the preceding enumeration. The hitherto introduced benefits offered by an SSE technology over WebSockets cover a fundamental aspect of the reliability essential. In particular, the *any place, any time and platform* principles are backed up by SSE. In combination with channels, the system gains scalability in reference to an arbitrarily high number of clients using the service at the same time.

Figure 1 is a representation of the client – server architecture based on Nginx, Nchan and the PUMA service.

Figure 1: Nginx, Nchan and PUMA service use channels.

The next ingredient in our reliability recipe contributes to maintain the service available to clients even when parts of the system are unavailable. *Nginx* [6] comes into play as a balancer to distribute the load across several instances of the PUMA server and at the same time,

through a PUMA *supervisor* service, to manage failover. Moreover, when Nginx and Nchan are combined with *Redis cluster* [7] (Remote Dictionary Server), channels attain high availability and failover capabilities [8].

## SECURITY

The goal is to realize a service and its context safe enough as to avoid tunnelling the traffic across a VPN. The latter implies additional software and configuration, hindering usability and reducing battery life, especially on mobile devices. At the moment of writing, the network architecture essential to achieve a proper level of security has still to be laid out. The observations made in the preceding section favour the choice of Nginx and HTTP over WebSockets as far as protection from DDoS (Distributed Denial of Service) is concerned. Nginx can be adjusted to limit the worker processes and connections, as well as the requests rate over time. Additionally, the number of connections that can be opened by a single client IP address can be curbed to protect the downstream PUMA services.

## SCALABILITY

A good infrastructure shall be designed with scalability in mind. Reliability and security will be inherently reinforced. Channels to which numerous clients tune in to receive messages are an obvious representative of scalability. Nginx combined with Nchan and Redis offer horizontal scalability to the PUMA service. Figure 2 shows this principle, while Fig. 3 illustrates the initial deployment of the PUMA service architecture at Elettra.

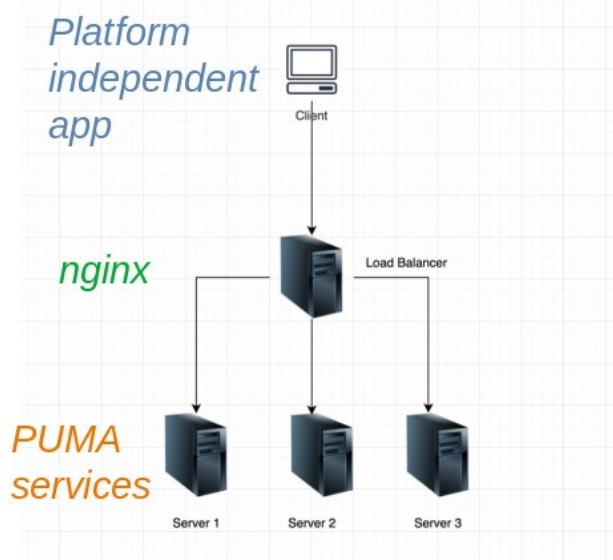

Figure 2: Horizontal scalability with Nginx.

## ACCESSIBILITY

The interaction with the service is performed through an open API relying on JSON (JavaScript Object Notation) both on the request and the reply sides. A simplified URL API for requests shall be included in a future release. The API serves the web, the mobile and the desktop applications.

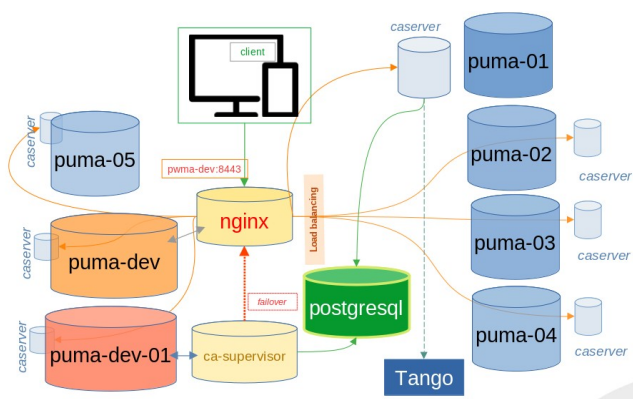

Figure 3: Horizontal scalability as deployed at Elettra.

Reliability, security, scalability and a generic API are the main principles of the PUMA service design rationale. In the following sections, the single components will be described in more detail.

## THE SERVICE

The *caserver* is the name given to the PUMA service mentioned several times in the preceding sections. Since PUMA is the evolution of an earlier project (dating to the year 2006) named Canone, *caserver* is a nickname referring to the Canone origins. As represented in Fig. 1 and Fig. 3, the client applications post their HTTPS requests to the Nginx web server. The latter forwards them to one or more *caserver* instances, working as a load balancer. The service is an object oriented, modular and plugin expandable C++ application relying on the *cumbia* and *cumbia-tango* [9] libraries to access the Tango control system in use at the Elettra synchrotron radiation facility. Once a request is received by the service, up to two actions take place:

- a synchronous reply is sent to the client immediately and normally carries either the result of the required operation enriched by additional information dependent on both the request and the underlying engine (e.g. from the Tango database) or an error message;
- if the operation is a subscription to the value of a source of data over time, updates are published on the channel the client subscribed to within the same request.

Clients, *caserver* and Nchan operate in a so called *pubsub* arrangement. The service publishes messages to channels using HTTP POST requests. Clients tune in to a channel to receive data through Server-Sent events.

The main type of requests that can be made to the server, herein named *methods*, are *read*, *conf*, *write* and *subscribe*. All of them are synchronous: an HTTP response is immediately sent back to the client. The subscribe method has the additional effect of data updates being delivered over a *pubsub* channel. A well behaved client shall pack together multiple requests into a single, more articulated, JSON string.

## Engines and Modules

The service code is organised into modules. The Tango control system in use at Elettra is accessed by a dedicated module. This can be replaced (for example by an EPICS engine) and the *caserver* adapts to another control system.

A module has an interface to process messages received from clients and through *factories* several implementations of a module can be installed. Thus we can let the *reader module* use both the Tango and the EPICS specific *reader* implementation. A module is registered on the server and several ones can be installed with a given priority. As a consequence, a message from a client can be processed in sequence until one (or no) module satisfies the request.

New modules can be written and added to the service, although the preferred extension strategy is through the plugin system.

## Cumbia

*Cumbia activities* use the standard C++ threads. Inspired by the Android *AsyncTask* interface [10] and paired with *cumbia timers* and *event loops* permit a multi threaded design of the service. Activities manage the transmission of data over the channels, the main socket server and plugins life cycles, the authorization process for write operations and so on. The *cumbia-tango* module is an abstraction layer facilitating the access to the namesake control system. Further implementation details are available on the project github page [11].

## Plugins

The service features can be extended by plugins. Plugins are dynamically loaded from a specific folder and can be disabled as simply as deleting the corresponding object from the file system. The *caserver* provides *hooks* to which the plugins can register in order to receive specific pieces of information. For example, hooks related to readings notify plugins upon new data, subscribe and unsubscribe operations. Likewise, the read module can switch from an active to an inactive state, a message can be delivered synchronously on a socket or entrusted to a channel. All these events can be monitored by plugins. The service *supervisor* [12], mentioned in the section dedicated to reliability, queries a PostgreSQL database to retrieve data about the health of the *caserver* instances in execution. Such records are written by the *ca-db-plugin* [13], hooked to the service socket receiver state change and the periodic *heartbeat* events. Another plugin [14] offers *introspection* capabilities straight through HTTP representing in JSON (JavaScript Object Notation) format diverse operating conditions of the server at a given moment (number of activities, threads, readings, and so on).

## THE SUPERVISOR

In the extent of the reliability of the PUMA service, and specifically for the accomplishment of the failover automation, the supervisor operates in conjunction with the *ca-db-plugin* discussed in the previous section. The

data recorded by the latter into a PostgreSQL database is analysed at regular intervals to determine whether every single *caserver* process is actually operating. Each instance is expected to register some kind of information periodically. If a unit fails, the supervisor undertakes recovery operations, redistributing the load formerly in charge of the missing service across the other processes online.

The architecture is designed so that if a policy of automatic and instantaneous restart of a broken down *caserver* is adopted, the restarted process regains control of its previous data *sources*<sup>1</sup>. The restart action must be undertaken promptly so that the supervisor is unaware of the failure.

The PostgreSQL database shall be centralised so that every instance of *caserver* can save its state regardless the host where it is executed.

## Qt CLIENTS AND LIBRARY

Alongside platform independent web interfaces, Qt [15] native applications written in C++ can be developed on top of a library named *cumbia-http*. They are expected to work on all platforms supported by the Qt framework itself. More generally, any application written on top of *cumbia* / Qt is able to run transparently either connecting to the native control system engine<sup>2</sup> or to the PUMA service. The application does not need to be recompiled in order to select the available or desired engine at startup.

### Cumbia-http

*Cumbia-http* is a *cumbia* module offered alongside engine specific ones such as *cumbia-tango* and *cumbia-epics*. Whilst the last two connect to the respective control systems natively and require complete access to the field and the software installation on the device as dependency, the HTTP module, connecting to the PUMA service, can be used by Qt applications from anywhere.

### Cumbia Multi Engine Applications

A *cumbia* Qt application is unaware of the module used to read from *sources* and write to *targets*. The same software can run in the control room, where the native control system is thoroughly accessible, and at office or at home on a computer laptop, wherefrom the control system is unreachable and the native libraries are not installed. A *cumbia* multi engine application loads the desired module at runtime and offers the same user experience and native performance both from the control room and from home. From the developer point of view, a control panel can be designed, built and tested with utmost efficiency from anywhere using the *caserver* and then deployed natively on the field. Developers and end users alike treasured *cumbia* multi engine while working from home during the COVID-19 pandemic.

<sup>1</sup> Cumbia and QTango adopt the term “source” to name the quantity data comes from, for example, a Tango attribute. Recovery pertains to the context of readers, thus every reader has a “source” of data.

<sup>2</sup> For example, Tango or EPICS native installations.

## WEB INTERFACES

Web interfaces are available on any device connected to the internet all over the world without any custom installation. Conversely, native applications benefit from having full knowledge of hardware. However, as soon as the quality and speed of web interfaces is close to native applications’, they are preferable because of their portability. An agnostic approach will implement all options letting the user choose the results rather than the technology. The same agnostic approach concerns the kind of devices supported; displays can be in a range about from 5 to 50 inches and can be touch or not; our goal is supporting as much devices as possible.

Mobile devices are usually strictly personal; this increases the opportunities of customization: apart from the style, the user can use predefined screens or create new ones arranging several items.

There is a particular screen called “starter”. Its purpose is to launch all other screens. Users can customize the starter screen either by a graphical tool or editing a JSON text.

Often the request of maintainability over years is in contrast with the choice of the most performing technologies available at the moment. So a compromise is necessary and the approach can be more aggressive or more conservative.

The choices made within the PUMA web interface development may be seen as conservative. We use JQuery [16] which enhances and simplifies JavaScript and has been quite stable over the past ten years. Bootstrap [17] is very helpful in being adaptive.

We had been using React for two years and decided to abandon it because in our particular use case the balance between the disadvantages (time consumed to keep the development environment updated) versus the advantages (modularity, state machine etc) was not satisfactory.

### Adaptive Design

Adaptiveness is mainly provided by Bootstrap (Fig. 4) and by flexbox [18], which is a standard of CSS3 (Cascading Style Sheet) [19].

Within the PUMA framework a web designer is available to produce device interfaces or simple dashboards, all responsive because based on flexbox. Screens are saved in JSON format in a PostgreSQL database. Any saved screen can be used as a component in a new screen. JSON screens are interpreted consistently also by a previous app [1].

Advanced users can import in PUMA any HTML (HyperText Markup Language) and SVG [20] file. We consider “advanced users” those with a good knowledge of HTML, JavaScript/JQuery and CSS, also the rest of this section is addressed mainly to advanced users. Other readers, if interested in such details, can find plenty of explanations on the web. We suggest MDN (Mozilla Developer Network).

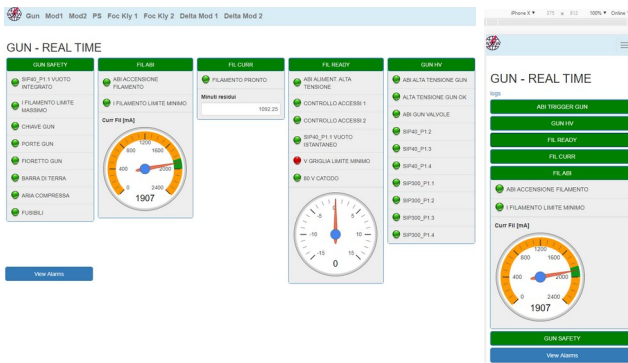

Figure 4: Desktop and mobile version of the same screen.

## Vector Graphics

SVG is used to produce 2D graphics, in particular large machine synoptics. In this way a very good flexibility in interaction with the user can be obtained; two different JavaScript libraries allowing zooming in and out by using the mouse wheel or by pinching are used. While zooming or moving around, some contents are added, removed or changed. In particular some variables are subscribed and unsubscribed on pan or zoom change so that only the visible ones (and a few side buffers) are continuously updated (Fig. 5). The JavaScript function which subscribes and unsubscribes variables, is called at a maximum rate of 2 times per second.

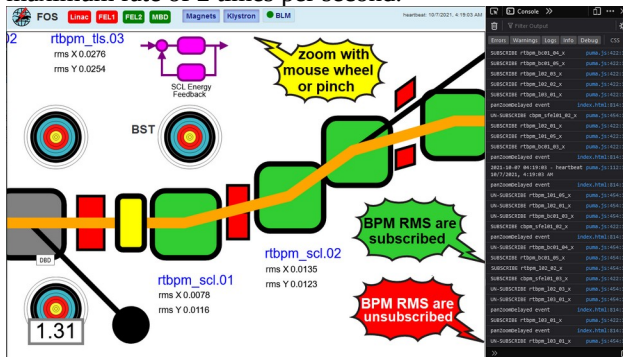

Figure 5: Some variables are subscribed and unsubscribed depending on the pan and zoom events.

In our working prototype this feature is completely transparent to the user, induced to believe that all variables are always updated without any loss in fluidity when moving the point of view. A demo is available on YouTube at the following URL: <https://www.youtube.com/watch?v=z7FUDB7w2aw>.

SVG is optimal for managing very complex 2D graphics and update any detail independently, but two main limitations subsist: it doesn't support 3D graphics and is not the best choice for displaying large quantities of data updated very quickly. WebGL [21] provides a very efficient solution to both problems.

PUMA provides an online HTML editor with a side preview which is constantly updated by the *keyup* event from the editor itself (Fig. 6).

Figure 6: Web text editor with preview.

An authorized user can insert any HTML source which may include JavaScript, CSS and SVG. The connection to the control system can be implemented in any HTML or SVG tag by inserting a class "puma", a unique id and a custom data attribute [22] named "data-src". Only these steps are those necessary to connect to PUMA and there is no need to include any JavaScript. There is another optional attribute called "data-onupdate". Its value is the name of a JavaScript function that is triggered when new data is ready preventing the default update action. The "data-onupdate" JavaScript function is called with 3 parameters: the new value, the id of the calling tag (the same function can be used for more than one PUMA tag) and the source timestamp.

A one to one correspondence between tag and data-src is considered normal, though for exceptional cases this correspondence can be superseded. For example an array of booleans may be displayed as a table with green and red icons in the first column and labels in the second; such a table can be implemented using a hidden tag to associate a data-src to a data-onupdate function switching the colours of all icons. If a tag has to be updated according to the value of two or more variables, all variables should be associated to a different tag (hidden if not directly displayed) and to the same data-onupdate which provides a data synchronization mechanism and ultimately updates the multi-dependant tag.

The same screen can be reused in different contexts by inserting parameters into the data-src value.

SVG tags behave essentially in the same way as HTML tags; nevertheless there are a few differences to be taken cautiously in consideration, for example the JQuery [16] expressions `.is(":hidden")` and `.is(":visible")` work fine on HTML and SVG tags on Firefox, but they don't work on SVG tags on Chromium; instead the almost equivalent JQuery expression `.css('display')=='none'` works on SVG on all the most popular browsers (Fig 7).

It isn't very difficult to produce a thousand SVG elements image with a text editor, although a few graphical editors are available, for example Inkscape [23]. They tend to produce a lot of extra tags, that can be reduced by external tools which simplify the files.

In PUMA there are simplified versions of generic tools to browse all available control system variables, start and stop servers, monitor trends of a single variable. We also experimented with launching both web screens and desktop native applications from a browser. The second operation is explicitly forbidden by JavaScript. We overcame this limitation with a tiny bash script which executes the browser with an id as parameter, and waits in long polling mode [24] for a command to launch. Long

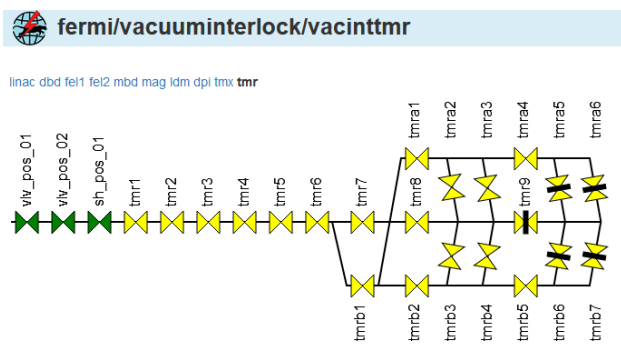

Figure 7: SVG on mobile.

polling is a cURL call to a particular page which receives an answer (resolves) only when there is a new event (a panel to be launched). Long polling is a technology much less advanced than WebSocket and SSE, but in this particular case it is still effective.

## TEST PHASE

The PUMA service, the web interfaces and the *cumbia* HTTP module have been used constantly and efficiently during the whole COVID-19 pandemic. A dedicated phase addressing stress and failover tests is currently underway. Web and Qt clients have been written to investigate and diagnose limits and points of failure. Examination results shall be stored into a database so that several parameters, such as synchronous reply time, speed and resource usage under pressure, can be monitored in the long run and improved across version updates. Initial experiments prove that a failing service process is detected by the supervisor and its load is redistributed amongst the online instances of the cluster.

In order to evaluate the overall performance of PUMA two web based tests have been developed: the first one subscribes and unsubscribes a configurable number of variables per second, the second one simulates panning and zooming of a real screen. As a result we reached about 300000 subscriptions per hour for several hours.

## CONCLUSIONS

The PUMA framework proved to be essential to develop and run graphical user interfaces from home during the COVID-19 pandemic, the other sole alternatives being either remote desktop solutions or X forwarding through SSH (Secure Shell). The first imply an amount of data compression degrading the graphics level of detail along with a moderately slow interaction, worsening to extremely sluggish in the second case. Actually, the authors' existing environment imposes two SSH tunnels over a VPN (Virtual Private Network).

The present day provides plentiful means in terms of computing speed and network bandwidth. Yet, they need to be economized. The data exchanged between the PUMA services and their clients involves only information relevant to the user: configuration and values from the control systems. In this sense, PUMA has an "ecological" approach: every bit is essential to

knowledge, not even one carries redundant data and the user experience is always immediate because the resources of the device are operated natively. In case of portable devices, a remarkable battery saving shall be expected. Furthermore, due to the publisher – subscriber pattern over channels, the deployment of the PUMA framework in the control room on behalf of the native control system would definitely relieve the pressure on the devices and their servers. One need only think that umpteen readings of the same variable by PUMA clients translate into a single one to the control system.

The PUMA architecture has been planned with security, scalability and fail-safety in mind. On one side, the design contributes to administer the access and relieve the pressure on the control system. From the clients perspective, they are conferred scalable fast data exchange and lean on a failover redundant structure.

# A MAJOR UPDATE OF WEB BASED DEVELOPMENT TOOLKIT FOR CONTROL SYSTEM OF LARGESCALE PHYSICS EXPERIMENT DEVICE

X. Xie, W. Zheng, M. Zhang, B. Rao, Y. Yang, F. Wu, Y. Jiang, P. Zhang, W. Wang, S. Li, International Joint Research Laboratory of Magnetic Confinement Fusion and Plasma Physics, State Key Laboratory of Advanced Electromagnetic Engineering and Technology, School of Electrical and Electronic Engineering, Huazhong University of Science and Technology, Wuhan, China

## Abstract

The deployment of the control system called CODAC (Control, Data Access and Communications) is necessary for the operation of large-scale experimental facilities. CFET (Control system framework for experimental devices toolkit) is a flexible SCADA (supervisory control and data acquisition) software tool, which is used for the construction of a CODAC. CFET is fully based on open web technologies, it is easy to integrate all kinds of systems and devices into CFET. This paper has undergone a major iteration of CFET. HMI has been redesigned and implemented. The control engineer can use a web based WYSIWYG HMI editor to compose the HMI. In CFET, InfluxDB has been integrated. It is used to store the engineering data, and also visualize the data on the website. Docker based microservices architecture has been designed, putting CFET and dependent packages into a lightweight container. At present, CFET has been used in the CODAC system of J-TEXT tokamak and HUST Field-Reversed Configuration facility.

## INTRODUCTION

For a long time, Experimental physics and industrial control system (EPICS) have been used to build large-scale experimental equipment control systems in the accelerator field. So far, the community has been very mature, and EPICS has very strong support for hardware equipment in the accelerator field [1-2]. ITER (as the world's largest tokamak) chose EPICS as the core framework of their control system [3-6], and chose EPICS Channel Access protocol as the communication protocol for the control network. Therefore, many other equipment in fusion field have chosen EPICS to build their own control systems. However, due to the differences in equipment and control requirements, EPICS has not demonstrated its advantages in the fusion community, and EPICS Channel Access protocol also has the problem of opacity and operability. Control system Framework for Experimental Devices Toolkit (CFET) framework is implemented as .NET standard libraries. It bases on Web technologies and uses HTTP as the control system communication protocol [7-8]. Web technology almost supported by all the devices. Countless web APIs have been published and consumed by all kinds of devices. It's also easy to integrate various new devices via the network, and provides flexible control system solutions for users in different scenarios. CFET is an efficient development tools with transparent protocol, and provides

stronger support for new devices, also has the characteristics of easy integration and strong interoperability between subsystems.

This paper first briefly talked about the basic concepts of CFET. The third section will introduce the support of new communication protocol. Section 4 will introduce the redesigned HMI. The engineering data storage and management system will be described in the fifth section. CFET also uses docker to realize the cross-platform deployment of the user side rapidly. In the end, the application of CFET on HFRC will be briefly demonstrated.

## BASIC CONCEPTS OF CFET

As mentioned before, CFET is a Web-based SCADA. Web plays a big role from websites (online services), online games, to smart sensor and IoT application. So CFET has good adaptability to a variety of different large-scale equipment, and can also meet new development models and new operating environments. HTTP is the most common communication protocol in web applications. The main communication module of CFET (CFET HTTP CM) uses the HTTP protocol of the RESTful architecture as the basic transmission protocol. The format of the RESTful framework is to use URI to locate resources and add verbs (intended action) in front of the resources. For example, if you need to know the switch status of light bulb A in the laboratory, the corresponding resource request should be "get + /lab/lightA/status". In HTTP CM, the client actions are mapped to HTTP verbs. There are three resource access actions, namely Get, Set and Invoke, mapping to HTTP Verb GET, PUT and POST. To different types of resources, HTTP verbs are different, otherwise an error that does not conform to the design principles will be reported.

The basis of interoperability is that every client in this system can understand each other conceptually, so we have to encapsulate the equipment in control system into a common model with consistent interfaces. The model has 5 types of resources: Thing, Status, Configuration, Method and event. Status, Configuration and Method are the property of Thing. A Thing can be either physical or logical. Event is a property based on publish/subscribe pattern. The subscriber can subscribe a resource and get notified on a certain condition.

## NEW CFET COMMUNICATION MODULE

A CFET application, in principle, is allowed mount multiple Communication Modules. Each Communication

Module corresponds to a protocol. When accessing resources, you can choose Communication Module via the protocol header, such as http://.

Due to increasing control requirements, CFET has developed some new communication modules: MQTT CM and WebSocket CM.

The HTTP protocol has a problem that only the client can send a request to the server, and the server return the query result. The HTTP protocol cannot enable the server to actively push information to the client. We can only use polling to get the current message if the server has continuous state changes. The biggest feature of WebSocket protocol is that the server can actively push information to the client, and the client can also actively send information to the server. CFET use WebSocket protocol to support remote events. WebSocket CM is integrated into HTTP CM, you don't need to change the protocol header, HTTP CM will automatically add 1 to its HTTP port number as the port number of WebSocket.

The MQTT (Message Queuing Telemetry transport) protocol is a protocol designed for communication between a large number of remote sensors and control devices that have limited computing power and work on a low-bandwidth, unreliable network. Provide one-to-many message publishing, uncoupling subscriber from publisher. MQTT has a wide range of applications in the Internet of Things, small devices, mobile applications, etc. CFET MQTT CM still uses RESTful architecture. The only difference from HTTP CM is that you need to replace "http://" in URL with "mqtt://" to select MQTT CM.

## HUMAN MACHINE INTERFACE

Human machine interface (HMI) are developed separately and deployed on the operator's console in traditional control systems and always be a fixed interface on a limited platform. In web based control system, all HMI is a web site running on web servers. CFET provides a component called "WidgetUI". It is a WYSIWYG HMI editor, and the application developer can compose their own HMI via dragging and editing Widget. The component library of WidgetUI provide many widget: Label, Configurator, Gauge, Video player, Switch, Status light and so on. The following Fig. 1. Shows a simple HMI.

Figure 1: The HMI of high voltage power supply.

The completed interface can be directly saved as a Json file, which can be saved locally or in a specified file path of CFET. The website can restore HMIs by parsing the

Json file. And the website can also be accessed as a RESTful API. When a request come from a browser, the server would know that and return a web page to visualize the resource instead of a JSON object.

It is worth noting that, in addition to supporting access to CFET resources through the HTTP protocol, the website also supports subscribe a remote events through WebSocket protocol, which can be done by simply clicking on the website.

## THE ENGINEERING DATA STORAGE AND MANAGEMENT SYSTEM

Engineering data refers to the non-experimental data generated during the experiment, such as sensor data, the voltage of the power and the temperature of the instrument, etc. Most of them have strong timing characteristics. Influxdb is purpose-built to handle the massive volumes and countless sources of time-stamped data produced by sensors, applications and infrastructure. CFET uses influxdb to store and monitor engineering data, which is capable of ingesting millions of data points per second. In CFET, we still write the control of Influxdb as a Thing with I/O interface exposed. Influxdb thing can be used with CFET Event to conveniently record any required engineering data.

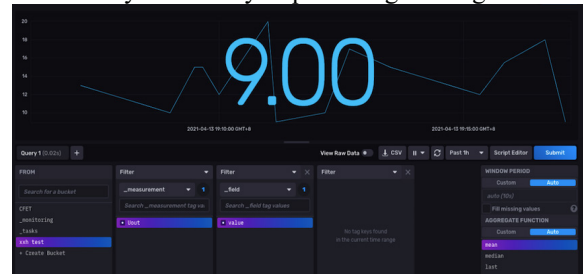

Figure 2: The interface of engineering data.

In addition to this, a dashboard interface (shown in Fig. 2.) and monitoring alarm interface built with Grafana are also used by CFET to visualize the engineering data.

## APPLICATION ON HFRC

The Field-Reversed Configuration (FRC) device is a complex magnetic confinement fusion research device and is also a new type of fusion research device proposed in recent years [9]. The position and structure of this device are quite different from those of previous fusion devices such as tokamak, and can generate high-parameter plasma. HFRC is a FRC device being researched by Huazhong University of Science and Technology. HFRC contains multiple complex subsystems such as vacuum, power supply, and diagnosis. It is particularly important whether the control system can have the coordinated control capability of these complex and diverse subsystems, the real-time control capability of the discharge pulse, and the ability to provide flexible control functions to complete specific experimental content. Due to the flexibility and compatibility of CFET, HFRC chose CFET to build his control system. With the CFET framework, each subsystem can know any message from each other, and the central control system

can coordinate and monitor by obtaining the status of each subsystem.

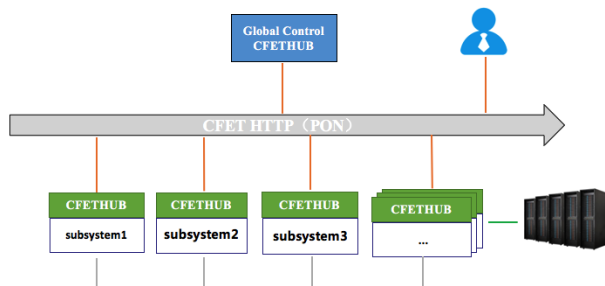

Figure 3: The Architecture of the control system of HFRC.

The HFRC control system is divided into two parts: the global control system and the sub-control system. The global control system coordinate subsystem to meet the control requirements of the overall operation of the device. The sub-control system consume these services by accessing CFET control system networks while exposing its own status API. The control system adopts a dynamic state machine mode to realize the process control of the discharge. Each subsystem can observe the state of the central control, execute its own actions and change its state according to the instructions of the central.

## CONCLUSION

This work is aim for update web based development toolkit CFET. CFET bases on Web technologies and uses HTTP as the control system communication protocol to improve the interoperability of control systems. Although CFET has begun to take shape, there are still many functions that need to be improved. First this work added two new communication protocol module (WebSocket CM and MQTT CM) in CFET. Then the HMI was redesigned, and the component library was added. Users can access the control interface without restriction in any scene through the browser. CFET also be able to access Influxdb, integrates the storage and management system of engineering data, and users can also use the dashboard to monitor engineering data. Finally, the updated CFET has been applied to the HFRC control system, which meets the control requirements of HFRC daily experiments more flexibly and comprehensively, and also allows developers to develop the HFRC control system more efficiently.

# MACHINE LEARNING FOR ANOMALY DETECTION IN CONTINUOUS SIGNALS

A. A. Saoulis\*, K.R.L. Baker, R. A. Burrridge, S. Lilley, M. Romanovschi  
ISIS Neutron and Muon Source, Didcot, UK

## Abstract

High availability at accelerators such as the ISIS Neutron and Muon Source is a key operational goal, requiring rapid detection and response to anomalies within the accelerator's subsystems. While monitoring systems are in place for this purpose, they often require human expertise and intervention to operate effectively or are limited to predefined classes of anomaly. Machine learning (ML) has emerged as a valuable tool for automated anomaly detection in time series signal data. An ML pipeline suitable for anomaly detection in continuous signals is described, from labelling data for supervised ML algorithms to model selection and evaluation. These techniques are applied to detecting periods of temperature instability in the liquid methane moderator on ISIS Target Station 1. We demonstrate how this ML pipeline can be used to improve the speed and accuracy of detection of these anomalies.

## INTRODUCTION

The ISIS Neutron and Muon source, located at the Rutherford Appleton Laboratory site in Oxfordshire, UK, creates neutron and muon beams used to perform a range of high quality scientific experiments. The facility has developed a great deal over its 35 years of operation [1], both increasing the complexity of the facility and the production of machine data. Currently, anomaly detection and response are generally handled manually by operators, and require large amounts of domain knowledge and expertise. Outlined in this paper is a pipeline to take unlabelled, continuous time series data and train a model that can detect anomalies on live data during operations, improving the response-time and effectiveness of reacting to these anomalies.

### ISIS TS1 Methane Moderator

The facility accelerates protons up to 800 MeV, which are used to generate neutrons through a spallation process at ISIS Target Station 1 (TS1) [1], the first of the two target stations at ISIS. These neutrons are moderated at TS1 through several different moderators, one of which is a liquid methane moderator, in order to perform neutron scattering experiments. For high quality experiment data, very stable temperature in the methane moderator is required.

Whilst methane has many properties that give it excellent performance as a moderator [2], it is well known that it is susceptible to radiation damage [3]. The irradiation of the methane produces long chain polymers and releases hydrogen [3,4], the former causing the moderator to fail and

require replacement roughly every six months. The build-up of free hydrogen within the moderator system causes loss of flow and leads to unpredictable pressure variability and spiking. This causes the temperature in the methane moderator to become unstable, which increases the variance of neutron energy leaving the moderator; it is therefore of key operational importance that these losses of flow are dealt with quickly. One method through which the operations team have dealt with this issue is through daily, scheduled "recoveries" of the moderator that consist of flushing through one third of the liquid methane in the system into a dump tank. This has improved its stability, but occasional periods of flow, and thus pressure and temperature variability, still occur.

The operations team currently have systems in place for detecting these instabilities, such as monitoring differential pressure in the system for any reduction in pressure. If an anomaly is detected, the operations team inspect the recent behaviour of the moderator and decide whether to run an unscheduled recovery in order to return the system to normal operation. The current systems often fail to flag up ongoing anomalies, leading to long periods of temperature variability that can cause the data recorded in downstream instruments to be unusable.

This paper will investigate the automated detection of these periods of temperature variability, with the goal of aiding the operations team to track down and fix issues faster. The paper will make use of supervised Machine Learning (ML) algorithms, which require labelled data (i.e. each data instance has an associated class label, such as whether it is "normal operation" or an "anomaly") to train a model. Finally, a brief description of the process of deployment of such trained models to live operation will be given.

## DATA PIPELINE

Here, a pipeline is given that takes raw time series data without labels and produces a dataset that is suitable for training ML models. In the case of the ISIS TS1 methane moderator, there was neither a logbook nor a convenient signal that could be used to automatically label temperature anomalies in the historic data. One key contribution of this paper is to define a general procedure for automatically labelling periods of anomalous behaviour in historic time series data so that models can be trained to detect these periods during live operation. Note that while this paper focuses on a single signal (i.e. a univariate time series), these methods are generalisable to multivariate time series.

\* alex.saoulis@stfc.ac.uk

## Raw Data

The ISIS accelerator control systems have recently undergone several upgrades [1, 5] that have allowed for the long term storage of time series data from a huge number of sources across the facility. This has provided a wealth of raw time series data of signals across the accelerator side of the facility stretching back to the end of 2018. As is outlined in [5], this data is stored in a database called InfluxDB [6], which specialises in time series storage. This allows for fast and simple access to this time series data, greatly easing the use of this data for data analysis and ML purposes.

The raw time series data is collected at intervals of approximately 2 – 3 s, provided the value of a signal has changed. This leads to irregular and unaligned raw data that must be preprocessed before use in ML applications. The temperature data used in this paper is taken from signal *TC68M*, a thermocouple located close to the liquid methane.

## Data Preprocessing

The first step of the data pipeline is to preprocess the data into a form that is practically useful and convenient for use in ML [7]. The preprocessing work was done in Python, primarily using the Python library pandas [8]. The data must be filtered such that only data covering operational periods of the accelerator is included in the training and test data. This is to ensure the training and test data matches the target domain data in production; in other words, the ML model should be trained and evaluated on the same type of data that it will see when it is detecting anomalies during live operation of the accelerator. This means that out-of-cycle periods, periods of bad/missing data (for example caused by a hardware malfunction), and periods outside normal operational bounds (such as temperature bounds beyond which it can be inferred that the moderator was not in use) must all be filtered from the data.

ML models require an input vector, also known as a feature vector, which must be of fixed length. For an irregularly sampled time series, simply using the raw data points as feature vectors would lead to temporally mismatched inputs to the model; a feature vector of length 100 could span from e.g. 3 minutes - 10 minutes, depending on how frequently the signal was changing during that period. Instead, feature vectors should be regularised such that each element of the feature vector corresponds to a fixed length of time. The raw temperature data is downsampled into bins of fixed time by taking a mean over that period. If there are no elements in a downsampled period, it is inferred that the temperature did not change from its previous value and the last known value is forward filled into the new bin.

The data must be scaled since the stability of many ML models require input data to be within reasonable bounds [7]. In the case of the TS1 methane moderator temperature, the mean of each temperature window was subtracted from the raw data. This ensured that the scaled values in the feature vectors always lay in the range of  $[-10, 15]$ , as well as helping to account for non-stationarity in the time series due to

Figure 1: A short excerpt from the raw temperature time series, as well as two sample feature vectors generated from the data. Sample 124 is an example of normal operation, and sample 125 is an example of an anomaly.

long-term drift of the moderator temperature. This choice was made for simplicity, and the conventional choice of z-scaling the data or normalising between  $[0, 1]$  would also do.

## Feature Vector Selection

In order to settle on a suitable feature vector, there are a few factors that must be taken into account. The window length must be long enough such that it can completely cover an anomaly event; this requires data exploration to look at the timescale over which anomalies occur in a system. A second important consideration is the bin lengths: these should be short enough to preserve any fine-grained structure in the time series that distinguishes normal operation from anomalies. Finally, in order to train models that can be evaluated constantly in real time, the feature vectors should be randomly sampled from the historic time series data such that a model can be applied at any moment in time

For the TS1 methane moderator, anomalies in the temperature tended to last between 1 – 2 hours, though certain indicators of anomalies such as rapid oscillatory periods occurred over much shorter timespans. As a result, 90 minute long feature vectors with bin lengths of 20 s were chosen, creating feature vectors of dimension (270, 1). The feature vectors were then generated by going through the downsampled time series data chronologically and extracting windows of length 270, skipping a small, random number of bins in between feature vectors to ensure that they had been randomly sampled. Roughly 4300 wholly distinct (i.e. no overlap) feature vectors were generated from the 2 years of historic temperature data, obeying the data preparation rules laid out above. Two such feature vectors, one from each class, are given in Fig. 1.

## LABELLING DATA

As mentioned earlier, in order to implement supervised ML algorithms, a class label corresponding to each feature vector is required. These are initially used to train a model to correctly identify the class of an input feature vector, and afterwards to evaluate the model on a test data set. Without any signals or logbooks that could be used to identify instances of anomalies in the historic data, labels must be generated directly from the feature vectors. This would typically be extremely time consuming and require a great deal of tedious manual work and expert knowledge. Here a generic method for partially automated labelling of time series feature vectors is presented.

### Clustering through t-SNE

t-distributed Stochastic Neighbourhood Embedding (t-SNE) [9] is a dimensionality reduction technique, differing from the well known Principal Component Analysis (PCA) [10] in that it is a non-parametric, non-linear technique for embedding high dimensional feature vectors into low dimensional space according to their similarities. The main advantage of this technique over other dimensionality reduction methods is that it tends to produce well defined clusters of similar data points, which can be used to generate labels from feature vectors. Since t-SNE is tailored for visualising high dimensional data, it proves very well-suited to the data labelling process that will be introduced in this section.

There are also difficulties associated with using t-SNE; suitable hyperparameters for t-SNE must be chosen in order to generate meaningful clusters of data, which can become a tedious tuning process. Additionally, since the algorithm is stochastic, it may take several runs with the same hyperparameters to generate well defined clusters. One other disadvantage of t-SNE is that it is a non-parametric dimensionality reduction technique, meaning that, in contrast to e.g. PCA, the algorithm doesn't produce a mathematical formula that can map any high dimensional feature vector to its low dimensional embedding. This means that new data points cannot be embedded into the low dimensional space after the algorithm has been run.

In this paper, t-SNE will be used to generate clusters of similar looking feature vectors, which in turn will be used to generate labels for a large percentage of the data with minimal manual labelling. This relies on one key assumption, which is that a similarity score between feature vectors can be defined which is able to meaningfully distinguish between anomalous feature vectors and normal operation. The original t-SNE algorithm used the Euclidean distance between two feature vectors to calculate similarity, but for time series that can be very misaligned (due to the fact that for continuous time signals, there are no preset start and end points), a Euclidean distance will fail as a similarity metric. Instead, a distance metric better suited to misaligned time series is required.

### Dynamic Time Warping

Dynamic Time Warping (DTW) [11] is an algorithm well suited to calculating the similarity between two misaligned time series. The algorithm is designed to work for time series that start and end at the same point, but whose main features vary in speed and so may be offset from each other along the time axis. There are a number of adaptations of DTW that can be used to tailor the algorithm for a specific use-case and set of constraints [12]. Even so, DTW works well even when there is no guarantee that two time series have the same start and end point; empirically, in preparation for this paper, standard DTW performed just as well as adaptations from [12] that accounted for these effects. As such, the standard DTW algorithm was used to calculate the similarity between feature vectors.

Note that in order to compare multivariate time series, the DTW algorithm can be applied to each individual signal (or a select few) across separate multivariate feature vectors, and a weighted sum of the individual DTW similarities can be used as the total similarity metric between two feature vectors.

### Labelling the Temperature Windows

In order to apply t-SNE, the parallelisable function `metrics.pairwise_distances` from the Python library `scikit-learn` [13] was used to generate a similarity matrix explicitly between every pair of feature vectors, using DTW as the "metric". This is a computationally expensive step that has computational complexity  $\mathcal{O}(n^2m^2)$ , where  $n$  are the number of feature vectors in the data set, and  $m$  is the length of each feature vector. This step took around 30 minutes to run for the temperature samples on six cores on a desktop class machine. Note that this method may quickly become infeasible for very large datasets (e.g. when the number of samples  $> 10^5 - 10^6$ ), or large feature vectors, without access to high performance computing clusters. Once the similarity matrix is computed, t-SNE can be run repeatedly for hyperparameter tuning without incurring the cost of calculating the similarity matrix each time. t-SNE embeddings of the temperature samples were created through a hyperparameter grid search until a suitable embedding was generated that had two distinct clusters of points. The final hyperparameters used for the `scikit-learn` function `manifold.TSNE` are given in Table 1.

Table 1: t-SNE Hyperparameters

Parameter name	Value
# Embedding Dims	2
Perplexity	30
Learning rate	25
# Iterations	5000
Method	"barnes_hut"
Angle	0.5

Figure 2: t-SNE plots showing the labelling process once two clusters have been generated. a) The raw 2D embedding generated by the t-SNE algorithm. b) The final labels assigned to the data after all labelling steps. The interactive plotting tool was used to get a first-pass estimate of the class boundaries, shown by the red lines.

In this case, as can be seen in Fig. 2, two large-scale, distinct clusters are easy to discern. An interactive plotting tool that allowed a user to select a point in the 2D embedding and view the corresponding time series was developed to inspect the data. Since the task was to classify normal operation versus anomaly, and not to distinguish between different types of anomaly, it was simple to manually define cutoff planes in the embedded space to make a first order approximation of the feature vector labels. If there are more than two classes, or the clusters are not simple to define manually, it could be preferable to use an unsupervised clustering algorithm such as k-means to calculate class boundaries. Then, the same plotting tool was used to manually change the label of any data points that were mislabelled on the first pass. This step can be time-consuming, especially in cases with large data sets and difficult-to-define class boundaries, and may need contributions from a domain expert to correctly classify edge-case time series.

One final step to ensure that this partially automated labelling process has generated accurate labels is to use a simple model or heuristic to classify the feature vectors, and compare the model classifications with the labels to check for bad labels. In this case, a rolling standard deviation of the time series was calculated, and feature vectors that exceeded a threshold were labelled as anomalies. This discovered a number of mislabelled data points, and was thus used to decrease the noisiness of the labels. Nonetheless, it should be borne in mind that no such labelling process will be perfect, and there will always be a degree of noisiness in the data set labels.

## NEURAL NETWORK MODELS

Once a labelled dataset has been generated, a model can be trained using supervised ML. Neural networks have shown great promise for time series classification tasks [14], with recent papers and architectures delivering state-of-the-art performance on benchmark time series datasets [15]. This paper will introduce, train and evaluate three different neural network (NN) based models, as well as explore the differences between them. All of the models were created, trained and evaluated in Python using Keras [16] as the frontend for the popular ML library Tensorflow [17]. Neural networks have an added bonus of generalising naturally to multivariate time series since they are data driven models.

### Feedforward Neural Network

The simplest type of neural network is a feedforward neural network, also known as a multi-layer perceptron. The input to the neural network is the time series feature vector. Each subsequent “layer” of the neural network can be thought of as a matrix multiplication by matrix of size  $m \times n$ , where  $m$  is the size of the input vector and  $n$  is the number of “nodes” in a layer, followed by an elementwise non-linear transformation acting on the result of the matrix multiplication, known as an “activation function”. The input is “fed forward” through the network of several layers, each of which can have different activation functions and numbers of nodes, until a final “output” layer that transforms the penultimate vector into a vector of length two, with each element corresponding to the probability that the feature vector belongs to either the “normal operation” class or “anomaly” class.

There are two main problems with using feedforward NNs for time series classification of the sort that has been described in this paper. Firstly, feedforward NNs learn the relationships between fixed elements in the input vector; since the position of features in the time series can occur at any point in the input, and their positions with respect to one another will be highly variable, a feedforward NN is not well suited to learning specific relationship between features. That said, for simple problems, it should still have some capacity to learn general features that it can use to make correct classifications. Secondly, feedforward NNs are generally thought of as black-box models, which means that it is very difficult to understand why a NN has made a particular classification. This can be problematic for models used in a control system to make decisions, since an operator may want to have some understanding of why a model detects an anomaly before making any changes.

### Attention-based LSTM

The Long Short-Term Memory (LSTM) network has emerged as a valuable tool for time series classification and prediction problems in ML [15, 18]. It is an improvement of the Recurrent Neural Network (RNN) architecture, which processes an input vector in temporal order, preserving the causal structure of a time series that is generally lost in

process, many of the “misclassifications” were actually the model outperforming the labelling process. In the case of the CNN, the majority of misclassifications were just bad labels, which suggested that the true CNN accuracy could be even greater than the accuracy given in Table 2.

## APPLICATION

Once these models were trained and evaluated, the feed-forward NN and ALSTM (the CNN was omitted due to time limitations), as well as a simple heuristic that used the rolling standard deviation of the temperature time series to calculate the probability of anomaly, were deployed into production. To do this, a software stack using Docker [22] containers that sat on top of the existing ISIS accelerator controls MQTT messaging [23] system was developed. In the existing ISIS accelerator control system, live changes are sent to an MQTT broker, which are then consumed by several downstream applications. These messages were processed in the same way the training data was generated in the data processing pipeline to generate rolling feature vectors every 20 seconds. The feature vectors were then fed into the neural networks each time a new bin was generated (again, every 20 seconds). The outputs of the networks were then sent over the same MQTT network, after which they were collected by the metrics aggregator Telegraf [24]. The outputs, alongside the raw time series data, were stored in an InfluxDB [6] database, and displayed in real time in a Grafana [25] dashboard. The software stack is shown in Fig. 4.

Once the software stack and models had been tested for robustness and stability for a few weeks on the live system, a feature was added to generate control system alarms that would appear in the Main Control Room once an anomaly was detected. In order to minimise the rate of false positives, an alarm was only generated if all models agreed with high probability that there was an anomaly for over 20 minutes. This alarm generation system was nominally successful, though since this work was done so near to the start of the ISIS long shutdown there was not enough time to generate data to report here.

## FUTURE WORK

A natural extension of the work in this paper would be to extend the anomaly detection problem to one of anomaly prediction. This has clear practical importance to operators, since it would provide warning that could be used to minimise the impact of an anomaly, or potentially even prevent it entirely.

Some preliminary work was carried out using results given in this paper: the labels generated during the t-SNE labelling process were used to get approximate timestamps of the beginnings of the anomalies. Then, a number of extra signals recommended by domain experts (such as pressures, beam current, etc.) were collected and added to a feature vector directly preceding the anomaly, giving a multivariate time series acting as the input to the model. A model com-

Figure 4: The software stack used to generate alarms and create live dashboards. The neural networks are evaluated in the data analysis layer, and their outputs are fed back into the MQTT messaging system.

binning a CNN and ALSTM (see [15]) was trained to identify whether a time series was a precursor to an anomaly (or not), but it performed very poorly even after a long period of hyperparameter tuning. Some steps that will be explored in future work include feature engineering (likely after including an even larger set of time series signals), different ML models such as Gradient Boosted Trees, and addressing the large class imbalance through data augmentation.

## CONCLUSION

A raw time series without labels was converted into a labelled data set using the clustering technique t-SNE. This dataset was then used to train several NN models which were first evaluated, and then deployed into live operations to generate alarms for the operations team any time an anomaly was detected. This pipeline provides a process through which anomaly detection can be applied to generic time series data streams, and proved a promising avenue for improving the response time to anomalies and thus availability of beam at large scale facilities.

# A LITERATURE REVIEW OF THE EFFORTS MADE FOR EMPLOYING MACHINE LEARNING IN SYNCHROTRONS\*

A. Khaleghi<sup>†1</sup>, Z. Aghaei, K. Mahmoudi, H. Haedar, I. Imani, Computer Group, Imam Khomeini International University, Qazvin, Iran

M. Akbari, M. Jafarzadeh, F.A. Mehrabi, P. Navidpour, Iranian Light Source Facility Institute (ILSF) for Research in Fundamental Sciences (IPM), Tehran, Iran

<sup>1</sup>also at Iranian Light Source Facility Institute (ILSF) for Research in Fundamental Sciences (IPM), Tehran, Iran

## Abstract

Using machine learning (ML) in various contexts is increasing due to advantages such as automation for everything, trends and pattern identification, highly error-prone, and continuous improvement. Even non-computer experts are trying to learn simple programming languages like Python to implement ML models on their data. Despite the growing trend towards ML, no study has reviewed the efforts made on using ML in synchrotrons to our knowledge. Therefore, we are examining the efforts made to use ML in synchrotrons to achieve benefits like stabilizing the photon beam without the need for manual calibrations of measures that can be achieved by reducing unwanted fluctuations in the widths of the electron beams that prevent experimental noises obscured measurements. Also, the challenges of using ML in synchrotrons and a short synthesis of the reviewed articles were provided. The paper can help related experts have a general familiarization regarding ML applications in synchrotrons and encourage the use of ML in various synchrotron practices. In future research, the aim will be to provide a more comprehensive synthesis with more details on how to use the ML in synchrotrons.

## INTRODUCTION

Synchrotrons light sources are very large-scale experimental facilities. A synchrotron is a large machine whose size is about a football field (Fig. 1). In these facilities, electrons are accelerated to almost the speed of light. By deflecting electrons through magnetic fields, they create incredibly bright light. The electrons are deviated in the storage ring by different magnetic components such as bending magnets, undulators, wigglers, focusing magnets. This deviation results in a tangential emission of X-Rays by the electrons. The resulting X-rays are emitted as dozens of thin beams, each channeled down "beamlines" surrounding the storage ring in the experimental workstations where the light is used for research. Each beamline is designed for use with a specific technique or type of analysis [1]–[3]. The produced light is advancing research and development in fields as diverse as biosciences, medical research, environmental sciences, agriculture, minerals exploration, advanced materials,

engineering, forensics [1]. The intense and highly focused light is used to study the dynamic and structure of materials down to atomic level using various techniques offered by different beamlines like diffraction, spectroscopy, tomography, and imaging [4]. Please see the references [1]–[3], [5] to see how a synchrotron works in more detail. Also, the list of light sources of the world can be found in [6].

Synchrotrons light sources worldwide are experiencing fast changes from traditional 3rd generation to multi-bend achromatic (MBA)-based 4th generation storage ring light sources to achieve high-brightness and low-emittance upgrades [7], [8]. The Advanced Photon Source (APS) and the Advanced Light Source (ALS) are both being upgraded

Figure 1: A 3D illustration of a synchrotron [2].

to MBA-based new rings. Diamond Light Source (DLS) designed a machine lattice based on double triple bend achromats [8]. The upgrades will substantially harness the light beam brightness from what is offered by the existing rings (the light brightness is much more greater than the sunlight) [7].

The rapid development of synchrotrons massively is accompanied by two significant challenges. First, the new rings drive for significantly lower emittances. Therefore, the beam dynamics in the rings become extremely nonlinear, causing smaller dynamic aperture and potentially smaller momentum aperture [7]. The extremely small emittance in a new ring needs much higher beam stability, which raises the need for a good understanding of the impact of environmental factors on the accelerator and

\* Work supported by Iranian Light Source Facility (ILSF)

<sup>†</sup> khaleghiali@ipm.ir

beams [7]. Second, the speed of doing experiments and the amount of raw data collected during each experiment is increasing [9], [10]. Typically, each light source theoretically can produce one petabyte of data per day [11]. Or accelerators can generate three-petabyte data just in one experiment [12]. The manual analysis of such massive data volumes is no longer possible [9], [10].

Moreover, the lack of automatic data analysis prevents the delivery of new science from analyzing many collected raw data. These effects are collectively called “data deluge”, which is a prevalent problem in synchrotrons [9]–[11]. To overcome issues such as data deluge, Machine Learning (ML), a subset of artificial intelligence that studies algorithms able to learn autonomously and directly from the existing datasets, can be very effective [13], [14]. Using ML in many contexts is increasing due to advantages such as automation for everything, trends and pattern identification, highly error-prone, and continuous improvement [15]. Even non-computer experts are trying to learn simple programming languages like Python to implement ML models on their data. Despite the growing practice towards ML, no study has reviewed the efforts made on using ML in synchrotrons to authors’ knowledge. ML can be used to achieve benefits like:

- Reducing unwanted fluctuations in the widths of the electron beams produced at synchrotrons that, in turn, can prevent experimental noises obscured measurements. This work can stabilize the photon beam without the need for manual calibrations of measures [16].
- Preventing data deluge [9], [10]
- Reducing user-in-the-loop decision-making [9], [10], [17]
- Harnessing the brightness of light sources [17]
- Supporting efficient and clever monitoring and fault detection [17]
- Optimal setup using automatic alignment [17]
- Supporting stable conditions by providing real-time feedback to the experiments and end-users [17]
- Allowing users to focus on experiments at hand and best use the allocated beam time rather than manual setups and justifications [17]
- Providing instant and straight feedback from speedy physics-based simulations [17]

In this paper, we are focusing on efforts investigated ML applications in synchrotrons. Also, the challenges of using ML in synchrotrons and a short synthesis of the reviewed articles were provided. Our literature review can help related experts have a general familiarization regarding ML applications in synchrotrons and encourage the use of ML in various synchrotron practices.

## MACHINE LEARNING AND ITS RELEVANT CONCEPTS

Machine learning is widely used to make predictions or decisions, a subfield of artificial intelligence and the process of making a mathematical model without being

explicitly programmed and using sample data, famous as “training data”. In other words, ML algorithms can learn to complete tasks using raw data [14], [18]. ML is usually applied for classification, regression, clustering, anomaly detection, dimensionality reduction, and reward maximization [13]. Generally speaking, ML techniques can be classified into three main categories, namely, supervised learning, unsupervised learning, and reinforcement learning (RL) [9]. Supervised learning is valuable when pairs of input and desired output are available. An algorithm can generalize the problem from the given structured data and predict unknown input. Unsupervised learning algorithms solve the tasks where only input data is available [19]. Recently, Reinforcement Learning (RL) has also attracted particular attention. RL is based on dynamic environment-agent interaction, similar to a Markov decision process [4], [20]. The agent starts an action on the environment, and the environment reacts to produce a reward, which the agent uses to learn how to enhance its subsequent actions. RL approach does not require a prepared data set consisting of input-output pairs since the agent learns by the continuous interaction with the environment, varying depending on the action and its dynamics [19]. Finally, semi-supervised learning is halfway between supervised and unsupervised learning. In this case, the algorithm is provided with both unlabeled and labeled data. This category is instrumental when available data are incomplete and to learn representations [21].

Among ML algorithms, clustering and deep learning (DL) are very popular. Regarding clustering is categorized as unsupervised learning (needs no labeled data). It groups data in some clusters. The similarity between the data within each cluster is maximum, and the dissimilarity between the data assigned to different clusters is minimum. Clustering algorithms are whether based on centroid research such as k-means or are density-based like DBSCAN. They see clusters as areas of high density separated by low density instead of determining the centroids. K-means is the simplest and most common clustering algorithm [19], and DBSCAN is robust against outliers. It can be applied to eliminate them on different stages of measurements and correction processes [22]. In recent years, deep learning has emerged as the leading class of ML algorithms, now almost synonymous with ML to the public. Deep learning uses neural networks (NNs) (Fig. 2) composed of hidden layers carrying out different operations to find and explore complex data’s representations. It improves the performance of classifiers beyond that common ML algorithms offer, especially in the circumstances involving large datasets with high dimensions [23], [24].

Figure 2: A fully connected NN with eight input features, two output labels, and two hidden layers including ten neurons each (Figure courtesy Alex LeNail).

## CHALLENGES OF USING MACHINE LEARNING IN SYNCHROTRONS

Many AI/ML platforms for beamline tuning have been planned. However, most of them can not eventually be used regularly as part of an accelerator's central control system, mainly due to limitations such as required hardware, algorithms, software packages, and limited accessibility of large and suitable datasets [14]. The most critical challenges to scientists and end-users at synchrotrons for utilizing machine learning are [10]:

- the necessity for long-term data preservation and transfer, as well as the demand for data analysis pipelines
- The requirement for instant feedback helping on-site scientific and technical decisions during beamtime: Such feedback dramatically depends on the accuracy and automation implemented using sufficient hardware and software infrastructure for the real-time data evaluation and processing at synchrotrons.
- The need for user-friendly software packages to effectively control the extensive data generated in synchrotrons experiments: most beamlines users are not experts in data computing and management.

Alizadeh and Khaleghi also listed the most critical data management issues, which include: multiple source data, data analysis, data storage, data accessibility, data process, data format, data transfer, expensive data analysis tools, online processing, clustering, storage reliability, data mining, replication, real-time data collection and visualization [12].

Regarding these problems, a cross-domain and cross-facility solution that can accelerate creating a real-time user-friendly, advanced data processing platform at synchrotrons is needed [10]. The solutions must be versatile and flexible enough to be integrated at various experimental stations and cope with the heterogeneous requirements of different beamlines and experiments [25]. For example, supervised learning algorithms need advanced data management platforms because they require large amounts of reliable training data to construct reliable models [19], [26]. Unfortunately, while experimentalists have access to large datasets, these data are typically not tagged appropriately and thus are not suitable for supervised ML methods. Continual advances in hardware and software have enabled tremendous increases in the

data collection rate. However, this boost in data throughput is not accompanied by a corresponding rise in identifying useful data and the value of each datum [27].

Some studies reported that a big data center which is termed a super facility is required for data management and processing [9], [10], [18]. Because the success of ML can be increased by the explosion in Big Data, advances in computational power, particularly the use of graphics processing units, and the development of more sophisticated ML techniques such as DL [18], [26].

In other words, these super facilities allow users to focus only on meaningful scientific data leading to discoveries and insights instead of dealing with unstructured and massive raw data. It can be achieved under users' simultaneous access to the synchrotrons' experiments with the designed real-time user-friendly platforms [9], [10]. In an interview conducted by Alizadeh and Khaleghi using ten light source facility members, it was concluded that 86% of participants were not familiar with big data [12]. Also, this study first classified synchrotrons experiments based on their techniques into three classes: imaging, scattering, and spectroscopy (Fig. 3). Then based on these main techniques, the researchers proposed a conceptual model for different data management aspects required for each method (Fig. 4). Some synchrotrons like the Shanghai Synchrotron Radiation Facility (SSRF) [9], the National Synchrotron Light Source II (NSLSII) [4], [17], and the Stanford Synchrotron Radiation Light Source (SSRL) [7] have made some efforts to provide the platforms needed for robust data analysis and management. The main work of these extensive platforms is that they should support a complete automated process for real-time and offline access for data management and computations to different operations of synchrotrons by providing sufficient hardware and software infrastructure [10].

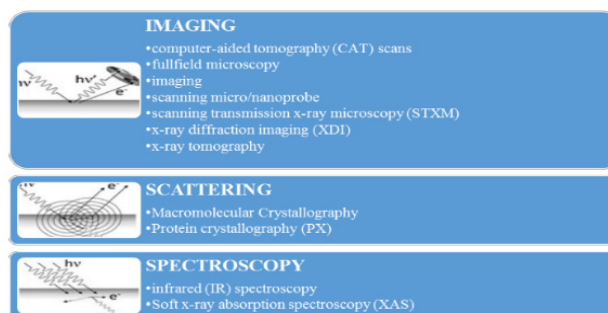

Figure 3: Synchrotrons experiments classification based on their techniques [12].

Figure 4: Different data management aspects required for each general synchrotrons experiments technique [12].

As the last point, we mention the concern that Hill et al. [22] noted that remote data analysis workflows and the use of distributed resources should be provided for ML purposes. The amount of beamtime required for a particular experiment reaches a limit as experiments become shorter. Therefore, it is no longer valuable for a user to visit the synchrotron physically. For this, remote data analysis and pipelines are essential in steering the experiment from a remote synchrotron and carrying out an optimal measurement.

## THE USED/ DEVELOPED ML ALGORITHMS, SOFTWARE, AND PLATFORMS FOR DATA MANAGEMENT

High performance and low latency ML models are necessary to use ML techniques in everyday operations of synchrotrons [28]. Among these models, Neural Networks in synchrotrons have attracted particular attention due to their ability to facilitate image-centric big data science and many scientific imaging problems, such as denoising, feature segmentation, image restoration, and super-resolution [10], [29], [30]. Furthermore, NNs can explore nonlinear and dynamic behaviors [24].

NNs process the feature of image pattern rather than the value of each pixel, as with classical methods [31]. Moreover, image-based diagnostics can be used directly in accelerators both as outputs and inputs [14]. NNs' accuracy and efficiency for image recognition and classification have been proved from various applications [31]. Several tools have implemented NNs for synchrotrons operations. The Xlearn toolbox implemented NNs for multiple synchrotron X-ray imaging problems, which is an open-source Python package. The Features of Xlearn are [31]:

- 1- Correction of instrument and beam instability artifacts
- 2- Improving low-dose images
- 3- Feature extraction and segmentation
- 4- Super-resolution X-ray microscopy

The Xlearn can be easily integrated into existing computational pipelines available at various synchrotron facilities [32]. Moreover, the Xlearn is based on Keras [33] and Theano [34] packages. Keras is a well-known platform for neural networks and Theano for tensor flow computing. Keras and Theano also include GPU acceleration, the critical feature of applying NNs on extensive datasets.

Please see [35] for source code, documentation, and information on contributing to this library. However, NNs are powerful in removing noise from reconstructed images. For training, they require collecting a dataset of paired noisy and high-quality measurements, which is a significant obstacle to their use in practice. In this regard, the Noise2Inverse was designed, a deep NN-based denoising method for linear image reconstruction algorithms that do not require any additional clean or noisy data. Recently, Hendriksen et al. [36] used the Noise2Inverse for deep denoising for multi-dimensional synchrotron X-ray tomography without high-quality reference data. This study applied the Noise2Inverse method to datasets acquired at two synchrotron beamlines. First, they used the technique on a static and a dynamic micro-tomography dataset from the TOMCAT beamline at the Swiss Light Source (SLS). Second, to investigate the possibility of accelerating the acquisition process using an X-ray diffraction tomography (XRD-CT), a dataset from the ID15A beamline at the European Synchrotron Radiation Facility (ESRF) was used. Results showed that Noise2Inverse is capable of accurate denoising and enables a substantial reduction in acquisition time while maintaining image quality. Liu et al. [30] introduced a deep NN model for real-time computed tomography at synchrotron light sources to improve the quality of tomographic reconstructions as data is collected. In turn, this method produces high-quality output more quickly and reduces the amount of data that must be collected. This method can be integrated into the real-time streaming tomography pipeline to enable better-quality images in the early stages of data acquisition. Using real-world datasets (tomography data, a common imaging modality at synchrotrons) collected at APS, results showed significant improvement in tomography image quality and system throughput.

Usually, different beamlines exit in a light source facility covering different scientific areas and utilizing different multi-dimensional detector technologies. Moreover, at synchrotrons, each beamline typically uses an individual streamline data acquisition software developed specifically for that beamline. The types of software are often incompatible with each other, making it difficult for scientists to compare data from different beamlines and other light sources. Therefore, AI/ML tools must also be compatible with these different beamlines [17], [37]. In this way, the NSLSII [17] developed the Bluesky Suite, a collection of Python libraries for data acquisition and management and mainly to tackle the data “variety” challenge and streaming and real-time data analysis at user facilities. There are capabilities like all data and metadata generated during an experiment can be emitted in real-time to other processes in the form of ‘documents’, Python dictionaries with comprehensible schema. The generated documents can be distributed locally or over a network. All beamline hardware is accessed via a library called ophyd. Or, the access to historical data is through an API called DataBroker.

In another study recently published by NSLSII investigated reinforcement learning [4]. This paper demonstrated the use of RL methods for optimizing beamline operations. This study also explained how the Python-based Bluesky suite of data acquisition software enables RL applications at a beamline. This functionality by solving a classical RL problem, cartpole, in the Bluesky environment was demonstrated. Furthermore, the use of RL methods to address a prevalent scenario existed on high-throughput beamlines: maximizing data quality across multiple samples of different scattering strength within a limited time window. Finally, the challenges and overall strategy to realizing extensive development of RL methods at large-scale user facilities were discussed.

The European Organization for Nuclear Research (CERN) is the Large Hadron Collider (LHC) site, the largest and highest-energy particle collider globally [13]. The CERN has mainly focused on applying supervised and unsupervised ML techniques for various domains associated with beam dynamics studies. Some of these areas include beam commissioning of the collimation system, optimization of beam lifetime and losses, detection of collective beam instabilities, heating detection from pressure readings, and numerical simulations of dynamic aperture. For example, a fully automated software for beam commissioning of the collimation system using ML algorithms was developed. This new fully automatic alignment software was successfully used throughout 2018 in the LHC operations. Furthermore, this software will be used as the default software at the LHC in 2021. The time to align the collimators at injection was decreased by 71.4%, compared to the semi-automatic alignment, namely from 2.8 h to 50 minutes. Also, this tool was incorporated into the angular alignment implementation and successfully decreased the alignment time by 70%, requiring no human intervention. For a complete review of how ML techniques have been incorporated at CERN, please see [13].

Topaz3 is data manipulation and machine learning package implemented with python libraries for Macromolecular Crystallography (MX) at DLS. Specifically, it transforms electron density map data obtained from diffraction experiments and uses machine learning to estimate whether the original or inverse hand has clearer information. Tensorflow-gpu is required to use the machine learning side of Topaz3, which speeds up the training and use of neural networks [38].

One of the decades-old problems in synchrotron light sources facilities is that they simultaneously deliver light to dozens of beamlines. One side effect of this is that the movements of specific insertion devices (IDs), i.e., undulators and wigglers with variable magnetic fields, cause the electron beam's size to fluctuate. These fluctuations affect other beamlines' performance. Usually, changes are reduced using corrections based on a combination of static, predetermined physics models and lengthy calibration measurements. It is periodically repeated to counteract drift in the accelerator and

instrumentation. Researchers at the ALS in Lawrence Berkeley National Laboratory showed that NNs algorithms can predict noisy fluctuations in the size of beams generated by synchrotron light sources. Therefore, they can correct changes before they occur (feed-forward vs. feedback correction). Consequently, this approach significantly helps attain order-of-magnitude enhancement instability that fulfils the requirements for different light sources. For training the synchrotron, researchers fed electron-beam data from the ALS, including the positions of the IDs and blips in electron-beam performance raised by ID adjustments, into a NN. One key advantage of this approach is that the required data for retraining NNs can be obtained constantly, even while the feed-forward system is active during a regular user run [16]. Furthermore, continuous retraining allows the neural networks to continually adapt to a drifting machine and changes in ID configurations during run periods, independent of static physics models. The developed algorithm then learned the complex nonlinear relationships between the ID settings and vertical beam size and made corrections to negate the blips. NNs stabilized the vertical beam size at 0.2  $\mu\text{m}$  or 0.4% of the beam size compared to 2–3% without correction [16].

Another light source facility that has heavily investigated using machine learning for light source facilities is the SSRL, a division of SLAC National Accelerator Laboratory, operated by Stanford University for the Department of Energy. A recent report which the SSRL published shows the research activities and achievements during the two-year R&D project of 'beam-based optimization and machine learning for synchrotrons' at SSRL [7]. R&D project was carried out in the development of machine learning techniques for synchrotron applications in three main areas: accelerator design optimization, beam-based optimization, and analysis of accelerator operation data. First, to implement online optimizations, they developed the Teeport platform. The control systems and programming environments on different machines may be different. Therefore, online optimization algorithms developed for one machine can not be easily applied to other systems. Usually, the optimizer is a Matlab script, and the evaluator is a Python script. Teeport decouples the algorithm implementation and the experimental systems by providing a universal middle layer that communicates between the optimizer and the evaluator. Therefore, they can communicate freely. In Teeport, a middleware between the evaluator and optimizer is inserted, acting as a data normalizer and signal forwarder. The data flows through the middleware. Therefore, to make the online optimization process more controllable and visible, one can add the control and monitor layers to the middleware (Fig. 5). The features of the platform include: online optimization experiment, fast switch between different optimization settings (the only necessary actions needed to switch between the different optimization settings concerning the code are switching the evaluator/optimizer id and/or update the configurations of

the evaluator/optimizer accordingly (Fig. 6)), optimization performance comparison, and optimization algorithm benchmark.

Figure 5: The architecture of Teeport. Teeport facilitates the application of optimization algorithms created in one programming environment to accelerators equipped with many different control systems and programming environments [7].

The Teeport platform can potentially become a centralized service for advanced optimization applications. It can be integrated lots of the optimization algorithms/test problems from various platforms, such as PyGMO, pymoo, PlatEMO, and Ocelot, to Teeport (Fig. 7). The R & D project also developed two ML-based global optimization algorithms for storage ring nonlinear beam dynamics optimization. The first is the multi-generation Gaussian process optimizer (MG-GPO) was used to solve multiple objective optimization problems. The second one is a neural network-based method to analyze accelerator operation data and study underlying environmental factors' impact on machine performance.

Figure 6: Fast switching between the simulation evaluator and the experimental evaluator [7].

Figure 7: Teeport as a unified interface for the optimization algorithms [7].

BESSY II Light Source is another synchrotron that has started to use machine learning. The primary efforts made by this synchrotron described in [39] are: (1) beam lifetime can be successfully predicted in a time-series fashion using supervised learning models trained only with 185

accelerator variables readbacks, i.e., excluding previous lifetime measurements, and (2) the prototypes towards self-tuning of machine parameters in different optimization cases like injection efficiency and orbit correction using deep reinforcement learning agents have been implemented.

The Delta synchrotron for orbit correction used machine learning techniques [40]. Conventional Feed-Forward neural networks were trained on measured orbits to apply local and global beam position corrections to the 1.5-GeV storage ring DELTA. According to this study, it can be demonstrated that ML techniques are an alternative approach for automated orbit correction of the DELTA storage ring.

Fol et al. [19] focused on applying ML for beam diagnostics and incorporating ML concepts into accelerator problems. They identified four main areas that ML algorithms can be helpful, including virtual diagnostics, optimization and operation, beam optics correction, instrumentation fault detection. This study shows how different ML approaches can be incorporated for various functions of accelerators. For example, it has been concluded that reinforcement learning is suitable for solving complex control tasks. Or unsupervised learning is helpful for anomaly detection tasks such as detecting instrumentation defects, e.g., using clustering for faulty beam position monitors signal so that these methods can be performed directly without training in accelerator systems.

## A SHORT SYNTHESIS OF THE REVIEWED ARTICLES

- To advance the field of incorporating ML in synchrotrons, a game-like project defining a reward scheme to train models to optimize a beamline efficiently is very effective.
- Good works have been done to facilitate data management and computing at synchrotrons, but they are ad-hoc based on different beamlines and synchrotron facilities. Therefore, future works can focus on converging these efforts in a seamlessly integrated platform for diverse beamlines with different requirements to provide impetus to employing ML in different operations of synchrotrons like accelerator design optimization, beam-based optimization, and analysis of accelerator operation data.
- Implementing remote data analysis workflows and the use of distributed resources are very effective for synchrotron practices. Because with the advances in synchrotron technologies, the amount of beamtimes needed for experiments is reduced tremendously, and an experiment can be done quickly. Therefore, physically visiting synchrotrons is no longer worthwhile.
- As evident from the above discussions, many researchers for developing ML models have used Python. There are three main reasons for this. First, for Python, such as HyperText Markup Language

(HTML), many existing codes are widely available for different use cases. By combining them, standalone platforms can be implemented more easily and rapidly. Considering such features, [14] suggested some people at accelerator laboratories can be determined to focus on the application of these tools to specific problems. Second, many libraries for ML purposes have been implemented in Python like Scikit-learn, TensorFlow, Keras, PyTorch, etc. Third, Python is very popular among non-computer experts due to its simplicity.

- Among existing ML algorithms and models, deep learning has been considered significantly. Almost, most of the reviewed articles have used NNs mainly due to their ability to explore nonlinear and dynamic behaviors and facilitate image-centric big data science.
- Unfortunately, on the Web, less publicly available good and large datasets are available for synchrotrons practices. It can mainly reduce the speed of using ML models in particle accelerators. By providing suitable datasets at cloud-based platforms like Kaggle in a short time, a variety of solutions can be provided for a given problem. For example, a successful competition was organized in 2014 by the high energy physics community, and it attracted over 1700 participants [14].
- Advanced online optimization using ML algorithms can support an efficient way of finding the ideal machine configuration.
- Combining big data with ML is already crucial. Storing, managing, and analyzing high-volume data are challenging problems that can be solved using this combination.
- In many contexts, usually, it is sufficient to use previously stored data for ML purposes. However, in synchrotrons, it is essential to develop online data streaming and management platforms because real-time usage of ML is vital for us in particle accelerators. Besides, processing and validating data after completing experiments lead to undetected problems and prevent online steering. Online ML algorithms and data processing platforms also can reduce the amount of data needed to be stored.
- The existing literature does not provide many direct comparisons between ML techniques using the same publicly available datasets. Therefore, to choose the best method that suits a given question, an empirical approach investigating different proposed ML methods on the same dataset is recommended.
- For storing data for ML techniques, mainly supervised algorithms, besides providing large datasets, it is essential to give techniques for tagging data and separating valuable and useful data from less or no useful data. This work reduces the amount of data needed to be stored and improves the efficiency of ML models.

## CONCLUSION

The suitability of ML methods has been clearly shown in the performed review for beam energy, brightness, stability, etc. But much is expected from further application and extension of these approaches to the most diverse beamlines at synchrotrons globally, offering advanced capabilities, exploring the most varied, time-varying, and nonlinear relationships. There are many efforts to provide data management platforms for machine learning models and algorithms. However, these efforts are sparse and heterogeneous based on different beamlines and synchrotrons. It is beneficial to integrate them to propose a more efficient environment for incorporating machine learning in everyday synchrotron practices. Generally, in large experimental facilities such as synchrotron, neutron, and x-ray free-electron laser (XFEL), unifying ML-ready solutions is needed such that they should be general and transferrable to different beamlines and particle accelerators. Moreover, ML algorithms should also have the capability to be used online by providing online powerful data analysis platforms. Otherwise, some errors and anomalies may not be detected, and the amount of data that need to be stored will increase. Feed-forward correction, evaluation, and optimization (e.g., Feed-Forward Neural Networks) are more beneficial than feedback ones for many synchrotron practices, according to our review. In future research, the aim will be to present a more comprehensive synthesis with more details on how to use the ML in synchrotrons.

## Abstract

Advancements in X-ray detector technology are increasing the amount of volumetric data available for material analysis in synchrotron light sources. Such developments are driving the creation of novel solutions to visualize large datasets both during and after image acquisition. Towards this end, we have devised a library called RemoteVis to allow the visualization of large volumes remotely in HPC nodes, using NVIDIA Index as the rendering backend. RemoteVis relies on RDMA-based data transfer to move large volumes from local HPC servers, possibly connected to X-ray detectors, to remote dedicated nodes containing multiple GPUs for distributed volume rendering. RemoteVis then injects the transferred data into Index for rendering. Index is a scalable software capable of using multiple nodes and GPUs to render large volumes in full resolution. As such, we have coupled RemoteVis with slurm to dynamically schedule one or multiple HPC nodes to render any given dataset. Remote-Vis was written in C/C++ and Python, providing an efficient API that requires only two functions to 1) start remote Index instances and 2) render regular volumes and point-cloud (diffraction)

backend. In-memory data is transferred directly to dedicated servers over the network via *Remote Direct Memory Access* (RDMA), without involving temporary file transfers or centralized storage. NVIDIA Index is a scalable software for interactive visualization of large volumes in full resolution, written in CUDA and designed to render data leveraging multiple GPUs and/or multiple nodes of a distributed HPC environment. When the volume is received by an instance of Index, it is immediately injected for visualization by the user, who can interact with the volume in real time using a web viewer.

The combination of RemoteVis and NVIDIA Index aims to overcome several limitations of existing open source and commercial visualization softwares. For instance, Neuroglancer [2] is a community-supported tool for visualization of very large volumes originally created by Google. It is capable of displaying arbitrary (non axis-aligned) cross-sectional views of volumetric data, as well as 3D meshes and line-segment based models (skeletons). Neuroglancer uses a tiling mechanism to handle zooming with different resolutions of large volumes, which are displayed on the web browser. Napari [3] allows simplified visualization of n-D data via Python, while ImageJ/Fiji contains plugins for rendering volumes [4]. 3D Slicer [5] is a rich application devoted primarily to medical imaging, containing several visualization tools for these types of data.

Despite some of the advantages of the aforementioned softwares, they either make limited use of GPU capabilities for rendering 3D volumes, relying on a single device to do so, or only displaying cross-sections of data, while providing less than optimal techniques to handle larger volumes (i.e., data sets with more than  $2048^3$  voxels). Even commercial solutions, such as ORS DragonFly [6] and Thermo Fisher OpenInventor [7] (Avizo/Amira), tend focus on single GPU/single node rendering, with limited APIs that can be used to address the needs of modern synchrotron light sources. Finally, those softwares are usually implemented considering that data is essentially stored on disk.

We initially designed RemoteVis to tackle the issue of sending volumes generated on local servers connected to X-ray detectors to remote dedicated servers for visualization. The local servers are freed to receive data at high frame rates and to perform local processing on the data using custom multi-GPU code. Such processing may involve, for instance, frame correction operations and even high performance tomography reconstruction [8]. In parallel, the remote servers receive the resulting volumes and are responsible for rendering them at full resolution, with interactive responsiveness.

## INTRODUCTION

Improvements in synchrotron light source technology are pushing forward the boundaries of X-ray microscopy imaging. Recently, 4th generation synchrotron light sources are increasing the amount of available beam flux and coherence, opening the doors to novel imaging techniques while representing an improvement of orders of magnitude with respect to previous generations. Hence, the entire imaging pipeline is evolving to make those powerful improvements available to the beamlines and their users; starting with the creation of fast X-ray detectors capable of acquiring frames at multiple kHz and reaching the development of high performance data processing, visualization, and analysis workflows.

In this paper, we propose a volumetric data visualization workflow in the form of a library called RemoteVis, to address some of the challenges imposed by the large data volumes being generated. RemoteVis is designed as an efficient C/C++ API for sending image volumes for remote 3D rendering, using NVIDIA Index [1] as the rendering

\* This is a joint work between the following groups of the Brazilian Synchrotron Light Laboratory: Sirius Scientific Computing (SSC – TVS, AZP, MLB, and EXM), Throughput Enhanced Processing Unit (TEPUI – FSF), and Beamline Software (SOL – DADA); in collaboration with the NVIDIA Index team (MN and AK). Corresponding author: Eduardo Xavier Miqueles (eduardo.miqueles@lnls.br).

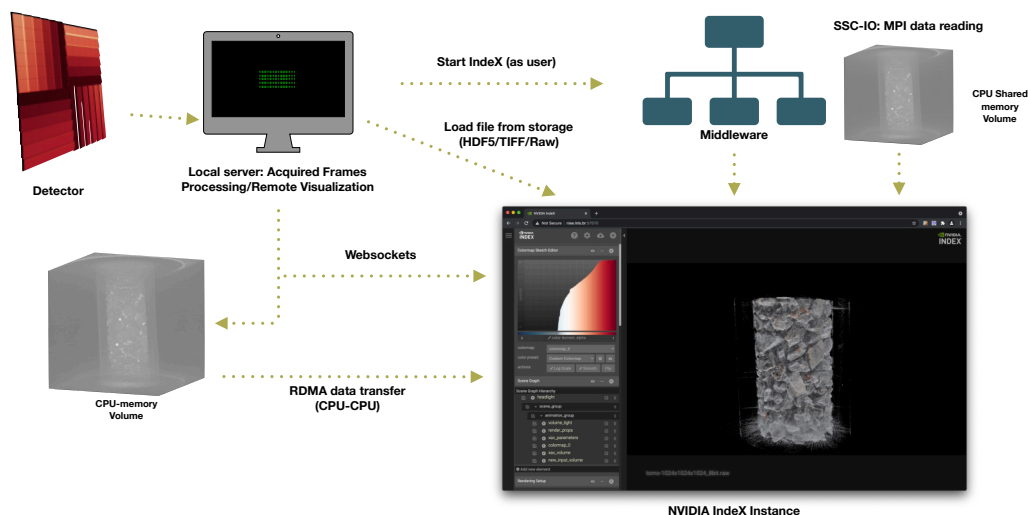

Figure 1: The proposed remote visualization workflow using the RemoteVis library to send volumes into NVIDIA IndeX for visualization, via RDMA data transfer.

The volume visualization solution we propose through RemoteVis provides much more than simple data transfer between nodes. We extended the library to serve as a platform for managing multiple instances of NVIDIA IndeX simultaneously, running in an HPC environment via job scheduling. Users of our APIs can transparently manipulate those instances with no more than a couple of C/C++ or Python functions calls. Furthermore, RemoteVis guarantees bidirectional data communication between NVIDIA IndeX and other softwares. This allowed us not only to send volumes, but also to retrieve portions of the volume that are being displayed for further processing. Moreover, NVIDIA IndeX provides two important functionalities that can be leveraged. First, the software implements the NVIDIA IndeX Accelerated Compute (XAC) facilities, through which custom functions can be created interactively for providing specific scientific visualization insights. Second, we are able to send pre-trained Deep Learning networks using RemoteVis to IndeX for inference. The software is then able to apply those networks instantaneously to the volume, thereby enhancing visualization via segmentation.

It is worth noting that Paraview [9] is an open source software that can use NVIDIA IndeX as a highly efficient rendering backend. We refrained from exploiting such integration to fully leverage the raw capabilities of IndeX in our workflows.

The paper is organized as follows. We first present the details about the RemoteVis library, including the capabilities of NVIDIA IndeX. We then briefly present some results before stating our concluding remarks.

## THE REMOTEVIS LIBRARY

We may divide the RemoteVis library roughly into two major components. The first is an API written in C/C++ and Python whose primary goal is to perform data transfer/com-

munication between NVIDIA IndeX and other softwares, which may be located in a same server or separated across an Ethernet network. The second is a middleware responsible for processing some of those API calls and for managing instances of IndeX, which may be running via a job scheduling mechanism such as slurm [10].

Figure 1 presents our visualization workflow combining RemoteVis and NVIDIA IndeX. Given a local server being operated by a beamline user for their experiment, the RemoteVis API is called to request a new IndeX visualization server instance. The RemoteVis middleware receives this request and initializes an instance on the beamline user's behalf in a remote server. All communication at this point is performed via TCP/IP socket transparently to the user of our API. While the NVIDIA IndeX instance is being initialized, the local server may be acquiring frames from the attached detector and/or conducting some processing on the received data, in order to produce the volume containing the sample of interest in CPU memory.

Once the sample volume is ready, yet another function call of RemoteVis performs two operations. First, the API asks the IndeX instance to prepare for receiving a new volume for data injection/rendering, using the software's websocket communication standard. Second, the volume is sent from the CPU memory of the local server directly to the CPU memory of the remote server running the IndeX instance via RDMA. When IndeX receives the volume, the software immediately injects the data into its rendering scheme by essentially transferring everything to multi-GPU memory.

RemoteVis is very flexible and its usage is not limited to transferring volumes from servers connected to detectors. Our API render volume function can be called with any 3D volume for remote rendering in CPU memory, regardless of the data origin. RemoteVis also provides another function to request the remote IndeX instance to directly load a file from

central storage. To further facilitate the use of RemoteVis by non-expert users, the library also incorporates a web interface through which the users can login and immediately start using an Index instance, without ever having to type a single line of code. In the next sections, we provide more details about NVIDIA Index and the components of RemoteVis.

### *NVIDIA Index*

NVIDIA Index is a 3D volumetric interactive visualization platform that allows scientists and researchers to visualize and interact with massive data sets, make real-time modifications, and navigate to the most pertinent parts of the data, all in real-time, to gather better insights faster [1]. To achieve high efficiency and handle arbitrarily large data sets, Index divides a volume into smaller cubes and sends them for rendering across multiple GPUs and/or multiple nodes. Index uses a truly distributed database/compute environment to process the workload.

We implemented a plugin for data injection using Index's compute API, such that volumes are directly copied from CPU memory into the rendering pipeline for immediate visualization. Our plugin activates data injection after the RemoteVis library transfers the volume into the CPU memory of the server in which the Index instance is running, as will be detailed later.

The NVIDIA Index Accelerated Computing (XAC) interface enables scientists to rewrite the core data visualization routines at runtime. XAC-based programs are written in CUDA, compiled, and injected into the inner loops of the volume or surface raycasters to provide scientists with real-time visual feedback. We created XAC kernels for specific use cases of the Brazilian Synchrotron Light Laboratory and present some renditions in the results section (Figs. 2 and 3).

### *Visualization Server Middleware*

NVIDIA Index ships with a web application built on top of the Index rendering library, consisting of a websockets server that receives JSON remote procedure calls from a React.js web viewer. The viewer displays the remotely rendered volume as an HTML5 video stream, with which the user interacts on their own web browser using mouse events. Those events are sent to the web server and effectively change the camera's position. We refer to this web application as a *visualization server instance* of NVIDIA Index in our work.

The RemoteVis library provides function calls to initialize, query, and shutdown instances of Index. The RemoteVis middleware is written in Python and processes those function calls, assigning a visualization server instance to the requesting user upon initialization. RemoteVis utilizes TCP/IP socket messaging between the user of our API and the middleware to ensure transparent client-server communication in a local Ethernet network. The visualization server instances may run directly on the server where the middleware resides as separate user processes or as scheduled slurm jobs, depending on the operation mode selected for the middleware. We detail later how slurm job integration works, but it is important to stress that regardless of the operation

mode, the Index instance is started by the middleware as a process with system permissions of the requesting user. We thus ensure that all data access permissions are granted accordingly and respect the underlying HPC environment policies. Moreover, we assume the user has been previously authenticated into the local HPC environment and has been given the necessary privileges to use the RemoteVis API in their code.

The middleware starts the NVIDIA Index web server instance on a randomly chosen TCP/IP port that is then associated with the user. A URL is sent back through the API as the result of the initialization function for the user to access the Index instance on their web browser. The user may also invoke a query operation to retrieve the URL information later, or request the instance to be shut down programmatically.

### *Slurm Scheduling Integration*

Since we propose RemoteVis as a framework for creating visualization workflows based on NVIDIA Index in an HPC environment, a common way of sharing resources in those settings is to make use of job schedulers such as slurm. When using the middleware in this operation mode, it starts visualization jobs via slurm and submits them to the job queues specified to run visualization server instances. Once again, those jobs receive the access permissions and slurm priority of the requesting user.

From the RemoteVis API perspective, the primary change in the slurm job operation mode is that the Index visualization server instance may not start immediately, depending on the state of the job queues. Hence, when the user requests an instance the middleware's default behavior is to create the slurm job and respond at once. Normally, the API function call is blocking, meaning that the user could readily send data for visualization once it returns, because the middleware waits for the instance to begin executing. This behavior changes when using the slurm backend, and the middleware returns the expected start date and time for the job instead of the URL. Currently, RemoteVis transfers the responsibility of verifying if the visualization job began to run to the user, who should use the API query function call to determine if the job has started.

When the Index instance job starts running, it communicates its current status to the middleware via RemoteVis. If the user queries the middleware at this point, the URL of the instance is returned as expected and data may be transferred to Index for visualization. It is worth noting that the NVIDIA Index job may be spawned on a server different than the machine in which the middleware resides, depending on the slurm configuration.

Since the user may not access the instance when the job begins its execution, possibly because the job started earlier than expected or the user forgot to check, the middleware automatically sends a shutdown command within a configurable grace period (usually 60 minutes) to release the computing resources for other jobs. The middleware also sends an estimated number of GPUs to slurm that are nec-

essary for rendering the volume, based on the size and data types requested by the user in the initialization function call. Those parameters are enforced during data transfer calls.

### *SSC-RDMA: RDMA-based Data Transfer Library*

RemoteVis implements data transfer to and from NVIDIA IndeX using RDMA. RDMA is a low latency protocol for reading and writing information stored on CPU memory remotely, bypassing the CPU to achieve high transfer rates. It was originally proposed for Infiniband networks, but has since been introduced to Ethernet through RDMA over Converged Ethernet (RoCE).

We created a standalone C library called SSC-RDMA (Sirius Scientific Computing RDMA) to achieve high data transfer rates using RDMA, based on [11]. SSC-RDMA's primary goal is to transfer image volumes. Hence, the library provides two high level functions that can be called in the receiver and sender sides, respectively. Both functions accept two char arrays that are used to transfer the volume of interest with arbitrary size and a header containing information to describe the volume. We represent a 3D volume in C array format (column-major) and therefore cast any type of volume to a char array for generic data transfer. The size of the linearized in bytes array must be shared between sender and receiver out-of-band, to ensure that both sides allocate the data with the proper size before the transfer takes place. The char header array assumes a fixed size of 128 KB and carries application-dependent encoded information about the volume (e.g., dimensions, data type).

When sending a volume to the visualization server instance for rendering, the C/C++-level RemoteVis `render_volume` function accepts as input a char array containing the volume data, the volume information (size and data type), and the information about the instance obtained during initialization or query. The RemoteVis `render_volume` function then sends a websocket message to IndeX to have it prepare for receiving a new volume with the corresponding size in bytes. Simultaneously, the SSC-RDMA data transfer `ssc_send` function is invoked by the RemoteVis `render_volume` call and waits for our IndeX plugin to connect for data transfer using the `receive_volume` function, from the RemoteVis API. The latter uses in turn the generic `ssc_receive` function of SSC-RDMA and data is finally transferred from the local server to the remote server where IndeX is running. Afterwards, our plugin immediately asks the IndeX library to render the volume by injecting it from the CPU to the GPU memory.

To retrieve a volume from NVIDIA IndeX, the process is similar to the above. The exception is that the `retrieve_volume` function from RemoteVis requests IndeX to send the volume that is being rendered via SSC-RDMA.

### *Python API and Jupyter*

RemoteVis provides full access to the underlying C/C++ functions from Python, which in fact are extremely similar. The primary difference between the functions is that the

Python version accepts Numpy arrays holding the volumes for remote rendering. Our API can be called directly from Jupyter notebooks and include a special function of RemoteVis that returns a screenshot of the current volume visualization using IndeX an RGBA numpy array.

### *Web Client for User-friendly IndeX Access*

Even though the RemoteVis API is very simple to use, many users are not interested in coding, or don't know how to code, an application. We provide a user-friendly web client through which the user logs into the system using their credential of the HPC system, and then the RemoteVis API is called to start an instance on their behalf.

Our web client communicates with a web server written in Python/Django, which validates the user credentials on the HPC system and calls the RemoteVis IndeX initialization function upon success. Since the RemoteVis API is used throughout the process, all IndeX access is unified through the RemoteVis middleware, thereby providing great flexibility for designing visualization workflows.

We have further expanded the original React.js IndeX web interface to allow users to load volumes from disk. The user may navigate on a centralized repository file system using a custom React.js component, select a volume for loading and pass the corresponding string to our IndeX plugin. That volume is read from disk and sent to IndeX for rendering.

### *SSC-IO: MPI-based Efficient HDF5 File Reading and Writing*

Since many synchrotron light sources have been adopting the HDF5 file format for storing various imaging formats, we implemented a library to efficiently read and write volumes into memory. This library is called SSC-IO and it was motivated by the fact that the supported way of reading and writing HDF5 files in parallel requires using the Message Passing Interface (MPI) standard. MPI has certain limitations that hinder its use with IndeX. In particular, IndeX implements an efficient pipeline for reading volumes from disk using parallel callbacks that are issued only for the visible portions of the volume. Those callbacks are issued by separate threads and work well for raw volumes. However, the HDF5 file format does not provide proper parallelization at the thread level, thereby decreasing performance

We designed SSC-IO to read volumes from HDF5 using MPI and storing the result in shared CPU memory. This is necessary because MPI spawns processes instead of threads to achieve parallelization. Once the volume is read, we implemented a custom loading callback plugin for IndeX that reads data directly from CPU memory. SSC-IO parallelizes writing a volume from CPU memory to disk in the same way. We designed the library in Python such that we can easily extend it to multiple HDF5 file structures.

## **RESULTS**

In the next sections, we present some results obtained using RemoteVis and IndeX. In particular, we focus on briefly

evaluating RDMA data transfer and detailing some of the rendering features of Index.

### RDMA-based Data Transfer

Table 1 presents some data transfer results using SSC-RDMA. We conducted 12 experiments using three servers, one IBM Power 9 and two NVIDIA DGX-A100s. The Power 9 is connected to the DGX-A100 through a high speed Ethernet switch at 50 Gb/s. The connection between the DGXs is via 100 Gb/s Ethernet. The results in the table are the average of 5 executions using float 32-bit volumes with 4 different sizes. As can be seen, SSC-RDMA is very efficient and requires roughly 20s to transfer over 100 GB of data (for volume with size  $3072^3$  voxels). The selected sizes reflect some typical volume sizes produced by fast detectors in a matter of seconds. As can be noted, SSC-RDMA achieves roughly 45 Gb/s data transfer rates, indicating that there is still room for improvement in our code, even though we are able to move large volumes without using centralized storage.

Table 1: RDMA-based data transfer times using SSC-RDMA. Three settings were tested between three different servers, one IBM Power 9 and two NVIDIA DGX-A100. The IBM Power 9 (P9<sub>50</sub>) is connected at 50 Gb/s to the NVIDIA DGX-A100 while the connection between the DGX servers is at 100 Gb/s. The selected volumes are of type float 32 bits (4 bytes per voxel) and vary in number of voxels. All times are in seconds. For DGX to DGX, the destination server was the same as P9<sub>50</sub> to DGX.

# vx	P9 <sub>50</sub> to DGX	DGX to P9 <sub>50</sub>	DGX to DGX
1024 <sup>3</sup>	0.87 ± 0.01	1.13 ± 0.20	0.86 ± 1.48
1536 <sup>3</sup>	2.58 ± 0.09	3.00 ± 0.65	2.53 ± 0.47
2048 <sup>3</sup>	5.99 ± 0.09	7.17 ± 1.47	5.98 ± 1.12
3072 <sup>3</sup>	20.30 ± 0.26	21.89 ± 4.90	19.16 ± 3.66

### XAC Rendering Kernels

We have implemented three different rendering techniques using XAC based on some use cases of LNLS. The first XAC kernel (S1) performs simple shading using local information such as gradient calculation on the volume. The second kernel (S2) simulates single scatter lighting and requires some extra memory for rendering, but produces shadow effects that improve visualization. The third is the most computationally demanding and is based on the ambient occlusion algorithm [12] (S3), requiring pre-computation to generate an auxiliary volume to determine shadow values. Note that all computation was done directly inside Index using the XAC technology.

Figures 2 and 3 presents two samples of X-ray computed tomography imaged at LNLS and rendered using XAC. The first figure compares basic rendering with (S1) and (S3), while the second compares (S1) and (S2). The original volume of the silica bead experiment (Fig. 3) can be seen segmented in Fig. 4.

### NVIDIA TensorRT CNN Inference

As previously stated, NVIDIA Index provides integration with TensorFlow/NVIDIA TensorRT such that pre-trained deep neural networks may be used to perform on-demand inference on the visible portion of the volume. We have devised softwares at LNLS capable of producing NVIDIA TensorRT-optimized inference engines from CNNs created for segmenting volumes, which can then be used with Index to provide advanced data interpretation.

Figure 4 presents an example of those results. In that case, we trained a 2D U-net [13] model to segment the phases of a silica bead fluid flow experiment containing four phases of interest (beads, water, gas, and background) using our custom softwares and then sent the resulting TensorRT engine for Index using RemoteVis. In that case, RemoteVis provides yet another function capable of taking a serialized engine and sending it to Index via SSC-RDMA for inference.

### Point Cloud Rendering

NVIDIA Index was designed not only to render regular volumes, but also irregular data such as meshes and particle volumes (i.e., point clouds). We have incorporated into RemoteVis the capability of rendering point clouds submitted by the user similarly to how it is done for regular volumes. The corresponding function call accepts an array holding the XYZ coordinates of the points and another with the values of each one. Then, RemoteVis invokes RDMA data transfer for each of those arrays into the server where the Index instance is running and requests the software to render the point cloud as a particle volume. The points are rendered as spheres with radii proportional to the point values. The API is accessible from C/C++ and Python as always. Figure 5 depicts an example of point clouds being rendered from data obtained for 3D reciprocal space mapping, a common experiment in synchrotron light sources.

## CONCLUSIONS

We presented the RemoteVis library as a framework for creating 3D visualization workflows using NVIDIA Index as the volume rendering backend. RemoteVis provides a data transfer mechanism via RDMA to allow volumes to be transferred from local servers to remote servers dedicated to visualization. The data in local servers may be acquired from X-ray detectors or simply produced by some other procedure. RemoteVis provides auxiliary functions that can load HDF5 files directly into Index very efficiently using MPI. Also, our library allows portions of the volume being rendered to be retrieved from Index into other softwares for further processing.

We also exploit in RemoteVis very useful techniques implemented in Index. First, we are able to create insightful rendering functions using the Index Accelerated Compute technique to provide advanced visualization for certain scientific cases. Second, we are able not only to render regular volumes but also point clouds in Index using RemoteVis, also via RDMA data transfer. Finally, we incorporate NVIDIA

Figure 3: Silica bead fluid flow experiment renditions using IndeX XAC operators. The original image with segmentation of the gas phase is depicted in Fig. 4 (left). Data courtesy: MOGNO beamline/Sirius, LNLS/CNPEM.

TensorRT-optimized pre-trained CNNs into IndeX, such that our models provide on-the-fly segmentation of the data that is used to enhanced visualization.

RemoteVis is very well suited for use in synchrotron light sources, although it is not limited to those use cases. RemoteVis and IndeX can be used in HPC environments where large data sets are produced and require fast and easy to use tools for visualization.

## ACKNOWLEDGEMENTS

We would like to acknowledge the Brazilian Ministry of Science, Technology, and Innovation (MCTI) for funding this work, through the Brazilian Center for Research in Energy and Materials (CNPEM). We would also like to thank the MOGNO and EMA beamline groups from Sirius/LNLS-CNPEM for the data used in this paper.

# PROCESS AUTOMATION AT SOLEIL: TWO APPLICATIONS USING ROBOT MANIPULATORS

L.E. Munoz\*, Y-M. Abiven, F. Briquez, J. Da Silva, E. Elkaim, A. Nouredine,  
V. Pinty, M. Valléau, Synchrotron SOLEIL, Saint-Aubin, France  
S. Bouvel, EFOR, Levallois Perret, France

## Abstract

Robot manipulators are an important component in most autonomous systems in the industry. Arc welding, machine tending, painting, picking, are only some examples where the robot manipulators are widely employed. In Synchrotrons some process can benefit from robotic approaches in order to improve automation. Automatic Sample Changer on beamlines is the most common example of automation. This paper describes two robotic applications developed at Synchrotron SOLEIL. Both applications use the SOLEIL robotic standard introduced some years ago [1]. The first application aims to automate the exchange of samples for powder diffraction experiment on the CRISTAL beamline. Hence, a pick-and-place robot is used to automate the process of picking up the sample holders and placing them on the goniometer. The second application, also of the pick-and-place type, is dedicated to the automation of the magnetic characterization of magnet modules of an U15 undulator. These modules, built with a permanent magnet and two poles, are measured using a pulsed wire method [2]. In this case, the robot picks the modules stored in boxes to then place them on the test bench of the U15 undulator.

## INTRODUCTION

According to the International Federation of Robotics (IFR) an industrial robot is an automatically controlled, re-programmable multipurpose manipulator programmable in three or more axes, which can be either fixed in place or mobile for use in industrial automation applications (ISO 8373:2012). At the beginning, since manipulators had no external sensing, they were used for simple tasks as pick and place, mainly doing monotonous, repetitive and dangerous tasks for humans. As a result of technological advances, robots could handle more complex motion and had external sensors and then, more complex applications followed like welding, painting, grinding and assembly. Nowadays, the use of an industrial robot, along with Computer-Aided Design (CAD) systems and Computer-Aided Manufacturing (CAM) systems, not only characterize the latest trends in process automation in the industry [3], but the robot manipulators are becoming essential components in various growing sectors such as medical.

In a synchrotron facility, the most common application of industrial robots is to use the manipulator as a sample changer. The principle of a robotic sample changer is to take samples from one place and put them in another place with

accuracy and repeatability. Thus, these robotic exchangers are widely used in experimental stations for Macromolecular Crystallography (MX), like is the case of the beamlines AMX and FMX at the National Synchrotron Light Source II (NSLS-II) [4], the beamlines I03, I04, I04-1 and I24 at Diamond Light Source (DSL) [5], the beamlines ID23-1 and ID23-2 at the European Synchrotron Radiation Facility (ESRF), among other MX beamlines. Some other techniques like biological Small-Angle X-ray Scattering (bioSAXS) at NSLS-II [4] and the powder X-Ray diffraction at the ESRF [6] integrate the sample changers to sample automation.

Nevertheless, the use of industrial robots is not limited to the sample changer, they can also be used to detector positioning: for Bragg CDI and Bragg-ptychography [7], to study structural dynamics with X-ray techniques [8], to enable coherent diffraction and SAXS experiments [9]; or even, robot manipulators can execute similar tasks to those present in the industry, such high precision manufacturing [10].

At Synchrotron SOLEIL, two robotic sample changers were installed on the beamlines PROXIMA-1 [11], and PROXIMA-2 [12], long before SOLEIL developed the robot standardization in 2019. This standardization, see Fig. 1, designed as part of a larger strategy in process automation, defines a robotic standard on both hardware and software which is versatile enough to cover the synchrotron requirements, while being easy to implement, to employ and to maintain in operation [1].

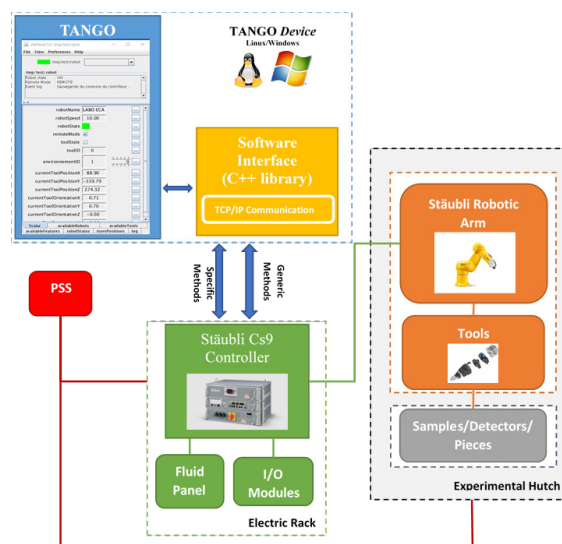

Figure 1: SOLEIL Robot Standardization Scheme.

\* laura.munoz-hernandez@synchrotron-soleil.fr

The robotic standard has allowed a rapid development and deployment of two new applications at SOLEIL. The first one, integrated by IRELEC company, is dedicated to accomplishing powder X-Ray diffraction measurements, where the robot is in charge of automating the sample changer. The second one, developed entirely in-house, differs from the application examples given above, since in this application the robot manipulator is used to automate the magnetic characterization of the modules of an U15 Undulator. Since measuring the magnetic field each of the modules is time-consuming and is often a repetitive and tedious task for human operators, the automation of this task can be perfectly achieved by an industrial robot.

In the following sections these two robotic applications are described in detail.

## CRISTAL BEAMLINE ROBOTIC APPLICATION

CRISTAL is an Undulator-based X-ray multi-technique diffraction beamline, which delivers high-brightness beam in the 5 to 30 keV energy range. It is dedicated to study single crystals and powders. All the standard techniques for structural analysis on single crystals and powders are implemented, as well as more advanced techniques like coherent diffraction imaging and time-resolved diffraction in a pump-probe scheme [13].

To improve the efficiency of powder diffraction measurements, the process has been automated using an industrial robot:

1. Automatic mounting of capillaries. The robot is in charge of mounting the capillaries to be studied on a 2-circle diffractometer, following the workflow shown in Fig. 2.
2. Sample self-centering task. The diffractometer is equipped with a spinner and a Y-Z translation stage. Both of them serve to the sample self-centering<sup>1</sup>.
3. Diffraction measurements. Measurements are performed by scanning the 2-circle diffractometer. The diffractometer includes two detectors. In order to obtain high-angular-resolution diagrams in less than one hour for ab-initio structure determinations a multi-crystal analyzer detector (21-Si(111) crystals) is employed. For phase analysis, in-situ or operando studies, a Mythen (from Dectris) curved pixel detector is used.
4. Automatic dismounting of capillaries. The robot returns the samples to their place in the sample store.

This process can be repeated without entering the experimental hutch as many times as necessary until the maximum capacity of the sample store is reached.

<sup>1</sup> How self-centering is implemented is outside the scope of this paper.

Figure 2: Robot Workflow: Sample Store to Diffractometer.

## Robotic Sample Changer

The robotic platform, shown in Fig. 3, is based on a Stäubli TX2-60L robot with six degrees of freedom, which is mounted on a mobile chassis and integrates the Cs9 robot controller, the electric rack, the fluid panel and the input/output modules. The TX2-60L was chosen for its radius of work of 920 mm and the load capacity of 3.7 Kg. sufficient enough to carry the robot end-effectors. The main end-effector is composed of a pneumatic tool changing system, a 3-finger centric gripper, a collision and an overload protection system and a laser sensor. The manipulator is equipped with solenoid valves that operate the gripper, the tool changing system and the collision device without external devices. The robot controller is interlocked with the beamline Personnel Safety System (PSS) such that no robotic movements are allowed unless the hutch has been locked.

The sample store is placed next to the robot base and it has a capacity of 36 samples. The samples are mounted on 17mm diameter cylindrical sample holders. It can be observed from Fig. 4 that the lower part of the sample holder has a female cone that is used to place it on the sample store. The TX2-60L robot has a positioning repeatability of 30  $\mu$ m and combined with a magnet housed in the bottom of the female cone, allows the accurate location of the sample holder on the diffractometer.

Although the position of the diffractometer is known, it has 1 degree of freedom (translation), thus the robot must be able to detect if it has been displaced. Furthermore, since the robot can be itself moved, a calibration process had to be implemented.

Figure 3: CRISTAL Robotic Sample Changer.

Figure 4: CRISTAL Sample Holder.

Calibration consists of measuring, with the help of a robot's tool equipped with a laser sensor (Keyence IL-30), the center of the placement area of the sample holder, located in the center of the diffractometer. If there is any difference between the calculated value and the value saved in the memory of the controller, the value save in memory is updated.

As it is described below in the **SOFTWARE INTEGRATION** Section, the robotic standard guarantees some flexibility in integration. Therefore, the calibration of the position of the diffractometer can be carried out when some movement in the translation of the diffractometer is performed or systematically at the beginning of a measurement campaign, i.e. before the execution of the 4 steps introduced above.

It is noteworthy that the execution time of the two first steps is about 1 minute and 30 seconds. This allows saving 5 minutes to 10 minutes if a human operator performs these tasks. In addition, the automated process gives the opportunity to almost uninterrupted use the beam 24 hours a day during the experiments.

## MAGNETIC CHARACTERIZATION ROBOTIC APPLICATION

In order to achieve high-performance Undulators, a magnetic characterization of the modules (a hybrid magnetic structure, made out of permanent magnets and iron poles) that compose the insertion device have to be accomplished. For each module, the magnetic field is measured with a Hall effect probe mounted on a trolley which moves on a rail, and a rotating coil, supported by a set of motorized stages, is responsible of the magnetic field integral measurements. These two measuring instruments are placed next to the magnetic measurement bench, where each module is positioned on the internal girder for the purpose of being measured. Despite the fact that the magnetic field measurements are done automatically, the positioning of the module on the magnetic measurement bench was effectuated until now, by a human operator. Performing this task is time-consuming and it becomes repetitive for the operator due to the hundreds of modules that have to be characterized. Hence, to fully automate the magnetic characterization, a robotic solution to position the modules was implemented. The simplify workflow of the automated process is shown in Fig. 5. Where the orange dotted-line blocks are the tasks performed by the robot and the blue dashed-line blocks by the other devices of the test bench.

Figure 5: Automatic Magnetic Measurements Workflow.

## Robotic Platform

The robotic platform is composed of a robot Stäubli TX2-60L mounted on a pedestal. The end-effector is formed by an electric 2-finger parallel gripper, a manual changing system and an ATI Force/Torque sensor system. The electric rack, the Cs9 robot controller and the Input/Output modules are placed in a separate bay. An optical table located next to the robot supports four boxes where 120 modules (30 per box) are arranged vertically. This optical table also supports a drop-off area that had to be implemented to be able to place the modules correctly on the measurement bench, see Fig. 6.

Since there are magnetic constraints, both the mechanical design and the design of the robot trajectories, were conceived taking into account these constraints. In addition, the gripper jaws were designed to be able to grasp the modules in two different ways, as it can be observed in Fig. 7. The “first configuration”, Fig. 7a, takes place when the modules are taken out of the boxes and positioned on the drop-off area; while the “second configuration”, Fig. 7b, is used when the robot takes the modules from the drop-off area and places them on the measurement bench and vice versa.

The Force/Torque sensor is used to ensure the accurate positioning of the module on the measurement bench. Once the module is released from the gripper, a series of movements is performed by the robot in such a way that the jaws push the module in the  $X - Y$  direction until a  $X - Y$  force threshold is reached.

The characterization of a module takes around 15 min, therefore the robot-based bench can work up to 30 hours without the need for human intervention.

Figure 6: Robotic Platform.

(a) Gripper Configuration 1. (b) Gripper Configuration 2.

Figure 7: Two-in-one Gripper.

## SOFTWARE INTEGRATION

It can be observed in Fig. 1 that a C++ library interface was developed to enable communication between TANGO and the robot controller. The library integrated into the TANGO Device communicates with the Cs9 controller via the Ethernet network using TCP/IP.

In order to facilitate the integration into the control system, a series of methods or routines are used to communicate and act on the physical environment of the robot. The so-called generic methods are instructions that can be applied to any robotic application, such as, turn the robot on/off, sending the robot to a parking position or home position. On the other hand, the specific methods are instructions dedicated to an application, i.e., they execute functionalities or features developed for a single application.

For the CRISTAL robotic application some of the implemented features are: *put* (take the sample from the sample store at coordinates *row,column*, and mount it on the diffractometer), *get* (take the sample from the diffractometer and put it back at its position in the sample store), *teachgonio* (launch the automatic teaching of the diffractometer position, i.e. the calibration process). For the magnetic characterization some of the implemented features are: *put* (take the module from the selected box at coordinates *box,row,column*), *get* (take the module from the measurement bench, flip it, and put it back at its position), *flip* (take the module from the measurement bench, flip it, and put it back on the measurement bench).

TANGO allows to individually manage each component of the experimental setups, i.e. the translation of the diffractometer, the spinner, and so on, in the case of the CRISTAL application; the Hall probe and the rotating coil in the case of the magnetic measurements. Thus, the whole process is managed at a higher level using the different TANGO bindings to other languages, see Fig. 8. This approach then provides that the process can be adapted and can evolve according to the needs, without having to modify the code programmed in the robot controller.

Figure 8: Software Integration Schematic.

## CONCLUSIONS

The standardization of robots has made possible to develop robotic applications in a relatively short period of time, considering that one of them was completely designed and developed in-house. These two applications have established the technical basis for the future development of robotic applications. Ten other applications have already been identified to include industrial robots in the automation of experiments. These identified applications are not only of the pick-and-place type, but also include the positioning of detectors and new assembly methods for SOLEIL future upgrade, which means that new challenges must be faced in the short and long term, notably avoiding obstacles. Besides, the sample environments are increasingly complex and more demanding in performance, reliability and safety. The integration of robot manipulators in the sample environments therefore becomes another challenge.

In order to better address the aforementioned challenges, SOLEIL is already working on some Collision Avoidance Systems (CAS) approaches, especially for systems who involves in limited workspaces, such as the sample environments. In the near future, adding CAS to the industrial robots will be an important step to accomplish.

## ACKNOWLEDGEMENTS

The authors thank all SOLEIL staff who have participated in one way or another in the development of the robotic applications.

# AN INTEGRATED DATA PROCESSING AND MANAGEMENT PLATFORM FOR X-RAY LIGHT SOURCE OPERATIONS \*

N.M. Cook<sup>†</sup>, E. Carlin, P. Moeller, R. Nagler, B. Nash, RadiaSoft LLC Boulder, CO 80301, USA  
A. Barbour, M. Rakitin, L. Wiegart, National Synchrotron Light Source II,  
Brookhaven National Laboratory, NY, 11973, USA

## Abstract

The design, execution, and analysis of light source experiments requires the use of increasingly complex simulation, controls and data management tools. Existing workflows require significant specialization to account for beamline-specific operations and pre-processing steps in order to collect and prepare data for more sophisticated analysis. Recent efforts to address these needs at the National Synchrotron Light Source II (NSLS-II) have resulted in the creation of the Bluesky data collection framework, an open-source library providing for experimental control and scientific data collection via high level abstraction of experimental procedures, instrument readouts, and data analysis. We present a prototype data management interface that couples with Bluesky to support guided simulation, measurement, and rapid processing operations. Initial demonstrations illustrate application to coherent X-ray scattering beamlines at the NSLS-II. We then discuss extensions of this interface to permit analysis operations across distributed computing resources, including the use of the Sirepo scientific framework, as well as Jupyter notebooks running on remote computing clusters.

## INTRODUCTION

X-ray light sources are prominent drivers of scientific discovery across a range of disciplines. These facilities serve a diverse user community, often providing concurrent beam time and user support to tens of domain scientists with unique backgrounds. Increasing demand for beam time, coupled with the increasing sophistication of experiments, places constraints on the infrastructure required to successfully carry out experiments within time and resource constraints. Recently, significant development efforts have been made towards improving experimental planning and execution; however, significant challenges remain to integrating real-time analysis tools within the experimental workflow. In this proceedings, we discuss a strategy for incorporating analysis pipelines within common experimental workflows, focusing on applications at the NSLS-II light source. We present a schematic workflow for orchestrating analysis in concert with experimental execution. We then demonstrate this workflow via an open source, browser-based interface furnishing beamline agnostic analysis pipelines.

## AN INTEGRATED FRAMEWORK FOR EXPERIMENT AND ANALYSIS

Our proposed strategy is to integrate a flexible analysis platform with a mature controls framework, leveraging pre-existing workflows and data schemes wherever possible. To this end, we have adopted the Bluesky Data Collection Framework, which is in active use across many beamlines at the NSLS-II [1]. BlueSky aims to provide end-to-end experimental planning, execution, and data acquisition tools through a set of interoperable Python libraries. We highlight a few of the critical libraries for the application discussed below. First, the eponymous bluesky library implements a run engine and event model to permit experimental control and data collection through the execution of high level plans. The ophyd library provides hardware abstraction to communicate plans to devices along the beamline. The databroker library implements an API for structured access to experimental data and metadata generated during an experiment executed by Bluesky.

For the analysis component, we chose to use the Sirepo platform to orchestrate execution of analysis pipelines. Sirepo is an open-source scientific computing gateway that provides access to community codes through custom, browser-based interfaces and an embedded JupyterHub instance. Sirepo is designed to be hardware agnostic; simulation environments are deployed via Docker containers, and can be executed across a range of computing systems, ranging from a laptop to a GPU cluster at a high performance computing facility. Sirepo provides support for numerous accelerator modeling and related tracking codes; existing applications have been employed to provide customized simulations of X-ray beamlines at the NSLS-II using the Synchrotron Radiation Workshop code [2]. Sirepo has also been integrated with Bluesky to enable the asynchronous execution of long-running SRW simulations to support multi-parametric optimizations of beamlines [3].

Our approach is to provide support for analysis pipelines that complements Bluesky's support for experimental execution. Figure 1 depicts a relational diagram between the different components of the envisioned platform. The Sirepo API and user interface will support the design, templating, and execution of analysis software, to be run in tandem with experimental execution. Sirepo templates simulations via JSON schemas, providing descriptive metadata, as well as mechanisms for sharing simulations or downloading and reproducing them elsewhere. This approach is akin to Bluesky's event model for describing documents generated by experimental plans. Sirepo enables hardware-independent descriptions

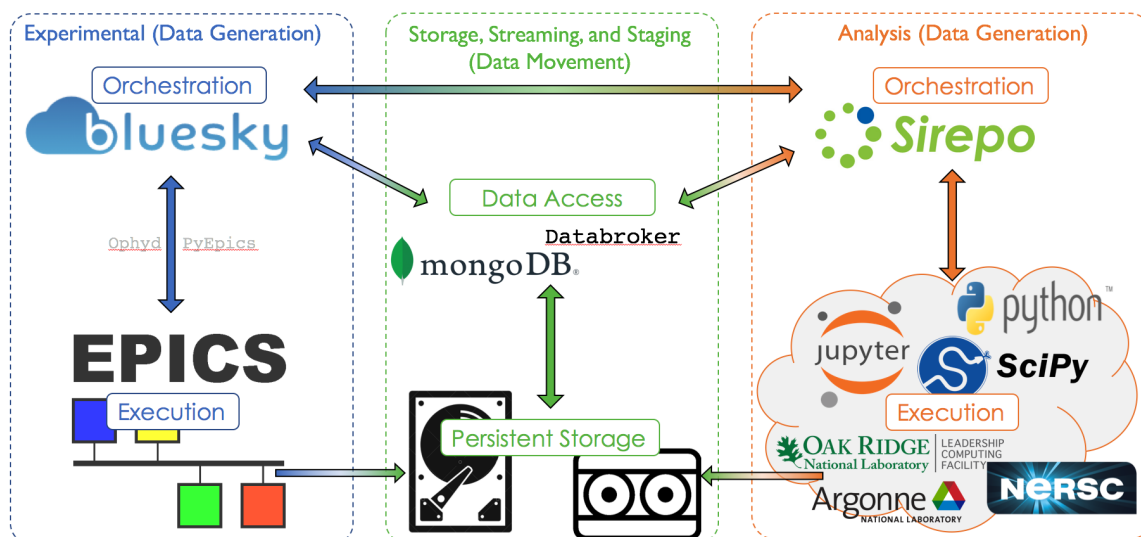

Figure 1: A high level schematic reflecting parallel implementations of Bluesky for experimental orchestration and Sirepo for analysis orchestration. While Bluesky provides schemas to define an experimental plan, along with high-level abstraction of the experimental hardware, Sirepo will provide schemas for analysis pipelines, along with access to requested computing resources, ranging from local endstations to remote high performance computing facilities. Both tools will leverage the databroker library to handle data selection, staging, and storage, relying on document schemas and searchable dictionaries to streamline access.

of simulations. Analyses can be executed across varied computational resources, ranging from local machines to high performance computing facilities, via the deployment of Docker images. Again, this approach has a parallel in Bluesky, which enables high-level abstraction of hardware, with low-level details handled by device-specific representations in the Ophyd library.

## A COMMON ANALYSIS WORKFLOW

To design an analysis platform that is beamline agnostic, we have extrapolated a high-level analysis workflow predicated on typical use cases at the Coherent Soft X-Ray (CSX) and Coherent Hard X-Ray (CHX) beamlines at NSLS-II. While this workflow does not uniquely specify all possible configurations, it aims to span a representative sample of workflows, and therefore serve as a rubric for guiding interface feature design. This workflow distinguishes five steps in the analysis procedure: staging, pre-processing, analysis, documentation, and post-processing. Figure 2 describes the resulting pipeline.

Our initial prototype aims to address the first three steps, without compromising existing documentation and post-processing capabilities in place for user's at NSLS-II. Specific emphasis has been placed on accommodating the analysis step, because it presents unique demands on software flexibility and resource management. At CHX and CSX, many users leverage Jupyter notebooks running IPython kernels [4] are customized to provide near real-time analysis for a subset of the data generated during runs. Executing these notebooks requires dedicated support for required dependencies, as well as sufficient computing resources to run

notebooks for each of the hundreds to thousands of datasets generated during a given experiment. Notebook execution may take 1 – 10 minutes depending upon the analysis, while data capture may only require a few seconds, meaning that the analysis step constitutes a bottleneck in completing the pipeline in real-time.

## A PROTOTYPE SIREPO INTERFACE FOR INTEGRATED ANALYSIS

With this pipeline in mind, we demonstrate a prototype browser-based interface for carrying out beamline agnostic analysis at X-Ray light sources, hosted by Sirepo, and to be used in conjunction with experimental execution carried out via Bluesky. The initial prototype consists of three tabs, addressing the first three stages of the previously discussed analysis pipeline.

Figure 3 depicts the data selection tab, which permits users to browse data generated by Bluesky runs at a particular beamline. By leveraging the databroker library's catalog structures, runs can be searched and filtered according to primary metadata such as start and stop time, unique identifier (UID), user, and other relevant flags. The search results can be subsequently sorted, and users may select a subset of remaining runs for further processing.

Following this selection, users are guided to the metadata tab, which enables additional inspection of high level metadata regarding the run, alongside specific device and analysis details provided by the Bluesky run documents. Currently, a fixed subset of metadata is presented to the viewer. However, future implementations will expand the ability to search metadata entries using queries permitted by databroker's

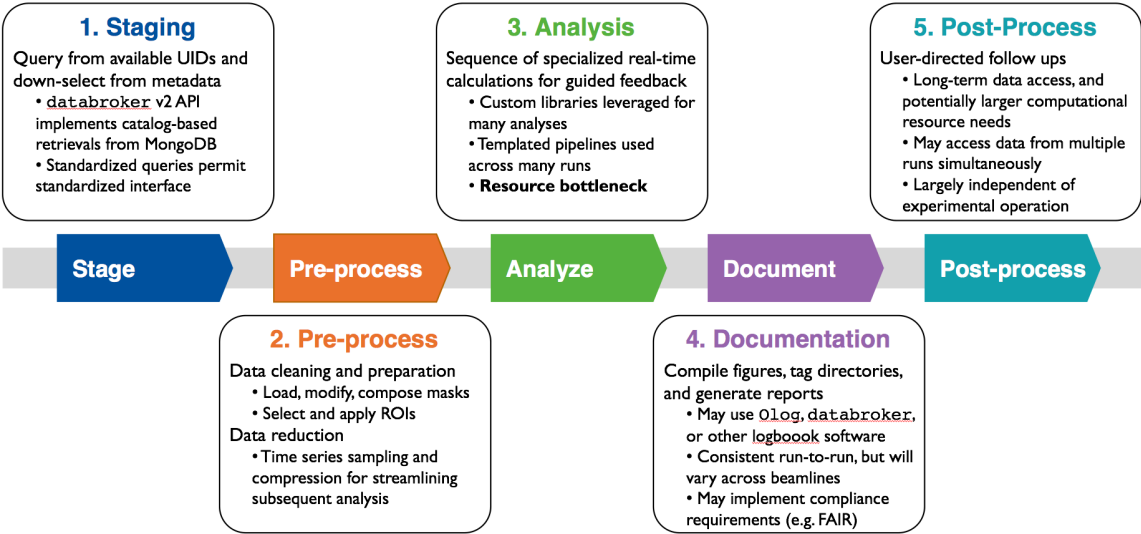

Figure 2: A high-level workflow characterizing an analysis pipeline which meets the needs for beamline experiments. During steps (1) and (2), Experimental schemas, in this case provided via databroker, are leveraged to provide metadata to support downselection and preparation of data for analysis. During step (3), an external codebase (e.g. Jupyter) may be employed to carry out specialized calculations. For experiments performed using Bluesky, documentation can be handled via databroker or Olog, while post-processing steps are often carried out off-site.

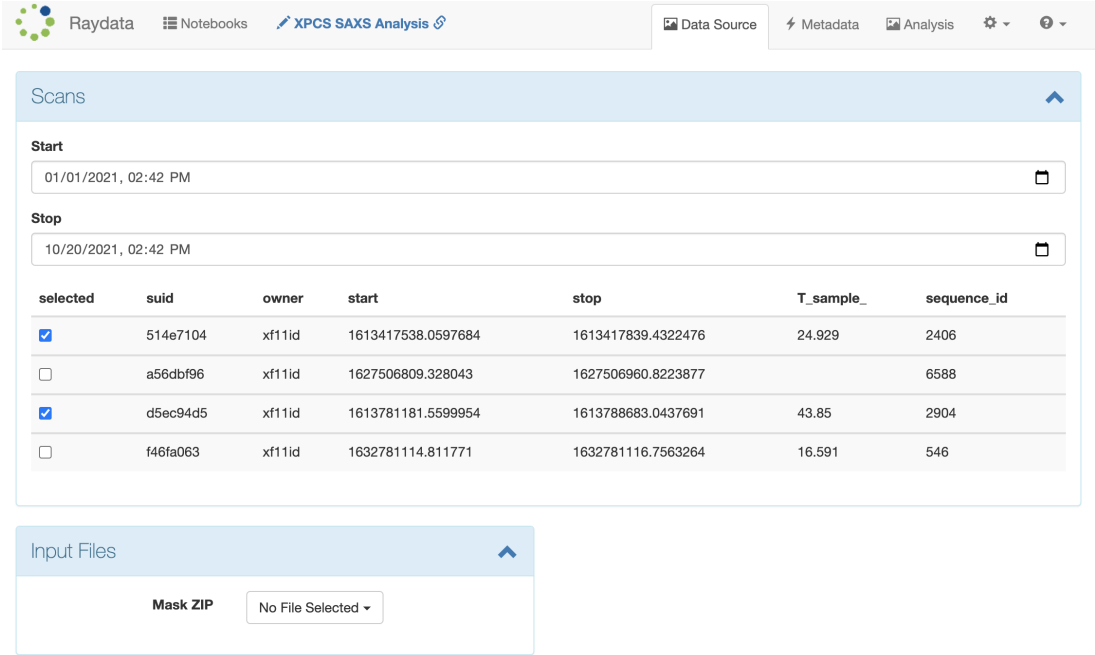

Figure 3: The data selection tab permits users to search, sort, and select from available runs in a prescribed catalog, using high level metadata to guide decisions about selections.

mongoDB-based implementation. Figure 4 illustrates the use of this interface for inspecting two selected datasets. Further improvements will permit quick snapshots of raw data files as guided by the user.

Lastly, the analysis tab addresses the analysis portion of the pipeline. For a given dataset, a user-specified Jupyter notebook is executed to carry out any specialized analysis of the initial datasets. The notebooks are executed via Docker

images designed to include all relevant dependencies for the calculations, permitting their deployment across distributed computational resources. Products of the analysis notebook, such as figures, are inspected by the interface and presented to the user immediately, enabling real-time feedback during execution. Figure 5 depicts a snapshot of the analysis tab, illustrating the generation of figure panels reflecting the products of the notebook.

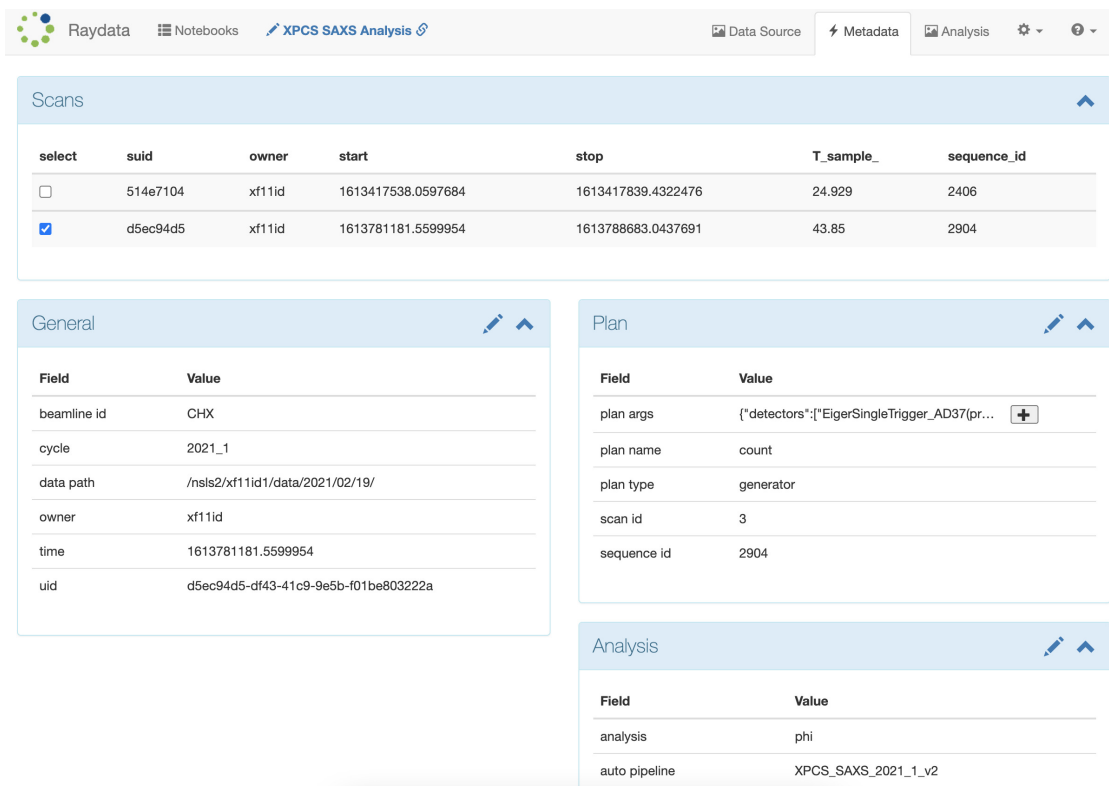

Figure 4: The metadata inspection tab provides additional details from the run metadata and start documents to permit inspection of selected runs.

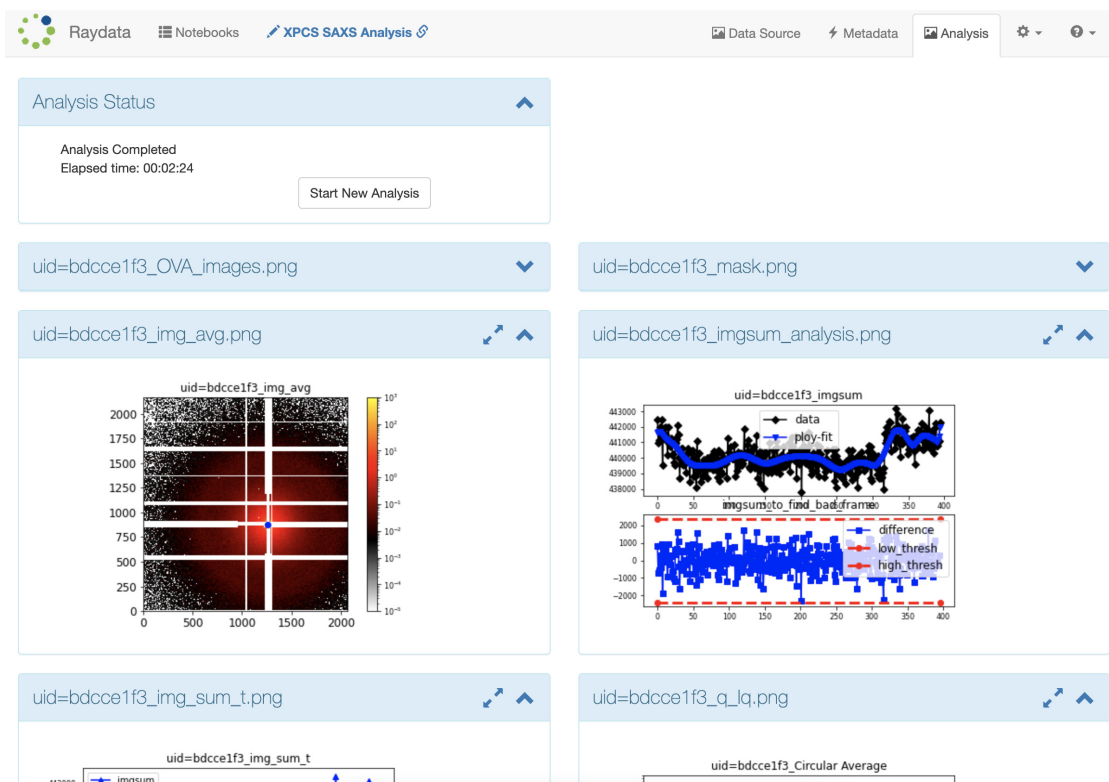

Figure 5: The analysis tab of the interface, displaying previews of several of the figures generated by running the analysis notebook for this particular run.

## CONCLUSION

We report on progress in the development of an interactive user interface for real-time analysis of X-ray light source experiments, built atop the Bluesky framework and Sirepo platforms. The interface leverages shared metadata structures provided by the Bluesky, making use of the databroker library to enable active searching, sorting, and retrieval of runs from catalog structures generated during experimental execution. Custom analysis routines are supported by deploying templated Jupyter notebooks via Docker images containing the necessary dependencies. Job management, resource allocation, and queueing are provided by Sirepo, along with real-time feedback through automated figure previews and reports. Future developments will enhance queueing capabilities to support user-directed screening and prioritization of data, with the goal of providing an inte-

grated, automated, and customizable analysis workflow to complement Bluesky's experimental procedures on active beamlines at NSLS-II and elsewhere.

## Abstract

The modernization plan for the experimental DAQ at the BESSY II [1] is underpinned by the capabilities provided by the Bluesky software ecosystem [2]. To interface with the hardware Bluesky relies on the Ophyd library, that provides a consistent high-level interface across a wide-range of devices. Many elements of the accelerator, some beamlines and endstations are adopting the Bluesky software. To meet FAIR data obligations, the capture of metadata with Bluesky and the export into a permanent and easily accessible storage called ICAT are investigated [3]. Finally, initial studies to investigate the integration of ML methods, like reinforcement learning [4] were performed. This paper reports on the work that has been done so far at BESSY II to adopt Bluesky, problems that have been overcome and lessons learned.

## INTRODUCTION

The modernization strategy for experimental DAQ at BESSY II [1] uses EPICS as the unique integration layer for subsystems and software packages. There are many different solutions in use on the experimental floor for the layer above EPICS at BESSY II. This layer has to facilitate experimental flow control, data and metadata collection, storage and analysis.

While various home-grown solutions are in use at BESSY II, most beamlines use spec [5]. This popular and flexible tool has an easy to learn command line interface, has been deployed for decades in production at facilities around the world and is known and understood by many beamline staff. However it is not open source, has a tiny developer community, uses a language that is not well known outside the research community and has no error checking.

Open source alternatives including Sardana [6], PShell [7] and Bluesky [2] were all considered. The Bluesky software ecosystem was judged the most promising tool. Many other synchrotron facilities in Europe (Alba, PETRA III, ESRF, ELI NP, MAX IV, SOLARIS ...) use Sardana interfacing with TANGO. In principle it's possible to use EPICS with Sardana, but the underlying data models of the frameworks differ extremely. Due to the complex adaptation effort required, no facility is doing this in production. Bluesky and Ophyd interface natively with EPICS and there is a large user community in the US (NSLS II, APS, LCLS, SSRL, ALS) and a growing community in Europe (BESSY II, MPG/FHI, Diamond, PSI/SLS ...) and around the world (CLS, ANSTO, PLS II). Like Sardana, it's also based on Python. The data

model of Ophyd devices is close to a corresponding TANGO device server instance. That might open opportunities to integrate complex TANGO units into Bluesky or take advantage of Sardana controlling Ophyd devices. Using a tool based on well known language with widely available training has made it easier to bring new people into the project.

This paper will report on progress in the deployment of Bluesky at the facility. First background on the infrastructure of BESSY II and a specific case study, the Energy Materials In situ Lab (EMIL) beamlines, is described. Then component integration, experimental flow control, data and metadata collection, user interfaces, and integration with machine learning (ML) tools are all explored.

## SPECIFICS OF BESSY II

From the accelerator commissioning test bed, Bluesky made its way to the experimental floor via instrument integration at the EMIL beamlines. With the aim of being able to collect metadata about the state of the entire beamline when running Bluesky plans, each element of the beamline was given a Python device abstraction using the Ophyd Python package. These general devices classes were then easily transferred to create an interface for a novel beamline project (U49/2 PGM-2, "Aquarius") and to aid replacement efforts at a spec [5] automated beamline ( $\mu$ Spot). Work now continues to integrate other beamlines.

ing motor controls, beamline commissioning relied on spec macros, continuous energy scan requirements are not eased by custom hardware connectivity, the instruments are owned by the independent legal bodies HZB and MPG. Nevertheless the whole EMIL set-up can be seen as a pathfinder project easing the general roll-out of Bluesky to the inventory of BESSY II beamlines.

### COMPONENT INTEGRATION

Ophyd allows us to solve one of the biggest problems with EPICS V3, that records have no inherent structure. EPICS V7 addresses this problem but it's not currently widely used outside areaDetector. Ophyd provides a framework to collect various signals connected to records together into groups which together form devices. It's then possible to read the status of an entire device in one go, and importantly for the collection of metadata it automatically gives context to individual parameters.

It does not solve the problem that values of components of a device can change while they are being read. This can only be solved at a lower level than the IOC to ensure that parameters update synchronously.

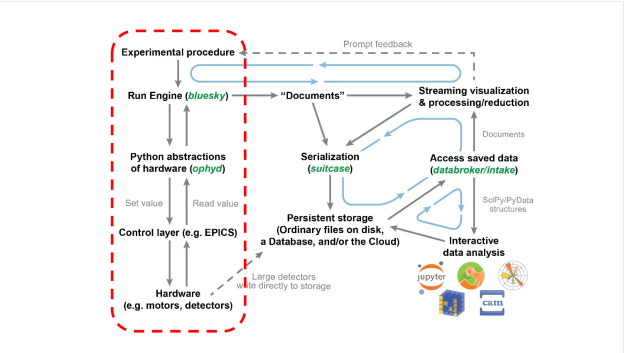

Figure 2: Device integration, abstraction.

Following the example set by NSLS II, LCLS and other labs a set of ophyd devices were created for every element of the EMIL beamlines. This was challenging because of a lack of standardization between different EPICS interfaces for different devices, and even within the same device types at BESSY. None of the motors on the beamline used the EPICS Motor Record, which meant that bespoke device classes had to be made and tested for each type. Despite this challenge the Ophyd framework proved very flexible, all devices were eventually integrated.

Of particular note were the devices on the beamline and at the end station which used the epics areaDetector interface. This included electron analyzers, cameras and spectrometers. Ophyd provided relatively easy integration for all of these, as well as providing the ability to use and control the areaDetector plugins.

Having created Python interfaces for devices, the use of pytest [8] for device level integration was investigated. The existing suite of tests used by the Ophyd package help to guarantee that the abstraction interface itself works as expected.

Tests were created to test that physical systems operated correctly. This was particularly important for the positioner device classes that had to be created because the standard EpicsMotor interface was not available. Various bugs that would otherwise have been missed were found by test scripts that attempted to move every motor on the beamline. More work is needed in this area at the beamlines but the ability to perform full integration level tests from Ophyd, through EPICS and to real hardware is promising.

In the accelerator, tools for aperture scans and a power supply multiplexer were developed and tested using a digital twin with an Ophyd interface to simulated hardware. By changing the EPICS PV name prefix passed to the Ophyd device it could be switched to point at the real hardware. A similar approach was used to develop a continuous energy scan plan for the beamlines using Ophyd to connect first to simulated and then real hardware. Digital twins were critical to the development of these tools because there are not spare monochromators or accelerators to test on, and the time given for commissioning is very limited.

### EXPERIMENTAL FLOW CONTROL

The commissioning of the EMIL beamlines was performed with spec. The task of converting these spec macros to Bluesky plans was relatively painless. Common spec macros like ascan have similar Bluesky equivalents. More bespoke macros that set up various elements of a beamline could also be easily converted.

Ultimately a beam time manager state machine will be needed, orchestrating sub use cases and handling the variety of experimental plans. This will be based on scripts and semaphores at the point of state transition.

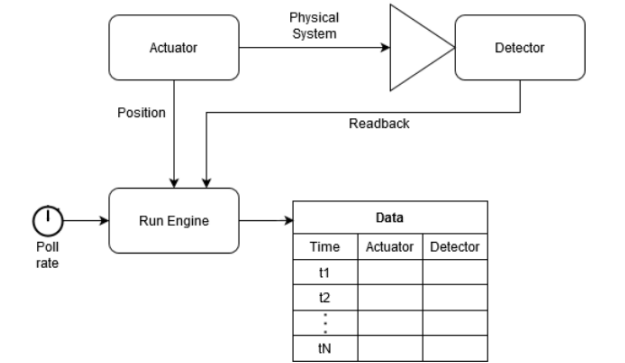

Figure 3: Values are grouped together in continuous energy scans by polling from the Bluesky run engine.

Continuous energy scans, in which a monochromator is commanded to move between certain energies at a certain rate while values are read from detectors on the beamline is implemented in a Bluesky plan. Values from the detector(s) and the energy of the monochromator are polled by the run engine at a fixed rate. The monochromator is assumed to move slowly enough that the error introduced by the energy and detectors being read at slightly different times is insignif-

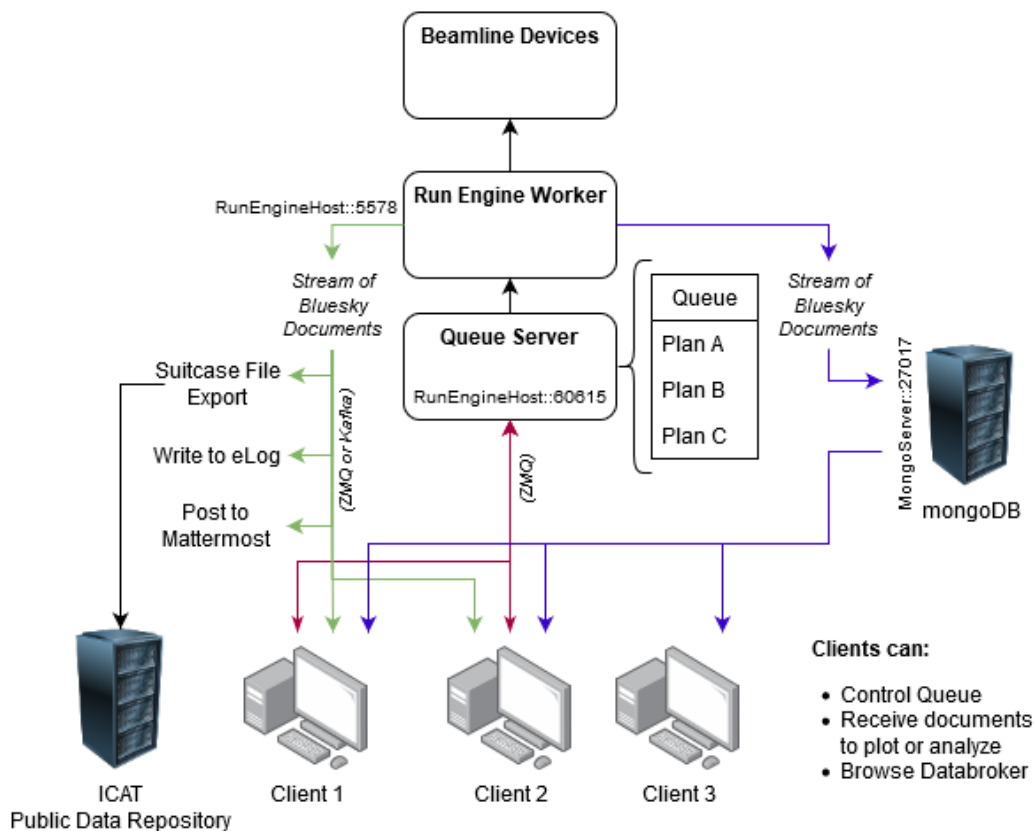

Figure 4: Connections between run engine and clients.

icant. Values of energy and detector readouts are presented live to the user. Bluesky offers a flexible framework for implementing this kind of scan, allowing for the integration of hardware trigger systems to replace polling where necessary in the future.

At both the beamlines and the accelerator the Bluesky run engine is currently interacted with directly, i.e it runs in the same process as the IPython session or Jupyter Notebook that it's run from. This is sufficient for our current use cases, but we are investigating running the run engine as a service using the Bluesky-Queueserver [9] package developed by NSLS-II (See Fig. 4). Operating the run engine as a service means that high importance tasks like data acquisition can be separated completely from less important tasks like displaying live data to clients, or writing to an eLog. If a graphical interface crashes, the run engine will keep performing the experiment.

The Queueserver additionally gives the ability for multiple clients to queue plans, and observe what is currently running. For complex beamlines like EMIL, user access rights for different beamlines or endstations change regularly between shifts. For example, in one shift one endstation might need control of both beamlines, and in the next two different endstations might need to control one beamline each. Using existing access controls based on the EPICS channel access gateway would be one solution, but is seen

as being too coarse and is problematic to implement on endstation machines which tend to have common experimental user accounts. It's hoped that adding logic based on agreed scheduling to the Queueserver and user authentication of the clients will allow us to avoid problems we currently experience with multiple simultaneous remote users affecting each other. Users should be allowed to run only particular plans with particular devices during times agreed beforehand. This idea will require considerable development.

## DATA AND METADATA

Documents generated by the Bluesky run engine are saved in a mongoDB. For scaler values and most waveforms, data is saved directly in the database. For images produced by detectors with an EPICS areaDetector [10] interface, Bluesky can instruct the EPICS IOC to save images on fast storage with unique names defined by the run engine. Those unique names and file locations are then saved in the metadata of the run stored in the mongoDB. When a client later wants to access the data from a run using the unique run identifier the Databroker [11] package fetches the image from the storage location and presents it to the client. To the client this is transparent, it is as if the image was saved in the mongoDB.

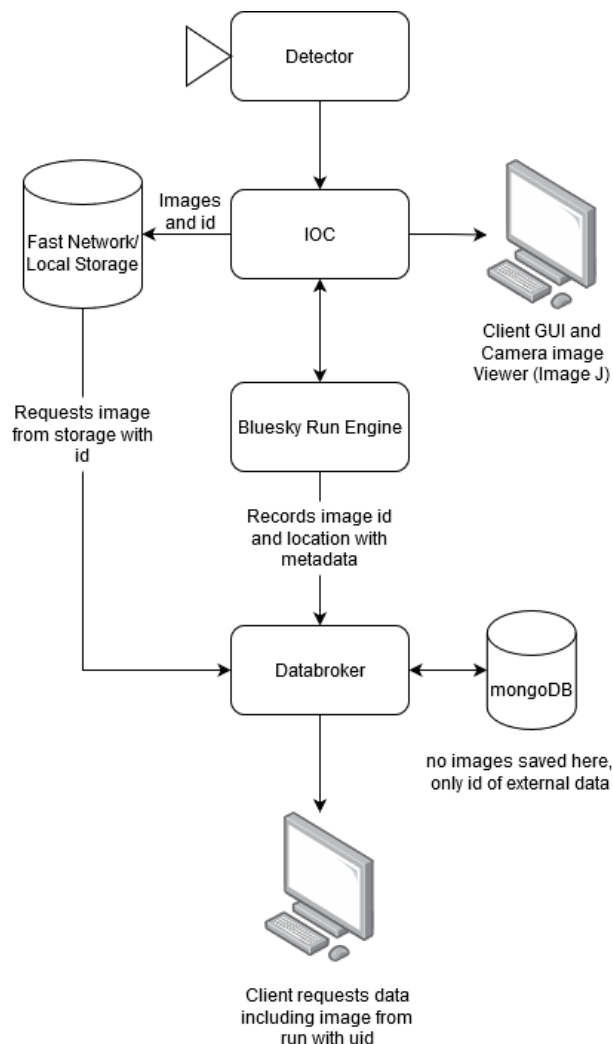

Figure 5: Accessing images by reference with Databroker.

Separating images from the metadata reduces the requirements for the mongoDB database storage and network.

Bluesky is critical to BESSY II achieving its FAIR data objectives. Every measurement taken with Bluesky can also acquire values describing the state of the entire machine. The structuring of devices with Ophyd gives context to the names of parameters.

Callbacks can be defined which inject documents from the run engine. These callbacks allow metadata to be harvested automatically about samples, repetitive important information added automatically to eLogs, and data and metadata to be exported to publicly accessible repositories like ICAT in standardized Nexus format. This was explored in a case study at EMIL [3]. Notably because documents can be subscribed to over ZMQ, these processes can be separated from the critical task of measuring and saving experimental data. (See Fig. 4)

## USER INTERFACES

To allow for simple overview representations synoptic screens will be needed showing positions within their lim-

its, status information, health of devices. For these more engineering screens CS-Studios Phoebus will be used.

Interacting with Bluesky can currently be performed in three ways. Each has benefits and drawbacks, and each is preferred by different users. All are being supported and developed at BESSY II.

IPython is the most mature and popular means of interaction, and the most familiar for users of spec. It can easily and reliably produce live plots of acquired data. Browsing acquired data through the Databroker is more cumbersome than the other interfaces.

Jupyter notebooks can also be used. It has been challenging to get live plotting to work consistently in this environment. For our users who like using Jupyter notebooks, the benefits of the environment have outweighed this issue. The ability to create demonstrations which can be run and shared has been useful for training and collaboration.

The package Bluesky-Widgets provides collection of QT widgets for standard tasks like browsing and plotting from the Databroker, interacting or monitoring the Queueserver, or editing and running plans. These can be integrated with existing QT based GUI's, but at development at BESSY II is focusing on building on the demo application provided with the package. The application is an excellent base which can be adjusted to the needs of a particular user.

Initial deployment of Bluesky at EMIL used the IPython environment, and exported data to .spec files which could then be opened with PyMca [12]. This provided the easiest path to getting a working system that was familiar to beamline scientists.

## INTEGRATION WITH MACHINE LEARNING TOOLS

An initial study was performed to investigate using a Reinforcement Learning (RL) agent with the Bluesky Run Engine (RE) with the aim of reducing harmonic orbit perturbations. An inhouse python package, called *Naus*, allowed for communication between the RE and the well established Tensorflow RL agent using ZMQ. Unfortunately this simple demonstrator set-up proved too slow to be used in production. Consequently developments of tweaked sub packages Bluesky-RL, Bluesky-Queueserver and Bluesky-adaptive are being followed now. Hopefully the *Naus* package can be refactored to take advantage of the Queueserver framework.

## OUTLOOK

Considerable progress has been made in the last year, and the success of the work at EMIL and at the accelerator bodes well for the roll out to other beamlines. A team of 6 engineers across different departments is now working together to develop the BESSY II Bluesky ecosystem. Bluesky implementation and development moved to the core of a BESSY II reinforcement and modernization program. Visible achievements are convincing enough to ask for additional support of the funding agency.

A route to making data acquired at the beamlines FAIR has been identified, and Bluesky has made it possible. Further work is needed to put this into production, not least making it easy for users to authenticate and associate their session with an investigation ID.

Authentication will also play a role in the development of access control at complex beamlines with shared resources like EMIL. Further work is required to understand how this can be incorporated with Bluesky.

The pathfinder study looking at integrating Bluesky with RL agents showed promise, but was not fast enough to be used in production in the accelerator. The work at other facilities on this topic is being followed closely.

The Bluesky user community continues to grow at labs of all sizes around the world. The energy and solution focused attitude of the people involved is one of the projects biggest assets.

## ACKNOWLEDGEMENTS

The authors thank all HZB staff members active in maintaining the complex controls infrastructure at BESSY II for many fruitful and clarifying discussions. This includes beamline and instrument scientists, accelerator controls, beamline optics as well as central IT networking and storage.

Additionally we would like to thank the developers of the Bluesky ecosystem for their work and help with our many questions.

# CONTINUOUS SCANS WITH POSITION BASED HARDWARE TRIGGERS

H. Enquist, A. Bartalesi, B. Bertrand, J. Forsberg, A. Freitas, V. Hardion, M. Lindberg,  
C. Takahashi, MAX IV Laboratory, Lund, Sweden

## Abstract

In traditional step scanning, repeated starting and stopping of motors leads to inefficient usage of the x-ray source. In addition to increasing measurement times, this also increases the risk of sample radiation damage. We have developed a system where scans are performed while continuously moving the motors. To ensure stable repeatable measurements, the detector triggers are generated, in hardware, from the motor encoder positions. Before the scan starts, a list of positions is generated. That is then used to generate the triggers when these positions are reached.

The solution is implemented with Tango and Sardana. The encoder signals from the motors are connected both to the IcePAP motion controller for closed loop operation, and a PandABox which is used as the trigger source.

The scan is controlled by a TriggerGate controller, that calculates the motor positions and configures the PandABox. The scanned motor can be either a single motor, for example a sample translation stage, or a combined motion like a monochromator. When combined motions are used, these are using the parametric trajectory mode of the IcePAP. This enables continuous scans of coupled axes with non-linear paths.

## INTRODUCTION

Many experiments require performing scans to measure some quantity as a function of another. The easiest approach is to use a step scan, and therefore this is very commonly used. In a step scan each step consists of moving the scanned axis to a certain position, then arming and triggering the detector, waiting for acquisition to finish, and finally reading out the data. This process is repeated for every step. Only the time spent acquiring the data is useful, while the rest can be considered deadtime. The starting and stopping of the scan axis (typically one or several motors), and the arming of the detector can take a considerable amount of time. Under typical conditions, scans can run no faster than a few points per second. If the acquisition time is then in the millisecond range, the deadtime tends to make up for the majority of the time required to perform the scan.

An alternative solution is to keep the scan axis moving continuously during the scan. This has previously been implemented using combinations of software and hardware solutions [1-3]. In this case, the scanned axis needs only to be started and stopped once. The acquisition

loop then consists of only triggering the detector, waiting for acquisition to finish, and readout. Many detectors are able to read out the data in milliseconds, meaning the scan can run at hundreds of points per second. This is the approach taken in this work. We have chosen to implement a system that handles the motions and trigger generation completely in hardware.

## CONTINUOUS MOTION

Letting the motion to run continuously during the scan is straightforward when the axis corresponds to a single motor that needs to run at constant speed. This is the case when for example scanning along the surface of a flat sample using a single motor. But in many cases the motion involves several motors, that can't simply be moved at constant speed. To scan for example the energy of a plane grating monochromator, both the mirror and grating positions must move according to some formulas. They also need to perform their motions synchronized, in order to keep the x-ray beam stable on the sample, with the right energy and properties. As illustrated in Fig. 1, a simple software pseudomotor will perform motions that start and end at the correct positions, but while moving, the path does not follow the ideal trajectory.

Figure 1: The difference between typical pseudomotions and parametric trajectories for a move along the parameter axis. The pseudomotor starts moving both motors at their nominal velocity. Once the first motor has reached its position, the second continues moving towards the target. The parametric trajectory on the other hand follows the trajectory the whole way by continuously adjusting the motor velocities.

## Parametric Trajectories

The non-linear motions and multi-motor synchronization can be solved by using a motor controller that supports motions following parametric trajectories. In this work we have used the IcePAP system [4].

The parametric mode presents one or several motors as a single axis, with a single position attribute. The position can be in any unit, for example nm or eV. This is achieved by generating a table for each motor, of physical motor position in motor steps versus trajectory position in the desired unit. These tables are then uploaded to each driver. Once all tables are uploaded, the motors can be moved together in the trajectory unit. When moving to a position between the points of the table, the IcePAP interpolates the individual motor positions from each table. Either linear or spline interpolation can be used, and the step size of the tables must be chosen to keep the maximum interpolation error within acceptable limits.

## Time-based Trigger Generation

During the scan, the detector must be triggered as the scan axis reaches the desired positions. The easiest approach is to use time-based triggers. The triggers are then generated from the estimated times for when the

scanned axis will reach each desired position. This works for any motor, without the need for extra cabling for encoder signals. The disadvantage is that there is some uncertainty of exactly when the motor will arrive at the desired positions, and the positions where the data was recorded may differ somewhat from the desired ones. This can be improved by capturing the motor positions at each trigger event. However this still can make comparing different scans challenging, since they were taken at slightly different positions.

## Position-based Trigger Generation

Instead of time based triggers, it's possible to monitor the motor positions, and generate the based on when the motors arrive at each position. This removes the uncertainty in the positions. In this work, we have used a PandABox [5] to generate the triggers. This device can support a very wide range of applications, and is easily configured by connecting and configuring functional blocks in a web-based gui. The blocks and connections between them are implemented in an FPGA. It can generate triggers based on numerous inputs, and is able to read standard motor encoder signals directly.

The employed configuration, or schema, for the PandABox is shown in Fig. 2. The “Sequencer” block of

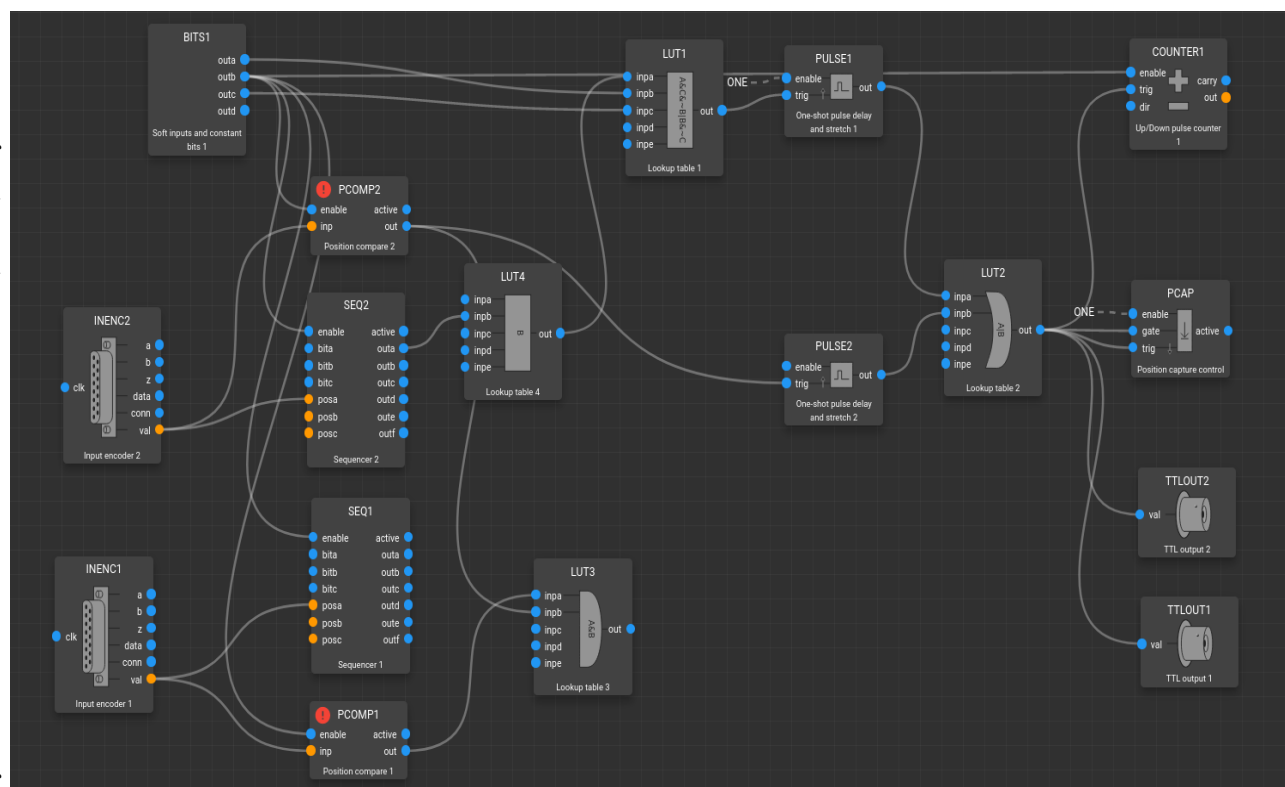

Figure 2: The PandABox schema. The encoder signals from the monochromator are connected to the INENC blocks. Currently the 2<sup>nd</sup> input, INENC2, is used for trigger generation. The sequencer block, SEQ2, is responsible for generating the triggers, based on a list of positions and the value from the encoder block. The output of the sequencer is connected to the TTL output via some logic blocks for selecting other operation modes, controlled via the BITS block. The COUNTER block keeps track of the generated triggers, and is useful for diagnostics. The PCAP block captures the values of selected variables when triggered. This is used to record the encoder signal values for both monochromator motors, as well as the undulator (not shown in the schema).

the PandABox compares its input value against a list, and generates output pulses as each value is reached. The input is wired to the encoder input block, and the output is routed to a TTL output for the detector. Additionally it's wired to the "PositionCapture" block, which is configured to capture the encoder values. This is used to record the positions for the motors in the scan data.

The values of the sequencer table are calculated using the same formulas as for generating the parametric tables for the motor controller. The equidistant trajectory positions are calculated from the scan parameters.

## SOFTWARE IMPLEMENTATION

The software for this project was developed as Sardana [6] controllers. Sardana is a scan framework based on Tango [7]. A total of three Sardana controllers were developed for this project.

- A TriggerGate that configures the PandABox to generate the expected timing. The timing system can be position based, if the scanned motor encoder is connected to the PandABox (the current implementation uses the monochromator mirror encoder), or time based, where the encoder is either not connected or there are no motors involved in the scan.
- A MotorController that enables motions using the parametric trajectory mode of the IcePAP. This is implemented to control the energy of a plane-grating monochromator via the mirror and grating angles.
- A CounterTimerController for reading out the captured encoder positions from the PandABox.

### *Procedure of a Scan*

Before a scan can be started, the parametric trajectory mode of the monochromator is initialized. This procedure is automated in the controller. It generates a list of motor positions for the two motors, for a range of energies configured by properties. It then uploads these to the motor drivers, and moves the motors onto the trajectory at a chosen energy value. To avoid collisions, this energy value must correspond to motor positions near where the motors are currently standing.

When launching a continuous scan of the monochromator energy, the following steps are performed:

- Sardana: Pass scan parameters to the TriggerGate (TG) controller and all involved detectors.
- TG: The list of energies is created. These are equidistant values from the start to the end position, with one value per step.
- TG: The corresponding motor encoder positions for the mirror is calculated for each step.
- TG: This list is sent to the Sequencer block of the PandABox.
- Sardana: Calculates start and end positions based on the motor acceleration and deceleration times, to

allow the motor to accelerate and decelerate outside of the scan range.

- Sardana: Move the motor to the start position.
- Sardana: Arm detector and TriggerGate controllers.
- Sardana: Sets the correct velocity of the monochromator motor in eV/s, and starts motion.
- TG: Each time the motor reaches the next position in the list it generates a trigger pulse.
- Sardana: While the scan is running Sardana polls the detectors for new data and appends the new points to it's record list. Depending on the speed the scan runs at, Sardana may receive zero, one, or several values from each detector per polling interval.
- Sardana: After the motion stops and all detectors finish their acquisition, Sardana saves the data to file.

Once the scan starts running, the motions and triggers are controlled completely in hardware by the IcePAP and PandABox. This allows scans to run at high rates without risk of missing or delayed triggers because of external factors such as network traffic or other load on the Sardana system. The role of Sardana during this stage of the scan is just to collect the recorded measurement values. Any delay that occurs during this loop will not affect the running scan.

This example did not include the undulator movement. For very short scans, the undulator can be left in one position if its bandwidth is sufficient to cover the scan range. Optionally, the undulator can also be moved during the continuous scan. In the present scope, the scans are limited to a small enough range to allow the undulator to move on a linear trajectory. The undulator is controlled by a dedicated IcePAP system. Sardana calculates and sets the velocity and acceleration time for this motion to match the scan parameters, and sends the command to start the motion to the motor controllers for monochromator and undulator at the same time. Because of possibly different network latencies this means the undulator and monochromator will not start at the exact same time. This can be overcome by letting one IcePAP trigger the motion of the other via a dedicated trigger cable. However, the relatively wide bandwidth of the undulator relaxes the mono-undulator synchronization requirements, and the uncertainty from the network falls well within acceptable limits.

## MEASUREMENTS

A set of measurements were performed to validate the performance of the continuous scans against normal step scans. The measurements were performed at the FlexPES beamline at MAX-IV Laboratory [8].

The sample was nitrogen, and the scan measured the absorption at the K-edge in the 400 – 402.5 eV range. The scans were done in steps of 0.01 eV, with 250 steps, a 100 ms exposure time and a 100ms latency time between points.

The data was collected using an Alba EM# electrometer [9].

For the particular measurement shown in Fig. 3, the step scan took 248 seconds, while the continuous took 57 seconds. The minimum possible time is  $250 \times (0.1 + 0.1) = 50$  seconds. The continuous scan comes close to this value, the extra time is spent on setting up all controllers, and the acceleration/deceleration phases of the motors.

Figure 3: Comparison of two absorption scans of the Nitrogen K-edge. The solid blue line shows a standard step scan, the dashed red line shows a continuous scan.

For the step scan, the scan took 248 seconds, meaning that about 80% of the time was spent on moving to the next point. Figure 4 illustrates the differences in how the time is spent during these two scans. Because only a minor part of the time during the step scan is spent on acquiring data, it cannot be made much faster by reducing the exposure time. If the exposure and latency times had been reduced by a factor 2, the step scan would have taken an estimated 223 seconds, while the continuous would have taken 32 seconds.

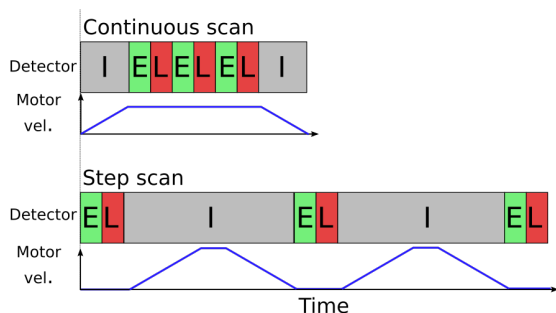

Figure 4: Illustration comparing how time is spent during a continuous scan and a step scan. For the detector, “E” denotes exposure, “L” latency (which also includes reading out the detector), and “I” idle. For clarity, this illustration shows a scan of only 3 steps.

## FAST ACQUISITION CHALLENGES

Continuous scanning, especially when acquiring at high rate, puts higher requirements on the used components than step scans.

### Detectors

Fast continuous scans means that the used detectors must sample the signal at a high rate. This can cause issues if the bandwidth of the equipment is too low. The Alba EM# electrometer has an optional low-pass filter in the analog path which is useful for illustrating this issue. This filter can be configured for a 10 Hz cutoff. It is then tempting to use this filter to reduce the noise in the recorded signals when acquiring at any rate below 10 Hz. When acquiring at frequencies approaching 10 Hz, it is then logical to assume a slight smoothing of sharp features. But a low-pass filter changes the phase of the signal, meaning that the value captured at each trigger will have been delayed by the filter. This effectively leads to a shift of the data along the scan axis, where the amount of shift is difficult to predict. The solution is to ensure that the analog bandwidth of each instrument is sufficiently high to keep this effect within acceptable limits.

### Motors

In case of sensitive equipment like a monochromator, the precision requirements are high already for step scans [10]. Adding the condition that these requirements must also be fulfilled while in motion leads to new challenges.

One is that the motions can create vibrations that may disturb sensitive equipment like monochromators. Vibrations tend to worsen with increased speed, and this may ultimately limit the achievable scanning speed for some systems.

Another issue arises if the motors rely on a closed feedback loop to reach the necessary accuracy. For step scans it can be tolerated that the position deviates while moving, as long as the position after the motion has stopped is accurate. But in continuous scans the closed loop must ensure that the motion closely tracks the target position during the entire motion. Careful tuning of the loop parameters can improve this. Lowering the scanning speed is also beneficial.

Best results are obtained for systems that were designed with continuous scans in mind. This means that vibrations are minimized, and the mechanical accuracy is high, to reduce the amount of corrections needed by the feedback loop.

## OUTLOOK

Performing continuous scans provides the obvious benefit that scans can be done considerably faster. This allows much more efficient use of the X-ray beam at storage ring facilities, where it often is the case that the signal level is strong enough to perform high quality measurements with short exposure times.

The increased speed leads to the added benefit that the sample is exposed to a much smaller radiation dose for each scan. This is an important factor for for example biological samples that are often sensitive and easily damaged by exposure during scans.

The continuous scans can be implemented for many types of measurements. Here we used it to scan the energy of a monochromator. A follow up project is planned to include the motion of the insertion device, also using the parametric trajectory mode of the IcePAP. This will allow scans over a larger energy range.

## ACKNOWLEDGEMENTS

The authors thank the staff at the MAX IV FlexPES beamline for performing the measurements.

## Institutes List

### 7S

Peligros (Granada), Spain

- Fernández, J.
- Gil, P.
- Ramirez, J.G.

### Aalborg University

Aalborg, Denmark

- Michalik, D.

### Aalto University, School of Science and Technology

Aalto, Finland

- Stockinger, E.

### ALBA-CELLS Synchrotron

Cerdanyola del Vallès, Spain

- Becheri, F.
- Blanch-Torné, S.
- Camps Gimenez, A.
- Cazorla, R.
- Costa, I.
- Cuní, G.
- Falcon-Torres, C.
- Fernández Maltas, T.
- López Sánchez, A.
- Pascual-Izarra, C.
- Reszela, Z.
- Rubio-Manrique, S.
- Salvat, D.

### ALMA Observatory

Santiago, Chile

- Sepulveda, A.
- Shen, T.C.

### ANL

Lemont, Illinois, USA

- Shen, G.

### ANSL

Yerevan, Armenia

- Sargsyan, L.

### Auenos GmbH

Baden-Baden, Germany

- Marsching, S.

### AS - ANSTO

Clayton, Australia

- Afshar, N.
- Baldwinson, B.E.
- Hogan, R.B.
- Ng, A.
- Wong, D.

### ASCo

Clayton, Victoria, Australia

- Clift, M.

### ASTRON

Dwingeloo, The Netherlands

- Juerges, T.
- Mol, J.J.D.
- Snijder, T.

### BARC

Trombay, Mumbai, India

- Ayyagiri, N.
- Behere, A.
- Deshpande, J.A.
- Joy, S.
- Mohanan, S.
- Nair, P.M.
- Neema, S.K.
- Punna, M.
- Sridharan, P.
- Srivastava, S.

### BESSY GmbH

Berlin, Germany

- Kuner, B.

### Bhabha Atomic Research Centre (BARC)

Mumbai, India

- Chandra, P.
- Godambe, S.V.
- Hariharan, J.

### BNL

Upton, New York, USA

- Barbour, A.M.
- Brown, K.A.
- Clark, S.L.
- Du, Y.
- Dyer, P.S.
- Giles, A.
- Jamilkowski, J.P.
- Lynch, J.
- Maldonado, J.
- Nemesure, S.
- Rakitin, M.S.
- Schoefer, V.
- Shroff, K.
- Sukhanov, A.
- Walter, A.
- Wiegart, L.

### byte physics e.K.

Berlin, Germany

- Braun, T.

### CAEP

Sichuan, People's Republic of China

- Li, L.
- Liu, J.
- Luo, J.
- Ni, Z.
- Yao, Ms.
- Zhou, X.

### Catalyst IT

Wellington, New Zealand

- [Harding, P.](#)

### CEA
